The option of sperm cryopreservation at the time of surgery should be offered to all men undergoing microsurgical reconstruction. Motile sperm harvested from the testicular end of the vas deferens or from the epididymis (during an epididymovasostomy) may be used for IVF-ICSI at a later time if the couple is unable to initiate a pregnancy by natural intercourse. Pregnancy and delivery rates using these cryopreserved sperm are comparable with other indications for ICSI (140). Approximately 35% of men undergoing vasectomy reversals will have motile sperm found that can be cryopreserved (31). In general, if only nonmotile sperm are identified, the surgeon should not search more proximally in the vas deferens or epididymis, unless sperm cryopreservation is a primary goal of the surgery. Consideration should also be given to cryopreserving ejaculated sperm after microsurgical reconstruction because of delayed failure rates. Approximately 10% to 21% of men with sperm appearing in the ejaculate after surgery may have subsequent azoospermia (194,266).

After a failed vasectomy reversal, repeat vasectomy reversals may provide patency and pregnancy rates of 67% to 79% and 30% to 43%, respectively (35,165,266). The likelihood of performing at least a unilateral epididymovasostomy approaches 75% (165,265). It has been recognized that the complete failure of vasectomy reversal usually is due to unrecognized epididymal obstruction at the time of the initial procedure, whereas late failure following initial patency suggests a compromised anastomosis.

Epididymovasostomy. Epididymal obstruction may require an epididymovasostomy. This obstruction can be iatrogenic, following a vasectomy in which an epididymal tubular rupture (“blowout”) occurs, or due to a congenital lesion in which the distal epididymis is no longer patent and a bypass procedure is needed to circumvent the area of obstruction. Inflammatory disease of the distal epididymis can also result in epididymal occlusion but is surgically a rare finding. Epididymovasostomy should be performed using a direct epididymal tubule–vasoluminal approach, which requires a microscope and an end-to-side technique. Because the decision to perform a vasovasostomy or epididymovasostomy can only be made intraoperatively, the surgeon must be capable and prepared to perform an epididymovasostomy at the time of microsurgical reconstruction.

The equipment and incision for microscopic epididymovasostomy are the same as for a microscopic vasovasostomy. Because even the slightest patient movement can jeopardize the procedure, we prefer a general anesthesia. If the patient is undergoing vasectomy reversal, the need for epididymovasostomy is indicated by thick, inspissated, vasal fluid with no sperm or the absence of vasal fluid. In the case of a patient who is azoospermic in the absence of previous vasectomy, testis biopsy may be indicated to confirm intact spermatogenesis. After the scrotal contents are exposed and the tunica vaginalis is incised, the epididymis is examined for gross evidence of obstruction. Next, patency of the distal (abdominal direction) vas deferens is confirmed by injecting 5 to 10 mL of saline via an angiocath sheath. Only rarely is a formal vasogram performed with either chromotubation and dye recovered from the catheterized bladder or with contrast material (Renografin 30) diluted 1:2 with saline.

Microscopic anastomosis of the vas deferens to a single epididymal tubule in end-to-side fashion is our preferred approach (Fig. 35.22). The site of probable epididymal obstruction can often be identified by careful inspection of the epididymis under 20× magnification. Dilated epididymal tubules filled with thick, inspissated material contain cellular debris and sperm fragments and are characteristic of an obstructed tubule. A portion of the epididymis just cephalad to such tubules is generally the most appropriate location for the performance of vasoepididymostomy. An appropriate site is identified, and a small portion of the tunica vaginalis is meticulously excised using fine microsurgical scissors, or an ellipse can be excised creating a larger lumen for the end-to-side anastomosis (261). To facilitate the subsequent anastomotic procedure, a minimal amount of tunica vaginalis should be excised. Exposure of approximately two to three loops of epididymal tubule is appropriate. Once a tubule has been selected, it is incised longitudinally using either a microsurgical blade or fine microsurgical scissors. Alternatively, an 11-0 suture may be placed at the apex of the tubule. This suture is gently lifted to tent up the tubule, which is then excised with microdissection scissors. The fluid emerging from the tubular lumen is then sampled and inspected under the microscope for the presence of sperm. The presence of intact sperm indicates epididymal patency and signifies an appropriate location for epididymovasostomy.

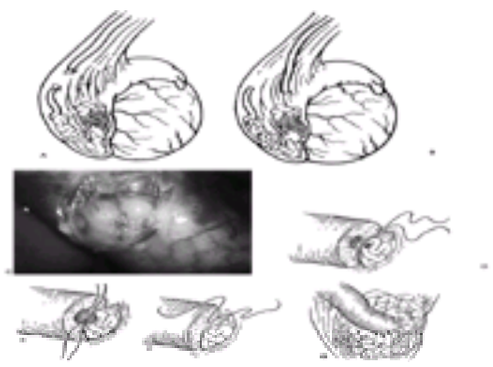

FIGURE 35.22. The microscopic end-to-side technique for epididymovasostomy. **A:** A secondary obstruction in the epididymis may develop after a vasectomy. This blockage may also occur after trauma, infection, or inflammation. **B:** The abdominal portion of the vas deferens must bypass this epididymal obstruction by being approximated proximal to the blockage. **C:** The epididymal tunic must be carefully opened to identify dilated tubules. **D:** The outer (serosal) layer of the vas deferens is secured to the epididymal tunica using interrupted 9-0 nylon sutures. The fluid from the opened epididymal tubule has been sampled for the presence of whole sperm. **E:** Two to three 10-0 nylon sutures are placed posteriorly between the inner layer of the vas deferens and the epididymal tubule. These sutures are tied down. **F:** Two to three more 10-0 nylon sutures are placed anteriorly and tied. **G:** The outer layer of the vas deferens is sutured with interrupted 9-0 nylon sutures to the epididymal tunica to complete the epididymovasostomy.

The vas deferens is then mobilized adequately to allow approximation to the selected portion of the epididymis. During this procedure, it is important to avoid devascularization of the vas deferens, which may contribute to future scarring and failure of the reconstructive procedure. The vas deferens is anchored to the most superficial aspect of the visceral layer of the tunica vaginalis with a 7-0 monofilament suture. This approximation is critical to avoid undue tension on the subsequent sutures. During this portion of the procedure, great care must be taken not to injure or compromise the underlying epididymal tubule. A two-layer microsurgical anastomosis is then performed. One or two 9-0 nylon sutures are placed at the 6 o'clock position to approximate the serosal component of the vas deferens to the visceral layer of the tunica vaginalis. Four to six 10-0 double-arm nylon sutures are placed to approximate the luminal aspect of the vas deferens to the incised epididymal tubule. Once the luminal closure has been accomplished, multiple interrupted 9-0 nylon sutures are placed to approximate the serosa of the vas deferens to the visceral layer of the tunica vaginalis. During the performance of the anastomosis, it is often helpful to place a few drops of methylene blue or indigo carmine on the epididymal tubule, as well as the lumen of the vas deferens. This will selectively stain the muscularis a bright blue and facilitate proper mucosal identification and suture placement.

The initial experience with microscopic epididymovasostomies used the end-to-end technique. The present-day standard of care is the end-to-side technique (418) because of its many advantages, including a relatively bloodless field from less dissection of the epididymis, a larger epididymal lumen for anastomosis, no need to search for the “single tubule” leaking the sperm-containing fluid, and anatomic and physiologic continuity of the entire epididymal tubular lumen proximal to the level of the obstruction. This last advantage may be the most important, because preservation of more “epididymal function” should enhance sperm “maturation” and the acquisition of the ability to fertilize an egg. Pregnancy rates for microsurgical epididymovasostomy may be as high as 30% to 40%, whereas macrosurgical pregnancy rates average 17% (418).

The triangulation vasoepididymostomy is a modification of the traditional end-to-side technique and has enjoyed increasing popularity over the last several years (39). The vas and epididymis are approximated in similar fashion, except that the epididymal tubule is not opened initially. Three double-armed 10-0 nylon sutures are placed in triangular fashion at the most prominent portion of the epididymal tubule (Fig. 35.23). The fluid that leaks from around the needle entry sites is sampled for the presence of sperm. If sperm are found, an opening is created using a microknife or the tip of a 9-0 cutting needle between the 10-0 nylon sutures. The three sutures are placed into the vasal lumen in inside-out fashion to create six points of fixation. This technique creates an intussusception of the epididymal tubule into the vasal lumen. A second layer is then completed using 9-0 nylon sutures in interrupted fashion. Using a modified two-suture invagination technique, Marmar (262) reported patency in seven of nine men (77.7%) having a bilateral vasoepididymostomy.

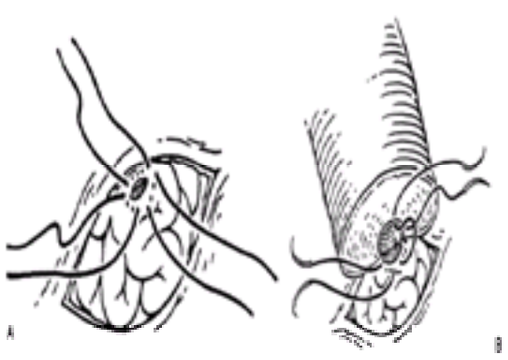

FIGURE 35.23. The Berger modification of the microscopic end-to-side epididymovasostomy: **A:** Three 10-0 nylon sutures are placed 120 degrees apart in an epididymal tubule. An epididymotomy is then carefully created between the sutures. The fluid is sampled for the presence of sperm. **B:** The six ends of the epididymal sutures are then placed in inside-out fashion to the inner layer of the vas deferens. The sutures are then tied to create an intussuscepted anastomosis. The outer layer is completed in similar fashion to the traditional end-to-side technique.

If there is a solitary functioning testis with an ipsilateral, irreparable excurrent ductal obstruction or agenesis, a crossover transseptal vasovasostomy or vasoepididymostomy can restore patency in most men, provided the contralateral vas deferens is patent (356). Contralateral testicular atrophy may be associated with prior hernia repair, varicocele, severe orchitis, cryptorchidism, testicular torsion, and trauma. Vas deferens pathology is associated with congenital absence of the vas deferens, pediatric inguinal surgery, hernia repair, and idiopathic causes.

The return of motile sperm in the ejaculate following a vasovasostomy or epididymovasostomy is time dependent. Motile sperm in the ejaculate appear on average 6 months following vasoepididymostomy and 2 months following vasovasostomy (266). The delayed appearance (mean delay 6 months) of sperm following an initially azoospermic sample is common, especially when an epididymovasostomy is performed (194). With a series of 200 vasectomy reversals, Matthews and colleagues (266) recommended that intervention for azoospermia is appropriate 6 months after vasovasostomy and 1 year after epididymovasostomy.

Repeat epididymovasostomy after failed initial epididymovasostomy is also feasible with modest success rates. In a series of 18 men with a variety of causes of epididymal obstruction, patency was demonstrated in 66% and pregnancy in 25% of patients with follow-up (321). An important surgical consideration when performing a primary or repeat epididymovasostomy is the effect of the level of anastomosis on pregnancy outcome. In the unobstructed epididymis, the sperm with the best motility and fertilizing capabilities are located distally in the cauda. The “inverted motility” present in the obstructed epididymis indicates that the sperm from the cauda have poorer motility but better fertilizing capability than sperm from more proximal sources. The outcomes of epididymovasostomy to the corpus and cauda epididymis are roughly equivalent and superior to the caput (192,220,394).

Sperm Retrieval Techniques

Microsurgical Epididymal Sperm Aspiration

In microsurgical epididymal sperm aspiration (MESA), a vertical scrotal skin incision is made and the testis and epididymis are exposed. A “mini-MESA” procedure using a 2-cm incision and leaving the intrascrotal contents *in situ* has also been described (432). With use of an operating microscope, a single epididymal tubule is opened and sperm are aspirated into a sperm-washing medium (Fig. 35.24). The general strategy is to work from the cauda toward the caput in order to spare as much functional epididymis as possible. However, in the obstructed epididymis, sperm of better quality are usually found more proximally toward the caput (373,383). Although we prefer to aspirate the sperm into a 1-mL tuberculin syringe and a shortened 25-gauge angiocath sheath, special apparatuses have also been described (139). This procedure may be performed with a general anesthetic or a local anesthetic with a spermatic cord block and intravenous sedation.

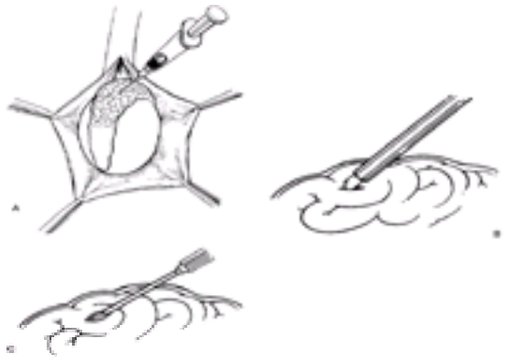

FIGURE 35.24. Microsurgical epididymal sperm aspiration (MESA). **A:** After the tunica vaginalis is opened, the epididymis is inspected for dilated tubules. A site is identified for tubule incision. **B:** The tubule is opened with a microknife. Alternatively, microdissection scissors may be used. **C:** Sperm are aspirated with a shortened 25-gauge angiocath sheath into a 1-mL tuberculin syringe containing sperm-washing medium. The fluid is examined under a microscope to ensure that motile sperm are present.

MESA has the ability to retrieve large numbers of sperm, which may be cryopreserved (frozen) and used in future cycles. Thus the need for future procedures is minimized and the amount of epididymal damage is limited. Many men may be candidates for a reconstructive epididymovasostomy (connection of the vas and epididymis, thereby bypassing a blockage) at the same time of sperm harvest, thus increasing the chances of having sperm appear in the ejaculate. Recovery time from this operative procedure is only a few days.

Although it is considered a minimally invasive procedure, MESA is more invasive and results in greater patient discomfort than percutaneous methods. Because of the need for an operating microscope and possibly a general anesthetic, costs are greater than office-based procedures. Complications such as infection or excessive bleeding are rare.

Percutaneous Epididymal Sperm Aspiration

Percutaneous epididymal sperm aspiration (PESA) is the aspiration of sperm from the epididymis using a small (21- to 23-gauge) needle. After immobilizing and isolating the specific portion of the epididymis between the thumb and forefinger, passes of the needle with negative pressure are made until sufficient numbers of sperm are obtained. No skin incision is required, and the procedure may be performed using intravenous sedation and a local cord block. The aspirate is then immediately placed in a warmed sperm buffer before analysis. Craft and colleagues (90,91) reported obtaining sperm suitable for ICSI in most of their patients with obstruction.

PESA has the main benefits of being successful in most of the cases while avoiding a skin incision. Costs are lower because an operating microscope, the skills of a microsurgeon, and the possibility of a general anesthetic are not necessary or likely. A series by Tsirigotis and colleagues (430) involving 59 cycles of IVF-ICSI demonstrated equivalent results with MESA procedures by revealing normal fertilization in 52.6% (274 oocytes), embryo transfer of more than one embryo in 91.5%, and a pregnancy rate of 30.5% per cycle.

The blind nature of PESA with potential damage to the delicate epididymal tubules represents its main risk. If multiple cycles of ICSI with PESA are required, the epididymis may be irreparably scarred, precluding a microsurgical reconstruction and possibly reducing the likelihood of further PESA. Hematoma formation may result from damage to the vascular supply to the epididymis; compression for several minutes may minimize this risk.

Testicular Sperm Extraction

Testicular sperm extraction (TESE) is the performance of an open testicular biopsy for sperm harvesting purposes. TESE is most applicable for men with testicular failure, but it may also be used for men with vasal obstruction. Using a local anesthetic with cord block, or a general anesthetic, a small incision is made on the anterior surface of the midportion of the scrotum. After the tunica vaginalis is opened and an eyelid retractor placed, the tunica albuginea is exposed.

When TESE is performed, the practical questions of how many biopsies to obtain and how to determine when enough tissue has been obtained arise. The amount of testicular tissue required is dependent on whether obstruction or testicular failure is the primary underlying disorder. In the case of normal spermatogenesis, only a

single small biopsy from one testis is required. When testicular failure is present, however, a larger sampling of tissue is necessary. One approach is to take a single large biopsy (375). In contrast, Tournaye and colleagues (426) obtained smaller individual samples from multiple sites, averaging 2.8 ± 2.5 biopsies (range of 1 to 12) in Sertoli cell only, 4.2 ± 4.5 biopsies (range of 1 to 20) in maturation arrests, and 1.5 ± 0.8 biopsies in hypospermatogenesis. The need for several testicular specimens, often from both testes, increases the likelihood of successful sampling due to intratesticular histologic variability. If one testis appears to be healthier (i.e., larger and firmer) than its counterpart, it is preferable to biopsy the better testis. The surgeon must realize and inform the patient that multiple biopsies or a single large biopsy may potentially, although rarely, damage the subtunical arterial supply to the testis, risking further testicular atrophy.

The ability to find sperm in the testis biopsies of men with testicular failure is clearly related to the heterogeneous nature of spermatogenesis and sampling error inherent in the procurement of the small, standard biopsy specimen. Small, focal areas of spermatogenesis may be identified even in the presence of overwhelming testicular failure. As an example, the pattern of Sertoli cell only with a small focus of normal spermatogenesis in an adjacent tubule has now been frequently observed, but it may be missed if a single small biopsy is obtained (Fig. 35.25). Perhaps even more important, the ability to find sperm requires extreme patience, diligence, and tissue preparation expertise on the part of the person processing the tissue (445).

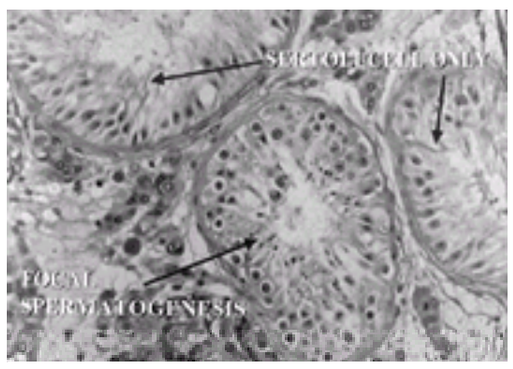

FIGURE 35.25. The heterogeneous nature of spermatogenesis is evident in this photomicrograph, which demonstrates a tubule with complete spermatogenesis surrounded by tubules with a Sertoli cell–only pattern (400×). A small, single biopsy may easily miss this small focus of sperm production. Although this patient is azoospermic, sperm may be recovered from this testis using TESE in preparation for ICSI.

When testicular failure is present, whether for diagnostic or therapeutic purposes, bilateral biopsies will increase sperm yield. Plas and colleagues (334) evaluated differences in bilateral testicular biopsies in azoospermic patients with regard to testicular histology and focal spermatogenesis. Histopathologic results of 100 testicular biopsies from 50 azoospermic patients were reviewed. After bilateral biopsy, a difference in testicular histology was found in 28% and identical histopathology was noted in 70% of patients. Testicular symmetry determined by a Prader orchidometer was noted in 54.8% of patients, whereas 45.2% had asymmetric testes. Bilateral biopsies increased the detection of focal spermatogenesis to 68%. If only unilateral diagnostic testicular biopsies had been performed, in 20% of patients focal spermatogenesis in the contralateral testis would have been missed. The study concluded that bilateral diagnostic testicular biopsies are recommended in the evaluation of patients with azoospermia.

Even more successes are evident using sperm harvested from the testis biopsies of men with an obstruction and normal spermatogenesis. However, procuring sperm from the epididymis is advisable because of a higher yield of motile sperm, unless severe epididymal scarring is present. Tournaye and colleagues (426) successfully recovered sperm in all 70 (100%) TESE procedures and had a normal fertilization and pregnancy rate of 62.5% and 43.5%, respectively. Instead of the standard open testis biopsy, percutaneous needle biopsy or percutaneous fine-needle aspiration may also be used with high sperm recovery rates (47,456). Because pregnancies have also been reported using frozen testicular sperm in men with obstructive azoospermia (174,219), an increasing practice is to cryopreserve a portion of the biopsy specimen for potential later use with ICSI. The long-term results of using sperm from frozen tissue aliquots remain to be reported.

During TESE, performance of a wet preparation or testicular touch preparation cytology intraoperatively is necessary to judge whether sperm are present (208,221) (Fig. 35.26B). Once sperm are identified, the procedure may be terminated with a reasonable degree of certainty that more sperm will be found with further tissue extraction. Because these analyses take time, especially if no sperm are initially found, consideration should be given to providing adequate sedation or general anesthesia for patient comfort. Testicular biopsies have also been obtained percutaneously using Tru-Cut and ASAP 14-gauge channel-cut biopsy system needles. Proponents of multiple core biopsies of the testis, rather than a single superficial sampling, argue that their deeper sampling may have a better yield by providing a greater cross-sectional tissue core.

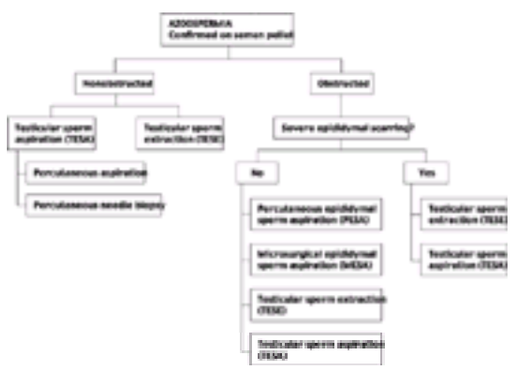

FIGURE 35.26. Algorithm for sperm retrieval techniques for intracytoplasmic sperm injection (ICSI).

A TESE microdissection technique to further assist in identifying tubules with active spermatogenesis was developed by Schlegel (372). With use of an operating microscope, identification of spermatogenically active regions of the testicle is possible by direct examination of the individual seminiferous tubules. The underlying concept for this technique is simple: seminiferous tubules containing many developing germ cells, rather than Sertoli cells alone, are likely to be larger and more opaque than tubules without sperm production. In a sequential series of TESE cases for men with nonobstructive azoospermia, the ability to find spermatozoa increased from 45% (10 of 22) to 63% (17 of 27) after introduction of the microdissection technique. Microdissected samples yielded an average of 160,000 spermatozoa per sample in only 9.4 mg of tissue, whereas only 64,000 spermatozoa were found in standard biopsy samples that averaged 720 mg in weight (p <.05 for all comparisons). For men in whom microdissection was attempted, successful identification of enlarged tubules was possible in 56% (15 of 27) of cases.

Tournaye and colleagues (426) have the largest reported series of TESE in men with nonobstructive azoospermia. In 54 TESE procedures, sperm were recovered in 81% of attempts with a sperm recovery rate of 84% in patients with incomplete germ cell aplasia and maturation arrest, 76% with complete germ cell aplasia or maturation arrest, and 100% with hypospermatogenesis. There was a normal fertilization rate of 45% with overall pregnancy rates per TESE procedure, per ICSI procedure, and per transfer of 33%, 41%, and 44%, respectively. Although follow-up on the offspring is limited, no increased incidence of congenital abnormalities has been noted in these children (104).

Su and colleagues (408) and Gil-Salom and colleagues (138) have confirmed the ability to find sperm in testis biopsies from men with testicular failure and azoospermia. Su and colleagues (408) were able to harvest sperm from 79% of men with hypospermatogenesis (31 biopsied), 47% with a maturation arrest (19 biopsied), and 24% with Sertoli cell only (21 biopsied). Of note, the testicular biopsy technique in this series involved 8× to 10× optical magnification and use of a generous incision in the tunica albuginea with a 15-degree ophthalmic knife. This magnification may be helpful for the avoidance of tunical blood vessels and identification of full tubules, which may contain mature sperm. Similarly, Gil-Salom and colleagues (138) had success rates for sperm retrieval of 54% of men with a

maturation arrest (24 biopsied) and 33% with Sertoli cell only (61 biopsied).

The specifics of tissue processing are beyond the scope of this review but generally involve mechanical separation of the sperm from the seminiferous tubules using mincing and vortexing procedures (90,445). If a small biopsy is required, complications are minimal but may include bleeding and temporary discomfort. Complications such as bleeding and testicular atrophy related to vascular injury may increase if a large biopsy is required. Caution should be exercised when performing a spermatic cord block because of evidence that in an animal model, a testicular atrophy rate of 5% was reported after needle puncture of the spermatic cord (141).

Testicular Sperm Aspiration

Testicular sperm aspiration (TESA), also known as *testicular fine-needle aspiration* (TFNA), may be performed under local anesthesia with cord block. With the testis immobilized and using a fine 21- to 23-gauge needle attached to a 10- to 20-mL syringe in a Franzen syringe holder, multiple passes with gentle negative pressure are made. The aspirate is then placed into a sperm-washing solution for analysis and preparation for ICSI.

Similar to PESA procedures, TESA has the main benefit of being successful in most of the cases while avoiding a skin incision. Also, costs are reduced because an operating microscope, the skills of a microsurgeon, and a general anesthetic are not necessary. Turek and colleagues (434) described the technique of testicular mapping of sperm using percutaneous fine-needle aspiration. Using matched testicular fine-needle aspirates and open testicular biopsy specimens, the authors found that 4 of 12 men with nonobstructive azoospermia had localized “patches” of sperm detected in areas distant from sperm-negative biopsy sites. They concluded that for sperm detection, fine-needle aspiration can localize areas of sperm production within the testis and accurately guide sperm extraction procedures in men with nonobstructive azoospermia. This technique has not gained widespread acceptance.

Because the ability to cryopreserve sperm with TESA is limited, repeated sperm retrieval procedures are required for each ICSI attempt. TESA and TFNA should be limited to patients with obstructive azoospermia, although a live birth has been reported using TFNA with testicular failure (240). In a series by Friedler and colleagues (127), TFNA was compared with TESE for sperm retrieval. Whereas TFNA allowed for the performance of ICSI in 4 of 37 patients (11%), TESE enabled ICSI in 16 of 37 patients (43%). Complications associated with TESA may include hematocele and hematoma formation.

Decision Making for Sperm Retrieval

Sperm harvested from the male reproductive tract in azoospermic men are used for ICSI. The method of sperm retrieval is dependent on whether obstructive or nonobstructive azoospermia is present (Fig. 35.26). When testicular failure (nonobstructive azoospermia) is present, the testis is the site of choice for retrieval. When an obstruction is present, sperm may be harvested proximal to the site of the blockage.

Obstructive Azoospermia

Obstructive azoospermia is the absence of sperm in the ejaculate secondary to a blockage within the male reproductive tract. In this situation, the testicular production of sperm is typically normal. Although the obstruction may be at any level from the rete testis to the ejaculatory duct, the most commonly observed sites of blockage are the epididymis and vas deferens. Conditions causing obstructive azoospermia for which ICSI may be appropriate include failed vasectomy reversal (vasovasostomy and epididymovasostomy), acquired or congenital epididymal and vasal blockages, and congenital bilateral absence of the vas deferens. Other causes of obstructive azoospermia such as previous vasectomy and ejaculatory duct obstructions may be surgically treated without the need for ICSI, depending on the specifics of the clinical situation.

Most commonly, these sperm are recovered from the testis or epididymis, but procurement may also be possible from the vas deferens or seminal vesicles, depending on the location of the obstruction. When the obstruction is in the vas deferens, such as after a vasectomy, sperm are most appropriately harvested from the epididymis or vas deferens. If the patient is considering microsurgical vasal reconstruction (i.e., a vasovasostomy), sperm may be harvested from the testicular end of the vas deferens at the time of surgery with a procedure called vasal aspiration of sperm. If no sperm are found in the testicular end of the vas deferens and the fluid quality is thick and unfavorable, an epididymovasostomy is required. In this latter situation, sperm may be harvested from the epididymal fluid using MESA, followed by microsurgical reanastomosis to the opened epididymal tubule.

If the patient does not desire reconstructive surgery, sperm may be harvested using MESA alone (374) or with PESA (91,396). Alternatively, sperm may be obtained directly from the testis using a percutaneous or open procedure. We choose to obtain sperm from the testis in obstructive azoospermia only if the epididymis is severely scarred and not amenable to a sperm extraction procedure.

Testicular Versus Epididymal Sperm

When obstructive azoospermia is present, high fertilization and pregnancy rates with ICSI are possible with either epididymal or testicular-derived sperm. This observation suggests that the complex mechanisms affecting sperm maturation during epididymal passage may not have a significant role when testis-derived sperm are used with ICSI (395). However, because significantly better fertilization and pregnancy rates have been observed using fresh ejaculated sperm compared with epididymal and testicular sperm (397), epididymal maturation of sperm probably has an important but incompletely understood role. In 1993, Schoysman and colleagues (377) described the first pregnancy using testicular sperm.

The largest experiences with testicular-derived sperm have been with fresh specimens. In a retrospective series, Silber and colleagues (395) reported that there was no difference in fertilization, cleavage, pregnancy, or take-home baby rates between fresh epididymal, frozen epididymal, and testicular sperm. In this early series, the fertilization and take-home baby rates for fresh MESA cases were 46% and 42%, respectively. Although the transfer rate was lower with TESE (84% versus 96%) and the spermatozoa could not be frozen and saved for use in future cycles, the results were not affected by whether the obstruction was caused by vasal agenesis or failed vasoepididymostomy (397). The only significant factor affecting results appeared to be the age of the woman.

Pregnancies have also been reported using frozen testicular sperm in men with obstructive azoospermia (174,219,335,350). Although most published accounts are only case reports and truly large series for comparison are unavailable, the success of this approach has prompted many centers to routinely cryopreserve a portion of testicular tissue at the time of a diagnostic testis biopsy before IVF-ICSI. Although the ideal technique for processing of the testis tissue and subsequent sperm isolation techniques have not yet been defined, many laboratories choose to freeze the tissue initially and focus on individual sperm isolation at the time of IVF-ICSI.

Nonobstructive Azoospermia

When nonobstructive azoospermia is present, the search for sperm is focused on the testis, rather than the epididymis. Sperm may be recovered using an open testicular biopsy method (TESE) or by percutaneous biopsy or aspiration (PESA) techniques. Several approaches with regard to timing may be used. Although there is no consensus as to the need for a prior diagnostic biopsy or the best method for sperm retrieval, the decision-making process must be highly individualized.

We have preferred to use a conservative approach of performing a diagnostic open testicular biopsy well in advance of an IVF-ICSI cycle for a patient with clinical evidence of testicular failure. At the time of this testis biopsy, a portion of the specimen is cryopreserved in case sperm are identified. A repeat testis biopsy for sperm extraction (TESE) is performed at the time of the actual ICSI cycle. The cryopreserved specimen may be used if sperm are not found on the TESE biopsy. By using this approach, the couple are better aware of the likelihood of identifying sperm at the time of ICSI and have time to contemplate the likelihood for requiring donor sperm backup.

Another approach is performing a TESE or TESA procedure on the day of IVF-ICSI without a prior diagnostic biopsy. The primary advantage is minimizing the need for a prior testis biopsy. The main disadvantage is the uncertainty on the couple's part about the chances of requiring donor sperm backup. If a couple is willing to use donor sperm without hesitation, this latter approach may be acceptable.

Testicular Biopsy

The indications for obtaining a testis biopsy have expanded significantly over the last several years as a result of ICSI. As a result, the testis biopsy now has new and important diagnostic and therapeutic implications for the infertile male. The urologist previously used the testis biopsy for diagnostic purposes only, that is, to

distinguish testicular failure, also known as *nonobstructive azoospermia,* from obstruction in the azoospermic patient (80). Testis biopsies are now commonly being performed for therapeutic purposes, and finding even a rare mature spermatozoa has new importance. Because the majority of patients with clinically apparent testicular failure may harbor sperm within the testis, a testis biopsy should be offered to these men if ICSI is an acceptable alternative for the couple. The pivotal role of the biopsy in differentiating normal spermatogenesis from hypospermatogenesis, maturation arrests, and the Sertoli cell–only states remains the most common and important indication for obtaining a testis biopsy. Much less commonly, testis biopsies may also be considered in the severely oligozoospermic (less than 1 million sperm/mL) male, if testicular size is relatively normal, to exclude a partial obstruction within the male reproductive tract, such as at the ejaculatory duct.

Before ICSI, the patient with testicular failure was told that adoption and the use of donor sperm were the only options available. For those men with azoospermia, testicular atrophy, and an FSH level greater than three times normal, a testis biopsy was considered unnecessary because nonobstructive azoospermia was certainly present (190). The finding of mature sperm in the testicular biopsy of 30% of such men demonstrates that even men with severe disorders are potentially capable of fathering children with ICSI (220). A current controversy is whether these men with obvious spermatogenic failure should have a diagnostic testis biopsy performed if they are intent on trying TESE with IVF-ICSI at a later time. Although several centers with extensive experience in harvesting sperm from biopsies of men with spermatogenic failure argue that a diagnostic biopsy is unnecessary and exposes the patient to additional morbidity, many couples prefer knowing the likelihood of obtaining sperm or requiring donor sperm backup at the time of IVF-ICSI and opt for a diagnostic biopsy. An interval of 3 to 6 months between a diagnostic biopsy and TESE has been recommended to allow for optimal healing of the testis.

Testicular biopsy can be performed with local or general anesthesia. If local anesthesia is used, either the spermatic cord or the area of the incision is infiltrated with lidocaine (Xylocaine). We prefer to anesthetize both areas. When vasography is also indicated, general anesthesia is suggested. If there is good reason to believe that there is no epididymal abnormality (e.g., the presence of testicular atrophy), a simple “window technique” can be employed as follows. With the scrotal skin stretched tightly over the anterior testicle and the epididymis carefully positioned posteriorly, a 1- to 2-cm incision is made and carried down to the tunica vaginalis. Commonly, when the tunica vaginalis is opened, a small amount of straw-colored fluid is observed. Before the tunica albuginea is cut, the conscious patient is warned that he may feel momentary lower abdominal pain when the tunica albuginea is incised and the parenchyma of the testis protrudes. Gentle pressure on the testis will cause additional extrusion of the stroma. A biopsy is then taken with a “no touch” technique, using a scalpel or very sharp scissors (Fig. 35.27).

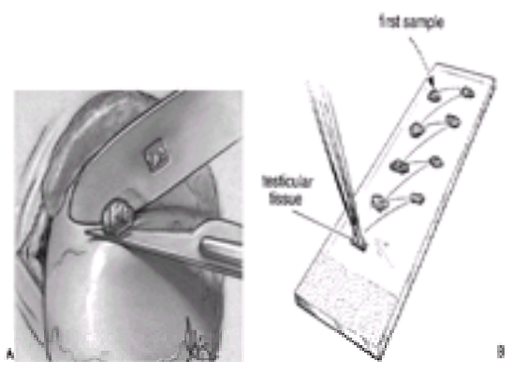

FIGURE 35.27. A: Tubules are shaved with a “no touch” technique using a no. 11 blade and an empty knife handle for support. **B:** A touch preparation cytology can identify mature sperm at the time of biopsy and aid in the decision regarding number of biopsies to obtain (**A:** From Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission. **B:** From Kim ED et al. Testicular touch preparation cytology. *J Urol* 1996;156:1412, with permission.)

The specimen is first touched gently at multiple sites on a sterile microscope slide, which is then passed quickly off the field, sprayed with fixative, and sent for hematoxylin-eosin staining for a touch preparation cytology (221). The specimen is then placed in Bouin's solution for formal paraffin embedding and staining. Formaldehyde should not be used because it distorts and partially digests the delicate germinal epithelium. The incision is closed in layers with resorbable sutures. The patient is encouraged to use a scrotal support for several days.

The testicular touch preparation cytology, also known as a “touch imprint,” allows for quick and reliable differentiation between normal spermatogenesis and a maturation arrest at the spermatid stage at the time of potential microsurgical correction of ductal obstruction. In the azoospermic patient, we also have found touch imprint cytology to be more rapid and informative than the frozen section technique in confirming intraoperatively that mature sperm are present in the biopsy. Although hematoxylin-eosin and Papanicolaou staining typically have been used after sending the cytofixed specimen to the frozen section pathology laboratory, the Diff-Quik staining method has recently been described (33). The advantages of this stain over hematoxylin-eosin and Papanicolaou stains are that slides are allowed to air-dry first, without a need for fixative, and that the skills of a histologic technician are not required because this method can be performed in the operating room by circulating staff. Similar to the other staining methods, simple and rapid identification of spermatozoa and spermatids is possible.

Jow and colleagues (208) described the technique of wet preparation analysis. Wet preparations are performed by placing a small sample of fresh testicular tissue on a slide, adding a drop of Ringer's lactate, and compressing the specimen under a glass coverslip. The finding of motile versus nonmotile sperm on a wet preparation has positive predictive values of 100% versus 81% for the presence of reproductive tract obstruction and 94% versus 86% for complete spermatogenesis, respectively. When any complete sperm with tail is found in a testis biopsy wet preparation, obstruction is likely. When used with TESE, the finding of sperm indicates that an adequate sampling of testicular tissue has been performed.

Transurethral Resection of the Ejaculatory Ducts

Transurethral resection of the ejaculatory ducts (TURED) is the treatment of choice for men with ejaculatory duct obstruction (144) (Fig. 35.15C). With use of regional or general anesthesia, a resectoscope loop is used to unroof the ejaculatory ducts just distal to the verumontanum. Intraoperative usage of TRUS may be helpful in identifying the location of an obstructing cyst and in determining the depth of resection, which may require an incision 5 to 10 mm in depth (34). After resection, there is a communication between the ejaculatory duct and the urethra. The latter will require a microscopic epididymovasostomy.

In a retrospective review of 46 cases, Turek and colleagues (433) reported significant and durable semen quality improvement after TURED. Sixty-five percent of the patients had improved semen quality (greater than a 50% increase in total motile sperm count), and 20% initiated a pregnancy an average of 6.1 months postoperatively. Statistically significant increases in total motile sperm count were achieved in men with azoospermia, as well as those treated for oligoasthenozoospermia. Persistent azoospermia after TURED may be a result of scarring at the site of the resection or in the epididymis from a “blowout” following long-term ejaculatory duct obstruction. Complications including watery, high-volume ejaculate (due to retained urine in the cyst cavity), urinary tract infection, and chronic epididymitis occurred in 20% of the men.

Adjunctive Therapy

Vibratory Stimulation and Electroejaculation

Although a small percentage of patients with spinal cord injuries maintain the capacity to ejaculate, this capacity tends to be unpredictable and is rarely effective in the initiation of a pregnancy. Because most of these spinal cord–injured patients are young at the time of their injury, many have not had the opportunity to start a family. Between 85% and 97% of these men experience permanent loss of ejaculatory function (114). Many other causes of neurologic injury such as multiple sclerosis, peripheral neuropathies such as diabetes mellitus, and retroperitoneal surgical damage to sympathetic nerves may result in similar anejaculatory states.

Recent successes with inducing ejaculation by means of rectal probe electrostimulation or vibratory induction combined with assisted reproductive techniques have enabled these affected couples to produce their own biologic offspring. Unfortunately, the often inherently poor quality of the sperm generated has contributed to relatively poor fertilization and pregnancy rates. With the introduction of ICSI, many of the problems associated with poor sperm penetrating abilities may be overcome.

Vibratory Stimulation

Vibratory stimulation, which appears to initiate an ejaculation reflex and usually produces an antegrade ejaculation, is most effective in patients with upper cord lesions. However, we suggest that all patients have an initial trial before electroejaculation (EEJ) because the lesion may be incomplete. When vibratory stimulation is unsuccessful, EEJ often works well (56).

After standard bladder preparation, a handheld, electrically or battery driven vibrator is applied initially to the dorsum of the glans and then to the frenulum and penoscrotal area. These commercially available devices cost approximately $350. Slow movement of the vibrator often identifies a “trigger” point, which is often found to be reproducible from one cycle to another. The selection of a frequency of 100 Hz and a peak-to-peak amplitude of 2.5 mm may be important for successful ejaculation (401). Patients who ejaculate using this form of stimulation usually do so within 5 to 10 minutes, and these patients will usually exhibit tumescence and pelvic floor contractions before ejaculation. In the absence of contractions, we stimulate for only 2 to 3 minutes before proceeding with EEJ. Most patients who respond to vibratory stimulation will exhibit antegrade ejaculation, but catheterization must also be performed because these patients frequently have incomplete closure of the bladder neck and may also have a significant retrograde component.

Brindley (56) achieved successful ejaculation using penile vibratory stimulation in 48 of 81 men (59%) with spinal cord injuries of more than 6 months duration (mostly complete). In a more recent series of 653 trials of penile vibratory stimulation in 211 men with spinal cord injury, successful ejaculations were achieved in 54.5% using high-amplitude stimulation versus 39.9% using low-amplitude stimulation (51). Success rates were highest in men with injuries at C-3 to C-7, followed by T-1 to T-5, T-6 to T-10, and T-11 to L-3. Ejaculation was reliable, because most men who ejaculated did so during 100% of the trials and within 2 minutes of stimulation onset.

Electroejaculation

In rectal probe electroejaculation, seminal emission depends on the sinusoidal electrical stimulation of sympathetic efferent fibers and smooth muscle. The best site for inducing seminal emission is in front of the bifurcation of the aorta and between the rectum and obturator nerves, where both preganglionic and postganglionic sympathetic fibers reside. Unfortunately, because electroejaculation does not stimulate the somatically mediated events of ejaculation or coordinate bladder neck closure essential to antegrade emission, pulsatile expulsion of seminal fluid does not occur. Rather, semen either dribbles from the meatus or is deposited retrograde into the bladder.

Electroejaculation is performed using a rectal probe containing a built-in thermistor for recording rectal mucosal temperature to prevent rectal burns resulting from unmonitored overheating. If the urine is sterile, the patients are prophylactically given ciprofloxacin 500 mg on the evening before their procedure and for 48 hours after the procedure. If a positive culture is found, culture-specific antibiotics are prescribed for 1 week before electroejaculation. Because the acidic pH of urine is highly toxic to spermatozoa, 600 mg of sodium bicarbonate is given orally, beginning the day before the procedure. Those patients who have had a poor response to either vibratory ejaculation or electroejaculation may be given Sudafed, 60 mg orally four times a day, beginning 2 weeks before the procedure, in an effort to augment emission and ejaculation through stimulation of adrenergic innervation. All patients are instructed to use their routine bowel preparation the evening or morning before the procedure.

The patient for EEJ is positioned in either the lateral decubitus or lithotomy position. General anesthesia is used in those patients with normal sensation or in those with incomplete lesions who are unable to tolerate electroejaculation. Initially, all patients are catheterized with a buffer-rinsed catheter (standard lubricant can potentially harm sperm motility) and the bladder is washed with a buffered phosphate solution. Approximately 30 mL of washed solution is left in the bladder, and the catheter is removed.

A preliminary digital rectal examination and anoscopy are performed to rule out any preexisting pathology, and the sphincter is dilated briefly before insertion of the probe. Once the probe has been placed in the rectal vault with the electrodes oriented anteriorly, upward pressure parallel to the prostate is used to ensure probe contact with the anterior rectal wall. Stimulations lasting approximately 2 to 4 seconds at increasing voltages are applied. Most patients exhibit a small amount of dribbling antegrade ejaculate when electroejaculation is successful, but this is unpredictable, and catheterization is always done to collect any retrograde semen. Because significantly impaired sperm motility and viability are commonly noted in the retrograde ejaculate, efforts should be directed toward maximizing the antegrade portion of the electroejaculate and optimizing the technique of preserving functional sperm in the intravesical compartment (167). After the probe is removed, anoscopy is again performed to confirm that no injury has occurred.

Most often, semen specimens are washed and subsequently used for IUI or IVF with ICSI. It is important that the female partner be properly evaluated and monitored for ovulation and reproductive tract abnormalities before EEJ. Adverse effects of the procedure are uncommon and usually consist only of a transient increase in extremity spasms. Rectal injury has been reported, but we have seen no significant injuries in more than 180 procedures using the previously described technique. Although autonomic dysreflexia and its attendant consequences are potentially serious complications, the use of nifedipine just before the procedure in patients at risk has significantly diminished these problems (404).

Results. The results of electroejaculation in terms of sperm harvesting have been excellent, with recent data suggesting that an ejaculate of sufficient quality to use in intrauterine insemination or IVF can be obtained in approximately 80% of individuals (378). Most patients tend to have good sperm concentrations, with averages of 180 to 300 million sperm recovered per ejaculate. The major problem has been that sperm motility has averaged only 11% to 22% with poor functional characteristics (60,101).

The poor sperm quality that has been a consistent finding in patients with spinal cord injury is probably due to a number of factors: chronic urinary tract infections and epididymitis, testicular hyperthermia as a result of sitting in the wheelchair and the loss of vasculogenic tone, infrequent ejaculations, stasis of sperm within the seminal vesicles (305), possible antisperm antibodies, and chronic long-term use of various medications. Repeating ejaculation procedures on successive days may improve sperm motility, but we have not found this to be a predictable occurrence. In addition, it has been suggested that the electroejaculation procedure itself may be detrimental to sperm because of the thermal and electrical effects of the procedure (340). However, *in vitro* studies using a simulated rectal model have failed to confirm this suspicion (466). Semen quality from vibratory stimulation may be superior to that obtained through EEJ (52).

The level of the spinal cord injury and the type of bladder management clearly affect the quality of the recovered sperm. Two studies reported that men performing intermittent catheterization, in contrast to all other forms of bladder management, had higher total sperm counts and motility (304,305). The reason for this beneficial impact is probably related to the maintenance of a lower-pressure bladder with resultant diminished risks of serious infections and reflux of urine into the ejaculatory ducts. Ohl and colleagues (304) also demonstrated that thoracic paraplegics and those with complete injuries had better overall semen parameters. The duration of time since spinal cord injury does not appear to affect semen quality (51). Several studies have also suggested that up to 50% of patients with spinal cord injury have histologic abnormalities on testicular biopsy (116,328,405).

To initiate a pregnancy following electroejaculation, IUI or IVF is required. Although the lower limits of acceptability vary, a minimum of 1 million total motile sperm is usually required for IUI. With other forms of assisted reproductive techniques, conception can occur with a much lower sperm density—as few as 50,000 sperm per oocyte for IVF and 1 sperm per oocyte with ICSI. Although results with these techniques have been encouraging, an accurate assessment of pregnancy rates has been difficult because of the lack of large published series.

Semen Processing

Impaired sperm activity or function (motility, forward progression, ovum penetrability), in the absence of antisperm antibodies, may be attributed to the presence of as yet poorly understood “seminal fluid factors.” Several reports in the literature attest to enhancement of sperm function achieved with a variety of *in vitro* manipulations, which in part may be related to the removal of these so-called seminal fluid factors (40,169,239). The ultimate objective of any sperm-processing procedure is to expose the oocyte to an optimal concentration of high-quality, motile sperm. The various methods for selection of motile spermatozoa for inseminations can be grouped into density centrifugation, swim-up, and sperm washing (41,308).

Density centrifugation of sperm using Percoll had been a standard procedure of preparing semen samples until its withdrawal in 1997. The removal of Percoll was related to difficulties in meeting U.S. Food and Drug Administration standards for clinical use. Isolate sperm separation medium, a colloidal suspension of silica particles, has gained in popularity. Processing semen with ISolate in a density centrifugation has been shown to provide an increased yield of motile sperm compared

with Percoll (3). OptiPrep, iodixanol, is another alternative for density centrifugation (76,160).

Similar methods with albumin gradients have also been used for “sperm enhancement.” The albumin “swim-up” technique is performed by layering semen beneath 2 mL of Hamm's F-10 solution and incubating at room temperature for 60 minutes. The upper layer is then carefully aspirated, washed twice in Hamm's solution, and resuspended to produce a concentration of 1×10^7 motile sperm per milliliter. After an additional 60 minutes, the upper interface is again aspirated and resuspended for later use.

Comparative evaluation of these techniques has demonstrated distinct differences in the final sperm preparations. A significant increase in progressive sperm motility has been reported for sperm separated by Percoll and albumin gradients when compared with controls (320). In addition, there are several reports in the literature describing pregnancies in previously infertile couples when variations of the aforementioned sperm-processing procedures were used (228). Despite differences in sperm recovery rates, whether fecundity rates vary is controversial when comparing methods (64,106).

Artificial Insemination

The development of artificial insemination of either the husband's semen or of donor semen (therapeutic insemination donor) has been closely linked with technical advances in semen processing and storage. Also known as *sperm banking,* semen cryopreservation should be offered to all men before chemotherapy if they desire to have future offspring (155,481). Cryopreservation of sperm for artificial insemination purposes is also performed before vasectomy and in donor programs. Sperm cryopreservation may also be offered to men at the time of vasectomy reversal and at the time of sperm retrieval procedures, but these sperm are destined for used with IVF-ICSI. Guidelines for anonymous donor sperm banking practices have been established by the American Society for Reproductive Medicine, and standards have been established by the American Association of Tissue Banks (AATB) (93). Donor sperm is widely available from a number of commercial sperm banks.

Intracytoplasmic Sperm Injection

Background

The origins of gamete micromanipulation can be traced to 1979 with the birth of the first IVF “test tube baby.” In IVF, human oocytes harvested from hyperstimulated ovaries are incubated in a culture dish with sperm. The successfully fertilized oocytes are termed *embryos* and are transferred into the uterus. The applicability of this assisted reproductive technology (ART) was initially directed at women with tubal occlusion or endometriosis, conditions that may physically impair the successful union of sperm and egg. Despite its successes, the limitations of IVF became apparent in couples with a severe male factor characterized by abnormal semen analyses and poorly functioning spermatozoa (478). Although highly variable, minimum criteria considered suitable for standard IVF include greater than 500,000 progressively motile sperm with a frequency of normal forms of greater than 3% using stict morphology criteria (314).

Interest in the initial types of micromanipulation procedures, such as zona drilling, partial zona dissection, and subzonal insertion of sperm, evolved because of the disappointing results of standard IVF for the male factor patient. One particular problem with these techniques, which was finally overcome with ICSI, was the high rate of polyspermy (up to 25%), a lethal condition involving the entrance of more than one sperm into the egg (413). Initially reported by Palermo and colleagues in 1992 (313), ICSI is now considered standard by major IVF centers and has made these other micromanipulation techniques obsolete.

Indications for Intracytoplasmic Sperm Injection (Table 35.19)

Female Factor
Failed routine IVF
Day 2 ICSI after failed IVF (rescue ICSI)
After failed previous trials of IVF
Male Factor
Severe oligozoospermia (decreased sperm concentration)
Severe asthenozoospermia (decreased sperm motility)
Abnormal sperm morphology (teratozoospermia)
Immunologic infertility
Obstructive azoospermia requiring MESA
Congenital bilateral absence of the vas deferens
Failed vasectomy reversal
Acquired epididymal or vasal obstruction
Abnormal sperm function
Defective acrosome reaction or capacitation
Abnormal sperm penetration

ICSI, intracytoplasmic sperm injection; IVF, *in vitro* fertilization; MESA, microsurgical epididymal sperm aspiration.

TABLE 35.19. INDICATIONS FOR INTRACYTOPLASMIC SPERM INJECTION

1. “Rescue” ICSI is the microinjection of mature oocytes that have failed to fertilize on the first day of egg retrieval using standard IVF. Complete fertilization failure after successful oocyte retrieval can occur in 10% to 27% of couples undergoing IVF (73). ICSI can then be performed on day 2, especially considering the poor results of second-day routine IVF insemination. As an example of outcome, Morton and colleagues (286) reported a fertilization rate of 45% and a pregnancy rate of 15% per cycle initiated. The generally poor results with rescue ICSI may be related to decreased oocyte quality 24 hours after retrieval or the presence of inherently abnormal oocytes (293,423,429). Thus “rescue” ICSI can only be considered a relative indication for micromanipulation.
2. The failure to fertilize in a previous cycle of IVF is an indication for ICSI because it suggests impaired sperm penetrating capabilities (211). Palermo and colleagues (314) demonstrated successful ongoing pregnancy rates of 37% in a large series of 227 couples who had previously failed IVF or had too few spermatozoa for conventional IVF. The success of ICSI is further confirmed by the report of a delivery rate of 47% per cycle in 25 couples experiencing unexplained fertilization failure with conventional IVF (36). However, ICSI is unlikely to overcome inherent oocyte defects, if present (133).
3. Antisperm antibodies, implicated in approximately 10% of infertile couples, have traditionally been treated with corticosteroid therapy, sperm washing, and routine IVF. Because of impaired sperm binding and decreased penetration of the zona pellucida when antibodies are present, these therapies have poor fertilization rates varying in the range of 30% to 40% (233). In contrast, a study of 55 ICSI cycles with sperm having positive antisperm antibodies demonstrated a normal fertilization rate of 75.7% and fetal sac formation rates of 26.4% (293). Based on this study's excellent results, ICSI should be the primary choice of treatment for this condition when high quantities of antisperm antibodies are present.
4. Poor results with conventional IVF have also been reported in the presence of severe teratozoospermia (abnormal sperm morphology). ICSI should be the treatment of choice after failed IVF when a severe decrease in normal sperm morphology is a reproducible finding (332,410).
5. Severe oligoasthenozoospermia (decreased sperm density and motility) is the most common indication for ICSI. Definitions regarding what constitutes “severe” are not precise; but from a practical standpoint, when sperm densities are less than 5 million sperm/mL, fertilization rates with standard IVF drop significantly (478). Men with diminished sperm motility also have poor fertilization rates with IVF (446). In these patients, as well as those couples who have failed previous IVF cycles, fertilization and pregnancy rates of 65% to 76% and 30% to 32% per cycle, respectively, have been published (396).
6. Obstructive azoospermia, accounting for about 7% of male subfertility (417), is now potentially treatable with ICSI (292). In this condition, testicular production of sperm is normal, but, because of a blockage within the male reproductive tract, spermatozoa are not present in the ejaculate. These sperm may be recovered from the testis or epididymis and used very successfully with ICSI. Conditions causing obstructive azoospermia for which ICSI may be appropriate include failed vasectomy reversal, acquired or congenital epididymal and vasal blockages, and congenital bilateral absence of the vas deferens. Other causes of obstructive azoospermia such as previous vasectomy and ejaculatory duct obstructions may be surgically treated without the need for ICSI. When ICSI is used for this indication, sperm must be retrieved using a variety of techniques previously described.
7. Nonobstructive azoospermia, also known as *testicular failure* and responsible for about 59% of azoospermia (190), describes a condition in which sperm production is markedly abnormal. These men were previously considered hopelessly subfertile and referred to adoption agencies. Sperm retrieval rates as high as 81% have been reported from testis biopsy specimens of men with azoospermia and testicular failure (103,426). Using TESE with ICSI achieved a fertilization rate of 47.8% and ongoing pregnancy rates of 25% to 31% for these men with testicular failure. TESE is the extraction of sperm that have been harvested from a testis biopsy. These men are not candidates for standard IVF because of the extremely low number of sperm recovered and their poor motility.
8. Anejaculation is a condition often associated with impairment of sperm function, especially in spinal cord–injury patients, who have preserved ejaculation in only about 20% of cases. Although experience is still somewhat limited and large-scale studies are unavailable, the poor fertilization rates with EEJ using IUI or standard IVF suggest an important role for ICSI.

Patient Selection

Proper patient selection, as determined by a comprehensive male evaluation, should be performed before proceeding with ICSI. Many men may have reversible or otherwise treatable etiologies, such as varicoceles, infection, and ductal obstruction, for their subfertility and may not need ICSI. The temptation to omit a male evaluation as a result of the erroneous thought that the success of ICSI bypasses the need for a urologic evaluation must be avoided for several reasons:

1. ICSI has a significant cost burden to the couple per “take-home” baby. Recent analysis by Schlegel (370) has demonstrated that after factors such as average number of cycles, multiple births, time lost from work, and costs directly applicable per cycle are factored, each live birth cost approximately $72,000 to $89,000 in 1994. In comparison, the costs per take-home baby with a varicocele repair for varicoceles and vasovasostomy or vasoepididymostomy for vasal obstruction are approximately $26,000 and $25,000, respectively. These figures were derived from results available from institutions with published or above average delivery rates. The costs, which are representative for a single child, are further accentuated if more than one child is desired.
2. ICSI with IVF exposes the female to potential significant complications of ovarian hyperstimulation syndrome and multiple gestation. Although this syndrome is not common, serious life-threatening maternal complications may occur. The most recent Society for Assisted Reproductive Technology data found that of reported IVF-related deliveries in 1996, a multiple gestation rate of 34.8% was observed (358).
3. Although uncommon, significant underlying medical illnesses may be discovered with subfertility as the presenting complaint. Potentially life-threatening abnormalities, including testicular, spinal cord, and brain tumors, were discovered in 1.1% of 1,236 new male infertility patients treated at two busy infertility clinics (172).

Technique

ICSI begins with oocyte retrieval using ultrasound-guided transvaginal puncture at the time of optimal follicular development following appropriate hormonal stimulation for an IVF cycle. After the oocyte has been stabilized by a holding pipette in a micromanipulator, an injection pipette with an outer diameter of 7 µmm and an inner diameter of 5 µmm is used to penetrate the thick zona pellucida of the oocyte (Fig. 35.28). After a brief incubation, those oocytes that have extruded the first polar body (now metaphase II) are candidates for ICSI. Sperm sources include fresh and frozen specimens from routine ejaculates, microsurgical epididymal sperm aspirates, testis biopsy specimens, and electroejaculated specimens. The micromanipulation procedures are then performed using an inverted phase-contrast microscope at 400×. Although costs of an IVF-ICSI cycle vary significantly, a rough current estimate per cycle is $7,000 to $12,000 in the United States.

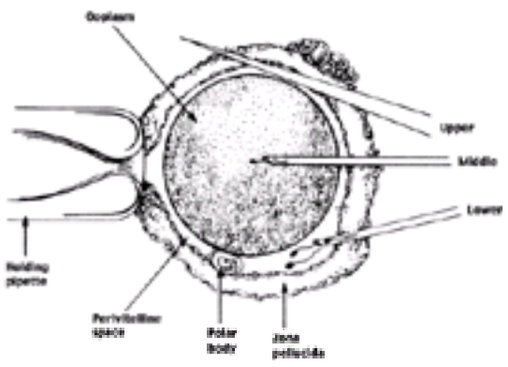

FIGURE 35.28. Intracytoplasmic sperm injection (ICSI). The oocyte is held in place using a microholding pipette in a micromanipulation apparatus. The polar body is positioned away from the site of sperm injection into the oocyte. A microinjection pipette is injected directly into the ooplasm *(middle).* Older methods, which are no longer being used, include subzonal insertion of sperm *(lower)* and partial zona dissection *(upper)*.

Results

The most recent data from the American Society for Reproductive Medicine/Society for Assisted Reproductive Technology Registry are from cycles completed in 1996 (358). This registry represents data collected from 300 programs across the United States. Overall for all indications, 14,049 cycles, representing 31.5% of all IVF cycles, of IVF-ICSI were reported. A delivery rate per retrieval of 25.9% was reported, with a 62.2% singleton pregnancy rate. The birth defect rate was 1.8%, identical to routine IVF.

An important trend observed with the 1996 data was that the presence of a male factor diagnosis had a much less significant impact on success rates than in previous years, suggesting that ICSI may mitigate the effects of male factor infertility. In fact, those couples with a male factor diagnosis had a higher rate (24.0%) of delivery per retrieval than those with other diagnoses (21.8%). In previous years' data, those couples with a significant male factor uniformly had poorer outcomes per female age grouping than when a male factor was absent. Because it appears that even the most severe sperm defects are treatable with ICSI, female factors such as age and oocyte quality are being examined more closely and will probably prove to be the main determinants of success.

The results of ICSI are best examined for the specific indication performed. The results and pertinent studies are discussed throughout the text of this review.

Genetic Concerns

Although ICSI is one of the most significant advances in the treatment of the otherwise untreatable subfertile male, significant concerns exist regarding the potential for transmission of abnormal genes to the offspring because many of the natural barriers to conception have been bypassed. Although these abnormal genes may result in similar types of infertility problems in the offspring (as in the father), an unanswered question is whether these genes may result in other disease states or systemic problems (234). The long-term genetic consequences in these offspring are largely undefined at this time. ICSI bypasses natural barriers to conception because sperm no longer need to penetrate the oocyte. With natural intercourse or standard IVF, in general, only the best sperm are able to penetrate the tough barrier provided by the zona pellucida of the oocyte.

A retrospective study by Palermo and colleagues (315) provided valuable insight regarding clinical outcome parameters of ICSI versus IVF. A total of 751 couples undergoing 987 ICSI cycles for male factor infertility were studied and had an overall clinical pregnancy (fetal heartbeat) rate of 44.3% and a resultant delivery rate per ICSI cycle of 38.7% (*n* = 382). In 8 of 11 miscarriages for which cytogenetic data were available, an autosomal trisomy was found, and 7 additional pregnancies were terminated because of a chromosomal abnormality after prenatal diagnosis. Of the 578 neonates resulting from treatment by ICSI, 15 (2.6%) had congenital abnormalities (9 major and 6 minor abnormalities). However, this frequency of malformations was lower than that observed in offspring born after standard IVF at their institution. Furthermore, when pregnancy outcome of ICSI versus IVF was analyzed in terms of semen origin, no differences were found in the frequency of miscarriages or in the rate of congenital malformations. This study concluded that the chromosomal abnormality rate was not higher in ICSI than in IVF. However, the true effect of ICSI on the offspring cannot be determined without long-term follow-up. Similarly, several reviews have concluded that ICSI does not appear to cause any significant increase in known genetic-based diseases or infertile males (117,252,371). This topic will remain controversial until much longer-term follow-up in larger groups of patients is obtained.

Future Directions

On the distant horizon is the micromanipulation procedure called round spermatid nuclear injection (ROSNI), presently considered experimental, but already described in several reports of viable human pregnancies (125) and live births (414). This technique is similar to ICSI, except that less mature, immediate sperm precursors are injected into the oocyte. Although this technique may be potentially a major advance for the future, similar significant and justified concerns regarding genetic transmission are being raised, especially because of the more severe nature of the male infertility. With each advance in the treatment of male infertility, ethical and genetic questions are raised and must be scientifically and socially addressed.

Preimplantation genetic diagnosis (PGD) may be performed on IVF- or ICSI-derived embryos as a form of prenatal diagnosis aimed at eliminating embryos carrying

serious genetic diseases before implantation (151,158,159). In PGD, a single cell is removed from an early eight-cell embryo and tested for various genetic disorders typically using *in situ* hybridization (ISH) or the polymerase chain reaction (PCR). ISH techniques allow the direct visualization of single genes and can be applied to single cells. The first clinical application of PGD was described in 1990 by Handyside and colleagues (157), who amplified Y chromosome–specific sequences using PCR to determine the sex of embryos from couples at risk of X-linked diseases. PGD may be used clinically for the detection of disease states associated with male infertility such as cystic fibrosis and numeric chromosomal abnormalities. PGD has also been used for detection of numerous other disease states, including Duchenne's muscular dystrophy, Tay-Sachs disease, fragile X, and Marfan syndrome.

The use of PGD in men with severe male factor infertility with additional adverse contributors such as advanced maternal age, repeated IVF failures, and altered peripheral blood karyotype was addressed by Gianaroli and colleagues (136). In this series of 40 men and 28 normal controls, no increase in chromosomally abnormal embryos was detected. With regard to translocations, Pierce and colleagues (331) demonstrated the use of PGD for the diagnosis of reciprocal translocations within the chromosomes 5 and 8 and Conn and colleagues (86) for couples with robertsonian translocations.

Germ cell transplantation may have clinical utility for patients undergoing gonadotoxic treatments for malignancy. As an example, a young gentleman receiving chemotherapy for testicular cancer could potentially have testicular germ cells removed before chemotherapy, then replaced afterward. Pioneering work by Brinster and Nagano (57) in mouse models has already demonstrated success.

Chapter References

The result of urethral injury, regardless of etiology, is the formation of scar tissue that may reduce the caliber of the urethral lumen and result in stricture. Such strictures were referred to in the writings of the ancient Greeks and Hindus, who reported the passage of various catheters to effect bladder drainage; indeed, pharaohs were entombed with brass dilators by their side lest their stricture problems recur in the hereafter (5). Historically, the major cause of stricture was gonococcal urethritis, but in modern communities, increased awareness and the availability of effective early treatment have lessened its impact on the urethra, and indeed in developed nations, trauma is now the leading cause.

The modern surgical era has seen a significant change in the management of urethral stricture disease, with the time-honored urethral sound playing a lesser role as an array of open surgical techniques, often utilizing tissue transfer, have become more successful. This chapter discusses the concepts germane to the successful management of this disease, identifying a rational approach based on the location, etiology, extent, and complexity of the stricture, and it describes the surgical techniques most commonly used and results achieved.

ANATOMIC CONSIDERATIONS

The male urethra is divided into anterior and posterior portions. The anterior portion comprises the glans meatal, the penile, and the bulbar urethras, and the posterior portion includes the membranous and prostatic urethras. The glans meatal urethra, contained within the glans penis and surrounded by spongy tissue, is a unique, vertically oriented, slit-shaped orifice that perfectly confines and directs the urinary stream. The penile or pendulous urethra extends from the glans to the suspensory ligament of the penis and is centrally located within the corpus spongiosum. Proximal to the suspensory ligament and surrounded by more developed spongy tissue is the bulbar portion (Fig. 36.1). The urethral lumen lies eccentrically (anteriorly) within this spongy tissue and is further enveloped by the bulbospongiosus muscles. Proximal to the bulbar urethra is the posterior urethra comprising the sphincter-active membranous portion and the prostatic portion. The membranous urethra is relatively unfixed to the surrounding structures, whereas the prostate is fixed to the pubis by the puboprostatic ligaments. The prostatic and membranous urethras are lined with transitional epithelium that gradually changes to squamous epithelium in the bulbar urethra and continues as such until changing to stratified squamous epithelium in the glans meatal urethra. As noted previously, the degree and distribution of spongy tissue envelopment of the anterior urethra vary according to location, with abundant posteriorly located spongy tissue in the bulbar urethra and relatively minimal and symmetrically surrounding spongy tissue in the pendulous urethra. This has some importance in stricture management because visual urethrotomy carries little success in the pendulous urethra, where there is little spongy tissue into which an incision can be made, as compared with the bulbar portion.

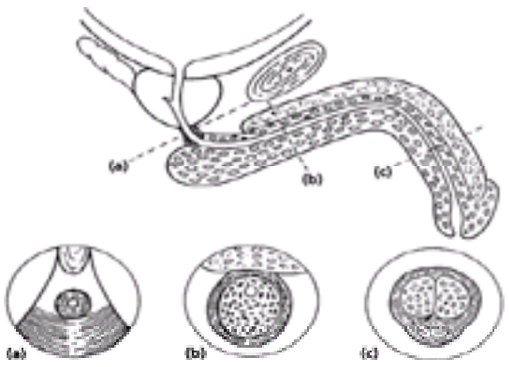

FIGURE 36.1. Anatomic divisions of the urethra. The envelopment of the urethra by spongy tissue differs from the membranous urethra *(a)* where there is none, to the bulbar urethra *(b)* and pendulous urethra *(c).* (From Webster GD, Khoury JM. Acute urethral trauma. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

The arterial supply of the male urethra has important therapeutic implications. It is supplied primarily by the bulbar arteries, which are proximal branches of the internal pudendal artery. Distally, it is supplied by the dorsal artery of the penis, which is a terminal branch of the internal pudendal artery. This dual blood supply allows the urethra to be detached at either end without compromise to its viability, a fact frequently used in urethroplasty (Fig. 36.2). Dartos fascia loosely envelopes

the penis and connects with the superficial Scarpa's fascia at the abdominal wall at the base of the penis. In the scrotum and perineum, the Dartos' fascia continues as Colles' fascia and attaches posteriorly to the central tendon of the perineum, and laterally to the ischium and inferior ramus of the pubis. Deep to this continuous fascial plane is the superficial perineal pouch. A condensation of Colles' fascia at the base of the penis forms the suspensory penile ligament. Buck's fascia is a dense but elastic layer deep to Dartos' and Colles' fasciae, and it envelopes the erectile bodies in the penis and extends into the perineum, where it separately envelopes each crus of the corporal cavernosa and splits to envelope the bulbar urethra. These fascial layers are important in urethral injury because extravasation will be contained and will migrate within the layers, depending on the degree of injury (Fig. 36.3).

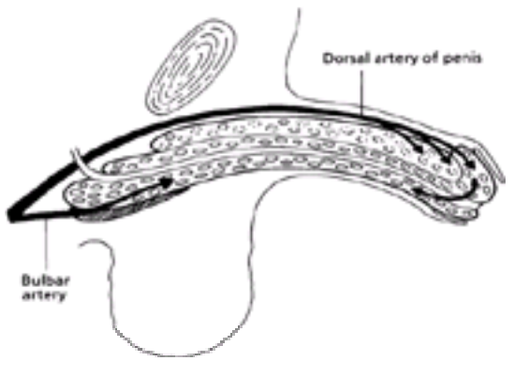

FIGURE 36.2. The urethral vascular supply is both proximal (bulbar arteries) and distal (collaterals from corporal bodies and dorsal penile arterial supply to glans penis). This allows the urethra to be transected proximally and mobilized as a “flap” on its distal blood supply. (From Webster GD, Khoury JM. Acute urethral trauma. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

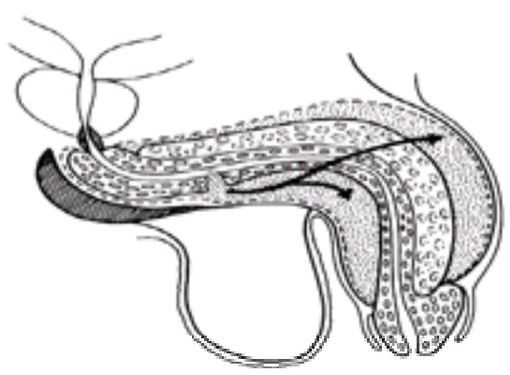

FIGURE 36.3. Fascial layers of the genitalia will determine the direction and extent of urinary and blood extravasation after urethral injury. Illustrated here is urethral injury with Buck's fascia remaining intact, directing extravasation along the penile shaft. (From Webster GD, Khoury JM. Management of acute urethral trauma. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

The entire posterior urethra in the male is sphincter-active, and any injury in this area will alter sphincter function to some degree. The proximal (bladder neck) and distal (external) sphincter mechanisms may be considered to function independently. Under normal circumstances, continence is maintained at the bladder neck level, with this mechanism only opening when the detrusor contracts, voluntarily or involuntarily (82). However, if rendered nonfunctional by prior surgery or injury, perfect continence can be maintained by the distal sphincter mechanism. This is confined to the 3- to 5-mm thickness of the wall of the membranous urethra from the level of the verumontanum down to the distal part of the membranous urethra where it merges with the bulbospongiosus tissue (Fig. 36.4A). The distal mechanism comprises an inner layer of slow-twitch, striated muscle fibers capable of the sustained contraction necessary for continence, and it is the distal two-thirds of this intrinsic mechanism that is most functional. Contrary to most anatomic descriptions, it has been shown that a urogenital diaphragm comprising a musculofascial “sandwich” does not exist (87). There is virtually no muscle anterior and anterolateral to the membranous urethra, and the only periurethral muscle directly related to this part of the urethra is that which inserts into the perineal body attached to the posterior surface of the bulbomembranous urethra (15) (Fig. 36.4B). These posterior periurethral muscles are capable of momentarily interrupting the voided stream by compressing the urethra from behind, but they are totally incapable of maintaining continence in the absence of a functional intrinsic mechanism.

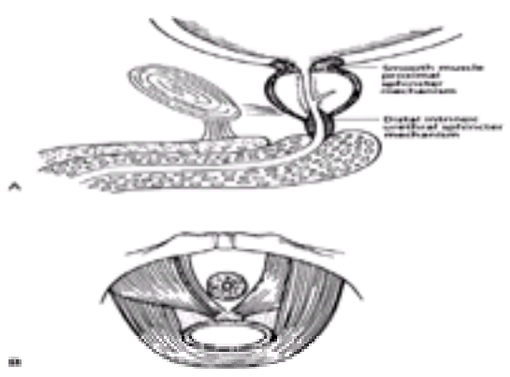

FIGURE 36.4. Male urethral sphincter mechanism. **A:** Smooth muscle proximal (bladder neck) mechanism, continuous with periprostatic musculature. Distal intrinsic sphincter mechanism resides within wall of membranous urethra. **B:** Distal extrinsic urethral sphincter mechanism (periurethral striated pelvic floor musculature) abuts on the urethra posteriorly and laterally only.

ETIOLOGY

The etiology of the stricture is not only of academic importance, but also it has considerable bearing on the type of stricture that will result, and hence on the type of repair that will be most appropriate. The urethral epithelium is extremely thin, and along the majority of the urethral length, it is based on underlying spongy tissue. In the membranous urethra, the mucosa is applied to the musculature of the intrinsic urethral sphincter. Thus for the majority of the urethra, any event that damages the epithelial lining immediately exposes a spongy bed through which infection or urinary extravasation may spread with resultant spongiofibrosis. The eventual stricture then will arise partly because of cross-healing of the denuded portions of the urethra at the site of trauma and partly because of cicatrization of the damaged spongy tissue. Spongiofibrosis may extend for a considerable distance proximal and distal to the actual stricture, surfaced by normal epithelium; failure to appreciate the true extent of the urethral stricture may be one of the main reasons for failure of stricture surgery. Urethroplasty therefore should encompass not only the definitive stricture, but also should include the spongiofibrotic urethra and extend for up to 2 cm into normal urethra proximal and distal to the limits. All urethral surgeons have encountered the thickened and often cornified mucosa proximal to a tight stricture. This cornification and underlying spongiofibrosis may be caused by extravasation of urine as a result of the pressure of urine behind this obstruction.

Congenital

Although congenital strictures undoubtedly do occur, they are rare. An embryologic explanation for their occurrence in the bulbomembranous region suggests that the

epidermal distal urethral anlage does not totally join the prostatic endodermal anlage just distal to the bulbomembranous junction, and thus a stricture represents incomplete rupture of the cloacal membrane. However, it is likely that their incidence is vastly overestimated because strictures occurring in patients who deny previous infection or trauma frequently are ascribed to a congenital etiology. Blandy (10) has alluded to these strictures, noting that, histopathologically, their wall shows smooth muscle rather than collagen-fibrous tissue, which would be expected were they of inflammatory or traumatic etiology. These strictures often are described as being soft, and because teleologically they should not be associated with spongiofibrosis, they should respond to careful endoscopic management. Cobb and associates (17) reported 26 such cases in children ranging from the newborn period to 16 years of age, none of whom had been instrumented previously, nor had they incurred trauma or urethritis.

Inflammatory

Inflammatory strictures usually are associated with gonorrhea or nonspecific urethritis, which often is caused by chlamydial organisms. Single infections, particularly if appropriately and rapidly treated, should resolve without significant injury to the urethral epithelium. However, repeated and incompletely treated infections cause severe local inflammation, particularly of the bulbar urethra, with resolution by scarring. Unlike traumatic strictures, which are frequently short and discreet, inflammatory strictures often involve a considerable length of the urethral epithelium and underlying spongy tissue, a fact of great importance in subsequent management. It is this degree of involvement of the underlying spongy tissue that will dictate the natural history of the stricture and its response to therapy. Superficial mucosal injury will result in strictures that probably result from cross-healing of the raw mucosal edges, and they will be diaphanous and soft and easily broken down by urethral bouginage, with low likelihood of recurrence. When infection causes deep and extensive spongy tissue fibrosis, the stricturing is because of narrowing of this deep scar, and urethroplasty management will likely become more necessary. The former superficial stricture may be converted to the latter dense one by traumatic management, allowing urinary extravasation or infection that will further injure the spongy tissue. Chronic specific inflammatory diseases are now uncommon, although tuberculosis and schistosomiasis rarely may have urethral manifestations.

Balanitis xerotica obliterans (BXO) also is associated with inflammatory strictures, particularly in the penile urethra. BXO is accepted as a cause of phimosis and meatal stenosis, but its extension to the penile urethra was thought to be caused by high-pressure voiding against an obstruction or as a result of the trauma of repeated dilations. This may not be true, and it may well be that the BXO process is locally extensive down the urethra. It appears that it may be a more common cause of penile urethral stricture disease than previously thought (90), and its recognition as the cause is very important because it affects the selection of technique for successful repair (see subsequent discussion).

Ischemic

Urethral strictures have been reported following cardiovascular surgery, and following extracorporeal circulation may occur in up to 22% of cases. The proposed mechanisms have included the type of catheter used and the duration of trauma of catheterization, but urethral strictures are thought by most to be caused primarily by ischemia (25). These strictures typically have been in the penile urethra and have varied in length and severity. The use of suprapubic catheters or small-caliber silicone urethral catheters has been suggested to reduce the risk of this complication (13,42).

Traumatic

The more common causes of trauma to the urethra include blunt perineal injury, penetrating injury resulting from gunshot or stab wound, iatrogenic injury resulting from urethral instrumentation, and injuries following pelvic fracture.

Blunt Perineal Injury

Most blunt perineal injuries are a result of straddle injuries where the urethra is trapped or compressed against the underlying symphysis. The force of the injury determines its extent, and in severe cases it may be transected completely, but in many cases it is partial and continuity is maintained. If Buck's fascia is ruptured, extravasated blood and perhaps urine will be contained within the confines of Colles' fascia with a resulting perineal and scrotal hematoma, often in a typical butterfly distribution. If Buck's fascia remains intact, extravasation will occur along the shaft of the penis and will result in edema and discoloration (Fig. 36.3).

Penetrating Urethral Injury

Penetrating urethral injuries are becoming more common as a result of violence in our society. The low muzzle velocity of most handguns means that bullet penetration leads only to local damage. However, high-velocity military weapons cause considerable damage distant from the bullet path. In the former, immediate debridement and repair is simple, whereas in the latter, subsequent death of unrecognized nonviable tissue may lead to poor results.

Iatrogenic Urethral Injury

Iatrogenic urethral injury is the leading cause of urethral trauma, the culprit being inept urethral catheterization or instrumentation. Common sites are the penoscrotal junction and the urethral meatus. Rigid instrument trauma often is to the bulbar urethra. Most modern endoscopic systems include a forward-viewing telescope, allowing for the placement of the endoscope under vision, and there is no reason for blind insertion of a cystoscope. Similarly, the practice of blind urethral calibration by the passage of urethral sounds in patients with voiding difficulty is not recommended. Such practices frequently result in urethral laceration at the site of the stricture, with the formation of false passages and failure to gain access proximally. A urethrogram performed at this juncture shows an “extravogram,” further confusing the issue. A retrograde urethrogram or endoscopy with stricture negotiation using a filiform is the optimal practice.

Urethral Injury Following Pelvic Fracture

Most pelvic fractures result from motor vehicle accidents, but they are also an occupational hazard among miners, lumberjacks, construction workers, and those working with heavy equipment and machinery. The prostatomembranous urethra is injured in approximately 10% of patients sustaining pelvic fracture, and the magnitude of the injury will determine the extent of the initial vesicourethral dislocation. At one end of the spectrum, only urethral contusion may result; in more severe distraction injuries, the urethra may be partially torn but continuity maintained; and in severe injuries, total disruption and separation of the torn urethra results (Fig. 36.5). The incidence of partial tears varies in reported series but averages 34%. The degree of injury is pertinent to management and outcome. Urethral elongation injuries generally are managed by urethral stenting, and will heal stricture-free, although there may be some distal-sphincter compromise. Partial tears also have the potential for stricture-free healing, if they are not aggravated by instrumentation or local infection, and a case is made for their management by temporary urinary diversion by suprapubic cystostomy in the acute phase. Total urethral distraction injuries will require realignment or reanastomosis, and philosophies regarding their management are presented subsequently.

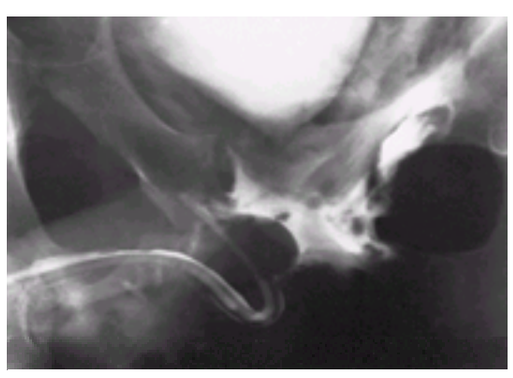

FIGURE 36.5. Total urethral disruption following pelvic fracture. A Foley catheter has been inserted and the balloon inflated in the retropubic space. Contrast injection shows the lack of urethral continuity, confirming total urethral separation.

Any pelvic fracture sufficient to damage the urethra generally will cause significant vascular and neural injury in the pelvis also, and this accounts for the high incidence of impotence in such cases. The cavernous nerves course in close proximity to the membranous urethra, and if not injured by the fracture itself, are at jeopardy during subsequent urethroplasty (71). The pattern of pelvic fracture has significant bearing on the likelihood of postinjury erectile dysfunction, and Crassweller and coauthors (20), as well as Mark and associates (49), have shown that fractures of both pubic rami are most likely to injure neurovascular structures bilaterally and lead to impotence. Obviously, every attempt must be made to avoid injury to remaining intact neurovascular structures at the time of surgical repair; however, it is important to recognize that there is a very high incidence of impotence attributable to the injury itself.

DIAGNOSIS

Urethral strictures generally present with the symptoms of obstructed voiding. Because the process of urethral cicatrization may be very slow, the slowing of the stream may be insidious, and delayed recognition is not uncommon. In some cases, the process is rapid and readily recognized, such as in the postmeatal stricture that occurs following transurethral resection of the prostate (TURP). Other presentations of urethral stricture include urinary tract infections, urethral bleeding, epididymitis, and in some communities, periurethral phlegmon or urethrocutaneous fistula. In older men, there is occasionally some difficulty in deciding whether the symptoms are caused by the stricture or prostate enlargement. It is well known that prostate size on rectal examination, or the appearance of occlusive lobes on endoscopy, do not dictate that prostate outlet obstruction exists. It is judicious to reassess the patient after urethral dilation to determine which of the two pathologies is the cause of the voiding difficulty.

Radiologic Studies

Excretory urography or renal ultrasonography ideally is performed at the time of diagnosis of significant and longstanding urethral strictures. Bladder and upper tract changes are uncommon but may be important in the overall care of the patient, and sometimes the excreted contrast can be voided as a “poor man's” cystourethrogram to delineate the urethra proximal to the stricture.

Retrograde urethrography is the mainstay of the radiographic investigation of stricture disease. A variety of techniques exists, but each emphasizes the need for sterility and the avoidance of further trauma to the urethra. Retrograde urethrography may be confusing and generally is avoided within 3 to 4 weeks of traumatic urethral instrumentation, because residual urethral epithelial injury may allow startling extravasation of contrast into the spongy tissue and into lymphatics and veins of the pelvis. Ideally, liquid contrast medium suitable for intravenous urography is used. Injection techniques utilize various clamp devices. However, the use of a syringe with a catheter irrigating tip, which is impacted in the urethral meatus, or the use of a small Foley catheter, the balloon of which is gently distended just proximal to the fossa navicularis to plug the urethra, are optimal. This latter method is attractive because it avoids contrast leakage around the genitalia and also allows the investigator to keep his or her hands well clear of the field of radiation.

The urethrogram not only should delineate the stricture but also should show the urethra proximal and distal to it (Fig. 36.6). The length, caliber, location, multiplicity, and proximity of the stricture to the sphincter all should be identified. This is best done by the gentle injection of a large bolus of water-soluble contrast medium with the patient in the half-lateral position with the top hip extended. If the caliber of the stricture is so small that contrast cannot be introduced in the retrograde manner, the more proximal urethra may be evaluated by voiding cystourethrography. This may be performed as part of the excretory urogram; however, the excreted contrast often is not sufficiently dense to give interpretable films. If the urethral stricture is not totally obliterative, a small feeding tube may be negotiated past the stricture, the bladder filled in this manner, and the contrast voided. In patients who have obliterative strictures, suprapubic cystostomy will have become necessary because of urinary retention, and voiding cystourethrography can then be accomplished by suprapubic tube filling of the bladder. If this study is not performed, a distal stricture may inadvertently be repaired and additional proximal disease may not be recognized.

FIGURE 36.6. A dynamic retrograde urethrogram showing a healthy anterior urethra up to a long proximal bulbar stricture. The sphincter-active portion of the urethra and prostatic urethra are delineated. Proximity of the stricture to the sphincter mechanism is demonstrated adequately.

Combined retrograde urethrogram–voiding cystourethrogram is indispensable in the evaluation of the obliterative urethral defect that follows pelvic trauma (Fig. 36.7). This study generally can be performed with the patient awake; however, in the face of total obstruction of the urethra, many patients are unable to generate a detrusor contraction to open the bladder neck and thus fail to fill the proximal urethra. Fortunately, the majority of patients will accomplish this if the bladder is filled under anesthesia, so the study can precede the urethroplasty should adequate radiography not have been obtained preoperatively. This combined urethrogram and voiding cystourethrogram will demonstrate the length of the obliterated segment, a point of great importance in obliterative posttraumatic defects such as those that follow straddle injury or pelvic fracture. Because misalignment of the urethral ends is not uncommon following pelvic fracture, films with differing obliquities may be necessary. The sonographic urethrogram has been reported to be equally efficacious and in some ways superior as a diagnostic modality when compared with the standard retrograde urethrogram. The stated advantages include the identification of the extent and thickness of periurethral fibrosis and spongiofibrosis, accurate measurement of urethral luminal size, and the noninvasive nature of the study (30,53). In addition, color Doppler can demonstrate the urethral arterial supply (16), which may have a role in the evaluation of impotence. Sonography has failed to replace retrograde urethrogram in clinical practice, probably because of the difficulties in interpretation and the lack of a permanent image.

FIGURE 36.7. A combined retrograde urethrogram and voiding cystourethrogram in a patient with a pelvic-fracture urethral-distraction defect. This film demonstrates the length of the defect and the healthy appearance of the anterior urethra. Competence of the bladder neck, essential for continence after repair, is demonstrated by radiographic exposure before the “voiding” film.

Magnetic resonance imaging (MRI) also has been described for the evaluation of pelvic-fracture urethral distraction defects before surgery (23).

Endoscopy

Although urethrography is the mainstay of investigation and identifies the important characteristics necessary for treatment selection, endoscopy is still valuable. “Grey” urethra, where spongiofibrosis extends beyond the limits of the definitive stricture, may not be apparent radiographically, but it often is evident urethroscopically and will inform the surgeon of the limits of the repair.

In patients with obliterative posterior urethral defects following pelvic fracture, retrograde urethroscopy and antegrade cystourethroscopy through the suprapubic cystostomy site give valuable information. Anastomotic repairs of such defects rely on a healthy distal urethra, and this may be confirmed urethroscopically. These patients usually have had a suprapubic tube in place for some time, and bladder stones are not uncommon and should be managed before or at the time of urethroplasty. The bladder neck will be the main source of continence in such men, because the distal sphincter mechanism usually is ablated by pelvic fracture injury of the urethra. Although the bladder neck's competence may be assessed by cystography, confirmation of its competence by antegrade cystoscopy is valuable. If a flexible cystoscope is used, further visualization of the prostatic and sphincteric portion of the proximal urethral stump is possible, thereby confirming its patency.

In rare instances, urethral carcinoma may masquerade as benign urethral stricture, but endoscopic finding of an exuberant or ulcerated urethral lesion should raise the clinician's suspicion and lead to biopsy.

MANAGEMENT

Urethral strictures are treated by a variety of techniques, including urethral dilation, urethrotomy, urethral stenting, and a repertoire of operative techniques. Philosophic differences among urologists exist regarding the role of each of these techniques in urethral stricture management; certainly the most commonly used methods continue to be dilation and urethrotomy. Surgical management, aiming at “cure,” has gained momentum in recent decades; however, the techniques are somewhat unforgiving, and the occasional urethroplasty surgeon with a limited repertoire of techniques may not achieve optimal outcomes.

No single operative procedure is appropriate for all strictures. Procedure selection is determined by many factors, including the location of the stricture, its etiology, its length, its multiplicity, proximity to the sphincter mechanism, and the presence or absence of such local adverse factors as fistula, false passage, or diverticulum. With these variables in mind, it is evident that no single surgical technique will be adaptable to all eventualities, and the surgeon managing stricture disease should be versed in a wide array of techniques, and in most instances, the appropriate procedure may be selected only at the time of surgery.

The operative procedures available for the repair of urethral stricture disease may be classified broadly based on three principles. These are regeneration procedures, excision and anastomotic repairs, and substitution urethroplasty. In some cases, repairs rely on a combination of these principles, and repairs may be performed in single or multiple stages, depending on individual requirements.

Regenerative Procedures

Regenerative procedures rely on reepithelialization of the urethra once the lumen has been restored. This technique tends to be the most successful for superficial strictures with little spongiofibrosis, where reepithelialization can occur on a virgin bed. Obviously, epithelialization on an underlying scar will result in restenosis, and this is generally the case following simple urethral dilation and accounts for the high failure rate. Urethrotomy attempts to circumvent this problem by incising the ring of underlying scar, in the hope that the cleft created will epithelialize and remain open. Although this does occur in a good percentage of cases, in many the cleft heals across and stricture occurs.

Indwelling urethral stents are a more recent innovation in the management of urethral stricture disease, using the principle of regeneration.

Anastomotic Repairs

Anastomotic repairs are the most successful techniques for stricture repair and are used primarily for the management of traumatic bulbar and membranous urethral stricture. To ensure success, the stricture must be excised circumferentially and a spatulated overlapping anastomosis of the healthy ends accomplished. This obviously will require urethral mobilization proximal and distal to the excision site, and will incur a degree of urethral shortening that potentially could result in penile shortening or chordee. This limitation generally contraindicates their use for the management of pendulous urethral stricture. This is also the primary limiting factor in the application of this repair for the management of bulbar urethral stricture where, in the adult, it is believed that only 2 cm of urethral shortening can be tolerated before penile chordee is possible. Accepting that 1-cm spatulations will be required to achieve an overlapping anastomosis, this leaves only 1 cm available for stricture excision. The principle of urethral reanastomosis can be used for longer repairs in the bulbar urethra by augmenting the anastomosis with a graft or flap, a technique called an *augmented anastomotic repair* (see subsequent discussion). Obviously, in the aged impotent male these limitations may be ignored.

On the contrary, anastomotic repairs invariably are applicable for the management of the pelvic-fracture distraction defect regardless of length, both because of the extensibility of the uninjured, surgically mobilized, bulbar urethra and the fact that a number of surgical maneuvers may be used to relieve tension on the anastomosis, as will be discussed later.

Substitution Urethroplasty

When anastomotic urethroplasty is not possible, substitution of the urethra is required. All techniques appear to suffer the same shortcoming, which is progressive restenosis in the long term in a significant number of cases. Mundy (63), reporting a series of 73 substitution urethroplasties, noted an attrition rate after 4 years of 5% per annum, with an ultimate 10-year successful outcome of 60%. This report did include a variety of techniques and substitution sources. This is in sharp contrast with the results for anastomotic repairs, where the majority of failures occur within the first year and the subsequent restenosis rate is very low. This emphasizes the fact that there is no ideal substitute for the urethra. In addition, it has been demonstrated that tube grafts are not as successful as patch grafts, and indeed, full circumference repair of the urethra rarely is ideal (95).

In an attempt to reduce the shortcomings of substitution urethroplasty, Turner-Warwick (84) described a variety of procedures applicable to a wide range of stricture situations, called *combination procedures.* The goal of these staged repairs was to create a fixed flat urethral roof strip, the remainder of the urethral lumen being reconstructed by substitution. This reduced the portion of substituted urethra to only approximately 50% of the total neourethral circumference. Recently, a number of authorities (32,33,96) have redefined this procedure to allow for transfer of tissue on to a urethral plate using a graft or a flap of penile skin in one stage, with success rates of approximately 85% being reported (96). This technique has been further modified by Barbagli (7), who creates a *floor* strip of native urethra, augmenting the urethra on its dorsal surface (the *dorsal onlay repair*). This technique is conceptually superior because the graft is spread-fixed to a well-vascularized, secure graft bed on the overlying corporal body (38).

Staged repairs currently are regaining in popularity, particularly in the penile urethra, and especially when the stricture etiology is BXO or when it is not possible to substitute onto a urethral plate, as in salvage hypospadias repairs. This change in philosophy has resulted from the poor results of tubed grafts and also from the ability to achieve improved cosmetic results with staged repairs.

Tissue Transfer

The “ideal” urethral substitute is moisture-resistant, hairless, in plentiful supply, easy to harvest leaving no visible scar, and has the ability to “take” easily in its new environment with little shrinkage. No one tissue has all of these characteristics. Over the years, various urethral substitutes have been used. Penile skin has been considered to be the ideal donor site for graft or flap repair of the urethra, because it has a characteristic moisture-resistant quality and, in most locations, is relatively hairless. However, it is not always available, particularly in patients who have had previous surgery. Scrotal skin was used extensively in the past, but with prolonged exposure to moisture tended to develop an eczematous change and this lead to restenosis. It now is considered to be a poor urethral substitute. Other problems related to the use of scrotum for urethral substitution include the fact that it is hair-bearing and has a tendency toward pseudodiverticulum formation, partly because of difficulty with operative sizing of the substitute. Extragenital skin may be used as graft, and the postauricular skin fulfills a number of the ideal criteria and has a more

predictable take than other skin. Recently bladder, and now buccal, mucosa have gained in popularity. Both are water resistant, but bladder mucosa is difficult to harvest. It requires suprapubic incisions and is difficult to handle, and desiccation leads to hypertrophic change. However, buccal mucosa is easy to harvest, is tough and thick, leaves a concealed scar, and is plentiful. It currently is enjoying considerable popularity, with good reported results, although these are all of relatively short duration.

It is likely that in the future, cultured urethral epithelial tissue will be available, with the potential to totally revolutionize the approach to this problem.

Flap Versus Graft

Logic would imply that flaps have a natural advantage over grafts because the success of the procedure does not rely on graft take. However, full-thickness skin grafts, particularly those obtained from the foreskin, and buccal grafts, do enjoy a comparable high success rate when used for the onlay repair of urethral strictures, particularly when the graft can be supported by a healthy, well-vascularized bed. However, the longer the graft, the higher the potential rate of failure; thus in long strictures or when it is likely that good vascular support for the graft cannot be ensured, flap repair may be desirable or a staged repair may be considered. In preparing a full-thickness graft, the removal of its subepithelial tissue is important, because this will facilitate the diffusion of nutrients from the graft bed into the epithelial cells during the period before vascular ingrowth (i.e., inosculation). Full-thickness skin graft has approximately a 20% shrinkage rate and this should be taken into account in sizing the initial graft. The shrinkage rate for buccal grafts remains unknown, and it also remains unknown whether the spread-fixation of the graft to the surface of the corporal body may reduce graft shrinkage. Any factor reducing the diffusion of nutrients will reduce the chance of graft take, and one of the common avoidable factors is hematoma developing beneath the graft. To avoid this, good bed hemostasis should be ensured; the graft should be fenestrated to allow any accumulated serum or blood to escape, and the graft should be sutured (quilted) to its underlying bed. Supportive dressings should maintain the graft-to-bed apposition without excessive compression. The stenting urethral catheter generally is fenestrated or ribbed, also to facilitate the drainage of the urethra at the graft site and to prevent the accumulation of urethral secretions and debris that might promote infection and jeopardize graft take. Premature voiding over the graft will jeopardize its survival; however, prolonged stenting may abrade or introduce infection to the graft site. Full-thickness graft repair most often is used in the bulbar urethra, in which situation stenting for 13 to 20 days is ideal and catheter removal and voiding are always preceded by a pericatheter urethrogram that ensures an absence of extravasation at the graft site. A suprapubic catheter placed at the time of repair will simplify the postoperative course because it will allow for timely stent removal but avoid premature voiding.

Split-thickness skin graft is inappropriate for the one-stage repair of urethral stricture because it has a high shrinkage rate (approaching 50%). It has been used for the staged reconstruction of complex strictures where thick split-thickness skin (0.02 of an inch), obtained from an extragenital source and meshed to a 1.5-to-1 ratio, is used (see subsequent discussion). (77)

As previously implied, flaps with an already established blood supply have been suggested (although unsubstantiated) to have a more predictable outcome, but flaps are not always available (12,70). Islands of appropriately sized and shaped penile skin, based on a subcutaneous random vascular pedicle, may be used for repair of pendulous, bulbar, and posterior urethral strictures, their use being limited only by skin availability and pedicle length. In the majority of cases, the subcutaneous penile tissue provides an adequate vascular pedicle; however, the fasciocutaneous pedicle may lend a degree of certainty to flap survival, as has been stressed by McAninch (52). In these repairs, the dissection of the subcutaneous pedicle is deep to Buck's fascia. This type of repair lends itself quite successfully to the repair of pendulous urethral stricture. In most previously unoperated patients, penile skin is sufficient to allow for the construction of an island of skin for urethroplasty, leaving sufficient penile skin for tension-free primary skin closure. In rare unoperated cases and in some previously operated cases, penile resurfacing may require the inventive rotation of scrotal skin flaps. Pedicled grafts of extragenital skin are uncommonly necessary and generally are indicated in cases of major urethral loss, such as those that may follow blast injury, burn, or local infective necrosis. Myofasciocutaneous gracilis flap, urothelial island–bladder wall flap, and even rectal mucosal flaps all have been described.

NONSURGICAL MANAGEMENT OF URETHRAL STRICTURE

Urethral Dilation

Although most strictures can be dilated, some may be inappropriate for such management. These include strictures requiring frequent dilation (more often than twice a year), which should be managed by one of the alternative methods, because their rapid recurrence generally is caused by surrounding spongiofibrosis. Safe dilation of multiple or long strictures often is difficult, and the risk of producing false passage and confluent scarring is high. Obliterative strictures also are inappropriate for dilation, and the practice of “breaking through” the obliterated segment blindly with a urethral sound is hazardous and generally leads to the formation of false passages. Strictures associated with false passages, periurethral phlegmon or inflammation, urethral fistula, and urethral calculus also may render dilation inappropriate. Strictures associated with false passage simply may be impossible to negotiate using the blind technique and require endoscopic passage of a filiform. Other complications of dilation are urethral hemorrhage and bacteremia. Hemorrhage usually is not prolonged, but can be quite startling. Bacteremia generally occurs following dilation in the patient with urinary infection, but may occur in its absence, and it can be hazardous. Patients predisposed to this event should undergo urethroplasty. Unless a child's stricture can be resolved by a single or very infrequent dilation, management by this technique also is inappropriate. It is inhumane to repeatedly dilate a young boy's urethra without anesthesia, and repetitive anesthetics are ill advised.

Despite these many relative contraindications, most strictures can be managed successfully by occasional bouginage. To ensure the appropriateness of this management, initial dilation always should be preceded by a retrograde urethrogram and endoscopy to ensure that none of these contraindications exist. Once assured, the physician should have available a variety of instruments, which should include a set of curved steel bougies (e.g., van Buren sounds) and filiform bougies with a screw fitting adaptable for either curved steel followers (e.g., Le Forte sounds); plastic, gum-elastic, or woven flexible followers; and a Council-Foley–type catheter with threaded guide.

Regardless of the instrument used, the process of dilation ideally should be a gradual one, because forcible disruption of the stricture simply incurs further mucosal and spongy injury, allowing extravasation of urine and subsequent inflammation, predisposing to further fibrosis. Hence, whether filiforms or steel bougies are used, the stricture should be dilated only until resistance to dilation is sensed. This usually will allow the patient to void, and he then may be redilated using the same technique on subsequent weekly occasions until a lumen of no more than 24-French (Fr) is achieved. Dilation over 24-Fr caliber has no advantage. Once full-caliber dilation has been achieved using this technique, longer dilation-free intervals are likely to be encountered, and the likelihood of the urethra being further damaged by the process is lessened.

Small-caliber metal sounds have extremely sharp tips and may inadvertently perforate the urethra and create a false passage; thus commencement should begin with a larger-caliber bougie, which has a more blunt tip. If this cannot be negotiated through the stricture, then a filiform and follower are a better option than the small-caliber sound. Should the preliminary retrograde urethrogram show a particularly long or tight stricture, the blind passage of metal sounds should not even be attempted, but rather the need for filiforms and followers should be accepted. When passing sounds, the urethra should be well-lubricated by filling it with lidocaine (Xylocaine) lubricating jelly. Recognizing the normal anatomic curvature of the urethra, the lubricated metal sounds initially are inserted with the penis extended vertical to the abdomen and the sound allowed to almost fall under its own weight until the tip reaches the curve at the bulbous urethra. At this point, as the sound is steadied, the penis is depressed gently in a caudally directed arc, negotiating the tip of the sound naturally around the curve of the posterior urethra and into the bladder. Almost the entire act can be accomplished by the weight of the sound itself, and there is little place for “probing” with the tip of the sound. At the point at which the stricture is encountered, gentle pressure alone usually suffices.

Filiforms are used for all difficult strictures and may be inserted blind or under endoscopic vision. A 5- or 6-Fr blunt-tipped spiral filiform is preferable. Should blind passage be unsuccessful, the filiform may be passed along the working channel of the urethroscope or, alternatively, may be passed down the urethra outside the lumen of the instrument. Once the filiform has been negotiated across the stricture into the bladder, either a flexible or a steel follower (Le Forte sound) is attached by screwing it to the male throat of the filiform and the stricture is then dilated without fear of inadvertently getting out of the urethral lumen.

On occasion, the stricture is so tight, and previously formed false passages so confusing, that the surgeon fails to find the urethra channel even under vision. Although this may be an indication for surgical repair by urethroplasty, the true urethral channel may be identified by percutaneously inserting a suprapubic cystotomy, filling the bladder with methylene-blue dye solution, and using Credé's compression of the bladder to force some of the blue solution down the urethra so that the stricture channel may be located by visualization of the wisp of blue.

Should the physician fear that the patient may be unable to void following initial dilation, or should a false passage have been created or excessive urethral bleeding encountered, a small suprapubic catheter may be inserted percutaneously for a few days. A Council catheter is designed for insertion over a filiform as a guide. This

Foley-type catheter with a hole in its tip is negotiated over a flexible guide screwed onto the end of a filiform that has been passed across the stricture into the bladder. Once a Councill catheter has been slid along the length of the urethra guided by the filiform, its retaining balloon is inflated in the bladder and the catheter guide and attached filiform are removed. Balloon-catheter dilation of strictures is favored by some and may have potential advantages, and its advocates suggest that it reduces local trauma (28).

The natural history of the stricture will declare itself during the weeks and months following initial dilation. Those that recur rapidly probably should undergo either direct vision urethrotomy or definitive urethroplasty. A retrograde urethrogram may be performed approximately 6 weeks following the initial dilation, because by this time the natural history of the stricture may be apparent, and the future management of the patient can be planned.

Self dilation on an “increasing interval schedule” is always an option to avoid an imminent urethroplasty. The majority of men can be taught to self-catheterize, and after dilation they are instructed to pass a 12- to 16-Fr catheter through the stricture (but not necessarily into the bladder) initially each day for 1 week, then every second day for the next 2 weeks, then every third day for 3 weeks, and so on, until either no longer required or a comfortable interval is reached.

Internal Urethrotomy

In the nineteenth century, Otis developed the Otis urethrotome; however, this more recently has been superseded by the direct vision, or optical urethrotome, which enables the operator to more definitively incise the stricture alone. The rationale behind urethrotomy is that the incised cleft created in the stricture should epithelialize in the open position. Unfortunately, cleft epithelialization is unpredictable, and maneuvers to promote it are unsuccessful. These have included prolonged catheterization and hydrostatic dilation performed by voiding into the urethra that is obstructed by pinching the glans. This maneuver causes extravasation.

Optical Urethrotomy

The optical urethrotome permits endoscopic incision of the stricture. Both adult- (approximately 20 Fr) and shorter pediatric- (approximately 14 Fr) size instruments are available, and both use a forward-viewing telescope. General, spinal, and local anesthesia all may be used for this procedure, but instillational anesthesia is appropriate for the majority of cases (45). Antibiotic prophylaxis may be given at the start of the procedure, and the patient may continue on prophylactic urinary antiseptics for the duration of postoperative catheterization, if a catheter is used.

With the instrument in the distal urethra and the urethra compressed around the sheath so that the inflow of fluid distends the urethra, the instrument is advanced until the stricture is seen. In some cases, the anatomy of the stricture is such that safe incision can be accomplished without further ado. If the stricture is of narrow lumen or if there is any question concerning where the correct lumen is, a filiform catheter can be negotiated along the working channel of the instrument or alongside the instrument itself and through the stricture. With this filiform as a guide, safe incision through the entire stricture length can be accomplished. The knife blade of this instrument is sharp and the scar tissue customarily is incised at the 12 o'clock position to avoid the main vasculature of the urethra. In the pendulous urethra, incision at the 12 o'clock position often fails to adequately open the stricture, because in this location the spongy tissue surrounding the urethra is thin and the urethra is broadly adherent to the overlying corporal bodies. Therefore bilateral (3 o'clock and 9 o'clock) position incisions may give a more satisfactory result. When the incision is in the dorsal position, it is carried through the entire thickness of the stricture often to, but not into, the corporal tunica. It is important not to cut too deeply in this dorsal position because fibrosis or inflammation of the elastic tissue may result in a Peyronie's-like plaque and eventually in ventral penile chordee. Similarly, the incision should not encroach upon the normal urethra proximal and distal to the stricture, particularly when incising posterior bulbar strictures that abut on the intrinsic urethral sphincter mechanism.

There is no consensus regarding the duration of catheterization following direct vision urethrotomy (1,21,67). It should be dictated by the degree of stricturing, with superficial mucosal strictures often requiring no stenting or stenting long enough for bleeding to subside, whereas dense strictures with full-thickness spongiofibrosis may require stenting for up to 3 weeks. For moderately dense strictures, 3 to 7 days' catheterization with an inert 18-Fr catheter usually is adequate.

Other methods that have been used to try to improve the success rate of direct vision urethrotomy include the injection of steroidal agents, such as triamcinolone, into the stricture at the site of incision (44). This is performed using a purpose-made endoscopic needle passed along the working element of the endoscope. Self-calibration or self-dilation by the patient with a lubricated soft catheter is probably the best method to avoid restricturing following either initial dilation management or urethrotomy (75). Optical urethrotomy also has been popularized using laser technology (68); it is proposed by some to have significant advantages over the cold knife, although this opinion is by no means universal and its use certainly adds considerably to treatment cost (78). Both neodymium:yttrium-aluminum-garnet (Nd:YAG) and argon laser treatment are reported (2).

Although urethrotomy is not complication free, problems are uncommon. The most common immediate problem is of local hemorrhage or extravasation of irrigating fluid or urine. Earlier, the possibility of erectile difficulties were alluded to, with ventral penile chordee and erectile impotence both having been reported rarely (31). Despite their rare occurrences, the possibility of such complications should be included in the preoperative counseling.

Stricture of the sphincter-active membranous urethra may follow pelvic-fracture urethral injury, extension of inflammatory disease from the bulb, or prostatectomy. In the former two events, urethrotomy may still be appropriate, recognizing that the incision will compromise the sphincter-active mechanism but that continence may still be preserved by the bladder neck. However, following prostatectomy, be it transurethral, retropubic, or radical, urethrotomy may be injudicious because it certainly will compromise continence (Fig. 36.8). In such circumstances, urethral dilation may be optimal because, although it also may compromise continence, this generally is short lived (65).

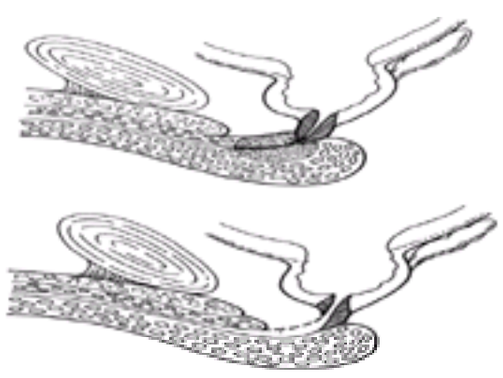

FIGURE 36.8. Following prostatectomy the bladder-neck sphincter is ablated, and continence resides in the distal sphincter mechanism. Urethrotomy or urethroplasty of a stricture at this distal site *(stippled)* may compromise continence. (From Webster GD, MacDiarmid SA. Posterior urethral reconstruction. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

Anastomotic contracture following radical prostatectomy occurs in approximately 5% of cases. A number of etiologies are possible. The most frequently cited causes of anastomotic contracture are distraction of the anastomosis attributable to insecure suturing, nonwatertight anastomosis with resultant local urinary extravasation, excessive local dissection and electrocautery, traumatic suture technique causing local tissue necrosis, excessively snug closure of the vesical neck, and local infection. Careful optical urethrotomy is used for such contractures should dilation fail, but extreme caution is needed to avoid compromising the remaining sphincter mechanism.

Results of Optical Urethrotomy

The published long-term results of internal urethrotomy and urethral dilation make their role in the management of stricture disease clearer. A comparison of internal urethrotomy and urethral dilation has shown no difference between the two (81). Recurrence rates after urethrotomy are in the region of 30% to 50% (3,72). Risk factors for recurrence are long inflammatory strictures and those in the penile urethra. In addition, further dilation or urethrotomy in strictures that reoccur early are of limited value (36). A rational approach to a new stricture would be to perform a single dilation or urethrotomy, and if this fails, consider urethroplasty before the

stricture extends due to spongiofibrosis resulting from repeated dilations or urethrotomy. For patients who do not wish to or are unfit to undergo surgery, a program of self-dilation may reduce the need for frequent dilations or urethrotomy.

Urethral Stents

Indwelling urethral stents are a relatively new development in the management of urethral stricture and currently are used primarily for patients with short strictures located in the bulbar urethra. Manufactured from stainless steel, titanium, or other alloys, these stents are placed endoscopically across the stricture following its dilation or optical incision. Initially exposed to the urethral lumen, the stent is covered rapidly by epithelium, the process being completed in 6 to 12 months. Endoscopic placement proves quite simple using the purpose-made deployment tool, and catheterization and hospitalization generally are not required. Since the initial report of its use by Milroy (54), the short-term success rates are in the range of 80% to 100% (97). Milroy reported results in 27 patients with follow-up over 5 years, with more than 90% patient satisfaction (55). However, nine patients had required a second overlapping stent. A recent study of 99 patients in Europe reported good results in 50% (58).

Of the problems that have been reported with the use of stents, recurrent stricturing occurs in approximately 30%, generally at the proximal or distal limit of the coil. In this circumstance, a further coil may be placed in continuity with the first. In the aforementioned report, hypertrophic scarring obliterates the lumen within the coil in 44%, and this is more common in cases where the patient has undergone prior urethroplasty and is very common when the device is used to treat obliterative strictures, such as those that follow pelvic-fracture urethral distraction injury. Too proximal placement of the coil may splint open the distal sphincter mechanism and potentially compromise continence (14%), particularly if the patient has undergone prior prostatectomy; there also may be some terminal dribbling caused by pooling of urine in the stented portion of the urethra. Compromise to erections is always a consideration and occurred in 44%, but provided the stent is not placed in the pendulous portion of the urethra, any such risk should be minimized. Although stent migration may occur during the early postinsertion phase, it is unlikely once epithelialization has commenced. Recurrent stricturing within the coil may be managed by TURP, but recurrent problems might require stent removal and urethroplasty, and to achieve this requires a complex staged repair. Urethral stents may have a role in bulbomembranous strictures, provided the patients is aware of the complications and difficulties that can arise with its use.

It is evident from the previous discussion of results that problems may outweigh the advantages at this time, and urethroplasty remains the optimal management for most strictures requiring more than urethrotomy or dilation.

SURGICAL REPAIR

Surgical urethroplasty is necessary for those patients in whom instrumental management is inappropriate or impossible. A wide array of operations is available and, although most operations can be adapted for use with any stricture in any location, this is unwise and there is a more logical approach to procedure selection. Accepting that the surgeon is versed in most techniques, it has been advocated that procedure selection should be dictated by the location, etiology, length, multiplicity, and presence of local adverse factors. Most believe that no single procedure is appropriate for the management of all strictures.

General Surgical Principles

Before surgery, it should be ensured that the patient's urine is uninfected; however, in those cases with an indwelling suprapubic tube, this may not be achieved. In this event, such patients should have had a recent tube change and appropriate broad-spectrum antimicrobials prescribed. Bowel preparation is not necessary, but an empty rectum is optimal. General anesthesia may be preferred if buccal mucosa is to be harvested, and also is preferred for the repair of pelvic-fracture urethral distraction defects, but for most other urethroplasties spinal anesthesia is acceptable. The patient should be positioned in lithotomy with the legs supported such that pressure areas and nerves are well padded and safe. Exaggerated lithotomy rarely is necessary and certainly carries a higher risk of neural injury and compartment syndrome. Uncommonly, in the repair of pelvic-fracture urethral distraction defects, access to the abdomen also is required, and patient positioning and draping should be varied appropriately. Methylene blue instilled per urethra differentially stains the urethral scar from healthy urethral mucosa, helping determine the limits of the stricture. The operation should be conducted with the surgeon seated, and a headlight is optimal, particularly for the deep perineal dissections required for the repair of pelvic-fracture defects. Ring retraction is ideal for urethroplasty in the bulbar or posterior urethras, and the “table-fixed” design is optimal (Bookwalter or Omni), although the Turner-Warwick perineal ring retractor also is successful. Absorbable polyglycolic acid (PGA) suture material has highly acceptable tensile strength, absorption rate, and tissue reactivity, and 4-0 and smaller generally is used. Wound drainage may be indicated, and an appropriate-sized suction drain is optimal. Surgical dressing should be supportive and not constrictive, the latter being particularly important following penile flap repairs. Urethroplasty requires urethral stenting using as small a catheter as will support the repair and accomplish urine drainage. In practice, a 12-Fr urethral catheter generally suffices. In bulbar and posterior urethral repairs, catheter fenestration or the use of a ribbed catheter that promotes the drainage of periurethral secretions is optimal. The placement of a suprapubic catheter at the time of urethroplasty facilitates urethral stent management later, allowing for urethral catheter removal without necessarily allowing the patient to void. The duration of urethral catheterization/stenting is determined by the type of repair, and is shortest for anastomotic repairs and most lengthy for one-stage repairs using full-thickness skin graft. Stent removal and, particularly, voiding per urethra always should be preceded by a retrograde urethrogram around the stenting catheter to ensure that healing is complete. Customarily, a retrograde urethrogram is performed at 3 and 12 months following repair. Uroflowmetry is inadequate for follow-up because reduction in urethral caliber to approximately 10 Fr is required before the urine flow rate will deteriorate. Because of the incidence of late failure, particularly following substitution urethroplasty, prolonged follow-up is indicated.

MEATAL STRICTURES

Meatal strictures are infrequent but may occur in young boys who have undergone circumcision, in which case they commonly will respond to occasional meatal dilation, and meatotomy occasionally is indicated (46). In adult males, postmeatal strictures commonly follow endoscopic procedures such as TURP; these strictures also generally respond to periodic dilation, often performed by the patient himself.

BXO is the most common condition resulting in meatal stenosis requiring surgical intervention. The condition affects not only the glans penis and meatus but also may involve the prepuce, the penile skin, and the distal urethra. In some cases, the urethral involvement may go as far back as the urethral bulb, leading to the need for a complex repair. The condition rarely responds to urethral dilation, and meatal reconstruction usually is necessary. The risk of BXO recurrence in the urethra substituted with local penile skin appears to be significant, and it recently has been suggested that excision of the diseased urethra and the use of extragenital skin for substitution in BXO strictures may have a lower recurrence rate (89). This has lead to enthusiasm for the use of buccal mucosa in this endeavor (90).

A variety of procedures have been described for the repair of meatal strictures, each of which gives excellent results when used in appropriate circumstances, including those by Cohney (19), Blandy and Tresidder (11), Jordan (40), and DeSy (22). These procedures are appropriate only for the repair of meatal strictures of non-BXO origin. Figure 36.9 illustrates the technique that reconstructs the terminal urethra with an onlay or full-circumference pedicled island of distal penile skin. The size of the skin island is tailored to the individual requirements and is based on a subcutaneous vascular pedicle in a fashion similar to that described for the transverse preputial island hypospadias repair. The lateral glans flaps can be developed so that they can be reapproximated ventrally over the neourethra, giving a normal glanular appearance and enhancing the chances of establishing a directable flow.

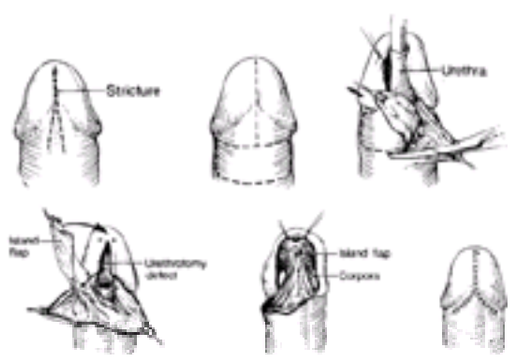

FIGURE 36.9. Repair of meatal and distal penile urethral stricture using a pedicled island of distal penile skin. This procedure allows for reapproximation of glans tissue around the neourethra, giving an excellent cosmetic and functional result. (From Webster GD, Khoury JM. Urethral stricture disease. In: Krane RJ, Siroky MB,

Fitzpatrick J, eds. *Clinical urology.* Philadelphia: JB Lippincott, 1994, with permission.)

Strictures of the glanular urethra resulting from BXO are best excised and repaired in two stages. This may seem excessive for such limited pathology, but the results of single-stage repair using penile skin flaps or grafts are wrought with failure. These authors prefer to excise the BXO-afflicted portion of the urethra by opening the glans and laying a buccal mucosal graft into the defect created. The graft is tubularized, and the glans is reconstituted in a second stage 4 to 12 months later.

STRICTURE OF THE PENDULOUS URETHRA

For the purpose of this discussion, the pendulous urethra describes that portion between the glans meatus and the suspensory ligament of the penis, at which point the bulbar urethra commences. Strictures in this location may result from proximal extension of BXO, from infection, or from catheter or instrument trauma; in the latter event, they are usually short and located at the penoscrotal junction somewhat opposite the suspensory ligament of the penis. Although very accessible to dilation or urethrotomy management, these techniques do not tend to be curative for reasons discussed previously. The cause of penile urethral strictures have changed in recent years, with those caused by BXO making up a higher proportion, in part as a result of more frequent recognition of the condition. BXO is the genital form of lichen sclerosis, and this may be the preferred terminology to bring us in line with dermatology and gynecology (73). In the male, it is a frequent cause of phimosis and, in the majority of cases, circumcision is curative. However, it may involve the urethra locally or extensively (80).

Anastomotic urethroplasty generally is inappropriate in this location because excision and spatulated reanastomosis of even the shortest penile urethral stricture will incur at least 1 cm of urethral shortening, which is sufficient to cause ventral chordee. Hence, anastomotic repairs should be reserved for the patient in whom sexual function is no longer a consideration. Substitution repairs employ either graft or flap. Full-thickness skin graft repairs in the pendulous urethra may use either preputial or extragenital skin and carry good results. They may be used as onlays to augment the strictured urethral lumen, and almost never should be used as a full-circumference urethral replacement. Graft take is good, and cosmetic resurfacing of the penile shaft can be accomplished using penile skin or a local scrotal skin flap. Recently, Barbagli and associates (6,7) have described a dorsal graft technique, with the graft bed being the undersurface of the adjacent corporal body. Full-thickness skin graft repairs generally maintain their caliber well (other than the approximately 20% expected graft shrinkage); however, they appear to exhibit poor longitudinal elasticity and hence have a tendency to produce ventral penile chordee, a major consideration when this repair is used in the sexually active male. This problem is more apparent when full-circumference or long skin-graft repairs are used.

For the aforementioned reasons, the optimal management for the one-stage repair of pendulous urethral strictures appears to be the use of a pedicled island of penile skin, generally as an onlay. A number of variations of the operation have been reported by Orandi (69), Quartey (74), Turner-Warwick (85), and Mundy and Stephenson (59). In the uncircumcised male, a pedicled island of foreskin may be used with excellent cosmetic outcome, also allowing the use of the moisture-resistant inner face skin to an advantage. Even after circumcision, there is invariably sufficient penile shaft skin to allow the island to be fashioned with its long axis along the shaft of the penis and with its pedicle based laterally (i.e., laterally pedicled island of penile skin). As mentioned previously, McAninch (52) has described such a repair with the skin island based on a fasciocutaneous rather than a subcutaneous vascular pedicle, improving its vascularity; he has used this technique to repair long strictures. In these circumstances, the skin island has been a distal penile circumferential island obtained by parallel circumcising incisions.

Most commonly, the island of skin is used as an onlay to increase urethral caliber at the stricture site (Fig. 36.10 and Fig. 36.11). The appropriately sized and shaped island skin is sutured to a roof strip of “native” strictured urethra and two-layer cover is achieved, trying to avoid overlapping suture lines. A small stenting catheter is used, and its removal approximately 14 days later is preceded by a pericatheter urethrogram. Postoperative dressings should be supportive and not constrictive, and when necessary, a microsuction drain may be placed along the shaft beneath the skin closure flap. The width of the pedicled island should be sufficient to create a urethra of at least 25 Fr. In practice, allowing for a small amount of shrinkage, and accepting that the native urethral roof strip adds some to the circumference, the island of skin needs to be between 2 and 3 cm in width. In the event the penile urethral stricture extends into the fossa navicularis, the distal part of the flap should be tunneled into the glans after the meatus, and the glandular urethra have been incised on the ventral surface. The flap then resurfaces the created glans cleft, with the tip of the flap being sutured to the edges of the glans at the meatus. This maintains the normal glans appearance and also avoids retrusion of the meatus. In the event the stricture extends into the scrotal urethra, the skin island needs to be planned inventively to avoid the use of hair-bearing penoscrotal skin. This usually is accomplished by raising the skin island along the ventral shaft of the penis at the required width and proximally coursing the island around the distal shaft of the penis in a circumcising fashion. In this manner, “J” flaps with lengths of up to 15 cm can be obtained, and in most, primary, tension-free skin closure is possible. In the event penile skin cover is not possible, a rotation flap of scrotal skin can be mobilized from the anterior scrotum to resurface the ventral shaft of the penis. Although hair-bearing, its ventral location will render it unobtrusive, and of course, epilation is a possibility.

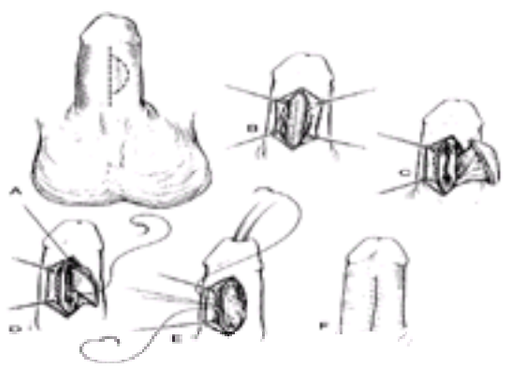

FIGURE 36.10. Onlay urethroplasty of a pendulous urethral stricture (Orandi repair). **A:** The stricture is approached through a ventral penile incision. The outline of the skin island to be used for onlay is marked once the stricture has been opened and its length and caliber determined **(B and C).** The skin island is raised on a subcutaneous vascular pedicle **(C).** The skin island is rotated inward and sutured as an onlay to augment urethral caliber **(D and E).** Skin closure is in at least two layers to avoid fistula formation **(F).**

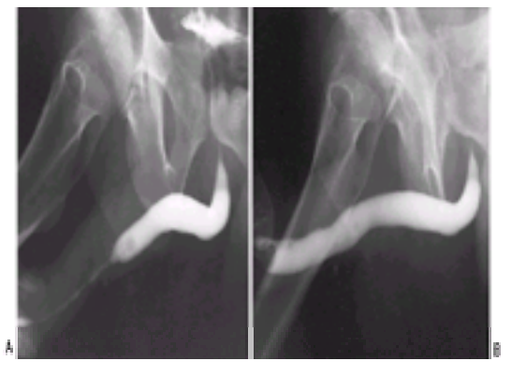

FIGURE 36.11. A: A long, tight pendulous urethral stricture. **B:** The same patient following tube replacement of the strictured urethra using a laterally pedicled island of penile skin. The island of skin was obtained in the vertical axis of the penis, and penile skin closure was accomplished primarily.

Staged repair of the pendulous urethra is necessary in complicated cases, including patients who have had multiple prior procedures where there is considerable local scarring and skin shortage, where onlay of a flap is not possible, or where BXO is the cause. In the latter circumstances, a full-thickness graft from an extragenital source will be introduced to resurface the ventral penis after the strictured portion of the urethra has been excised. This source may be either buccal graft

or postauricular skin, or combinations of the two when the extent of the replacement is extensive. Interim revision of the proximal urethrostomy may be required if there is any evidence of narrowing. At the second stage, at least 6 months later, the neourethra is tubularized from the graft, with the native penile skin being used to resurface the penis. Although simple in concept, this repair relies on full-thickness graft take on the ventral shaft of the penis, and this is not always predictable. The recent introduction of buccal mucosa has lead to renewed interest in the free grafts in the anterior urethra. As previously mentioned, buccal mucosa is easy to harvest from either the inner cheek or the lip. Some prefer to infiltrate with 1 in 100,000 epinephrine to aid the dissection, and an ellipsoid incision is made avoiding the salivary duct. Even without epinephrine bleeding is minimal, and the graft dimensions may be as high as 3 cm × 6 cm at the largest axis. Discomfort or problems with the donor site are minimal and large grafts can be taken. The graft take with buccal mucosa has been excellent thus far, but results are still very short term.

STRICTURES OF THE BULBAR URETHRA

Strictures of the bulbar urethra generally occur as a result of inflammatory disease or urethral trauma from straddle injury. Trauma generally leads to a short, dense stricture with healthy adjacent urethra, whereas infection results in a long, irregular stricture, often with diffuse proximal and distal spongiofibrosis and mucosal damage. These differences dictate the different optimal surgical approaches for strictures that have failed more conservative management.

Most surgical techniques for urethroplasty can be adapted for use in the bulbar urethra; however, optimally, the repair chosen should be dictated by a variety of factors. These include stricture length; the extent of local spongiofibrosis proximal and distal to the stricture; other local factors that may influence outcome, such as false passage, fistulae, or excessive scarring; and the availability of penile skin for urethral substitution. The available repairs are discussed in the following sections, and the surgical techniques are presented thereafter. As noted previously, stricture excision and reanastomosis are appropriate for short strictures of less than 1 cm with healthy adjacent urethra, typified by the stricture resulting from a straddle injury (Fig. 36.12 and Fig. 36.13). In those cases in which the stricture is longer than 1 cm, primary anastomosis may cause penile chordee, and onlay substitution repairs are suggested. Strictures between 1 and 2 cm in length may be handled by a combination urethroplasty, which includes excision of the stricture (less than 2 cm) and anastomosis of the spatulated ends as an open floor or roof strip. The anastomosis is then augmented (patched) by a diamond-shaped–full-thickness skin graft or pedicled island of penile skin. Because less than 2 cm of bulbar urethra is excised and provided adequate mobilization of the proximal and distal urethras is accomplished, little or no penile chordee or retraction results. This approach, originally described by Turner-Warwick (84), was called an *augmented anastomotic repair* (see subsequent discussion). The advantage of this procedure is that healthy urethra is anastomosed to healthy urethra, albeit only as a floor (or roof) strip. Hence, in the event of graft or flap failure, continuity is still maintained. In circumstances where it is evident that the urethral defect remaining following stricture excision would preclude tension-free urethral floor or roof strip reanastomosis, a number of other options remain. Most commonly, the repair selected would be an onlay repair. In this procedure the urethra is incised or opened along the length of the stricture and for 1.5 to 2 cm proximally and distally into healthy urethra. The native strictured urethra remains as a floor or roof strip and an onlay repair using a pedicled island of penile skin or graft of penile skin or buccal mucosa is then used to augment urethral caliber. More recently, dorsal onlay urethroplasty has gained in popularity. Originally described by Barbagli (7), the stricture is opened longitudinally on the dorsal surface and the graft spread-fixed on the surface of the corpora cavernosa overlying the opened portion of the urethra. This technique achieves a number of goals, including the apposition of the graft to a secure, well-vascularized surface; the avoidance of the possibility of sacculation; and the fact that spread-fixation likely deters shrinkage. In the majority of circumstances, full-circumference urethral replacement using full-thickness skin graft or flap carry unpredictable results because graft or flap failure will be followed by urethral obliteration and thus are uncommonly recommended.

FIGURE 36.12. A: A short midbulbar urethral stricture following straddle injury. **B:** Urethrogram following stricture excision and spatulated anastomotic repair. This repair was appropriate in view of the short length of the stricture.

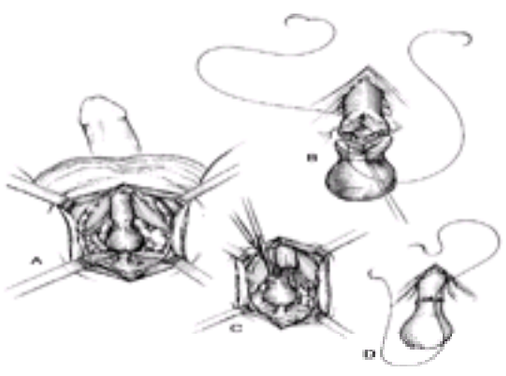

FIGURE 36.13. Anastomotic repair of bulbar urethral stricture that may follow straddle injury. **A:** The urethra is exposed through a midline perineal incision, and the stricture site is identified and excised. **B:** Following stricture excision, opposing spatulations of 1 cm are accomplished. **C:** The distal urethral opening is spread-fixed to the underlying corporal body and spatulated anastomosis performed with interrupted sutures. **D:** The anastomosis is completed and additional tension-relieving sutures are placed between urethral adventitia and adjacent corporal bodies to avoid anastomotic tension during erection.

Staged bulbar urethral reconstruction is used in circumstances in which the success of a one-stage procedure seems in jeopardy; it is particularly applicable to lengthy complex strictures with associated local adverse features, such as extensive scarring, inflammation, fistulae, false passage, and diverticulum. The staged repairs allow for the supervision and continued surgical access to the region during the interim phase, facilitating local revision procedures or adjustments of the roof strip and hair-follicle destruction in the neourethral area of the inlay. It is only when healing of the inlay or roof strip is seen to be satisfactory, and both proximal and distal urethral ostia remain stable and stenosis free, that the ultimate urethral tubulization can be performed. This entire process often requires more than two stages, and it is a misnomer to call these procedures two-stage repairs. The originally described procedures all marsupialized the strictured urethra to scrotal skin, the various techniques differing only according to the manner in which the flaps were constructed and deployed to the urethra (9,14,29,34,47,85). The major disadvantage of these repairs was that the ultimate neourethra would be constructed from scrotal skin, although sometimes the skin would be epilated before neourethral construction. As noted previously, scrotal skin is a poor urethral substitute with a high incidence of dermatitis from exposure of the skin to urine, often resulting in later restenosis. Currently performed staged repairs generally combine urethral marsupialization with the introduction of a full-thickness or split-thickness skin graft, or buccal mucosal graft into the area around the marsupialized urethra, so that the neourethra subsequently will be formed from it rather than the scrotum. Chapple and Turner-Warwick (14) have described elaborate combination-staged repairs where the urethral roof strip is reconstructed from available urethra or full-thickness skin graft and is left accessible by scrotal drop back so that its healing can be supervised and revised as necessary. Schreiter and Noll (77) describe a less elaborate technique in which meshed split-thickness or full-thickness preputial skin, when available, is transplanted adjacent to the native urethral plate after the stricture has been incised or excised. This technique is described later in the chapter.

Anastomotic Bulbar Urethroplasty

Recognizing the surgical principles and selection criteria discussed previously, this urethroplasty is used primarily for the repair of short (less than 1 cm) posttraumatic strictures, as identified by the preoperative urethrogram, and confirmed at the time of surgery. The salient surgical features are that the perineum is incised in the

midline, with the incision being bifurcated posteriorly to improve access. The bulbospongiosus muscles are mobilized from the underlying bulbar urethra, which is then dissected circumferentially for a few centimeters proximal and distal to the stricture site, which is identified by the passage of a catheter. The urethra is transected at the distal limit of the stricture, and the strictured portion of the urethra is opened dorsally until healthy urethra is again encountered. If the stricture length proves to be less than 1 cm, the strictured portion of the urethra is excised. The proximal healthy urethra is then spatulated on the contralateral–ventral side so that opposing 1-cm urethral spatulations are created (Fig. 36.13). The ventrally spatulated proximal urethral opening is then spread-fixed to the overlying corporal body, the distal (dorsally spatulated) urethra then being anastomosed to it with interrupted 4-0 and 5-0 polyglycolic acid (PGA) sutures. To relieve tension, the proximal and distal urethras may be further mobilized, but the latter should not be mobilized beyond the suspensory ligament of the penis, to avoid penile chordee or retraction. Stenting is with a fenestrated 12-Fr inert catheter, and perineal closure is in layers, a suction drain being optional. This procedure currently is performed as an outpatient in most cases, and catheter removal (preceded by a urethrogram) usually is anticipated at 7 to 10 days following surgery.

Augmented Anastomotic Repair

The augmented anastomotic repair combines stricture excision and urethral floor (or roof) strip reanastomosis with augmentation of the anastomotic area using either a penile skin flap or a full-thickness graft. The urethra is approached as for a standard anastomotic repair, being transected at the distal limit of the stricture and the strictured portion of the urethra is then opened proximally on its dorsal surface. Strictures appropriate for this repair are those that are too long for a tension-free anastomosis without risking chordee by excessive distal urethral mobilization. The urethral ends are spatulated proximally and distally for 1.5 cm at the 12 o'clock position (Fig. 36.14 and Fig. 36.15). After appropriate and judicious urethral mobilization to relieve tension, the floor of the urethra is anastomosed with interrupted 4-0 PGA sutures. In this fashion, a healthy, wide floor strip of urethra is created, but the lumen now needs to be completed by either a full-thickness graft or flap of penile skin. In general, the island of buccal mucosa or skin will be approximately 2 cm in width, and its length and shape will be determined by the length of the spatulations at the anastomosis. The urethra is stented with a fenestrated catheter.

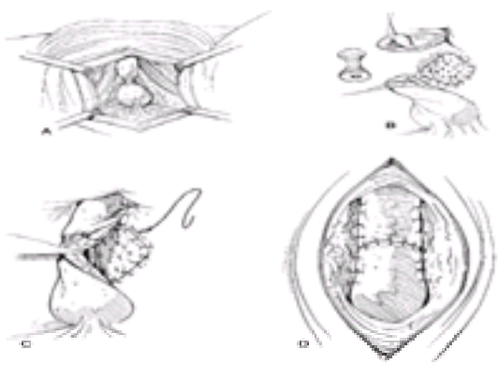

FIGURE 36.14. The augmented anastomotic bulbar urethroplasty includes short-segment stricture excision and dorsal onlay graft. **A:** Strictured urethra is approached through a perineal incision. **B:** After circumferential mobilization of the urethra at the stricture site, the short stricture is excised and the urethral ends are spatulated dorsally. The appropriately sized and shaped graft is sutured to the corporal bodies overlying the spatulation. **C:** The floor strip of the urethra is anastomosed and margins of the spatulation are sutured to the margins of the spread-fixed graft. **D:** Completed repair.

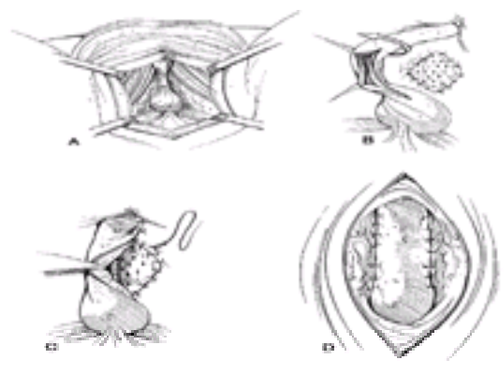

FIGURE 36.15. The dorsal onlay bulbar urethroplasty. This repair is used for bulbar strictures in which stricture length precludes excision. **A:** Bulbar urethra exposed through perineal incision. **B:** Urethra is circumferentially mobilized at stricture site and rotated to allow dorsal urethrotomy through the stricture. Appropriately sized and shaped graft is sutured to the corporal bodies overlying the stricturotomy. **C:** Margins of the urethra are sutured to the margins of the spread-fixed graft, thereby augmenting the size of the urethral lumen. **D:** Completed suture.

In the event an adequate graft bed cannot be ensured, the anastomotic area is best augmented with a pedicled island of penile skin. The appropriately sized island is outlined on the ventral non–hair-bearing surface of the shaft of the penis and the skin is incised. The subcutaneous pedicle to the island is developed proximally, with the deep layer of dissection being on the surface of Buck's fascia and the superficial being just deep to the penile and scrotal skin blood supply. In practice, a triangular-shaped pedicle (based posteriorly) results, and the island of skin then can be transferred or tunneled to the perineum, through the scrotum (Fig. 36.16). Dissection of the pedicle is critical; it must be adequate to avoid tension but must be limited to avoid compromise. The penile skin defect is closed primarily, and the island of penile skin is sutured into the urethral anastomotic area, augmenting it appropriately. Drainage, stenting, and catheter management are similar for those described for the graft repair.

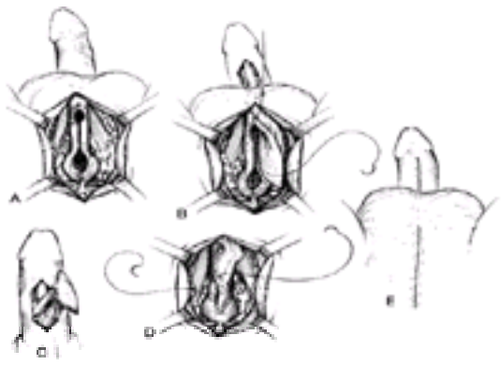

FIGURE 36.16. A: The urethra at stricture site is exposed to the perineum and the urethral incision opens the stricture and 1 cm of healthy proximal and distal urethra. The stricturotomy may be ventral (as shown) or dorsal following circumferential urethral mobilization. The advantage of dorsal onlay is lesser chance of pseudodiverticulum. **B–D:** An appropriately sized and shaped island of ventral penile skin is raised on a vascular pedicle and transferred through the scrotum to be onlayed over the urethral defect, augmenting the urethral caliber at the stricture site. **E:** Closure.

Bulbar Onlay Graft

Longer strictures of the bulbar urethra, particularly those of inflammatory origin, that cannot be managed by excision are best treated with an onlay repair (6,38,89).

The onlay may be graft or flap, although the former is currently preferred by most, and the graft source may be either penile skin or buccal mucosa. The selection of graft versus flap for the onlay depends on the nature of the graft bed, and to some degree on the philosophy of the operating surgeon. Graft survival is surprisingly predictable; although the longer the stricture, the greater the chance of graft failure, and graft survival is enhanced by the quality of the graft bed. The urethra is approached as described for the aforementioned procedures, with the strictured portion being circumferentially mobilized and then opened longitudinally through the stricture by dorsal (or ventral) incision. The incision should be carried proximally and distally into healthy urethra for 1.5 cm (Fig. 36.15). The appropriately sized and shaped graft is then sutured to the corporal body overlying the dorsally opened, strictured urethra using 5-0 Vicryl sutures. The graft is spread-fixed so that the graft is secured to its corporal-body bed, enhancing the probability of graft take. The margins of the opened urethra are then sutured to the margins of the graft, thereby augmenting its lumen by the width of the graft. The repair is stented for approximately 3 weeks with a 12-Fr fenestrated catheter, and catheter removal is preceded by a urethrogram to ensure absence of extravasation. An additional suprapubic tube is favored by some.

Staged Bulbar Urethral Reconstruction

The indications for staged bulbar urethral reconstruction were detailed previously. Although these were the standard techniques in the past, they were superseded by one-stage procedures that often were elaborated beyond their true applicability. The current role of staged repairs has gelled to their more frequent use, particularly for pendulous urethral stricture resulting from BXO, and for extensive stricture involving the full length of the urethra. Staged repairs are performed either with marsupialization of the strictured portion of the urethra to scrotal skin margins, or by the application of a graft (split-thickness skin, full-thickness preputial skin or buccal mucosa) to the margins of the opened urethra. The latter is preferable so that it will be the graft and not scrotal skin that is tubularized at the second stage, to form the new urethra. Every attempt should be made to ensure that the neourethra is not constructed from scrotal skin, which has a poor history of success because of long-term restricture, pseudodiverticulum formation, neourethral hair growth, and stone formation.

In the past, the application of a meshed split-thickness skin graft to the periphery of the marsupialized urethra has been reported when a multistage approach is indicated. Patient position and surgical draping should facilitate access to the thigh from which the split-thickness graft may be obtained using a pneumatic dermatome. Perineal approach to the strictured urethra is through a midline incision bifurcated posteriorly, the distal limit of the incision being dictated by the distal extent of the stricture; in uncommon instances, the scrotum may be bivalved and the entire urethra laid open. Once the ventral incision has been made through the entire length of the stricture and proximally and distally into good urethra, the skin graft is raised generally from the inner thigh (which is close to the operating field) to a thickness of 0.02 inch. The skin is meshed to a ratio of 1.5-to-1, using the meshing roller. An adequate width (3 cm or more) of meshed graft is then sutured in place to surround the marsupialized urethra, interposed between it and the skin edges (Fig. 36.17). It is sutured in place with 4-0 or 5-0 PGA sutures and bolstered with moist dressings (Xeroform and cotton balls soaked in Bunnell's solution) for 5 to 7 days. Graft take generally approaches 100%, and urethral catheter removal is at approximately 10 days, with voiding being avoided by continuing suprapubic drainage for approximately 2 weeks. In the interval stage before final closure, the patient must be seen frequently, with cross-bridging of the graft and exuberant granulation being appropriately managed. Careful perineal toilet is essential and, ideally, closure should be deferred until graft stability and softening is obvious. Closure has been reported as early as 8 weeks following initial grafting, but 6 months is ideal. Shrinkage of the split-thickness graft is considerable, particularly in areas where the graft is laid onto nonsupportive tissue, such as fat. Fortunately, neourethral tubulization requires only a thin strip of grafted skin around the marsupialized strictured urethra to create a 24- to 28-Fr sized lumen. At the time of urethral closure, the strip of skin around the marsupialized urethra is demarcated, incised, and tubularized over a stenting catheter using lengths of continuous 4-0 or 5-0 PGA suture. Layered perineal closure supports the repair, and a suction drain may be placed. Stenting is continued for 14 to 20 days, and voiding is deferred until a retrograde urethrogram shows an absence of extravasation.

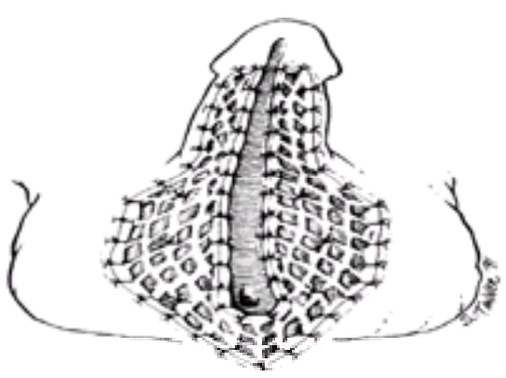

FIGURE 36.17. Staged urethroplasty for full-length stricture disease using meshed split-thickness skin graft. The meshed graft is laid alongside the marsupialized urethra so that the neourethra will be tubularized from the graft rather than from hair-bearing scrotal skin. Tubulization of the neourethra is delayed for 2 to 6 months. (From Webster GD, Khoury JM. Urethral stricture disease. In: Krane RJ, Siroky MB, Fitzpatrick J, eds. *Clinical urology.* Philadelphia: JB Lippincott, 1994, with permission.)

In the uncircumcised male, the foreskin may be harvested and inlaid around the marsupialized strictured urethra in place of the split-thickness graft. This may provide a superior quality skin, but full-thickness graft take is not as predictable and preputial skin may be insufficient to surround a lengthy stricture. In the latter circumstance, the graft may be meshed to increase graft surface area and possibly to enhance graft take. Schreiter and Noll (77) reported 96 patients with long and complicated strictures managed with this technique. Full-thickness penile skin was used in 76 patients and split-thickness skin graft was used in 23. In addition, postauricular skin or buccal mucosa may be used in this situation, and the graft origins may be mixed if availability is a problem.

Technically, these procedures are time-consuming, and in the event the stricture extends proximally into the membranous urethra, the suture fixation of the graft in the deep perineal funnel is difficult. Despite these technical difficulties, the results appear superior to those of simple scrotal inlay repair using scrotal skin.

Results of Anterior Urethroplasty

Expectations of a successful outcome are the greatest in anastomotic repairs of the bulbar urethra for traumatic strictures, and failures generally present within the first year (39). Mundy (62,63) has shown that in patients undergoing substitution urethroplasty, full-circumference tubed repairs fare less well than onlay (i.e., patch) repairs; Mundy suggests that, unlike anastomotic repairs, there is a steady annual attrition rate after approximately 4 years of approximately 5% per annum. He also noted that scrotal skin repairs do much worse. Mundy concludes that in the long term (more than 10 years), all skin inlays have a tendency to deteriorate. Nonetheless, this may be an acceptable situation considering the alternatives (dilation or urethrotomy management), and providing patient selection is appropriate. Others have reported good long-term results even from repairs using scrotal skin (76). Blandy's group (9) followed 194 patients undergoing a one-stage scrotal patch repair who were followed from 3 to 20 years, and noted stricture recurrence in only 7%, but some were as late as 15 years. The results using the aforementioned combined approach of onlay techniques, grafts when penile skin is unavailable, and a staged repair with grafting in complex cases and when circumferential substitution is required, is reported to give an 85% overall success rate (96). Newer techniques such as the dorsal onlay urethroplasty and the use of buccal mucosa show promise and conceptually seem to be superior, but long-term results are needed before their place in urethral stricture management can be confirmed (6,33,38,51).

One of the concerns of bulbar urethroplasty is postoperative impotence. In the past, an incidence as high as 15% had been suggested; however, this is no longer the case with current practice, and Mundy (62) reported a 33% temporary and a 0.9% permanent (more than 3 months) rate.

STRICTURES OF THE POSTERIOR URETHRA

Stricture or obliteration of the posterior or membranous urethra most commonly result from urethral disruption at the time of pelvic fracture, although they also may follow prostatectomy.

Prostatomembranous urethral injury occurs in approximately 10% of patients sustaining pelvic fracture, the majority being the result of automobile or occupational injury. The magnitude of the initial trauma will determine the amount of prostatovesical displacement on which the degree of urethral injury will depend. In the majority of pelvic fractures, the urethra either is not injured or is simply contused and/or elongated with minimal residual sequelae. If urethral disruption does occur, it may be

partial or complete, and retrograde urethrography will diagnose the extent. Patients with contusion and/or elongation injury require a temporary urethral Foley catheter; however, in those with a partial tear in whom retrograde urethrography will show continuity but some extravasation, optimal management is by suprapubic cystostomy alone until the urethra heals. Urethral catheterization is considered injudicious in this scenario because it is considered that it may convert the partial tear into a complete tear. Often, however, an attempt has been made during the resuscitation of the patient before the urethral injury has been suspected or assessed.

Once the diagnosis of total prostatomembranous urethral disruption is made by retrograde urethrogram, excretory urography also should be performed to evaluate the upper tracts and the bladder, because bladder rupture occurs simultaneously in up to 10% of cases. A small percentage of cases demand immediate surgical intervention (Fig. 36.18) (92). These include the patient with an associated rectal injury in whom early exploration is needed to evacuate the contaminated hematoma and to perform a colostomy. Urethral realignment over a stenting catheter is appropriate in such cases. Patients in whom both the prostatomembranous urethra and the bladder neck are injured by the fracture also should undergo exploration so that the bladder neck can be debrided and repaired. This is to improve the chance of continence.

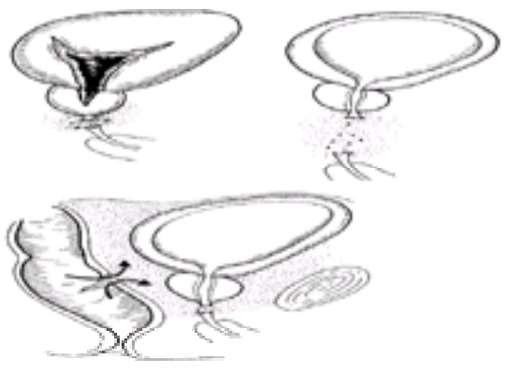

FIGURE 36.18. Primary indications for “early” intervention in cases of posterior urethral injury after pelvic fracture. These include associated rectal tear, associated injury to the bladder neck, and excessively long distraction defects. (From Webster GD, Khoury JM. Management of acute urethral trauma. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

The management of patients other than these is controversial. The debate centers on the timing of intervention and the use of endoscopic or open surgical repair. Repair can be immediate, delayed (within 1 to 2 weeks), or late (after 3 months). At each of these times, the urethra can be repaired by endoscopic or open surgical techniques. The outcomes debated with the use of these different approaches are the incidence of strictures, impotence, and incontinence. For a number of decades, placement of a suprapubic catheter and open surgical repair at 3 to 6 months has been the gold standard, with successful outcome reported in more than 95% of patients. Numerous reports advocating the use of endoscopic techniques to reestablish urethral continuity are currently appearing. The difficulty in defining the role of endoscopy is that the numbers are small, follow-up is short, and the variety of different techniques used make comparison with open surgical repair difficult.

Immediate Urethral Realignment

Advocates of immediate urethral realignment stress the advantage of the immediacy of managing the problem, thereby avoiding the need for prolonged suprapubic catheterization while awaiting secondary repair. In this approach, the injury is explored at the time of presentation, the pelvic hematoma is evacuated, and the urethra is realigned over a stenting catheter using one of a variety of techniques. Unfortunately, conditions rarely are ideal for cautious surgery soon after pelvic fracture, and early exploration often results in catastrophic new bleeding. An historic review of 15 reported series encompassing 301 patients managed in this fashion showed that only 69% of them had stricture-free healing of the urethra in any event (92). Of these patients, 40 of 201 (20%) were incontinent, and 102 of 252 (40%) were impotent. This is in sharp contrast to the results of accumulated series of 236 patients managed by delayed intervention in whom only 4 (1.7%) were incontinent and 26 (11%) were impotent. Although these results do reflect the results of surgery performed in a prior surgical era, the discrepancy in outcomes still leads one to view aggressive early intervention with caution.

Instances in which patients who have been catheterized using endoscopic techniques within the first few hours of injury have been reported. Herschorn and associates (35) reported on immediate catheterization, with a concluding comment that careful urethral catheter realignment (either immediately or within 5 weeks of injury) is safe and obviates total urethral closure. Their method of catheterization was retrograde or antegrade, primarily using the linked-catheter technique; they comment that 54% of patients managed in this fashion subsequently developed a stricture in follow-up and required urethrotomy or dilation, and no patients developed incontinence. They also suggest that the rate of impotence was related to the extent of injury rather than injury management. Elliot and Barrett (26) recently reported a historic series with results of immediate realignment of complete urethral disruption in 56 patients. Although the risk of incontinence and impotence in this series is similar to that of other methods, postrealignment strictures that required further treatment occurred in 68%. In addition, many patients with pelvic-fracture urethral disruption have other injuries, and the urethral injury is not a priority in their management at this stage. A further consideration is that urethral catheterization may introduce infection and cause further bleeding, and in the long term, two-thirds of the patients will still be left with a urethral stricture.

Delayed Primary Repair

Delayed primary repair requires that the patient with prostatomembranous urethral disruption from pelvic fracture be managed by suprapubic catheter placement at the time of injury, and that the disruption then be realigned endoscopically over a stenting catheter or repaired surgically at the next opportunity (usually within the first 10 days) when the patient's general condition has stabilized. The advantage of this technique is purported to be an avoidance of the high risk of pelvic exploration during the immediate postinjury period.

Mundy (64) reported 17 men with pelvic-fracture urethral distraction defect in whom he performed abdominal exploration with pelvic hematoma evacuation and sutured anastomotic repair over a stenting catheter. In 12 cases, the site of injury was immediately subprostatic, but he noted that in 5, the rupture was as much bulbar as it was membranous urethral, but in all cases he was able to place six anastomotic sutures. Follow-up was not long at the time of publication, but thus far no patients have required subsequent urethroplasty, and four have required dilation or urethrotomy (61). Of the 13, 5 are potent and none are incontinent. Chapter author, George Webster, has had similar unreported experience with delayed primary repair, performed per perineum rather than abdominally. The advantage of the perineal approach is the simplicity of the anastomosis and the lesser operative morbidity as compared with the laparotomy approach. However, a disadvantage is that many patients cannot be placed in the lithotomy position so soon after pelvic-fracture injury.

Delayed endoscopic realignment is being reported increasingly. The techniques used are evolving, and currently include combinations of antegrade and retrograde endoscopy, fluoroscopy, and magnetic interlocking sounds. Cohen and colleagues (18) reported on five cases with complete posterior urethral disruption following pelvic fracture managed by endoscopic realignment 7 to 19 days following injury. This was performed using a flexible endoscope passed through a suprapubic tract and a rigid or flexible cystoscope negotiated per urethra. Once a guidewire was negotiated across the injury, a catheter could be guided over the wire and left indwelling for 5 to 10 weeks. Their patients performed intermittent self-catheterization for up to 6 months following catheter removal. They had a successful outcome in four; one patient was unable to perform the self-catheterization and ultimately required urethroplasty because of obliteration. Two patients were potent and none were incontinent. One criticism of their technique is their use of Foley-catheter traction, presumably to facilitate healing at the realigned injury, and the use of traction has now been largely abandoned because of the risk of damage to the bladder neck. Indeed it is probable that intraabdominal pressure will force the bladder and prostate back to the pelvic floor without traction, the direction of descent being simply guided by the stenting catheter. Further reports of these different realignment techniques have been published and it may be that they have a role in management, but at present the numbers are small and the follow-up has been short.

A recent literature review (43) compared all immediate realignment with late repair and found a similar risk of incontinence, but half the risk of stricture. The risk of impotence in this review was doubled with early realignment; however, this may reflect the severity of the injury rather than the results of the intervention. They concluded that the various procedures complement each other in the management of these patients. The reported results need to be evaluated with care, because success after endoscopic procedures often includes those patients who require outpatient dilation, which in open surgical repairs would be considered a failure.

Secondary Repair of the Distraction Defects Following Pelvic-Fracture Urethral Injury

The delayed management of membranous urethral injuries again falls broadly into two categories: (a) endoscopic procedures, including direct vision internal urethrotomy and urethral dilation and (b) open surgical procedures, including anastomotic and substitution urethroplasties. Procedure selection is dictated by the nature of the urethral defect (obliterative or nonobliterative); the length of the defect; the presence of complicating factors, such as urethral cavitation, fistulae, or bladder neck injury; and to some degree, by the treatment philosophy of the surgeon.

Delayed Endoscopic Management of Posterior Urethral Strictures and Distraction Defects

The role of urethral dilation and direct vision internal urethrotomy has been well-established for the treatment of nonobliterative membranous urethral strictures following partial urethral tears. Although recommended as first-line therapy in these cases, it must be recognized that few strictures are cured, with most requiring long-term, periodic dilation management and many requiring eventual open urethroplasty.

More controversial is the use of visual urethrotomy, better known as *cut-for-the-light technique,* in the management of obliterative membranous urethral defects. Variations of this technique have been described by Barry (8) and Marshall (50) and many other small series. A more recent report by Spirnak and co-workers (79) presented five patients with distraction defects less than 3 cm in length, which were managed an average of 4 months following injury. Once urethrotomy had been accomplished through the obliterated segment, a stenting catheter was left for 3 to 7 days, and after removal, the patient was placed on a 3-month regimen of urethral self-dilation. They noted three totally successful outcomes an average of 31 months following treatment, whereas two, who failed to perform self-dilation, required repeat urethrotomy. Of the latter patients, one is now a success, but the other has required urethroplasty. El-Abd (24) reported a series of *core-through* procedures performed in 79 patients. Strictures longer than 2.5 cm were treated by open urethroplasty. Half of the patients were considered a success but still required an average of two procedures to achieve stability. Although if successful, this procedure may spare the patient an open urethroplasty, it may result in a number of complications, and often requires multiple anesthetics. False passages may be created that bypass the sphincter, and fistulae may be established between urethra and rectum. At best, if the procedure is successful, urethral continuity is reestablished, but the channel created lies in dense scar tissue, and generally requires long-term dilation and often, eventual surgical urethroplasty.

The role of this technique in the management of pelvic-fracture urethral distraction defects remains to be established by long-term follow-up of larger series of cases. Optimal techniques (e.g., radiographic versus stilette directed versus endoscopically guided) need to be established, as do patient-inclusion criteria for the technique (length of defect) and appropriate timing (from time of injury). It is likely that until these questions are answered, the procedure cannot universally replace the surgical management of these defects, and enthusiasm for this nonoperative approach must be tempered with caution.

Delayed Surgical Repair of Pelvic-Fracture Urethral Distraction Defects

There is no panacea for the management of posterior urethral distraction defects, but Webster and colleagues believe that the optimal repair is by a one-stage anastomotic procedure, preferably performed through the perineum alone (94,95). This repair has proven to be remarkably versatile and durable, and has been used successfully for distraction defects as long as 7 cm. It also is the opinion of these authors that only extremely complex strictures will require an abdominoperineal approach or a substitution urethroplasty. Experience proves that fewer than 5% of cases will be classified as complex because of associated adverse local features impacting upon repair selection, and these features are noted in Table 36.1. Certainly, those reconstructive urologists dealing primarily with war rather than automobile injuries will have a higher incidence of such complicated cases.

Long urethral defect	Associated anterior urethral stricture
Chronic periurethral cavity	Factors limiting surgical access
Rectal, cutaneous, and peri-urethral bladder base fistula	History of prior failed repair
Incontinence

TABLE 36.1. FEATURES ASSOCIATED WITH *COMPLEX* POSTERIOR URETHRAL STRICTURES

Progressive Perineal Approach for the Repair of Posterior Urethral Distraction Defects

A 3-month delay before embarking on repair generally is sufficient. Longer delays have not proven advantageous, and the proposal that the length of the distraction defect reduces with time is not borne out by experience. A combined cystogram–retrograde urethrogram will have evaluated the complexity and length of the defect, the competence of the bladder neck, and the normality of the anterior urethra. In addition, antegrade and retrograde cystoscopy will have been performed to verify the radiographic findings and also to rule out bladder stones, which are present as a result of the long-term catheterization.

The patient is placed in the lithotomy position, and both the abdomen and perineum are prepped in case combined retropubic access is required intraoperatively. Excellent exposure of the posterior urethra is obtained by a midline perineal incision bifurcated posteriorly, and the bulbospongiosus muscle is divided in the midline (Fig. 36.19A). The bulbar urethra is then mobilized circumferentially as far proximally as the obliterated segment where it is transected, and distally to a few centimeters distal to the crura (Fig. 36.19B). The anterior urethra in essence becomes a urethral flap depending on collateral retrograde blood supply from the corpora cavernosa and glans. Previous anterior urethral surgery or strictures and significant hypospadias may jeopardize the blood supply to the flap, precluding this mobilization and dictating an alternative repair. In addition, this blood supply seems less well-developed in prepubertal boys. The blood supply can be assessed using Doppler ultrasound.

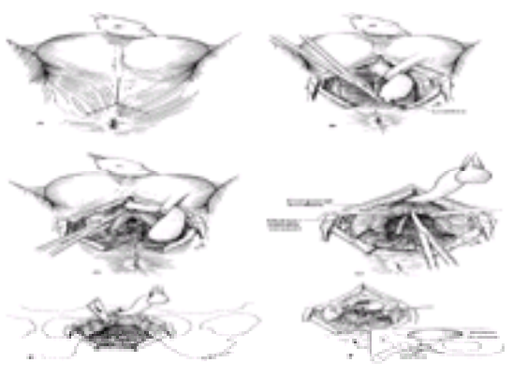

FIGURE 36.19. Perineal repair of pelvic fracture urethral distraction defects. **A:** A midline perineal incision is bifurcated posteriorly. **B:** After dissecting the bulbospongiosus muscle from the bulbar urethra, it is circumferentially mobilized proximally to the obliterative defect. Incision of the posterior urethral attachments *(scissors)* facilitate mobilization. **C:** Once transected posteriorly, the urethra is mobilized distally as far as the suspensory ligament of the penis, if necessary. **D:** Penile corporal bodies are separated, right from left, from the crus distally for 5 to 7 cm. The dorsal penile vessels dorsal to the corpora lie beneath the inferior ramus of the pubic above. **E:** A channel is excised from the inferior ramus of the exposed pubis between the separated corporal bodies using bone osteotome and/or bone rongeur. **F:** The corporal body is dissected circumferentially and the mobilized urethra rerouted around it and through the resected bony defect. The mobilized bulbar urethra is spatulated dorsally for anastomosis to the posteriorly spatulated prostatomembranous urethra. *(Inset)* Supracrurally rerouted urethra shown traversing

resected inferior bony defect to facilitate bulboprostatic anastomosis. (From Webster GD, MacDiarmid SA. Posterior urethral reconstruction. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

Through the suprapubic tract, a urethral sound is then negotiated carefully through the bladder neck and into the prostatic urethra until its tip can be palpated in the perineum, then a vertical incision is made through the perineal scar onto its tip. Adequate exposure is obtained with a nasal speculum inserted retrogradely into the membranoprostatic urethra (replacing the antegrade sound), allowing the membranous urethra to be spatulated at the 6 o'clock position as far proximally as the verumontanum. The bulbar urethra is spatulated on its opposite side to ensure an ultimate 40-Fr–sized bulboprostatic anastomosis.

At this point, it will become apparent whether a simple tension-free anastomosis is possible or whether further lengthening procedures are required. These further maneuvers are carried out in a progressive, stepwise fashion as the need for further lengthening is required (95). In order, these maneuvers are performed as follows:

1. *Further circumferential mobilization to the suspensory ligament.* Careful dissection is required to avoid dissection into the spongy tissue, which could jeopardize the blood supply of the flap. If mobilization is taken beyond the suspensory ligament, penile chordee may result (Fig. 36.19C). Up to 2 cm of lengthening can be obtained by this maneuver because of the elasticity of the healthy bulbar urethra.
2. *Separation of the proximal corporal bodies.* If the urethra is allowed to course between the separated corporal bodies rather than over them, at least 1 or sometimes 2 cm of apparent urethral lengthening can be achieved. The proximal 4 to 5 cm of the corporal bodies can be separated by careful sharp dissection along a relatively avascular plane in the midline (Fig. 36.19D). Beyond this point, the corporal bodies are connected more intimately making further separation too difficult.
3. *Inferior pubectomy.* The two aforementioned maneuvers achieve a tension-free anastomosis in approximately 50% of cases. A further 1 to 2 cm can be gained by redirecting the urethra through a bony channel excised from the inferior pubic bone now exposed between the separated corporal bodies. A small wedge of bone only is removed using an osteotome and bone rongeur (Fig. 36.19E), facilitating the anastomosis in an additional 28% of cases. In an attempt to preserve the more laterally situated neurovascular bundle along the inferior surface of the pubis, excision of bone must be limited to the midline.
4. *Rerouting the urethra around the corporal body.* As a final maneuver, the urethra can be rerouted laterally around the corporal body and through the tunnel created by the inferior pubectomy (Fig. 36.19F). A tunnel is created in the soft tissue around the corporal body, taking care to avoid the corporal body, thereby preventing damage to the neurovascular bundle close to its surface. This supracorporal rerouting achieves at least a further centimeter of urethral lengthening and is required in approximately 23% of cases.

It is difficult to predict preoperatively which patients will require these final two maneuvers, because urethrograms only estimate the length of the distraction defect in one radiographic plane and give little information about associated spongiofibrosis and urethral elasticity. Subsequent transurethral instrumentation or insertion of a penile prosthesis has not been affected adversely by the new course of the urethra.

The Anastomosis. The anastomosis can be difficult, particularly when the prostate is riding high and all four maneuvers were needed to reduce anastomotic tension. A long nasal speculum is inserted retrogradely into the prostatic urethra, and under direct vision a spatulated end-to-end bulboprostatic anastomosis is performed using interrupted 4-0 PGA sutures. The verumontanum is an important landmark, and identification of the prostatic urethral mucosa also is important. Using needles bent into a “J” shape (Fig. 36.20), each suture is inserted before being individually tied. The needles are advanced through the prostatic urethral edge from outside to inside; the point of the needle being retrieved within the prostatic urethra and advanced until the hub of the needle clears, and then withdrawn. Approximately eight sutures are inserted commencing at the 12 o'clock position and proceeding clockwise before each is tied in the same order as they were inserted.

FIGURE 36.20. A: Bulboprostatic anastomosis is facilitated using a standard suture needle bent into a “J” shape. The needle is advanced through prostatic urethral edge and the needle tip is retrieved in the prostatic lumen. The needle is advanced through the bladder neck to clear needle, and then is withdrawn. **B:** Suture placement is commenced with the 12 o'clock suture in the prostatic urethra. **C:** Sequential sutures are then placed in a clockwise direction around the prostatic urethral opening but are not tied. Hemostats placed on the end of each suture are stacked sequentially on an Allis clamp. After approximately eight sutures have been placed, they are then individually tied, commencing with the 12 o'clock suture proceeding clockwise. A catheter is inserted following suture placement and tying. (From Webster GD, MacDiarmid SA. Posterior urethral reconstruction. In: Webster GD, Kirby R, King LR, et al., eds. *Reconstructive urology.* Oxford: Blackwell Scientific Publishers, 1993, with permission.)

A 12-Fr fenestrated silicone catheter is inserted once the anastomosis is complete, together with a suprapubic cystostomy tube. A periurethral Jackson-Pratt drain may be inserted for wound drainage and, in most cases, is removed the following day.

Urethral stenting with an indwelling Foley catheter is required for approximately 2 to 3 weeks, and the stent is removed only after a retrograde urethrogram around the catheter proves no extravasation. The suprapubic catheter usually is removed on the same day after a successful trial of voiding. A retrograde urethrogram is performed 3 and 12 months postoperatively.

Results of Anastomotic Urethroplasty of Posterior Urethral Injury

In the chapter authors' experience with this technique, in 113 cases of pelvic-fracture distraction defects, the overall stricture-free success rate was 97%. Patient ages ranged from 9 to 69 years (mean 36 years), and the causes of injury were automobile related in 71 and occupational in 42. Obliterative defects ranged from 1.5 to 7 cm (only three cases were strictures) and the maneuvers used to facilitate the tension-free anastomosis are shown in Table 36.2. Complications were uncommon and included temporary peroneal nerve dysfunction in four and persistent incontinence attributable to preexisting bladder neck dysfunction in two (see subsequent discussion). Other authors have reported similar success rates (60).

Urethral mobilization	9	(8%)
Corporal separation	46	(41%)
Inferior pubectomy	31	(28%)
Supracorporal rerouting	27	(23%)
	113	(100%)

TABLE 36.2. MANEUVERS TO FACILITATE ANASTOMOSIS

Impotence is a frequently reported complication in this group of patients. Often debated is whether impotence is caused by the injury itself or is a consequence of the surgery. This has become more controversial as the endoscopic procedures have been noted to have a high rate of impotence (43). In a group of 92 patients in whom follow-up data could be obtained, it was noted that 57 (62%) patients remained potent in the long term, with a median follow-up of 48 months; importantly, the operation did not render impotent any patient who was preoperatively potent. Self-injection with vasoactive agents was successful in 24 of 27 (89%) impotent patients, suggesting a predominant neurologic etiology. Of 30 patients in whom original postinjury radiographs could be examined, the pattern of bony injury was able to be correlated with incidence of impotence. The authors found that bilateral pubic rami fractures correlated with impotence, with 13 of 15 being impotent, whereas 11 of 15 with unilateral fractures or no fractures remained potent (49). It is likely that disruption of the cavernous nerves lateral to the prostatomembranous urethra behind the symphysis pubis is the most likely etiology of impotence in this injury.

Factors Complicating Perineal Anastomotic Repair

As noted previously, a number of uncommon complicating factors may render perineal anastomotic repair inappropriate, but in recent experience they account for fewer than 5% of cases (Table 36.1).

Long urethral defects may be avoidable by early intervention following the initial pelvic fracture. In those cases with massive pelvic hematoma and resulting “pie-in-the-sky” appearance of the bladder on the early cystogram, some consideration should be given to early hematoma evacuation and urethral realignment over a stenting catheter. This may be performed endoscopically, as noted previously. In the event the defect is long (more than 5 cm), a perineal approach is not negated but all of the tension-relieving maneuvers likely will be needed. The tubed perineoscrotal flap procedure or a tubed full-circumference substitution urethroplasty has been suggested for such cases, but certainly gives suboptimal results and generally is resorted to only as a salvage maneuver.

Chronic periurethral cavity occurs in those cases in which the pelvic hematoma liquefies and evacuates through the urethra, leaving cavities within the pelvic floor that may become epithelialized and ultimately may be a source of chronic infection and stone formation. These epithelialized pelvic floor diverticula may become infected and discharge into the rectum, creating fistulae, or may be associated with pelvic osteomyelitis. When identified, these cavities suggest the need for an abdominoperineal repair so that the pelvis can be cleaned out and omentum brought into the pelvis to facilitate absorption and healing.

Rectal, cutaneous, and periurethral bladder-base fistulae may occur from the injury itself, from the aforementioned complication of pelvic floor abscess, or from inept urethral instrumentation, particularly at the time of cut-for-the-light endoscopic urethroplasty. These fistulae do not necessarily preclude an anastomotic repair.

Incontinence is uncommon following pelvic-fracture injury. The urethral injury itself or the subsequent urethroplasty are likely to compromise the distal sphincter mechanism, but fortunately the bladder neck remains competent and functional. However, any prior bladder neck surgery or injury obviously may adversely affect continence. In Webster and Venn's experience, and as reported by others, incompetence of the bladder neck on the preoperative cystogram does not necessarily translate into postoperative incontinence, and for this reason, these authors hesitate to perform bladder neck reconstruction at the time of the urethroplasty (37,48). Webster reviewed 15 patients with open bladder necks on cystography who had undergone posterior urethroplasty, and of these, six were continent and eight were incontinent posturethroplasty. Of the eight, six were managed successfully by bladder neck reconstruction, one underwent artificial sphincter implantation, and one was improved with collagen injections. Individualized management is needed in such cases, and in some, simultaneous or staged bladder neck reconstruction may be justified. Cystoscopy is helpful in the evaluation of the bladder neck, and the patient who has an obvious sector scar is the best candidate for bladder neck reconstruction.

Associated anterior urethral stricture may complicate significantly the management of postpelvic-fracture membranous urethral strictures both by interfering with the retrograde urethral blood supply after urethral mobilization and by reducing urethral elasticity. In this scenario, substitution repairs may find their place.

Factors that limit surgical access may complicate the repair because of an inability to achieve the degree of lithotomy position needed to gain exposure. It does not necessarily preclude a perineal approach; however, it may dictate that the urethra be circumferentially mobilized perineally, but the anastomosis be performed abdominally.

Once prior repair has failed, the subsequent salvage repair has a number of additional problems to contend with, not the least of which is the fixation of the bulbar urethra in perineal scar. Surprisingly, however, anastomotic repairs as described previously are still possible in the majority of cases (93). In the event these are not possible, a one-stage substitution urethroplasty using a pedicled island of penile skin mobilized from the penis on its subcutaneous vascular pedicle, or a staged scrotourethral inlay-type procedure, may be performed.

Combined Abdominoperineal Transpubic Approach for More Complex Injuries

In the past, abdominoperineal transpubic repairs have been used extensively; however, they now are used most often in a limited fashion, when circumstances necessitate (51). Some of the aforementioned features indicate a need for this repair, the chief of which are fistulous tracts, inability to achieve the lithotomy position, and pelvic floor cavities. Bladder neck incompetence, as noted previously, is not in itself an indication for abdominoperineal repair, and its management should be deferred to a secondary procedure.

If this deferred approach is required, a lower midline abdominal incision is made after the perineal dissection of the anterior urethra has been completed (as previously described), and the bulbar urethra has been transected at the level of the obliteration. Indeed, the further steps of corporal-body separation and wedge excision of the inferior pubis may have been performed. Through the abdominal incision, the prevesical and retropubic spaces are dissected carefully down to the level of the apex of the prostate, staying close to the periosteum of the retropubis, until communication with the perineal dissection is made. To avoid injury to the bladder neck, it is wise to open the bladder high on its anterior wall so that an intravesical finger can help direct the retropubic dissection. It rarely is necessary to excise the entire anterior wedge of pubis as previously described by Waterhouse and colleagues (91), because equally good access is achieved by partial removal of the posterior surface of the pubis using a Capener gouge (82). This wide access anterior to the prostate will facilitate the anastomosis of the mobilized bulbar urethra to the spatulated prostatic urethra. In addition, the retropubic bone removal will improve access to the pelvic floor to deal with the complicating features, which, as previously discussed, are the indication for this approach. Most important is that the omental wrap be fashioned into a pedicle and placed around the anastomosis and bladder neck, filling the space resulting from bony excision.

Substitution Urethroplasty

In the past, this approach was the preferred technique of many surgeons, particularly after Morehouse and associates (56) reported good outcomes in 1972. Now, these repairs should be used only when associated anterior urethral stricture disease is compromising the retrograde urethral blood flow and hence precluding anastomotic repair, and in rare complex salvage situations (57). Substitution procedures may be performed in one or two stages. The one-stage repairs include pedicled skin island and free full-thickness skin graft repairs; two-stage procedures include a variety of scrotourethral inlay operations sometimes combined with full-thickness or meshed split-thickness skin graft inlay. The complexities of the individual situation dictate which repair is most appropriate, but in general, graft repairs do poorly in pelvic-fracture cases because of the lack of a well-vascularized bed.

Postprostatectomy Strictures of the Posterior Urethra

Strictures of the posterior urethra following open prostatectomy or TURP are not uncommon. The mechanism for injury during a TURP is multifactorial and includes mucosal denudation caused by the tight gripping of an inadequate urethra over a poorly lubricated over-sized sheath, overaggressive distal resection and electrocoagulation involving the membranous urethra, and Foley-catheter irritation. During open prostatectomy, the membranous urethra can be injured during finger or sharp transection at the prostatic apex.

Prostatectomy ablates the proximal sphincter mechanism, and therefore continence is threatened by any injury and stricturing of the distal urethral sphincter.

Fortunately, the majority of these strictures are superficial and are best managed by periodic urethral dilation. Direct vision internal urethrotomy is absolutely contraindicated as discussed previously. Urethroplasty also threatens the distal sphincter mechanism, although an elaborate continence-preserving, push-in bulbourethral-resleeving procedure was described by Turner-Warwick (83). Wallstent placement across the stricture has been successful, but requires the implantation of an artificial sphincter at a more distal site to salvage continence.

Urethral carcinoma is an uncommon disease. Although it was first described in men and women in the early 1830s, through 1980 the number of reported cases in men was approximately 600, and approximately 1,200 cases had been reported in women (54). Thus urethral carcinoma is the only shared genitourinary malignancy that is more common in women than in men. This fact has been confusing to students of the disease because the male urethra is longer and more complex. Because urethral carcinoma is uncommon, no single institution has a sufficient number of patients to define clearly the natural history of the disease or to examine prospectively the different treatment options. As a result, there is no standardized approach to managing primary urethral carcinoma.

ANATOMY

The male urethra is an epithelium-lined tubular structure that is surrounded by connective tissue, smooth muscle, elastic fibers, and the richly vascular corpus spongiosum. There are several glands of Littré along the length of the urethra and the paired Cowper's glands, which empty into the posterior aspect of bulbar urethra. The urethra has an average length of 21 cm. The mucosa of the urethra consists of transitional epithelium in the prostatic portion; stratified or pseudostratified columnar epithelium in the pendulous, bulbous, and membranous portions; and nonkeratinized stratified squamous epithelium at the meatus and fossa navicularis (Fig. 37.1). By anatomic convention, the prostatic and membranous urethra make up the posterior urethra, and the more distal segments are considered to be the anterior urethra. However, when discussing urethral carcinoma, previous authors considered the bulbous urethra with the posterior segment because of differences in treatment and prognosis of tumors of this segment as compared with those in the penile or pendulous urethra. Therefore, in this discussion, posterior urethral carcinoma includes lesions that arise in the prostatic, membranous, and bulbar urethra.

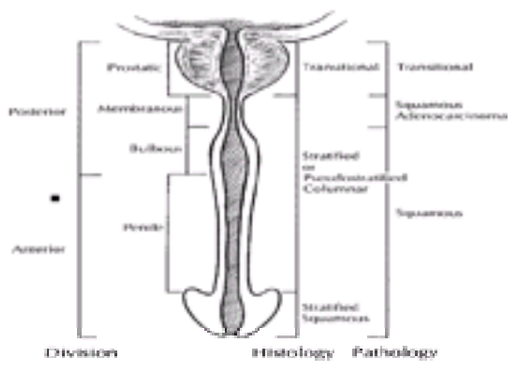

FIGURE 37.1. Divisions, histology, and pathology of the male urethra.

The lymphatic drainage of the anterior urethra parallels that of the glans and corpus spongiosum into the superficial and deep inguinal nodes, which then drain to the external iliac nodal chain (Fig. 37.2). Tumors of the prostatic, membranous, and bulbar urethra drain along three pelvic lymphatic channels: one parallel to the dorsal vein of the penis to the external iliac chain, one to the obturator and internal iliac group along the pudendal artery, and one into the presacral nodes (16).

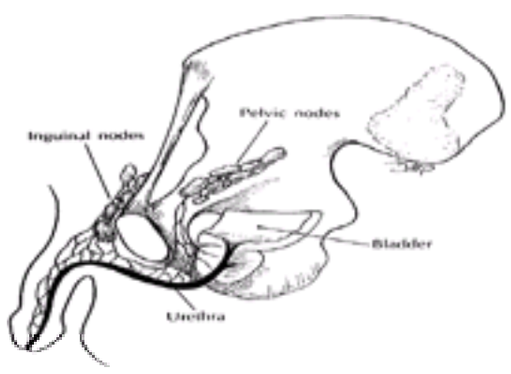

FIGURE 37.2. Lymphatic drainage of the male urethra.

The female urethra is also an epithelium-lined tube supported by submucosal connective tissue, elastic and muscle fibers, and a rich venous network. The average length is 4 cm.

The epithelium of the distal two-thirds consists of stratified squamous epithelium, which is continuous at the meatus with the epithelium of the vulva. The proximal one-third is lined by transitional epithelium, which is continuous with the mucosa of the bladder (Fig. 37.3). As in the male urethra, several small glands lie along the urethra and open into the urethral lumen. The periurethral glands of Skene are concentrated near the meatus but extend along the entire urethra (3,4). Although no definite anatomic divisions exist for the female urethra, Grabstald (41) described carcinoma as anterior when limited to the distal third, and entire (posterior) when the proximal two-thirds is involved. Again, this arbitrary division reflects the differences in treatment and prognosis associated with the location of the tumor in the urethra.

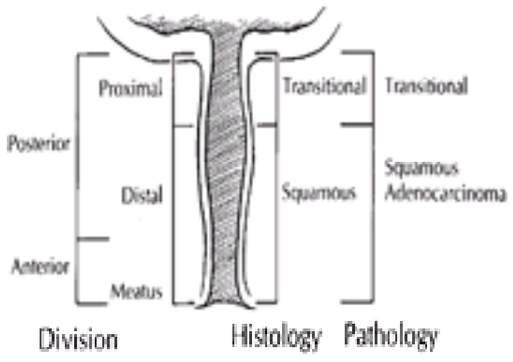

FIGURE 37.3. Divisions, histology, and pathology of the female urethra. (Adapted from Droller MJ, Nyberg L. *Urethral carcinoma.* AUA Update Series, 1983, vol 2, lesson 19, with permission.)

The lymphatic drainage of the female urethra follows two courses. As in the male urethra, the drainage of the distal urethra is to the superficial and deep inguinal nodes, and the drainage of the proximal urethra is to the external iliac, obturator, and presacral nodes (Fig. 37.4).

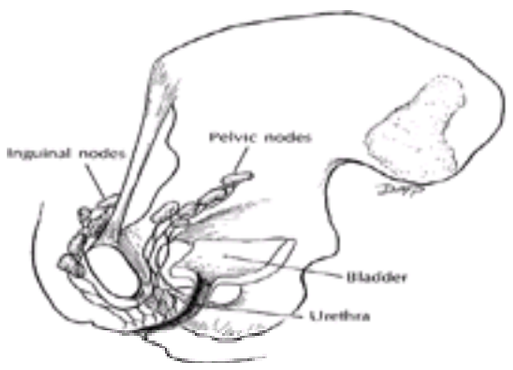

FIGURE 37.4. Lymphatic drainage of the female urethra.

URETHRAL CARCINOMA IN MEN

Epidemiology and Etiology

The peak age of incidence for primary urethral carcinoma in men is in the sixth decade, although it has been reported in both teenagers and men in their nineties (63). There are no racial predilections. The exact cause of urethral carcinoma in men is unknown, but chronic inflammation and the presence of the human papillomavirus (HPV) have been identified as causal factors. Approximately 35% to 88% of men with urethral cancer have an antecedent history of stricture, and 37% to 44% have a history of sexually transmitted diseases (57,63,101). The association between urethral carcinoma and urethral stricture is further strengthened by the fact that the bulbomembranous urethra is the most common location for both disease processes. In addition, squamous metaplasia commonly occurs at the site of urethral stricture in epithelium that is normally columnar (11).

Significant evidence also links the presence of HPV with the genesis of urethral carcinoma in men. The HPV-16 and HPV-18 genotypes are implicated in 70% to 90% of invasive cervical carcinomas, and they are also the genotypes most strongly implicated in urethral cancer. Using polymerase chain reaction (PCR), HPV-16 DNA exclusively was found to be associated with squamous cell carcinoma (SCC) of the male urethra in 4 of 14 (29%) patients (122). Tissue from metastatic sites revealed HPV-16, and metastatic deposits in the ten patients with primary tumors negative for HPV-16 were found to be negative as well. Thus complete concordance of HPV-16 status in primary and metastatic specimens was demonstrated, strongly supporting HPV as an etiologic factor in SCC of the male urethra.

The presence of HPV-16 has been specifically associated with cancer in the pendulous portion of the urethra as opposed to bulbar urethral tumors. Cupp and colleagues (21) detected HPV-16 DNA by PCR in all 6 patients with SCC of the pendulous urethra, whereas none of 12 control urethral tissue specimens were positive. Furthermore, no patients with SCC of the bulbar and posterior urethra tested positive for HPV, suggesting a possible etiologic difference between SCC of the distal and proximal urethra.

Signs and Symptoms

The signs and symptoms of urethral carcinoma can be vague and nondescript, but they may also mimic those of urethral stricture and its complications of abscess and fistula formation. In the series by Kaplan and associates (63) of 232 patients, 47% had symptoms of obstruction, 39% had a palpable mass, and 31% had a periurethral abscess. Grabstald (41) reported that in many instances skin ulceration is the primary finding on physical examination. Other less common symptoms, in descending order of frequency, included urethral discharge or hematuria, fistula, retention, inguinal mass, priapism, penile gangrene, and incontinence (63). The possibility of urethral carcinoma should be considered in the setting of perineoscrotal abscess or fistula and stricture disease in men without a history of trauma.

Diagnosis and Staging

Because of a much higher incidence of benign urethral strictures, it is understandable that this diagnosis often is made initially. Only after the “stricture” is noted to warrant much more frequent dilation or to bleed excessively after dilation is a malignant process considered and the proper diagnosis made. Biopsy is essential for the diagnosis of urethral carcinoma. Usually, urethroscopy with transurethral biopsy of suspicious, friable, or necrotic-appearing tissue is adequate. In many instances, however, repeated deep biopsies must be taken in areas of abscess or phlegmon. Transcutaneous needle core biopsy of a palpable urethral mass is at

times a useful diagnostic maneuver. The index of suspicion must be high.

Careful staging of urethral carcinoma is very important in planning proper therapy and predicting prognosis. The extent and location of the primary lesion are more closely associated with treatment and prognosis than is the cell type. Historically, several staging systems have been reported. Ray and associates (101) proposed a staging system that has been used by many authors (116,120). Although this staging system is common in the older literature, the tumor, node, and metastasis (TNM) classification is the standard staging system for both male and female urethral cancer (Table 37.1) (3). This classification is based on the depth of invasion of the primary tumor and the presence or absence of regional lymph node involvement and distant metastases.

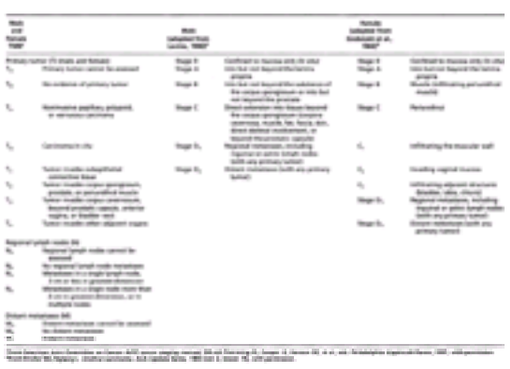

TABLE 37.1. STAGING OF MALE AND FEMALE URETHRAL CARCINOMA

Adequate staging includes cystourethroscopy and bimanual examination. Preoperative bimanual examination under anesthesia helps determine the local extent of tumor, including infiltration of adjacent organs and structures, associated prostatic abnormalities, or pelvic sidewall adherence (126). Thorough palpation of the inguinal region is important because, unlike penile carcinoma, inguinal adenopathy usually indicates metastatic disease rather than infection (63,101). In the setting of organ-sparing surgery, urethroscopy is critical with biopsy of the proximal urethra to ensure adequate margins.

Computed tomography (CT) helps define the extent of the disease and often is useful in evaluating the regional lymph nodes. However, its accuracy is limited by the size of the nodes and the presence of inflammation and induration of the soft tissues secondary to abscess or extravasated urine. All patients should undergo a CT of the abdomen and pelvis as part of their metastatic evaluation. Magnetic resonance imaging (MRI) appears to offer no advantage over CT in the evaluation of lymphadenopathy. Fine-needle aspiration of suspicious lymph nodes should be considered to confirm metastatic disease.

CT has very limited accuracy in defining local tumor extent because of poor soft tissue discrimination. When the extent of local tumor infiltration is questionable after cystourethroscopy and bimanual examination under anesthesia, MRI may provide useful additional information. MRI appears to be the best option for evaluating the local extent of the primary lesion. It provides superior soft tissue contrast imaging in any plane and therefore is better at assessing local invasion of the corpus spongiosum or corpora cavernosa as well as adjacent soft tissue, organs, or bone (Fig. 37.5) (62).

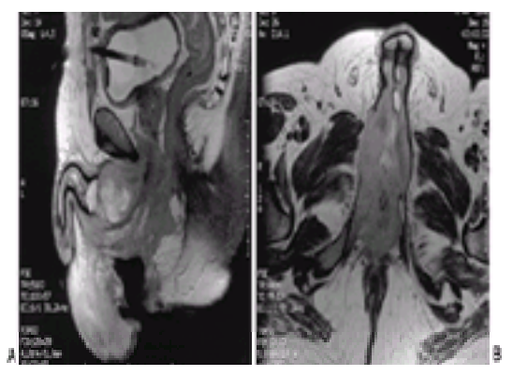

FIGURE 37.5. Magnetic resonance imaging scan of male urethral carcinoma: **A:** Sagittal T_2-weighted image demonstrates extension to the prostatic capsule, pubic symphysis, and anus and invasion of corpora cavernosa. **B:** Axial T_2-weighted image of the same lesion demonstrates possible involvement of the right pectineus, adductor longus, and adductor brevis muscles.

Other imaging studies may be necessary depending on the clinical situation. A chest radiograph is routinely obtained to rule out pulmonary metastases, and bone scans are obtained selectively when the possibility of osseous metastases is considered. The entire urothelium is assessed with either intravenous pyelography or retrograde pyelograms in patients with transitional cell carcinoma (TCC). Retrograde urethrograms suggested urethral carcinoma in 60% of the patients in one series (101). Although these studies may show long, irregular strictures with extravasation, fistula formation, or obstruction, the utility of urethrography is limited in the era of urethroscopy and typically delineates only luminal defects (119).

With TCC of the prostatic urethra, the prostate may be nodular and indurated on digital rectal examination if there is invasion of the prostatic stroma. Lesions that invade the stroma, ejaculatory ducts, and periprostatic tissues appear hypoechoic on transrectal ultrasound imaging; however, a lesion confined to the prostatic urethra usually is not detected in this manner (117). Unlike in the much more common adenocarcinoma of the prostate, the serum acid phosphatase level and prostate-specific antigen (PSA) are normal, skeletal metastases typically are osteolytic rather than osteoblastic, and there is no response to hormonal manipulation. Transurethral biopsy of the prostate is necessary to assess the ducts and stroma for the presence of invasion or limitation to the epithelium. Furthermore, bladder tumors originating in the trigone or bladder neck with local extension to the prostate and prostatic urethra may be erroneously considered primary urethral carcinoma unless careful examination and biopsy exclude the bladder as the site of origin.

Histopathology

Male urethral carcinoma occurs in the bulbomembranous, penile, and prostatic urethra in approximately 60%, 30%, and 10% of cases, respectively. Histologically, approximately 80% of these tumors are SCCs, 15% are TCCs, and 5% are adenocarcinomas or other rare cell types including neuroendocrine, lymphoma, sarcoma, and myeloma.

Natural History

Male urethral carcinoma spreads by direct extension into adjacent structures, and metastases occur largely by the lymphatogenous route to regional nodes which are palpable in 20% to 40% of patients at the time of diagnosis. Ray and associates (101) reported that at presentation 26% of patients had stage C disease and 43% had stage D disease. Advanced disease at the time of diagnosis is especially common in patients with posterior lesions, which were stage C or D in 86% of patients. In contrast, stage A or B disease was identified in 55% of patients with anterior carcinoma. Earlier presentation is attributed to an earlier onset of symptoms in patients with anterior lesions. However, symptoms of carcinoma of the prostatic urethra are more often confused initially with a more benign process. The median time period between development of symptoms and presentation for treatment was 5 months in one large series, with a range from 1 day to 15 years (63). This delay in diagnosis has also been reported by others and would be expected to contribute to the significant proportion of patients with advanced disease at diagnosis (41,76).

Most patients have only locally advanced disease or regional lymph node metastases when they die, with death occurring secondary to sepsis or bleeding (63). Distant hematogenous spread is unusual and is reported in less than 15% of patients (64,83). Of these patients, 62% had involvement of the corpora cavernosa when

the diagnosis was made (63). The most common sites of distant metastases are the lungs, liver, and bones (63,101).

Survival rates are related to the clinical stage at the time of presentation. In general, lesions of the distal urethra tend to have a lower clinical stage than tumors of the proximal urethra. Five-year survival rates for men with tumors of the anterior urethra regardless of stage are approximately 40% compared with 5% for invasive bulbomembranous tumors (6).

TCC of the prostate behaves differently, with a propensity for lymphatogenous and hematogenous dissemination. Carcinoma *in situ* begins in the prostatic urethra or ducts and is believed to be the precursor of invasive carcinoma (32,84,118). Stromal invasion is a poor prognostic indicator, with metastatic disease reported in up to 100% of patients (123). Thus treatment and prognosis for TCC of the prostatic urethra also depend on local tumor extent.

BOX 37.1 MALE URETHRAL CARCINOMA: ETIOLOGY, DIAGNOSIS, STAGING, AND NATURAL HISTORY

Chronic inflammation and the presence of human papillomavirus have been identified as causal factors in male urethral carcinoma.
Maintaining a high index of suspicion for urethral carcinoma in patients with urethral stricture and its complications is crucial for prompt diagnosis.
Careful staging, including examination under anesthesia, cystourethroscopy, and selected imaging studies, is important in planning therapy and determining prognosis.
With the exception of prostatic urethral transitional cell carcinoma, male urethral cancer spreads by direct extension and to regional lymph nodes; distant metastases are uncommon.

Surgical Treatment

Surgery with or without radiation therapy has been the treatment of choice in managing urethral carcinoma in men. Although local tumor control has been reported with radiation therapy, in practice, it is largely reserved for low-stage anterior urethral tumors in patients who refuse surgery or are not surgical candidates. Although potentially phallic preserving, definitive radiation therapy for urethral carcinoma in men is associated with significant morbidity, including chronic penile edema and urethral stricture. The extent of surgery depends on both tumor stage and location in the urethra. In general, anterior urethral tumors are more amenable to surgical control, have a better prognosis, and more often warrant less radical surgery than posterior urethral tumors.

Anterior Urethral Carcinoma

Carcinoma of the anterior urethra accounts for approximately 30% to 40% of all urethral carcinomas (63). These tumors often are amenable to less radical forms of therapy than those of the posterior urethra. Cure depends on adequate local control (63,70). Surgical treatment options include transurethral resection (TUR), local excision, partial penectomy, or radical penectomy with or without emasculation (70).

For the uncommon carcinoma *in situ* and papillary noninvasive T_a lesion involving the distal urethra, local excision may suffice. Konnak (67) described five patients with low-grade stage T_a TCC or SCC who underwent local resection and fulguration. Although three patients developed local recurrence, they were treated conservatively, and all five patients were free of tumors 18 months to 14 years after initial therapy. Dalbagni and associates (22) also reported successful management of superficial or *in situ* tumors of the anterior urethra with periodic TUR and fulguration. In 30 such patients with long-term follow-up, none progressed to invasive disease despite a high recurrence rate. The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is an additional therapeutic option for these low-stage lesions. It has been useful with similar lesions in the bladder and can be applied transurethrally. Such therapy may result in less scar formation than use of the resectoscope (113).

Invasive tumors of the anterior urethra often can be controlled by partial penectomy with a proximal 2-cm margin (63). For more proximal or extensive anterior urethral tumors, total penectomy with perineal urethrostomy usually is necessary (63,101). In addition, emasculation should be considered when there is tumor involvement of the scrotal skin or genitalia.

In the Memorial Sloan-Kettering Cancer Center series reported by Dalbagni and associates (22), 7 of 8 patients with invasive distal urethral cancers were cured with partial penectomy with or without ilioinguinal lymphadenectomy. This included one patient with completely resected inguinal metastases. After more than 5 years of follow-up, 4 of 7 patients with more proximal or extensive anterior urethral carcinoma were alive without disease after total or partial penectomy with ilioinguinal lymph node dissection. Three died with lung metastases at a mean of 24 months postoperatively. The overall survival at 5 years was 36%.

Bird and Coburn (10) advocated subcutaneous penectomy as an alternative between limited local excision and formal amputation in patients with larger tumors. This mode of phallus preservation reportedly provides an acceptable cosmetic, psychologic, and reconstructive outcome without apparently compromising cancer control in three select patients followed for an average of 12 months.

Posterior Urethral Carcinoma

Carcinoma of the proximal or bulbomembranous urethra makes up 50% to 60% of male urethral carcinomas (72). The difficulty in managing posterior tumors is the location of adjacent organs and structures and extent of proximal invasion. Most patients have bulky tumors infiltrating adjacent structures at the time of diagnosis, and overall survival of these patients is poor despite aggressive radical exenterative surgery (13,101). However, multiple series document favorable long-term survival when local tumor control can be achieved.

Local resection, TUR, or laser photoirradiation may be feasible for the very unusual finding of early superficial tumors of the bulbomembranous urethra. However, the presence of extensive local disease necessitates wide radical excision to offer any hope for disease control. Despite seemingly adequate radical surgery, local recurrences are common and have always been associated with eventual death (13,101).

Previous authors recommended radical cystoprostatectomy with pelvic node dissection and en bloc penectomy and scrotectomy (13,41,46,63,101,107,116). Pubic resection has also been recommended to facilitate exposure and complete resection (74,111). Marshall (78) reported success in the treatment of bulbomembranous carcinoma in 1957 with anterior exenteration and total emasculation. He was able to achieve 5-year survival in 4 of 5 patients. The one death in this group was a result of sepsis and uremia, and autopsy performed 58 days after surgery revealed no residual cancer. In contrast, less extensive surgery or radiation therapy with an attempt at bladder preservation failed in three out of four patients so treated. Farrer and Lupu (35) reported the UCLA series with deep male urethral carcinoma. They combined their series with others between 1957 and 1983 and cited a 5-year disease-free survival rate of 30% (9 of 30) with radical surgery. Only 1 of 33 patients treated without radical surgery was disease free at 5 years.

Radiotherapy alone has yielded poor results (13,63,101). However, the role of planned preoperative radiotherapy is unclear but does have support (13,41,70,116). Preoperative radiation may downstage the tumor and permit excision of lesions that otherwise would be unresectable or make it possible to obtain tumor-free margins. Hopkins and associates (55) reported on a series of 16 male patients with proximal or distal urethral carcinoma. Although the mean survival of patients was only 15 months, the authors concluded that a combination of radiation therapy and radical extirpative surgery was the best therapy for proximal carcinomas. A Memorial Sloan-Kettering experience in 12 patients with invasive (T_3) disease in men and women treated with en bloc radical excision and inferior pubic rami resection coupled with preoperative radiation therapy suggests an advantage over less extensive surgery in terms of local control and survival (66). At a mean follow-up of 40 months, the overall local control rate was 83%. Postoperative complications were common, including pelvic abscess, intestinal fistulae, and superior pubic rami fractures.

Although recent literature reports an improvement in prognosis, it remains very poor for patients with bulbomembranous disease (27,63,78,101). Therefore investigators recently advocated a multimodality approach integrating chemotherapy, radiation therapy, and surgery. In a series of 46 men (40 treated with surgery alone) treated between 1958 and 1996, the overall 5-year disease-specific survival was 50% (83% for low-stage and 45% for high-stage tumors) (22). No difference in outcome was found for patients treated before or after 1975. The authors argued that surgery alone is suboptimal management of male urethral carcinoma, and they propose chemoradiation and surgery for high-stage disease.

Dinney and colleagues (27) recently reported the experience from the M.D. Anderson Cancer Center demonstrating better outcomes over the last decade than in their earlier series reported in 1980. Using primary surgery, the authors reported that 52% of patients had no evidence of disease over a mean follow-up of 50 months (27).

However, those with bulbomembranous disease still had only a 25% 5-year disease-free survival rate. Emphasizing the importance of locoregional control, they concluded that radiotherapy was largely ineffective and that local control was achieved only with radical surgery. They attributed the improved outcome in their patients to a combination of factors including earlier intervention, use of adjuvant chemotherapy, and refinement in surgical technique.

In a series reported by Gheiler and associates (40), patients with low stage (T_{a-2}) disease experienced excellent outcome after treatment with surgery or radiation therapy. Furthermore, in patients with higher-stage disease, their data suggest higher survival rates for patients treated with multimodal therapy than for those treated with surgery or radiation monotherapy.

Management of Lymph Nodes

Palpable lymph nodes generally indicate the presence of metastatic disease in 80% to 100% of patients. Inguinal lymphadenectomy can be curative if nodal spread is confined to the inguinal nodes (13,27,55,63,78,87,101,126). Thus palpable inguinal nodes are an indication for ilioinguinal node dissection at the time of cystoprostatectomy. However, lymphadenectomy is indicated only for palpable nodal disease because there is no evidence of clinical benefit from prophylactic lymphadenectomy in the setting of clinically normal nodes (8). However, with improved techniques associated with less morbidity, prophylactic dissection may be warranted in patients at high risk for nodal disease (17,126). The proper management of the pelvic nodes in the setting of positive inguinal nodes is not entirely clear because most patients with pelvic adenopathy die of their disease. Radical surgery in this situation probably is unwarranted because long-term survival is very unlikely. These patients probably are best approached with chemotherapy and further locoregional therapy depending on the response.

Radiation Therapy

Data on the role of radiation therapy alone in managing male urethral cancer are limited. In general, radiation therapy has been reserved for low-stage distal urethral carcinomas in patients refusing surgical management. The primary advantage of radiotherapy is potential organ preservation. However, complications are common and include woody penile edema, penile atrophy, and urethral stricture (120).

Chemotherapy and Chemoradiation

Existing data on chemotherapy for urethral cancer are difficult to assess reliably because of insufficient sample sizes and variability of patient selection factors and primary treatments (31). The best-studied single-agent drugs are cisplatin, bleomycin, and methotrexate. All are inadequate as single agents. Trials with multiple-agent chemotherapy have led to organ-sparing management of anal and head and neck cancers. These regimens include cisplatin with fluorouracil; cisplatin, methotrexate, and bleomycin; cisplatin, fluorouracil, and leucovorin; fluorouracil, mitomycin, and radiation therapy; and cisplatin with vindesine (31). Few data exist regarding combination therapy for urethral cancer, but future efforts to improve outcomes in advanced disease and possibly allow organ preservation in selected cases are warranted.

Concomitant external beam radiation with fluorouracil and mitomycin C has been shown to provide effective treatment for locally advanced SCC of the esophagus and anal canal, with increased local control, increased control of nodal disease, increased survival, and preservation of anal function, and has become the standard of care in these patients (8,72). Chemotherapy given concomitantly with radiation acts as a radiosensitizer and interferes with cell repair after a sublethal dose of radiation.

Recently, there have been encouraging results with these multimodality approaches in urethral cancer (8,61,72,73,91,110). Oberfield and associates (91) reported on two men with locally advanced SCC of the proximal urethra treated with chemoradiation. Forty-five Gy in 25 fractions over 5 weeks was delivered to the penis, perineum, and regional lymphatics in addition to mitomycin C (10 mg/m^2) and 5-fluorouracil (1 g/m^2 per day) for 4 days at the start of the cycle and 28 days later. Both patients were free of tumor at 1.5 and 4 years. Furthermore, Baskin and Turzan (8) treated a patient with high-stage SCC of the penile urethra with a similar protocol followed by partial urethrectomy and perineal urethrostomy. The pathologic specimen demonstrated no evidence of residual tumor. Further research in this area is warranted.

BOX 37.2 TREATMENT OF MALE URETHRAL CARCINOMA

The possibility for cure of urethral carcinoma depends on adequate local control.
The extent of surgery necessary to obtain local control depends on tumor stage and location in the urethra.
Despite aggressive surgical resection in the setting of bulky posterior tumors, local recurrence is common and prognosis is poor.
Encouraging preliminary results suggesting improvements in outcome have been reported using a multimodality approach combining surgery, radiation, and chemotherapy.

TRANSITIONAL CELL CARCINOMA OF THE PROSTATE

Primary TCC of the prostate implies no preexisting or concomitant bladder cancer and is a rare entity. In the Mayo Clinic experience, only 37 of 5,700 men with prostate cancer had primary TCC (127). The etiologic factors for TCC of the prostate are considered to be the same as those for bladder TCC (79). Primary prostatic TCC makes up approximately 9% of the total number of urethral carcinomas, and very little information is available about the most effective treatment options (116). Usually, stromal invasion is present at diagnosis, and the prognosis is poor (104). Patients often present with hematuria and the irritative voiding symptoms of frequency, urgency, and dysuria.

TCC of the prostate is most commonly associated, either synchronously or metachronously, with bladder TCC. The increasing use of intravesical therapy to treat bladder cancer has altered the natural history of the disease and may be contributing to an increasing incidence of prostatic TCC (79).

Prostatic urethral neoplasms arising from the prostatic urethral epithelium or the periurethral portion of the prostatic ducts are considered urethral neoplasms distinct from those arising elsewhere in the prostate (3). Previous attempts at staging primary TCC of the prostate used staging systems for adenocarcinoma of the prostate. These methods are unsatisfactory because of differences in the natural history and pathologic features of the disease processes. The current American Joint Committee on Cancer TNM staging system for primary TCC of the prostate is depicted in Table 37.2. Accurate staging is vital because patients with carcinoma *in situ* or ductal involvement have a very different prognosis from those with stromal invasion (80).

Primary Tumor (T)	
T_{is} pu	Carcinoma *in situ*, involvement of the prostatic urethra
T_{is} pd	Carcinoma *in situ*, involvement of the prostatic ducts
T_1	Tumor invades subepithelial connective tissue
T_2	Tumor invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle
T_3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension)
T_4	Tumor invades adjacent organs (invasion of the bladder)
Regional Lymph Nodes (N)	
N_x	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastases
N_1	Metastases in a single lymph node, 2 cm or less in greatest dimension
N_2	Metastases in a single node more than 2 cm in greatest dimension, or in multiple nodes
Distant Metastases (M)	
M_x	Distant metastases cannot be assessed
M_0	No distant metastases
M_1	Distant metastases

TABLE 37.2. STAGING OF TRANSITIONAL CELL CARCINOMA OF THE PROSTATE

Wood and associates (125) conducted a prospective study to determine the most effective means of diagnosing TCC of the prostate in a group of 25 patients with bladder carcinoma, all of whom underwent radical cystectomy. Precystectomy prostate needle biopsy, fine-needle prostatic aspiration, and TUR biopsies of the

prostate were performed in all 25 patients. Ten patients were found to have prostatic involvement upon examination of the cystectomy specimen. The accuracy of the three detection methods was 20%, 40%, and 90%, respectively. All patients with prostatic involvement were identified correctly using a combination of the three methods. Therefore TUR biopsy should be performed in patients at high risk for TCC of the prostate or in patients with a positive urine cytology and normal bladder urothelium proven by cystoscopy and biopsy. It should be performed with generous sampling of the tissue between the bladder neck and verumontanum at the 5 and 7 o'clock positions. Because isolated TCC of the prostate is very uncommon, careful exclusion of concomitant bladder disease is imperative (85).

As previously noted, there is very little information about the efficacy of various treatment modalities for TCC of the prostate. Intravesical bacille Calmette-Guérin (BCG) has been used with excellent results to treat prostatic TCC *in situ.* However, as it extends deeper into the prostate along the ducts, the ability of BCG to come in contact with the cancer may be inconsistent (85). TCC of the prostate may be treated with BCG in the setting of minimal ductal involvement, but posttreatment TUR biopsies of the prostate must be performed to ensure adequate response (85).

Treatment of carcinoma *in situ* of the prostatic urethra probably is best achieved by TUR followed by intravesical BCG, although excellent and similar results have also been reported without TUR (79,93,96). The resection is believed to allow better contact between BCG and the prostate, and this belief has been supported by multiple series (15,52,112). If this approach fails in patients with carcinoma *in situ* or there is disease progression with extensive ductal invasion or stromal involvement, cystoprostatectomy with urethrectomy is indicated.

Prostatic stromal invasion portends a very poor prognosis because these tumors have a tremendous propensity for lymphatic and hematogenous dissemination. Therefore exenterative surgery has been recommended historically. Radical cystoprostatectomy is recommended over radical prostatectomy because TCC often is a multifocal disease with frequent involvement of the bladder and urethra (41). Definitive radiotherapy as the sole form of treatment is unpredictable and generally not used (76). It should be reserved for select patients who are not surgical candidates.

Investigators at Memorial Sloan-Kettering Cancer Center used a multimodal approach with chemotherapy and TUR and preservation of urinary function in selected patients with prostatic TCC. This approach includes four cycles of methotrexate, vinblastine, Adriamycin, and cisplatin (M-VAC) chemotherapy followed by extensive TUR of the prostate. If there is no tumor in the resection specimen, these patients may be observed with surveillance biopsy at regular intervals. If there is residual disease or a recurrence during surveillance, radical prostatectomy is performed with preservation of urinary function (44).

In a report by Cheville and colleagues (19) on 50 patients with TCC of the prostate without invasive bladder cancer, locoregional spread was the strongest predictor of patient survival. Their study demonstrated a 5-year disease-specific survival rate of 100% for patients with carcinoma *in situ* compared with 45% for urethral submucosal and stromal invasion. The anatomic barrier to extension of tumor was the basement membrane of the urethra, periurethral glands, and prostatic ducts and acini.

Wishnow and Ro (123) studied 23 men with TCC of the prostate detected in radical cystoprostatectomy specimens. They found that radical surgery was curative in 89% of 18 patients with carcinoma *in situ* or ductal involvement, with 11% developing metastases. All five of the patients in their series with stromal invasion developed metastatic disease.

TCC of the prostate in patients with preexisting or concurrent TCC of the urinary bladder has received substantial attention in recent years because of the popularity of orthotopic continent urinary diversion. Prostatic involvement of TCC, especially stromal invasion, is a clearly defined risk factor for urethral recurrence after cystectomy. Wood and associates (124) demonstrated that 43% of 84 cystectomy specimens for bladder cancer contained TCC of the prostate.

Esrig and colleagues (34) compared the natural history of patients with bladder cancer and prostatic stromal involvement occurring via direct extension through the bladder wall with that of stromal invasion arising intraurethrally. Based on data from 143 patients with prostate involvement after cystoprostatectomy, they proposed a staging classification that distinguishes between these two groups. Previous reports in the literature and staging systems did not address the two completely different natural histories. The authors determined that patients with P_1 bladder tumors with prostatic stromal invasion arising intraurethrally clearly had a higher overall 5-year survival rate (65%) than those with P_{4a} tumors with prostatic stromal invasion from a bladder primary tumor invading through the bladder wall (21%). Furthermore, they determined that TCC of the prostatic urethra confined to the mucosa or ducts and arising separately from a concomitant bladder tumor did not alter survival after cystectomy based on the primary bladder tumor stage. However, stromal invasion that arises intraurethrally places patients with P_1 bladder cancer into a higher-risk group with prognosis similar to that of muscle-invasive bladder cancer. Thus to precisely categorize the disease and the response to adjuvant therapy protocols, a designation of prostatic stromal invasion arising intraurethrally should be made along with the primary bladder stage.

BOX 37.3 DIAGNOSIS AND MANAGEMENT OF PROSTATIC TRANSITIONAL CELL CARCINOMA

Primary prostatic transitional cell carcinoma (TCC) implies no preexisting or concomitant bladder cancer and is rare.
The presence and extent of prostatic TCC are best determined by deep transurethral biopsies between the bladder neck and verumontanum at the 5 and 7 o'clock positions.
Initial management of prostatic TCC confined to the mucosa or prostatic ducts generally is transurethral resection and adjuvant bacille Calmette-Guérin.
Stromal invasion of prostatic TCC portends a poor prognosis and usually is treated with cystoprostatectomy.
Further experience with multimodality therapy and possible preservation of urinary function is warranted.

URETHRAL CARCINOMA IN WOMEN

Epidemiology and Etiology

Although the source of urethral carcinoma in women is not entirely known, there have been weak associations with both urethral caruncle and chronic irritation caused by infection, coitus, and childbirth (116). Marshall and colleagues (77) reviewed 376 cases of urethral caruncle and found carcinoma in 9 patients (2.4%). Another series reported less than a 1% incidence of a positive history for urethral caruncle in women with urethral carcinoma (82). It is possible that early urethral carcinoma may have been mistaken for caruncle, and only after the lesion failed to respond to therapy was the correct diagnosis made. This underscores the need for a biopsy of any urethral lesion that does not respond promptly to conservative therapy, is associated with persistent bleeding or symptoms, or enlarges.

Another potential origin of urethral carcinoma is the urethral diverticulum. Sixty-eight cases of carcinoma in urethral diverticula have been reported in the English literature (100).

The major cell type of these diverticular carcinomas is markedly different from that of urethral carcinoma. Adenocarcinoma accounts for approximately 60% of these lesions, followed by TCC (27%) and SCC (12%). The most common symptoms reported in one series were irritative voiding (67%), followed by hematuria (49%) (100). Infection and urinary stasis may contribute to the malignant change. Reported cases of malignancy are few in contrast to the more common incidence of urethral diverticulum; therefore the relationship between the two is unclear. Many cancers that may have originated in a diverticulum are seen at an advanced stage with tissue destruction to the extent that the diverticulum is not observed. The presence of a diverticulum and bleeding should arouse suspicion of carcinoma.

As in male urethral carcinoma, an association with HPV has been reported. In one series, PCR-based analysis demonstrated HPV (types 16 and 18) genotypes in 59% of cases (121).

Signs and Symptoms

The symptoms of urethral carcinoma in women are nondescript. In most reports, the most common symptom is urethral bleeding or spotting, which occurs in more than half of the patients (26,40,41 and 42,70,116). Other symptoms are commonly associated with bladder irritation and include urgency, dysuria, frequency, pain, dyspareunia, and incontinence. However, in the series by Grabstald and associates (42), 38% of patients had a palpable mass, 4% had a vaginal fistula, and 4% were asymptomatic. Two recent series reported obstructive symptoms in approximately 50% (14,60).

Diagnosis and Staging

When the previously mentioned signs and symptoms occur, one must have a high degree of suspicion and include urethral carcinoma in the differential diagnosis to avoid delays in therapy. The symptoms of urethral carcinoma are shared by more common benign urethral lesions, including caruncle, polyp, erosion, urethral prolapse, hemangioma, fibroma, diverticulum, and urethrovaginal fistula. The liberal use of biopsy of any suspicious urethral lesion and endoscopy to evaluate lower tract symptoms will result in earlier initiation of appropriate therapy with a potential increase in survival.

Careful clinical staging is important because therapy depends more on stage, location, and size of the tumor than cell type or grade. The meatus, labia, clitoris, vagina, and groin must be inspected to detect areas of local infiltration or induration. Bimanual examination under anesthesia allows evaluation of extent and fixation of the mass as well as assessment of inguinal and pelvic lymph nodes. Biopsies of the vulva, vagina, and bladder should be obtained as suggested by findings on bimanual examination and cystourethroscopy. CT is helpful in evaluating local extension and especially the status of the pelvic lymph nodes. The intravenous urogram, bone scan, liver profile, and chest film with tomography as indicated by findings will help detect distant metastases.

MRI has become the standard modality to evaluate local extent of disease because CT has poor soft tissue contrast (Fig. 37.6) (58). The normal female urethra on T_2-weighted or gadolinium-enhanced T_1-weighted images demonstrates a characteristic targetlike appearance (58). The outer ring of low signal intensity probably corresponds to the outer muscular layer, the middle layer of high signal intensity probably corresponds to submucosa, and the central low-intensity layer probably represents mucosa. There is accurate size assessment with MRI and excellent sensitivity and negative predictive value in assessing tumor extent. However, there is potential for overestimation caused by inflammation and edema. Local coils may be used to further improve imaging resolution in MRI (98). Lymphadenopathy is underestimated with MRI, and CT remains the study of choice for nodal assessment (58).

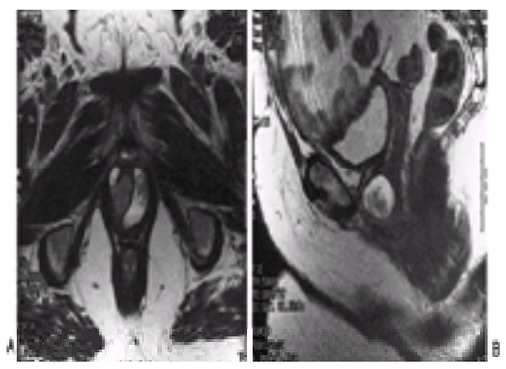

FIGURE 37.6. Magnetic resonance imaging scan of adenocarcinoma of the female urethra involving a urethral diverticulum. **A:** Coronal T_2-weighted image demonstrates a polypoid soft tissue mass within a left urethral diverticulum. **B:** Sagittal T_2-weighted images of the diverticulum and soft tissue mass.

The clinical staging system proposed by Grabstald and colleagues (42) has been widely used in the past (Table 37.1) (42). Therapy and prognosis are closely related to stage and location of the tumor. Although this staging system is still common in the older literature, the newer TNM classification is currently the standard staging system for both male and female urethral cancer (Table 37.1) (3).

Histopathology

The three predominant cell types are SCC, TCC, and adenocarcinoma. SCC accounts for approximately 55% of cases, adenocarcinoma and clear cell adenocarcinoma for 15%, and TCC for 15% (89). The remaining approximately 10% of cases are rare cell types including neuroendocrine tumors, sarcomas, lymphomas, and melanomas. Lesions are equally distributed between the proximal and distal urethra.

In the recent literature, there is an increasing experience with clear cell carcinoma, a distinctive tumor primarily of the female urethra that has generated interest with respect to prognosis and relationship to urethral diverticula (4). One review of 19 cases describes the clinical and pathologic features of this now widely accepted subtype of urethral carcinoma (92). Rarely described in men, the majority of these tumors are papillary and typically arise in dilated paraurethral glands more commonly called diverticula. These tumors may include areas that microscopically appear to be nephrogenic adenoma, but evidence that these tumors arise from malignant transformation of nephrogenic adenoma is inconclusive (4). There appears to be a more favorable prognosis associated with clear cell adenocarcinoma (4,29,75,92).

Immunostaining of female urethral adenocarcinoma for PSA and prostatic acid phosphatase has been described for both clear cell and non–clear cell types (30,92,114). However, in more recent series, clear cell adenocarcinoma was not found to be positive for PSA and prostatic acid phosphatase immunostaining and thus is unlikely to originate in Skene's glands (4,29,75,92). Drew and associates (29) suggest a müllerian derivation for clear cell adenocarcinoma based on a histologic pattern similar to other tumors of the female genital tract and positive reactions with the CA-125 antigen. The histogenetic origin of this subtype of adenocarcinoma remains to be determined.

Natural History

The natural history of urethral carcinoma in women is very similar to the natural history of the disease in men. Although urethral carcinoma has been reported in patients as young as 4 years, more than 75% of patients are in the postmenopausal age group, with a mean age of 61 years (103,116). There is a higher incidence among white women (88%) than African American women (12%) (89). The average delay in diagnosis after the appearance of symptoms has been reported to be 5 months (116). Eighty-four percent of patients already have muscular invasion or involvement of regional lymph nodes at the time of diagnosis (14).

Spread occurs by local extension to adjacent structures and to regional lymph nodes. Early invasion may involve the periurethral connective tissue, urethrovaginal septum, vagina, bladder neck, or vulva. Large, fungating meatal lesions may be difficult to differentiate from primary vulvar carcinoma. Surprisingly, involvement of the pubic bone is unusual (103). Carcinoma of the entire urethra tends to be more locally advanced at initial presentation, possibly because of a delay in diagnosis (7,14). In one series, 13% of patients with an anterior lesion had metastases to lymph nodes, in contrast to 30% of patients with posterior tumors of the urethra (7).

Lesions of the anterior urethra tend to metastasize to the inguinal nodes, whereas lesions of the posterior or entire urethra spread to the pelvic lymph nodes (Fig. 37.4). Clinical evidence of inguinal adenopathy is seen in 35% to 56% of patients, but pathologically proven metastasis occurs in only 12.5% to 35% of the total number of patients seen with this disease (14,26,41,42,116). This has created controversy as to whether adenopathy usually represents metastatic disease rather than secondary infection. Whereas Grabstald (41) found histologic evidence of cancer in 24 of 25 patients with enlarged nodes, Desai and associates (26) reported that only 2 of 6 patients with adenopathy had positive biopsies. However, most authors consider inguinal adenopathy to represent metastatic disease (41,42,70,116). In patients who underwent pelvic lymphadenectomy, 50% were found to have positive nodes (42).

As is the case with urethral carcinoma in men, distant metastatic spread is uncommon at the time of diagnosis. In the original series of Grabstald and associates (42), 11 of 79 patients (14%) had distant metastases, but metastases were present in only 5 patients initially. Patients with adenocarcinoma were more likely to have distant spread. Lung, liver, bone, and brain are the most common areas of involvement (41). Untreated female urethral carcinoma has a dismal prognosis, with a mean survival of 12 months (81). The most important prognostic parameter is location of tumor and stage of the disease. Dalbagni and associates (23) report a 5-year disease specific survival of 89% for low-stage and 33% for high-stage disease and 69% and 18% for disease of the anterior and entire urethra, respectively.

Surgical Treatment

In the treatment of low-stage disease, mucosal lesions can be treated effectively with TUR and fulguration or laser ablation. Local excision for anterior lesions that are

externally visible may be sufficient. Tumors involving a greater length of urethra but still restricted to mucosa or submucosa can be effectively treated with TUR. Partial urethrectomy may be performed for low-stage lesions localized to the distal urethra as long as an adequate proximal surgical margin can be obtained and urinary continence is not compromised.

In selected patients with stage T_2 or T_3 disease, total urethrectomy may occasionally be an alternative with bladder preservation. This is seen primarily with anterior lesions in which adequate margins cannot be obtained by local excision (89). Bladder-sparing surgery may be a reasonable surgical option in the properly selected patient. Hedden and colleagues (49) describe a small series of patients with locally advanced stage C disease without bladder involvement treated with wide local excision with or without neoadjuvant radiation, bladder preservation, and either ileovesicostomy or continent catheterizable stoma. Local control was achieved in all patients with a median follow-up of 42 months, suggesting that bladder-sparing surgery is possible and feasible.

In high-stage disease (as most proximal tumors are), which includes involvement of the entire urethra with extension to bladder and vagina, a multimodality approach probably is most appropriate (89). Radiation alone or surgery alone generally results in poor survival rates, with a 5-year survival of 0% to 17% (14,26,42). Surgically, these patients are treated with anterior exenteration along with en bloc resection of the pubic symphysis and inferior rami. A somewhat better prognosis may result from treatment with preoperative irradiation followed by anterior pelvic exenteration (14,41). The amount of recommended radiation varies from 20 Gy in 5 days to 50 Gy over 5 weeks (14,41). One radiation–surgery protocol involves preoperative interstitial irradiation delivering 60 Gy for 4 days followed by anterior exenteration 2 weeks later (56). The rationale for preoperative irradiation is an attempt to decrease the rate of local recurrence, which has occurred in 66% to 100% of patients treated with one form of therapy only (20,41).

Tumors arising from urethral diverticula are most commonly adenocarcinoma (61%), followed by TCC (27%) and SCC (12%). Aggressive surgical treatment consisting of anterior exenteration with total urethrectomy and wide excision of vaginal wall is the standard of care in these patients because local recurrence has been documented in 44% of those treated by diverticulectomy or radiation (100).

Treatment and prognosis depend primarily on location, stage, and size, not cell type. Five-year survival has been reported as 40% for anterior carcinoma, 13% for carcinoma of the entire urethra, and 26% for the group as a whole (120). Bracken and colleagues (14) found that 5-year survival was 45% for lamina propria invasion, 41% for periurethral muscle invasion, 26% for extension beyond the urethra, and 18% for metastatic disease in a series involving 64 patients. The 5-year survival of patients with tumors that were less than 2 cm in size was 60%, and that for patients with lesions greater than 5 cm in size was 13%.

As in male urethral cancer, local recurrences are common, and failure to achieve local control of the disease most often results in death. Bracken and co-workers (14) report local recurrence in 33 of 71 patients (46%); only 3 of these patients survived after additional forms of therapy were administered.

Inguinal lymphadenectomy has been recommended only in cases of palpable lymphadenopathy. However, Foens and associates (36) demonstrated a 10% inguinal failure rate in patients who received groin treatment (surgical or radiation) at the time of diagnosis and a 52% failure rate in patients who did not initially receive groin treatment. Their retrospective study included 42 patients seen over a 47-year time frame. Indications for prophylactic inguinal treatment surgically or with radiotherapy must be evaluated further (17).

Radiation Therapy

Radiation techniques include external, interstitial, and intracavitary radiation and combinations of external beam with interstitial or intracavitary radiation. Early lesions can be treated effectively with interstitial radiation. In larger tumors, implants rarely can deliver adequate dosages without excessive tissue toxicity, so external beam with interstitial boost is recommended. In very advanced tumors, external beam radiation alone is used (37).

Radiation may be a reasonable alternative to local surgery for patients with low-stage urethral cancer, with cure rates averaging about 75% (45,69,105). Dosages in various series range from 50 to 60 Gy for brachytherapy alone to 40 to 50 Gy of external beam with a 20- to 25-Gy brachytherapy boost. The rate of complications in women ranges from 0% to 49%, with strictures being the most common, followed by fistulae, incontinence, urethral necrosis, and cystitis (39,105).

Two recent series of the use of modern radiation therapy techniques to treat female carcinomas stress the combined use of external and interstitial irradiation (2,105). In the series by Ali and associates (2), three patients with muscle invasive tumors did well without recurrence at up to 30 months with a combination of external and interstitial radiation. In addition, Sailer and colleagues (105) report 5-year survival rates of 60% to 80% for low-stage disease treated with combination radiation therapy. They used 45 Gy external radiation plus interstitial and intravaginal radiation sufficient to achieve a total dosage of 65 to 70 Gy. These authors recommend a combination of surgery and radiation therapy for advanced disease.

Grigsby (43) recently reported a series of 44 women treated by radiation or preoperative radiation and surgery. On multivariate analysis, tumor size was the most important prognostic factor. This author recommends treating women with tumors less than 2 cm with surgery or radiation. If radiation is the chosen modality and the lesion is less than 1 cm, interstitial radiotherapy at dosages of 30 to 65 Gy may be given. If a lesion is 1 to 4 cm, the radiotherapy regimen may include combination external radiation and intracavitary or interstitial radiation to dosages of 70 to 85 Gy. If a lesion is greater than 4 cm, patients may be more effectively treated with preoperative radiation to dosages of 45 to 50 Gy (43). Ten-year cause-specific survival in this series for lesions less than or equal to 2 cm, 2 cm to 4 cm, and 4 cm or more were approximately 90%, 30%, and 20%, respectively.

Foens and associates (36) compared the roles of surgery and radiation therapy in managing female urethral cancer. Only 36% of those treated with radiation alone and 60% of those treated with surgery alone had local recurrence, and the best results were those of combined interstitial and external beam radiation. There was also a significantly lower inguinal failure rate of 10% in those who received inguinal radiation compared with 52% in those who did not.

Garden and associates (39) presented their results with radiation therapy for female urethral cancer and reported that patient prognosis had remained essentially unchanged since 1976. Patients presenting early with only partial urethral involvement had a 74% local control rate and 48% 10-year overall survival rate. The length of urethra involved was an independent factor affecting overall survival, disease-free survival, and local control. The results for advanced disease were very poor, with only a 16% 5-year survival for fixed lesions. Based on their results they drew a number of conclusions about radiation therapy. First, early distal lesions can be treated with radiation only, which usually consisted of interstitial brachytherapy alone using 60 to 66 Gy. A reasonable surgical candidate may benefit from preoperative external beam radiation of 45 to 50 Gy. If the lesion is not amenable to surgery or the patient is not a surgical candidate, then 45 to 50 Gy external beam radiation followed by 20 to 30 Gy interstitial therapy is a reasonable approach. Even though histologic type did not affect outcome, it did affect natural history. Nodal disease was more common with SCC, and it was recommended that the inguinal nodes receive external beam radiation. Finally, these authors suggest that radiation is reasonable for palliation, although any potential benefit generally is of short duration.

Chemotherapy and Chemoradiation

Cisplatin, bleomycin, methotrexate, and 5-fluorouracil have demonstrable activity in urethral carcinomas. However, studies are limited to small series, often with widely variant treatment regimens and inconclusive results (31). Because of the small number of cases in any particular series and the wide variations in treatment modalities, it is difficult to evaluate with any certainty the various forms of therapy. There are no well-controlled studies comparing different approaches.

As discussed in male urethral cancer, a number of recent case reports and small series have demonstrated excellent results with chemoradiation consisting of 5-fluorouracil, mitomycin C, and external beam radiation as primary therapy for advanced SCC of the female urethra (69). Regimens similar to those used with head and neck and anal malignancies may be promising for female urethral cancer in improving efficacy and potentially allowing organ preservation. Licht and co-workers (72) reported on two men and two women receiving 5-fluorouracil and mitomycin C with 30 to 50 Gy pelvic irradiation. Three had complete responses and one had a partial response, whereas none of 15 other patients with advanced disease treated with surgery with or without radiation therapy had a durable complete response. Johnson and associates (61) demonstrated successful treatment of a bulky advanced stage SCC of the entire female urethra using low-dose preoperative radiation therapy with concomitant chemotherapy. At the time of report, this patient was free of disease 28 months after therapy completion.

BOX 37.4 DIAGNOSIS AND TREATMENT OF FEMALE URETHRAL CARCINOMA

As for male urethral carcinoma, a high index of suspicion with biopsy of any urethral lesion worrisome for carcinoma or not responding to conservative therapy is important for prompt diagnosis.
Careful clinical staging is important in determining appropriate therapy and prognosis.
Natural history of urethral carcinoma in women is similar to that in men; spread occurs primarily by local extension and to regional nodes.
Radiation therapy plays a more important role in the management of urethral carcinoma in women than in men.
Further experience with multimodal approaches is warranted based on encouraging initial results.

MANAGEMENT OF THE URETHRA AFTER CYSTECTOMY

Male Urethra

TCC often is a multicentric disease, and although it is most common in the bladder, it may occur anywhere along the urothelium. This has led to controversy about the need for prophylactic urethrectomy in men who undergo radical cystoprostatectomy (1,108). Approximately 4% to 15% of these patients develop neoplasms in the urethra at some time in the course of their disease (47,101,109). Prophylactic urethrectomy adds length to an already time-consuming operation and increases overall morbidity (108). In one series of 110 patients undergoing a prophylactic urethrectomy at the time of radical cystectomy, a 12% complication rate as a result of the additional urethrectomy was reported (108).

Urethral recurrence is a significant threat to survival, especially when associated with invasion into the richly vascular corpus spongiosum. Ahlering and associates (1) reported four deaths attributed to urethral carcinoma occurring after cystectomy. All four patients had invasive lesions, with a mean interval between cystectomy and urethrectomy of 46.5 months. This emphasizes the importance of identifying risk for urethral recurrence early.

Many patients are asymptomatic, even though they have epithelial changes, carcinoma *in situ,* or invasive tumor in the urethra. Urethroscopy and urethrograms have a low degree of accuracy (108). Cytologic changes may be the first sign of epithelial dysplasia or carcinoma before the development of overt tumor. In the series of Schellhammer and Whitmore (108) of men undergoing delayed urethrectomy, washings for cytologic analysis were positive in 14 of 15 patients, with the false-negative result occurring in a patient from whom only one specimen was collected.

Hickey and colleagues (51) reported on a group of patients who had undergone radical cystoprostatectomy for carcinoma of the bladder. Seventy-two patients underwent urethral surveillance consisting of urethral wash cytologies every 6 months. Seven (10%) had positive findings and underwent urethrectomy, and all were found to have carcinoma *in situ.* At the time of reporting, 6 of 7 were free of disease. There were no false-positive findings, and no patient has had a local recurrence without a positive finding. After cystoprostatectomy, urethral cytology should be performed semiannually for the remainder of the patient's life (106). It is important that normal saline washings be done without lubrication of the catheter because the lubricant may interfere with the cytologic examination.

Hermansen and associates (50) demonstrated the usefulness of flow cytometry to detect urethral recurrence after cystectomy. They reported on four patients, all of whom had positive flow cytometry that demonstrated perfect concordance with wash cytologies. All of the tumors were aneuploid. No data are available regarding ability to detect diploid tumors. Flow cytometry is less subjective than cytology but is more expensive. Its true diagnostic information over cytology awaits further studies with larger groups of patients.

The most common symptom in men with a urethral recurrence is a bloody urethral discharge (1,108). This has been seen in up to 80% of cases (1). Other symptoms include pruritus at the meatus, perineal pain, and fullness or mass along the urethra. It is imperative to counsel patients after cystectomy to promptly report the onset of bloody urethral discharge, which in itself is an indication for urethrectomy.

In this era of orthotopic neobladder reconstruction, the indications for prophylactic urethrectomy at the time of cystectomy must be clarified. For many years, debate has occurred as to which patients are at high enough risk for urethral recurrence to warrant prophylactic urethrectomy. Historically, prophylactic urethrectomy has been recommended for patients with diffuse carcinoma *in situ,* multifocal tumors, and tumors involving the bladder neck and prostatic urethra. This broad grouping may limit the pool of patients for whom orthotopic reconstruction may be an option. Recent data are beginning to shed light on which of these patients are likely to be at highest risk for urethral recurrence (33,38,47,71,115).

Levinson and associates (71) documented prostatic involvement as the most important risk factor, with urethral recurrences occurring in 4 of 24 patients (17%) who had disease extending into the prostate, including 3 of 10 (30%) of those with stromal invasion. They also noted recurrence in only 1 of 22 (4.5%) with either carcinoma *in situ* or multifocal tumors not involving the prostate and in none of the 9 patients with tumors at the bladder neck alone. Hardeman and Soloway (47) reported similar results in a group of 86 men monitored with urethral washings for a mean of 40 months after radical cystectomy. They found urethral recurrences in 1 of 27 (3.3%) with solitary tumors not at the bladder neck and 1 of 29 (3.6%) with multifocal tumors, carcinoma *in situ,* or tumors near the bladder neck but not involving the prostate. Of 30 patients with tumors in the prostate, 11 (37%) suffered urethral recurrence. When this group was further broken down according to degree of prostatic involvement, none of the 8 with disease confined to the urethra, 2 of 8 (25%) with ductal involvement, and 9 of 14 (64%) with stromal involvement experienced urethral recurrence. Tumor characteristics in the bladder or distal ureters do not seem to be nearly as strong a predictor of urethral recurrence as disease involving the prostate. Erckert and co-workers (33) found a 6.1% overall incidence of secondary urethral tumors in 910 men managed conservatively and there was a significant difference between the occurrence in patients with an initial solitary TCC of the bladder (2.6%) and those with recurrent multi-focal cancer (10.1%). In addition, they did not see an increased risk for urethral tumors with bladder carcinoma *in situ.*

Freeman and associates (38) compared the urethral recurrence rate after cystectomy in men with an orthotopic ileal neobladder and men with a cutaneous diversion. In their study population of 436 men, carcinoma *in situ* and multifocal tumors of the bladder were not individually associated with a significant risk of urethral recurrence, whereas prostatic involvement was. Interestingly, they found that patients with an ileal neobladder were at a significantly lower risk for urethral recurrence at 5 years (2.9%) than those with a nonorthotopic urinary diversion (11.1%). More specifically, in patients with prostatic urethral involvement, the 5-year probability of recurrence was 5% and 23.7% for orthotopic and nonorthotopic diversion, respectively. They hypothesized that this difference may be attributed to physiologic, biochemical, genetic, or immunologic characteristics of the ileum, continued exposure to urine, or unknown systemic effects of orthotopic diversion.

Current data support the conclusion that patients with no evidence of prostatic involvement on preoperative staging and negative intraoperative frozen section of the urethral margin can safely be offered a continent diversion to the urethra. It may even be possible to stratify patients with prostatic involvement based on the extent of prostatic disease when an orthotopic neobladder is being considered. Men with extensive prostatic ductal or stromal invasion or TCC involving the bulbomembranous urethra should undergo en bloc urethrectomy at the time of radical cystoprostatectomy.

All men with a urethral remnant after cystoprostatectomy should undergo periodic urethral washings, and urethrectomy should be performed if cytologic findings are positive. Furthermore, a bloody urethral discharge is an indication for urethrectomy. Urethrectomy should also be considered after cystectomy in men who are found on pathologic analysis to have positive margins at the prostatic urethra or prostatic ductal or stromal invasion. This should be performed within 2 to 3 months of the cystoprostatectomy. When performing urethrectomy, it is advisable to include the fossa navicularis and meatus with the specimen. Schellhammer and Whitmore (109) reported that 7 of 27 patients (26%) who previously had undergone urethrectomy developed a tumor in the meatal remnant.

Female Urethra

Stenzl and colleagues (115) evaluated the long-term risk of urethral involvement in women with bladder cancer and the indications for orthotopic reconstruction of the urinary tract. Historically, a high incidence of urethral involvement in women with bladder cancer has been reported, so urethrectomy has been routine at the time of radical cystectomy in women (25). However, these reports did not examine the relationship between the site of the bladder primary and urethral involvement. Recently, Stenzl and co-workers (115) reported only a 1% incidence of secondary urethral cancer in 104 women with localized, invasive disease. More importantly, there was no urethral involvement without concomitant involvement of the bladder neck. There was a marginally significant correlation with trigone involvement and no correlation with any other bladder regions. These authors concluded that in women without tumor at the bladder neck and with a negative intraoperative proximal urethral frozen section, a portion of the urethra can be preserved for orthotopic reconstruction with minimal risk of urethral recurrence.

Another study by Chen and associates (18) of women undergoing radical cystectomy also evaluated the risk of urethral as well as vaginal and cervical involvement. Their results were consistent with prior studies in that only bladder neck involvement was predictive of urethral involvement, with 7 of 21 (33%) patients with bladder neck involvement having urethral involvement. However, 2 of 9 patients with secondary urethral involvement had no evidence of tumor at the bladder neck. Therefore

they recommended that women who are candidates for orthotopic neobladder undergo examination under anesthesia, bladder neck and urethral biopsies, and frozen section of the proximal urethra. Patients with palpable masses on bimanual examination should also undergo transvaginal biopsies if considering orthotopic diversion.

Hollier and colleagues (53) reported that bladder neck and trigone involvement in women represented a 33% and 20% risk of urethral involvement, respectively. Furthermore, higher tumor stage (T_3 and T_4) also correlated with a 20% risk. Based on their data, they concluded that any woman with higher stage tumors or involvement of the bladder neck and trigone is at high risk for urethral involvement and should not be considered a candidate for orthotopic diversion.

As in men, there is growing evidence that a significant segment of the female urethra can safely be left intact in carefully selected women to permit orthotopic urinary reconstruction. The appropriate method of surveillance for both men and women with continent diversions via an intact urethra is not known. Whether a voided urine cytology or an endoscopic observation is optimal remains to be seen.

BOX 37.5 MANAGEMENT OF THE URETHRA AFTER CYSTECTOMY

Urethral recurrence occurs in 4% to 15% of patients after radical cystoprostatectomy.
Close follow-up of the urethral remnant with interval cytology is important. Positive urethral wash cytology findings and bloody urethral discharge are indicators for urethrectomy.
The most important risk factor for urethral recurrence is prostatic stromal invasion in men and involvement of the bladder neck in women.
Men without prostatic stromal invasion and women without tumor involvement of the bladder neck may undergo orthotopic neobladder reconstruction if intraoperative frozen sections of the urethral margin are negative. The risk of urethral recurrence is low in this setting.

RARE AND BENIGN URETHRAL TUMORS

Male Urethra

Primary sarcoma, melanoma, and adenocarcinoma occur rarely in the male urethra (12,95). Metastases to the male urethra from prostatic, colonic, rectal, bladder, renal, ureteric, and testicular sources have been identified (86).

The presenting signs and symptoms of sarcomas, arising from the supportive tissue of the corpus spongiosum, include the presence of a mass, pain, or obstruction. Aggressive surgical therapy must be used for potential cure.

Primary malignant melanoma of the urethra has been reported in 36 cases, with a much higher predilection in white men (99). Patients typically present in the sixth to eighth decades with symptoms including palpable mass, hematuria, bloody urethral discharge, fistula, persistent dysuria, and obstructive symptoms. However, melanuria is more specific for this disease. Delays in diagnosis are common, with the interval from onset of symptoms to diagnosis averaging 24 months (99). Tumors may be multifocal and occur in any portion of the urethra but are most common in the fossa navicularis (approximately 50%). Only 20% of malignant melanomas occur in the proximal urethra (97). Treatment has ranged from partial or total penectomy to emasculation with cystoprostatectomy with or without bilateral inguinal or pelvic lymph node dissection. Multimodality therapy, including radiotherapy and immunotherapy, may be useful adjuncts to surgery or as palliation. Despite these efforts, dissemination is common and occurs by direct extension, lymphatics, or hematogenous routes. Survival is poor, and most tumor-related deaths occur within 3 years of diagnosis (9,94,97). Only three patients have been reported to survive longer than 5 years after diagnosis (97). Ander and co-workers (5) reported an additional patient who survived 8 years after local excision, radiation, and chemotherapy. The rarity of this lesion and the great variability in applied therapy make an assessment of the most beneficial therapy difficult.

Adenocarcinoma is a very rare urethral cancer thought to arise in Cowper's gland. However, local necrosis and tissue destruction may prevent exact localization of the site of origin in many cases. All patients have demonstrated obstructive symptoms, and 52% had pain with defecation or constipation. Most have also had a palpable perineal mass. In 13 reported cases there were no 5-year survivors, despite therapy (12).

Congenital cysts occur in the urethral meatus or Cowper's gland and are rare. Excision is curative in meatal cysts. Transurethral unroofing is effective with small Cowper's gland cysts. Open excision may be necessary for large ones.

Urethral polyps are congenital lesions that occur most often in the prostatic urethra with an attachment to the verumontanum. They have been described in the anterior urethra as well. Presentation usually occurs in the first decade of life, with obstruction the most common symptom. Other symptoms include hematuria and enuresis. Diagnosis usually is by cystourethroscopy, although ultrasound has been described as diagnostic in a recent report. This lesion also has been reported in adults (90). Transurethral or suprapubic excision is curative.

Angiomas rarely occur in the urethra, with only 13 cases described in the literature (102). They may cause hematuria or bloody urethral discharge. Invasion has not been noted, but recurrences are typical unless adequate margins are obtained. Although fulguration may suffice in the small lesion, radical surgery has been necessary at times. Cure has been achieved with excision and reconstruction of the urethra (84).

Although they may involve the entire urethra, the most common meatal and parameatal neoplasms in men are papillomas and condylomata acuminata (59). Condyloma acuminatum makes up approximately 30% of all primary tumors of the male urethra (41,84). Patients with squamous papillomas may have hematuria, dysuria, pressure sensation, or pruritus. A typical reddish-purple, mulberry-like lesion often is visible on physical examination (59). Many times, simple eversion of the meatus is sufficient to demonstrate the presence of papillomas. Condylomata acuminata may show similar symptoms and may be difficult to distinguish from papillomas on gross examination. They more commonly involve the skin of the penis or perianal region in men 20 to 40 years old. Condyloma acuminatum is autoinoculable, and, like squamous papillomas, the lesions tend to be multiple. Histologically, both are composed of squamous epithelium in a papillary configuration, but condyloma acuminatum has a thin supporting stalk, a keratinized superficial layer, and an abundant infiltration of lymphocytes at the base of the lesions. The squamous papilloma has a prominent central vascular stalk and no keratinization of the superficial cell layer and has been considered the male analogue of the urethral caruncle in women (59,84). Treatment with excision and fulguration of the base usually suffices for lesions located at the meatus.

Intraurethral condylomata acuminata occur in 5% of patients with disease of the external genitalia. The lesions may occur anywhere along the course of the urethra but are typically intrameatal. Symptoms include hematuria, pyuria, and urethral discharge. TUR with fulguration of the base has been used, but condyloma lesions often are multiple, and this form of therapy carries a significant risk for scarring and stricture formation. Of the various therapeutic agents used, topical fluorouracil has been effective and has no injurious effects on the uninvolved areas of the urethra (28). Side effects usually consist of urethral irritation and burning in one quarter of patients and typically respond well to local application of 2% lidocaine jelly (68). The Nd:YAG laser may also be effective and may result in less urethral scarring than TUR and fulguration (113). It has been suggested that both squamous papillomas and condylomata acuminata are caused by HPV (24,88). This viral agent has also been linked to cervical dysplasia in women, resulting in speculation of carcinogenic potential (24,88).

Female Urethra

Malignant melanoma is one of the most unusual tumors of the female urethra, with only 48 cases reported (65).

However, the urethra is the most common site for primary melanoma of the genitourinary system in men and women, usually occurring in the distal urethra (64). This tumor often is in an advanced stage at presentation; thus survival is poor. Only six 5-year survivors are known (65).

Twelve cases of lymphoma presenting in the urethra have been reported, and 10 of these 12 were in women. One case of primary urethral large cell lymphoma, B cell subtype in which the patient presented with obstructive voiding symptoms was reported by Hatcher and Wilson (48). The patient was treated with an outpatient chemotherapy regimen with complete resolution of the mass.

Ovarian, uterine, pulmonary, and lymphoma metastases to the female urethra have been reported (86).

CONCLUSIONS

Carcinoma of the urethra is an uncommon disease characterized by extensive local invasion in both sexes. Although it is often advanced at presentation, distant metastatic spread beyond regional lymph nodes is unusual. It is thought to result from chronic irritation, stricture, infection, and diverticulum formation. Signs and symptoms are nondescript for carcinoma and are typical of the more common benign conditions of the urethra, often resulting in a delay in diagnosis. Despite aggressive therapy using radiation, chemotherapy, surgery, or a combination of modalities, local recurrence is common with proximal lesions, resulting in death. Only with early recognition and prompt initiation of appropriate therapy can improvement in survival be seen. Novel, more effective therapies clearly are needed. The diagnosis of urethral carcinoma should be considered in any patient of either sex who has lower genitourinary tract or urethral symptoms.

PELVIC FLOOR RELAXATION DISORDERS

As the population ages, more women are seeking care for pelvic organ prolapse. Treatment of prolapse makes up approximately 20% of gynecologic surgical workload (295). Olsen and colleagues (229) found an 11% lifetime risk of surgery for pelvic organ prolapse or urinary incontinence by age 80 years and a 29% reoperation rate for failed procedures. Pelvic organ prolapse is a protrusion of the pelvic organs into or out of the vaginal canal (7). According to Nichols and Randall (223), genital prolapse may result when normal pelvic supports are subjected to chronic increases in intraabdominal pressure or when congenitally defective genital support responds inadequately to normal intraabdominal pressure (223). However, the relationship between pelvic organ support and pelvic organ function is complex and not completely understood (275).

Pelvic Floor Anatomy

The pelvic diaphragm consists of passive and active support structures (301). The passive support structures are the bony pelvis and connective tissue, including visceral and parietal fascia, the arcus tendineus levatoris ani, and the arcus tendineus fascia pelvis. Active support structures are the muscles (the levator ani, iliococcygeus, and pubococcygeus) and the nerves (pudendal and sacral plexus). The pelvic floor lies at the bottom of the abdominal cavity and acts as a supportive layer to prevent the abdominal and pelvic organs from falling through the opening within the bony pelvis (80).

Connective Tissue

Organized, dense collagen form ligaments or tendons. Loosely arranged collagen, smooth muscle, elastin, adipose tissue, blood vessels, lymphatics, and nerves

contiguous with the pelvic organs have been controversially called *endopelvic fascia* (323). Parametrium and paracolpium “fascial” attachments form the uterosacral and cardinal ligaments (300).

The attachments of the arcus tendineus fascia pelvis and arcus tendineus levatoris ani consist of dense connective tissue originating from the obturator and levator ani fascia and provide anterolateral support of the vaginal wall. They insert anteriorly at the pubic rami bilaterally and extend posteriorly to the ischial spines (Fig. 38.1) (300). The urethra lies on a hammocklike supportive layer composed of the endopelvic fascia and anterior vaginal wall (83).

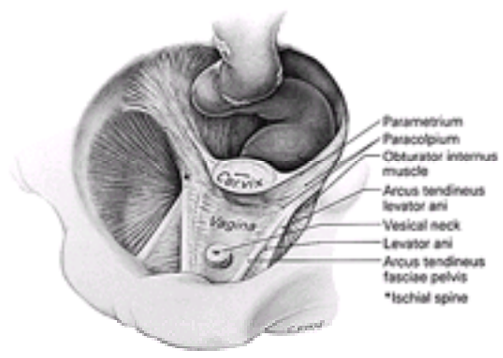

FIGURE 38.1. Cervix, vagina, and supportive structures drawn from dissection of a cadaver of a 56-year-old woman after hysterectomy. The bladder has been removed above the vesical neck. The paracolpium extends along the lateral wall of the vagina. (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission.)

DeLancey (79) initially described the concept of dividing the pelvic supports system into three levels. Levels I, II, and III represent apical, midvaginal, and distal vaginal supports, respectively. Level I defects are associated with uterine prolapse, enterocele, and posthysterectomy vaginal vault eversion. They are caused by a loss of support of the paracolpium and parametrium (uterosacral and cardinal ligaments). Level II defects affect the fibromuscular integrity of the vagina and its lateral supports (arcus tendineus fascia pelvis and arcus tendineus levatoris ani) and may appear clinically as cystocele, rectocele, or paravaginal defects. Level III defects correspond to loss of perineal body integrity or fusion of the distal urethra to the pubic bone at the perineal membrane. The perineal membrane is the triangular sheet of dense fibromuscular tissue spanning the anterior half of the pelvic outlet (318). It is also called the *urogenital diaphragm.* Loss of level III supports results in descent or separation of the perineal body or urethral hypermobility (Fig. 38.2).

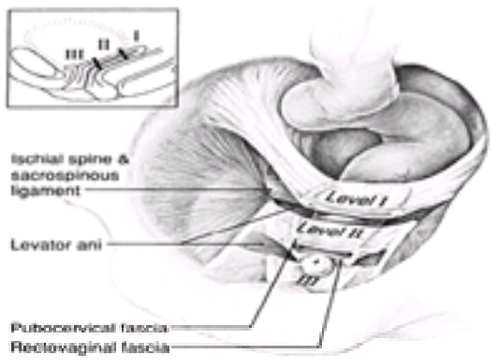

FIGURE 38.2. Levels of support of the upper and midvagina. In level I (suspension), the endopelvic fascia suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and posteriorly toward the sacrum. In level II (attachment), the vagina is attached to the arcus tendineus fascia pelvis and superior fascia of the levator ani. (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:1717, with permission.)

Muscles

The levator ani muscle and associated connective tissue attachments to the pelvis form the hammocklike pelvic diaphragm, which extends between the pubes anteriorly and the coccyx posteriorly. The levator ani consists of two parts, the diaphragmatic part (coccygeus and iliococcygeus muscles) and the pubovisceral part (pubococcygeus and puborectalis muscles). The coccygeus muscles extend bilaterally from the coccyx and sacrum to the ipsilateral ischial spine. The iliococcygeus muscle extends from the lateral pubic symphyses, over the pelvic sidewall (obturator internus muscle), attaching to the arcus tendineus levatoris ani laterally and meeting in the posterior midline at the anococcygeal raphe and coccyx. This forms the levator plate (Fig. 38.3). The pubovisceral portion of the levator ani arises from the inner pubic bones, attaching to the lateral vagina and rectum, and extends bilaterally to the anococcygeal raphe and coccyx (318). Understanding of pelvic floor anatomy has been greatly enhanced using magnetic resonance imaging (MRI) (Fig. 38.4).

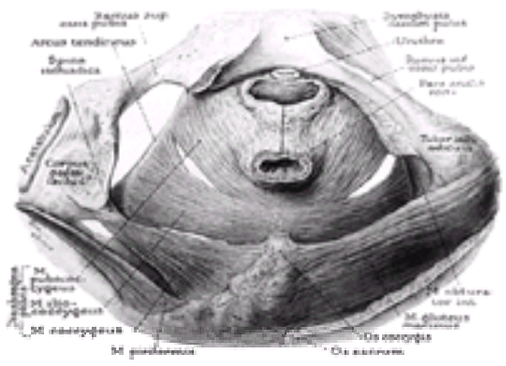

FIGURE 38.3. The levator ani muscle as seen from below. (From Anson BJ. *An atlas of human anatomy.* Philadelphia: WB Saunders, 1950:366, with permission.)

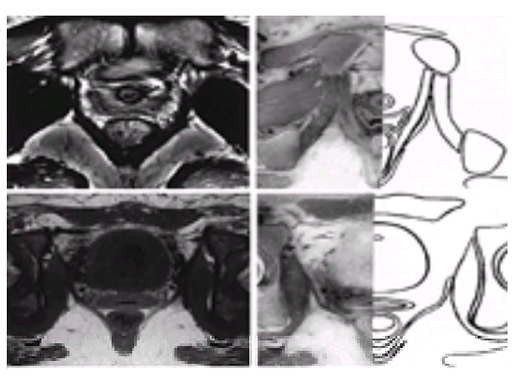

FIGURE 38.4. Axial views of the pelvis near the pubic symphysis. Proton density magnetic resonance image of 28-year-old living patient using a pelvic phased-array coil (repetition time 3,800 ms, echo delay time 18 ms, field of view 20 cm, scan time 8:59 minutes). **A:** Cross-sectional anatomy of the right hemipelvis. **B:** Corresponding diagram of the left hemipelvis. Axial view of the pelvis 3 cm cephalad to above. **C:** Cross-sectional anatomy of right hemipelvis. **D:** Corresponding diagram of the left hemipelvis. (From Strobehn K, Ellis JH, Strobehn JA, et al. *Obstet Gynecol* 1996;87:277, with permission.)

The levator ani muscle consists of slow twitch (type I) fibers, which maintain constant tone, and fast twitch (type II) fibers, which are responsible for reflex and voluntary contraction (318).

Nerve Supply

Innervation is supplied by sacral nerve root S-2, S-3, S-4, with possible contributions from pudendal nerve branches.

Etiology

Multiple factors contribute to the development of genital prolapse and urinary incontinence. Although the inherent strength of the muscles and connective tissue is important, they may deteriorate with age, prolonged lifting, or chronic cough causing long-term increase in intraabdominal load (81), decreasing estrogen with menopause (7), and pelvic support damage caused by vaginal birth (6,236). Previous gynecologic surgery, such as hysterectomy, predisposes to vaginal prolapse (79). Native connective tissue quality may play a role in isolated breaks in fascial attachments of the pelvic organs when subjected to chronic wear and tear (248).

Vaginal Birth

Delee (84) described the anatomic injuries associated with vaginal birth. The vagina is detached from its fascial anchors as the fetal head passes through the genital hiatus. Posteriorly, the levator ani muscles and connective tissue are torn from the rectum, and muscle separation occurs with tearing or overstretching. Anteriorly, vaginal attachments to the bladder may be torn, causing weakness of the attachment of the levator ani to the pubic symphysis. Factors associated with weakness of the pelvic floor include forceps delivery (247,302), episiotomy (143,247), prolonged second stage of labor, and increased fetal size (6,247). Levator ani muscle denervation has been detected in 50% of women with symptomatic pelvic organ prolapse (272). Parous women demonstrate more obvious histologic and electromyographic evidence of denervation (272). Cesarean delivery is considered protective against pudendal nerve injury (114). In 20 nulliparas, vaginal birth was associated with significant loss in pelvic muscle strength, whereas cesarean delivery was not (262).

Signs and Symptoms

Women with symptomatic genital prolapse complain of pelvic pressure, a feeling of heaviness, and often a visible protrusion of tissues. Sacral backache may be caused by traction on the uterosacral ligaments (81). They may also report a sensation of perineal wetness, vaginal bleeding caused by vaginal wall ulceration and atrophy, and difficulty with sexual intercourse.

Women with anterior wall prolapse also complain of urgency, urge incontinence, and frequency. Loss of support of the urethra and lower vaginal wall is associated with stress urinary incontinence. Loss of support of the upper anterior vaginal wall and bladder base can cause urinary retention and difficulty voiding. Apical prolapse may be associated with similar symptoms (81). Posterior wall prolapse has been associated with difficulty emptying the rectum, sometimes necessitating manual depression of the posterior vagina for defecation. Weber and Walters (323) found that there was no correlation between bowel symptoms and the presence of a rectocele. It is important to consider other causes of constipation, especially in older women.

Multiple sites of prolapse commonly are present simultaneously (Fig. 38.5). Therefore prolapse, bowel, bladder and sexual function are dynamically related (275).

FIGURE 38.5. Prolapse of the anterior, superior, and low position vaginal walls associated with a cystocele.

Prolapse and Urinary Tract Dysfunction

Fifty percent of women with genuine stress urinary incontinence have clinically important prolapse of the anterior vaginal wall (295). In as many as 80% of previously continent women, stress urinary incontinence can develop as a new condition after repair of severe prolapse (30). Occult or potential incontinence is defined as unmasked stress urinary incontinence, which may be caused by a mobile urethra after prolapse reduction (306). When the urethra is mobile or there is leakage when a cystocele is reduced during evaluation, an appropriate urethral suspension should be done with the cystocele repair (190).

Procidentia may occasionally imprison the ureters, leading to hydroureter and hydronephrosis. The diagnosis is made by intravenous urography with the patient upright.

Evaluation and Diagnosis

Pelvic organ prolapse is a clinical diagnosis based primarily on the physical examination. Traditionally, prolapse is subclassified according to pelvic organ. At physical examination, areas of prolapse should be assessed initially with and without Valsalva maneuver in the lithotomy position. It may be necessary to examine the woman in the sitting or standing position to reproduce maximal conditions (7). Each area of weakness in pelvic support must be graded individually according to maximal degree of descent to or beyond the introitus during maximal straining. Rectovaginal examination may assist in evaluation of the posterior vaginal wall (46). In the presence of a history of vaginal bleeding, investigations to rule out malignant or premalignant sources may be necessary, especially in the menopausal woman.

The simplicity of Baden's (18) system of classification and grading of pelvic organ prolapse severity has greatly contributed to its wide usage for many years (Table 38.1). Although it is easily amenable to clinical practice, this system has been associated with variable interobserver reproducibility and the inability to definitively ascertain the organs behind the visualized vaginal bulge. Therefore, in 1996, Bump and associates (46) proposed the International Continence Society standardization of terminology for female pelvic organ prolapse. This is a descriptive system of site-specific measurements of the pelvic supports. It attempts to objectively assess six defined points along the uterovaginal axis and includes measures of the genital hiatus, perineal body, and total vaginal length (Fig. 38.6). The complete quantitative description corresponds to specifically defined overall stages of prolapse. The system attempts to quantify prolapse and improve precision, although it is not organ specific. It has become a useful research tool.

Cystocele
First degree: The anterior vaginal wall, from the urethral meatus to the anterior fornix, descends halfway to the hymen. Second degree: The anterior vaginal wall and underlying bladder extend to the hymen. Third degree: The anterior vaginal wall and underlying urethra and bladder are outside the hymen. This cystocele is often part of the third-degree uterine or posthysterectomy vaginal vault prolapse.

Uterine or Vaginal Vault Prolapse
First degree: The cervix or vaginal apex descends halfway to the hymen. Second degree: The cervix or vaginal apex extends to the hymen or over the perineal body. Third degree: The cervix and corpus uteri extend beyond the hymen or the vaginal vault is everted and protrudes beyond the hymen.

Rectocele
First degree: The saccular protrusion of the rectovaginal wall descends halfway to the hymen. Second degree: The sacculation descends to the hymen. Third degree: The sacculation protrudes or extends beyond the hymen.

Enterocele
The presence and depth of the enterocele sac, relative to the hymen, should be described anatomically, with the patient in the supine and standing positions during Valsalva maneuver.

From Webster MD, Kieran MM, eds. Urogynecology and reconstructive surgery. St. Louis: Mosby, 1999:38, with permission.

TABLE 38.1. CLASSIFICATION OF THE SEVERITY OF PELVIC ORGAN PROLAPSE AS DESCRIBED BY BADEN (1968) AND MODIFIED BY BEECHAM (1980) ACCORDING TO MOST DEPENDENT POSITION OF THE PELVIC ORGAN DURING MAXIMAL STRAINING OR STANDING.

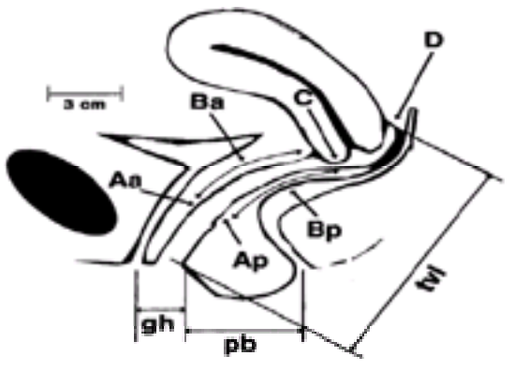

FIGURE 38.6. Six sites (points *Aa, Ba, C, D, Bp,* and *Ap*), genital hiatus *(gh),* perineal body *(pb),* and total vaginal length *(tvl),* used for pelvic organ support quantitation from the International Continence Society. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10, with permission.)

Other tools for assessing genital prolapse include imaging procedures such as ultrasonography, contrast radiography, computed tomography (CT), and MRI. Techniques to assess urethral hypermobility include videocystourethrography, Q-Tip test, and ultrasonography. Videocystourethrography may also demonstrate central and lateral defects of the anterior vaginal wall (Fig. 38.7). Ultrasonography displays dynamic descent of the urethrovesical junction in real time.

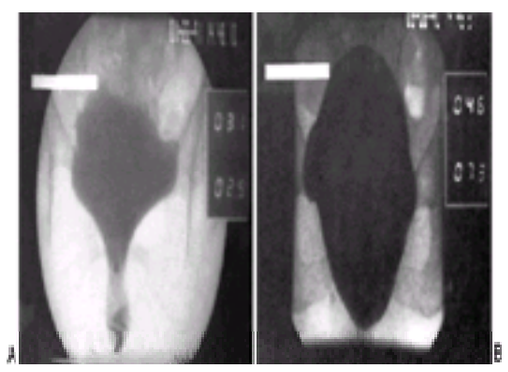

FIGURE 38.7. Videourodynamic study with the patient upright showing anterior wall defects. **A:** A cystocele with a narrow central defect in the pelvic floor is shown. Despite equal pressures in the bladder (31) and urethra (29), no leaking occurs because of the protective effect of the cystocele on the urethra. **B:** A large cystocele descends because of a defect in the vaginal support laterally at the arcus–ischial junction. This is a lateral defect.

Treatment

Issues such as future fertility, future sexual function, severity of symptoms, impact on quality of life, and the presence of medical complications affect treatment choices. Because genital prolapse usually is a quality-of-life problem, the potential risks and benefits of treatment must be evaluated individually. Nonsurgical and surgical management options should be considered.

Prophylaxis

Preventive measures include managing respiratory and metabolic disorders, which cause chronic increase of intraabdominal pressure. Weight control, nutrition, smoking cessation, and avoidance of occupational and recreational activities that stress pelvic supports also are important. Changing obstetric management to minimize instrumental trauma and prolonged labor may help preserve the pelvic floor (7). Postmenopausal estrogen replacement increases skin collagen content and improves vaginal epithelialization (38). Its direct effect on preexisting genital prolapse is unclear. Pelvic muscle exercises may strengthen the pelvic diaphragm and prevent pelvic relaxation.

Nonsurgical

Treatment of chronic respiratory conditions, weight loss, estrogen replacement, pelvic floor exercises, and biofeedback may improve conditions. Vaginal pessaries may be used in women awaiting surgery, women with prolapse during pregnancy, and women with medical contraindications for surgery. These rings are individually fitted to reduce genital prolapse. Local estrogen cream may decrease discomfort and erosion. Temporary relief of symptoms by pessary reduction of prolapse may indicate amelioration of prolapse symptoms with surgery.

Surgical

Apical Support Defects

A fascial break at the vaginal apex may result in an enterocele, a hernial sac that consists of peritoneum in contact with vaginal mucosa with no intervening fascia (Fig. 38.8) (249). Therefore excising the enterocele sac and reestablishing the continuity of pubocervical and rectovaginal fascia at the vaginal apex regardless of the anchoring site is recommended (79). For women who have completed childbearing, hysterectomy usually is combined with a technique for apical support restoration. Once the uterus is removed, the vaginal apex should be fixed to a higher point in the pelvis (79).

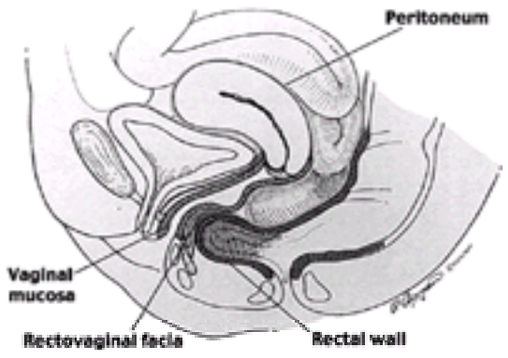

FIGURE 38.8. Posterior enteroceles. The fascial defect with the uterus in place *(left)* and with the uterus removed *(right).* (From Richardson CA. The anatomic defects in rectocele and enterocele. *J Pelvic Surg* 1995;1:214, with permission.)

Sacrospinous Ligament Suspension. The sacrospinous ligament suspension involves unilateral or bilateral fixation of the vaginal apex to the sacrospinous ligament and coccygeus muscle complex by a vaginal approach. The reported success rate ranges from 83% to 97% (278). An 18% recurrence rate has been cited (304). The lateral and posterior deflection of the vaginal axis associated with the typical unilateral fixation has been criticized as being not anatomic. Described complications include recurrent anterior wall prolapse (278), vaginal shortening, sexual dysfunction, pain, and hemorrhage. The notable procedure risks are related to injury to the nearby pudendal nerves and vessels, the gluteal vessels, and the sacral nerve roots.

Iliococcygeus Suspension. Considered a less morbid procedure, the iliococcygeus suspension involves attaching the vaginal apex to bilateral iliococcygeus muscle just anterior to the ischial spine (277). In contrast to the sacrospinous ligament suspension, the point of fixation is removed from critical structures. The reported anterior wall prolapse recurrence rate ranges from 4% (207) to 19% (277). Foreshortening of the vaginal length is a drawback of this procedure.

Uterosacral Suspension. Uterosacral suspension involves bilateral suspension of the vaginal vault from the origins of the uterosacral ligaments (214). McCall combined this with a culdoplasty, where the uterosacral ligaments are plicated and the cul-de-sac is obliterated. Currently, uterosacral suspension is more often performed by vaginal or laparoscopic approach. Reported recurrence rates range from 0% to 11% (95). Intraoperative cystoscopy is recommended because of the close proximity of the ureters to the uterosacral ligaments and the increased risk of ureteric entrapment or obstructive attenuation.

Abdominal Sacral Colpopexy. Abdominal sacral colpopexy involves placing a synthetic bridge between the prolapsed vaginal apex and the anterior surface of the sacrum. The sacral promontory to the upper third of the sacrum is considered the safest site of fixation (2). Separate pieces of mesh material often are attached to the anterior and posterior vaginal wall. It is often accompanied by a Halban or Moschowitz culdoplasty to obliterate the cul de sac, incite scarring, and potentially reduce the risk of enterocele formation behind the posterior mesh. A 90% cure rate has been reported (2). Failure usually occurs at the vaginal fixation site. Specific risks include life-threatening hemorrhage from injury to the sacral venous plexus, bowel obstruction, and mesh erosion.

Colpocleisis. In older women who will no longer be sexually active, a LeFort colpocleisis may be the preferred management of massive vaginal vault eversion. It is associated with less perioperative morbidity. It consists of denuding a rectangle of vagina anteriorly and posteriorly and reapproximating the underlying tissue. If left *in situ,* the uterus and the cervix remain hidden behind the new vaginal septum, and channels are left open below the cervix and lateral to the closure to allow any secretions and uterine bleeding to be noted. Endometrial carcinoma or hyperplasia must be ruled out before this procedure is performed. Stress incontinence may develop after colpocleisis because of flattening of the posterior urethral–vesical angle (223).

Anterior Wall Support Defects

Anterior wall defects have been described as lateral, superior, and midline. Specific repairs address specific defects. Some women with cystoceles may also have concomitant genuine stress urinary incontinence. In this scenario, a combined antiincontinence procedure may be needed.

Anterior Colporrhaphy. Anterior colporrhaphy or cystocele repair addresses central anterior defects. A vaginal approach is used. The vaginal epithelium is incised and dissected from the underlying endopelvic fascia to reveal the defect. The area of dissection extends from the descending pubic rami to the bilateral pelvic sidewall. The endopelvic fascia is plicated to reinforce the anterior vaginal wall and reduce the anterior herniation. Synthetic material, cadaveric fascia, or autologous fascia sometimes is used to reinforce or substitute for endopelvic fascia (Fig. 38.9) (165).

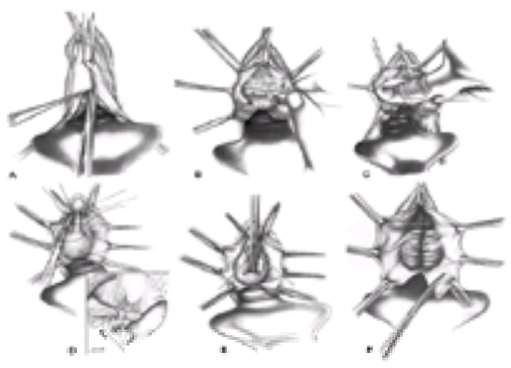

FIGURE 38.9. Technique of anterior colporrhaphy. **A:** Scissor dissection of vaginal mucosa to the region of external meatus with traction on the vagina along the course of dissection to separate bladder from vaginal mucosa. **B:** Sharp dissection of the white, avascular plane between the adherent fascia and vaginal mucosa. **C:** Blunt finger dissection with gauze sponge to free fascia from mucosa beneath the urethra and bladder. **D:** Beginning at the external meatus, successive vertical mattress sutures are placed in the mobilized paraurethral fascia (Kelly plication). **E:** Successive sutures are continued along the posterior floor of the bladder and urethra and are tied. **F:** The normal urethrovesical anatomy is restored. The excess vaginal mucosa is excised. The vaginal mucosal edges are reapproximated in the midline. (From Thompson JD. Surgical correction of defects in pelvic support: anterior compartment defects. In: Rock JA, Thompson JD, eds. *TeLinde's operative gynecology,* 8th ed. Philadelphia: Lippincott-Raven 1997: 980, with permission.)

Paravaginal Defect Repair. Performed both by abdominal and vaginal approach, the paravaginal defect repair is an attempt to restore lateral anterior wall defects. Abdominally, the retropubic space is dissected to expose the arcus tendineus fascia pelvis, the pubic bone, and the ischial spines. The separation or detachment of the arcus tendineus fascia pelvis and lateral vaginal sulcus from the pelvic sidewall indicates a paravaginal defect. Repair involves suturing the detached fascia to the pelvic sidewall along its anatomic line of attachment between the pubic bone and the ischial spines (276). By the vaginal route, the anterior vaginal wall is opened, as in the anterior colporrhaphy, and the arcus tendineus fascia pelvis is reattached to the pelvic sidewall. Macer (195) reported a cure rate of 78% and 92% for vaginal and abdominal approaches, respectively.

Posterior Wall Defects

Posterior Colporrhaphy. Posterior colporrhaphy remains the mainstay procedure for posterior wall defects. It involves incision and dissection of the posterior vaginal wall to expose the defect. Traditionally, as described by Nichols (223), transverse plication of the detached rectovaginal fascia separate from the vaginal mucosa has been advocated. More recently, Richardson (249) suggested site-specific reapproximation of discrete breaks in the rectovaginal fascia, without levator plication, as a more anatomic repair that minimizes bowel symptoms and dyspareunia postoperatively. Rectocele repair often entails simultaneous perineal reconstruction to

reapproximate separated superficial perineal muscles. This results in an increase in perineal body length and restores the normal caliber of the genital hiatus.

VAGINAL INFECTIONS

Bacterial Vaginitis (Nonspecific Vaginitis)

Gardnerella vaginalis is the organism most often associated with bacterial vaginitis. The organism was named for Gardner, who, with a co-worker, in 1955 described a vaginal infection caused by the organism *Haemophilus vaginalis* (184). More recently, the disease has been called bacterial vaginosis because the condition is characterized by vaginal discharge but the absence of true tissue invasion or local tissue inflammatory changes (97,286). In addition to *G. vaginitis,* other anaerobic organisms often are present in the vagina and vaginal discharge of patients with nonspecific vaginitis or bacterial vaginosis (200). The basic cause of the anaerobic bacterial overgrowth is not known. Whether bacterial vaginosis is a sexually transmitted disease is also unknown (283). The anaerobic overgrowth is associated with a change in the normal flora of the vagina, particularly the population of lactobacilli, the predominant organisms in a normal vaginal flora. There are 100-fold to 1,000-fold decreases in the usual bacterial counts of lactobacilli in patients with symptomatic bacterial vaginosis. In addition, unusual species of lactobacilli can be cultured from the vagina. The underlying mechanisms involved in the changes in bacterial flora are unknown. Moreover, the presence of *Gardnerella* organisms is not universally associated with symptoms or vaginal discharge (97,115,184,286,330).

Symptoms

Patients generally complain of a malodorous discharge, particularly after intercourse. On examination, there is a thin, watery, usually grayish-white discharge. Most patients with typical bacterial vaginosis do not complain of pruritus, dysuria, or true dyspareunia (211). When exposed to potassium hydroxide (KOH), amines present in the vaginal discharge volatilize and release a characteristic fishy odor. There is an increased rate of vaginal cell exfoliation, which contributes to the discharge. Typically, *Gardnerella* bacteria are attached to the exfoliated cells.

Diagnosis

The diagnosis is based on the presence of a grayish-white discharge, which is adherent to the vaginal epithelium, a vaginal pH greater than 4.5, a positive amine test in the presence of KOH (whiff test), and the detection of “clue” cells in the vaginal discharge. Clue cells are exfoliated vaginal epithelial cells covered with *G. vaginalis* organisms, which gives the cells a stippled, granulated appearance and blurs the cell borders (115,211). There are few polymorphonuclear leukocytes (PMNs) in the discharge. Generally, cultures are not useful because it is not the presence of the organism that defines the disease. Other exfoliated cells, called comma cells, are covered with adherent curved rodlike bacteria on Gram stain; they also are associated with bacterial vaginosis in the absence of true clue cells.

Treatment

Oral metronidazole, 800 to 1,100 g per day for 1 week, constitutes standard therapy. This is associated with a 90% cure rate. Oral clindamycin also can be used, 300 mg twice a day, or it can be applied as a 2% vaginal cream or used as a suppository once daily for 7 days. The latter treatment is indicated in women sensitive to metronidazole, pregnant women, or those who cannot tolerate the side effects of systemic therapy. Amoxicillin and ampicillin also have been used, particularly in pregnant women, but these drugs are less effective than clindamycin and metronidazole (58,245,287).

Treating the sexual partners of women with bacterial vaginitis has not been shown to improve outcome when compared with placebo treatment of the sexual partners (185).

Candida and Other Yeast Infections

Although only 5% of women develop recurrent yeast infections, 75% experience at least one infection, and 50% experience more than one infection (292). *Candida* species are commonly isolated in the vaginal flora of healthy asymptomatic women (115). Factors responsible for overgrowth of the yeast organism and symptoms include antimicrobial therapy, pregnancy, high estrogen levels, diabetes mellitus, corticosteroid therapy, and altered immunologic status. The role of other factors that putatively have been related to yeast infections is controversial. These latter factors include sexual activity and many other less well-established associations (110). Most symptomatic infections are caused by *C. albicans,* but *C. tropicalis* and *Torulopsis glabrata* also can be pathogenic (154). The precise cause of *Candida* infections is not established. Sexual transmission has been studied but has not been proven to be a causal factor (110,153). Altered immunologic status has been suggested as a cofactor, related to a reduction in cellular organism immunogenicity associated with secretion of a carbohydrate “mannan” by the organism, which may induce specific T-cell suppressor lymphocytes (148,153,166).

Symptoms

Vulvar pruritus and a cheesy-white vaginal discharge, together with dyspareunia, burning vulvar pain, and occasional dysuria, are typical symptoms. In diabetic patients, involvement of the vulva and intertriginous areas is common. On examination of the vagina, white adherent patches are seen, which resemble the patches seen in the throat in patients with thrush. The vaginal epithelium is inflamed, but the cervix usually is normal (246).

Diagnosis

The diagnosis is based on typical findings on examination, a vaginal pH less than 4.5, and a saline and KOH prep (10% to 20% KOH) that demonstrates budding yeasts, or hyphae with branches. Microscopic tests are valuable if positive, but they are not very sensitive. Cultures are specific, but they take at least 24 hours and often are not done in physician's offices. A rapid slide test using a latex agglutinin technique is available; it is more specific but not much more sensitive than the microscopic test (98).

Treatment

The imidazoles are the first line of therapy. Topical agents are available as over-the-counter preparations. *C. tropicalis* and *Torulopsis* species usually are not very sensitive to imidazoles. The imidazoles include butoconazole, clotrimazole, miconazole, and terconazole (212,270,285). There do not appear to be any significant differences in efficacy in this group of agents, with the possible exception of butoconazole, which may be more effective at smaller dosages.

Initial therapy fails in approximately 20% to 25% of women. This may occur because the organisms are not sensitive or for other reasons.

Culture identification of the organism is thought to be helpful when the initial trial of therapy fails. Long-term oral therapy, such as ketoconazole 100 mg daily for 4 to 6 weeks has been found effective (270). Idiosyncratic toxic reactions to the imidazoles have been reported, including hepatitis, but these are unusual. For highly recurrent infections resistant to standard therapy, painting the affected tissue with gentian violet can be effective though inconvenient and messy.

Although none of the oral agents currently available are approved by the U.S. Food and Drug Administration (FDA) for vaginal infections, almost all of them have been used as oral therapy for *Candida* infections. Oral therapy is equivalent or superior to local therapy. Ketoconazole (40 mg daily for 5 days), fluconazole (150 mg as a single dose), and triaconazole (200 mg daily for 3 days) have been found to be equally effective. Safety of the oral agents in pregnancy has not been demonstrated. Local agents are used during pregnancy, but some systemic absorption of these also may occur, with potential for fetal effects (96,270).

Trichomonas vaginalis

Infection with *Trichomonas,* a protozoan parasite, is perhaps the third most common vaginal infection. This is a sexually transmitted disease, and its incidence varies from 2% to 5% in a general gynecologic office practice to 5% in family planning clinics and 10% to 25% in gynecology clinics in university hospitals. It affects perhaps 5% of the U.S. population between ages 16 and 35 (252,307). The organism is strictly anaerobic and attaches to epithelial cells in the vagina and urethra and in Skene's glands in women and in the urethra and prostate in men as well as beneath the foreskin in uncircumcised men. Systemic therapy usually is needed for cure.

Symptoms

As many as 50% of affected women are asymptomatic. When symptoms occur, they classically include a profuse, frothy, greenish watery discharge. In fact, the discharge often is indistinguishable from that seen in patients with nonspecific bacterial vaginosis. Other symptoms include pruritus, dysuria, and dyspareunia. *Trichomonas* has a positive association with bacterial vaginosis. However, the typical vaginal discharge is different with a combined infection because all *Trichomonas* infection discharges contain large numbers of PMNs, in contrast to the discharge in patients with bacterial vaginosis.

Diagnosis

The vaginal pH generally is 5 or higher. The characteristic discharge may or may not be present. White blood cells are present in the discharge, and the trichomonal organism may be visualized on a saline prep, identifiable by its rapid flagellar movement. Often, the organism also can be identified in urine specimens. The false-negative rate for wet mounts is as high as 50%, so culture is the most reliable method. The organism grows on selective media, but identification takes 2 to 7 days, much too long for clinical utility (178). Two new monoclonal antibody stain methods are available, which are comparable in specificity to culture and nearly equal to culture in sensitivity (188).

Treatment

Primary therapy is with metronidazole (250 mg three times a day for 7 days). Single oral doses of 2 g provide comparable outcome, or a 90% to 95% cure rate at 10 days. The organism does not persist in the male genital tract, but concurrent treatment of sexual partners is recommended to prevent the short-term risk of reinfection in women treated with short-course therapy. Treatment failure is unusual; a second course of therapy is recommended in such instances. Clotrimazole can be used as local therapy, but it is much less effective; however, it must be used during pregnancy (184,188,245,286). Side effects of metronidazole are common and include glossitis and nausea. The drug also has Antabuse-like properties, and severe, violent reactions can occur if patients drink alcohol while taking the drug.

Newer Therapy and Changing Concepts of Epidemiology

Povidone-iodine pessaries have been used for the local therapy of *Candida* and *Trichomonas* and nonspecific vaginitis. These nontoxic suppositories containing 200 mg of povidone-iodine have been shown useful in small series without placebo controls (341).

In the United States and Europe, *Trichomonal* vaginitis is much less common than it was 10 years ago, and *Candida* infections have become much more common (169). Vaginitis still is one of the 25 most common problems in clinical medicine in the United States, and with the increase in incidence of candidiasis, it has come an increase in the incidence of yeast infection caused by noncandidal organisms, which are resistant to standard therapy.

However, failure of treatment to resolve symptoms of vaginitis may be the result of a noninfectious cause. At least two studies have suggested that, rather than failure of antimicrobial therapy, failure of response simply may reflect a noninfectious problem (259,264).

Ray and co-workers (241) did vaginal cultures in 100 women with “vaginitis” and 50 age-matched “normal” controls. *T. vaginalis* was cultured from 11% of symptomatic patients, *Candida* from 31%, and *Gardnerella* from 31%. In the control group, 22% were positive for *Gardnerella,* 14% for *Candida,* and none for *Trichomonas.* These findings suggest that cultures are not specific for any diagnosis (241).

Another study, from Denmark, found no difference in the concentration of *G. vaginalis* in women with and without a symptomatic vaginal discharge. In other words, the concentration of organisms in patients without the disease was about the same as it was in patients with symptomatic vaginal discharge (40).

Furthermore, women with infrequent vulvovaginal candidiasis often have an identifiable cause for the infection, whereas those with highly recurrent or resistant infections often do not. Although noncandidal species are more common in recurrent infections, resistance to imidazoles is rarely responsible by itself for recurrent infections (284). Treatment of presumed gastrointestinal reservoirs or sexual partners is rarely effective in women with relapsing infection (270). Immunologic studies suggest the existence of an acquired *Candida* antigen–specific immunologic deficiency that is hormone sensitive (148,166).

Genital Herpes

Genital herpes is a common condition, and it is estimated that about 20 million acute and recurrent infections occur in the U.S. population annually (213). Herpes is a sexually transmitted disease, and the incubation period is 2 to 10 days. Transmission is not efficient; transmission to an infected person's sexual partner is approximately 10% annually (184).

Acyclovir therapy has reduced the severity of acute episodes and decreased the incidence of recurrence and the severity of recurrent exacerbations.

Pathogenesis

Herpes simplex virus type I and II cause infections of the oral and genital mucosal surfaces. The type II variety causes 80% of genital infections. These are DNA viruses, which can be typed using monoclonal antibodies (213).

Symptoms

A prodromal symptom complex of paresthesias precedes by 12 to 48 hours the appearance of vesicles and pustules, which usually occur in groups. The paresthesia reflects the diffuse sensory neural involvement by the virus. The vesicles rupture, leaving very painful ulcers, which are sometimes clean based and sometimes purulent. A primary infection is severe in patients who have previously been unexposed to herpes simplex virus because there are no preformed antibodies. Systemic symptoms are more common with the first episode and include fever, myalgia, headache, and malaise. Acute urinary retention may occur in acute episodes, particularly during pregnancy. With the initial episode, herpes simplex type II usually can be cultured from the cervix or the base of the ulcers if they are not secondarily infected. With subsequent episodes, positive herpes simplex cultures are less common (213,255).

Dysuria is a prominent symptom; urinary retention related to cord or root involvement may necessitate intermittent catheterization for 4 to 8 days. Rarely, with extensive neural involvement including transverse myelitis, intermittent catheterization may be needed for several weeks. The major differential diagnosis is a syphilitic ulcer (255). Herpes tissue culture or a cytologic diagnosis by a Papanicolaou smear, viral antigen, or DNA detection is the most specific methods of diagnosis. Tzanck stains also can be used. These are fresh preparations, stained with Wright's stain, of scrapings from vesicles. The technique detects the multinuclear giant cells typical of herpetic infection. Stains are 50% to 80% specific (184).

Treatment: Dosage and Route

Acyclovir is the acyclic analog of guanosine, which is a competitive inhibitor of herpes simplex virus DNA polymerase, which slows viral replication. For acute infections, the dosage is 400 mg acyclovir three times daily for 10 days. Topical treatment is much less effective but can be used (168). Recurrent episodes are treated with 200 mg acyclovir daily for 2 to 5 days or 800 mg twice daily for 5 days; 400 mg twice daily is used for prophylaxis of recurrent episodes. The usual duration of prophylactic treatment is 1 year, followed by a period of observation to see whether there is a recurrence. The incidence of side effects in patients treated for as long as 3 years has been minimal. For a severe or critical disease, as may occur in pregnancy, the intravenous route is used (5 mg/kg every 8 hours for 5 to 7 days) (103). Immunodepressed patients fare poorly with herpes simplex infections, and increased dosages of acyclovir are needed. Safety of acyclovir in pregnancy has not been determined; the drug is not used unless life-threatening infection is present.

Genital Warts

Human papillomaviruses (HPVs) that cause genital warts are ubiquitous; the true incidence is unknown but is thought to be high. There are numerous HPV types; types 16, 18, and 31 appear to be more oncogenic than others. The association between HPV and genital malignancy is fairly strong and convincing; however, the

relationship is based primarily on the common finding of HPV-DNA sequences in malignant tissue (157). Patients with HPV infection should undergo regular evaluation, particularly for cervical malignancy.

Clinical Expression

Cauliflower-like lesions, called *condyloma,* arise on the external genitalia and anal regions and occasionally are present in the oral cavity. These are soft, white sessile tumors with fingerlike projections, especially on the vulva. On the skin, the lesions are more keratotic. There may be small, papillary lesions that may coalesce. Subclinical infections can be recognized by application of dilute acetic acid, which turns the lesions white.

Diagnosis

Usually, the diagnosis is obvious, but some clinical cases may be diagnosed by Pap smear, colposcopy, or acetic acid test. The acetic acid test involves soaking the skin or genital area in 3% acetic acid for 5 minutes and then examining the area under magnification. A shiny white appearance of the skin may occur on the lesions, but these findings are nonspecific. The typing of HPV is based on DNA hybridization. This is the only method that allows differentiation of the more than 60 HPV types (49).

Treatment

No satisfactory treatment exists for HPV, and no treatment eradicates the infection. Treatment is directed only at the unpleasant or unsightly lesions, and that does not get rid of the virus. Patients, treated or untreated, are infectious to their sexual partners and should be advised to use condoms. Once present in the female genital tract, HPV infection is a multicentric disease. Patients with evidence of HPV infection should have regular colposcopic examinations of the entire genital tract for malignancy.

VULVAR PAIN AND VULVAR VESTIBULITIS SYNDROME

One of the most frustrating problems facing gynecologists and urologists is that of chronic vulvar discomfort and dyspareunia. Terms such as *focal vulvitis, vulvar adenitis,* and *vulvar hyperesthesia* have been used to describe this condition. Friedrich (111) coined the term *vulvar vestibulitis syndrome* (VVS) in 1987. VVS is a chronic clinical syndrome or constellation of symptoms limited to the vulvar vestibule and characterized by the following criteria: severe pain on vestibular touch or attempted vaginal entry, tenderness to pressure localized within the vaginal vestibule, and physical findings confined to vestibular erythema of various degrees (111,240). It has been proposed that VVS should be differentiated from vulvodynia, which is chronic vulvar discomfort usually characterized by burning, and from pruritus vulvae, which is associated with chronic itching. The discomfort of VVS may be characterized by a sharp pain or a sensation of rawness. The *sine qua non* is introital dyspareunia, but the pain may be elicited by tight clothing, biking, or tampon insertion (202).

On physical examination, there is localized erythema of the vestibular fossa, commonly involving the fourchette. When even mild pressure is applied to the affected areas with a cotton-tipped applicator, an immediate and marked pain response is elicited.

VVS occurs predominantly in Caucasians between ages 20 and 40 (111,129,199). The cause of VVS is not known. A number of studies have documented an increased incidence of candidal and HPV infections in affected patients (111,130,199,233,240). However, other investigators have not confirmed these findings (25,113,201). Furthermore, the presence of HPV infection does not affect treatment results (35). Neither gonorrhea, chlamydia, *Mycoplasma, Gardnerella, Ureaplasma,* nor *Trichomonas* appears to be causal (25). Urine-born oxalate crystals (288) have been implicated as possible etiologic agents in some patients. Fitzpatrick and associates (108) reported the association of VVS with interstitial cystitis in three patients and proposed that both syndromes may represent a disorder of the urogenital sinus–derived epithelium because both bladder and vestibular mucosa are derived from the urogenital sinus. Histologic and immunohistochemical analyses of affected regions demonstrate greater inflammation and nerve fiber density when compared with control tissues (33,55,240,333).

There is no consensus about the appropriate treatment for VVS. Nonspecific therapies (sitz baths, lubricants, antiinflammatory agents) are rarely successful. Mild cases of discomfort may respond to topical lidocaine jelly. Antifungal and antibiotic creams should be prescribed only in cases of documented infection. Indiscriminate use of these agents is expensive and may worsen symptoms by inducing an inflammatory reaction. Patients with concomitant HPV infections and VVS may benefit from intralesional injections of alpha-interferon (152). Other treatments that have been used include long-term oral antifungal medications, acyclovir, amitriptyline, calcium citrate with low-oxalate diet, *N*-acetylglucosamine, and topical capsaicin (112,202,288). Biofeedback with pelvic floor muscle exercises may improve symptoms in some patients (126). When medical treatment is unsuccessful, surgical excision of the tender areas (perineoplasty) is performed. Published success rates of this procedure range from 43% to 100% (29).

ESTROGEN REPLACEMENT THERAPY

The increasing life expectancy in women over the last 50 years has led to the fact that approximately half of a woman's adult life is spent after menopause (87). The median age of natural menopause in the United States is 51.4 years (90). Approximately 1% of women become postmenopausal before age 40, and 5% become postmenopausal after age 55 (3). With the permanent cessation of ovarian activity and a subsequent fall in estrogen levels, there is a dramatic increase in the serum levels of follicle-stimulating hormone (FSH). Most women develop some features of estrogen deficiency such as thermoregulatory dysfunctions (e.g., hot flashes, sweats), vaginal thinning and atrophy, osteoporotic changes, menstrual irregularities, changes in the endometrium, and neurologic and emotional changes (90,225).

Estrogen replacement therapy (ERT) for postmenopausal women counteracts some of the effects of estrogen deficiency. In a study of the value of ERT in a hypothetical cohort of 10,000 women, it was estimated that using estrogen for 25 years would produce a gain of 3,951 “quality-adjusted life years” compared with the same number of women not using estrogen (134). In a study of 685 women given estrogen therapy who were designated at risk for osteoporosis, only 49% were still taking estrogen at the end of 1 year. In the group of women who had undergone hysterectomy, the 1-year compliance was 59% (308). In the National Health and Nutrition Examination Survey (NHANES) I study, 50% of women sampled used estrogen therapy for more than 1 month, but only 20% continued its use beyond 5 years (37). However, ERT is not without risk, and each patient should be thoroughly examined and counselled before ERT is initiated (23,68,134,225). Postmenopausal hormone replacement therapy (HRT) is individualized, and the ultimate decision and responsibility lies with the patient.

Effects of Estrogen Replacement Therapy

Short-term Effects

Postmenopausal women may experience menstrual irregularities, hot flashes, sleep and mood disturbances, decreased libido, and vaginal dryness (8). Hot flashes may cause irritability and sleep disruption. The incidence of hot flashes increases in the presence of smoking or a maternal history of hot flashes (296). Fluctuating hormone levels are associated with an increase in emotional lability (194). Breast atrophy and dyspareunia caused by vaginal atrophy are later indications of estrogen loss (28). ERT has been shown to be the most effective therapy for treating hot flashes related to estrogen deficiency (291).

Effect of Estrogen on Bone

Osteoporosis is defined as a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, causing an increase in bone fragility and susceptibility to bone fracture (69). Twenty-eight million Americans have varying degrees of osteoporosis. Women make up 80% of this group (9). More than 40% of women over age 50 experience osteoporosis-related fractures (124). Peak bone mass in men and women is attained by age 30 years, with a subsequent 0.4% bone loss per year in both sexes. In women, there is an annual 2% cortical bone and 5% trabecular bone loss for 5 to 8 years after menopause (9). It is estimated that women hospitalized for hip fractures have an overall mortality rate of 30% within 1 year of hip fracture (9).

Estrogen therapy is the only pharmacologic approach that has been widely recommended to treat osteoporosis. It has an antiresorptive effect that decreases osteoclastic bone resorption and directly increases bone mass. It is associated with a 50% reduction in the risk of hip fractures. In women with proven osteoporosis, it the first-line therapy for fracture prevention. The effect of estradiol on bone mass probably is both dosage and time dependent (9). When estrogen is combined with progesterone for hormone replacement, the progesterone component does not significantly increase bone mass.

For osteoporosis prevention in the menopause, early institution of ERT is recommended. Beyond 5 years of menopause, ERT is suggested if osteoporosis is established by bone densitometry. Other therapies that are effective in preventing bone loss include alendronate, sodium fluoride, and intranasal calcitonin. Adequate dietary calcium intake, vitamin D, and weight-bearing exercises also contribute to reduction in fracture risk (9).

Effects of Estrogen on the Cardiovascular System

At age 50, women have a 50% risk of coronary artery disease (CAD) and a 30% risk of CAD mortality (135). CAD is considered the leading cause of death among women beyond 65 years of age, accounting for more than 400,000 deaths per year (8). Epidemiologic and observational studies suggest a 35% to 50% reduction in coronary heart disease with postmenopausal estrogen use (24,135,293). In the Nurses' Health Study, 59,337 postmenopausal women were followed to provide 337,854 person-years of follow-up. The age-adjusted relative risk of major CAD in current estrogen users was 0.60 when compared with women who never used estrogen. The relative risk for women who used a combination of estrogen and progesterone was 0.39. Estrogen use alone or combined estrogen and progesterone was not found to be associated with stroke (294).

In the Leisure World study, estrogen users with previous myocardial infarction, stroke, or hypertension were found to have a 50% decrease in risk of death from subsequent stroke or myocardial infarction (146). This was also reinforced by the Lipids Research Clinics study, in which there was an 85% reduction cardiovascular risk in estrogen users with previous cardiovascular disease, especially in women with severe disease (48).

Estrogen has direct and indirect effects on the cardiovascular system. Estrogen increases the plasma enzyme hepatic lipase, which catalyzes the hydrolysis of phospholipase and irreversibly degrades lipoproteins (316). In the Heart and Estrogen/Progestin Replacement Study (HERS), postmenopausal estrogen use was associated with an 11% reduction in low-density lipoproteins (LDLs) and a 10% increase in high-density lipoproteins (HDLs) when compared with a placebo group (155). As an antioxidant, it elevates nitric oxide levels and directly reduces vascular wall lipid uptake (261). It also acts as a calcium antagonist, causing vasodilation (328). Other metabolic effects of estrogen include a reduction in fasting glucose and fasting insulin levels (50). However, ERT has been found to increase triglyceride levels. In general, alteration in lipid profile is thought to contribute to 25% of the total cardioprotective effect of estrogen (48).

In the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial (339), a randomized, controlled trial, estradiol combined with medroxyprogesterone was associated with less favorable changes in HDL than estradiol alone or estradiol combined with micronized progesterone. Observational trials show no difference in cardiovascular risk in estrogen alone versus combined estrogen and progesterone therapy.

Although observational and epidemiologic studies support a significant cardioprotective effect of ERT, the HERS (155) was the first randomized, double-blind, placebo-controlled trial that examined estrogen and progesterone use in secondary CAD prevention. A total of 2,763 women less than 80 years old with CAD were randomized to placebo or a combination regimen of continuous estrogen and progesterone. The subjects were followed for 4.1 years. The investigators reported a 50% increase in coronary heart disease events within the first year of hormone use but a significant decrease in risk in years 4 and 5 (RH 0.67). Overall, there was no difference in CAD events (RH 0.99). They concluded that oral conjugated equine estrogen plus medroxyprogesterone acetate did not reduce the overall rate of CAD events in postmenopausal women with established coronary disease. However, they suggested that continuation of treatment in women already receiving ERT might provide protection against CAD events after several years of therapy. Although the results of this trial raise some concerns, clinicians should consider all evidence available when assessing individual patient needs.

Effects of Estrogen on the Lower Urinary Tract

The urethra and vagina are embryologically derived structures that contain estrogen receptors (158). In the menopausal state, there is a decrease in mitotic activity of vaginal and urethral mucosal epithelium, a decrease in exfoliation of surface cells, a decrease in tissue vascularity, and thinning of the mucosal layer. These changes cause vaginal dryness, dyspareunia, and atrophic vaginitis and urethritis (8). ERT causes hypertrophy and thickening of the urethral mucosa with engorgement of blood vessels in the submucosal tissue, thus increasing the efficiency of mucosal closure (319). Vaginal estrogen may increase the sensitivity of a-adrenergic receptors in the urethral musculature and thus may improve genuine stress incontinence and the urethral response to a-adrenergic medication (320). However, in a study of 83 hypoestrogenic, incontinent women, 3 months of cyclic oral HRT had no effect on clinical or quality-of-life variables associated with urinary incontinence. No significant changes in incontinent episodes, diurnal or nocturnal voluntary micturition, or fluid loss was noted (100).

Local estrogen therapy can occasionally improve the irritative symptoms of the urethral syndrome and may prevent urinary tract infections by restoring vaginal pH to premenopausal levels, which reestablishes the normal vaginal flora (242). It has also been used in the local treatment of urethral caruncles (250). To obtain the effect on the urethra and vagina, estrogens are best administered vaginally at a dosage of half an applicator (2 g or its equivalent) every other day, with that dosage reduced by half after a response occurs. Systemic absorption does occur with intravaginal therapy and, though small, may warrant concomitant use of progesterone.

Effect of Estrogen on Cognitive Function

Estrogen promotes the growth and survival of cholinergic neurons and could decrease cerebral amyloid deposition, both of which may delay or prevent Alzheimer's disease. In a longitudinal study of aging and health in a New York City community, 1,124 older women who were initially free of Alzheimer's disease, Parkinson's disease, and stroke were assessed cognitively and followed for 1 to 5 years. In the group of women who were current or past users of ERT (12.5%), the age of onset of Alzheimer's disease was significantly later, and the risk of disease was 60% lower. Duration of use corresponded with greater risk reduction. Other studies report a risk reduction of 60% to an increase of 10%. However, these are uncontrolled studies with small sample sizes and short duration of follow-up (305).

In controlled studies, estrogen maintains short- and long-term memory. Its antioxidant nature is partially responsible for its neuroprotective actions. The effect of improved glucose transport into the brain may improve cerebral blood flow and explain acute memory enhancement (273).

Effect of Estrogen on Colon Cancer

Colon cancer is the fourth most common cancer and is the second leading cause of death in the United States (34). Meta-analysis of case control and prospective studies has shown a 20% reduction in the risk of colon cancer and a 19% reduction in the risk of rectal cancer in postmenopausal women who reported any use of ERT regardless of duration of use. The differences in health and socioeconomic factors, including frequency of medical visits between estrogen users and nonusers in these studies, suggest that women who choose to take postmenopausal hormones are characteristically different (139).

The postulated mechanism of action is related to the significant decrease in bile acid synthesis in women on ERT. Secondary bile acids are believed to initiate or promote malignant change in colonic epithelium (99). Estrogen receptors are found in normal colonic mucosa (208). Estrogen is thought to have a direct effect on the mucosa and act as a tumor suppressor (208). It has also been shown to decrease levels of insulin-like growth factor–1, which is a cell mitogen (51). Further studies are needed to better define the relationship between colon cancer and estrogen therapy.

Effect of Estrogen on Gynecologic Malignancy

Both endometrial hyperplasia and endometrial adenocarcinoma have been associated with unopposed estrogen therapy. Postmenopausal estrogen therapy is associated with a threefold to fourfold increase in the relative risk of endometrial cancer. With 5 to 10 more years of exposure, the increase is about tenfold. The incidence of endometrial carcinoma in patients who receive both estrogen and progesterone is significantly lower than in those receiving estrogen alone (90). In the PEPI trial, 875 postmenopausal women were randomized to receive estrogen alone, estrogen plus progesterone, or placebo. Endometrial histologic findings were examined. Women receiving placebo or estrogen plus progesterone exhibited a 1% incidence of atypical endometrial hyperplasia, compared with a 34% incidence in women who received estrogen alone (138). Therefore progestin administration usually is considered mandatory in women with an intact uterus (23,134). Side effects associated with progestational therapy include weight gain, fluid retention, breast tenderness, and depression. Progesterones inhibit growth of endometrial cells, decrease the number of cytoplasmic estrogen receptors, and counteract the effects of estrogen on the endometrial lining.

Although it has been shown that premenopausal progestins in the form of oral contraception decrease the incidence of ovarian cancer, the effect of postmenopausal HRT on the risk of ovarian cancer is not clear. A recent meta-analysis showed that HRT was associated with an increased risk of epithelial ovarian carcinoma, especially when used for more than 10 years (119).

Effect of Estrogen on Breast Cancer

There is a 1 in 9 lifetime risk of developing breast cancer in the United States. The relationship between ERT and breast cancer remains unclear. Results from the Nurses' Health Study suggest that the risk depends on age and duration of exposure. In women receiving hormones for more than 5 years, increasing age was correlated with increasing breast cancer risk. In addition, longer duration of use was associated with increased relative risk (66,67). This study has been criticized for biases between the study groups. Meta-analysis continues to yield conflicting results. Three of six meta-analyses showed no overall effect, no dose-related effect, and no duration of use effect (17,65,91,135,279,298). Some studies suggest that long-term use of combined estrogen and progesterone therapy is associated with decreased risk of breast cancer. The relationship of HRT to histologic types of breast cancer is also unclear. An observational study of 37,000 women reported an association between HRT use with an increased risk for invasive breast cancer that had favorable histologic characteristics (118).

Similarly, the results of studies conducted to assess the effects of progesterone on breast cancer are conflicting and warrant further evaluation. In a recent cohort study of 46,355 postmenopausal women, 2,082 cases of breast cancer were identified. Increases in risk with regimens of estrogen only and estrogen–progestin combination were restricted to use within the previous 4 years. The investigators also reported a slight increase in breast cancer risk with the estrogen–progestin regimen beyond that associated with estrogen alone (66). Despite these findings, the protective effects of progesterone against estrogen-induced endometrial neoplasia cannot be discounted.

Dosage and Route of Administration

Women who decide to begin HRT should undergo annual physical examination, including breast and pelvic examinations. Routine assessment of blood pressure, Pap tests, lipid profile, and mammography should be performed. For perimenopausal women (45 to 50 years), it may difficult to determine whether menopause has actually occurred. Women with FSH levels greater than 40 mIU/mL can be started on HRT (291).

The generally effective daily dosage of oral conjugated estrogens is 0.625 to 1.25 mg. Equivalent dosages of other estrogens (as compared with 0.625 mg conjugated estrogen) are 1 mg oral micronized estradiol, 0.75 mg oral estropipate, and 0.05 mg per day transdermal estradiol (8). The lowest dosage that relieves symptoms and affords cardiovascular and bone protection should be used. Although there is no evidence that one form of estrogen is superior to another, most studies addressing the protective effects of ERT are based on the use of 0.625 mg oral conjugated estrogens. Whereas oral therapy is associated with immediate impact on the lipoprotein profile, transdermal administration is associated with changes in the lipoprotein profile within 6 months. The methods of administration of estrogen in current use are shown in Fig. 38.10.

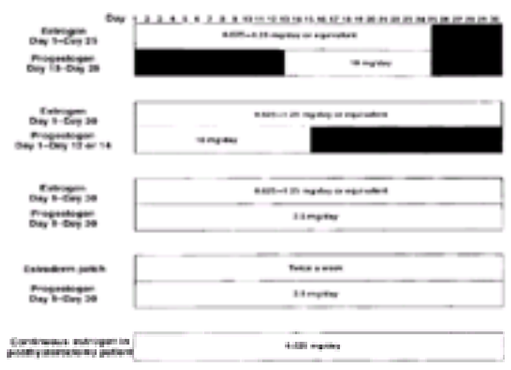

FIGURE 38.10. Diagram of estrogen replacement therapeutic plans available.

In women with an intact uterus, it is necessary to add a progestin to the estrogen to prevent endometrial neoplasia (339). With cyclic hormone therapy (5 to 10 mg medroxyprogesterone acetate for 12 to 14 days of each month), withdrawal bleeding is more common but more predictable than with continuous treatment (2.5 mg medroxyprogesterone acetate daily). Continuous combined estrogen and progesterone treatment produces a thin, atrophic endometrium, which can be associated with amenorrhea in up to 75% of women after 1 year of use (8).

In women who do not have a uterus, the addition of a progestin to ERT affords no additional advantage.

Risk Factors

Thromboembolic Disease

Recent studies have reported a twofold to fourfold increase in the risk of venous thromboembolism associated with ERT (74,137,141,163). This is thought to be related to altered hepatic production or metabolism of coagulation factors, causing elevation of factor VII (209,220) and protein C (220) and a reduction in fibrinogen and plasminogen activator inhibitor type 1 (173). In contrast, some studies suggest that estrogen increases fibrinolytic activity.

Observational studies quote a 1 to 2 per 10,000 incidence of thromboembolic events per year in low-risk HRT users (74,137,141,163). Because the baseline risk of venous thromboembolism is low in users and nonusers, the increased risk associated with HRT must be weighed against benefits for the individual patient. Risk factors such as family history of venous thrombosis, gross obesity, and a previous episode of thromboembolism associated with immobilization should be considered (8).

Endometrial Hyperplasia and Endometrial Cancer

Endometrial hyperplasia and cancer are estrogen-dependent tumors. ERT use in women with previously diagnosed endometrial cancer should be considered carefully. Although patients with stage I adenocarcinoma of the endometrium can be treated with estrogen without fear of recurrence, data on the effect of estrogen on more advanced endometrial cancer are not conclusive. Because progestational agents have a protective effect on the endometrium, combination therapy seems indicated whenever estrogens are used. An undetected estrogen-dependent tumor may become apparent earlier with use of ERT.

Breast Cancer

Regarding estrogen use in patients with a diagnosis of breast cancer, the literature is controversial. There is concern that estrogen may stimulate residual cancer cells to proliferate. No definitive studies show the effect of estrogen on breast cancer recurrence or survival. Breast cancer survivors should undergo extensive counseling from the oncologist when considering HRT. Close surveillance is recommended in breast cancer survivors who choose ERT. In women with risk factors for breast cancer, the data remain inconclusive.

Hepatobiliary Disease

Use of ERT in women with liver or gallbladder disease and familial hyperlipidemias (elevated triglycerides) may increase the risk of gallstone formation. In the HERS, gallbladder disease was significantly higher in the hormone-treated group of women with coronary heart disease (155).

Alternative Therapy

Alternative therapies to relieve vasomotor symptoms include clonidine hydrochloride, phenobarbital, ergotamine, and belladonna alkaloids. However, none of these therapies afford the additional benefits associated with ERT. Some dietary sources of estrogen such as phytoestrogens, available from soy products, may reduce hot

flashes by 45%, compared with an 80% to 90% reduction with ERT and a placebo response of 30% (5). They have been shown to decrease LDL cholesterol and triglyceride levels (13). Achieving therapeutic levels of phytoestrogens would require enormous consumption of soy products (145).

More recently, selective estrogen-receptor modulators (SERMs) have been proposed as an alternative to traditional HRT. These compounds bind with high affinity to estrogen receptors and activate them, eliciting specific agonist or antagonist activity depending on the tissues involved (196,290). Common types of SERMs currently available include triphenylethylenes (tamoxifen, clomiphene) and the benzothiophenes (raloxifene). In a large randomized trial, tamoxifen was shown to reduce the risk of breast cancer in high-risk women by 45% (105). However, tamoxifen use increases the risk of venous thromboembolism and uterine cancer (230). It has not been shown to affect osteoporosis or heart disease. A randomized trial of 7,000 women with osteoporosis showed that raloxifene decreased the incidence of breast cancer by 75% and the incidence of fractures by 50% without increasing the risk of endometrial cancer (71). It also improves LDL cholesterol levels without affecting triglyceride levels. The recommended daily dosage of raloxifene is 60 mg (8). Effects of SERMs on cognition and coronary heart disease remain unknown. Unfortunately, SERMs aggravate hot flashes. The FDA has approved the use of tamoxifen for primary prevention of breast cancer in high-risk women and for secondary prevention of breast cancer for up to 5 years. The FDA has approved raloxifene for preventing osteoporosis.

ENDOMETRIOSIS

Endometriosis is the presence and growth of the glands and stroma of the lining of the uterus in an aberrant or heterotopic location (315). The most common locations include the dependent portions of the pelvis, most often on the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the broad ligaments, and the uterus (156). Extrapelvic endometriosis can involve the intestines, ureter, bladder, and lungs (215,221,325). Rarer sites include surgical scars, lymphatics, skin, spinal column, and nose.

Endometriosis is a benign but often progressive disease. It is an estrogen-dependent or estrogen-facilitated condition affecting up to 14% of premenopausal women (75,142). Treatment generally involves removing the ovarian source of estrogen.

Pathogenesis

Several theories have been developed to explain the histogenesis of endometriosis. The leading theories include retrograde menstruation with implantation and growth of endometrial cells, metaplasia of celomic epithelium, hematogenous or lymphatic spread, and iatrogenic dissemination (162,228,263). Studies have demonstrated abnormalities in the cell-mediated immune system of patients with endometriosis, and a genetic predisposition with polygenic multifactorial inheritance pattern has been found. An investigation by Simpson and associates (280) demonstrated a sevenfold increase in the incidence of endometriosis in relatives of women with the disease. A higher incidence of endometriosis is observed in women with müllerian anomalies and uterine outflow obstruction. Endometriosis has been reported in men who have received treatment with estrogen for prostatic carcinoma and in postmenopausal women on ERT (238,266).

Prevalence

Endometriosis occurs in 3% to 10% of women of reproductive age and in 25% to 35% of infertile women (228). The typical age at which endometriosis is diagnosed is between 25 and 29 years. The peak incidence is between 20 and 40 years, and only 2% to 4% of all women needing laparoscopy for endometriosis are postmenopausal.

Symptoms and Signs

Approximately one-third of patients with endometriosis are asymptomatic. The most common symptoms are chronic pelvic pain and infertility. Chronic pelvic pain presents as dysmenorrhea, dyspareunia, lower abdominal pain, or low back pain. Some women with extensive endometriosis have little or no pain, whereas others with only minimal disease complain of severe pain. Infertility can result from tubal blockage by adhesions, ovulatory dysfunction, prostaglandins, disordered follicle growth, or chemical toxins produced by peritoneal macrophages. The uterus is most commonly retroverted and fixed. The ovaries may have blood-filled cysts called endometriomas. The uterosacral ligaments may be tender and nodular. Adnexal masses and parametrial thickening may be present. Cutaneous lesions may be present on the vagina, perineum, and umbilicus and within surgical scars (215).

Diagnosis

Laparoscopy is the optimal diagnostic method for endometriosis. Typical lesions have been described as red, black, white, or as having a “powderburn”-like appearance. Ultrasound, CT, and MRI are helpful only if ovarian enlargement or large masses are present. Colonoscopy, barium enema, and intravenous pyelography (IVP) are important diagnostic tests if the history and physical examination suggest advanced disease or extragenital involvement. Microscopically, endometriosis contains four major components: endometrial glands, endometrial stroma, fibrosis, and hemorrhage. Not all the components are identifiable in every case, and in postmenopausal women only hemorrhage may be present. Serum levels of cancer antigen 125 (CA-125) may be used as a chemical marker and noninvasive test for endometriosis. Serum concentration of CA-125 is elevated in most patients with advanced endometriosis (231). As a screening test, CA-125 lacks sensitivity and specificity. CA-125 may also be helpful as a marker of treatment response and of recurrence (101).

Treatment

Therapy for endometriosis is based on the patient's age, her future reproductive plans, the location and extent of disease, the patient's symptoms, and associated pelvic disorders.

Medical Treatment

Medical therapy is advised for most patients with mild to moderate disease (21). The ectopic endometrial tissue contains hormone receptors and is hormone responsive (183). Therefore the medical treatment of endometriosis consists of prolonged courses of hormone agents that suppress ovarian function or have a direct effect on endometriotic tissue. The medications used are oral contraceptives (estrogen–progesterone acetate), progestin (norethindrone, medroxyprogesterone acetate), androgens and their derivatives (danazol, gestrinone), and gonadotropin-releasing hormone agonists (leuprolide acetate, goserelin, nafarelin). Low-dose estrogen combination birth control pills produce amenorrhea by suppressing FSH and luteinizing hormone (LH). The usual dosage is one pill per day continuously for 6 to 12 months. Both oral and injectable medroxyprogesterone acetate, a progestational agent, have been effective in treating endometriosis by causing deciduation and atrophy of endometrial tissue (227). Side effects include weight gain, fluid retention, breakthrough bleeding, and depression. Danazol is a synthetic derivative of the androgen ethisterone. Dosages of 800 mg daily produce amenorrhea and inhibit ovulation. The standard length of treatment is 6 to 9 months. Adverse effects of danazol include fluid retention, migraine headaches, dizziness, fatigue, depression, oily skin, hirsutism, and deepening of voice. These side effects occur in up to 80% of women and have limited its widespread use. Gestrinone, an antiprogestational steroid, decreases FSH and LH secretion and is administered only twice a week. Side effects include androgenic and antiestrogenic sequelae. Chronic administration of gonadotropin-releasing hormone (GnRH) agonists (leuprolide and nafarelin) suppress gonadotropin secretion, producing a medical oophorectomy. They can be administered intramuscularly, subcutaneously, by vaginal pessary, or by intranasal absorption. Side effects of GnRH agonists are menopausal symptoms caused by hypoestrogenic state, including vaginal dryness, hot flushes, and a decrease in the density of trabecular bone. Recovery of bone loss may take 6 months to 1 year after discontinuation of therapy (76). Long-term GnRH agonist use may cause osteoporosis (269). For this reason, therapy generally is limited to a single 6-month course. In response to these concerns, various hormonal add-back regimens (progestins or estrogens) have been combined with a GnRH analog. The rationale for this approach is that low levels of serum estradiol may promote normal bone metabolism while maintaining endometrial suppression (22). Preliminary studies demonstrate that these regimens appear to preserve the efficacy of GnRH analog therapy while overcoming the hypoestrogenic side effects (151,216,303).

Surgical Treatment

Definitive surgical therapy consists of hysterectomy with bilateral salpingo-oophorectomy (92,317). Conservative surgery is done in patients who want to retain fertility. This includes excision or destruction of implants, lysis of adhesions, excision of endometriomas, and sometimes an anterior uterine suspension. The use of presacral neurectomy to treat pelvic pain has proved effective for dysmenorrhea, but the effect on other pelvic pain, back pain, and dyspareunia is inconsistent. Conservative surgery can be accomplished by laparoscopy using cautery or laser, thereby reducing operating time and hospital stay and minimizing blood loss (227). Laparoscopic fulguration has limitations; ureteral injury can occur during fulguration of endometrial implants of the uterosacral ligaments.

Patients with severe disease may benefit from a 4- to 6-week preoperative course of GnRH agonists or danazol to reduce local vascularity. Postoperatively, hormonal intervention has been suggested to eliminate all endometriotic implants. ERT can be given after total abdominal hysterectomy and bilateral salpingo-oophorectomy; however, endometriosis can recur in 5% to 10% of cases (89).

Endometriosis of the Urinary Tract

Bladder

Approximately 1% of women with endometriosis have urinary tract involvement; the bladder is affected in approximately 85% of these women (85,123,170,205,274). Symptoms often closely mimic those of interstitial cystitis (suprapubic pain, frequency, urgency, and dysuria) (282). The classic finding of menstrual hematuria is present in less than 25% of cases (274). There should be a high index of suspicion for this entity in patients with a prior diagnosis of endometriosis who are referred for irritative voiding symptoms, especially if they are receiving HRT. Such therapy usually is safe in these patients, but it can reactivate previously dormant endometrial implants (131,167,180,260).

Cystoscopic findings are variable. No disease may be evident if the endometrial tissue is confined to the serosa of the bladder. Deeper lesions appear as bluish submucosal nodules that may ulcerate and bleed. These nodules usually are located behind the trigone or at the bladder dome. Disease foci may be solitary or multiple (123,221) and may almost disappear between menstrual periods. Malignant transformation of vesical endometriosis has been reported (4,312). Any lesions discovered at cystoscopy should be biopsied for histologic confirmation of the diagnosis. Treatment consists of initial hormonal therapy followed by partial cystectomy if necessary.

Ureter

Ureteral endometriosis commonly involves the lower third of the ureter and is bilateral in 15% of cases. Ureteral obstruction is most likely to occur when the cardinal and uterosacral ligaments are involved (85,123). More than 126 cases of ureteral endometriosis have been reported, with permanent renal damage in up to 30% (205). Two types of ureteral endometriosis have been described: extrinsic, in which extensive scarring and fibrosis caused by endometriotic implants lead to obstruction, and intrinsic, in which the ureteral wall is invaded by endometriotic tissue. The former is more common (170,205). Symptoms may include flank pain, dysuria, urgency, and hematuria (123,164).

Endometriosis must be considered in the differential diagnosis of unexplained ureteral obstruction occurring in any woman past the age of menarche. If there is any clinical evidence of ureteral obstruction, ultrasound or IVP should be performed (Fig. 38.11 and Fig. 38.12). A few cases of endometriosis of the kidney have been reported (123,164). All occurred in women between 22 and 49 years of age, and the most common symptoms were lumbar pain and hematuria. The correct diagnosis was made only after surgical removal and histologic study.

FIGURE 38.11. Antegrade pyelogram demonstrating a fixed site of ureteral narrowing in a 42-year-old woman 2 years after hysterectomy. The surgical clips and the prior hysterectomy led to a tentative preoperative diagnosis of iatrogenic ureteral fibrosis. Histopathologic analysis of the affected ureter obtained at the time of ureteral reimplantation demonstrated secretory and proliferative endometrial tissue of the invasive variety, with extensive local scarring.

FIGURE 38.12. Typical appearance of a ureter affected by an endometrial implant, proven by tissue examination after excision.

Ureteral endometriosis has been successfully treated by medical means using danazol, GnRH agonists, progestins, and estrogen–progestin combinations (117,121,253,254). However, recurrence of ureteral obstruction after cessation of medical management is common. If medical therapy is attempted, close surveillance of renal function is mandatory. The standard therapy of ureteral endometriosis is surgical and includes ureterolysis or segmental ureteral resection with ureteroneocystostomy and castration. Renal involvement usually is treated with nephrectomy.

Tamoxifen and Endometrial Disease

Tamoxifen is a synthetic nonsteroidal estrogen antagonist and agonist that is widely used as adjuvant therapy for breast cancer in postmenopausal women. While acting as an estrogen antagonist in the breast, it has estrogen agonist activity in other tissues, including the endometrium (133). Consequently, patients who receive tamoxifen therapy are at greater risk for endometrial abnormalities. Most of these abnormalities are benign, including endometriosis (218), adenomyosis (64), and endometrial polyps (226). However, there is also a twofold to threefold higher risk of developing endometrial carcinoma (73). Any vaginal bleeding in women treated with tamoxifen should be investigated promptly and thoroughly.

RETAINED OVARY: THE OVARIAN REMNANT SYNDROME

The ovarian remnant syndrome occurs in women who have undergone a bilateral salpingo-oophorectomy in whom ovarian tissue remains (297,322). Usually, these patients also have had a hysterectomy. The ovarian remnant becomes a cause of chronic pelvic pain. Because of the extensive prior surgery, patients with this kind of chronic pelvic pain syndrome often are considered to suffer from “nongynecologic” disease (61). The ovarian remnant may result in ureteral obstruction, the most common urinary tract involvement, but it also can induce bowel obstruction and may be associated with painful pelvic masses and, on occasion, urinary retention (27,198,237). Generally speaking, laparotomy is needed to remove all ovarian tissue. That tissue may be extremely difficult to identify (237). More recently,

laparoscopic surgical techniques have been used to treat ureteral obstruction related to residual ovarian tissue.

Diagnosis

Peripheral estrogen levels greater than expected for surgically menopausal women, after complete cessation of HRT, suggests the diagnosis of retained or residual ovarian tissue. In addition, premenopausal levels of LH and FSH in women after bilateral salpingo-oophorectomy suggest functioning ovarian tissue. Clomiphene citrate administration has been used before surgical exploration to stimulate the retained residual ovarian tissue to facilitate ultrasonic localization and complete surgical removal (177). Ovarian function may reactivate endometrial implants in patients with that problem before total abdominal hysterectomy and bilateral salpingo-oophorectomy (237).

POSTMENOPAUSAL BLEEDING

Postmenopausal bleeding is bleeding that occurs after 1 year of amenorrhea without HRT. Bleeding that accompanies cyclical withdrawal bleeding from progestins is not considered postmenopausal bleeding. However, new onset of bleeding after established amenorrhea or outside cyclic withdrawal bleeding while using HRT is considered abnormal and warrants assessment.

Etiology

The most important cause of bleeding is endometrial carcinoma or complex endometrial hyperplasia with atypia. It is estimated that 5% to 10% of unexplained postmenopausal bleeding is related to these serious disorders. Therefore 90% to 95% of bleeding results from benign causes such as endometrial atrophy, endometrial polyps, or simple endometrial hyperplasia (16). However, 10% to 20% of cases involving endometrial neoplasia result from malignancy. Other sources of bleeding must be considered. Women may report bleeding that originates from various vulvar lesions, vaginal cancer, vaginal foreign bodies, cervicitis, cervical polyps, cervical ulcers, or cervical cancer. In addition, urinary tract bleeding may be mistaken for postmenopausal uterine bleeding.

Clinical Evaluation and Diagnosis

The major diagnostic consideration is to ensure that the origin of bleeding is determined. Pelvic examination, Pap smear, endocervical curettage and colposcopic biopsy, endometrial biopsy, and transvaginal sonography generally reveal a genital cause of bleeding. Test for occult blood in the stool rules out a gastrointestinal source of bleeding. Fractional curettage may be necessary to distinguish between cervical and uterine lesions. Endometrial biopsy is a crucial component of postmenopausal bleeding assessment. It is an office procedure in which a sample of endometrial tissue or cells is obtained by brushing, scraping, washing, or vacuum. The sensitivity for detecting pathologic tissue ranges from 88% to 97%, which is comparable that of to dilation and curettage (299). However, a negative endometrial biopsy is not necessarily diagnostic, and repeat sampling may be necessary, depending on the clinical situation. Histologic examination of the sampled endometrium determines the course of treatment. In some patients, dilation and curettage may be necessary to obtain an adequate histologic sample, especially in patients with cervical stenosis.

Transvaginal ultrasonography is an accurate method for assessing endometrial thickness. There is a strong correlation between increased endometrial thickness and pathologic involvement. An endometrial stripe of 4 to 6 mm is considered the threshold for an increased risk of serious endometrial disease. Suspected endometrial neoplasm detected by ultrasound must be further assessed by histologic sampling (182). The sensitivity of transvaginal ultrasonography ranges from 81% to 100%, and the specificity ranges from 61% to 100%.

In sonohysterography, the endometrial cavity is distended with 10 mL sterile saline to detect focal areas of endometrial thickening. Submucous fibroids and endometrial polyps can also be detected by this technique. Endometrial sampling is necessary in cases of increased endometrial thickening. Areas of endometrial hyperplasia and cancer often are found in endometrial polyps.

Hysteroscopy may be performed with a rigid scope using a fluid distending medium and heavy sedation. It is used for diagnosis and therapeutic procedures. Office hysteroscopy involves a flexible fiberoptic cable with a carbon dioxide distending medium. Flexible hysteroscopy allows office visualization of the endometrial lining. It is used for diagnosis and simple biopsies, directed biopsies, and polypectomy.

Cancer of the Endometrium

Adenocarcinoma of the endometrium is the most common gynecologic malignancy in the United States, accounting for 34,000 cases of invasive endometrial cancer each year. In the United States, 2% to 3% of women develop cancer of the endometrium (11). It is found primarily in postmenopausal women. The peak age incidence is seen in women in their late fifties and early sixties. The diagnosis is made by histologic evidence. The most common symptom is bleeding.

Risk factors for the low-risk subtype are related to an increase in circulating estrogens: obesity, chronic anovulation, menstrual irregularities, nulliparity, early menarche (younger than 12 years), late menopause (older than 52 years), estrogen-secreting ovarian tumors, unopposed ERT, and tamoxifen use (20). Diabetes, hypertension, and previous pelvic irradiation are also considered risk factors (39,321). Smoking and the use of oral contraceptives decrease the risk (11). Carcinoma of the endometrium is also associated with hereditary nonpolyposis colorectal cancer (HNPCC) (47). Onset of endometrial cancer in this group occurs an average of 15 years earlier than sporadic cases. Endometrial screening is recommended for patients with HNPCC (186).

Treatment

Patients with adenomatous hyperplasia without atypia can be treated with medroxyprogesterone acetate 10 mg daily for 12 to 14 days each month. A follow-up biopsy in 3 months is recommended to confirm reversal of pathologic tissue changes (257). Endometrial hyperplasia with atypia is managed surgically by a total abdominal hysterectomy and bilateral salpingo-oophorectomy because 25% of patients with atypical hyperplasia found on endometrial sampling are found to have endometrial adenocarcinoma on surgical specimen. Postoperative irradiation is given depending on surgical stage. Because postmenopausal bleeding occurs early in the natural history of estrogen-related endometrial adenocarcinoma, the diagnosis often is made at an early stage of disease.

THE ADNEXAL MASS

Anatomically, the adnexa encompasses the region within the pelvis that includes the ovaries, fallopian tubes, round ligaments, and structures arising from associated embryologic rests. The spectrum of disease arising from the adnexa is diverse. The annual hospitalization rate for ovarian neoplasms in the United States ranges from 160,000 to 289,000 women (72,127,331). It is estimated that 5% to 10% of women in the United States will undergo a surgical procedure for suspected ovarian neoplasm in their lifetime (219). In women with no family history of ovarian cancer, the incidence of ovarian malignancy is 1.4 per 100,000 women less than 40 years old and 45 per 100,000 more than 60 years (144).

Etiology

Adnexal masses may be physiologic, infectious, nonneoplastic, or neoplastic. They may originate from any component of the adnexa. Pedunculated uterine fibroids may mimic the clinical presentation of adnexal masses. The most common benign ovarian neoplasms are benign cystic teratomas and serous cystadenomas. The most common malignant ovarian neoplasm is epithelial carcinoma. Age is the most important predictor of malignancy (175). There is a twelvefold increase in risk of ovarian carcinoma from age 20 to 29 years to 60 to 69 years (175). During reproductive years, the most common ovarian mass is the functional cyst (Fig. 38.13). Endometrioma should be considered in the premenopausal woman. In younger patients with a solid adnexal mass, the common malignant neoplasm is the ovarian germ cell tumor.

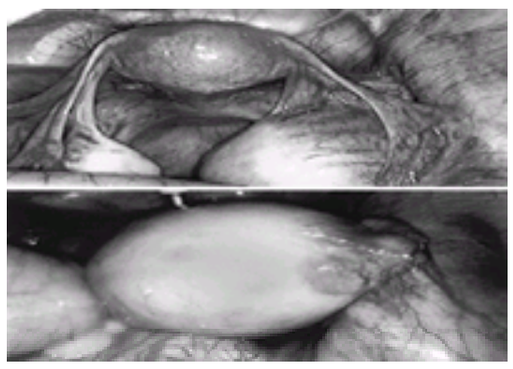

FIGURE 38.13. Large right cystic teratoma. Normal left ovary, bilateral fallopian tubes, uterus, and cul de sac are seen.

Clinical Presentation and Evaluation

The initial symptom associated with an adnexal mass may be acute onset of lower abdominal pain, which may be related to torsion of the mass at its stalk or rupture of a cystic mass with release of fluid or blood into the peritoneal cavity. The most common and important differential diagnosis is appendicitis. Chronic, intermittent pain may reflect the twisting and untwisting motion of the mass. Other symptoms include midcycle pain (Mittelschmerz pain), dysmenorrhea, and menstrual disturbances. Clinical symptoms often reflect mass compression on local pelvic organs and include nausea and vomiting, sensation of abdominal bloating, dyspepsia, early satiety, constipation and change in stool caliber, and urinary retention. Most symptoms are nonspecific.

In addition to a complete history, physical examination is important in assessing characteristics of the mass and the presence of accompanying adenopathy. Malignancy may be suspected in the presence of a palpable mass, generalized abdominal discomfort, and ascites. Endometriotic mass may be associated with a retroverted uterus, cul de sac nodularity, uterosacral shortening, and tenderness. Asymptomatic masses may be detected on routine pelvic examination.

In reproductive-age women, a serum pregnancy test is necessary to rule out an ectopic pregnancy, especially in the acute situation.

Transabdominal and transvaginal ultrasonography has become a useful diagnostic tool for assessing adnexal masses. An ovarian cause can be determined easily in most cases. Ovarian size and shape can be visualized. The normal premenopausal ovary measures 3.5 × 2 × 1.5 cm. The normal postmenopausal ovary measures 1.5 × 0.7 × 0.5 cm 2 to 5 years after menopause (147). Wall structure, septations, echogenicity, and shadowing of the mass are considered to predict malignancy (86). Current ultrasonography techniques have demonstrated improved sensitivity, specificity, positive predictive value, and negative predictive value for diagnosing adnexal malignancy. Use of color-flow Doppler to determine malignancy is controversial (41,265).

White blood cell count may indicate a tuboovarian mass secondary to pelvic inflammatory disease. Serum CA-125 level in the postmenopausal woman has improved sensitivity and specificity for predicting malignancy related to epithelial carcinomas (104). In the premenopausal woman, a mildly elevated CA-125 level is found in a variety of benign conditions. In the younger patient with a solid adnexal mass, elevated serum b-human chorionic gonadotropin (b-hCG) and a-fetoprotein suggest a malignant germ cell tumor (10).

When malignancy cannot be ruled out or when symptoms resist conservative management, laparoscopic assessment of the adnexal mass may be warranted. The patient's entire clinical picture must be considered. Laparoscopic diagnosis of adnexal masses is reliable and safe, allowing immediate and adequate surgical treatment (52).

Management

In the premenopausal woman, an asymptomatic cystic mass less than 10 cm may be initially managed by observation (19); 70% of these masses resolve spontaneously (289), although the recurrence rate is unknown. Follow-up physical examination and repeat ultrasound after the next menstrual cycle should be done. In a large multicenter trial, the risk of malignancy in this group has been reported to be essentially nonexistent (268). With the persistence of findings or a change in ultrasound findings toward a more complex mass, surgical assessment is indicated. A cystectomy is preferred, but an oophorectomy may be necessary in the presence of benign disease. For women in their reproductive years, every attempt should be made to preserve ovarian function and fertility potential in the presence of benign conditions. Cyst aspiration is not recommended because 66% of cyst aspirates are read as benign when they are actually malignant (311). If a solid mass or other findings suggestive of malignancy are present, surgery is indicated.

In postmenopausal women, most adnexal masses warrant surgical assessment to determine the presence of a malignancy. The exception is the asymptomatic postmenopausal woman with a simple, unilocular cyst measuring less than 5 cm with a normal CA-125 level. In this situation, conservative management may be offered with close follow-up. When the physical examination, ultrasound findings, and serum markers suggest malignancy, more than 75% of postmenopausal women have ovarian carcinoma. When all modalities suggest a benign process, 5% of postmenopausal women have ovarian carcinoma (256).

The standard surgical approach has been laparotomy for cystectomy or oophorectomy. However, laparoscopic assessment of ovarian masses, including laparoscopic cystectomy and oophorectomy, has become acceptable. Laparoscopy allows inspection of the mass, pelvis, and abdominal cavity. This approach is indicated if suspicion of malignancy is low or questionable. However, even in this scenario, patients should be advised of possible conversion of a laparoscopic procedure to a laparotomy if probable malignancy is found and confirmed by pathologic frozen section evaluation of tissue biopsy. In the presence of a malignancy, the appropriate surgical management is a staging laparotomy and debulking of tumor burden. Because of the proximity of the adnexa to the urinary tract, care must be taken to avoid inadvertent ureteric injury. If malignancy is highly suspected preoperatively, the surgeon should proceed directly to laparotomy. Currently, the prognostic implication of intraoperative rupture of a malignant ovarian cyst has been undetermined.

CARCINOMA OF THE CERVIX

A dramatic increase in the early diagnosis and treatment of cervical cancer and subsequent vast improvement in survival in the United States in the last four decades are attributable mostly to the widespread use of screening cervical cytology and aggressive management of cervical intraepithelial neoplasm. However, cervical cancer continues to be a leading cause of death in underdeveloped countries. It is the third most common genital malignancy after endometrial and ovarian cancer. In 1993 the American Cancer Society estimated that there will be approximately 16,000 new cases of invasive cervical cancer and 5,000 deaths from cervical cancer each year in the United States.

Epidemiology and Etiology

Cervical cancer tends to occur in women in their forties to sixties, with a median age of 54 years. Various epidemiologic factors are associated with cervical cancer, such as sexual intercourse at an early age, multiple sexual partners, multiparity, low socioeconomic status, cigarette smoking, and sexually transmitted diseases such as genital herpes and condylomata acuminata. The rising incidence of cervical cancer in younger women is attributed to the increased incidence of cervical intraepithelial neoplasia, perhaps associated with genital viral infections. Eighty-five percent of cervical cancers are squamous cell, and 10% to 15% are adenocarcinomas. Very rare adenosquamous carcinomas also occur.

Clinical Symptoms

Cervical carcinoma usually is asymptomatic in the early stages. The most common symptoms are vaginal discharge, irregular vaginal bleeding, and postcoital or postmenopausal bleeding. Advanced cervical cancer may present with backache, hematuria, ureteric obstruction, urinary and rectal fistulae, and rectal bleeding. Cervical cancers may be characterized by gross appearance as exophytic or endophytic. Exophytic lesions protrude from the cervix and can be visualized easily. Late

detection of endophytic lesions may contribute to a poor prognosis. These cancers may not be apparent on cervical cytopathologic specimens.

Staging of Cervical Cancer

The staging of cervical cancer is based on a clinical examination. The international classification of cancer of the cervix is as follows:

Stage 0	Carcinoma *in situ,* intraepithelial carcinoma.
Stage I	Carcinoma strictly confined to cervix.
Stage IA	Preclinical carcinomas of the cervix, that is, those diagnosed only by microscopy.
Stage IA1	Minimal microscopically evident stromal invasion.
Stage IA2	Lesions detected microscopically that can be measured. The upper limit of the measurement should not show a depth of invasion of more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates, and a second dimension, the horizontal spread, must not exceed 7 mm. Larger lesions should be staged as IB.
Stage IB	Lesions of greater dimension than in stage IA2, whether seen clinically or not. Preformed space involvement should not alter the staging but should be specifically recorded to determine whether it should affect treatment decisions in the future.
Stage II	Involvement of the vagina but not the lower third, or infiltration of the parametria but not out to the sidewall.
Stage IIA	Involvement of the vagina but no evidence of parametrial involvement.
Stage IIB	Infiltration of the parametria but not out to the sidewall.
Stage III	Involvement of the lower third of the vagina or extension to the pelvic sidewall. All cases with hydronephrosis or a nonfunctioning kidney should be included unless they are known to be attributable to other causes.
Stage IIIA	Involvement of the lower third of the vagina but not out to the pelvic sidewall if the parametria are involved.
Stage IIIB	Extension onto the pelvic sidewall or hydronephrosis or nonfunctional kidney.
Stage IV	Extension outside the reproductive tract.
Stage IVA	Involvement of the mucosa of the bladder or rectum.
Stage IVB	Distant metastasis or disease outside the true pelvis.

Pretreatment Evaluation of Cervical Cancer

Pap smears may be “negative” in 30% of women with invasive cancers. Biopsy of any suspicious cervical lesion is essential even if the smear is normal. All patients with cervical cancer should undergo a thorough history and physical examination. Other diagnostic tests to be done include chest radiograph, colposcopy, cystoscopy, proctosigmoidoscopy, IVP or CT scan, or barium enema.

Treatment

Microinvasive carcinoma with an invasion depth of 3 mm can be treated satisfactorily with cone biopsy if the margins of the core are free of turnover. Frequent follow-up is mandatory.

For microinvasive carcinoma 3 to 5 mm deep, radical hysterectomy with pelvic lymphadenectomy is recommended.

For invasive cervical cancer of stage IB and IIA, radical hysterectomy with pelvic lymphadenectomy or pelvic irradiation is equally effective. The treatment of stage III and IV cervical cancer is palliative.

COMPLICATIONS OF SURGERY FOR STRESS INCONTINENCE

Treatment Failure

Reported failure rates for stress incontinence surgery at 5 years or more are high (62,232,309). The success rates for slings are somewhat better than for other procedures (32,53,217). Late outcomes for needle suspensions and retropubic suspensions are roughly equal (62,309). When outcomes are studied long after a procedure, the data often are gathered by telephone or mailed questionnaire and not direct clinical assessment. The accuracy of these data with respect to a precise clinical and urodynamic diagnosis has not been determined. In studies in which tentative diagnoses established by responses to questions in standardized survey instruments were compared with a diagnosis arrived at as a result of a rigorous clinical and urodynamic assessment, poor agreement has been found (12,172). A person who reports wetting might be considered to have experienced treatment failure when that is not the case. The symptom “occasionally wet” does not differentiate those who have a recurrence of the original problem treated (e.g., intrinsic sphincter dysfunction or urethral hypermobility) from a new problem. Even more problematic is the fact that often we do not know precisely what original problem was treated other than presumed stress incontinence, which is clearly not one condition but a complex of interrelated conditions. Some degree of incontinence is reported by 15% to 30% of women in very large population surveys. Thus some incidence of incontinence in a study population obviously exists, and this should be considered in assessing the responses given by treated women to survey questions (187). That has not been done, and by inference the normal population has been considered “never wet.” Conclusions about the value of any procedure drawn from late outcome data probably are invalid because it is usually not clear what conditions existed before the operation and what condition caused the positive response to the survey question. The mere fact that incontinence is a problem after surgery does not by itself establish failure of the operative procedure. Incontinence, even when specifically characterized as “stress, urge, or mixed,” is not equivalent to a diagnosis. Thus failure rates, although interesting, have no particular relevance to selection or nonselection of a given operation in a particular patient. In addition to problems with questionnaire-based diagnoses, there is a curious lack of agreement between patient responses to questions about incontinence and responses to the question, “Are you satisfied with the treatment that was provided to you for the condition stress incontinence?” Even though “incontinence” rates range from 12% to 53%, “satisfied” rates are much higher (217,309). Perhaps the women understand something the survey instrument does not measure.

Voiding Dysfunction

Retention

After sling procedures, retropubic suspensions, and occasionally after needle suspension, short- or long-term complete or partial urinary retention may occur. Mean hospital stays less than 24 hours are not compatible with resumption of normal voiding in many patients after urethral suspension, especially if the urethral procedure is combined with repair of genital prolapse or a hysterectomy (217). Kursh (179) reported that 81% of patients who underwent needle suspension were unable to void completely at a mean interval of 22 days after the procedure. Korda and co-workers (176) reported a mean period of catheter drainage of 10 days after a retropubic suspension, and 25% of patients still had difficulty with bladder emptying beyond that point. Morgan and co-workers (217) noted that a mean 8.4 days of intermittent catheterization was needed after a sling procedure. The prevalence of prolonged retention after sling procedures or other suspensions generally ranges from 3% to 10% (32,197,244,324). Some workers have reported higher rates after polytetrafluoroethylene sling procedures (327,340). Other workers have reported higher rates of partial and complete retention after some procedure, especially retropubic suspensions (116,343).

Treatment

There are few data on what constitutes an abnormal duration of retention. Spontaneous resumption of normal voiding as late as 10 weeks after a procedure is rare but does occur. Most authors suggest some kind of takedown procedure to relieve obstruction at or around 10 to 12 weeks, or even earlier in some cases. Foster and

McGuire (109) reported a 65% success rate, or resumption of normal voiding without stress incontinence, after a urethral takedown procedure done late after the original suspension procedure. Nitti and colleagues (224) described a similar series in which 71% of patients subjected to urethrolysis and a repeat suspension resumed normal voiding. Since the latter report, most authors have not combined urethral mobilization procedures with a resuspension of the urethra. Thus Carr and Webster (54) reported resumption of normal voiding without recurrence of stress incontinence in 86% of patients subjected to a retropubic urethrolysis, 73% of those who had a vaginal approach, and 25% of those who had an infrapubic procedure. Brubaker (42), McLennan and Bent (193), Goldman and associates (132), Cross and associates (70), and Ghoniem and El-gamasy (125) all reported series in which a vaginal procedure designed to take down or modify a urethral suspension was done in an effort to restore normal voiding. None of these workers combined the procedure with a repeat urethral suspension. In general, the operative procedures that led to the takedown operation were not needle suspension procedures, and thus these patients may be different or have had a different operation than those described by Nitti and colleagues (224). Moreover, 8 to 35% of the patients in the more recent series failed to achieve normal voiding after a takedown operation. Thus a presumed obstructive process was not always relieved by an operation designed to undo the effects of a sling or suspension procedure. The imperfect outcome here may reflect a change in the type of operative procedure done for stress incontinence, a problem with detrusor function that was not recognized before the primary procedure or one that developed after that procedure, or a lack of efficacy of the procedure used to take down the suspension. From a review of the literature it is not clear which of these variables is the main cause of failure of a procedure done to undo the suspension. It does seem clear that a resuspension at the time of a takedown procedure is not needed, and the real problem seems to be related to achieving sufficient urethral mobility and function to permit resumption of normal voiding. Although most workers have settled on a transvaginal approach or rarely an infrapubic approach or abdominal approach, others have reported on a transurethral resection of the obstructive bladder neck in two planes (102). Gronbaek and associates (140) successfully used bladder neck incision at 4 and 8 o'clock. They noted that initial improvement could be followed by later deterioration, but overall they achieved a 76% success rate, which compares favorably with the results of “urethrolysis” described by most American centers. Late follow-up seems important in these cases, and a French study reported initial success in 80% that fell to 40% at 6 months, suggesting that rescarring and fixation can be a problem (258). In addition, there is no systematic study of the incidence of obstructive uropathy by operation, and there is no way to be sure that the same conditions are present in two groups of patients who are subjected to different operations with different outcomes. None of these studies was prospective.

Uncontrolled Detrusor Contractility: Urge Incontinence

Some 12% to 65% of women with stress incontinence, where that diagnosis is made by clinical assessment or by video urodynamic testing, also have motor urge incontinence symptoms or an unstable contraction of the bladder on a cystometrogram (1,191). In the past, the diagnosis of motor urge incontinence was permissible only if an unstable bladder contraction was noted on a cystometrogram. That view is no longer tenable. As many as 50% to 60% of patients with motor urge incontinence (where urinary leakage is driven by an uncontrolled contraction of the detrusor that occurs suddenly, without warning) have a stable bladder during a cystometrogram. Urge incontinence is then a clinical diagnosis, not a urodynamic one (136). Where significant stress incontinence is objectively identified, operative therapy that cures the stress incontinence often is associated with resolution of motor urge incontinence symptoms (217). If an operation fails to cure the stress incontinence, motor urge incontinence often continues to be a problem. For example, in a 1989 study Peattie and Stanton (232) reported on 44 women with genuine stress incontinence subjected to a needle suspension operation. Before the operation 6 of these women had detrusor instability, and a larger number had urge incontinence symptoms but a negative provocative cystometrogram. Postoperatively, 27 of these patients still had stress incontinence, and 15 had detrusor instability. Thus an operation that fails often is associated with persistent urge incontinence symptoms. Most surgeons no longer regard urge incontinence as a relative contraindication to surgery for coexistent stress incontinence because outcome data in the literature suggest that stress incontinence is causally related to urge incontinence (32,53,217,342). Although this seems to be the case in 60% to 75% of patients in whom preoperatively both stress and urge incontinence exist, in 25% or more urge incontinence persists despite successful surgical resolution of the stress incontinence. In another 7% to 14%, pronounced symptoms of urge incontinence seem to occur *de novo* only after the operative procedure. The occurrence or persistence of severe motor urge incontinence after a procedure that cures stress incontinence is a real problem that is often difficult to treat successfully. Efforts to determine preoperatively which patient might not be relieved of her urge incontinence or to predict patients who might develop urge incontinence have not been successful. Most workers now regard preoperative urge incontinence symptoms or the finding of overt detrusor instability as indeterminate with respect to overall outcome of treatment of urethral dysfunction and stress incontinence (217).

Complications Related to Materials Used in Urethral Suspension Procedures

Simple needle suspension procedures often are associated with early and late failure (106,310). More complicated procedures developed to improve efficacy used bolsters of foreign material in an effort to provide better tissue purchase for the suspension sutures. Various synthetic materials has been used to enhance suture tissue purchase. These materials can be associated with draining sinus formation, fistulization, and erosion into the bladder, urethra, or vagina. Richardson and co-workers (251) reported a 5% rate of delayed reaction to Dacron buttress material used to enhance tissue purchase by urethral suspension sutures. Dwyer and coworkers (93) reported a number of complications in 1,164 women treated with a retropubic suspension or a Stamey type procedure for stress incontinence. These complications included ureteral ligation and intravesical placement of or erosion or migration of sutures and bolsters into the bladder. The latter conditions were associated with pelvic pain, urinary infection, and severe urinary irritative symptoms. Pohl (239) reported a case of abdominovaginal fistula related to a Dacron bolster that became obvious only after 12 years had elapsed from the date of the procedure. Thus late problems can occur. In addition to problems related to sutures placed in or eroding into the bladder (Fig. 38.14), which cause terrible bladder symptoms, failure of these procedures led to efforts to improve them. Appell and co-workers (14) reported on the use of percutaneous bone anchors to stabilize suture suspension and thus improve results. Appell and Leach (15) reported good results with the new technique a few months after the procedure. With time, however, failure occurred as it had with the earlier needle suspensions (267). Schultheiss and associates (267) in Hannover followed a large group of patients and compared the results of needle suspension with and without bone anchors. They found no difference, and overall results were poor. Further efforts involved use of slings of natural and synthetic material combined with bone anchor fixation. Good early results were reported by several workers (150,234). Unfortunately, it became clear that synthetic slings had a tendency to erode into the vagina, urethra, or bladder (Fig. 38.15) (63). The polypropylene sling bone anchor device was withdrawn from the market because of these problems. A number of these procedures were done, and there is a delay between the operation and the appearance of a definite erosion, so patients who have had such a procedure (and perhaps any procedure in which foreign material was used) are at risk. The rate of risk is unknown. Generally, these patients complain of pain with voiding, a vaginal discharge, vaginal bleeding, or incontinence (63). Occasionally, the site of erosion is difficult to visualize because the anterior vaginal wall is elevated and fixed in a high retropubic position. Chai and Sklar (56) described the use of a flexible cystoscope used as a vaginoscope to more easily visualize the site of erosion. Removal of the sling and all foreign material, if possible, seems advisable because there are now several reports of osteomyelitis associated with bone anchors, especially those associated with erosion into the vagina or urethra (107,206,334).

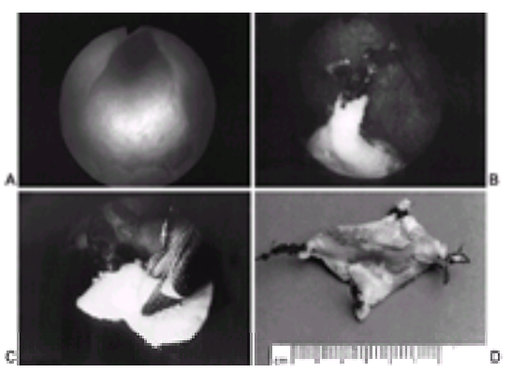

FIGURE 38.14. Recurrent urinary tract infections after pubovaginal sling in a 78-year-old woman. Cystoscopic view from urethra **(A)** demonstrates a large stone at the bladder neck. View from within bladder **(B)** shows nonabsorbable suture and sling material with stone attached. The stone was grasped and fragmented **(C),** and the sutures were cut to remove the specimen **(D)**.

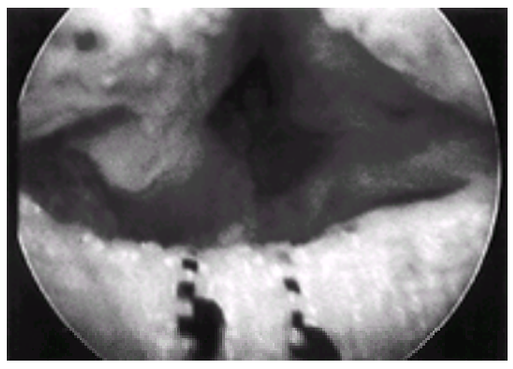

FIGURE 38.15. Cystoscopic view from urethra demonstrating entire eroded polyester sling within urethral lumen. See also Color Figure 38.15.

Other materials used for slings have been reported to cause similar problems. For example, Melnick and Lee (210) reported transsection of the urethra related to a Mersilene sling placed many years before the occurrence of the problem. Bent and colleagues (26) reported a high rate of tissue reaction and infection associated with polytetrafluoroethylene woven material used for suburethral slings. Reactive complications occurred in 23%. DeBodinance and co-workers reported that Gore-Tex slings were “rejected” or poorly tolerated in 23 of 72 consecutive patients and therefore suggested prudence in the use of such materials (78). Chin and Stanton (59) used silastic slings for stress incontinence recurrent after failure of a prior operative procedure in 74 women. They noted that 4 women needed removal of the sling for obstruction, and 10 women developed erosion of the sling into the bladder or urethra or vagina. That is an adverse event rate of 19%. Of 74 women, 29 had persistent or new detrusor instability postoperatively. Only 23 women had reached 5 years after the surgical procedures, so these results should be considered short term. Weinberger and Ostergard (326) described outcomes after use of Gore-Tex slings in 62 women who responded to a telephone survey. They noted a 40% wound complication rate, and sling removal was needed in 22%. In a later report by the same authors (327) involving the same cohort of 108 patients, a high rate of obstruction was noted with Gore-Tex slings. The mean length of postoperative catheterization was 10.7 weeks, and the authors concluded that this type of sling commonly produces voiding difficulty. The voiding difficulty was not always resolved even after sling removal. Cholhan and Stevenson (60) reported spontaneous transection of the urethra by a polytetrafluoroethylene sling. The authors noted that sling transection was a rare complication, but that assessment may be incorrect. In view of the time course for erosion or reaction to foreign material, this problem may be with us for the foreseeable future (159,251).

Bone Anchors

Bone anchors were borrowed from orthopedics to stabilize needle suspension to prevent late failure. These devices did not improve the poor late outcome associated with needle suspension procedures, and these devices have been associated with some complications. These include osteomyelitis, displacement and migration (Fig 38.16), hernia formation through the fascial defect created to place the bone anchor, osteitis pubis syndromes, suture and sling suspension failure, and inadvertent transvesical placement (107,332). Rarefaction of the bone around the bone anchor, demonstrated on a plain film, or a positive bone scan suggests osteomyelitis and should prompt bone anchor removal (271). Erosion of foreign material into the urinary tract opens a pathway along the suture to the bone anchor, and in this circumstance it is preferable to remove the bone anchor when the sling material and the sutures are removed. If there is rarefaction of the bone, removal is very easy; if not, the anchors must be unscrewed from the bone.

UROLOGIC COMPLICATIONS OF PELVIC MALIGNANCY TREATMENT

Treatment of cervical or endometrial carcinoma by radiation therapy or radical extirpative surgery can have serious consequences with respect to urinary tract function.

Radical Hysterectomy

A small percentage of patients subjected to radical (Wertheim) hysterectomy suffer prolonged neural injury or irreversible damage to the neural apparatus controlling bladder or urethral function (57,189). Initially, urologic dysfunction is expressed as difficulty with volitional micturition, which often is treated by prolonged catheter drainage (57). That treatment in conjunction with the neural injury appears to lead to an alteration in bladder compliance. The condition is very similar to that which occurs in patients who develop bladder dysfunction after abdominal perineal resection for carcinoma of the rectum (189). In both cases, the dysfunction may be confined to transient loss of the micturition reflex, which is best managed by intermittent catheterization. In a small number of patients, a permanent neural injury is associated with complete loss of low-pressure bladder storage function, loss of reflex micturition, and an open, nonfunctional internal sphincter mechanism that resists abdominal pressure extremely poorly (337,338). This kind of urethral dysfunction results in urinary leakage associated with very minimal activity. Such a combination of conditions—an areflexive, poorly compliant bladder, and an open, nonfunctional internal sphincter mechanism—cannot be managed by intermittent catheterization alone because stress incontinence continues to be a problem despite the effect of intermittent catheterization on bladder compliance (338).

This constellation of lower tract problems also occurs in children with myelodysplasia: a nonfunctional internal sphincter and an areflexive bladder that stores urine poorly and gains pressure with filling. Because incontinence, caused by internal sphincter dysfunction, is such a problem, treatment is undertaken early. Because the areflexive detrusor gains pressure with volume, an effort to halt the gradual deterioration in compliance can be made by instituting intermittent catheterization in combination with anticholinergic agents. Bladder pressure control does not circumvent leakage driven by changes in abdominal pressure, which continues unless the internal sphincter is closed by treatment (171,337). Treating the incontinence by chronic catheter drainage only makes bladder compliance and complications worse over time.

If normal bladder compliance has been preserved, a procedure that effectively closes the nonfunctional internal sphincter will restore continence (e.g., a pubovaginal sling, an artificial sphincter, or an injectable agent such as collagen or fat). If bladder compliance is abnormal, achieving a satisfactory urethral continence mechanism by closing the urethra must be done in conjunction with some treatment that increases bladder capacity, such as an augmentation cystoplasty (171).

Radiation Therapy

The overall incidence of serious bladder injury from radiation therapy for carcinoma of the cervix is estimated to be 3% to 5%. The actual incidence may be higher in long-term and very-long-term survivors of radiation therapy, however, and the various types of radiotherapy in use 25 years ago can be related to very late onset of lower urinary tract problems (313).

Whereas more acute problems, including radiation cystitis with bleeding and vesicovaginal fistula formation, may be apparent within 3 years after cessation of radiation, late fistula formation and serious hemorrhage or problems with incontinence related to detrusor fibrosis and urethral sphincter failure may occur as long as 10 to 28 years after radiation therapy (313).

In 1933, Dean (77) defined three phases of bladder injury by radiation therapy: acute, subacute, and chronic. The acute phase, which starts 3 to 6 weeks after treatment, is characterized by vascular congestion and mucosal and submucosal edema, as well as degenerative changes, epithelial cell death, inflammation, desquamation, and ulceration. Focal deep muscular changes also occur. Subacute changes are characterized by variable fibrosis and healing, but the tissue remains abnormal for years. Chronic changes include obliterative endarteritis, proliferation of capillaries with capillary vascular ectasia, mucosal atrophy, ulceration, fibrosis and hyalinization, bleeding, contracture, and fistula formation. The late chronic injury phase may be exacerbated by small vessel disease associated with aging or other diseases.

Symptoms

Symptoms usually are incontinence with urgency, frequency, dysuria, or bleeding in association with bladder irritative symptoms. Any patient with a history, recent or remote, of radiation therapy within the pelvis should be evaluated carefully for the most likely expressions of radiation injury. Among these are hemorrhagic cystitis, usually associated with progressive fibrosis; and a small-volume, high-pressure, noncompliant bladder with or without a nonfunctional urethral sphincter. The late effects of radiation on bladder and urethral function include loss of normal low-pressure bladder urine storage; failure of the urethra to function as a sphincter, with a lack of resistance to abdominal pressure; and failure of the urethra to act as a compliant conduit during voiding attempted by the Valsalva maneuver, caused by a loss of detrusor reflex function. Valsalva voiding is rarely efficient and often is associated with significant residual urine volumes. Despite incontinence, the total picture is that of leakage driven by high ambient detrusor pressures and residual urine (344). High bladder pressures may lead to hydroureteronephrosis, vesicoureteral reflux, and renal damage or failure. These problems that accompany urinary incontinence, which is often the presenting complaint, become progressively worse as bladder storage function deteriorates. High bladder pressure, residual urine, and infection may result in severe, intractable vesical hemorrhage. In addition to these problems, large vesicovaginal and vaginal rectal fistulae may develop, spontaneously complicating the picture of incontinence.

In patients with fistulae, occlusion of the fistula with a large-balloon catheter is useful during videourodynamic study, or fluoroscopy alone without pressures, to determine proximal urethral competence, bladder compliance, and the presence of vesicoureteral reflux. Multiple biopsies should be taken near the fistula and along its course, together with random bladder biopsies, to determine whether recurrent carcinoma, or perhaps *de novo* carcinoma development, is involved in fistula formation. The classic site of a radiation fistula is posterior, involving the area of the trigone or the area just above the trigone (43,44). In patients incontinent without fistula formation, a very careful assessment of bladder storage activity is important before any procedure on the urethra. A poorly compliant bladder may look normal if continuous leakage occurs during the study. Moreover, incontinence related to poor bladder compliance often is exacerbated by activity, and, historically, the description of incontinence related to poor compliance often is identical to that related by patients with stress incontinence. However, because detrusor pressure is the driving force for the wetting, a urethral procedure will not be effective in curtailing the incontinence. The treatment of leakage driven by detrusor pressure entails bladder enlargement (171,338).

Treating Poor Bladder Compliance

The initial treatment is by anticholinergic agents, combined with intermittent catheterization if residual urine is present. If that treatment is unsuccessful, augmentation cystoplasty may be needed. In some cases, where destruction of the trigone has occurred as a result of radiation, supravesical diversions may be the only viable option.

Treating Radiation Fistulae

Closure of a fistula related to radiation therapy usually entails interposition of vascularized tissue. The techniques vary, but the majority of these fistulae are closed transvaginally. Elkins and colleagues (94) reported excellent results with a Martius labial fat pad interposition technique. Others have used bulbocavernosus grafts with good results; additional techniques include the use of gracilis muscle, as reported by Garloch (122) in 1928 and others (94,204).

Ureteral Obstruction After Radiotherapy

The incidence of radiation-induced ureteral obstruction has been reported to be between 0.4% and 8.0% (174). The combination of radiotherapy and radical surgery has resulted in an increased incidence of ureteral obstruction. In one series the incidence was 41.7%. In recent years, the incidence of major urologic complications has fallen markedly (235). Ureteral complications of irradiation occur later, with 80% occurring within 48 months after treatment and most occurring more than 24 months after treatment.

In 1972, Alfert and Gillenwater observed that after irradiation, ureteral obstruction is caused by recurrent tumor in two-thirds of cases and sclerotic fibrosis after destruction of malignant disease in the other third. With improved irradiation regimens, whether these proportions are still applicable is uncertain. A more recent review of urinary diversion in gynecologic malignancy reported on a series of 19 patients with ureteral obstruction (161). Only 2 patients in this series had ureteral obstruction caused by irradiation alone.

Reported ureteral complications related to irradiation include strictures, retroperitoneal fibrosis–induced ureteral obstruction, hematuria caused by ureteritis, or more rarely, ureteroarterial fistula (45). Ureteral obstruction also may be related to poor bladder compliance. The most significant determinant of irradiation injury is the dose of irradiation. With doses of irradiation less than 8,000 rads, the incidence of major complications is low. Interestingly, patients who developed irradiation-related major complications in one study had survival rates better than those who did not develop complications (45).

If ureteral obstruction is identified after irradiation for gynecologic malignancy, a cystometrogram and computed axial tomography with or without needle biopsy and other measures may be needed for accurate diagnosis and planning of effective therapy.

Radiation Cystitis

The onset of acute radiation cystitis is 3 to 6 weeks after the start of irradiation, with symptoms indistinguishable from those of bacterial cystitis. Urinalysis shows a variable combination of leukocytes, erythrocytes, unusual epithelial cells, necrotic debris, and bacteria. Secondary bacterial infection is common. Urine culture, sensitivities, and appropriate antibiotics are recommended (329). Late hemorrhage occurs in 3% to 12% of patients after pelvic irradiation (120).

A number of specific and nonspecific strategies exist to control the hematuria. Initial management includes cystoscopy with evacuation of clots, with bladder biopsy and fulguration of bleeding areas. After a cystoscopy, irrigation is continued until the drainage is clear, and management is essentially the same as that after a bladder tumor resection. Not infrequently, hematuria persists despite this management. Coagulation defects, especially disseminated intravascular coagulation and systemic hyperfibrinolysis, may be present. An intravenous urogram is necessary to evaluate the upper urinary tract, which may be the source of the hematuria.

If hematuria continues despite conservative measures, other measures can be used. These include instilling epsilon aminocaproic acid (EACA), intravesical alum, intravesical formalin, desmopressin, hyperbaric oxygen, temporary urinary diversion with ureteral occlusion catheters, arteriographic embolism, or surgical supravesical diversion (120,314,329).

EACA is a fibrinolytic agent that can be given orally, parenterally, or intravesically (120,281,329). It is contraindicated in disseminated intravascular coagulation because it may exacerbate small vessel thrombosis in this condition (120). It can be administered by continuous bladder irrigation after clot evacuation. This causes superficial protein precipitation and decreased cell permeability and stops small vessel bleeding.

Alum is instilled into the bladder as a 1% solution at a rate of 5 ml/minute (128). In the presence or renal impairment, especially with an eroded mucosal surface, serum aluminum levels should be monitored because central nervous system and bone marrow and renal toxicity have been caused by systemic absorption.

Formalin, an intravesical agent, acts by coagulating the tissues. Administration is very painful and necessitates anesthesia. In the presence of vesicoureteral reflux, it

may cause renal injury. If reflux is present, formalin still may be used if ureteral occlusion balloon catheters are inserted (120). A recommended starting dosage for formalin is 0.5% to 1.0% solution given for 10 minutes. Formalin can exacerbate bladder fibrosis, further impairing storage activity.

Desmopressin is a vasopressin analog that increases levels of factor VIII and von Willebrand factor and may shorten bleeding times. It is a useful adjunct for treating intractable hematuria. Other methods for controlling hematuria include hyperbaric oxygen, administered in daily treatments for 2 months. Before supravesical diversion, control of hematuria with bilateral ureteral occlusion balloons should be tried. The patient with severely contracted, fibrotic, noncompliant bladder may need surgery, either augmentation cystoplasty or urinary diversion.

HISTORY

Urethritis was recognized in antiquity and has been documented since the dawn of recorded history. According to Herodotus, Venus cursed the Scythians for pillaging her temple with “the woman's disease,” characterized by a discharge from the penis. Those attacked by this disease were looked on as accursed (133,165,166). Galen (c. A.D. 130–201) coined the term *gonorrhea,* combining the roots *gonus,* or “seed,” and *rhoea,* or “flow” (133). Thus *gonorrhea* literally means “leakage of semen.” The celebrated Arabian physician Maimonides distinguished urethral discharge from semen: “The fluid escapes without erection and without feeling of pleasure” (133).

Eventually, it was recognized that urethritis followed intercourse with an infected woman. This idea led to efforts to control venereal disease by regulating prostitution (133,165,166,327,389). According to legend, during the Middle Ages prostitutes in Paris were restricted to domiciles called *clapiers.* This explains the origin of the term *clap.* Another approach to control sexually transmitted diseases was taxation of afflicted men. For example, Elizabeth I (1533–1603), the “virgin queen,” decreed that every male attendant “who had a running from the pentle, should pay into the public treasury 40 shillings” (78).

During the nineteenth century, the predominant viewpoint of the medical community was that venereal disease was “punishment for the Lewdness of Mankind” (306). As stated by Dr. Samuel Dolly of the Royal College of Surgeons, “could the disease be eradicated fornication would ride rampant through the land,” an unfortunate (in his opinion) situation (327). Patients with sexually transmitted diseases were ostracized and confined to institutions such as the Social Evil Hospital in St. Louis (35).

The scientific foundation for the diagnosis of urethral inflammation dates from 1879, when Neisser demonstrated the bacterium, now known as *Neisseria gonorrhoeae,* in stained smears of urethral, vaginal, and conjunctival exudates (143). Thus it was possible to distinguish gonococcal urethritis from nongonococcal urethritis (NGU). The distinction was important clinically once effective therapy for gonorrhea became available with the development of sulfonamides in the 1930s.

DEFINITIONS

Urethritis is the response of the urethra to inflammation of any cause (52,293). Such inflammation results in the classic symptoms of urethral discharge accompanied by burning on urination or an itching sensation. Urethral discharge is the characteristic finding on physical examination. The pathognomonic laboratory finding is an increased number of leukocytes on Gram's stain of the urethral smear or first-voided urine specimen. Urethritis may be classified as infectious if a microorganism with pathogenic potential is identified or noninfectious in the absence of a recognized pathogen. Infectious urethritis is classified as gonococcal, or gonorrhea, in the presence of *N. gonorrhoeae.* If *N. gonorrhoeae* is not detected despite objective evidence of urethral inflammation, the patient has NGU. This condition was formerly called *nonspecific urethritis,* but *nongonococcal urethritis* is preferred because specific causes of NGU may be identified in most patients. *Postgonococcal urethritis* is the term used for NGU that occurs shortly after effective therapy for gonorrhea.

INCIDENCE

Up to 50% of the U.S. population will acquire a sexually transmitted disease by age 30 to 35 (123). Urethritis is one of the most common problems in ambulatory medical practice. Despite recent declines in incidence, gonorrhea remains one of the most frequently reported infectious diseases in the United States, with approximately 600,000 cases reported per year in men from 1975 and 1991 (45,52,144). The best estimate is that approximately 40% of cases of gonorrhea are reported (30,105). In Great Britain, where infectious disease reporting is more complete and all forms of urethritis are reportable, 34% of patients with urethritis had gonorrhea (399). Less complete data suggest that NGU is also more common than gonococcal urethritis in the overall U.S. population (49,162,408). It is estimated that gonorrhea accounts for approximately 35% of cases of acute urethritis in men. This leads to an estimate of at least 4 million cases of urethritis per year among men in the United States (30,105). The estimated annual incidence is 3.7 cases of urethritis per 100 males older than age 15 years (105).

The relative proportions of gonococcal urethritis and NGU depend on many factors, including the population studied, geography, socioeconomic factors, sexual orientation, age, and race (144). For example, the reported incidence of gonococcal infection in patients attending clinics for sexually transmitted diseases was highest in inner-city populations: 90% in Lexington, Kentucky, 64% in Detroit, and intermediate in cities such as Denver, New Haven (45), and Seattle (140). College students had the lowest reported incidence (8%) of gonococcal disease in heterosexual men with urethritis (231). NGU is more common in patients from higher socioeconomic groups (292). Heterosexual black men with urethritis have a higher incidence of gonorrhea (58% to 70%) than heterosexual white men (25% to 37%) in most studies (153,408).

Although national gonorrhea rates have declined since 1986, rates for minority adolescents and young adults, especially in inner cities, continue to be high. Recent data suggest that rates were 5,715 per 100,000 for black adolescents aged 15 to 19 and 6,339 per 100,000 for black adults aged 20 to 24, compared with rates of 189 per 100,000 for white adolescents and 186 per 100,000 for young white adults (49,144). Because there is no evidence of differences in racial susceptibility to gonorrhea or NGU, these differences may reflect the willingness of patients from higher socioeconomic groups to be treated for the milder symptoms characteristic of NGU (292). Thus equating signs of acute urethritis with gonorrhea often is in error, especially in private practice.

ETIOLOGY

Urethritis is a clinical syndrome with many causes (Table 39.1). The cause is commonly infectious, resulting from exposure to microorganisms spanning the full spectrum of medical microbiology. From a microbiologic viewpoint, these organisms have little in common other than the potential to cause urogenital tract disease and to be commonly transmitted by sexual contact (194). This mode of transmission and the epidemiological risk factors for sexually transmitted diseases imply that patients with one of these diseases are at risk for others because multiple pathogens may be acquired simultaneously. Some patients develop symptoms of urethritis that reflect infection with microorganisms acquired through means other than sexual contact, or they have symptoms without objective evidence of an inflammatory response or a recognized pathogen (196).

Sexually transmitted	
Gonococcal	
Neisseria gonorrhoeae	Bacterial
Nongonococcal	
Chlamydia trachomatis	Bacterial (chlamydia)
Ureaplasma urealyticum	Bacterial (mycoplasma)
Uncommon causes	
Trichomonas vaginalis	Protozoan
Herpes simplex virus (types 1 and 2)	Viral (DNA*)
Human papillomavirus	Viral (DNA*)
Rare or debatable causes	
*Mycoplasma hominis**	Bacterial (mycoplasma)
Haemophilus ducreyi	Bacterial
*Bacteroides ureolyticus**	Bacterial (anaerobic)
Neisseria meningitidis	Bacterial
Candida albicans	Yeast
*Corynebacterium genitalium**	Bacterial
Other organisms	
Non–sexually transmitted	
Associated with genitourinary infection or abnormalities	Bacterial
Prostatitis	
Urethral stricture	
Instrumentation	
Foreign body	
Immunologic	
Reiter's syndrome	Infection associated
Wegener's granulomatosis	
Stevens-Johnson syndrome	
Chemical allergy (rare)	
Food allergy (doubtful)	
Chronic irritation	

*These organisms are suggested as cause in the literature but are not established; most experts consider them possible or doubtful causes.

TABLE 39.1. CAUSES OF URETHRITIS IN MEN

The following sections consider the most significant causes of urethritis in clinical urology. We emphasize treatable, infectious causes of urethritis. For each pathogen there is a limited discussion of microbiologic characteristics of the organism that have important clinical implications. Attention then is directed to relevant considerations of the epidemiology, diagnosis, and treatment of that pathogen. Non–sexually transmitted conditions are discussed in the differential diagnosis of urethritis. Finally, we consider specific complications of urethritis and related conditions.

DIAGNOSTIC TESTING

Testing to establish the presence of urethral inflammation is highly desirable in any clinical setting (52). This is especially true in urological practice, where patients often are referred for evaluation of atypical or persistent signs and symptoms. Urethritis can be documented by the presence of any one of the following findings: mucopurulent urethral discharge, a Gram stain of urethral secretions demonstrating five or more leukocytes per oil immersion field, or presence of leukocytes in the first-void urine.

The Gram stain is preferred as a rapid diagnostic test for evaluating possible urethritis (52). This test is a highly sensitive and specific method for documenting both urethritis and the presence of gonorrhea in patients who have leukocytes containing intracellular, Gram-negative diplococci. In patients who refuse the urethral smear, or for screening populations at high risk for infection, the first-void urine is an alternative to the traditional urethral smear. A positive leukocytes esterase test or ten or more leukocytes per high-power microscopic field is considered diagnostic of urethritis.

If none of the criteria for urethritis is present, then treatment should be deferred pending diagnostic test results unless the patient is considered unlikely to return. Testing should be done for both *N. gonorrhoeae* and *Chlamydia trachomatis,* with arrangements for close follow-up of a positive result. Patients with positive test results for either of these organisms should have appropriate treatment, as described later in this chapter. In addition, sex partners should be referred for evaluation and treatment. Empirical treatment of symptoms without documentation of urethritis is recommended only if the patient is considered at high risk for infection and is also considered unlikely to return, such as adolescents with multiple sex partners.

Documenting presence of specific pathogens is highly desirable. Such information supports treatment compliance and partner notification. Positive test results also support the need for counseling in behavior modification and testing recommendations for both syphilis and HIV. Negative test results and poor response to previous therapy support the need for additional evaluation and etiological testing, as described later in this chapter.

GONOCOCCAL URETHRITIS

Biology of *N. gonorrhoeae*

N. gonorrhoeae is a Gram-negative, non–spore-forming bacterium that usually appears as diplococci (Fig. 39.1). On light microscope examination, gonococci appear encapsulated and exhibit a characteristic “twitching” motility (336). Identifying *N. gonorrhoeae* in culture usually depends on typical appearance of the colonies, Gram stain, oxidase reaction, and carbohydrate uptake (244).

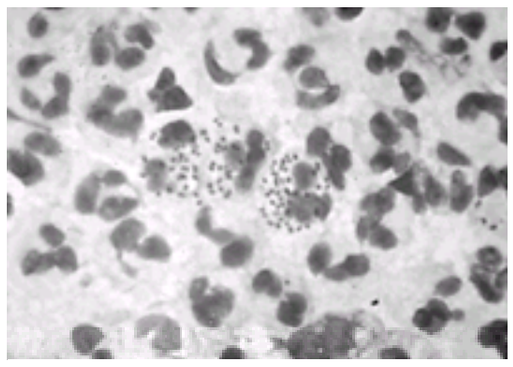

FIGURE 39.1. Gram-stained urethral smear from a patient with gonorrhea. There is a profuse inflammatory infiltrate with polymorphonuclear leukocytes containing characteristic Gram-negative intracellular diplococci.

Although *N. gonorrhoeae* does not grow on simple laboratory media such as nutrient agar, there are a variety of commercial and completely defined growth media (144,336). Most media incorporate antimicrobials, such as vancomycin or nystatin, to inhibit overgrowth of other bacteria. Gonococci are strict aerobes, but increased carbon dioxide tension (5% to 10%) is needed for growth. This is usually provided in a candle jar or carbon dioxide incubator. Specific nutritional requirements (auxotypes) vary from strain to strain and form the basis for one classification scheme for gonococcal strains (45). There is geographic variation in the distribution of

different auxotypes (143). In addition, particular auxotypes of gonococci may be associated with specific disease syndromes. For example, 88% of cases of disseminated gonococcal infection (187) and more than 90% of asymptomatic urethral infections among men in Seattle were caused by strains needing arginine, hypoxanthine, and uracil (70). In contrast, this auxotype caused only 33% of uncomplicated gonorrhea.

Although auxotyping has been used in conjunction with antibiograms to monitor outbreaks of antimicrobial-resistant gonorrhea, this method has limited usefulness for differentiating between strains (186). More sophisticated methods use serologic classification based on antigenic differences in gonococcal outer membrane protein I (144,188). Monoclonal antibodies against different outer membrane proteins can distinguish particular serotypes (188,356). The combination of auxotyping and serovar analysis proved useful for epidemiological studies of *N. gonorrhoeae* strains (143). New molecular techniques, such as fingerprinting using plasmid profiles, and restriction endonuclease analysis also have proven useful for epidemiologic investigations (372). Thus we can now monitor the dynamics of gonorrhea outbreaks on a molecular level.

Variation in the appearance of *N. gonorrhoeae* colonies becomes apparent when organisms are grown on solid media (154,277). Colonies are described as small or large, opaque or transparent. Because there is no useful animal model, human studies of gonococcal virulence factors are ongoing (55,57). Inoculation studies demonstrated that organisms from the small colonial variants were virulent, whereas the large colonial variants were avirulent (174,176). These characteristics are determined by opacity proteins. Subsequent studies demonstrated that bacteria from the small colonies had pili, but organisms from the large colonies had no pili. Gonococcal pili are believed to facilitate attachment to host cells. Gonococci of one colonial type rapidly change in both colony appearance and piliation on cultivation (336). Almost all gonococcal strains studied contain plasmids (336). Plasmids are inherited, extrachromosomal, genetic elements that are not essential to the host cell. Some plasmids, called *R-plasmids,* code for characteristics that make bacteria resistant to antimicrobials. *N. gonorrhoeae* containing R-plasmids were first isolated in 1976 (85,342,371). Biochemical evidence suggests that these R-plasmids were acquired from strains of *Haemophilus influenzae.* The R-plasmids code for b-lactamase production, activity that confers absolute resistance to penicillin. Strains of *N. gonorrhoeae* with a b-lactamase are called *penicillinase-producing N. gonorrhoeae* (PPNG). PPNG strains originally were isolated from patients in certain areas of Africa and the Far East. Before 1980 there was a gradual increase in the incidence of PPNG in the United States, and most cases could be traced to Far Eastern sources (143). Beginning in 1980, however, there was an increase in PPNG in the United States, and these strains have become endemic in certain areas of the (48,123,143,311,397). To date, five different b-lactamase plasmids have been described in *N. gonorrhoeae* (156). In addition, gonococci have acquired another plasmid from streptococci that confers high-level resistance to the tetracyclines (156).

Chromosomal mutations are the second mechanism for developing drug resistance in *N. gonorrhoeae* (156,191). Such strains are called *chromosomally mediated resistant N. gonorrhoeae* (CMRNG) (48). Unlike the PPNG, the CMRNG strains do not produce b-lactamase (92). Chromosomally mediated resistance to penicillin generally is low and has been associated with mutations at four sites (156). However, the effects of these mutations are additive. The combination of several mutations may increase penicillin resistance 100-fold or more. A second problem is that the CMRNG strains also exhibit high-level resistance to other drugs, particularly tetracyclines and most cephalosporins (156). Other *N. gonorrhoeae* strains have been described with chromosomally mediated resistance to many other classes of antimicrobials, including aminoglycosides, spectinomycin, sulfonamides, trimethoprim-sulfamethoxazole, and quinolones (156). Thus gonococci now have multiple mechanisms for developing resistance to antimicrobial drugs.

Studies of other potential virulence-associated factors are limited by the lack of an animal model for gonorrhea. Humans are the sole host of *N. gonorrhoeae,* and efforts to develop a suitable experimental model have met with limited success (57,336). Despite these problems, several lines of evidence suggest that gonococcal pili may be important in disease development (174,336). Presence of pili was associated with small colonies *in vitro* and with virulence in both human volunteers and in animal models. Pili increased the adherence of gonococci to a wide variety of cells, including tissue culture cells, erythrocytes, polymorphonuclear leukocytes, vaginal epithelial cells, buccal epithelial cells, and fallopian tube explants (235,272,336). Because adherence is the first step in pathogenesis for many organisms, presence of pili appears to be associated with gonococcal virulence. There is distinct antigenic variation between pili isolated from different gonococcal strains. Evaluating these strain-specific and common antigens of pili is an area of active research by workers trying to develop gonorrhea vaccines (31). To date, however, none of the vaccines has proven effective in clinical trials (20). Like other Gram-negative bacteria, *N. gonorrhoeae* contain lipopolysaccharide in their cell membranes (4). Lipopolysaccharide has been associated with endotoxin activity, with toxic effects in animal models and with toxic effects in tissue culture systems (336). Gonococci also elaborate an enzyme that inactivates host immunoglobulins (Ig), specifically IgA (18). This enzyme may allow gonococci to persist at host mucosal surfaces despite a host immune response.

Epidemiology

Case-finding and contact-tracing efforts have resulted in a dramatic reduction in the incidence of gonorrhea in much of western Europe and Canada (144). However, gonorrhea remains common in the United States and the developing world. Part of the decline in incidence has been attributed to behavioral changes related to the HIV epidemic. Rates have declined in homosexual and bisexual men, in whites, and in older adults. In contrast, gonorrhea rates remain high in younger populations and in blacks.

Approximately 17% of men develop gonorrhea after a single episode of vaginal intercourse with an infected woman (145). The transmission rate increases to 60% to 80% after four exposures. Approximately 90% of women who are secondary sexual partners of infected men have gonorrhea (369), but no studies controlled for the number of exposures.

Recent reports emphasize the role of men with asymptomatic infections in the epidemiology of gonorrhea. It was believed that almost all women with gonorrhea were asymptomatic, whereas almost all men developed symptoms. The problem was that reports of carefully defined groups of patients were generalized to the overall population. For example, studies reporting that more than 80% of women with gonorrhea had no symptoms were based on surveys of sexual contacts with men with gonococcal urethritis; women evaluated because of lower genital tract symptoms generally were excluded (143,275). However, fewer than 25% of women with gonorrhea attending acute care facilities were asymptomatic (125,233). It also has become apparent that asymptomatic urethral infection in men is important in the epidemiology of gonorrhea. In one study only 2 of 81 men (2.5%) infected at a known time remained asymptomatic for 14 days (128). The problem is that asymptomatic men tend to accumulate in the general population and remain active sexually, whereas symptomatic patients tend to seek medical care (125,143,144,233). For example, an unannounced “short-arm” inspection revealed that 2.2% of a large group of military personnel had gonococcal urethritis; most were asymptomatic or had ignored minimal symptoms. It is now believed that such patients are primarily responsible for transmitting the disease. Thus most men named as source contacts of women with gonococcal pelvic inflammatory disease or gonococcal arthritis were asymptomatic or had ignored minimal symptoms of gonorrhea (89,125). Asymptomatic urethral carriage of gonococci also may represent a hazard to the patient. For example, gonococcal epididymitis has been well documented in men with no previous history of urethritis (14).

Clinical Manifestations

N. gonorrhoeae infects mucous membranes lined by nonsquamous epithelium (276). Adherence of the bacteria to mucosal surfaces appears to be the initial event in pathogenesis (144,228). Mucosal invasion occurs within 24 to 48 hours (276). This is accompanied by a marked polymorphonuclear leukocyte infiltration, submucosal microabscesses formation, and inflammatory debris exudation into the urethral lumen, resulting in the characteristic discharge (55,56,57). In untreated patients a gradual accumulation of mononuclear cells that may persist for months. Before the appearance of effective antimicrobials, urethral discharge persisted for an average of 8 weeks, and 95% of patients became asymptomatic within 6 to 8 months (141,276).

Acute urethritis is the most common manifestation of gonococcal infection in men. The incubation period was 2 to 5 days in 36 of 44 men (82%) in one study (129) and usually ranges from 1 to 14 days (143). Observations suggest that certain strains of gonococci may have unusual incubation periods. For example, some strains from the western Pacific may produce symptoms and positive cultures within 12 hours after exposure, whereas other strains may take as long as 3 months to produce symptoms (128).

Patients usually complain of dysuria and urethral discharge. The discharge initially may be slight and appear mucoid, but most patients develop purulent, milky discharge within 24 hours (144,276). On occasion, urethral discharge comes to the patient's attention as an unpleasant odor on urination or observation of mucous strands in the urine. The discomfort experienced by patients with urethritis usually manifests as dysuria. Some patients may localize this discomfort to the meatus or distal penis or along the shaft. Occasionally, patients report that dysuria increases after ingestion of irritants such as alcohol or spicy foods. This observation may lead the patient to believe that his disease is a food allergy. Other patients experience discomfort during urination, described as pain, itching, urinary urgency, or heaviness in the genital area (234,292).

The intensity of dysuria is variable, ranging from minimal discomfort with micturition to exquisite tenderness. Similar variability also is present in the quantity of discharge. In some patients the discharge may be profuse and occur spontaneously. Other patients may have minimal discharge that presents as a crust covering the

meatus or a small drop of increased moisture at the meatus that is apparent only on arising. In one review, 31% of men with gonococcal urethritis had a discharge that was mucoid in appearance, closely resembling the discharge observed in patients with NGU (30). In addition, a small group of men never develop overt signs or symptoms of urethritis (125,144). Therefore the characteristics of the urethral discharge by themselves are not sufficient for determining whether the patient has gonococcal or NGU.

Diagnosis

If possible, the patient should be examined at least 2 hours after his most recent urination and ideally before his first void of the day (292). This facilitates detection and examination of minimum amounts of discharge (353). If spontaneous discharge is not apparent, discharge may be observed at the meatus after urethral stripping or prostatic examination. Some patients with objective laboratory evidence of urethral inflammation lack physical signs of urethritis.

Laboratory diagnosis of gonococcal infections depends primarily on identification of the gonococcus in stained smears or cultures from infected sites. Microscopic examination of the urethral specimen is the first procedure for evaluating symptoms or signs of urethritis. Specimens should be obtained with calcium alginate swabs inserted at least 2 cm into the urethra and rotated gently (24,128,292). Standard cotton-tipped applicators should not be used to obtain urethral specimens because their large size makes insertion uncomfortable, and free fatty acids in the cotton fibers may be toxic to fastidious pathogens (175). Ideally, the swab should first be inoculated in culture media, then applied to the microscope slide (128). Duplicate swabs should be obtained in situations in which this procedure is impractical. The swabs should be rolled over the slide rather than “streaked” because the latter procedure may distort cellular morphology. The slide should then be air-dried, heat-fixed, and stained with one of the many Gram stain procedures.

Microscopic examination of urethral specimens is a mandatory adjunct to urethral cultures. This procedure facilitates diagnosis and immediate presumptive therapy of patients with urethritis. A small subset of men (less than 2%) with symptomatic urethritis also have typical organisms on Gram stain but negative cultures for gonorrhea. Such false-negative cultures occur because some *N. gonorrhoeae* strains are inhibited by the small concentration of antimicrobials used in standard, selective media for isolating gonococci (117,292). The Gram-stained urethral specimen should be examined with the oil immersion objective. Because the distal urethra is colonized by a variety of bacteria, observing varied extracellular organisms is of no particular importance (292). Two findings have diagnostic significance: presence of inflammatory cells and the presumptive identification of gonococci. The finding of acute inflammatory cells, particularly polymorphonuclear leukocytes, in the urethral specimen is abnormal, as discussed in the next section. Identification of typical, Gram-negative, intracellular diplococci within polymorphonuclear leukocytes (Fig. 39.1) by experienced microscopists has a 95% sensitivity and a 99% specificity for diagnosing gonococcal urethritis (161). Gonococci are not randomly distributed among polymorphonuclear leukocytes but are found in large numbers in few cells.

Two culture media are most effective for isolating *N. gonorrhoeae*–modified Thayer-Martin medium (367) and New York City medium (119,296). Both media give excellent results. Various other tests based on serologic and fluorescent antibody methods, as well as detection of bacterial endotoxin, have been developed to diagnose gonorrhea. However, the high sensitivity and specificity of the urethral Gram stain and culture combination make routine use of these diagnostic methods unnecessary (128,144).

Nonculture tests for diagnosis of *N. gonorrhoeae* have become available during the last decade. These tests are especially useful in settings where culture viability can be jeopardized by temperature variability and delays during transportation to the microbiology laboratory. These tests include both nonamplified and amplified DNA probe tests (144) that provide sensitivity and specificity comparable to culture. Some amplified DNA tests have proven useful for screening first-void urine specimens. This approach has proven useful for screening high-risk populations without the need for a urethral swab (54,271).

Treatment

Historically, gonococcal urethritis was managed by local measures, such as salves and ointments, intraurethral antiseptic solutions, and assorted instruments (128,131,165). These treatments became obsolete during the 1930s with the availability of the sulfa drugs (74). By 1943, however, most *N. gonorrhoeae* isolates were resistant to sulfadiazine. Gonococcal urethritis was first treated with penicillin in 1943, and over the next four decades the dosages of penicillin necessary for curing gonorrhea increased steadily (128). Drugs in the penicillin class are no longer recommended as first-line treatment for gonococcal urethritis.

Current recommendations for treating gonococcal urethritis are outlined in Table 39.2 (50). Each recommendation has advantages and disadvantages. Thus treatment should be individualized. Intramuscular aqueous procaine penicillin accompanied by probenecid was a time-honored regimen that can no longer be recommended (143,144,234). Problems include the large, painful injections that limit patient acceptance and the parenteral administration of a large amount of procaine, which may be toxic. Increasing resistance of the gonococcus to penicillin also has limited the effectiveness of penicillin treatment.

Oral regimens
Cefixime 400-mg single dose *or*
Ciprofloxacin 500-mg single dose *or*
Ofloxacin 400-mg single dose
Plus
Azithromycin 1-g in a single dose *or*
Doxycycline 100 mg twice daily for 7 days
Parenteral regimens
Ceftriaxone 125 mg intramuscularly
Plus
Azithromycin 1-g single dose *or*
Doxycycline 100 mg twice daily for 7 days
Special considerations
For patients allergic to cephalosporins or fluoroquinolones, substitute spectinomycin 2 g intramuscularly

Adapted from 1998 Guidelines for treatment of sexually transmitted diseases. Centers for Disease Control, 1998. MMWR 1998;47(RR-1):1, with permission.

TABLE 39.2. RECOMMENDED TREATMENT REGIMENS FOR UNCOMPLICATED GONOCOCCAL URETHRITIS

Effective single-dose treatments are available. These agents include the gold standard parenteral treatment with ceftriaxone (125 mg intramuscularly). Single-dose oral treatment is an attractive alternative. Effective agents include cefixime (400 mg), ofloxacin (400 mg), and ciprofloxacin (500 mg) (52,249,285,286,357). Because treatment may be administered as a single dose under direct supervision of the physician, it is ideal for patients who are not reliable (47,128,249,285,286,357).

Possible coexisting chlamydial infection is an important consideration for all patients with gonorrhea. Such infections occur in up to 45% of patients with gonorrhea (49). Therefore all recommended regimens in Table 39.2 include treatment for possible chlamydial infections. Current recommendations are treatment with doxycycline (100 mg twice daily) for 7 days or a single (1 g) dose of azithromycin, an effective alternative that offers the advantages of single-dose treatment.

Routine follow-up evaluation is no longer recommended for patients with uncomplicated gonococcal urethritis who receive one of the recommended regimens (52). If symptoms persist and there is evidence of urethritis, patients should be recultured. Documented *N. gonorrhoeae* should be tested for antimicrobial susceptibility. Recurrent infections after treatment with one of the recommended regimens most often result from reinfection by contact with an untreated partner. This emphasizes the need for effective counseling and treatment of both the patient and his partners (128). All patients with gonorrhea should receive appropriate evaluation and treatment for other sexually transmitted diseases, including syphilis and HIV testing.

NONGONOCOCCAL URETHRITIS

Comparison of Clinical Features of Gonorrhea and Nongonococcal Urethritis

There are differences between populations of men with gonococcal urethritis and NGU in epidemiologic studies (22,140,228). For example, comparison of 113 men with NGU and 69 men with gonococcal urethritis demonstrated that patients with NGU were more often white, better educated, more likely to be students, and of higher socioeconomic status (140). Patients with NGU were older at first intercourse, had fewer sexual partners, and were less likely to have had a previous episode of gonorrhea but more likely to have had previous NGU (22,140,153). Unfortunately, such demographic characteristics have limited value in assessing individual

patients.

The usual incubation period for NGU development is 1 to 5 weeks after sexual intercourse with an infected partner, and most cases occur between 2 and 6 weeks (21,22,228). This is longer than the usual 2- to 6-day incubation period for gonorrhea, and the onset of symptoms of gonorrhea usually is more abrupt (144). However, there is wide variation in the incubation period for both infections, and a significant proportion of both groups remains asymptomatic. Gonococcal urethritis and NGU may produce similar symptoms and signs. Both conditions commonly cause urethral discharge, dysuria, and itching, whereas increased urinary frequency and urgency occur less often.

In general, symptoms are more severe in patients with gonorrhea. In one report, discharge and dysuria occurred in 71% of 185 men with gonococcal urethritis but in only 38% of 214 men with NGU (153). Discharge was apparent on physical examination of 99% of men with gonorrhea, and discharge was apparent in 81% of men with NGU. Gonococcal infections tend to be associated with more profuse and purulent discharges (30). There is sufficient overlap in the clinical characteristics of patients with gonococcal urethritis and NGU that distinction based solely on physical examination is associated with a high probability of error.

Occasionally, the discharge associated with NGU is manifest only before the first micturition of the day as meatal crusting or staining of underwear. On initial evaluation some patients may have no objective evidence of urethral inflammation. Almost 50% of such patients had objective evidence of urethritis (mainly NGU) on reexamination before voiding in the morning (332). This implies that when a discharge is suspected on clinical grounds but not apparent on physical examination, the patient should be reevaluated in the morning after not voiding overnight.

Diagnostic Criteria for Nongonococcal Urethritis

By definition, NGU is diagnosed when microscopic examination of the urethral smear demonstrates inflammatory cells, usually polymorphonuclear leukocytes, without *N. gonorrhoeae.* Observation of more than four polymorphonuclear leukocytes per ×400 oil immersion microscopic field is abnormal and occurs in 60% to 90% of men with symptomatic urethritis (24,292,305,354). Alternative criteria used in clinical investigations of NGU include the combination of urethral discharge and 20 or more polymorphonuclear leukocytes in two or more of five random ×400 microscopic fields of the initial 10 to 15 mL of the urinary stream (21,28). Such definitions are useful in clinical investigations that are limited to evaluating patients with clear-cut disease. In everyday clinical practice, however, these criteria are too restrictive (21,292). Between 16% and 50% of men with culture-proven urethritis have fewer than four polymorphonuclear leukocytes per high-power microscopic field of the urethral specimen (75,320,342). Micturition reduces the number of urethral polymorphonuclear leukocytes (332), and there may be a marked variation in the number of inflammatory cells reported by different observers (398). Presence of even an occasional polymorphonuclear leukocyte suggests urethritis, especially in a patient with symptoms or a small amount of discharge (292). This viewpoint is supported by isolation of *C. trachomatis* from symptomatic men with little or no evidence of increased numbers of polymorphonuclear leukocytes in urethral smears or first-voided urine specimens (22,305). Therefore smears or first-voided urine may be used as a rough guide to the presence of urethral inflammation. As with gonococcal urethritis, cultures or other laboratory tests are necessary to exclude urethral infection with recognized pathogens in men with minimal objective evidence of urethritis (22).

There are few characteristic clinical features that permit distinction between the various causes of NGU (Table 39.1). The two most common causes of NGU are *C. trachomatis,* which is responsible for 30% to 50% of cases, and *Ureaplasma urealyticum,* which may be related to 25% to 35% of cases (21). Various other organisms have been implicated as less common causes of NGU. The remainder of this section considers the epidemiology, biology, diagnosis, and treatment of NGU caused by these organisms.

C. trachomatis

Biology

Although they were initially considered to be large viruses, the chlamydiae are now recognized as small bacteria with a unique growth cycle (317). Chlamydiae are complex microorganisms that have cell walls closely resembling the cell walls of Gram-negative bacteria (38,230,316). Like the viruses, chlamydiae are obligate intracellular parasites. Their genomes are among the smallest of all organisms, but unlike viruses they contain both DNA and RNA. Chlamydiae contain only enough DNA to code for approximately 1,000 ordinary-sized proteins. By comparison, bacteria such as *Escherichia coli* contain sufficient genetic material to code for roughly 3,000 proteins. Chlamydiae thus share many of the basic characteristics of other bacteria, including the presence of both DNA and RNA, a similar cell wall, ribosomes, metabolic enzymes, multiplication by fission, and susceptibility to antimicrobials (195).

The genus *Chlamydia* contains two species: *C. psittaci,* an important pathogen of birds and domestic mammals that rarely causes disease in humans, and *C. trachomatis,* now recognized as a major human pathogen (315). A newly recognized species, *C. pneumoniae* (formerly TWAR), has recently been identified as a cause of acute respiratory disease, including pneumonia (120,183,317).

The species differ in their inclusions and sensitivity to antimicrobials (317). *C. trachomatis* inclusions contain glycogen and therefore stain with iodine, whereas *C. psittaci* inclusions do not stain with iodine. Strains of *C. trachomatis* are sensitive to sulfonamides. In contrast, *C. psittaci* stains usually are sulfonamide resistant. Both species contain a variety of strains with different characteristics. The remainder of this discussion is limited to *C. trachomatis.*

Strains of *C. trachomatis* may be classified according to biologic and immunologic characteristics. *C. trachomatis* strains can infect a limited range of host cells. Non-lymphogranuloma venereum (LGV) strains infect mucosal surfaces but are inefficient at infecting host leukocytes (314,317,345). In contrast, LGV strains infect lymphoid cells and are more efficient at replication in macrophages. Differences between LGV organisms and other *C. trachomatis* strains also are apparent in experimental animals (279,316). LGV strains are not lethal after intracerebral inoculation of mice but do produce conjunctivitis in primates. Thus LGV strains are more invasive in both human hosts and animal models, whereas non-LGV strains of *C. trachomatis* tend to infect mucosal surfaces.

Immunologic studies have identified 15 serotypes of *C. trachomatis,* which can be considered in three broad groups (serovars) based on their clinical syndromes and immunologic characteristics (121,279,383,407). Strains in three serotypes, L1, L2, and L3, are associated with LGV. Serotypes A, B, Ba, and C are associated with hyperendemic-binding trachoma in undeveloped countries. *C. trachomatis* strains belonging to serotypes D through K have been associated with a wide variety of clinical syndromes, including urogenital tract infections such as NGU, epididymitis, cervicitis, and salpingitis, as well as other conditions such as proctitis, pharyngitis, inclusion conjunctivitis (both infant and adult), and infantile pneumonia (128,195,316,343,345).

Their unique life cycle distinguishes the chlamydiae from other microorganisms (195,314,316,317,345). Like viruses, chlamydiae are obligatory intracellular parasites and thus cannot be cultured on artificial growth media. There are two distinct morphologic forms, the elementary body and the reticulate body, and both forms play essential roles in the chlamydial life cycle (Fig. 39.2) (195,315,316). The elementary body is the infectious particle that is able to survive in the extracellular environment but has limited metabolic capability. The initial step in pathogenesis appears to be attachment of the elementary body to the surface of a susceptible host cell (37,216). Phagocytosis of the attached elementary body is induced by the chlamydial particle. After penetration of the host cell, chlamydiae are contained within the phagocytic vesicle, where they specifically inhibit phagolysosomal fusion and release of the toxic products that normally defend against infection of host cells (316,317). After ingestion, the elementary body undergoes a poorly understood reorganization process to become a reticulate body. The reticulate body is the metabolically active and replicating form of chlamydiae. Reticulate bodies can use host macromolecules for synthesis of chlamydial nucleic acids and proteins but cannot make their own high-energy compounds and therefore are “energy parasites” (14). The reticulate bodies divide by binary fission, starting approximately 8 hours after infection. A second reorganization process begins 18 to 24 hours after infection, as some reticulate bodies transform into elementary bodies. The cycle ends with rupture of the host cell and release of infectious elementary bodies after 48 to 72 hours.

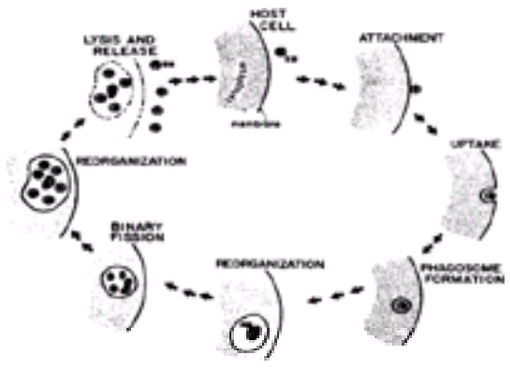

FIGURE 39.2. Life cycle of *C. trachomatis.*

Epidemiology

It has been estimated that there are 89,000,000 *C. trachomatis* infections per year worldwide (345), including 4,000,000 to 5,000,000 infections per year in the United States (51). These infections cost the U.S. health care system an estimated $2.4 billion dollars per year.

C. trachomatis is a major urogenital tract pathogen that is responsible for a significant proportion of NGU (314,345). Several types of evidence support this conclusion, including isolation rates of *C. trachomatis* from different patient populations, studies of anti– *C. trachomatis* antibody titers, and investigations of the postgonococcal urethritis syndrome. The isolation rate of *C. trachomatis* is lowest among asymptomatic men. Especially low rates of chlamydial isolation were reported in studies of asymptomatic men who were screened to exclude pyuria: Only 0% to 3% of such patients had positive urethral cultures (20,29). In other investigations, the incidence of urethral infection with *C. trachomatis* ranged from 0% to 7% of asymptomatic men seen in general medical settings to 15% to 20% of all men attending sexually transmitted disease clinics (140,261,280,314,319,404). In a military population, the 11% incidence of asymptomatic chlamydial infections of the urethra was higher than the 2% incidence of asymptomatic gonorrhea (342). Patients with gonococcal urethritis have chlamydial isolation rates ranging from 4% to 34%, usually 15% to 25% (22,25,140,261,297,365,380,404). Men with NGU had the highest incidence of urethral chlamydial infections, with reported rates ranging from 20% to 58%, usually 30% to 40% (22,140,261,280,297,305,354,365,404).

Serologic studies are complicated by the high background prevalence of antichlamydial antibodies in most adult populations (22,140,314). There is one well-controlled study of men with initial episodes of NGU and few previous sexual partners (29). In this carefully selected population, significant increases in antibody titers occurred in sera from nine of ten men who had symptoms for less than 10 days and positive chlamydial cultures. Measurements of IgM, a transiently detectable antibody that permits diagnosis of recent systemic infection in patients with preexisting antibodies, also supported a role for chlamydiae in NGU. Antichlamydial IgM antibodies were detected in 16 of 20 sera from men with positive urethral cultures but in only 3 of 39 men with NGU who had negative urethral cultures ($p < .0001$) (29). These findings support the idea that NGU was associated with recent acquisition of chlamydial infection rather than reactivation of a latent infection.

Postgonococcal urethritis is a syndrome of recurrent urethritis after effective treatment for gonorrhea. It is believed that postgonococcal urethritis results from a dual infection with *N. gonorrhoeae* and another pathogen, most often *C. trachomatis.* In one study, penicillin was used to treat 14 men with dual infections with both chlamydiae and gonococci: 11 patients (79%) subsequently developed postgonococcal urethritis (297). Similar results were obtained in studies with penicillin and other antimicrobials, such as ampicillin, spectinomycin, and gentamicin, that are ineffective against chlamydiae (22,140,262). Two additional observations support a role for *C. trachomatis* in approximately 70% of men with postgonococcal urethritis (22,314). The rate of postgonococcal urethritis is much higher in men simultaneously infected with both *C. trachomatis* and *N. gonorrhoeae* than in *Chlamydia*-negative men with gonorrhea. The rate of postgonococcal urethritis is especially low if a drug such as tetracycline, which also is effective against chlamydiae, is used to treat men with gonococcal urethritis. Thus some men have simultaneous urethral infections with both gonococci and chlamydiae. Because of the shorter incubation period, such patients may develop symptoms of gonorrhea and seek treatment during incubation of their chlamydial infections. Postgonococcal urethritis develops if a drug with no effect against *C. trachomatis* is used for therapy.

Diagnosis

Many methods have been used for laboratory diagnosis of chlamydial infections. Older urologists are familiar with delayed hypersensitivity tests, such as the Frei test, that used a crude antigen preparation to diagnose LGV (316). Variability between antigen lots, cross-reactivity between common antigens of LGV and non-LGV strains of *C. trachomatis,* and availability of more sensitive and specific methods have supplanted use of delayed hypersensitivity tests. Cytologic staining procedures, such as Papanicolaou's stain, also have been used to demonstrate chlamydial inclusions in clinical specimens (316,318). Although useful in diagnosing acute chlamydial ophthalmia neonatorum (128), cytologic methods cannot be recommended to diagnose other clinical syndromes because of their low sensitivity. For example, the accuracy of cytology is only 15% to 20% for diagnosis of chlamydial urogenital tract infections (316,318). Serologic tests are another way to diagnose chlamydial infections. In routine clinical situations such tests are not useful because of the high background prevalence of antichlamydial antibodies in most populations (316,318,384). Although almost all culture-positive patients have antibodies, many culture-negative patients also have positive reactions. Thus a positive serologic test for chlamydiae has low predictive value for current infection. There are certain situations in which serologic tests may have value. A negative serologic test should have a high predictive value for ruling out past chlamydial infections (316). In patients with initial attacks of NGU and few past sexual partners, it may be possible to document seroconversion (29). Serodiagnosis is also useful in cases of chlamydial pneumonia in infants (128) and in diagnosing LGV (316).

Isolating the organisms in culture is the traditional gold standard for diagnosing chlamydial infections. Unfortunately, culture techniques are slow and take a major commitment of laboratory resources and personnel. Early studies used yolk sac isolation procedures taking up to 6 weeks and thus were not useful clinically (157,158,316). Tissue culture methods for *C. trachomatis* were a major advance that permitted screening of large numbers of specimens, with results of initial isolation attempts within 48 to 72 hours (118). Because chlamydiae are obligate intracellular parasites, highest isolation rates are obtained from specimens containing as many epithelial cells as possible (342). Optimal specimens from men with urethritis may be obtained with thin urogenital swabs on an aluminum shaft to obtain intraurethral scrapings, which are preferred to specimens of purulent discharges, secretions, or urine (342). Refrigerated specimens should be transported to the laboratory within 24 hours because inclusion counts decline rapidly after that period. The clinical specimens are inoculated onto tissue culture cell monolayers that have been treated with antimetabolites or radiation to inhibit host cell replication. Mature chlamydial inclusions then are detected in infected cells with iodine, Giemsa, or immunofluorescent stains (342,370). Widespread availability of these methods has been limited by the expense and time needed to isolate *C. trachomatis* in culture.

Automated molecular methods for detecting amplified *C. trachomatis* DNA or RNA are an important advance in chlamydial diagnostics (345). The most widely used methods depend on the ligase chain reaction (LCR) or the polymerase chain reaction (PCR). In high-risk populations, both approaches have proven effective for evaluating urethral and urine specimens. The specificity of these methods has consistently been above 99% (36,71,110,289). LCR and PCR target nucleotide sequences on the *C. trachomatis* plasmid, which is present in multiple copies within each elementary body (317,345). Among high-risk males, these methods have 87% to 100% sensitivity for testing first-void urine. Such molecular approaches detected up to approximately 40% more infections than urethral culture in some studies.(289).

Other approaches to diagnosing chlamydial infections include enzyme immunoassays and PCR and LCR assays (6,94,111,115,130,155,221,323,325,326,328). Each of these techniques offers advantages of speed and sensitivity and obviates routine tissue culture to diagnose chlamydial urethritis. The sensitivity of these new diagnostic methods can exceed that of culture under certain circumstances. Thus screening of urine specimens as an alternative to urethral swabs can be used to evaluate high-risk populations (112,130,155,325,326).

Treatment

Various techniques for *in vitro* susceptibility testing of *C. trachomatis* have been proposed, but there is no widely accepted method (246,314,318,373). The tissue culture assays are in general agreement in demonstrating that the most effective drugs against *C. trachomatis* are rifampin and the tetracyclines (317,345). The macrolides, sulfonamides, some quinolones, and clindamycin are somewhat less effective (246,298,314,316,317,342,373).

Based on clinical data, drugs in the tetracycline and azalide classes are considered the first-choice regimens for uncomplicated *C. trachomatis* infections in adults (Table 39.3) (26,47,48,316,370). Using the tetracyclines, treatment for 7 days or longer appears superior to shorter courses.

Recommended regimens
Azithromycin 1-g single oral dose
Doxycycline 100 mg orally twice a day for at least 7 days
Alternative regimens (if tetracyclines and azithromycin are contraindicated or poorly tolerated)
Erythromycin base 500 mg orally four times a day for at least 7 days
Erythromycin ethylsuccinate 800 mg orally four times a day for at least 7 days
Ofloxacin 300 mg orally twice daily for at least 7 days
Special considerations (if only erythromycin can be used but the patient cannot tolerate high-dose schedules)
Erythromycin base 250 mg orally four times a day for 14 days
Erythromycin ethylsuccinate 400 mg orally four times a day for 14 days

Adapted from 1998 Guidelines for treatment of sexually transmitted diseases. Centers for Disease Control, 1998. JAMWR 1998;47(RR-1):1, with permission.

TABLE 39.3. TREATMENT FOR NONGONOCOCCAL URETHRITIS

Doxycycline (100 mg orally twice a day) for at least 7 days is a highly effective and inexpensive regimen (72). Azithromycin (1 g orally as a single dose) offers the advantages of a single-dose oral regimen. Treatment with erythromycin (500 mg orally four times a day) or ofloxacin (300 mg orally twice a day) for at least 7 days is an alternative for patients in whom tetracyclines are contraindicated or not tolerated (48,258,303). In contrast to ofloxacin, another fluoroquinolone, ciprofloxacin, had unacceptable failure rates when used to treat chlamydial urethritis in men (147,258,303).

Although some patients have not responded to treatment with tetracycline, the recovered organisms were susceptible *in vitro,* and resistance to tetracycline has not yet been demonstrated in clinical isolates (316). Some studies suggest that occasional isolates of *C. trachomatis* have developed resistance to erythromycin *in vitro,* but this has not reached clinically significant levels (246,316). The sulfonamides are effective both in laboratory studies and clinically for treating patients with trachoma and LGV (318,378). The sulfonamides have not been evaluated extensively for treating other chlamydial genital tract infections because they are not active against other microorganisms that cause similar diseases (47,269,316,318).

Single-dose treatment with azithromycin (1 g by mouth), a new azalide drug, proved effective for uncomplicated *C. trachomatis* infections in a number of recent studies (149,227,252,340,346,395). Single-dose treatment is attractive because such therapy can be administered under supervision to increase patient compliance. Although azithromycin is more expensive than the tetracyclines, this drug is now considered one of the first-line treatments for chlamydial infection (50).

There is no indication for treatment of chlamydial infections with other classes of antimicrobials. Drugs in the penicillin and cephalosporin groups have some activity *in vitro* against *C. trachomatis* but are not useful clinically (25,314,316). Studies in animal models imply that dosages of 20 to 30 million units of penicillin per day would be necessary for clinical efficacy. Occurrence of postgonococcal urethritis amply illustrates the ineffectiveness of suboptimum dosages of drugs in the penicillin class to treat chlamydial urethritis. Rifampin is also active against *C. trachomatis* in tissue culture assays. However, other laboratory studies indicate that chlamydiae rapidly develop resistance to rifampin. There are no current indications for this drug to treat chlamydial infections (67,179,316). Aminoglycosides have no effect against *C. trachomatis* and are widely used to prevent bacterial contamination during growth of chlamydiae in culture. Other antimicrobials, such as cephalosporins, antifungal antimicrobials, and nitroimidazoles, are inactive against chlamydiae (314,320).

Careful evaluation of men with chlamydial urethritis for simultaneous infection with other sexually transmitted pathogens is an important aspect of treatment. Particular attention also should be directed to evaluating and treating sexual partners. Women who are partners of men with NGU should be treated empirically for chlamydial infections with one of the regimens in Table 39.3 (47,52,342). At least 33% have positive cultures, and many infected women are asymptomatic. The doxycycline and azithromycin regimens described earlier are the first choice unless the patient is pregnant. Erythromycin is the treatment of choice for women who are pregnant or possibly pregnant.

U. urealyticum

Biology

U. urealyticum is one of the mycoplasmas, a diverse class of organisms isolated from numerous members of the animal kingdom (101,359). The mycoplasmas are aerobic bacteria that may be cultivated in complex artificial media (178). The organisms are membrane bound but do not appear on Gram stain (178). Although a number of species have been isolated from humans, most attention has been directed to three species: *Mycoplasma pneumoniae,* a major cause of primary typical pneumonia; *M. hominis;* and *U. urealyticum,* commonly isolated from urogenital tract sites. *U. urealyticum* were formerly known as the *T-strain mycoplasmas* because of their characteristic “tiny” colonies when grown on standard media to isolate mycoplasmas. These organisms were renamed *U. urealyticum* because they are distinguished from other mycoplasmas by their ability to hydrolyze urea, which is a growth-limiting requirement (177,178,331), and because they are the only mycoplasmas inhibited by high concentrations of ammonium (313). The genital mycoplasmas and ureaplasmas are the smallest-known free-living microorganisms. They may be cultured with both solid and liquid media (108). On most solid media the colonies produced by *U. urealyticum* are smaller than those of the other classic mycoplasmas and have a characteristic appearance. A positive reaction for urease activity is used to confirm that colonies with characteristic morphology represent ureaplasmas (108). Because ureaplasmas can be cultured in liquid media without producing the turbidity characteristic of other bacteria, a pH indicator and urea are incorporated into the media (108,330). Breakdown of urea to ammonia results in a change in color of the indicator. There are at least 8 to 14 distinct serotypes of *U. urealyticum* (108,217). However, different systems for serotyping have been described, and there are no generally accepted methods. To date there are no convincing data that particular *U. urealyticum* serotypes are associated with distinct disease syndromes (108,359).

Epidemiology

Neonates are commonly colonized with genital mycoplasmas during vaginal deliveries, but neonatal colonization tends to be transient (108,184,359,362). Cultures of urine or genital specimens from prepubertal boys are rarely positive for the genital mycoplasmas (100,108). Similarly, sexually mature patients with no history of sexual contact are seldom colonized with ureaplasmas or *M. hominis.* Among sexually experienced people the incidence of colonization increases in proportion to the number of sexual partners. In one study of normal men the incidence of colonization with ureaplasmas was 3%, 19%, 41%, and 56% among men with 0, 1, 3 to 5, and more than 14 partners, respectively (232). Black race and lower socioeconomic status have been associated with a higher prevalence of ureaplasmas (108,361). These findings indicate that asymptomatic genitourinary tract carriage of ureaplasmas is remarkably common in adult men.

Evaluation of the importance of *U. urealyticum* as a cause of NGU must account for the high background prevalence of colonization among asymptomatic men (359). Patients and control subjects must be matched carefully for previous sexual experience; comparisons of cloistered monks and patients attending sexually transmitted disease clinics are inappropriate. In addition, laboratory evaluation must include cultures for both *N. gonorrhoeae* and *C. trachomatis,* which are clearly urethral pathogens. For these reasons it is difficult to evaluate most studies of the role of *U. urealyticum* in NGU done before the mid-1970s.

Three lines of evidence support the viewpoint that *U. urealyticum* is an important cause of *C. trachomatis*–negative NGU: isolation studies, antimicrobial treatment studies, and urethral inoculation studies. In some investigations, ureaplasmas were isolated significantly more often from patients with nonchlamydial NGU than from men with *C. trachomatis*–positive urethritis or control populations (29,287,404). However, other investigations have not supported these findings (140,361). Another approach was to compare the numbers of ureaplasmas in men with NGU and in asymptomatic men. In one study of 69 men with NGU, 11 (16%) had both *C. trachomatis* and *U. urealyticum;* 15 (22%) had *C. trachomatis* only; 35 (51%) had *U. urealyticum* only; and 8 (12%) had neither organism (28). Colony counts of *U. urealyticum* were higher in men with nonchlamydial NGU than in men with chlamydial urethritis or matched control populations without urethritis. These data are consistent with the view that larger numbers of ureaplasmas are present when ureaplasmas are urethral pathogens than when they are commensal organisms (28,29,108).

Antimicrobial treatment studies, in which ureaplasmas were selectively eliminated, support the idea that ureaplasmas may be pathogens in NGU (22,257). Some drugs, such as sulfonamides and rifampin, are effective against *C. trachomatis* but not against *U. urealyticum* (22,362). Other drugs, such as spectinomycin and streptomycin, are ineffective for treating *C. trachomatis* but active against *U. urealyticum* (257,362). *C. trachomatis*–negative, *U. urealyticum*–positive NGU responded poorly to treatment with sulfonamides or rifampin (23,67). In contrast, treating similar patients with spectinomycin or streptomycin resulted in elimination of *U. urealyticum* and good clinical responses in most instances (23). In other studies, presence of tetracycline-resistant strains of *U. urealyticum* was associated with persistent urethritis in patients treated with tetracyclines or minocycline (90,305,349).

Intraurethral inoculation was used to fulfill Koch's postulates, demonstrating that ureaplasmas may cause NGU. The authors of one study (360) inoculated themselves with *U. urealyticum* isolates from patients with NGU. Both men developed objective evidence of urethritis. Intraurethral inoculation of primates was associated with colonization with *U. urealyticum* for varying periods and with polymorphonuclear leukocytes on urethral smears from some animals (27,363).

On balance, these data support a role for *U. urealyticum* as an opportunistic pathogen in some cases of NGU (36,359). Some authors maintain that ureaplasmas may be responsible for 30% to 40% of NGU (21,22). However, these organisms also may be isolated from the urethras of many men who have no symptoms or signs of urethritis (232,362). Thus the precise proportion of NGU attributable to *U. urealyticum* is unknown. In urologic practice this proportion appears to be significantly lower than 30%. It is also apparent that isolating *U. urealyticum* from a man with NGU is not equivalent to demonstrating that ureaplasmas are pathogens in that case (108).

Diagnosis and Treatment

Culture systems for isolating *U. urealyticum* are not generally available. Thus diagnosis depends primarily on clinical recognition of syndromes, such as *C. trachomatis*–negative NGU, that can be caused by *U. urealyticum* (359).

The tetracycline and macrolide drugs are most commonly used to treat *U. urealyticum* infections (21,359,365). Because tetracyclines are also the treatments of choice for *Chlamydia*-positive NGU, many strains of ureaplasmas are eliminated simultaneously by such wide-spectrum antimicrobial therapy. Tetracycline-resistant *U. urealyticum* constitute 10% or more of strains in some studies (90,108,349). Tetracycline resistance is caused by the *tet M* plasmid, the same plasmid that codes for tetracycline resistance in *N. gonorrhoeae* (301). Isolating tetracycline-resistant strains from patients with NGU has been associated with lack of response to tetracycline therapy (90,349). Re-treatment with erythromycin is recommended for such patients. A reasonable recommendation is erythromycin stearate 500 mg orally four times daily for at least 7 days, or equivalent dosages of other forms of erythromycin (22). The newer macrolides or quinolones have also been suggested for treating tetracycline-resistant organisms (359). There is little indication for treatment of NGU with the combination of an aminocyclitol (active against ureaplasmas) and a sulfonamide (active against chlamydiae). Drugs such as trimethoprim-sulfamethoxazole or the penicillins are inactive against ureaplasmas.

If cultures for *U. urealyticum* are available, the indications for obtaining such information are not clear-cut. Obtaining routine cultures for *U. urealyticum* can be recommended only in research settings because many perfectly normal, sexually experienced men have positive cultures. Considering ureaplasmas as the primary cause of urethritis in such situations is not warranted (108,232). Obtaining cultures for ureaplasmas from men with *C. trachomatis*–negative NGU who have not responded to conventional therapy may be more reasonable, especially if sensitivity testing is available. In this situation it is more likely that ureaplasmas may be pathogens, and documenting antimicrobial resistance may direct therapy.

Chlamydia-negative, Ureaplasma-negative NGU

Clearly there are patients with NGU in whom neither *C. trachomatis* nor *U. urealyticum* is implicated as a pathogen. Crude estimates may be made about the size of this group of patients. As summarized earlier, *C. trachomatis* has been recovered from the urethras of 25% to 60% (usually 30% to 40%) of men with NGU (21,22). Several lines of evidence suggest that chlamydiae are rarely responsible for NGU in men whose initial cultures are negative. Repeated cultures in untreated men with negative cultures usually are also negative, and such patients rarely have serologic evidence of recent infection with *C. trachomatis* (28,29,124). Chlamydiae are rarely isolated from cervical specimens from sexual partners of patients with negative urethral cultures (140,213,268). Finally, men with *C. trachomatis*–negative NGU usually respond poorly to treatment with antimicrobials effective against *C. trachomatis* (23,29,67,124,148). *U. urealyticum* has been implicated as a pathogen in at most 20% to 25% of patients with NGU (22). Thus neither chlamydiae nor ureaplasmas are implicated in 20% to 50% of cases of NGU. A large number of these patients consult urologists for evaluation.

A wide variety of microorganisms are considered potential pathogens in *C. trachomatis*–negative, *U. urealyticum*–negative NGU. There is good evidence that some organisms, such as *Trichomonas vaginalis,* herpes viruses, and human papillomavirus (HPV), may cause urethritis in men, but the proportion of NGU attributable to infection with these organisms is uncertain. Many other organisms (Table 39.1) also have been associated with NGU in some studies. In the following sections we consider the varied causes of *C. trachomatis*–negative, *U. urealyticum*–negative NGU and appropriate therapy, when indicated, for these infections.

T. vaginalis

Epidemiology and Pathogenesis

The significance of *T. vaginalis* as a cause of genitourinary tract disease in men is controversial (193,206). Many European studies identify *T. vaginalis* as a major cause of morbidity (160,193). Urologic diseases attributed to trichomoniasis include NGU (69,134,392,400), prostatitis (207,209), urethral stricture disease (44,392), balanoposthitis (142), epididymitis (96), and infertility (376).

In epidemiologic studies, NGU was the syndrome most closely associated with *T. vaginalis* (142,193,206). Men with no genitourinary complaints are rarely infected with *T. vaginalis* (209,396). In other studies, *T. vaginalis* was isolated from 1% to 18% of men with gonococcal urethritis (193,388,396). Trichomonads were isolated most often from men with NGU: In one review of 12 studies, 1% to 68% of such patients were infected with *T. vaginalis,* with a mean prevalence of 11% (193). In clinical studies, approximately 16% of sexual contacts of women with trichomonal vaginitis developed NGU within 3 to 8 days (68,69). In another study, Weston and Nicol (392) evaluated 206 sexual contacts of women with trichomoniasis: 93 developed NGU within 5 days. During follow-up studies without therapy, 50% were clear of their infections within 2 weeks, whereas the remaining patients had persistent infections. The prevalence of trichomoniasis was especially high, up to 85%, in men who had not responded to multiple courses of antimicrobials and who had long-standing symptoms (142,193,209). As a rule, these studies suffer from several methodological problems. Control groups generally were inadequate or were poorly matched with cases. In addition, most studies did not investigate other potential pathogens, such as *C. trachomatis,* that may cause NGU.

The alternative viewpoint is that *T. vaginalis* rarely causes symptomatic disease in men (193). In several studies using methods for isolating multiple pathogens, *T. vaginalis* was an unusual cause of acute urethritis (21,22,140). Most of these investigations were concerned primarily with other pathogens, and evaluation for *T. vaginalis* was included primarily for completeness. Thus negative results for fastidious pathogens such as trichomonads must be interpreted cautiously. One potential explanation for the benign and apparently self-limited nature of trichomonal infection in many men is that *T. vaginalis* strains are killed rapidly by zinc salts and other components of prostatic secretions (201,202).

Current ethical standards precluded repetition of human inoculation studies performed from 1940 to 1955, a period before effective antitrichomonal therapy. These studies fulfilled Koch's postulates for *T. vaginalis* as a human pathogen in both sexes (132,212). Of particular interest is the study by Lancely and McEntegart (212), who inoculated five subjects intraurethrally with *T. vaginalis*. Three developed urethral discharge containing protozoa, whereas two had mild urethritis without cultivable organisms. Five control patients inoculated with sterile growth medium showed no abnormalities.

Several recent studies may help resolve these issues. A comprehensive investigation of 447 sexually active heterosexual men found that men with trichomoniasis were significantly more likely to complain of urethral discharge, to have discharge on examination, and to have inflammatory cells in their urethral secretions. *T. vaginalis* remained associated with nongonococcal nonchlamydial urethritis after adjustment for race, age, number of sex partners, exposure to a partner with trichomoniasis, and history of trichomoniasis, urethritis, or gonorrhea (199). Besides nonchlamydial NGU, trichomoniasis was associated with sexual contact with an infected woman and a history of treatment for trichomoniasis or NGU (203). A longitudinal study found that spontaneous resolution occurred in 36% of untreated men, but one asymptomatic man had persistence of *T. vaginalis* throughout a 4-month period (204). Nongonococcal nonchlamydial urethritis was documented in 12 of 21 men (57%) at the visit before treatment or spontaneous resolution, compared with only 2 (10%) after elimination of *T. vaginalis* (p <.001).

On balance, these data support the idea that *T. vaginalis* may cause NGU in some men, particularly patients with disease that is unresponsive to conventional

antibacterial therapy or that is long-standing (36). It is also possible that geographic variations in antigenic composition of the parasite (197) or differences in intrinsic virulence of various strains (200,210) may explain apparent differences in clinical presentation of male trichomoniasis in various studies. Clearly, the importance of trichomoniasis as a cause of morbidity in men merits further investigation.

Diagnosis and Treatment

Routine evaluation for trichomoniasis is not indicated for men with uncomplicated, acute NGU (21,22,36,294). However, there are groups of men with NGU who merit investigation for *T. vaginalis,* particularly patients with urethritis that has been unresponsive to previous antibacterial therapy, including tetracyclines; men with long-standing symptoms; or patients whose partners have signs or symptoms suggesting trichomoniasis (36,193,292,294).

Diagnosis based solely on the clinical picture is unreliable because symptoms and signs associated with trichomonal urethritis significantly overlap the clinical picture of NGU caused by other pathogens. Diagnosis of trichomoniasis traditionally has depended on direct microscopic identification of motile parasites (142,193,292,294). Most often, a saline wet mount of urogenital secretions or freshly voided urine is examined. Best results are obtained by evaluating specimens with phase contrast or by racking down the condenser of a standard bright-field microscope (292). In expert hands, these methods have a 60% to 70% sensitivity in women when compared with culture but are much less reliable in men (193,196,310). Various staining procedures have been used by different workers. However, such techniques have few advantages over careful examination of the saline wet mount (142,193,229,352). Culture techniques using various liquid and semisolid media proved most accurate for diagnosing trichomoniasis in clinical studies (76,114,136,396). Unfortunately, reliable culture systems are unavailable in most clinical microbiology laboratories. Developing broad-spectrum monoclonal antibodies against *T. vaginalis* has promise for direct diagnosis of protozoa in clinical specimens (196,198). However, molecular detection methods are even more promising (379).

Metronidazole is the treatment of choice for *T. vaginalis* infections in both men and women (105,193,294). Metronidazole is the prototype of the 5-nitroimidazole class of antimicrobials. These drugs have selective activity against anaerobic protozoa and bacteria because the metabolic pathways in such organisms reduce the nitro group producing toxic metabolites (193,294). Aerobic and facultatively anaerobic organisms may absorb metronidazole but do not metabolize the drug. *T. vaginalis* organisms resistant to high levels of metronidazole have been isolated from patients with refractory trichomoniasis (238,239). Unfortunately, alternative therapy has been limited to other 5-nitroimidazole drugs, which offer no particular therapeutic advantages (193,196,294).

Although some studies have been done in men (45,135,355), most studies evaluating treatment of trichomoniasis have been done in women (105,294). The conventional treatment has been metronidazole 250 mg orally three times daily for 7 days, resulting in cure rates of approximately 95% (291). Several studies using a single oral dose of 2 g of metronidazole have reported cure rates of 85% or more (83,98,204,291).

Trichomoniasis is common in sexual partners of infected women. In one study (392), *T. vaginalis* was isolated from 70% of men who had contact within the past 48 hours. At 2 weeks after the last sexual exposure, 30% remained infected. Simultaneous treatment of male sexual partners of infected women has not been shown to affect the cure rate with the long course of therapy (291). This presumably is related to spontaneous clearance of infection in many asymptomatic men. Simultaneous treatment of sexual partners increases the cure rate with single-dose metronidazole therapy (83,122,291). In addition, treatment is recommended for asymptomatic partners of infected women for epidemiologic reasons and because the long-term effects of a chronic inflammatory focus in the male genitourinary tract are unclear (294). Infected men who have symptoms of NGU, prostatitis, or other urologic conditions need specific therapy. Patients with trichomoniasis and their partners also should be evaluated for other sexually transmitted diseases and treated appropriately.

Viruses

NGU is associated with two viruses: herpes simplex virus (HSV) and HPV.

Genital Herpes Infections

Biology

The term *herpes* originated from the Greek verb meaning “to creep.” *Herpes* is the family name for a group of viruses that infect a wide range of vertebrate and invertebrate species (282,337). The herpes viruses contain linear double-stranded DNA and possess a distinctive morphology and characteristic lipid envelope (337). To date, eight human herpes viruses have been identified: varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, HSV type 1 and type 2 (HSV-1 and HSV-2), and human herpes virus types 6, 7, and 8 (282).

The herpes viruses share several characteristics, including the capacity to cause primary infection in anyone and viral latency and reactivation, with the ability to cause both asymptomatic and symptomatic infections (7). Sexual contact is a significant mode of transmission with cytomegalovirus, HSV-1, and HSV-2. Infection with HSV-1 and HSV-2 may cause urogenital lesions, and both viruses have been associated with NGU (59,60 and 61,63).

Epidemiology

Genital herpes is one of the three most prevalent sexually transmitted infections in the United States (with chlamydial and HPV infections) and, apart from AIDS, probably is of most concern to sexually active people (62). Studies suggest that the incidence of genital herpes increased during the last three decades (59,66). Current estimates suggest 270,000 to 600,000 new cases of genital herpes per year in the United States (12,250). Other estimates indicate that 31 million people in the nation are infected with genital HSV (254). Genital HSV infections are responsible for almost 250,000 initial visits to physicians' offices per year (49). Serologic studies suggest that the prevalence of antibodies to genital herpes is approximately 22% in the general U.S. population, meaning that as many as 45 million people may be infected (62).

The highest prevalence of clinically diagnosed genital herpes is in middle- and upper-class whites (59). In inner-city clinics for sexually transmitted diseases, herpes is diagnosed only one-tenth as often as gonorrhea (349). In contrast, student health clinics treating middle- and upper-class young adults report infections with genital herpes seven to ten times more often than gonorrhea (351). Similar reports from Scandinavia and Japan confirm that genital herpes infections occur most often among single, well-educated patients in their midtwenties (59,171,335).

Transmission of HSV infections usually occurs by close contact with a person who is actively shedding viral particles at a peripheral site, mucosal surface, or secretion (59,60 and 61,63). Genital infections may be transmitted during periods of both symptomatic and asymptomatic viral shedding (66,240). Asymptomatic shedders of virus appear to be important in transmitting HSV genital infections. After primary infection, herpes viruses may enter a stage of latency involving dorsal root ganglia (59,337). Subsequent reactivation may occur despite the presence of circulating antibodies and sensitized lymphocytes (65). Reactivation usually is associated with skin lesions (vesicles) that tend to occur in the same location. The intervals between bouts of recurrent disease vary widely among infected patients.

Clinical Findings

The clinical manifestations of genital HSV infections are highly variable and are determined largely by whether the infected person is experiencing an initial episode of infection or recurrent disease (59,63,65,66,394). First episodes of genital herpes infections may be considered in two groups, depending on whether patients have clinical or serologic evidence of prior HSV infections (59,65). Patients with primary genital herpes lack evidence of previous HSV infection. Primary genital herpes often is associated with systemic symptoms involving multiple genital and extragenital sites, prolonged viral shedding, and lesions. Urethral discharge and dysuria may occur with either HSV-1 or HSV-2 infections. The best data are available for patients with primary HSV-2: 44% of men experienced dysuria, and 27% had urethral discharge, lasting a mean of 6 to 7 days (59). In such patients, HSV may be isolated from both urethral swabs and first-voided urine specimens. The discharge usually is clear or mucoid in character and has a typical appearance of NGU on Gram stain. Patients who have first clinical episodes of genital herpes but who also have clinical or serologic evidence of previous HSV infections usually experience milder disease than patients experiencing true primary genital herpes.

Approximately 80% of patients with HSV-2 infections experience recurrences after primary genital infections (66). This is higher than the 50% recurrence rate for patients with HSV-1 primary genital infections. Thus the proportion of patients with HSV-2 genital infections tends to increase with time. Recurrent genital herpes is less severe than initial infections (59,60 and 61,63,290). The disease is localized to the genital area. Symptoms are milder and of shorter duration. Dysuria or urethral discharge occurs less often, 9% and 4%, respectively, in one study (59).

NGU caused by genital herpes infections is characteristically associated with external genital lesions. Clinical differentiation of herpetic lesions from other causes of genital ulceration may be difficult (59,60 and 61,63). Patients with urethritis and genital lesions may also suffer from many possible combinations of infectious conditions. Thus laboratory confirmation of the diagnosis is recommended for patients in whom a definitive diagnosis cannot be made (59,60 and 61,63). Specific diagnosis is also helpful in certain situations, such as planning treatment with acyclovir, diagnosing atypical lesions, and educating patients about the risk of transmission (7,66).

Diagnosis and Treatment

Clinical differentiation of genital herpes infection from other genital infections can be difficult. If the patient has multiple grouped vesicles or if there is a history of previous lesions of similar size, duration, and character, then HSV is likely. However, diagnostic testing is recommended because multiple infectious pathogens may be present, to support partner notification and evaluation, and because typing of the viral isolate has prognostic implications.

Isolating HSV in tissue culture is the most sensitive and specific way to diagnose genital herpes infection (59,60,61 and 62). Improved culture methods can diagnose herpes virus infections in 24 to 48 hours (7). Cultures are especially accurate for vesicular lesions but have substantially lower sensitivity for diagnosis of crusted lesions (7). Other diagnostic techniques using antigen detection, PCR, or serologic methods may be useful in some clinical situations, as in patients with crusted lesions or in population surveys (66).

Systemic antiviral chemotherapy for genital HSV can partially control signs and symptoms of primary and recurrent infections and can reduce the frequency of recurrent episodes (52,66). Treatment does not eradicate latent virus and does not affect the risk frequency or severity of recurrences when treatment is discontinued.

Three drugs have been proven effective in randomized clinical trials: acyclovir, famciclovir, and valacyclovir (52,66). The antiviral compound acyclovir has the longest clinical record (59,247). Acyclovir is a nucleotide analog that is selectively phosphorylated by viral-directed thymidine kinase, forming acyclovir monophosphate (64,217,219). Intravenous acyclovir is useful for treating severe infections (60,61,63,312). Oral acyclovir capsules, administered in several dosage regimens, shortened the course of both initial and recurrent genital HSV infections and were effective in reducing the frequency of recurrences (33,62). Valacyclovir is a valine ester of acyclovir that has enhanced absorption after oral administration. Famciclovir, the prodrug of penciclovir, also has high bioavailability after oral administration and high efficacy. Because topical therapy with acyclovir is less effective than systemic treatment, this route of administration is discouraged. Recommended treatment regimens are summarized in Table 39.4.

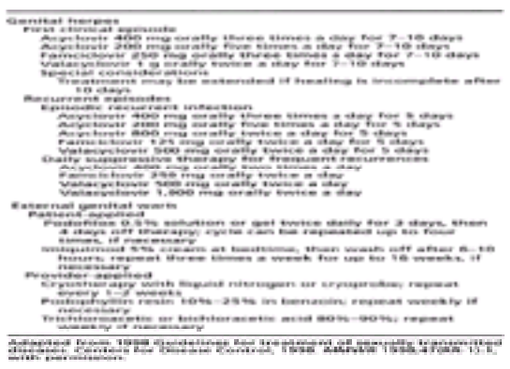

TABLE 39.4. MEDICAL TREATMENT FOR GENITAL VIRUS INFECTIONS

Although antiviral therapy may be effective in promoting lesion healing and reducing symptoms, an effective vaccine would be the best approach (3,59,66,337). Heterologous vaccines to other viruses proved ineffective for treating patients with HSV infections. Inactivated HSV vaccines are currently in use in Europe. However, there have been no well-controlled clinical studies of these vaccines. Many authorities in this country are concerned about the oncogenic potential of viral genetic material present in the inactivated virus vaccines. Thus inactivated vaccines are unavailable in the United States. Development of purified subunit HSV vaccines is an active area of research (3,59,282).

Human Papillomavirus

Biology

Genital warts, also known as *venereal warts, gonorrheal warts, condyloma acuminatum,* and *fig warts,* are caused by HPV (224,256,259). These double-stranded DNA-containing viruses also cause warts in other locations, including plantar and palmar surfaces, skin, larynx, and oral and anal cavities (107,189,256,260). After infection of a susceptible cell, the virus stimulates rapid cell division with duplication of the virus (225). Released viral particles are then transmitted by autoinoculation to other anatomic areas and to other people who contact the infected site (46,225,259).

There was little progress in this field until the late 1970s. Although HPV still cannot be cultivated in the laboratory (107,152,189), advances in molecular biology led to cloning of the HPV viral genetic material and logarithmic increases in our understanding of these viruses (93,152,390). Because much new information is in the general medical and gynecology literature, we briefly summarize important findings and then discuss specific urologic issues.

To date more than 80 distinct HPV types have been described. These are called *genotypes* because classification depends on DNA composition rather than structural antigenic characteristics. More than 30 HPV genotypes infect the urogenital tract predominantly (95,107,189). Genital HPV genotypes may be considered low, intermediate, or high risk for malignancy. HPV types 6, 11, 42, 43, and 44 are associated with low risk (95). Classic, exophytic genital warts usually are caused by HPV types 6 and 11. In addition, these genotypes are associated with low-grade cervical dysplasia (CIN I to II). HPV types 31, 33, 35, 45, 51, 52, and 56 are associated with an intermediate risk for genital malignancy. These genotypes usually are found in low-grade cervical dysplasia and occasionally in high-grade dysplasia and cancers. HPV types 16 and 18 are associated with a high risk of malignancy. These HPV types are seldom found in patients with obvious clinical lesions but often found in genital cancers and high-grade cervical dysplasia (CIN III). Other HPV types have been identified in the urogenital tract, but it is not yet possible to definitely assess their role in neoplasia.

Several lines of evidence support the association between HPV and genital tract cancers. Women with cervical cancer are significantly more likely to have HPV infections than control subjects. In some studies, more than 50% of cervical, vulvar, vaginal, and anal cancers contain HPV types 16 and 18 DNA (116,152). HPV DNA has been identified in cervical cancer metastatic to lung, pelvis, and lymph nodes (37,104). HPV can transform or make normal cells immortal, a critical characteristic of malignancy (107,189).

Three key points from the gynecology literature deserve emphasis. First, although cervical HPV infection is strongly associated with dysplasia and cancer, HPV DNA can be detected in up to 15% of women with normal cervical cytology. Second, HPV types 16 and 18 are the genotypes found most often in women with cervical cancer. Whether women with HPV 16 or 18 and normal cervical cytology are at risk for dysplasia and cancer is uncertain at present. Third, there is no clear evidence that treating asymptomatic male sexual partners changes the natural history of genital HPV infections in women. In fact, limited data suggest that treating subclinical HPV infections in such men makes little or no difference (300).

Epidemiology

Since 1968, there has been a substantial increase in the number of patients with exophytic venereal warts. Recent estimates indicate that there are 24 million people infected with genital HPV infection in the United States (254) and that genital HPV infections are responsible for approximately 300,000 initial visits to physicians' offices per year (49). The annual number of patient visits to physicians for this condition has leveled off at 1 million in the United States; this figure includes more than 64,000 urologic consultations (47,224,245). Epidemiologic evidence supports the idea that genital warts are transmitted sexually in almost all cases (9,109,255).

Approximately two-thirds of sexual contacts of infected patients develop similar lesions (9,224,255,256). The usual incubation period appears to be 1 to 2 months but may be up to 9 months in some cases (224,256).

Clinical Findings

As a rule, condylomata occur in areas where stratified squamous epithelium is thin, or on mucous membranes, and have a characteristic appearance, as described in the chapter on skin diseases. Presence of external warts is considered an indication for internal examination by urethroscopy, anoscopy, or speculum because up to 50% of such patients also have internal lesions (224,256). Intraurethral warts often are associated with complaints of urethral discharge, dysuria, bloody spotting on undergarments, or initial hematuria (Fig. 39.3) (21,22,106,225,256,259,292). Most exophytic intraurethral warts are located in the distal urethra (237,368). Cases have been described of intraurethral spread of condylomata to involve the bladder and ureter (251,283,409). HPV viral antigen also has been described in bladder tumors (32). However, in our (unpublished) experience, NGU is an unusual presentation of intraurethral condylomata in patients without visible lesions on the external genitalia or fossa navicularis. HPV infection has been associated with carcinomas of the penis and scrotum (34,284,309).

FIGURE 39.3. Normal external genitalia in patient with gross, painless hematuria. **B:** Intraurethral condyloma acuminatum visible only on careful inspection of the fossa navicularis.

Subclinical HPV infection is a new clinical problem. These infections occur in asymptomatic men who are sexual partners of women with HPV. Diagnosis of HPV infections in women is facilitated by characteristic cytologic findings and specific probes for HPV DNA (182,390). After acetic acid is applied, characteristic white areas may be identified on the external genitalia of most sexual partners (216,410). HPV DNA probes and cytology may also help identify urethral infections in such men (241,308,410). The HPV genotypes most often identified are 16 and 18, which are associated with the highest risk for malignancy. Normal tissue also may be infected with HPV (93,220). There is a strong temptation to treat such men aggressively with subclinical infections. The problems with this approach include treatment-associated morbidity, which may be substantial; difficulties in defining the necessary extent of treatment; high recurrence rates; and no evidence that aggressive treatment for subclinical disease alters the natural history of HPV infection in female sexual partners (52,300,410). Thus insufficient data are available to define optimum strategies for managing subclinical HPV infections, but most experts recommend that these men receive no treatment (52).

Medical Treatment

Various treatments for genital warts have been used, but there have been few well-controlled clinical studies (Table 39.4) (52). None of the currently available treatments is completely satisfactory. Caustic agents, such as 10% to 25% in compound tincture of benzoin, are the traditional therapies. Podophyllin has several substantial limitations: Often, several applications are needed; systemic absorption may be associated with toxicity, particularly if the drug is applied to mucosal surfaces; there is potential for stricture formation; and there is a high rate of recurrence. Currently, podofilox, an antimitotic agent, is recommended for self-administered outpatient therapy for exophytic genital warts (50). A 0.5% solution is applied to the lesions twice daily for 3 days, followed by 4 days without treatment. If necessary, the 1-week cycle can be repeated up to four times. Adverse reactions occur in most patients treated with podofilox, especially burning, pain, inflammation, and itching. Data are unavailable on podofilox treatment of warts in the perianal area or genital mucous membranes (urethra, rectum, or vagina). Alternative modes of therapy include surgical excision, cryotherapy, laser therapy, and electrocautery (16,52,109,122,192,224).

Antimetabolites such as 5% 5-fluorouracil or thiotepa may be useful for intraurethral condylomata, but neither has been evaluated adequately (224,225,381). Immunotherapy with interferons is under active investigation for treating patients with genital warts (87,102,173,224,225,322,378). To date, however, the limited efficacy of systemic interferon does not justify the observed toxicity, and the efficacy of topical interferon is uncertain (181). Topical imiquimod (5% cream) is a new immune-enhancing agent that has proven effective for treating external genital warts (15,218,281,377). Patients apply the cream three times per week for up to 16 weeks.

Patients with genital HSV or HPV infections should be evaluated for other sexually transmitted diseases. Particular attention should be directed to patient counseling about the transmissibility of these infections and to evaluation of sexual contacts.

Cryotherapy and Surgery

Cryotherapy uses liquid nitrogen to destroy warts by thermal-induced cytolysis (16,52). Its major drawback is that without substantial training, warts often are overtreated or undertreated, leading to either efficacy or increased complications. Pain after application of the liquid nitrogen, followed by necrosis and sometimes blistering, can occur. Although local anesthesia is not used routinely, its use facilitates treatment if there are many warts or if the area of warts is large.

Surgery is most beneficial for patients who have a large number or area of genital warts. Surgical removal has the advantage or rendering the patient wart-free, usually with a single visit (16,52). Once local anesthesia is achieved, visible genital warts can be destroyed by electrosurgery, by tangential excision with a pair of fine scissors or scalpel, or by curettage. Because most warts are exophytic, treatment usually can be accomplished with wounds that extend only into the upper dermis. Carbon dioxide laser and more extensive surgery may be useful in managing extensive warts or intraurethral warts, particularly for patients for whom other treatments have failed. Biopsy should be considered for patients with atypical or extensive lesions.

Other Potential Pathogens

Many other organisms are represented as causes of NGU, including fungi, *M. hominis,* and other aerobic and anaerobic bacteria. Fungi are suggested as one cause of NGU. Although occasionally men with yeast balanitis have symptoms of urethritis, controlled studies indicate that fungi rarely are pathogens in NGU (21,28,140). *M. hominis,* the classic large-colony mycoplasma organisms, were first associated with NGU more than four decades ago. These organisms are transmitted by sexual contact and often are isolated from men with NGU (257,362). *M. hominis* may be associated with increased maternal and perinatal morbidity (40,42). However, studies of patients and control subjects who were carefully matched for past sexual experience demonstrated that *M. hominis* is isolated with similar frequency in both populations (41,257,362); thus the current consensus is that *M. hominis* is not a cause of NGU (41,257,362).

M. genitalium is a newly described mycoplasma that was first isolated from the urethras of two men with NGU (374). These organisms are fastidious, and few isolates have been cultivated. In animal models, *M. genitalium* colonization is associated with urogenital inflammation and a significant antibody response (359,375). Because optimum culture systems are unavailable, sophisticated techniques must be used to detect specific DNA sequences (359). There are conflicting data on the role of *M. genitalium* as a cause of urethritis in humans. British investigators used sophisticated molecular methods to detect *M. genitalium* in urethral samples from 24 (23%) of 103 men with acute NGU but from only 3 (6%) of 53 men without NGU ($p < .006$) (359). They also found that the mycoplasma-positive men responded to treatment with doxycycline, suggesting that the association of *M. genitalium* with NGU was causal. Other investigators could not confirm this association (146). Thus, of the genital mycoplasmas, only *U. urealyticum* is generally accepted as a significant cause of urethritis.

H. ducreyi, the cause of chancroid, causes urethritis in infected men (304). However, this disease is uncommon in the United States. Results of some antimicrobial treatment studies suggest a potential role for bacterial pathogens in patients with *Chlamydia*-negative, *Ureaplasma*-negative NGU (22,25,287). In one study 46 such

men were treated with minocycline (25). Symptoms persisted or recurred in 24 patients within 6 weeks, but 23 of these “treatment failures” actually improved during therapy. Although this initial response to therapy is consistent with a bacterial cause of *Chlamydia*-negative, *Ureaplasma*-negative NGU, no organism has been established as a pathogen. To date, comparison of the aerobic and anaerobic urethral flora has revealed no significant differences between men with *Chlamydia*-positive and *Chlamydia*-negative NGU (28,354,406). A number of reports describe urethritis associated with *N. meningitidis* infection (126,163,236,400). The clinical presentation of urogenital disease associated with such nongonococcal *Neisseria* appears similar to disease caused by *N. gonorrhoeae.* Various investigators have suggested urethral organisms such as *Staphylococcus saprophyticus* (151), *Corynebacterium genitalium* (103), and *Gardnerella vaginalis* (387) as causes of NGU. However, in controlled studies these organisms were isolated more often from asymptomatic control subjects that from patients with NGU (22,28,29,292). Many other organisms have been suggested as causative agents of NGU in uncontrolled studies, including *H. parainfluenzae* (91), *H. equigenitalis, Clostridium difficile, Branhamella catarrhalis* (22,292,358), and *Bacteroides ureolyticus* (405).

In summary, despite many studies, the cause is unknown for 20% to 30% of NGU cases.

Chronic Urethritis Syndrome

Chronic urethritis can be defined as persistent urethral inflammation without *N. gonorrhoeae* or *C. trachomatis* (198). Patients usually relate the onset to sexual activity and often to an episode of acute urethritis (22,28). Symptoms often improve during antimicrobial therapy but recur after completion of therapy. The causes and pathophysiology of this syndrome are poorly understood (198).

Several observations suggest that endoscopic examination of the lower genitourinary tract may be useful for evaluating chronic urethritis. Certain infections, such as intraurethral condylomata, may be apparent only on urethroscopy (225). Chronic urethritis may occur with stricture disease, bacteriuria, prostatitis, periurethral abscess, and presence of a foreign body (as discussed later in this chapter). The problem is that few studies have evaluated the role of endoscopy in men with clinically and microbiologically characterized urethritis.

One prospective study evaluated 36 men with chronic urethritis (198). Patients had symptoms for an average of 12 months and failed to respond to an average of five courses of antimicrobial drugs. Structural abnormalities were documented in 9 (25%) of 36 patients but were considered clinically significant in only 4 patients (11%). Physical examination and uroflow testing led to clinical suspicion of anatomic abnormalities in all four patients with significant lesions, including urethral strictures in three and benign prostatic hypertrophy in one patient. Additional abnormal findings included wide-bore strictures in three patients and developmental abnormalities of doubtful significance in two patients. This study suggests that among men with chronic urethritis, careful physical examination and uroflow testing can be used to screen for evidence of structural abnormalities that merit endoscopic evaluation.

NON–SEXUALLY TRANSMITTED URETHRITIS

Bacterial Urethritis

Urethral discharge may be one feature of many urologic conditions such as urethral stricture disease, phimosis, bacterial prostatitis, and genitourinary tract catheterization, instrumentation, or presence of a foreign body (274). In these cases, the discharge is associated with urinary tract infection and objective evidence of inflammation (polymorphonuclear leukocytes on Gram stain). The causative agents are those commonly associated with bacteriuria. Appropriate antibacterial therapy is important, but often the condition persists until underlying anatomic abnormalities are corrected.

Noninfectious Urethritis Syndrome

Because of the psychologic importance of the genital tract, a significant proportion of patients who complain of urethral discharge or “burning” do not have organic disease. Often, such patients are concerned about the possibility of venereal infection or have feelings of guilt about masturbation or other activities. Microscopic examination of the urethral specimen reveals no evidence of an inflammatory response. An occasional patient repeatedly strips the urethra searching for a discharge that may eventually appear (292).

Infections with recognized urethral pathogens may have minimal symptoms. Some patients with urethritis have totally negative urethral Gram stains on initial examination, particularly if this study is done shortly after micturition. Thus symptomatic patients with negative examinations should be reevaluated before voiding.

COMPLICATIONS OF URETHRITIS

Urethritis in men is associated with a wide variety of potential complications. Significant complications may result from apparently trivial or totally asymptomatic urethral infections. In this section we consider some of the potential complications of urethritis in infected men, in their sexual partners, and in children. Finally, attention is directed to several syndromes that are related to diseases considered in this chapter.

Complications of Urethritis in the Patient

Epididymitis

Epididymitis accounts for more than 600,000 physician visits per year in the United States and is responsible for more days lost from military service than any other disease (14,403). Sexually transmitted pathogens are responsible for most cases of epididymitis in men younger than 35 years (14,196). Epididymitis is a well-documented complication of gonorrhea. Before the availability of penicillin, epididymitis occurred in 10% to 30% of men with gonococcal urethritis (39,276). In recent studies, *N. gonorrhoeae* was isolated from 16% of men with acute epididymitis in the military (386) and from 21% of men in the civilian population (14). *C. trachomatis* is now recognized as the most common cause of epididymitis in younger, sexually active populations (13,14,127). Formerly, such patients were considered to have idiopathic nonspecific epididymitis. In a careful study, Berger and associates (13,14) identified chlamydiae as the cause of 17 of 34 cases of epididymitis in men younger than age 35 years but in only 1 of 16 cases of epididymitis in men older than 35 years. Other investigators reported similar findings (79,194).

Most cases of epididymitis result from retrograde ascent of urethral pathogens via the ejaculatory duct and vas deferens to the epididymis (13,14,194,195,321). Patients with clinical evidence of epididymitis usually have concomitant disease involving the testis; thus most patients really have an epididymo-orchitis (194,195,253). Inflammation of the epididymis precedes involvement of the testis, and the epididymis is the predominant site of disease. Testicular damage and infertility may persist after resolution of acute epididymitis (253,263). Some studies suggest that many patients with epididymitis also have involvement of the prostate (79) and seminal vesicles (208).

Epididymitis usually is accompanied by a hydrocele, caused by an inflammatory exudate between the layers of the tunica vaginalis. In severe cases, vascular compromise of the terminal branches of the spermatic vessels may occur, resulting in testicular infarction with abscess formation (150,194,195,266,295,334). The abscess may rupture into the tunica vaginalis, resulting in development of a pyocele. Both grayscale (324) and color-flow Doppler (86,205,242) ultrasonography are useful for evaluating patients with complicated epididymitis.

Painful scrotal swelling is the usual complaint of patients with epididymitis. Swelling may occur over 1 to 2 days or may be more gradual in onset and is commonly accompanied by dysuria or urinary frequency. Urethral discharge is common but often is mild or asymptomatic, especially in patients with chlamydial disease (14,194,195). Initial laboratory studies should include a urethral specimen for Gram stain, urinalysis, and culture of midstream urine. Indications for additional cultures, diagnostic tests, and therapeutic measures depend on the clinical setting and results of these initial studies.

Many patients with sexually transmitted epididymitis do not complain of urethral discharge, and some patients may not have a history of recent sexual contact (14,386). These findings suggest that urethral pathogens may be carried asymptomatically for prolonged periods before the development of epididymitis. Underlying anatomic abnormalities are uncommon in young men with sexually transmitted epididymitis. Accurate diagnosis depends on a high index of clinical suspicion and laboratory evaluation for sexually transmitted pathogens. Specific antimicrobial therapy, generally with drugs active against both *N. gonorrhoeae* and *C. trachomatis,* is the most important aspect of therapy (52,194,195). As a rule, complete anatomic evaluation is not indicated for patients with uncomplicated sexually transmitted

epididymitis.

The clinical considerations in older men with epididymitis contrast sharply with those for patients younger than age 35 years. In older men, most cases of epididymitis are related to infections with coliforms, species of *Pseudomonas,* or Gram-positive cocci (13,14,402). Patients with bacterial epididymitis have a high prevalence of underlying urologic disease and often have a history of recent genitourinary tract instrumentation (14,194,195,321). Epididymitis may occur weeks, or rarely months, after urologic operations or manipulations (194,195). The incidence of epididymitis may be reduced by avoiding surgery or instrumentation of an infected urinary tract, if possible, or by using appropriate antimicrobials if manipulation of the infected urinary tract is essential. Specific antimicrobial therapy, accompanied by local measures, such as bed rest, ice packs, and scrotal elevation, is adequate in most cases. Surgery may be necessary to treat complications such as testicular infarction, scrotal abscess, or pyocele of the scrotum (150,324,402). Scrotal exploration with orchiectomy and drainage usually is the treatment of choice. Patients with well-documented bacterial epididymitis also merit thorough urologic evaluation and correction of significant anatomic abnormalities.

Urethral Stricture Disease

Development of urethral stricture has long been recognized as a complication of urethritis (302). Most studies are in the older literature and do not distinguish between structures associated with gonococcal and nongonococcal infections. In 1948, Beard and Goodyear reported a group of patients with urethral strictures who had initial management before the availability of penicillin. In 190 of 211 cases (90%) the strictures were related to past episodes of “gonococcal urethritis.” The shortest time interval between the episode of urethritis and development of the urethral stricture was 18 months, and the longest interval was more than 30 years. An average of 21.5 years elapsed between the episode of urethritis and development of the stricture. These findings were confirmed in a study of patients in undeveloped countries: 91 of 643 men with gonococcal urethritis (14%) developed strictures after an average of 15 years (180). A more recent study found that urethritis was the primary etiologic factor in 45% of 120 consecutive urethral strictures (347).

Complications of stricture disease were common in older series, including acute urinary retention (59%), severe prostatitis (21%), paraurethral abscess (17%), urethral calculi (7%), and urinary extravasation (6%) (11). Inflammatory strictures still account for approximately 20% of cases in contemporary surgical series (19,248). A British study assessed the risk of stricture in 490 men with urethritis; there were 2 strictures in 113 patients with gonorrhea (2%) and 16 strictures in 328 patients with NGU (5%), with short-term follow-up (80). Although the data are incomplete, they support the idea that urethral strictures may complicate both gonorrhea and NGU. It appears that the availability of effective antimicrobials has reduced the incidence of stricture disease, but inflammatory strictures remain a significant problem in urologic practice.

Systemic Diseases

Urethritis may be significant as a cause or an effect of systemic disease. Urethritis may be one clinical feature of generalized conditions, such as Wegener's granulomatosis or the Stevens-Johnson syndrome (292). Primary urethral infections may also result in systemic diseases such as disseminated gonococcal infection or Reiter's syndrome.

Disseminated Gonococcal Infection

Disseminated gonococcal infection is one of the most important complications of gonorrhea. This syndrome occurs in approximately 1% of patients with *N. gonorrhoeae* infections of mucosal surfaces (243). The risk of disseminated infection appears to be higher in women, particularly in association with menstruation or pregnancy; in whites; and especially in patients with abnormalities of the serum complement system (214,243). Development of septic arthritis or tenosynovitis is the most common clinical manifestation of disseminated gonococcal infection (187,243,329). Other manifestations include hepatitis, myopericarditis, meningitis, and adult respiratory distress syndrome (243). Most patients with disseminated gonococcal infection do not experience symptoms at the initial mucosal site of infection (243). A wide variety of bacterial virulence factors distinguish strains of *N. gonorrhoeae* associated with systemic infections, such as resistance to the bactericidal action of human serum, particular growth needs and colonial morphology, and specific outer membrane proteins (243). Fortunately, gonococcal isolates associated with disseminated disease are susceptible to penicillin (243).

Reiter's Syndrome

Approximately 1% to 4% of cases of NGU are followed by development of Reiter's syndrome (22,129,159,292). Other elements of Reiter's syndrome include arthritis and uveitis. Lesions of the skin and mucous membranes are common. Reiter's syndrome is the most common peripheral inflammatory arthritis in young men (5,292). The condition appears to result from an abnormal host response to a number of infectious agents (5,99,159,292). The current idea that Reiter's syndrome represents an idiosyncratic immune response is supported by the finding of histocompatibility antigen HLA-B27 in 60% to 97% of patients with Reiter's syndrome (164,215). Most cases in Europe and North America follow an episode of sexually transmitted urethritis, but some cases occur after bacterial gastroenteritis. Urethritis usually occurs first, and other features of the syndrome occur 1 to 4 weeks later (391). Arthritis tends to be the most persistent feature of the syndrome and may last 2 to 6 months after resolution of other aspects (5). The syndrome usually resolves spontaneously, but recurrent disease occurs in 35% to 70% of patients, and some patients experience permanent disability.

Urethritis as a Cofactor for HIV Infection

HIV causes AIDS and related conditions. Sexual contact with an infected person is a major mode of transmission of HIV, but the precise risk factors of HIV transmission during sexual contact are not completely understood. Because HIV preferentially infects certain classes of white blood cells, it is reasonable to expect that genital tract inflammation, as described in this chapter, might increase the efficiency of HIV transmission (43,137,341). Epidemiological data suggest that a twofold to fivefold increase in sexual transmission of HIV is associated with other sexually transmitted diseases (139,385). Postulated mechanisms include breaks in the mucosa and recruitment of inflammatory cells (82,134,401). Recent studies also show that HIV levels in seminal plasma are reduced dramatically by treatment of urethritis (58). Limited clinical observations also suggest that other sexually transmitted disease pathogens might adversely influence the clinical course of HIV infection (333).

Complications in Sexual Partners and Children

The most devastating complications of sexually transmitted urethritis occur in female sexual partners of infected men and in children. For this reason every effort should be made to evaluate and treat sexual contacts of men with urethritis.

Female Sexual Partners

Serious complications in sexual partners include development of urogenital cancer and pelvic inflammatory disease and its complications. Epidemiologically, carcinoma of the uterine cervix is a sexually transmitted disease (270). Various sexually transmitted organisms have been associated with cervical carcinoma, including *Treponema pallidum, N. gonorrhoeae, T. vaginalis, C. trachomatis,* HSV, and HPV. The closest associations are with HPV (170,270). There is also limited evidence that other gynecological cancers, such as carcinoma of the vulva, may be related to infection with sexually transmitted organisms.

Development of pelvic inflammatory disease is a consequence of ascending infection by cervical organisms (73,108,138,167,394). Most cases of pelvic inflammatory disease are associated with infection by *N. gonorrhoeae* or *C. trachomatis,* but genital mycoplasmas and a wide variety of aerobic and anaerobic bacteria may also be important (88). Salpingitis is the most common serious infection in young women. Current estimates are that the annual rate of salpingitis is 1.5 per 100 women aged 15 to 19 years, 1 per 100 women aged 20 to 24 years, and less than 0.5 per 100 women over age 25 years (393). These figures lead to estimates that 15% of American women will have had pelvic inflammatory disease by age 30 years (72,88,223,267,393). Besides the cost of caring for patients with acute infections, the social and economic impacts of pelvic inflammatory disease are immense. Tubal damage results in a risk of infertility of about 1 in 25 after a single episode of mild salpingitis. After a moderately severe episode the risk of infertility is one in seven, and after a severe episode the risk increases to one in three. After multiple episodes of pelvic inflammation, more than 60% of patients become infertile (223,394). Pelvic inflammatory disease has also been associated with a sevenfold increased risk for ectopic pregnancy and with chronic pelvic pain (88,394).

Less severe conditions develop in other women whose sexual partners have urethritis. Although dysuria, frequency, and urgency are common complaints of women with bacterial cystitis, many women with urethral syndrome do not have conventional bacterial urinary tract infections. *C. trachomatis* is commonly isolated from women with dysuria and frequency (106,344). Other sexually transmitted pathogens such as *N. gonorrhoeae* and *T. vaginalis* also may cause irritative lower urinary

tract symptoms (292). Sexually transmitted vaginitis is also a common cause of morbidity among women who are sexual partners of men with urethritis (200).

Neonatal Syndromes

Maternal infections with pathogens such as *T. pallidum* or *N. gonorrhoeae* have long been recognized as causes of neonatal disease, congenital syphilis, and gonococcal ophthalmia neonatorum. However, the full range of perinatal morbidity attributable to sexually transmitted pathogens was recognized only in recent years. Spontaneous abortion, stillbirth, premature delivery, low birth weight, neonatal pneumonia, and congenital abnormalities have all been associated with infections acquired *in utero* or during birth (278,279), especially neonatal herpes and HIV infections, which have high mortality and morbidity (62).

RELATED CONDITIONS

Lymphogranuloma Venereum

LGV is caused by certain serotypes of *C. trachomatis,* as discussed earlier in this chapter. The disease is also known as *climatic bubo, strumous bubo, poradenitis inguinalis, Durand-Nicolas-Favre disease,* and *lymphogranuloma inguinale* (278,279). Although common in areas of Africa, Asia, and South America, LGV is encountered only sporadically in the United States (264,278).

LGV is a chronic disease with a wide variety of clinical manifestations (264,278). Three stages of infection usually are described. The primary infection is an inconspicuous genital ulcer, most often located on the genitalia (264,278). Although urethritis may occur, most primary lesions are asymptomatic. The secondary phase is characterized by the inflammatory lymphangitis, which may be accompanied by a painful swelling and purulence in the inguinal nodes; “bubo” formation, known as *inguinal syndrome;* or acute hemorrhagic proctitis, known as *anogenital syndrome* (264,265,278,288). Constitutional symptoms may be marked during this phase. Most patients recover from the secondary phase with no sequelae. A tertiary phase occurs in a few patients. This phase is characterized by a chronic inflammatory response and development of genital ulcers, fistulae, strictures, and genital elephantiasis. In contrast to most other *C. trachomatis* infections, serologic tests are useful in diagnosing LGV. Cultures from genital sites are positive in about one-third of cases (21,278).

Doxycycline 100 mg orally two times a day for at least 3 weeks is the treatment of choice for LGV (Table 39.2) (52). Erythromycin 500 mg orally for a minimum of 3 weeks is the recommended alternative for patients who are allergic or who cannot tolerate the tetracyclines (52). Patients should be followed until all clinical signs and symptoms have resolved. Local lesions commonly warrant management. The current recommendation is that fluctuant lymph nodes be aspirated through healthy adjacent skin with a large-bore needle. More conventional procedures for incision and drainage may result in prolonged drainage and delayed healing (52,279). Surgery may be necessary to treat tertiary complications such as strictures or fistulae.

Paraurethral Gland Infections

Infection of paraurethral structures may complicate urethral or cutaneous infections with sexually transmitted pathogens (226,307,350). Such patients may show minimal symptoms of urethritis and have fluctuant lesions of the median raphe of the penis, of the paraurethral glands, or of congenital defects such as cysts and sinus tracts resulting from incomplete fusion of embryological structures (53,350). Antimicrobial therapy depends on results of appropriate cultures. Surgical excision of abnormal glandular or cystic structures may be necessary in selected cases after the acute inflammatory response resolves (53).

Fournier's Gangrene

In 1883, Fournier described a fulminating gangrenous disease of the male genitalia. Three characteristics were stressed: abrupt onset in a previously healthy young man, rapid progression, and absence of other predisposing conditions. During the twentieth century, a wide variety of alternative names were applied to this disease, including *necrotizing fasciitis of the genitalia* (8,211), *synergistic gangrene of the scrotum and penis* (97), *necrotizing infection of the scrotum* (17), *polymicrobial genital gangrene* (366), and *necrotizing perineal infection* (190). During this period the clinical definition of Fournier's gangrene was enlarged to encompass patients ranging in age from neonates to older adults, patients experiencing a more gradual onset of disease, and patients with a variety of predisposing conditions (1,2,185,212,272,348).

Typically, patients experience swelling and erythema of the genitalia accompanied by fever, chills, and malaise. Physical examination may demonstrate crepitus caused by presence of subcutaneous gas. The inflammatory process may extend along the fascial planes superiorly to the axillae and inferiorly to the perineum (160,222,338). A feculent odor usually is apparent. Predisposing conditions are present in most patients with Fournier's gangrene, including systemic diseases, particularly diabetes; genitourinary tract diseases, especially urethral stricture disease, trauma, or infection; and gastrointestinal diseases, most often perirectal abscess (77,113,160,168,169,338,382). Aerobic and anaerobic cultures usually isolate a mixture of organisms, commonly including aerobic Gram-negative rods, aerobic Gram-positive cocci, and strict anaerobes, particularly *Bacteroides* species and occasionally clostridia (10,84,160,366).

Fournier's gangrene has a high mortality rate, up to 45% in recent series (160,272,338,348). Cases associated with perirectal disorders appear to have a higher mortality rate (272,348). Early aggressive management offers the best chance for cure. Broad antimicrobial coverage with drugs effective against aerobic Gram-negative rods, aerobic Gram-positive cocci, and anaerobes should be instituted promptly. Surgical drainage is necessary in all cases. Most authorities recommend radical debridement of devitalized tissue (97,160,338). One report of four patients has advocated more limited debridement with placement of through-and-through drains (172). Limited debridement may be effective in some cases, but our experience is that patients with the full-blown syndromes are best treated with aggressive debridement of devitalized tissues. Use of hyperbaric oxygen therapy has been recommended (299) and is reasonable if such facilities are available (1).

AIDS is the most severe clinical manifestation of infection with HIV. This syndrome is defined by development of serious opportunistic infections, neoplasms, or other life-threatening conditions resulting from progressive immunosuppression caused by HIV infection. The first cases of AIDS were described in 1981, and the number of reported cases has increased rapidly. The first 100,000 AIDS cases were reported during an 8-year period, whereas the second 100,000 cases were reported in a 2-year period (70). Despite these dire statistics, dramatic progress has led to improved management of opportunistic infections, specific antiviral chemotherapy, and improvements in length and quality of life for infected people.

BIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUS AND RELATED RETROVIRUSES

This section defines the unique properties of retroviruses and considers HIV, the causative agent of AIDS, in the context of other retroviruses.

Retroviruses

The usual flow of genetic information is from DNA to RNA, a process called *transcription,* then from the RNA to protein, a process called *translation.* In retroviruses, this flow of genetic information is different. Retroviruses contain their genetic information in RNA. During replication, a copy of the viral RNA is transcribed by the viral DNA polymerase. This process of reverse transcription is the distinctive characteristic of the retroviruses. The viral DNA is integrated into the host cell genome to establish infection (89,96). Infection with retroviruses seldom results in lysis of host cells. Thus retroviral infection tends to be permanent. Viral propagation within the infected cell can proceed either through production of new virus particles followed by infection of new cells (horizontal transmission) or by replication of infected cells (vertical transmission).

Identifying HIV

AIDS was first described based on several features that suggested an infectious cause. These features included clustering of cases and transmission by sexual contact and blood products. In 1983, Barre-Sinoussi and associates identified a retrovirus that ultimately proved to be the causative agent (4). The causative agent is now called *human immunodeficiency virus type 1* (HIV-1). The fact that the causative agent of AIDS is a retrovirus made it possible to predict many of the unusual virus–host relationships and the formidable difficulties that must be overcome to control a slow virus infection (45,89).

Pathogenesis of HIV-1

After the virus gains entry to the host, the first step in HIV-1 infection is binding of the virus particle to the surface of a target cell. After binding to the host cell surface, the virus is internalized and its genetic material is released into the host cell cytoplasm. The viral RNA is then transcribed by the reverse transcriptase enzyme into a linear, double-stranded viral DNA in the host cell cytoplasm. Identification of reverse transcriptase as essential for HIV-1 replication highlighted this protein as a key target for antiretroviral therapy. The viral DNA is transported to the nucleus, where it is integrated into the host cell genetic material. This process is mediated by the viral integrase protein. After integrating the viral genetic material, the host cell is persistently infected. This means that the only way to eliminate the infection is to eliminate all infected cells in the host.

Virus Production from Infected Cells

The integrated viral DNA, called *provirus,* is transcribed into messenger RNA (mRNA) by the host cell's RNA polymerase. Viral mRNAs are translated into structural polypeptide precursors. The HIV-1 viral protease is essential for proteolytic processing of these precursors. Because such processing steps are necessary for infectivity, the viral protease has become an important target for anti-HIV therapy. HIV-1 can also induce fusion of host cells with other cells, forming large syncytia. In this fashion, infected and uninfected cells can fuse. Thus HIV-1 may also be transmitted from one host cell to another without being exposed to the humoral immune system of the host.

Because the CD4 molecule is the primary receptor for HIV-1, any cell that expresses this protein is a target for HIV-1 infection (6). The CD4+ T lymphocyte is extraordinarily susceptible and is the predominant cell type targeted by HIV. However, cells of the monocyte or macrophage lineage also express CD4 and can be infected. Although the hallmark of infection with HIV is progressive depletion of CD4+ T cells, a broad array of defects also occurs in function of a variety of immune cell types.

Pathogenesis

HIV-1 infection is a chronic viral illness that results in gradual destruction of the host immune system, with the occurrence of infections, malignancies, and other signs of immune impairment. Depletion of a particular type of T cells (CD4+) is a primary manifestation of HIV-1 infection. HIV-1 can lyse cultured CD4+ T-cells, but the basis for this is incompletely understood (38,96). One aspect appears to be formation of large, multicellular syncytia in which one infected cell can account for the death of many other noninfected cells. This process appears to depend on expression of the CD4 antigen on the surface of susceptible cells.

Monitoring the total CD4+ T-cell count is the standard method for following disease progression because these levels correlate with the severity of immune suppression. The case definition of AIDS was modified to include patients with a total CD4+ T-cell count below 200/mm ^{3} without symptoms or any other AIDS-defining illness. The time from infection until development of AIDS can vary greatly, ranging from less than 3 years in some people to decades in others (38). Some infected people may become long-term nonprogressors, but this is rare.

An acute illness resembling mononucleosis may occur at the time of seroconversion, but HIV-1 infection is characterized by prolonged clinical latency (65), with the median period of latency estimated to be approximately 10 years (86). Viral replication continues, associated with a gradual erosion of immune competence during

this clinically quiescent period. Opportunistic infections and malignancies develop as the person becomes progressively immunosuppressed.

Antiretroviral Strategies

HIV-1 has developed mechanisms that allow it to persist, spread, and cause disease in the presence of natural immunity. As summarized earlier, these mechanisms include covert infection of cells and tissues, blood, and secretions, as well as refuge in the central nervous system outside the blood–brain barrier. The second major problem is that HIV-1 can produce antigenic variants that may be freed temporarily from immune restraints. Because of these problems, many workers believe that the only way to control HIV-1 is to view it as an intracellular pathogen, seek methods to maintain dormancy of the virus, and prevent progression to disease. A second strategy is to develop means to prevent infection in the first place.

Avoiding Infection

At present, the only way to control HIV-1 infection is to avoid exposure to the virus. For this reason, education is critical to persuade people to avoid high-risk behaviors, in particular intravenous drug use and promiscuity. Current programs for screening blood for antibodies to HIV-1 have almost totally eliminated transfusion-associated infections in this country. The problem remains that many people are already infected and that others will continue to practice high-risk behaviors. Thus additional strategies are needed for dealing with this infection.

Vaccines

Developing a vaccine to prevent infection by HIV-1 is an attractive strategy. However, many difficult obstacles must be overcome (37). First, the high degree of variability among HIV-1 strains may make development of a vaccine difficult. An effective vaccine must be active against a broad range of types of this virus. Unfortunately, very small changes in the *env* gene may produce large changes in the viral surface, limiting the ability to develop neutralizing antibodies (89,96). A second problem is that there is no good animal model system in which to test vaccines. Use of chimpanzees has been the standard to date, but these large apes are scarce and expensive to maintain, and infected animals do not develop disease. A third problem with vaccine development is that people with natural infections are known to develop antibodies against HIV-1. Such people develop AIDS despite the presence of these antibodies, suggesting that it may be difficult for many humans to mount a long-lasting, protective response against HIV-1 (96). Many investigators hope that if we can develop higher levels of antibodies before the first exposure to the virus, then protection against infection might occur.

Antiviral Chemotherapy

Treatment is necessary for people who are already infected to eliminate or limit the spread of the virus. As antiviral therapy has become more potent, many researchers and clinicians have begun initiating therapy early in the course of HIV-1 infection (38). The goal of such treatment is to reduce the HIV-1 viral load and to limit the rate of disease progression.

During the past decade, a number of agents have been developed that have proven useful (32,38). Established agents fit in one of three categories: nucleoside analog reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, and protease inhibitors. The nucleoside reverse transcriptase inhibitors have been available longest. These compounds inhibit the viral reverse transcriptase that is essential for HIV-1 replication. These drugs include zidovudine (ZDV, AZT), the first effective antiretroviral, which is an analog of thymidine. Other drugs in this group include didanosine, an analog of adenosine; zalcitabine and lamivudine, analogs of cytidine; and stavudine, also a thymidine analog. The major problem is that these drugs have low potency when used as single agents. All nucleoside reverse transcriptase inhibitors have significant side effects that complicate long-term use. In addition, resistance has been described for all available agents in this class.

The nonnucleoside reverse transcriptase inhibitors also target the HIV-1 reverse transcriptase (38). However, these agents are noncompetitive inhibitors that bind tightly and specifically. Unlike the nucleoside analogs, the nonnucleoside reverse transcriptase inhibitors do not require intracellular activation to interact with the reverse transcriptase. Thus these agents show activity against HIV-1 in resting as well as activated host cells, an important property because resting cells can serve as reservoirs for latent virus. Currently, three nonnucleoside reverse transcriptase inhibitors are approved: nevirapine, delavirdine, and efavirentz. Each of these agents has its own side effect profile. Rapid emergence of resistant HIV-1 strains is the major limitation of the nonnucleoside reverse transcriptase drugs (35,38). Thus the major use of these agents will be in combination with other antiretroviral drugs. Recent data suggest that nonnucleoside reverse transcriptase agents may also be synergistic in combination with various nucleoside analogs, interferons, and protease inhibitors.

Development of the highly active protease inhibitors is the most exciting therapeutic development during the last decade. In short-term studies, the protease inhibitors are at least ten times more potent than previously available drugs in reducing the HIV-1 viral load (88). The amino acid cleavage sites for the HIV-1 protease are specific for HIV-1 and differ from the cleavage site of human host proteases. These agents offer several advantages, particularly the ability to inhibit HIV replication in cells that are chronically infected by a mechanism that is distinct from the mechanism of action of the HIV reverse transcriptase inhibitors. Synergism between the reverse transcriptase inhibitors and the protease inhibitors has been readily demonstrated *in vitro.* Because the protease inhibitors constitute a different class of agents from the reverse transcriptase inhibitors, the toxicity profiles of these two classes of agents are very different, facilitating development of combination chemotherapy. Currently available agents are competitive inhibitors that bind to the active site of the HIV-1 protease. Available agents in this class include saquinavir, indinavir, ritonavir, nelfinavir, and amprenavir. Clinical experience suggests that the HIV-1 protease inhibitors are highly effective agents that are well tolerated by patients (30,51,88). However, each of these agents has a distinct toxicity profile (38).

Combination Antiretroviral Therapy

Clearly, the era of monotherapy for HIV infection is over, with most interest now centered on selecting optimal antiretroviral drug combinations (88). Current strategies institute therapy with a combination of agents, especially with agents that would require HIV-1 to have multiple, separate mutations to develop resistance to all agents in the combination (38). This strategy should reduce or delay the appearance of new mutations and result in substantial and long-lasting reductions in the viral load. Fewer viral replication cycles reduces the likelihood that mutants will arise that escape the immune response of the host. Other potential advantages of combination therapy are that targeting different stages of viral replication and different tissue and cellular reservoirs of HIV-1 replication may produce synergistic effects of the antiviral agents.

Nevertheless, a number of experts caution that although we are making advances toward the goal of transforming AIDS into a chronic disease whose effects can be largely held in check by treatment, long-term studies with greater numbers of patients are needed. Such caution reflects earlier experience with zidovudine, the first effective antiretroviral drug. Initially high hopes for zidovudine arose from short-term studies showing that zidovudine appeared to extend life in HIV-infected patients. However, zidovudine proved to have only limited ability to reduce viral load. HIV, with its high replication rate, rapidly becomes resistant to zidovudine. AIDS researchers had a rude awakening in 1993. A 3-year study found that asymptomatic patients who began taking zidovudine in the early stages of HIV infection lived no longer than those who began treatment after the onset of AIDS. Researchers wary of premature enthusiasm also point to evidence that HIV can become resistant to the new protease inhibitors. Some suggest that this problem may not be inevitable if these potent drugs, in combination with other agents, can suppress virus levels dramatically, forestalling development of resistance. Other clinicians are concerned about the long-term toxicities of antiviral therapies that may be administered to asymptomatic people for decades. Other potential disadvantages of combination therapy are that treatment with multiple agents may increase the potential for patients to develop multidrug-resistant HIV-1 variants early in the course of infection. In addition, use of multiple agents means that patients must comply with complicated regimens, taking large numbers of pills with substantial side effects over long periods.

DIAGNOSIS, NATURAL HISTORY, AND CLASSIFICATION OF HIV-1 INFECTION

Diagnosis of HIV-1 Infection

Infected patients usually are diagnosed by serologic tests that recognize antibodies against HIV-1 antigens (31). Detecting anti–HIV-1 antibodies by enzyme-linked immunosorbent assay (EIA) is highly sensitive (greater than 99%) and specific (95% to 99%) (80). Current technology is in the second or third generation, with EIAs using polypeptide antigens of the HIV-1 core and envelope produced by recombinant DNA technology. Recently developed nucleic acid amplification tests can detect viral RNA or proviral DNA in nearly all HIV-1–infected people (31). Serum samples that are reactive should be retested and repeatedly positive specimens confirmed with a second highly specific test. The most commonly used test is the Western blot. The risk of a false-positive result is estimated to be 1 to 5 per 100,000 people screened. Perhaps more important from a clinical perspective, estimates of the false-negative rate for HIV-1 antibody testing range from 1 in 40,000 to 1 in 1 million.

The median time between HIV-1 infection and confirmed seropositivity is approximately 3 months, with 95% or more of infected people positive by 6 months (31). However, the more sensitive third-generation assays have shortened the window period between infection and detection of a serum antibody response. Testing strategies such as HIV culture nucleic acid detection tests may also prove useful (31).

Natural History of HIV-1 Infection

Deficient Cell-mediated Immunity

HIV-1 infection leads to a sequential decline and finally ablation of cell-mediated immunity, eventually leading to manifestations of opportunistic diseases. Therefore HIV-1 infection results in a wide range of clinical presentations ranging from totally asymptomatic carriage of the virus to life-threatening disease (Table 40.1).

Bacterial infections, multiple or recurrent in children <18 years old
Candidiasis of bronchi, trachea, lungs, or esophagus
Cervical cancer, invasive*
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month duration)
Cytomegalovirus Disease other than liver, spleen, or nodes Retinitis (with loss of vision)
Encephalopathy (HIV related)
Herpes simplex, chronic ulcers (>1 month duration) Bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month duration)
Kaposi's sarcoma
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia in children <13 years old
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary of brain
Mycobacterium avium–intracellulare complex or *M. kansasii*, disseminated or extrapulmonary
M. tuberculosis, any site (pulmonary* or extrapulmonary†)
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis carinii pneumonia
Pneumonia, recurrent*
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome caused by HIV

*Conditions added to the 1993 AIDS surveillance case definition.
†From Centers for Disease Control and Prevention. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR* 1992; 41(RR-17):1–19.

TABLE 40.1. AIDS CASE DEFINITION

Occasional patients are repeatedly positive by EIA but indeterminate by Western blot (14). Clinically, the concern is that some of these people are in the early window period. However, approximately one-third of the people with indeterminate test results are negative on repeat testing. In general, people considered at low risk for infection who are nonreactive on repeat testing do not need further follow-up. In contrast, high-risk patients should be followed serologically for at least 6 months. Most patients who are infected and asymptomatic may not be ill, but they have a chronic progressive disease that may ultimately lead to significant immunologic impairment or death.

Clinical Spectrum and Progression

The spectrum of HIV-1 infection ranges from asymptomatic infection to severe immunodeficiency with serious secondary infections, neoplasms, and other conditions (27). Initial or primary infection with HIV-1 is associated with an acute mononucleosis-like illness in 50% to 70% of patients. This acute illness associated with seroconversion is characterized by fever, lymphadenopathy, night sweats, myalgia, arthralgia, rash, malaise, lethargy, and sore throat. The interval between exposure and development of the acute retroviral syndrome usually is 2 to 4 weeks, with the illness lasting from 1 to 2 weeks. The rate of progression from asymptomatic disease to AIDS is high and increases with the length of follow-up (66).

Effective antiretroviral therapy and widespread prophylaxis against *Pneumocystis carinii* pneumonia have substantially altered the natural history of AIDS (26). The median survival in treated patients with AIDS ranges from 2 to 3 years. Antiretroviral therapy and prophylaxis against opportunistic infections also extend the clinical incubation from infection with HIV-1 to AIDS. Prophylaxis against opportunistic infections, such as *P. carinii,* means that diseases that occur later during HIV-induced immunodeficiency, such as *Mycobacterium avium–intracellulare complex* bacteremia or cytomegalovirus (CMV) organ disease, may be the first clinical manifestation of HIV disease.

EPIDEMIOLOGY

The AIDS Epidemic

The AIDS epidemic usually is dated from the 1981 description of *P. carinii* pneumonia and Kaposi's sarcoma in previously healthy homosexual men. By 1992, AIDS was the leading cause of death for men and the fourth leading cause of death for women 25 to 44 years old (9). Because the surveillance system for AIDS cases relies on availability and willingness of physicians to diagnose and report AIDS cases through local regional and national agencies, there is concern that AIDS cases may be underreported. In 1998, 297,137 people were reported to be living with AIDS in the United States, a 10% increase from the previous year (20). The U.S. Public Health Service has estimated that approximately 650,000 to 900,000 are infected with HIV-1, of whom 200,000 are unaware of their infections (91). Annually, 41,000 new infections occur, and half of the newly infected patients are younger than 25 years (49,72).

Worldwide predictions indicate that the epidemic will continue to grow, with an increasing proportion of infected people living in developing countries. In 2000, an estimated 40 million people were infected with HIV-1, with more than 16,000 new infections per day and with the developing world having approximately 84% of all infected people (70,71).

Modes of Transmission and Major Risk Groups

Three modes of transmission have been described for HIV-1: direct sexual contact, exposure to contaminated blood and blood products, and perinatal transmission. These modes of transmission can occur under a variety of circumstances, and many factors influence the spread of HIV-1.

Sexual Transmission

Sexual transmission of HIV-1 infections may occur between homosexual and heterosexual people. The majority of people with AIDS in the United States are in homosexual or bisexual men. HIV-1 seroprevalence rates in homosexual and bisexual men range from 10% to 70% (22). However, the HIV-1 infection rates in selected cohorts of homosexual men in major cities have clearly declined, reflecting the efficacy of education efforts in this population (48). This has been attributed changes in sexual practices, particularly limiting sexual partners, using condoms, and other practices to avoid exchange of semen. Supporting data for such changes include the declining incidence of other sexually transmitted diseases, such as gonorrhea, in homosexual men since 1982. The increasing use of effective therapy, such as prophylaxis against *Pneumocystis* and antiretroviral therapy, has also delayed the occurrence of AIDS-defining conditions in many HIV-1–infected men.

Heterosexual transmission is now recognized as the major route for spread of HIV-1 in Africa (74). In developed countries, heterosexual transmission appears to be an increasingly common mode of infection. Since 1986, the rate of increase in this group has been higher than the rate of increase of any other exposure category. The increase has been most striking for women infected through heterosexual contact. The number of cases among women infected through heterosexual contact exceeded those infected through injecting drug use for the first time in 1992 (23). The average risk of HIV-1 infection from a single heterosexual contact may be less than 0.1% (69).

Blood-borne Transmission

Intravenous Drug Users

Intravenous drug users are the second largest category of AIDS patients in developed countries. The current seropositivity rate in this population has been estimated to be as high as 60%. Intravenous drug users also appear to be a potentially important link between the reservoir of HIV-1–infected people and the uninfected heterosexual population. For example, women who acquire HIV-1 infection by sexual contact often have partners in high-risk groups, especially intravenous drug

users. Female-to-male spread of HIV-1 is commonly associated with commercial sex workers. Many of these women are intravenous drug users or the sex partners of intravenous drug users.

Blood and Organ Recipients

The probability of infection after receiving a single-donor blood product documented to be HIV-1 positive approaches 100% (27). Since the spring of 1985, essentially all units of blood collected in the United States and all organ donors have been screened for HIV-1 antibodies. The result has been near elimination of new HIV-1 infections from blood transfusions and organ donation.

Hemophiliacs

The typical hemophiliac receives approximately 70,000 units of clotting factor concentrates per year (48). Thus hemophiliacs are exposed to many blood-borne infections, particularly viruses. Current studies of hemophiliac men in the United States indicate that the seroprevalence increased from approximately 10% in 1980 to 70% to 80% in 1984. In 1984, heat treatment was found to be effective in eliminating HIV-1 from factor concentrates. This method has been widely adopted, and very few infections currently occur in people receiving factor concentrates (48).

Health Care Workers

See Protecting Yourself and Your Staff later in this chapter.

Perinatal Transmission

Children can acquire HIV infection during delivery, via breast milk, or through any of the mechanisms discussed so far, including blood or blood factor transfusion or sexual exposures. However, most HIV disease in children results from transmission from a parent who is at risk for AIDS. Pooled data from a variety of large studies suggest that infants born to infected mothers have an approximately 25% risk for acquiring HIV. Assessing infection in newborns is complicated by the presence of passively acquired maternal antibody. Thus HIV antibody tests do not reflect the infection status of the infant before clearance of maternal antibodies.

Unproved Modes of Transmission

Other potential modes of HIV spread, including casual contact, human or insect bites, fomites, food, and water, have been investigated. To date there is no proof that HIV infection can be contracted from such sources (27). Combining data from several studies (48), approximately 450 family members and household (nonsexual) contacts of patients with AIDS have been investigated. None was seropositive, although they shared eating utensils, toothbrushes, razors, and toilet articles or kissed patients with AIDS on the lips. In addition, more than 30 patients have been reported who have been bitten by people with AIDS, but none seroconverted (48). There has been some concern about transmission via mosquito bites, but this also appears unlikely. Finally, there are no reports of HIV transmission by food, water, or other articles.

AIDS AND HIV INFECTIONS IN UROLOGIC PRACTICE

Genitourinary Tract Involvement

The genitourinary tract may be involved in HIV infections as the site of infections or sequela of immunosuppression.

Immunodeficiency and Urology

Given the systemic nature of AIDS, it is not surprising that the genital tract is involved. This is especially true in patients who die of opportunistic infections. For example, one study (83) of 80 autopsies in patients with AIDS demonstrated that 2 of 11 cases with systemic toxoplasmosis involved the testes, 4 of 48 cases of systemic CMV infection involved the prostate and 1 involved the testes, and 1 of 27 cases of systemic candidiasis involved the prostate. The testes in most patients exhibited marked spermatogenic arrest, germ cell degeneration, peritubular fibrosis, and Leydig cell depletion, nonspecific findings that probably reflect the severe systemic disease in these patients. Other immunocompromised patients develop symptomatic genitourinary tract infections with both common and unusual organisms, such as epididymitis caused by *Candida* (90) or CMV (75).

Renal Infections

Resurgence of tuberculosis is related to the HIV epidemic. The number of new tuberculosis cases in the United States has increased each year since 1986 (27). This increase is closely associated with the HIV epidemic. More than 100,000 people in the United States are coinfected with HIV and *M. tuberculosis*. Although pulmonary findings typically are present in HIV-positive patients, it is not uncommon for genitourinary and genital tuberculosis to be the initial finding (97).

There has been a notable rise in drug-resistant tuberculosis in the United States. People with or at risk for HIV infection appear to be at greater risk for active infection with drug-resistant strains of *M. tuberculosis*. People coinfected with HIV and *M. tuberculosis* have a much greater likelihood of developing clinical tuberculosis, including extrapulmonary disease, and may be more difficult to diagnose and to treat than non–HIV-infected people (27,82). The importance of these trends is that genitourinary and genital tuberculosis are again considerations in evaluating and treating urologic patients.

Other common renal infectious manifestations of AIDS include CMV, *Aspergillus,* and *Toxoplasmosis* infections. CMV is a common opportunistic infection in immunocompromised patients. Renal infection is most commonly noted in widespread disease in association with acute tubular necrosis (57). Although it has been suggested that CMV infection of the kidney might facilitate the development of HIV-associated nephropathy (HIVAN), a recent retrospective study of 75 autopsy kidneys has suggested that the two findings are unrelated (67). *Aspergillus* and *Toxoplasmosis* are common opportunistic infections of the kidney. Both organisms are treated with systemic therapy. Profound infections, as manifest by abscesses, warrant percutaneous drainage.

Penile and Urethral Infections

Both men and women with HIV infection are at increased risk for genital tract infections (26). Genital herpes virus infections may be chronic or recurrent and are associated with increased likelihood of HIV transmission to sexual partners. Genital warts may also be severe and chronic (Fig. 40.1). Other sexually transmitted diseases, such as syphilis, may have more atypical and prolonged manifestations in people with HIV infection.

FIGURE 40.1. Extensive condyloma acuminata in a patient with AIDS and human papillomavirus infection.

The first rheumatic disease reported in HIV-positive patients, Reiter's syndrome, consists of uveitis, urethritis, and arthritis and often presents in incomplete form (84). The link between Reiter's syndrome and AIDS is poorly understood. The syndrome, particularly the urethral discharge, usually is refractive to antibiotic therapy. Pelvic inflammatory disease appears to be more common, to be more severe, and to necessitate more frequent hospitalization and surgical intervention in HIV-seropositive women.

Prostatic Infections

The prostate gland is a common site for a variety of opportunistic infections in HIV-positive patients. In one study, bacterial prostatitis was diagnosed in 17 (8%) of 209 men hospitalized for treatment of HIV infections (59). The clinical presentation varies based on the severity of the infection but includes fever, obstructive and irritative voiding symptoms, and a tender prostate on digital rectal exam with possible fluctuance. A superimposed urinary tract infection may be present in up to 22% of patients with AIDS (50). Diagnosis includes broad cultures for aerobes, anaerobes, fungi, and mycobacteria. Prostatic abscesses necessitate open, transrectal, or endoscopic drainage. Bacterial prostatitis necessitates prolonged (6-week) courses of antibiotics with high levels of prostatic penetration. Fungal prostatitis initially is treated with two-agent therapy (amphotericin and flucytosine) with long-term oral fluconazole for persistent or recurrent infections.

Testicular and Epididymal Infections

The most common testicular disorder in AIDS is testicular atrophy (58) secondary to endocrine imbalances, febrile episodes, malnutrition, toxic effects of therapeutic agents, and testicular infections. Autopsy studies have demonstrated opportunistic infection of the testicles in up to 39% of men with AIDS (36). Clinically, scrotal infections usually present as epididymoorchitis. Clinical relapse is common and may result in persistent symptoms or fulminant infection with abscess formation. Documented infection of the epididymis associated with HIV often is secondary to tubule obstruction. Treatment includes initial antibiotic treatment followed by long-term maintenance suppression.

Lymphadenopathy

Generalized lymphadenopathy is common among HIV-infected people, often beginning with the acute retroviral syndrome (26). It is now recognized that 50% to 70% of infected people develop persistent generalized lymphadenopathy and that the natural history of HIV infection associated with persistent generalized lymphadenopathy does not differ from that of HIV infection without generalized adenopathy (26). Involution of enlarged lymph nodes, reflecting degeneration of follicular germinal centers and loss of hyperplasia, often accompanies progression of HIV infection.

Urologic Malignancies

Given the large numbers of HIV-infected people, it is to be expected that a broad range of malignancies has been described in patients with AIDS and other HIV infections (95). These malignancies include squamous cell carcinomas in various sites, malignant melanoma, testicular cancers of all histologies (1,58,98,99), Hodgkin's disease, and cervical carcinoma (27,95).

Therapy selection for neoplasms in HIV seropositive patients is influenced by several factors. The first is clinical stage of HIV infection. In general, asymptomatic or minimally symptomatic patients should receive standard therapy. Characteristics associated with an increased risk of toxicity following cancer therapy include bone marrow suppression by antiretroviral therapy, leukopenia, and significant immunodeficiency. AIDS-related life expectancy may influence the therapeutic decisions.

Although there is minimal evidence that any cancer is caused by the HIV-induced immunologic deficits, Kaposi's sarcoma, primary central nervous system non-Hodgkin's lymphoma, and high-grade peripheral B-cell lymphomas are now diagnostic of AIDS in patients with HIV infections (19). Although the cause of these AIDS-associated malignancies has not been clearly defined, most authorities believe that deficient immune surveillance is the key factor (95).

Kaposi's Sarcoma

In 1872, Kaposi's sarcoma was first described in older men with pigmented skin neoplasms (10). Classic Kaposi's sarcoma affects the feet and lower extremities of men of Mediterranean and eastern European descent. This disease, rare in the United States before 1981, ran an indolent course that was not associated with HIV. Beginning in the early 1970s, cases of Kaposi's sarcoma were described in patients with organ transplants, particularly kidneys. Kaposi's sarcoma is the most common malignancy in patients with AIDS (64) and was seen in some of the initial cases. The predominant group affected appears to be homosexual men.

In 1981, Friedman-Kien (40) described an aggressive form of Kaposi's sarcoma in 50 previously healthy homosexual men. Epidemiologic, geographic, and molecular biologic evidence suggests that development of Kaposi's sarcoma may be related to coinfection with a second infectious agent (6,24,64). The incidence of Kaposi's sarcoma in HIV-seronegative homosexual men is higher than expected, supporting the hypothesis that the etiologic agent can be sexually transmitted and distinct from HIV. Sophisticated molecular studies identified the newly described Kaposi's sarcoma–associated herpes virus (human herpesvirus 8) in lesions from patients with Kaposi's sarcoma and in some AIDS-related B-cell lymphomas (24).

The typical lesion appears as a subcutaneous, painless, nonpruritic nodule. Lesions often are pigmented and red to blue. Exophytic masses can occur, and they may present with bleeding or pain. Lymphedema is common, as would be expected from any lymphatic lesion (95). Up to 2% of patients with AIDS initially present with penile Kaposi's sarcoma (81). Eventually, up to 20% of patients with Kaposi's sarcoma develop genital lesions. Involvement of the lower extremities is common and may be associated with marked scrotal and penile edema.

Diagnosis usually is made by biopsy. However, once the diagnosis is confirmed, additional lesions can be recognized based on their characteristic clinical appearance. Three variants have been reported (spindle cell, anaplastic, and mixed), but the mixed cellular variant is by far the most common type in patients with AIDS (95). Kaposi's sarcoma is characterized histologically by proliferation of abnormal vascular structures. Three diagnostic features are vascular structures with slits lined by large malignant-appearing endothelial cells, surrounding spindle cells, and extravasated erythrocytes. Most authorities believe that the origin of the tumor is endothelial.

The natural history of AIDS-associated Kaposi's sarcoma is highly variable. Newly diagnosed Kaposi's sarcoma as an initial manifestations of AIDS warrants a multidisciplinary approach (2). Aggressive antiretroviral therapy may significantly influence the course of disease. However, because response to therapy can be highly variable, simultaneous local and systemic therapy against Kaposi's sarcoma often is initiated at presentation. Patients with constitutional symptoms such as fever, night sweats, and weight loss do poorly (95). In the usual setting of HIV infection, Kaposi's sarcoma appears to progress rapidly, often with visceral involvement. Patients who have had previous opportunistic infections, anemia, low CD4 cell counts, and gastrointestinal or pulmonary disease appear to do especially poorly (95). In contrast, patients with a few small lesions and no evidence of opportunistic infection or constitutional symptoms do well.

The optimal therapy is unclear for several reasons. First, the natural history of this tumor is highly variable. Second, no therapeutic agent has been proven to reduce the underlying immune deficit. Third, conventional cytotoxic therapy may cause further impairment of cellular immunity. Classic Kaposi's sarcoma responds well to radiation. The response to radiation is less durable in HIV-positive patients. However, radiation therapy has proven somewhat useful for symptomatic, local disease, with an optimal dosage of approximately 2,500 rads (95). An additional study demonstrated that higher dosages of fractionated radiation therapy improved local control rates (87).

Surgery usually is reserved for biopsy to confirm the diagnosis or for palliation of lesions that bleed or are uncomfortable. Cytotoxic agents also have been used to treat HIV-associated Kaposi's sarcoma with widespread mucocutaneous disease with some durability. The most active agents include liposomal anthracyclines, paclitaxel, vinca alkaloids, and bleomycin (42,43 and 44,93). Cytotoxic agents are recommended for selected patients with favorable prognostic indicators (26). Biologic agents including a-interferon are now considered first-line therapy for cutaneous Kaposi's sarcoma. Depending on overall CD4 counts and concomitant antiviral therapy, remission rates as high as 60% have been noted.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma was first associated with HIV infection in 1982. The CDC definition for AIDS (15) now includes patients with high-grade B-cell non-Hodgkin's

lymphoma in the setting of documented HIV infection. AIDS-associated non-Hodgkin's lymphoma closely resembles that associated with other immune deficiency states.

Invasive Cervical Carcinoma

Women with HIV are at greater risk for invasive cervical carcinoma. Cervical disorders are common in HIV-seropositive women (26). The incidence of cervical lesions increases as immunosuppression progresses. Human papillomavirus coinfection appears to play a major role in the development of cervical atypia and squamous dysplasia. Thus frequent evaluation, including cervical cytology, colposcopy, and other indicated studies, is recommended for women with HIV infection.

Testicular Cancer

Some evidence suggests that an increased incidence of germ cell and non–germ cell testicular tumors may be associated with HIV infection (11,57,58,98). On retrospective review of 3,000 patients enrolled in an HIV clinic, the rate of testicular neoplasms was 50 times greater than that found in the general population (99). HIV-positive patients have a greater risk of tumor bilaterality and a greater risk of developing high-grade testicular lymphoma than HIV-negative people (3,85). The therapeutic dilemma in patients with testicular tumors and HIV-1 infection is that accepted treatments for testicular neoplasms, except surveillance, may result in additional immune suppression. Furthermore, patients with AIDS often tolerate radiation and chemotherapy poorly. This may necessitate major modifications of standard treatment protocols, resulting in decreased effectiveness. Despite these limitations, most experts recommend that men with AIDS or HIV and testicular neoplasms should receive standard treatment as indicated by the tumor histology and stage (98).

Renal Disease and AIDS

Renal disease in AIDS has a varied presentation: electrolyte abnormalities, renal insufficiency, and renal failure. Whether there is a specific AIDS-associated nephropathy is debatable (26). The problem is that many patients with AIDS are at high risk for renal disease because of concomitant factors that have all been associated with renal disorders, such as hepatitis B infection, treatment with toxic drugs, fluid and electrolyte abnormalities, opportunistic infections, and malignancies.

HIV nephropathy, as described in 1984 by Rao (76), is characterized by proteinuria and elevated serum creatinine and by focal and segmental glomerulosclerosis on biopsy. These findings are noted in 5% to 10% of HIV-positive patients. Although this disorder closely resembles heroin-associated nephropathy, only half the patients had a history of drug use. In a review of 75 consecutive patients with AIDS in Miami, 43% had proteinuria (68), and among 36 autopsies, 17 people had renal disorders, including 5 with focal glomerulosclerosis and 12 with mesangial proliferation (68). This AIDS-associated nephropathy is most common in the eastern United States, where there are large numbers of patients who have AIDS associated with intravenous drug use. In contrast, patients with AIDS in San Francisco, Seattle, and other cities have much less renal involvement than those in New York and Miami.

Renal dysfunction associated with HIV disease usually is diagnosed incidentally in patients presenting with opportunistic infections and CD4+ cell counts less that 200/mm^3 (26). The clinical course of AIDS-associated nephropathy is variable. Patients with other causes of renal dysfunction, such as nephrotoxic drugs or acute tubular necrosis, may improve. Others experience rapidly progressive clinical deterioration. Activating cellular immunity through chronic dialysis may accelerate HIV pathology. Renal failure is best managed via peritoneal dialysis, despite the risk of peritonitis, secondary to an overall lower risk of exposure to infections (29). When hemodialysis is instituted, the 2-year survival rate is 50% (39).

Urolithiasis

Indinavir, the third available protease inhibitor, has important urologic toxicity. Kidney and ureteral stones are the most serious adverse effect observed so far in patients taking indinavir, appearing in about 2% to 3% (38,60), but rates as high as 12% have been reported (46,77). The stones are caused by precipitation of indinavir crystals that are nonopaque and may be associated with minimal findings on noncontrast computed tomography examination (7,41). Our experience is consistent with recommendations for conservative treatment in most cases, consisting of hydration, analgesics, and temporary cessation of indinavir (46,52). Indications for intervention include persistent fever, intractable pain, inability to tolerate oral hydration, or the presence of a solitary kidney. Indinavir crystals, which develop at pH 7.0, can be dissolved when the pH is lowered to 4.0. This suggests that short-term urinary acidification may be valuable for stone dissolution. After resolution of the acute symptoms and passage of the stone, indinavir therapy can be restarted with aggressive oral hydration (28).

Voiding Dysfunction

Because AIDS and HIV infection affect both central and peripheral nervous systems, voiding dysfunctions are expected. Urinary retention is the most common voiding dysfunction (54%) seen by urologists, although detrusor hyperreflexia (27%) and outflow obstruction (18%) have been documented during urodynamic evaluation of patients with AIDS and voiding symptoms (92). For patients in urinary retention secondary to bladder dysfunction, intermittent catheterization is the treatment of choice. When the patient lacks sufficient manual dexterity, indwelling urethral or suprapubic catheterization is used.

Fournier's Gangrene and AIDS

Fournier's gangrene has a propensity to occur in immunocompromised hosts (12,33,78). This aggressive, progressive, necrotizing fasciitis has been documented as the presenting finding in previously undiagnosed patients with AIDS (63). Treatment of Fournier's gangrene depends on rapid diagnosis, wide surgical debridement, hemodynamic support, and prolonged antibiotic therapy. Diverting colostomy and partial or complete scrotectomy are commonly used during operative debridement. Health care providers must exercise particular caution in the postoperative management of open surgical wounds (discussed later).

HIV, Semen, and Cervical Secretions

Direct contact with semen is important for sexual HIV transmission (34,69). HIV has been isolated by cocultivation of seminal cells and donor lymphocytes (47,100). We found that asymptomatic and minimally symptomatic seropositive men shed HIV in their semen (55,56). Clinical stage of infection, counts of CD4+ cells in peripheral blood, and zidovudine treatment had minimal impact on seminal shedding. These findings are controversial because other studies suggest that HIV shedding in semen occurs most often among men with low CD4+ cell counts in their blood and that antiretroviral therapy reduced shedding (1). In recent studies, HIV was cultured from 36 (17%) of 215 semen specimens from 56 seropositive men, and cytomegalovirus was cultured from 30% of the specimens (54). The CD8+ cell count in peripheral blood was the best predictor of HIV shedding in semen. HIV shedding was more closely associated with concomitant shedding of cytomegalovirus than with the CD4+ count, and antiretroviral therapy had minimal influence on HIV shedding. Lack of a strong relationship between CD4+ cell counts and HIV shedding may be explained in part by recent observation of large differences in virus load in the systemic compartment among subjects with similar CD4+ counts (S.A. Fiscus, R.W. Coombs, and associates, unpublished data). Differences in CD8+ cell counts may help resolve the controversy over the significance of systemic immunologic function, chiefly assessed by CD4+ counts, as a predictor for HIV shedding in semen. Recent studies suggest that treatment with a combination of a protease inhibitor and nucleoside analogs causes a dramatic decrease in cell-free HIV-1 RNA in semen (61,94). This finding could have implications for sexual HIV-1 transmission.

Contact with cervicovaginal secretions of infected women is also believed to be important for sexual HIV-1 transmission. In one study of HIV-seropositive prostitutes (53), cervical HIV DNA was detected in 40 (44%) of 92 women. Presence of cervical HIV was associated with cervical inflammation, suggesting that controlling conditions associated with cervical inflammation might reduce sexual HIV transmission.

Abnormalities on Urinalysis

Abnormalities on urinalysis are common and include hematuria, pyuria, bacteriuria, and proteinuria. One recent study suggested that hematuria occurs in 25% of people infected with HIV (25). Although hematuria may be related to many causes, genitourinary tumors appear to be uncommon, particularly in young men. Thus complete urologic evaluation can be ruled out in young men with asymptomatic microscopic hematuria (25). Proteinuria is also common in certain populations of HIV-positive patients, as considered earlier.

Protecting Yourself and Your Staff

As of June 1997, there were 52 reports of HIV seroconversion in health care workers associated with an occupational HIV exposure (73). Possible occupational transmission, cases in which transmission is likely but for which the CDC's strict criteria were not met, was reported in 114 other health care workers (16). These cases of occupational transmission included three surgeons. In a recent study of 51 seroconversions in health care workers, there was a 95% seroconversion rate within 6 months of exposure (79).

A number of studies evaluated the risk of occupational transmission to health care workers after exposure to HIV-seropositive patients (48). The risk of seroconversion after a needle-stick injury appears to be approximately 0.3% (5). The seroconversion rate after cutaneous exposures to HIV-infected blood is less than 0.09% (17). Several factors may increase the risk of seroconversion for health care workers: a visibly, grossly contaminated needle; a contaminated needle placed directly in a vein; a deep injury; or a hollow-bore needle injury (13,62).

Uniform body substance precautions (18,22) are strongly recommended because all patients are considered potentially infected with HIV. Paramount in this concept is avoiding direct contact with potentially infected body substances, especially blood, urine, semen, and tissue (e.g., during surgery).

To maximize infection control, the urologist must observe three rules. First, there should be no direct contact of blood, semen, or urine with your mucous membranes or nonintact skin. Second, extraordinary care should be used to prevent injuries by sharp instruments during invasive procedures and operations. Recapping needles is especially dangerous and should not be done under any circumstance. Refining puncture-resistant gloves and redesigning needles and other sharp instruments will further reduce injury rates (27). Third, health care workers with exudative skin lesions or weeping dermatitis should not perform invasive procedures. Disturbing case reports document the importance of these recommendations (21).

Postexposure Prophylaxis

Despite the extremely low risk of seroconversion after a health care worker's exposure to HIV-1, the issue of postexposure prophylaxis must be addressed. In deciding whether to proceed with such therapy, several factors are considered: the nature of the exposure, the volume of blood or fluid involved in the exposure, and the infectivity of the exposure source. Because HIV infection does not occur immediately after exposure, there is a chance to intervene before viral replication.

Postexposure prophylaxis must be considered by a health care site well before any potential exposure. Because animal studies suggest that prophylaxis should begin as soon as possible (8), rapid consultation with a provider expert in the field is crucial to discuss the efficacy and toxicity of the involved agents. Although zidovudine is the only agent shown to prevent HIV transmission in humans, combination therapy (including protease inhibitors) may be recommended depending on the nature of the exposure and the resistance of the involved organism.

Chapter References

The anatomy and physiology of the scrotum and its contents are discussed in detail in Chapter 1. In this chapter, infections and benign and malignant masses of the scrotum and its contents are discussed.

INFECTIONS OF THE SCROTUM AND CONTENTS

Scrotal Cellulitis

Acute cellulitis of the scrotum typically causes pain and swelling and may include purulent discharge. Associated systemic signs and symptoms include fever and chills and also may reflect the presence and severity of comorbid conditions such as diabetes, malignancy, and obesity. On physical examination, the affected scrotal skin is warm, thickened, and tender and may have areas of fluctuance or purulent discharge. Presence of necrosis or crepitus suggests Fournier's gangrene (see later discussion). A foul odor may indicate presence of anaerobic organisms in addition to the usual causative agents. In isolated cellulitis, the testes and epididymis, if they can be palpated, are normal, whereas scrotal palpation in patients with secondary skin involvement of an underlying process reveals abnormal intrascrotal findings. Unusual etiologies of scrotal abscess include presentation as a complication of ruptured appendicitis (1,79,134,173) and as urethral or scrotal squamous cell carcinoma (119). Scrotal ultrasonography often is useful when the physical findings are inconclusive.

Causative organisms are typically those associated with cellulitis elsewhere; *Staphylococcus* sp., and *Streptococcus* species, particularly group B, are isolated most frequently (12,74). Unusual organisms such as *Pseudomonas* species from hot tub exposure (55), *Haemophilus influenzae* (18), and *Candida albicans* (87) also are reported.

Therapy is dictated by the physical findings. Culture of purulent material and antibiotics are the mainstay of therapy. Control of associated comorbid conditions such as diabetes also is important. Surgical debridement, dressing changes, and hydrotherapy often are helpful. Unfortunately, infection of the scrotal wall or contents may progress to become a life-threatening, necrotizing fasciitis involving the scrotum and perineum; therefore careful follow-up is important.

Epididymitis and Orchitis

Acute infection of the epididymis and testis typically causes scrotal pain and a local mass. Timing of the onset of symptoms is variable because symptoms may not develop for weeks and, rarely, months following exposure. Often, systemic symptoms of fever, chills, and abdominal pain also are seen with an acute infection of the scrotum. Early physical findings usually allow localization of the infection; however, later in the course of the disease, development of epididymoorchitis or an inflammatory hydrocele may obscure physical findings, and in the more severe forms, testicular infarction/abscess formation also may occur (Fig. 41.1). Generally, tenderness and swelling associated with viral orchitis are localized to the testis, and the epididymis and cord structures are normal to palpation. Acute epididymitis, on the other hand, results in induration and tenderness of the affected epididymis and is often associated with thickening and tenderness of the vas deferens. Extension of the epididymal mass and tenderness that also involves the testis heralds development of epididymoorchitis. However, the epididymal component is typically both earlier and predominant in symptomatology (99,100,136).

FIGURE 41.1. Testicular abscess involving the scrotal wall. Necrotic testicular tubules are present in the center of the wound in this paraplegic patient.

Other causes of acute scrotal pain and swelling of the testis/epididymis such as torsion must be excluded (see Chapter 53). Establishing the etiology of the acute scrotum is critical to appropriate management. Scrotal ultrasonography with or without Doppler flow studies often is helpful in identifying abscess formation and excluding torsion in young patients (52,103,121,171). Initial studies should include urinalysis with culture following urethral swab for Gram stain. Additional tests are directed by the history and physical examination.

The causative agent of isolated orchitis is typically viral, whereas the cause of epididymitis and the more advanced epididymoorchitis is almost always bacterial. Viral etiologies primarily include mumps in the postpubertal patient (60); however, immunization-induced orchitis and other rare viral orchitis, including coxsackie A and B virus, have been reported (104,122,208,215). Infections of the vas deferens and epididymis often are associated with infection of the lower urinary tract. As discussed in Chapter 38, in men younger than 35 years of age, the most likely pathogens are sexually transmitted bacteria (9,101,102) (Table 41.1). In fact, in the antibiotic era, *C. trachomatis* is the most commonly isolated pathogen in this younger population (9,10,73).

Cell Type	Average Incidence (%)	Range (%)
Seminoma	42	34–55
Embryonal carcinoma	26	23–34
Teratocarcinoma	26	9–32
Teratoma	5	1–6
Choriocarcinoma	1	1–4

Data tabulated from Johnson DE. Epidemiology. In: Johnson DE, ed. Testicular tumors, 2nd ed. Flushing, NY: Medical Examination Publishing, 1976:37.

TABLE 41.1. PRIMARY CELL TYPES OF GERM CELL TESTIS TUMORS IN 2,562 CASES FROM NINE SERIES

In the older age group and in patients with congenital or acquired defects of the genitourinary system, such as benign prostatic hyperplasia, spinal cord injury, or recent instrumentation (9,10,99,100,168), the most prevalent organisms include the coliforms, *Pseudomonas* species and Gram-positive cocci (9,10,211). Other rare infections of the epididymis and testes include tuberculosis, brucellosis, histoplasmosis, and idiopathic granulomatous epididymoorchitis (31,67,155,165). Last, in a Houston inner-city hospital, some 30% to 50% of patients with epididymoorchitis presenting in the emergency center are newly found to be HIV positive (24).

Coinfection with HIV is well documented in patients diagnosed with bacterial urethritis (82,205). Therapy includes antibiotics directed at likely pathogens, bed rest, and scrotal elevation. Surgical exploration and drainage occasionally are required to treat complications such as infarction or abscess (83,171,211). Unfortunately, testicular injury with persistent infertility following resolution of infection may occur (136,141).

Fournier's Gangrene

Fournier first described necrotizing fasciitis of the perineum in 1883 when he described five cases of an idiopathic fulminant necrotizing fasciitis in otherwise healthy young men (54). More recent series recognize a synergistic polymicrobial disease affecting the scrotum, penis, and perineum originating from genitourinary, colorectal, or idiopathic sources (5,6,7,22,76). Infection arising from penile and periurethral sources is discussed in Chapter 38.

Clinical presentation is highly variable, and a high index of suspicion and knowledge of the clinical appearance are important for recognition and prompt treatment of this life-threatening infection. Smith and co-workers reported pain, erythema, scrotal swelling, shock, ileus, delirium, and crepitus (50% to 62%) as the most common physical findings (180). Recent series report 32% to 60% of patients are diabetic (22,76,180). Additional conditions associated with Fournier's gangrene include alcoholism, AIDS, prolonged hospitalization, malignancy, intravenous drug use, and malnutrition, all of which represent some degree of immune suppression (7,49,76,106,118,131,132,180).

This rapidly progressive infection represents a polymicrobial infection involving primarily *Escherichia coli*, *Bacteroides*, staphylococci, *Proteus*, streptococci, *Pseudomonas*, enterococci, and *Clostridium perfringens* (6,22,43,145).

Anatomically, the fascial planes of the perineum determine the extent and direction of spread. Condensation of Colles' fascia to form the perineal body with lateral fixation at the pubic rami and fascia lata tends to define the posterior and lateral extension. On the anterior abdominal wall, Colles' fascia becomes Scarpa's fascia and becomes the dartos on the penis and scrotum, allowing free progression of the disease onto the anterior-abdominal wall and thorax to the axillae. Scrotal wall and testicular sources tend to follow along these same planes. Infection arising from the periurethral glands may penetrate Buck's fascia and, rarely, the urogenital diaphragm to involve the space of Retzius. An anorectal source may follow the aforementioned planes or may spread into the space of Retzius, then down along the spermatic cord to involve the testis, scrotum, and penis. Smith and co-workers suggest that perianal involvement can be used to distinguish between an anorectal source and a urogenital source (180).

Treatment of Fournier's gangrene has not changed significantly following availability of antibiotics; it remains a surgical emergency. The infection can spread within a few hours; therefore prompt recognition; stabilization; broad-spectrum antibiotics covering Gram-positive, Gram-negative, and anaerobic organisms; and surgical debridement are indicated. Typically, a penicillin to cover Gram-positive organisms, a third-generation cephalosporin or aminoglycoside to cover Gram-negative organisms, and metronidazole to complete coverage of anaerobic organisms are used. The mainstay of treatment remains early surgical debridement. Physical findings typically under estimate the extent of the disease (Fig. 41.2A and Fig. 41.2B). The surgical team should be prepared for the possibility of laparotomy, extensive debridement, diversion of the fecal and urinary streams, and placement of enteral or parenteral access as indicated. Before debridement, proctoscopy, retrograde urethrogram, or cystoscopy should be performed. The goal of surgical debridement is to remove all devitalized tissue. The urethra and uninvolved testicles can frequently be preserved (Fig. 41.2A and Fig. 41.2B). Placement of the testes in abdominal or thigh pouches has been advocated; however, the authors prefer to cover the testes with saline soaked dressings, allowing granulation with delayed coverage with split-thickness skin grafting. Generally, areas of fascitis involvement can be identified easily and all overlying necrotic tissue should be removed until the wound borders contain viable tissue.

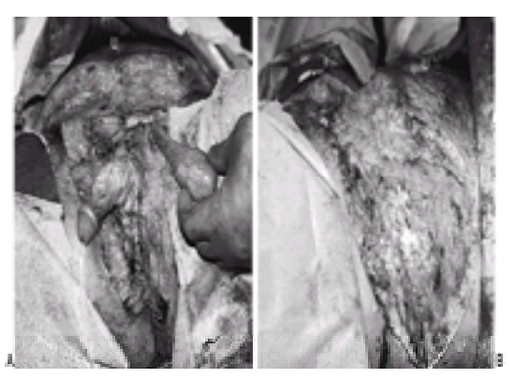

FIGURE 41.2. Fournier's gangrene arising from a right scrotal wall source in a patient with diabetes and hepatic insufficiency. The left testicle is shown with its intact tunica vaginalis in **A**. In **B,** the lateral and superior extent of disease progression is demonstrated. Before debridement, examination under anesthesia and

proctoscopy confirmed a scrotal source, then all necrotic tissue was removed. Following debridement, a diverting colostomy was performed along with placement of an internal feeding tube before transfer to an intensive care unit. The urinary system was managed by Foley catheter (the urethra and its blood supply also were preserved.) LF, left flank; T, testis; U, umbilicus. (From Johnson DE, Woodhead DM, et al. Cryptorchism and testicular tumorigenesis. *Surgery* 1968;63:919, with permission.)

These patients are critically ill and commonly require correction of electrolyte abnormalities (including hemodialysis), mechanical ventilation, volume expansion with colloids, or blood products and crystalloids. Pressure support with dopamine or epinephrine is also commonly required. Of paramount importance is sufficient caloric and protein intake to allow wound healing. Some authors also have advocated use of hyperbaric oxygen (19,148,216) although it remains controversial and should not delay prompt surgical debridement (180). Local wound care should follow standard surgical principles, with wet to dry dressings, using saline in combination with hydrotherapy and sitz baths. Others have recommended peroxide, Dakin's solution, or honey during dressing changes (43).

Once the infection has cleared, the surgical defects can be allowed to close by secondary intention with skin grafting as needed. Nonmeshed skin with a ventral Z-plasty closure for the penis and meshed skin over the granulating testes and cord structures works well. Ventral Z-plasty graft closure on the penile shaft minimizes ventral chordee, and meshed graft over the testicles and cord structures simulates the rugated appearance of the scrotum.

Despite early recognition and prompt surgical debridement, Fournier's gangrene remains a disease with significant mortality. In modern series, mortality ranges from 18% to 25%, including HIV/AIDS patients who fare no worse than average (6,7,22,43). Age, extent of disease, spread onto the abdominal wall or thighs, shock or sepsis at presentation, positive blood cultures, lack of colostomy, and elevated blood urea nitrogen (BUN) (greater than 50 mg/dL) are reported as risk factors (7,43).

BENIGN LESIONS OF THE SCROTUM AND CONTENTS

Spermatocele

A spermatocele is a cystic structure that arises from the epididymis. It usually is located superior to the testis within the tunica vaginalis and represents aneurysmal dilation of a rete testis tubule. Infection, obstruction, and trauma have been proposed as etiologic factors. On examination, the structure will transilluminate. Spermatoceles are filled with a milky fluid that contains spermatozoa. They are found most commonly in middle-aged men.

The diagnosis usually is made easily upon physical examination. Scrotal ultrasound is very helpful in confirming the diagnosis if there is any doubt on physical examination. No treatment is needed unless the patient has significant discomfort from the mass. However, caution is advised in patients still considering fertility because either direct injury or perioperative fibrosis may affect adjacent rete testis tubular patency. Elective, simple transscrotal excision is satisfactory treatment as long as there is no evidence of a testis tumor.

Varicocele

A varicocele is a dilation of the pampiniform venous plexus and the internal spermatic vein. This condition is present in up to 20% of males. It is usually present on the left side. Incompetence of the venous valves where the left gonadal vein inserts into the left renal vein is most often cited as the cause of a varicocele. Distention of the veins is more prominent when the patient is standing and generally decreases when he is supine.

Retroperitoneal pathology such as left renal tumor with vascular invasion, retroperitoneal lymphadenopathy, or retroperitoneal sarcomas can cause venous obstruction with the formation of a varicocele. The sudden onset of a varicocele or an isolated large right varicocele should prompt investigation of the retroperitoneum.

In most patients, a varicocele is of no clinical significance. A small percentage of patients are hypofertile. A varicocele is associated with oligospermia, decreased sperm motility, and an increase in the percentage of abnormal sperm forms (stress pattern). Brown and colleagues demonstrated venous communications between the two testes and pampiniform plexuses (14). Although several causes of the infertility have been proposed, the venous communications between sides probably accounts for the generalized changes seen in the presence of a unilateral varicocele.

Symptomatic varicoceles include a patient with infertility and stress pattern on semen analysis or if he complains of scrotal or testicular pain. Patients usually describe their pain as an ache or heaviness exacerbated by prolonged periods of standing or straining. Ligation of the ipsilateral internal spermatic vein through an inguinal incision is recommended under these circumstances. Many patients enjoy an improvement in sperm counts and quality. Scrotal ligation of the veins has been unsuccessful because of development of collaterals. Internal spermatic vein ligation also is performed for those patients who have severe local symptoms from large varicoceles. In the last several years, ligation of the internal spermatic vein has been performed with laparoscopic techniques by some urologists. Recurrent or persistent varicocele has been treated with transcutaneous embolization (194).

Hydrocele

A hydrocele is a fluid collection in a serous space, usually between the layers of the tunica vaginalis (Fig. 41.3). This space can be totally isolated around the testicle (hydrocele of the testis); it can occur as an isolated structure along the tunica vaginalis of the cord (hydrocele of the cord); or persistent patency of the tunica vaginalis can allow the sac within the scrotum to communicate with the peritoneum (congenital or communicating hydrocele). The hydrocele fluid is usually amber and translucent. Its specific gravity generally ranges from 1.010 to 1.025, consistent with an exudate. The albumin content varies between 3 and 6 g/dL. An example of a hydrocele of the testis (around a normal testis) is shown in Fig. 41.4. *Hydroceles* may occur as a congenital abnormality where the process vaginalis fails to close. In this case, an inguinal hernia is virtually always associated with the malformation. Congenital hydroceles are most common in infants and children. In adults, hydroceles are more frequently due to infection, tumor, or trauma. Infection of the epididymis of testes often results in the development of a secondary hydrocele. Tropical infections such as filariasis also may produce hydroceles, with marked fibrous thickening of the tunica, and the hydrocele contains a milky fluid with a rather large amount of sediment. The turbidity of the fluid is due to chylous drainage caused by lymphatic obstruction (89). If the hydrocele is caused by filariasis, cholesterol and calcium deposits in the tunica are common. Tumors are a less common, although certainly more significant, cause of hydrocele development. The most common tumor is a germ cell testis tumor, followed by tumors of the testicular adnexa. Hydroceles also can result from trauma to the testis and cord structures. One additional cause of hydrocele is ipsilateral renal transplantation. It has been estimated that in up to 70% of patients with ipsilateral renal transplantation, hydroceles develop from division of the vas deferens and spermatic vessels (182).

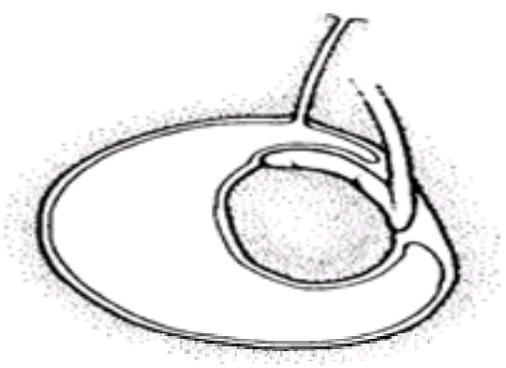

FIGURE 41.3. A hydrocele is a fluid collection in the serous space between the layers of the tunica vaginalis. The process vaginalis may or may not remain patent, allowing the hydrocele to communicate with the peritoneum.

FIGURE 41.4. Ultrasonograph of a normal testis within a hydrocele.

After the cause of a hydrocele has been determined in an adult, no therapy is needed unless the hydrocele is large enough to make the patient uncomfortable or there is a significant underlying cause for the hydrocele, such as a tumor. In the past, “conservative” treatment consisted of aspiration of the hydrocele with or without the injection of a sclerosing agent to attempt to fix the tunica vaginalis to the tunica albuginea. These treatments generally were unsuccessful and are discouraged. Andrews and Wylly described one of the first surgical corrections in 1907. They named the procedure the “bottle operation.” In this procedure, the hydrocele was opened high along its anterior aspect. The testicle was delivered through the incision, and the inverted hydrocele sac was tacked to the cord structures behind the testis. In a variant of this procedure, the hydrocele was incised anteriorly, the excess of the hydrocele sac was trimmed away, and the cut edges were oversewn with sutures for hemostasis and were tacked posterior to the testis and cord structures (Fig. 41.5). In 1964, Lord described a procedure for the repair of hydrocele that was thought to be an improvement based on the fact that the previously reported procedures often were accompanied by the development of hematomas. The Lord procedure is illustrated in Fig. 41.6. Twenty-two consecutive cases were reported without hematoma (114).

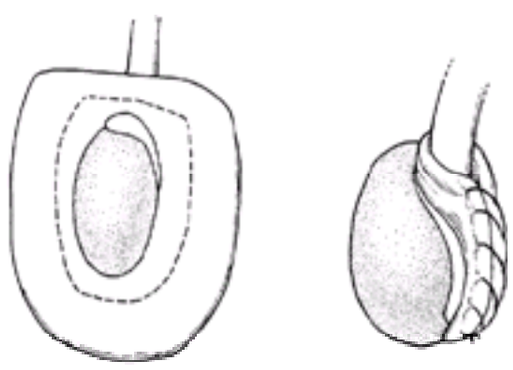

FIGURE 41.5. Jaboulay and Winkelmann modified the procedure described by Andrews and Wylly by excising the excess hydrocele sac before sewing the edges of the sac posterior to the testis.

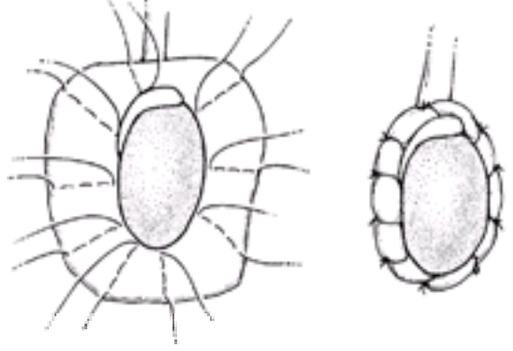

FIGURE 41.6. In the Lord procedure, radial sutures are used to gather the hydrocele sac around the posterior aspect of the testis and epididymis.

Of the various procedures, the Lord procedure seems to be the most appropriate for thin-walled hydroceles, and the excision eversion (Jaboulay-Winkelmann) procedure seems more appropriate for patients with a thickened, indurated tunica. Frequently, a scrotal drain is left for 24 to 48 hours after repair of the hydrocele.

MALIGNANT LESIONS OF THE SCROTUM AND CONTENTS

Testis Tumors

Epidemiology

In 2000, testis tumors will account for approximately 1.1% of all neoplasms in males (71). Historically, testis tumors are the second most common malignancy (behind leukemia) in the 20- to 35-year-old age group (143). The classic article by Dixon and Moore on testis cancer cited an incidence of 2.8 cases per year per 100,000 men in the U.S. Army between 1940 and 1947 (32). A similar incidence of 2.3 cases per year per 100,000 men in England was reported by Collins and Pugh (25). This report was from data gathered in the late 1950s and early 1960s. More recently, an incidence of 2.8 per 100,000 is reported in the Surveillance Epidemiology and End Results (SEER) database from 1992 to 1996 (71).

A longitudinal study of the incidence of testis tumors in males in Copenhagen was reported by Clemmensen (23). The incidence of tumors rose from 3.2 per 100,000 in 1943 to 6.3 per 100,000 in 1962. A similar rise was noted by Skeet in England (178). The author reported an increase in incidence from 2.3 per 100,000, as reported by Collins and Pugh from the late 1950s and early 1960s, to 3.76 per 100,000 in the period 1967 through 1971. The 2000 edition of the SEER database summary allows comparison of trends in SEER incidence over the 1975 to 1979 and 1992 to 1996 periods. The incidence rose 3.2% in the former and fell 2.8% in the latter period (71).

Dixon and Moore's publication of the Armed Forces Institute of Pathology classification of testis cancer made it possible to collect data on the various histologic types of testis cancer. Before that time, inconsistent terminology made it difficult to compare the distribution of tumor types in different series. These authors reported that 97% of all testis neoplasms were of germ cell origin, while 3% were of non–germ cell origin. Many series of testis cancers have been published since the Dixon and Moore report in 1952 (32). Johnson reported the distribution of the predominant cell type in testis in tumors in nine series (92). A total of 2,562 cases were reported. Seminoma was the most frequent predominant cell type, followed by embryonal carcinomas, teratocarcinoma, teratoma, and choriocarcinoma. Table 41.1 shows the average percentage of each tumor cell type along with the range of percentages reported for each cell type.

Testis tumors have been reported from infancy to age 89 years. Seminomas tend to appear later, and the average age of appearance in various series ranges from 30.7 to 41.9 years (142,143,193). Embryonal carcinoma is seen slightly earlier, with an age range from 26.1 to 33.0 years (95,144). For choriocarcinoma, the average

age of onset is lower, ranging from 24.0 to 26.3 years (95).

The incidence of testis tumors in different racial and geographic populations has been studied and reported by many authors. Dixon and Moore reported that the incidence of testis tumor was lower in nonwhites than in whites (32). They found that testis tumors in nonwhites constituted 1.5% of their series, although nonwhites made up 6.07% to 8.5% of the total U.S. Army population, which was the source of their series. Teppo reported a set of data showing that the rate of testis tumors was less than 1 per 100,000 in nonwhite populations, while most white populations had an incidence of greater than 1 per 100,000, with the exception of Finland, which had a rate of 0.9 per 100,000 (192). A more detailed report on testis tumors in black Africans showed that the low incidence of tumor was due primarily to an exceedingly low incidence of seminoma and teratoma, while the incidences of other cell types were similar to those in white populations (191).

It also is interesting to note that there is a difference in the incidence of seminomas in rural and urban populations within the same country. An increased rural incidence was reported by Lipworth and Dayan for England and Wales during the period of 1961 through 1967 (111). The same observation was made in New York by Sharma and associates from Roswell Park Memorial Institute (174).

Testis tumors seem to be slightly higher in incidence in the right testicle than the left. Several authors propose that this can be explained by the higher incidence of cryptorchism on the right, and by the association of testis cancer with cryptorchism (107). The relationship of testis cancer and cryptorchism is discussed further in a subsequent section of this chapter.

In summary, testicular tumors are several times more common in most white populations than they are in nonwhite populations. In general, the incidence of testis cancer seems to be increasing with time (23). The existence of multiple tumor registries will make it possible to record pertinent epidemiologic data with greater detail in the future.

Etiology

Many authors have postulated chemical or viral exposure as possible etiologic agents for testis cancer; however, trauma, atrophy, and cryptorchism are the factors most commonly thought to be associated with the disease.

A history of testicular trauma has been reported in 8% to 25% of all patients with testis cancer (25,97,142). Most of these authors feel that trauma does not have a role in the history of testis cancer, but more likely provides the mechanism for the discovery of a testicular mass by the patient. From his review of patients in the literature, Gilbert promoted the role of atrophy as a possible etiologic factor in testis cancer when he reported that 80 of 5,500 patients (1.5%) with testis tumor had developed the tumors in atrophic testes (65). The cause of atrophy of the testis in these patients was not specified. A history of mumps orchitis with subsequent atrophy of the testis was present in 24 patients (0.5%) who developed testis cancer. In light of this association, although this is a small percentage of the total patients with testis cancer, Hausfield and Schrandt recommended immediate orchiectomy if any suspicious mass was noted in an atrophic testis (75). This is probably sound advice in the case of an atrophic or a normal testis. Fortunately, additional diagnostic aids such as ultrasound and tumor markers are now available to help make the diagnosis.

The potential for a cryptorchid testis to develop a tumor was first described by LeComte in 1851 (108). Data from several series indicate that even after orchiopexy is successfully performed, the testis in question has a persistently elevated risk of development of a subsequent testis tumor. Johnson and colleagues have demonstrated that the contralateral testis also is at risk, even if it was normally descended at the time of birth (93). In approximately one-fifth of patients with a history of cryptorchid testis and subsequent development of testis cancer, the tumor occurs in the contralateral, normally descended testis (81).

The general consensus at this time is that orchiopexy should be performed between the ages of 1 and 2 years. Orchiopexy before age 1 year is contraindicated because of the possibility of spontaneous descent of the testicle within the first year of life. If a cryptorchid testis is still present and has been untreated after the patient has reached puberty, the testis should be removed instead of being relocated in the scrotum. This recommendation is made on the basis of observations that the cryptorchid testis has lost the capacity for spermatogenesis. Even in patients who have undergone early orchiopexy, long-term follow-up is required because of the increased incidence of subsequent development of testis tumor in this patient population. It is critical that the patient be taught the techniques of self-examination of the scrotal contents as soon as he is old enough to thoroughly understand the procedure.

Pathology

As previously noted, primary neoplasms of the testis fall into two groups. The majority are tumors arising from germ cells; these account for 94% to 97% of cases (32,126). The remaining portion of primary testicular neoplasms is made up of tumors arising from nongerminal elements. These account for 3% to 6% of all testicular neoplasms.

Classification of testis tumors has fallen along two different lines: the American and British classifications. The early foundations of the American classification were based on work by Friedman and Moore (59). Proposed in the 1940s, this classification was based on a study of 1,000 testicular neoplasms from the Army Medical Museum that were collected during World War II. In this scheme, each group of tumors was assumed to be a distinct histologic type. The five categories suggested were seminoma, embryonal carcinoma, choriocarcinoma, teratoma, and teratocarcinoma.

Further studies in this area by Dixon and Moore (32) and Mostofi and Sobin (127), reporting the consensus of the World Health Organization classification of testis tumors, and Teilum (190) have helped develop the current American working classification of testis tumors. This classification is based on the premise that all seminoma and nonseminomatous tumors originate from totipotent germ cells. A schematic diagram of this concept based on work by Teilum (190) and Friedman and Moore (59), among others is presented in Fig. 41.7. Embryonal carcinomas can develop further into embryonic structures, such as teratoma, or into extraembryonic structures, such as yolk sac tumors or choriocarcinoma.

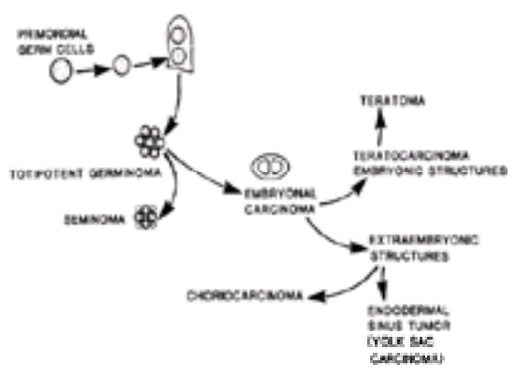

FIGURE 41.7. Schematic drawing of the origin of germ cell testis tumors and analogous germinal, fetal, or placental structures.

By contrast, the British scheme, which was presented initially by Willis (209) and modified and expanded by Collins and Pugh (25), is based on the concept that nonseminomatous tumors develop from teratoma. Embryonal carcinoma fits into this scheme as a single cell-type tumor developing from teratoma. As in the American system, the British system agrees that seminoma develops from germ cells. For the remainder of this chapter, the current American pathologic classification of germ cell testis tumors is used. This classification is given in Table 41.2.

Precursor lesion
Intratubular germ cell neoplasia (unclassified type equivalent to "carcinoma *in situ*")
Tumors of one histologic type
Seminoma
Variant: seminoma with syncytiotrophoblastic cells
Spermatocytic seminoma
Variant: spermatocytic seminoma with a sarcomatous component
Embryonal carcinoma
Yolk sac tumor (endodermal sinus tumor)
Choriocarcinoma
Teratoma
Mature teratoma
Immature teratoma
Teratoma with an overtly malignant component
Monodermal variants
Carcinoid (pure and with teratomatous elements)
Primitive neuroectodermal tumor
Tumors of more than one histologic type
Mixed germ cell tumors (specify individual components)
Polyembryoma and diffuse embryoma

TABLE 41.2. CLASSIFICATION OF TESTICULAR GERM CELL TUMORS

Seminoma

Seminoma is the most common tumor of a single cell type. At presentation, the testis may be enlarged as much as ten times without loss of its normal shape. On cut surface, the tumor is usually solitary with distinct borders. It is pink-white, smooth, and usually homogenous (125). In addition to primary tumors in the testicle, seminoma can occur in extragonadal sites such as the retroperitoneum, mediastinum, pituitary, or pineal regions. Seminomas also are more common than nonseminomatous tumors in undescended testes. As noted earlier in the chapter, the patient's age at presentation is generally several years older than for nonseminomatous tumors.

Microscopically, the seminoma cells are uniform and have clear cytoplasm and well-defined cell borders (125). In the ovary, this tumor is called *dysgerminoma.* Three histologic types of seminoma have been described: typical, anaplastic, and spermatocytic (124). Initially, the anaplastic variety was thought to carry a graver prognosis, while the spermatocytic variety, which usually presented later in the patient's life, was thought to carry a more optimistic prognosis. Currently, the differences in prognoses of patients with these tumors are debatable.

Embryonal Carcinoma

At the time of clinical presentation, embryonal carcinoma usually is seen as a smaller, more asymmetric testicular mass than seminoma. Grossly, on the cut surface, the embryonal carcinoma is very heterogeneous (125). Microscopically, the tumor usually occurs in a solid form and does not have the lobular pattern of seminoma. Embryonal carcinoma cells tend to be larger, demonstrate more pleomorphism, have more mitoses, and have less distinctive cell membranes with nuclear overlapping than seminomatous tumor cells. Glycogen can be shown in embryonal carcinoma cells by the periodic acid–Schiff technique (126). Embryonal carcinoma tends to metastasize early and often demonstrates other cell types in the metastatic sites.

Yolk Sac Tumor (Endodermal Sinus Tumor)

This was originally described as a rare tumor of infancy and childhood. Telium thought that the histologic findings in this tumor were similar to the endodermal sinuses present in the rodent (189). Pierce and coauthors compared the tumor to a mouse yolk sac or vitelline tumor (146). Synonyms for this tumor include *infantile embryonal carcinoma, orchidoblastoma, embryonal carcinoma of infants and children,* and *embryonal carcinoma of the prepubertal testis.* Yolk sac elements are found in 38% of adult patients with testis tumors. In 10% of patients, the yolk sac tumor is the dominant element of mixed adult testis tumors. No pure adult yolk sac tumors have been reported in series by Talerman (186) or Roth and Panganiban (161).

In gross appearance, the yolk sac tumor is very similar to embryonal carcinoma. Microscopically, four patterns have been recognized in the testis (187,190). The first microscopic pattern is the *microcystic and myxomatous pattern.* Microscopically, under low power, the tumor is similar in appearance to a honeycomb. Cysts are lined by flat mesothelium-like cells, and many mitoses are present. The second histologic pattern is called the *endodermal sinus pattern.* Perivascular formations known as Schiller-Duval bodies are present. Schiller-Duval bodies are similar to the endodermal sinuses seen in the rat placenta. The third microscopic formation is called the *solid cellular pattern.* In this group, aggregates of small polygonal cells with clear cytoplasm and frequent mitoses are present. The fourth pattern seen in testis tumors is the *alveolar glandular* or *cystic pattern.* Eosinophilic globules are noted inside and outside tumor cells and have been shown to contain a-fetoprotein. They are considered analogous to Reichert's membrane in the mouse embryo (147).

Polyembryoma

Polyembryoma is an unusual tumor composed primarily of embryoid bodies (127). The embryoid body is described as a structure containing a disk and cavities surrounded by loose mesenchymal cells simulating an embryo of approximately 2 weeks' gestation. The presence of embryoid bodies does not make the tumor a polyembryoma. Actually, embryoid bodies are found more often in embryonal carcinoma and teratoma because the polyembryoma tumor is so rare.

Choriocarcinoma

At clinical presentation, choriocarcinoma tumors are often extremely small. Despite their small size, wide metastatic spread is common. On cut surface, the tumor tends to show large areas of hemorrhage with a small rim of viable tumor. Microscopically, two cell elements must be present to qualify as choriocarcinoma: syncytiotrophoblasts and cytotrophoblasts. Pure choriocarcinoma is rare. It is found much more often in association with other tumor elements. Syncytiotrophoblasts often form the leading edge of the tumor and allow it to erode in blood vessels, which probably accounts for the large amount of hemorrhage found in the primary and metastatic tumor sites (124).

Teratoma

By definition, teratoma consists of two or more embryonic germ cell layers (endoderm, mesoderm, and ectoderm). Typical endodermal structures seen in teratoma are mucus-secreting glands as in the gastrointestinal, genitourinary, or respiratory tracts. Mesodermal elements often present in teratoma include cartilage, bone, muscle, and lymphoid tissue. The ectoderm may be represented by stratified squamous epithelial cell–lined cysts and neural tissue elements (126). Mature and immature elements of each of these germ layers may be present in the teratoma. At presentation the teratoma may vary greatly in size, and on cut surface, the gross specimen is markedly heterogeneous. Often, both solid and cystic-appearing areas are present within the same mass. In the more cystic tumors that appear to be “benign,” 30% metastasize in 5 years. Adenocarcinoma or epidermoid carcinoma can develop in the epithelial components of teratoma (126).

Simple Epidermoid Cysts

Price and Mostofi (153) described these lesions as keratinizing, stratified, squamous cell–lined cysts supported by fibrous tissue. These tumors are considered special cases of teratoma, but not truly teratoma because only a single germinal layer, not the required two layers, is represented. The simple epidermoid cyst accounts for approximately 1% of testicular tumors. The behavior appears to be totally benign; no incidences of metastasis have been reported in 69 cases found in the American Testicular Registry (151).

Carcinoid Tumor

Talerman and associates (188) reported 23 cases of carcinoid tumor of the testis. Seventeen of these tumors were primary testis tumors, three of which had elements of teratoma present as well. The remaining six tumors were metastatic carcinoid tumors of the testis. The patients may or may not have the clinical syndrome associated with carcinoid tumors. Recent reports on a total of five patients with carcinoid tumor of the testes noted that none of these patients had clinical carcinoid syndrome (96,214). However, in all of the tumors, the argentaffin reaction was noted histologically. The prognosis appears to be excellent in primary tumors; in

metastatic tumors the outlook has been poor.

Mixed Histologic Germ Cell Tumors

Approximately one-fourth of germ cell tumors are composed of multiple cell types. The most common of these mixtures is embryonal carcinoma and teratoma. Together these cell elements are commonly referred to as *teratocarcinoma* (Fig. 41.7). Sixty-four percent of teratocarcinoma tumors also contain elements of seminoma. The next most common mixture is embryonal carcinoma and seminoma, which accounts for approximately 5% of testis tumors (126). Although hundreds of other combinations are possible, no other combination presents more than 3% of the total incidence of these tumors. In general, the behavior of mixed tumors is similar to that of its most aggressive element; that is, teratocarcinoma behaves in a manner similar to embryonal carcinoma.

Stromal Tumors of Mixed Cell Type

When both Sertoli (tubular) and Leydig (interstitial) cell elements are present in a tumor, it is called an *androblastoma.* This is a "male" presentation of these structures. When thecal stroma and granulosa complexes are present, the tumor is called a *gynoblastoma* and represents a "female" manifestation of these tumors. It is often difficult to differentiate androblastomas from gynoblastomas (204). When both male and female structures are clearly present, the tumor is designated a *gynandroblastoma.* Despite the predominance of male or female structures, these tumors can produce male or female hormones or both (58). Cheville recently reviewed germ cell and sex cord–stromal tumors. A description of the use of special histologic stains employed to make the diagnosis of each of these tumors is given (21).

Mixed Germ Cell and Stromal Tumor (Gonadoblastoma)

The gonadoblastoma is a mixed cell type tumor containing large germ cells similar to seminoma, and small cells similar to immature Sertoli and granulosa cells. Elements similar to Leydig or interstitial cells also may be present. These tumors are associated with dysgenetic gonads, either a streak gonad or a testis. They also are known to occur in patients with intersex disorders (170). Chapman and others reported a case of gonadoblastoma in a genotypically and phenotypically normal, fertile man with scrotal testes (20). A careful review of 10 cases of sex cord–stromal tumors showed that 9 of the 10 cases were a combination of sex cord elements and entrapped germ cells of the testis based on inhibin staining patterns. This suggests that true unclassified mixed germ cell sex cord–stromal tumors have not yet been observed (197).

Somatic (Nongerminal) Tumors

Somatic tumors of the testis also have been known as *gonadal stromal tumors* or *sex cord mesenchymal tumors.* These designations have been used to differentiate them from germ cell tumors. The term *somatic* or *nongerminal* seems most appropriate for these tumors in light of our current understanding of their origin and structure.

Sertoli (Tubular) Cell Tumors

Sertoli (tubular) cell tumors usually have a glandular; tubular; or a fused, solid epithelium-lined structure. These formations are similar to areas found in prepubertal testicular tubules or those areas found in cryptorchid testes. Differentiation between hamartoma, hyperplasia, and neoplasia is difficult (59). Metastasizing carcinomas of Sertoli cell origin are rare (185). Sertoli cell tumors can occur in children and represent 1.3% of all testis tumors in this group. These tumors can vary greatly in histologic appearance and endocrine activity (11).

Malignant Lymphoma of Testis

Malignant lymphoma of the testis can occur as either a primary or secondary tumor. The terminology involving malignant lymphoma has been somewhat confusing. Other synonymous terms used in the literature include *lymphosarcoma, reticular cell sarcoma,* and *lymphoblastic lymphoma.* According to Gowing, malignant lymphoma is the second most common testis tumor in patients older than 50 years of age (68). The peak incidence of presentation of malignant lymphomas of the testis is between ages 60 and 80 years. The disease can be unilateral or bilateral. Bilateral tumors can occur either synchronously or metachronously. Because survival is usually good after orchiectomy alone, many of the tumors must be primary tumors of the testis.

A recent report of diffuse large-cell lymphoma of the testis, on the other hand, showed poor response to chemotherapy overall, with a median survival of 41 months in patients with limited disease (Ann Arbor stage I/II) and 16 months in patients with advanced (Ann Arbor stage IV) disease (195).

Metastatic Tumors to the Testis

Metastatic tumors to the testis are theoretically possible from any blood-borne tumor. These tumors are unusual and represent 0.9% of 2,739 testis tumors reported by Pugh (154). The most commonly reported site of the primary is the prostate, with eight cases noted; bronchus and bowel are the next most frequent sites of primary tumor spreading to the testis (15). Other reported sites include pancreas, skin (malignant melanoma), bladder (transitional cell carcinoma and sarcoma), thyroid (carcinoma), and neuroblastoma. A new report on 738 patients who died from solid malignant neoplasms noted metastases to the testes in 5 (0.68%) patients. There were three cases of bronchial carcinoma, one of melanoma, and one of pancreatic endocrine carcinoma (61).

CLINICAL MANIFESTATIONS OF GERM CELL TESTIS TUMORS

The most common symptom or finding associated with testicular tumors is scrotal swelling. Also identified with testis cancer is a sensation of fullness or heaviness of the scrotum, which is occasionally described as pain. On rare occasions, patients have manifestations of metastatic disease such as hemoptysis, a mass noted in the supraclavicular area, or a large abdominal mass. Also, patients occasionally have systemic endocrine effects, such as gynecomastia.

Unfortunately, the diagnosis of testis cancer is often delayed by confusion regarding the scrotal findings and symptoms. Not infrequently, the patient is treated for presumed epididymitis. The key to success in this particular dilemma is follow-up examination. After the patient has been treated with antibiotics for the presumed epididymitis, he should be reexamined after the course of the antibiotics has been completed to make certain that no residual mass is palpable. All too often the index of suspicion of a testis tumor is too low, and the patient goes on either with no treatment for his disease or with repeated or continuous treatment for presumed epididymitis. Public awareness of testis cancer is increasing, and campaigns for testicular self-examination have had an impact on earlier detection and diagnosis of testis cancer.

Fortunately, very sensitive serum markers have been found. The most sensitive and useful markers are serum human chorionic gonadotropin (hCG) levels, serum a-fetoprotein (AFP) levels and lactate dehydrogenase (LDH) levels. hCG is measured as the b-chain of the protein (b-hCG). hCG is produced by the syncytiotrophoblast, whereas AFP is produced by the yolk sac cell. Syncytiotrophoblasts have been demonstrated to be present, usually as isolated cells, in up to 10% of seminomas. Syncytiotrophoblasts also are present in choriocarcinoma. Yolk sac cells are found in embryonal tumors as well as in pure yolk sac tumors. LDH is a nonspecific marker, which may be elevated in the absence of b-hCG or AFP elevation and has been incorporated as a part of the primary node (T), regional lymph nodes (N), distant metastasis (M), and serum tumor markers (S) (TNMS) staging (TNMS) system for germ cell neoplasms in the fifth edition of the American Joint Committee on Cancer Staging (AJCC) criteria, thus adding $T_xN_xM_xS_x$ to the staging criterion. Overall, more than 70% of patients with testis tumors will have one or more of these serum markers elevated. In the case of possible testis tumor, serum markers should be obtained. A positive marker has great significance; however, a negative marker does not exclude the presence of a germ cell testis tumor.

DIAGNOSIS OF GERM CELL TUMORS

Any mass within the body of the testicle itself must be considered a germ cell tumor until proven otherwise. Once a testis tumor is suspected, it is advisable to have the patient examined by a trained urologist. The urologist should be able to help differentiate the physical findings between epididymitis, spermatocele, varicocele, hydrocele, and testicular cancer. One of the most important aspects of physical examination is determining the location of the mass in question. The examiner should use two hands. One hand steadies the testicle and the other grasps it, using the fingertips and the tip of the thumb to try to differentiate between a mass located in the body of the testicle and a mass located in the epididymis. Transillumination is helpful to detect solid versus fluid-filled masses. Ultrasonography has been helpful in

differentiating between solid and cystic lesions and also in helping pinpoint the location of the lesion. Figure 41.8 and Figure 41.9 show examples of a normal testis and a testis with a germ cell tumor (seminoma). Epidermoid cysts of the testis usually can be diagnosed with ultrasound or magnetic resonance imaging (MRI), each showing an onion ring appearance with alternating bands of signal intensity (105). Ultrasound also helps elucidate the status of the underlying testicle in a patient who has a hydrocele that is too tense to allow adequate examination (Fig. 41.4). Doppler flow studies often can demonstrate blood flow within an intratesticular mass, increasing the likelihood of tumor presence. The absence of blood flow in the onion ring lesion seen on ultrasound or MRI further supports these lesions being benign epidermal cysts (105). Testicular lesions may have a uniform appearance suggesting seminoma (Fig. 41.9) or a heterogenous appearance suggesting presence of a mixed tumor or a tumor with teratomatous elements. More recently, testicular microlithiasis has been associated with testicular intraepithelial neoplasia or frank carcinoma in up to 35% of cases (8).

FIGURE 41.8. Longitudinal cut of an ultrasonogram of a normal testis. Note the relative uniformity of the body of the testis.

FIGURE 41.9. Longitudinal cut of an ultrasonogram of a testis with a tumor located on the posterior aspect replacing over half of the testis . Note changes in the echo pattern.

If a mass in or adjacent to the body of the testis cannot be satisfactorily identified with physical examination, transillumination, and ultrasonography, then the burden of proof is on the urologist to examine the mass further through surgical exploration. Because the lymphatics of the testis flow along the cord structures, it is important to explore the testicle through an inguinal incision to avoid contamination of the superficial inguinal lymphatics by the testicular lymphatics. Figure 41.10 indicates the location of the inguinal incision. After the incision is made, the external oblique aponeurosis is incised in the line of its fibers. The cord structures are mobilized; the easiest way to get around the cord structures is to sweep from lateral to medial at the level of the pubic tubercle. Care should be taken to make certain that the vas deferens and the testicular vessels are included in this bundle of tissue. Once the cord structures are isolated, they can be dissected more proximally, and a Penrose drain or noncrushing clamp can be placed on the cord to help prevent any spread by lymphatics (although this route of spread is only theoretic) or any blood-borne metastasis during the remainder of the surgical procedure. At this point, the testicle can be delivered into the incision by placing traction on the cord structures. Loose connective tissue and cremasteric fibers often must be mobilized from the cord structures to allow delivery of the testicle. The testicle will still be attached to the dependent portion of the scrotum by the gubernaculum of the testis.

FIGURE 41.10. A curvilinear incision is made in the skin lines at a spot overlying the internal inguinal ring, which is approximately two-thirds of the way from the pubic tubercle to the anterosuperior ileal spine, just cephalad to the inguinal ligament.

At this point, direct examination of the testis should be accomplished. If the mass is clearly within the body of the testicle and is solid, an orchiectomy should be performed by ligating the cord structures at the level of the internal inguinal ring. During this part of the procedure, one should take care to separate the vas deferens from the vasculature. These should be tied separately and mobilized to allow separation of the two structures. This aspect is important, because separating these structures at the time of orchiectomy facilitates the dissection of the gonadal vessels in the retroperitoneum if a node dissection is required.

If, at the time of exploration, the location and consistency of the mass is not obvious, then the tunica vaginalis can be incised to expose the tunica albuginea of the testis. If with this level of observation, it is still not possible to distinguish the exact nature of the mass in question, a biopsy can be performed. Before performing a biopsy, however, it is recommended that the testicle be walled off with dry laparotomy pads to avoid any potential spill into the wound. If there is any doubt at the time of biopsy and frozen section, the testicle should be removed. It is an error of much greater significance if a testis with a tumor is left in place than if a testis without a malignant neoplasm is removed. If the mass is shown to be benign, the tunica albuginea of the testis can be reapproximated with an absorbable suture and the testis can be returned to the scrotum. Because noncrushing clamps are used, the blood supply of the testis should not be jeopardized.

In prepubertal males, lesions consistent with teratoma or epidermal cyst, with negative tumor markers, and a benign clinical evaluation can be excised using a testis-sparing technique. Frozen sections should be obtained at the time to confirm the benign nature of the lesion (62,201). The same is true for postpubertal males with findings consistent with epidermal cysts (105).

Serum markers (b-hCG, AFP, and LDH) should be obtained before surgical exploration in anyone suspected of having a testis tumor. This will be helpful later in monitoring the level of markers as an indication of response to therapy.

When a non–germ cell tumor is encountered, the same inguinal orchiectomy with high ligation of the cord also is indicated. Often, simple surgical excision of these tumors is satisfactory treatment; however, because one cannot be certain ahead of time of the precise diagnosis of the tumor, it is advisable to treat it in the same manner as one would a potential germ cell tumor.

In the case of either a suspected germ cell tumor or a non–germ cell tumor, a transscrotal approach to open biopsy or needle aspiration of the mass is ill-advised. The inguinal approach is definitely recommended to avoid potential cross-contamination of different lymphatic drainage systems.

Patients who have had previous inguinal or scrotal procedures for conditions such as cryptorchidism, inguinal hernia, or hydrocele should be approached in the same manner as a patient with no previous procedure in this area. The one exception to this recommendation is a testicular tumor encountered through a scrotal incision. In this instance, an inguinal approach for the orchiectomy should be used and a hemiscrotectomy also should be performed to excise the area of potential wound contamination. If there is obvious extension of the tumor into the scrotal wall, a combined inguinal approach along with a hemiscrotectomy should be used to achieve en bloc resection of the testis, cord structures, and scrotal wall.

When a scrotal violation has occurred, there is a possibility of metastases to the inguinal lymph nodes. The patient must be followed for evidence of inguinal adenopathy in addition to the normal follow-up. However, inguinal node involvement is rare unless there has been gross tumor spillage, which has been untreated for several months.

Orchiectomy for a metastatic lesion to a testis is rarely indicated. Normally, the primary source of tumor is recognized, and because it is often a late manifestation of disease, the precise knowledge of metastasis to the testis plays little role in management of the patient.

STAGING OF TESTIS TUMORS

Definition of Stages

As with most solid tumors, the AJCC has developed a TNMS system for germ cell neoplasms. Seminoma and nonseminomatous germ cell tumors (NSGCT) including teratoma, yolk sac tumor, choriocarcinoma, embryonal carcinoma, teratocarcinoma, and mixed other cell types are included. Rare non–germ cell tumors such as stromal cell tumors, Sertoli cell and Leydig cell tumors are not included in the current TNMS classification. In 1997, the AJCC in collaboration with the World Health Organization (UICC) updated the TNM classification to include presence of lymphovascular invasion and serum markers as part of the staging criterion (Table 41.3). The updated system allows more precise definition of both the clinical and pathologic stage of germ cell tumors and therefore simplification of treatment and prognosis decision-making schema. Table 41.4 provides a comparison between the updated TNMS staging schema between the 1997 fifth edition AJCC schema and its predecessors, the 1992 AJCC schema and the Indiana schema.

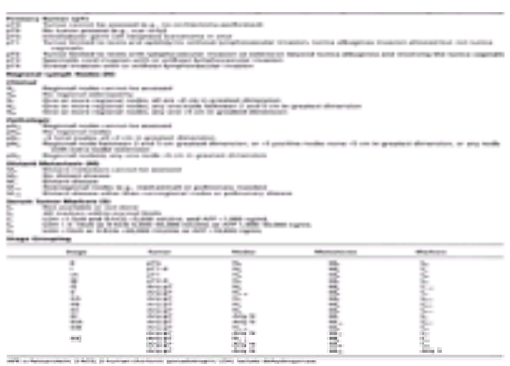

TABLE 41.3. AMERICAN JOINT COMMITTEE ON CANCER, FIFTH EDITION FOR TESTICULAR NEOPLASMS: SEMINOMA, EMBRYONAL CARCINOMA, YOLK SAC TUMOR, TERATOMA, CHORIOCARCINOMA, OR MIXED

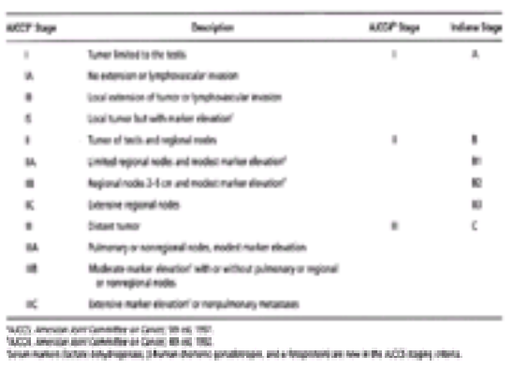

TABLE 41.4. CLINICAL STAGES OF TESTIS TUMORS

Clinical Staging

Clinical staging must be accomplished to appropriately plan the initial therapeutic approach to the patient. As shown in Table 41.3, clinical stages are grouped into stage I, with tumor with or without lymphovascular invasion, with or without marker elevation limited to the testis cord structures and scrotum; stage II, with tumor confined to the retroperitoneal lymph nodes; and stage III, with tumor involving the abdominal viscera or extending above the diaphragm.

Repeated serum markers (AFP, b-hCG, and LDH) should be obtained at intervals after the radical orchiectomy is performed. If the patient had elevated markers before radical orchiectomy, following up the serum markers is helpful in determining whether residual tumor is definitely present. The b-hCG has a half-life of approximately 1 day, the AFP has a half-life of approximately 5 days, and the LDH half-life is approximately 3 days. Knowing the half-life, it is possible to estimate whether residual disease is still present based on the observed rate of degradation of the markers in those patients who had initially elevated markers. Unfortunately, some patients will have degradation of the markers at the normally expected rate and will still have residual tumor. Again, just as in the initial presence or absence of the marker, a positive or elevated value has significance, while a normal level value does not necessarily exclude presence of residual tumor.

Presence of pulmonary parenchymal metastases can be satisfactorily evaluated with either whole lung tomography or computed tomography (CT) scans. Numerous reports in the literature support the sensitivity and specificity of each of these modes of examination. The choice of the examination should be in the hands of the individual practitioner and should be based on the instrumentation available and the skill and experience of the radiologist at the institution. In general, chest CT scans are used rather than tomography. If retroperitoneal lymph nodes are not enlarged, conventional chest radiograph is probably sufficient. If pulmonary parenchymal lesions are evident, the patient's tumor would be classified as clinical stage III.

The abdomen is evaluated by abdominal CT scan, which allows assessment of the major viscera such as the liver, spleen, and kidneys as well as the retroperitoneal lymph nodes. The threshold of detection for an abnormal mass by CT scan is approximately 1.0 cm. When this criterion is used, sensitivity is in the range of 70%, with an approximately 30% false-negative rate. This limitation is readily explained by the presence of microscopic or small volume gross nodal involvement. The quality of CT also can be eroded by lack of retroperitoneal fat in these young, otherwise healthy, frequently thin patients. Leibovitch and co-workers have reported a sensitivity increase to 91% by decreasing the size criterion to 3 mm for nodes located within the predicted landing zones and 1 cm for all other areas. This modification yielded a

10% false-negative rate but decreased specificity to 52% (109). If one or more enlarged retroperitoneal lymph nodes are noted and all are less than 2 cm, the patient's disease is classified as clinical $T_xN_1M_xS_x$, stage IIB disease. Patients with one or more retroperitoneal lymph nodes between 2 and 5 cm are classified as clinical $T_xN_2M_xS_x$, also stage IIB disease by the revised classification (Fig. 41.11), and any retroperitoneal lymph node larger than 5 cm is classified as clinical $T_xN_3M_xS_x$, stage IIC disease (Fig. 41.12). Presence of extraretroperitoneal lymph nodes is classified as clinical $T_xN_xM_{1a}S_x$, stage III disease, and presence of visceral, pulmonary, or other metastases are classified as clinical $T_xN_xM_{1b}S_x$, stage IIIC disease.

FIGURE 41.11. Abdominal computed tomogram showing a 2-cm-by-1.5-cm mass *(white arrow)* in the left periaortic area just anterior and medial to the left ureter, which is opacified with contrast *(white area).* This represents clinical stage IIB ($T_xN_2M_xS_x$) disease.

FIGURE 41.12. Abdominal computed tomogram showing a 5-cm-by-6-cm mass *(white arrow)* anterior to the right psoas muscle, which also obscures the vena cava. The 1997 revision of the AJCC staging criteria also categorizes these findings as stage IIC disease, but with $T_xN_3M_xS_x$, TNMS nomenclature.

The workup just described is performed in the case of all types of germ cell tumors. Historically, patients with seminoma also were studied with lymphangiogram (Fig. 41.13). A lymphangiogram was thought to be valuable for definition of radiation ports in the treatment of seminoma. Currently, at the authors' institution, a lymphangiogram is not used for seminoma or nonseminomatous germ cell tumors because the findings would not influence treatment.

FIGURE 41.13. A bipedal lymphangiogram of a patient with left testicular seminoma. Distortion and obstruction of the lymphatics in the left periaortic area at the L-2 to L-3 level *(black arrow)* suggests stage II disease.

MRI is a promising technique for imaging the body. The technical aspects of the procedure are improving steadily. A comparison of images from some of the first-generation MRI instruments did not show any advantage over conventional CT scans (50). The quality of the new images on the improved instrumentation may well change that status.

The 1997 revision of the AJCC staging criteria brought incorporation of two significant changes. First, recognition of the importance of lymphovascular invasion within the primary tumor was addressed by redefining clinical $T_1N_xM_xS_x$ tumors as those tumors limited to the testes and epididymis without lymphovascular invasion, and clinical $T_2N_xM_xS_x$ tumors as those that extend beyond the tunica albuginea *or* contain lymphovascular invasion. Secondly, the 1997 revision, for the first time, incorporates the serum markers b-hCG, AFP, and LDH into the clinical staging criteria. Thus all three markers are within normal limits at diagnosis for $T_xN_xM_xS_0$ disease. Elevation of LDH less than 1.5 times normal, b-hCG less than 5,000 mIU/mL, *or* AFP less than 1,000 ng/mL is defined as clinical stage $T_xN_xM_xS_1$ disease. For $T_xN_xM_xS_2$, any one marker is above the S_1 criterion but less than 10 times normal for LDH, *or* less than 5,000 mIU/mL for b-hCG *or* less than 10,000 ng/mL for AFP and for $T_xN_xM_xS_3$ any one marker above 10 times normal for LDH, *or* greater than 50,000 mIU/mL for b-hCG *or* greater than 10,000 ng/mL for AFP. Additional markers are available but are not widely used because of cost and lack of close correlation with disease stage or specificity (e.g., placental alkaline phosphatase, LDH isozymes). Numerous molecular markers also are being studied, but none are clinically applicable for general use at this time.

Combining clinical T stage, N stage, M stage, and S stage allows more precise clinical staging of germ cell neoplasms (Table 41.3).

Overall, the accuracy of clinical staging varies between 20% and 40% (159,164). The 1997 revision of the AJCC TNMS staging system incorporates improvements in clinical and radiographic staging of the retroperitoneum and chest and recognizes the importance of lymphovascular invasion within the primary tumor and the value of serum markers in this disease. This matter is discussed more fully later in this chapter; however, on a practical basis, patients with nonseminomatous, low-stage tumors (clinical stages I through IIB) undergo a primary surgical staging by retroperitoneal lymph node dissection, whereas patients with high-stage disease (stages IIC and III) undergo treatment with primary chemotherapy. At some centers, patients with clinical stage IA disease are observed without surgical staging. This point also is discussed more thoroughly later in the chapter.

Surgical Staging

Retroperitoneal lymph node dissection (RPLND) serves two purposes in the setting of low-stage disease. First, because approximately 30% of clinical stage I patients

are pathologic stage II ($T_xN+M_0S_x$), RPLND serves a staging purpose in that it reliably identifies the pathologic stage II patient early in the course of his disease. Second, the removal of metastatic disease by RPLND in pathologic stage II patients is therapeutic in approximately 50% to 70% of patients. That is, in patients proven to have small- to moderate-volume retroperitoneal metastasis, RPLND can provide long-term cure to 70%, without the necessity of subsequent chemotherapy (39).

RPLND originally was perfected and described by Cooper and Leadbetter and associates (26) who used an extraperitoneal thoracoabdominal approach. The extraperitoneal thoracoabdominal approach is useful in dealing with patients who have bulky retroperitoneal disease high in the abdomen. This extraperitoneal thoracoabdominal approach is still in use in many centers for RPLND in patients with low-stage disease (Fig. 41.14).

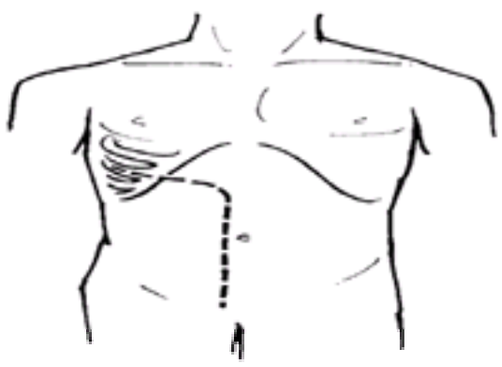

FIGURE 41.14. Thoracoabdominal approach used by some centers for a radical retroperitoneal lymph node dissection. This is an extraperitoneal approach.

Donohue perfected and popularized a transabdominal approach, which avoids a thoracoabdominal incision, does not require the incision of any muscle, and provides excellent bilateral exposure (35). The original technique uses a midline xiphoid-to-pubis incision followed by mobilization of the right colon and root of the small bowel (Fig. 41.15). An incision is performed from the foramen of Winslow to the cecum, then cephalad to the ligament of Treitz. The inferior mesenteric vein is divided, and the root of the small bowel and right colon is mobilized off the retroperitoneum and placed in a bowel bag on the patient's chest. The split and roll maneuver, whereby lymphatic tissue is split over the aorta and the vena cava and rolled medially and laterally, is then performed. The inferior mesenteric artery is identified and divided, and the mesentery of the left colon retracted laterally. This exposure allows completion of the traditional full bilateral RPLND (Fig. 41.16). The borders of this dissection include the crus of the diaphragm superiorly, the bifurcation of the common iliac arteries distally, and the ureters laterally. After the split and roll maneuver (Fig. 41.17) is performed, the aorta and vena cava can be retracted from the posterior body wall. Lymphatic tissue is then harvested in four packages: right paracaval, interaortocaval, left periaortic, and interiliac areas. No effort is made during full bilateral RPLND to preserve sympathetic efferent fibers. Hence, virtually all patients who undergo full bilateral RPLND lose emission/ejaculation.

FIGURE 41.15. Surgical incision and site of peritoneal incision to mobilize the small bowel and right colon for an anterior approach for a radical retroperitoneal lymph node dissection. (From Donohue JP. Retroperitoneal lymphadenectomy: the anterior approach including bilateral suprarenal-hilar dissection. *Urol Clin North Am* 1977;4:509, with permission.)

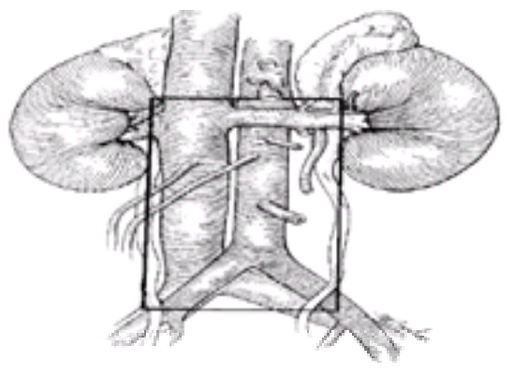

FIGURE 41.16. Margins of dissection of full bilateral retroperitoneal lymph node dissection, including right and left suprahilar areas.

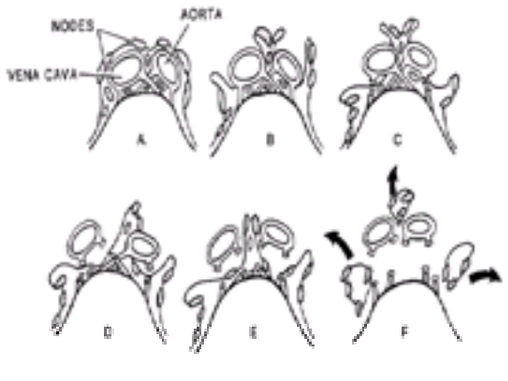

FIGURE 41.17. A–F: “Split-and-roll” technique, which has been modified such that the tissue adjacent to the aorta and vena cava is removed in three bundles: right pericaval group, interaortocaval group, and left periaortic group.

Mapping studies performed by Donohue and others subsequently proved that a full bilateral dissection was not necessary in all patients (40). These mapping studies showed that in patients with low-volume retroperitoneal disease, the site of the disease in the retroperitoneum could be predicted based on the side of the primary and the volume of retroperitoneal disease. Therefore patients with low-volume retroperitoneal disease at laparotomy underwent a modified template, en bloc dissection

(Fig. 41.18). The advantage of the modified template dissection is the preservation of ejaculation in some but not all patients. In addition, because the retroperitoneum is not dissected bilaterally, the procedure requires less time in the operating room and generally a shorter period of postoperative ileus. Thus modified template dissections allow maintenance of the staging and therapeutic aspects of the procedure but eliminate some of the morbidity of the procedure, that is, loss of ejaculation.

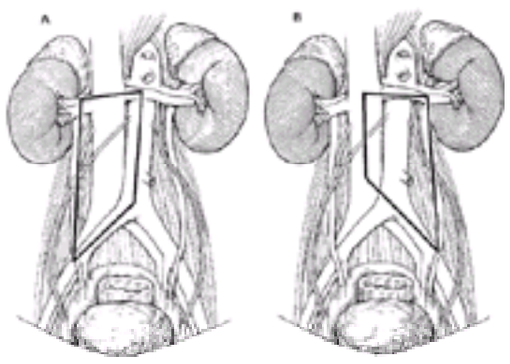

FIGURE 41.18. Templates for right **(A)** and left **(B)** modified nerve-sparing retroperitoneal lymph node dissection.

As surgeons became more experienced with the retroperitoneum, it became apparent that the sympathetic efferent fibers could be reliably identified and dissected in the course of a retroperitoneal lymph node dissection. Donohue, Jewett, and others subsequently showed that these fibers could be dissected followed by either a full bilateral or a modified unilateral lymph node dissection (36,91). The advantage of a nerve-sparing dissection over a modified template dissection is that ejaculation is preserved at the 99% level with nerve-sparing RPLND, as opposed to 50% to 90% with modified template unilateral RPLND. In addition, it is now clear that modified template nerve-sparing RPLND maintains both the staging and therapeutic aspects of the procedure because local recurrence in the retroperitoneum after nerve-sparing RPLND is rare.

The surgical approach for a nerve-sparing dissection usually requires an incision only in the root of the small bowel mesentery, as shown in Fig. 41.19. The zones of dissection are similar to the modified template dissection. The modified templates for nerve-sparing RPLND are depicted in Fig. 41.20.

FIGURE 41.19. A retroperitoneal window is created to give exposure for nerve-sparing retroperitoneal lymph node dissection. The *dashed line* indicates the peritoneal incision needed to mobilize the remainder of the small bowel and ascending colon if more extensive exposure is required.

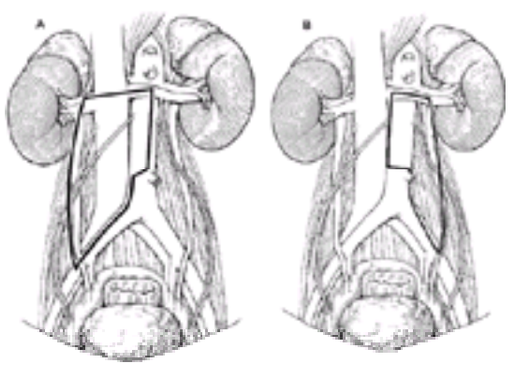

FIGURE 41.20. Templates for right **(A)** and left **(B)** modified retroperitoneal lymph node dissection.

It is well recognized that some patients with testicular cancer are hypofertile at the time of diagnosis, before any therapy. Thus the question of whether nerve-sparing RPLND is reasonable has been raised. The fertility of patients who have undergone nerve-sparing RPLND has been studied, and it is known that at least some of these patients are fertile at diagnosis. Nerve-sparing RPLND reliably preserves this fertility potential because approximately 80% of couples who attempt pregnancy after nerve-sparing RPLND are successful (56).

Therefore, as the template of dissection has evolved from full bilateral to a modified to a modified nerve-sparing approach, the staging and therapeutic aspects of the procedure have been maintained while reducing the risk of loss of emission to 1% to 2%.

Patients scheduled for nerve-sparing RPLND are admitted to the hospital the morning of surgery. Routine blood chemistries and a urinalysis are obtained the morning of surgery if the patient has not been seen recently. A type and screen is obtained; transfusion is rarely necessary during routine modified template nerve-sparing RPLND.

Standard modified template nerve-sparing RPLND requires approximately 2 to 3 hours operative time. A nasogastric or orogastric tube is placed after induction of anesthesia. After evacuation of stomach contents at the completion of the procedure, the tube is removed.

The patient is sent to a normal hospital room after the recovery room. Clear liquids are begun the following day because a significant ileus is not usually present. The diet and activity are rapidly advanced, with the hospital stay averaging 3 to 5 days.

TREATMENT OF LOW-STAGE TESTIS TUMORS

Stage I Nonseminomatous Germ Cell Testis Tumors

In patients who had clinical stage I nonseminomatous germ cell testis tumor as evidenced by no metastases in the chest on radiologic evaluation, no evidence of retroperitoneal metastases as shown by abdominal CT scan, and normal serum levels of b-hCG, AFP, and LDH, the standard treatment historically was a full bilateral radical RPLND, as originally described by Donohue (34). See Fig. 41.21 for schema. Postoperatively, if disease in these patients was truly pathologic stage I (no

retroperitoneal metastases), the patients were observed without adjuvant therapy. Using this treatment regimen, 154 patients were described by the Southeastern Cancer Study Group. Of these, 15 patients (9.7%) had relapse of the tumor, and of these, 3 died (2% of patients). Two of these three patients declined chemotherapy, and the third patient received chemotherapy in what would now be considered suboptimal doses. In light of this overall cure rate in excess of 98%, adjuvant chemotherapy does not seem to be needed for pathologic stage I testis tumors as long as careful follow-up is obtained.

FIGURE 41.21. Algorithm for the diagnosis of testis cancer and for the treatment of low-stage disease. Note that the treatment of high-stage tumors (IIC and III) is shown in Fig. 41.22. AFP, a-fetoprotein; CT, computed tomography; b-hCG, b-human chorionic gonadotropin; RPLND, retroperitoneal lymph node dissection.

Because of the problems with ejaculatory impotence after a full bilateral dissection, most centers have used a modified set of boundaries for radical RPLND in patients with no gross evidence of metastatic disease in the retroperitoneum. The margins of the modified template dissections used at Indiana University are shown in Fig. 41.18A and Fig. 41.18B. These modifications were made on review of the distribution of positive nodes in patients with pathologic stage IIA disease. In this study, virtually no metastatic lesions were noted in the area lateral to the midplane of the contralateral great vessel. Also, virtually no metastases were present in the suprahilar zones. Rare metastases were noted in the presacral areas (40). By modifying the boundaries of dissection, the rate of ejaculatory impotence was reduced significantly. In one series reported by Richie and Garnick, 17 of 19 patients who underwent a modified dissection had preservation of antegrade ejaculation (158). One patient had antegrade ejaculation after taking imipramine, and 1 of the 19 patients had retrograde ejaculation. Another series of 145 patients, reported by Weissbach and Boedefeld, compared the rate of postoperative ejaculation, rate of progression, and postoperative complications of 36 patients undergoing a full bilateral radical RPLND with the same rates in 68 patients undergoing a modified RPLND (206). Ejaculation was successfully preserved in 75% of those patients undergoing a modified RPLND and in 23% of those undergoing a full bilateral radical RPLND. The relapse rates in the two groups were 22% in those who had a full bilateral dissection and 12% in those who had a modified dissection. One needs to remember that there was a selection bias in this group because this was not truly a randomized study. No significant difference was noted in the complication rate between the two groups, with a 12% rate in the full bilateral dissection group and a 17% rate in the modified dissection group.

Beginning in 1985, true nerve-sparing procedures were performed at Indiana University for those patients with no evidence of gross disease, and a desire to preserve emission. The surgical approach and boundaries of dissection have been shown in Fig. 41.19 and Fig. 41.20. A review revealed preservation of emission in 72 of 73 patients. The recurrence rate [4 of 73 (5%)] has not been significantly different from the rate of those patients who had undergone full bilateral or modified node dissections in the past. A more recent report from Indiana University has verified the early experience with nerve-sparing RPLND (39). The recurrence rate has remained unchanged from the earlier experience in both pathologic stage $T_xN_{1-2}M_0S_x$ patients. Ejaculation is preserved in more than 98% of patients.

In light of the high success rate of treating germ cell testis cancers with systemic platinum-based combination chemotherapy, some authors have proposed conservative management of clinical stage IA testis tumors. The Medical Research Council in the United Kingdom, for example, performed a retrospective multivariate analysis that suggested four prognostic factors: vascular invasion, lymphatic invasion, presence of embryonal carcinoma, and absence of yolk sac tumor (57). A prospective study designed to test this hypothesis supported a prognostic index based on these factors (157). Subsequent studies were unable to distinguish between lymphatic and vascular invasion but confirmed its importance (63,86,90,129,135,172,181,183). Presence of embryonal carcinoma (41,86,128,129,135,181) and absence of yolk sac tumor (98) also have been confirmed as prognostic indicators in this patient population. In addition to the normal clinical evaluation—chest evaluation by CT scan, abdominal and retroperitoneal evaluation by abdominal CT scan, and measurement of serum markers—some centers that are pursuing an observation protocol also evaluate their patients with a lymphangiogram. If all of the studies are negative, then the patients are followed conservatively. The optimal follow-up schedule for patients managed by surveillance is controversial. Most groups recommend more intensive follow-up in the early years of surveillance, with lengthening of the follow-up period as the time from diagnosis increases. What is apparent, however, is that abdominal imaging is absolutely necessary in patients managed by surveillance because most of the patients whose disease recurs manifest recurrence as an abnormality in theretroperitoneum on abdominal CT scanning. It also is clear that this follow-up in patients managed by surveillance must be prolonged because recurrences in patients managed by surveillance are not rare after the second year of follow-up. In contrast, recurrences greater than 2 years after a nerve-sparing RPLND are rare. Therefore compliance with follow-up is a major consideration in a patient considered for surveillance.

The Medical Research Council group in Great Britain has reported its experience using surveillance in clinical stage I patients (157). The overall survival in the short term was 98%. Of the patients whose disease recurred in this report, 20% went on to require postchemotherapy RPLND. It is clear that surveillance done effectively with good compliance yields roughly equivalent results as RPLND for clinical stage I patients in the short term. However, because unresected retroperitoneal germ cell cancer can remain indolent for significant periods of time only to reactivate later, long-term follow-up and reporting of patients managed by surveillance is absolutely necessary. A recent report (3) confirms that unresected germ cell cancer can remain indolent for significant periods in a certain percentage of patients. Therefore lifelong follow-up is mandatory.

Because nerve-sparing RPLND and surveillance yield roughly equivalent results in properly managed patients in the short term, the morbidities of these two therapies become increasingly important as a determinate of which management scheme is appropriate in an individual patient. The morbidity of nerve-sparing RPLND is low (3) and consists of short-term management of pain and the 1% risk of small bowel obstruction secondary to postoperative adhesions. Because nerve-sparing RPLND almost always preserves ejaculation, it rarely impinges upon fertility in this group of patients.

Patients managed by surveillance whose disease does not recur have low morbidity. Although patient anxiety can be a problem, these patients incur no additional morbidity. However, the 30% to 40% of patients who do develop recurrence are given chemotherapy, which has very definite morbidity. Because chemotherapy has a definite effect on spermatogenesis, long-term reports are needed concerning spermatogenesis in patients administered current chemotherapeutic regimens for testicular cancer.

Stage II Nonseminomatous Germ Cell Testis Cancer

Historically, patients with clinical stage II nonseminomatous testis cancer have undergone full bilateral radical RPLND as their primary treatment. Fig. 41.21 also includes stage II treatment schema. The relapse rate after radical RPLND has been proportional to the bulk of disease present in the retroperitoneum. In patients with microscopic disease only ($T_xN_1M_xS_x$), the relapse rate has been approximately 25%. In pathologic stage IIB ($T_xN_{1-2}M_xS_x$), the relapse rate has been approximately 40%. In patients with pathologic stage $T_xN_3M_0S_x$ or $T_xN_xM_1S_x$ disease, the relapse rate has varied between 75% and 100%. Because the relapse rate in this group has been so high, most centers treating testis cancer believe that the appropriate initial therapy in this group should be systemic chemotherapy. The aspects of this form of treatment are discussed in a later section of this chapter.

As previously discussed, if no gross disease is noted at the time of RPLND and the patient is presumed to have clinical stage I disease ($T_xN_0M_0S_x$), a modified nerve-sparing RPLND is carried out. Again, from the distribution of positive lymph nodes in patients with stage $T_xN_1M_xS_x$ carcinoma (40), a modified dissection is satisfactory for removing disease because in the absence of gross disease, virtually no presacral, suprahilar, or contralateral (lateral to the midplane of the contralateral major vessel) metastases occur.

Many authors have addressed the issue of additional therapy after RPLND for stage $T_xN_{1-2}M_0S_x$ testis cancer over the years. One of the authors of this chapter (RGR) has participated in a study of 240 patients with stage ($T_xN+M_xS_x$) disease. Half of these patients were assigned to observation postoperatively and half were assigned

to two courses of adjuvant combination platinum chemotherapy [cisplatin (*cis*-diaminedichloroplatinum), vinblastine, and bleomycin (PVB)]. Each arm was balanced with an equivalent number of stage N_1 and N_2 cases. Forty percent of the observation cases relapsed and were treated with four courses of PVB chemotherapy. Of the 40% who suffered relapse, all but four (3%) of the patients are alive and free of disease. Four patients have died. The regimens of three constituted protocol violations, and they did not receive the normal full-dose PVB therapy.

In the patients treated with two courses of adjuvant PVB chemotherapy, only 1 of 120 has suffered relapse. This patient is now free of disease after surgical excision of the residual tumor. One other patient died of gastrointestinal complications 2 months postoperatively. Overall, survival in the adjuvant PVB group is 99.2% (38). Similar results have been reported by other institutions using a vincristine, doxorubicin (Adriamycin), bleomycin (VAB-6) protocol (199).

When stage N_1 and N_2 tumors are considered together, the overall survival rate is 98%. The difference between observation with delayed chemotherapy, if needed, and adjuvant chemotherapy is very small. One issue that needs to be settled is the difference in the two groups in terms of long-term side effects of adjuvant chemotherapy.

Currently, the authors recommend individualization of the treatment of stage N+ testis cancer. After a node dissection is performed, the bulk of the metastatic disease and the reliability and availability of follow-up to the patient are considered. If for any reason follow-up of the patient for at least 2 years would be suboptimal, two courses of adjuvant chemotherapy are recommended (Fig. 41.21). On the other hand, if one is dealing with a very reliable patient who understands the potential for relapse, observation and treatment with four courses of bleomycin, etoposide, and cisplatin (BEP), if recurrence is identified, are appropriate. Treatment with two courses of adjuvant BEP extends the period of disability only approximately 1 month. After undergoing the adjuvant chemotherapy, the patient has a very high likelihood (greater than 99%) that he will not require any subsequent therapy for testis cancer that will interrupt his ability to lead a productive life.

An alternative approach to the management of clinical stage $T_xN+M_0S_x$ testis cancer is the administration of primary chemotherapy (85). In this report, survival was comparable to the Indiana University experience with clinical stage II disease in the short term. Approximately one-third of clinical stage II ($T_xN+M_0S_x$) patients managed with primary chemotherapy will require postchemotherapy RPLND. Similar to clinical stage I ($T_xN_0M_0S_0$) patients, what is needed in clinical stage $T_xN+M_0S_x$ patients managed with primary chemotherapy is information relative to short- and long-term side effects of therapy in the entire group, and frequency of late recurrences (recurrence of disease greater than 2 years from completion of initial therapy).

It is now clear that nerve-sparing techniques can be used in patients with evident retroperitoneal disease (91). Hence, patients with clinical stage $T_xN+M_0S_x$ disease who are subjected to RPLND now may have their disease resected and maintain ejaculatory competency postoperatively. If these patients do not subsequently require chemotherapy, their fertility status has not been affected by their therapy. Therefore the necessity of reporting long-term morbidity of clinical stage $T_xN+M_0S_x$ patients managed by both nerve-sparing RPLND and primary chemotherapy is apparent in order to allow an individual patient to make a decision regarding therapy.

Low-stage Seminoma

For patients with clinical stage I pure seminoma, some centers perform lymphangiography in addition to routine staging tests. If a patient's disease is still found to be stage I (no evidence of retroperitoneal metastases), the patient undergoes radiation to the ipsilateral inguinal and iliac area and the periaortic and pericaval areas to the level of the diaphragm (Fig. 41.21, left poststaging branch). In a series of 62 patients treated this way, 59 were free of disease after a 3-year follow-up (88). The normal treatment is 2,500 rad delivered over a 3-week period. This 95% cure rate is representative for other series in the literature. Surveillance also has been used in a study setting for clinical stage I seminoma. The short-term results are good. However, long-term follow-up is necessary because seminoma may recur many years after initial diagnosis (203).

In patients with clinical stage IIB ($T_xN_2M_xS_x$) pure seminoma, which is diagnosed by grossly enlarged lymph nodes in the retroperitoneum seen on CT scan or by positive nodes seen at the time of lymphangiography, a controversy exists in terms of the fields for radiation therapy. Hussey and Doornbos recommend mediastinal and left supraclavicular radiation as well as periaortic, pericaval, and ipsilateral inguinal radiation (88). In their experience, those patients receiving only iliac and periaortic radiation had a 55% cure rate. Other centers have adopted a policy of radiation limited to the retroperitoneum below the diaphragm, based on the observation that their recurrence rates have been similar regardless of whether or not they had radiation to the mediastinum and supraclavicular area (202). Also, it has been noted that if a patient has had full radiation both above and below the diaphragm, his ability to receive full-course chemotherapy in the event of a relapse has been severely limited. In light of these findings, plus the observations that seminoma responds well to platinum-based combination chemotherapy, physicians in many centers think that stage IIB seminoma should be treated with radiation to the diaphragm only. Shipley reports a combined series of data from the literature indicating that in 164 stage IIB patients with pure seminoma, the cure rate was 85% with radiation therapy alone (176). The radiation dose to the retroperitoneum is usually in the range of 3,000 rad, with some centers using an additional boost of up to 600 rad in areas where gross disease was shown on CT scan or lymphangiogram. Radiation to the retroperitoneum is normally well tolerated. When radiation is limited to the retroperitoneum and inguinal area, full-dose chemotherapy may be used if the patient has a relapse.

Stage III seminoma is treated in the same manner as a nonseminomatous tumor, using primary chemotherapy.

TREATMENT OF HIGH-STAGE GERM CELL TESTIS TUMORS

Over the last 10 to 15 years, the treatment of high-stage testis cancer has changed dramatically. The survival rates in advanced disease previously were in the range of 5% to 10%. The initial approach to high-stage disease was surgical resection or debulking, followed by chemotherapy. Although this made a dramatic advance in the survival rates over those of surgery alone, the rates at the time were considerably lower than currently are available using multimodal therapy. In 1976, Merrin and colleagues filed an initial report on 11 patients who underwent primary cytoreductive surgery followed by postoperative chemotherapy using a six-drug regimen. Although they initially reported a complete response in three patients, a follow-up report quoted the survival rate in this group as 43% (120). A similar result was noted in a small group of patients from Indiana University. Seventy-five percent of those patients treated with primary cytoreductive surgery suffered relapse (37).

The subsequent development of effective cell cycle–specific agents used in combination made it possible to reverse the order of treatment in disseminated disease. Einhorn and Donohue (45) made a milestone report in this area. In this series of patients, cytoreductive chemotherapy was the primary treatment followed by adjunctive surgery to resect any residual masses that were present. Merrin and associates also reported a satisfactory result with this new approach (120).

Another significant advance in the treatment of disseminated testis cancer was made by Samuels and associates (166), who noted that the combination of vinblastine and bleomycin produced a complete response rate in 17 (33%) of 51 patients. This complete response rate was higher than would be predicted from single-agent data, thus demonstrating a strong synergistic effect. Other reports gave similar results using the combination of vinblastine and bleomycin with the addition of actinomycin D (28,212).

The next significant advancement in cure rates for advanced testis cancer came with the use of cisplatin. This agent was reported initially by Rosenberg and colleagues to cause a significant inhibition of bacterial replication (160). Higby and associates, in a phase I trial, showed that it was active against testicular carcinoma (78).

In light of the encouraging reports about cisplatin, platinum-vinblastine bleomycin (PVB) was started in August of 1974 at Indiana University. Fifty patients were treated using the PVB regimen between 1974 and 1976 (46). Of 47 evaluable patients, 33 (70%) achieved a complete clinical remission with a combination of the three drugs. The remaining 30% experienced a partial remission. One-third of these patients subsequently were rendered disease free by surgical resection of the remaining tissue masses. In those patients who achieved a complete clinical remission by chemotherapy alone (70%), only 9% had a subsequent relapse. In the initial series of 50 patients, 4 patients died in complete remission. Two of the deaths were attributed to the side effects of chemotherapy. One died of Gram-negative sepsis and the other of bleomycin-induced pulmonary fibrosis. The other two deaths were thought to be due to preexisting conditions. The report of an additional 78 patients using PVB, with or without doxorubicin, noted no additional drug-induced mortality (47).

Although in the overall experience, the rate of mortality was relatively low, the rate of granulocytopenic fevers (38%) and sepsis (15%) was significant. To try to reduce toxicity of the primary chemotherapy, a three-arm study was undertaken by the Southeastern Cancer Study Group (47). One arm received the standard PVB treatment course using 0.4 mg/kg of vinblastine. The second group received a reduced dose of vinblastine (0.3 mg/kg). The last group received 0.2 mg/kg of vinblastine with an addition of 50 mg/m^2 of doxorubicin. All groups received cisplatin at a rate of 20 mg/m^2 each of 5 days at the beginning of each 3-week course of chemotherapy. In addition, each patient received 30 units of bleomycin intravenously weekly for the 12-week treatment course. In this study, the difference in the

response rates among the three different groups was not significant. The decrease in the toxicity of the regimen in terms of granulocytopenic fevers and sepsis was significant. The group that received the smaller dose of vinblastine (0.3 mg/kg) without doxorubicin had the lowest rate of granulocytopenic fever (15%), and no sepsis was documented in the 27 patients assigned to this treatment arm. Because of the lower rate of toxic effects in the 0.3-mg/kg group, this regimen became the standard treatment.

Maintenance therapy had originally been used with patients receiving vinblastine, 0.3 mg/kg monthly for an additional 20 months. A randomized trial to study the efficacy of the maintenance therapy was performed. In 113 patients studied, there was no significant difference in the relapse rate in the maintenance group receiving monthly vinblastine (9%) versus the group with no maintenance (7%). The disease-free status also was similar (44).

In reviewing a total of 125 patients who were treated with the basic PVB combination with or without doxorubicin, the overall complete response rate was noted to be 69% (47). In this report, the response to disease was essentially inversely proportional to the amount of disease present. If serum markers only were elevated and there was no demonstrable gross disease, the complete response rate was 100%. On the other hand, if there was advanced pulmonary disease—defined as masses greater than 2 cm in diameter or more than six pulmonary metastases per lung—the complete response rate was 55%. In advanced abdominal disease—defined as presence of masses greater than 6 cm in diameter—the complete response rate was 46%. A report by Vugrin and associates (198) at Memorial Sloan-Kettering Cancer Institute has noted a similar (68%) complete remission rate using the VAB-6 protocol, which also contains cisplatin.

The next significant development in chemotherapy was the substitution of etoposide for vinblastine. This reduced toxicity but maintained the same efficacy rate. Einhorn and his associates (48) reported a study comparing three versus four courses of cisplatin, etoposide, and bleomycin (BEP) in low-risk patients with metastatic disease. The study showed that three courses were as effective as four in this patient population.

An additional study by Loehrer and co-workers (112) looked at the possibility of deleting bleomycin in the aforementioned regimen. The results in this 166-patient study showed the need to maintain bleomycin to keep up efficacy. As a result, cisplatin, etoposide, and bleomycin are the current agents used in many centers for chemotherapy for germ cell tumors.

Progress in Diagnosis and Staging

Another significant improvement in the treatment of advanced testis cancer is the increase in the ability to accurately diagnose and stage advanced disease. As pointed out earlier in this chapter, the development of CT scans has aided greatly in the diagnosis and staging of testis cancer. Although truly massive disease is not a diagnostic dilemma in most patients, correct assignment of a patient to a low-stage approach with primary surgery versus a high-stage approach with primary chemotherapy is aided greatly by evaluation of retroperitoneal and chest masses using CT scans in the abdomen, and CT scans or whole-lung tomograms in the chest. In one series reported in the literature, the detection rate of stage IIC disease was virtually 100% (164). For low-stage disease, improvements in CT scanning technology has prompted several authors to propose modification of the staging criteria for the retroperitoneum. In 1997, Hilton and co-workers reviewed CT nodal staging criteria for 10-mm metastases and found a sensitivity of 37% and specificity of 100%; however, by decreasing the primary landing zone minimum size to 4 mm, the sensitivity increased to 93% and specificity fell to 58% (80). The false-negative rate decreased from 63% for 10-mm node size criterion to 7% using a 4-mm node size criterion. Liebovitch and co-workers proposed decreasing the size criterion located within the primary landing zones and reported a sensitivity of 91% (10% false-negative rate) and specificity of 52% (109). The value of MRI and positron emission tomography (PET) scanning for staging tumors and characterizing abnormal tissue masses is currently under study.

With questionable pulmonary metastases and without retroperitoneal masses, the use of serum markers (AFP, b-hCG, and LDH) can be useful. If any of the serum markers are elevated, then a patient can be assigned reliably to primary chemotherapy without mass biopsy or excision.

Current Approach to the Treatment of High-stage Disease

In view of the advances in chemotherapy, diagnosis, and staging previously cited, the primary treatment of advanced testis cancer has changed from cytoreductive surgery followed by chemotherapy to primary chemotherapy followed by surgical resection of any residual disease. This approach has led to a doubling of the survival rates compared with the surgery-chemotherapy approach used initially. Figure 41.22 shows the procedure used for treatment of patients with advanced disease. When patients with advanced disease are treated with primary chemotherapy, approximately 70% enjoy a complete clinical remission. This overall 70% complete rate of remission varies inversely with the amount of tumor present at the time of initiation and treatment (44). Patients with only elevated markers had a 100% response rate to chemotherapy, whereas patients with advanced or bulky abdominal disease had a 46% complete remission. Vugrin and associates have demonstrated similar findings using VAB-6 as their primary chemotherapy treatment (199).

FIGURE 41.22. Algorithm for the treatment of high stage disease. BMT, bone marrow transplant; CR, complete clinical remission; NED, no evidence of disease; PR, partial clinical remission.

After patients have undergone four courses of primary chemotherapy, complete clinical reevaluation is needed. This evaluation should include serum markers (LDH, AFP, and b-HCG), and chest and abdominal CT scans. With this testing, if there is absolutely no evidence of residual disease, then the patient can be observed. If, on the other hand, a partial remission is shown to have occurred by virtue of any of the above tests not indicating completely normal results, surgical resection of the tumor is indicated. The one exception to this rule is in patients with pure seminoma whose AFP level was never elevated (Fig. 41.21). This recommendation is based on the following observations at Indiana University: virtually all patients with disseminated seminoma that have never had an elevated AFP level have no active disease present at the time of excision of residual masses after four courses of chemotherapy. In all cases, resection of such tissue has yielded only scar or necrotic tumor. No teratomas or cases of persistent carcinoma have been observed. An exception to this scenario is the patient who has discrete residual retroperitoneal masses greater than 3 cm after chemotherapy, in contrast to sheets of residual “scar” tissue. In this case, the discrete masses yield residual tumor in at least one-fourth of the patients. Therefore postchemotherapy RPLND is recommended if discrete masses greater than 3 cm are present.

If a patient has persistently elevated serum markers after four courses of chemotherapy, CT studies are reviewed. If findings are localized and amenable to resection, the masses are resected. However, if diffuse or disseminated disease is identified, salvage chemotherapy should be undertaken.

In patients with negative markers in whom only a partial remission of disease is achieved, based on chest and abdominal CT scan findings, surgical resection of the tumor is performed. The surgical approach used to resect the residual masses is based on the size and location of disease. Table 41.5 shows the indications of various surgical approaches used in resecting disease. Depending on the amount of disease present, the procedures for resection of residual chest disease may be separated by several weeks from the procedure for resection of abdominal disease. However, in most instances it is possible to carry out resection of both chest and abdominal disease as a combined surgical procedure.

	RPLND	Thoracotomy	Median Sternotomy
Residual abdominal mass on CT	+		
Retrocrural mass on CT	+	±	±
Unilateral parenchymal		+	
Lung mass on CT or WLT			
Bilateral parenchymal or mediastinal masses			+
Elevated AFP or β-hCG[a]	±	±	±

[a]Persistent modest elevation of markers with potentially resectable mass.
AFP α-fetoprotein; β-hCG, β-human choronic gonadotropin; CT, computed tomography; RPLND, retroperitoneal lymph node dissection; WLT, whole-lung tomography.

TABLE 41.5. INDICATIONS FOR SURGICAL APPROACHES AFTER CHEMOTHERAPY FOR ADVANCED TESTIS TUMORS

In patients undergoing resection of residual masses after four courses of primary chemotherapy, approximately 44% have scar or necrotic tumor as their only pathologic finding at the time of surgery. Teratoma is found in an additional 44% of the surgical specimens, and carcinoma is present in approximately 12%. Patients having scar or teratoma are observed carefully using a course of follow-up outlined in a later section of this chapter. It should be noted that in patients with teratoma, in addition to undergoing the standard follow-up as previously outlined, additional follow-up for at least 10 years is necessary because of the rare instance of a late recurrence of teratoma.

In patients with residual carcinoma of their resected residual masses, further therapy is determined by whether the tumor was completely resected as evidenced by persistence of negative markers and the surgeon's findings at the time of operation. If all evidence indicates that complete resection of residual tumor mass was accomplished, then patients normally are followed carefully. If complete resection was not accomplished at the time of surgery, or if markers become positive in the postoperative period, then salvage chemotherapy is given.

Of the 70% of patients who achieve a complete clinical remission after four courses of primary chemotherapy, only 10% subsequently relapse. This represents approximately 7% of the initial population who were treated with primary chemotherapy for advanced disease. In this patient population, approximately 80% will achieve a second complete clinical remission with salvage therapy. This patient population is observed carefully for recurrence for a minimum of 2 years. In patients who receive a partial remission (20%) after salvage chemotherapy, the same principles apply to the resection of residual masses as previously outlined for patients who have a partial remission after primary chemotherapy alone. One significant difference, however, is that the distribution of pathologic findings in this group is considerably different from that in patients having surgery after primary chemotherapy. As shown in Fig. 41.21, only 10% of patients undergoing surgery for residual masses after a partial remission with salvage chemotherapy have scar or necrotic tumor as the only pathologic finding. Again, approximately 40% will have teratoma in the specimen, while 50% will have residual carcinoma. Patients with scar and teratoma are observed as they would be after surgery for a partial remission after primary chemotherapy. The same caution applies to patients with teratoma: they must have long-term follow-up because of potential late recurrences. Patients with carcinoma in their surgical specimen whose markers return to normal values are followed. In patients with carcinoma in the surgical specimen and elevated markers, third-line or tertiary chemotherapy (autologous bone marrow transplantation) is given.

Salvage surgery has been performed in a series of chemorefractory patients at Indiana University (130). In a group of 48 chemorefractive patients, a total of 60% were rendered grossly disease free and achieved negative markers after surgery. Twenty-one percent have maintained a durable complete remission a mean of 46 months after salvage surgery.

Overall, emphasis in the treatment of advanced disease has switched from primary surgical cytoreduction followed by adjuvant chemotherapy to primary cytoreductive chemotherapy followed by adjuvant surgical resection of any residual masses.

Retroperitoneal Lymph Node Dissection in Patients Treated with Chemotherapy

If RPLND is indicated because of a partial response to primary or secondary chemotherapy, several additional points must be considered before the operation. In addition to routine evaluation of the patient, as would be carried out before a primary RPLND, the patient must be monitored for any potential side effects of chemotherapy that could interfere with optimal care at the time of surgery. The notable point in this area is potential restrictive lung disease due to pulmonary fibrosis caused by bleomycin. Patients who have received bleomycin as part of their chemotherapy regimen should undergo screening pulmonary function studies and blood gas analyses performed on room air. It is not uncommon for patients to have an arterial oxygen content in the range of 70 to 80 mm Hg. These patients also may have a diffusion defect and a moderate decrease in their forced expiratory volume (FEV_1). Mild to moderate diffusion and restrictive defects have not been detrimental in the management of these patients.

Another area to consider is possible renal toxic effects from exposure to cisplatin. If the patient's serum creatinine level is elevated, a baseline evaluation with a creatinine clearance is suggested. In all of these patients, care must be exercised to avoid potentially nephrotoxic agents because they seem to potentiate the toxic effects of cisplatin. Special care must be taken in patients who have significant impairment of renal function at the time of surgery. The greatest concern is the use of potentially nephrotoxic antibiotics.

Another area of concern is potential myelosuppression in patients who have received vinblastine. Such myelosuppression is normally short lived, and because the surgical resection of residual tumor masses is not usually carried out until 5 to 6 weeks after the last course of chemotherapy, myelosuppression after chemotherapy is rarely a problem. After four or more courses of chemotherapy, the patient may still be anemic at the time of readmission for resection of residual tumor. If the hemoglobin level is less than 10 g/dL, the patient should be given a preoperative transfusion.

Usually, patients scheduled to undergo postchemotherapy resection of residual disease (RPLND with or without thoracotomy or median sternotomy) are admitted to the hospital 24 hours before surgery. In addition to standard preoperative testing, additional monitoring to look for pulmonary and renal toxic effects is carried out. The patient undergoes a mechanical bowel preparation with a clear liquid diet and citrate of magnesia as a cathartic. In the afternoon of the preoperative day, an intravenous line is established and the patient is hydrated with dextrose and 0.5 N saline at the rate of 100 mL per hour until the time of surgery. This prevents dehydration of the patient from the bowel preparation. Also, if a patient appears to be volume depleted, an additional 500 mL of 5% plasma protein can be given. This will help maintain a normal intravascular osmotic pressure, which seems to be important in terms of preventing pulmonary problems at the time of surgery. Also, to help during the postoperative period, the patient is instructed in pulmonary exercise techniques including the use of incentive spirometry and blow bottles or suction devices. The patient's prior knowledge of these techniques seems particularly helpful in enabling him to effectively exercise the pulmonary system in the postoperative period.

Surgical Preparations

Patient warming devices such as warming blankets or heat-reflective coverings should be used. This is critical because the procedures performed in these patients are frequently lengthy, and because incisions are often large, the potential for loss of body heat is considerable. Normally, the anesthesiologist should make preparations for heating and humidifying the gases used during the procedure, as well as warming intravenous fluids that are used. If an RPLND alone is planned, the patient is placed on the table in a supine position. If a combined thoracoabdominal incision is planned, the patient is placed in the appropriate torque position after induction of anesthesia. In these instances, along with the cases in which a median sternotomy is performed in combination with an RPLND, the chest portion of the procedure usually is performed first. The chest incision is left open to provide additional exposure to the upper retroperitoneum because there is often persistent bulky tumor in this area. After the RPLND is completed, the wound generally is closed using a two-team approach, with the thoracic surgeon closing the chest and the urologist closing the abdominal portion of the incision.

Technical Considerations of Postchemotherapy Retroperitoneal Node Dissection

Based on experience gained through the analysis of the distribution of scar tissue, teratoma, and carcinoma in the specimens resected from patients undergoing postchemotherapy RPLND, Donohue and associates found that, contrary to previous experience with patients undergoing primary RPLND, the distribution of the

pathologic findings in this group could not be predicted (40). The histologic findings were extremely heterogeneous. Because of the heterogeneity in findings and the presence of pathologic findings in the contralateral side, suprahilar zones, and presacral areas, a full bilateral RPLND is indicated in almost all of these patients regardless of the gross findings at the time of surgery.

In most instances, the standard “split-and-roll” technique (Fig. 41.17A to F) can be used with patients having a postchemotherapy RPLND. In some instances, however, if rather massive residual disease is still present, special techniques can be applied. Figure 41.23 illustrates a technique developed by Donohue in which the bulky disease is systematically dissected away from the critical structure, such as the aorta and vena cava. Once this bulky tissue is rolled out of the way, the surgeon can return to the routine techniques of doing a systematic full bilateral RPLND, as originally described by Donohue (34). A modification of the dissection of the suprahilar zones is shown in Fig. 41.24. This modification is based on the observation that the lymph nodes are located primarily posteriorly at the level of the crus of the diaphragm (Fig. 41.25). After completion of the procedure, the retroperitoneum is closed by replacing the bowel in its normal location and reapproximating the root of the small bowel mesentery to the retroperitoneum, as well as reapproximating the lateral attachments of the right colon to the colic gutter with running absorbable sutures. The abdominal incision usually is closed with interrupted, inverted figure-of-eight sutures of a nonabsorbable monofilament, no. 0 or 1 suture. If the patient has been particularly debilitated or had a particularly large-volume tumor, abdominal retention sutures are used as well for approximately 3 weeks.

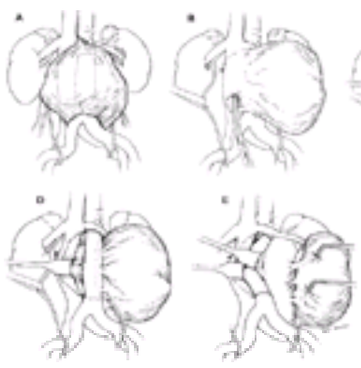

FIGURE 41.23. A–E: Technique for removing bulky tumor during a postchemotherapy retroperitoneal lymph node dissection (RPLND). The mass is removed by separating it into a bundle anterior to the midportion of each of the great vessels and the ureters. Once the bulky mass has been resected, a standard full bilateral RPLND can be performed.

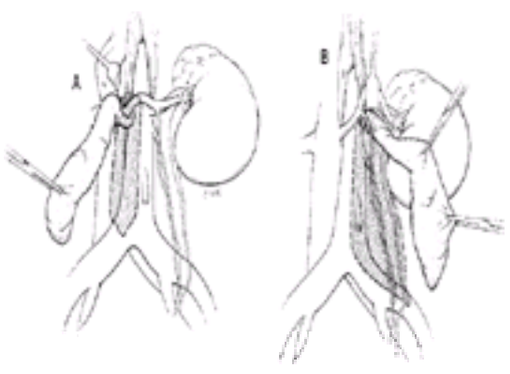

FIGURE 41.24. A: Modification of the right suprahilar dissection. In view of the posterior location of the nodes in the suprahilar zone shown in Fig. 41.23, the right suprahilar nodes are removed en bloc with the interaortocaval zone. The dissection is extended cephalad posterior to the right renal artery and left renal vein in the area of the crus of the diaphragm. **B:** Modification of the left suprahilar dissection using the same line of reasoning. The left suprahilar zone is removed en bloc with the left periaortic tissue by extending the dissection posterior to the left renal artery and vein.

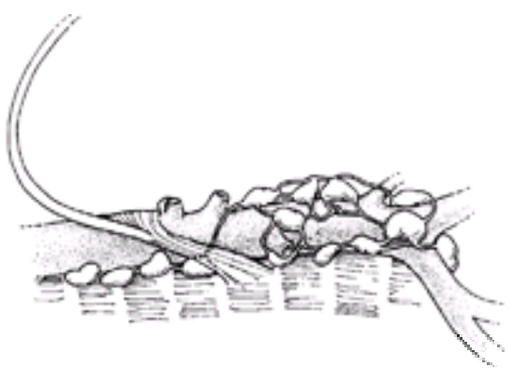

FIGURE 41.25. Lateral view of the location of the lymph nodes relative to the aorta. Note that at the level of the crus of the diaphragm, the nodes are located posterior to the vessel.

In highly select patients in whom the retroperitoneal disease has been confined to one area, nerve-sparing techniques can be applied to other zones. This allows preservation of emission in some patients. It should be noted that even if emission is preserved by the nerve-sparing technique in the contralateral side, the patient may still be infertile based on oligospermia or aspermia from chemotherapy.

Postoperative Care

Unlike patients undergoing primary RPLND, those who have had prior chemotherapy usually are sent to a surgical intensive care unit for the first 24 hours after surgery. This allows careful monitoring of central venous pressure, arterial pressure, blood gases, and urinary output. During the first 24 to 48 hours, 5% plasma protein may be administered at a rate of 250 to 500 mL every 8 hours as part of fluid replacement. This is necessary because of high third-space loss postoperatively. Again, because of preoperative exposure of most of these patients to bleomycin, it is critical to avoid overhydration with crystalloids by the use of intravenous colloids. The maintenance of a normal or slightly increased osmotic pressure seems to be effective in preventing the development of significant pulmonary compromise. After the initial 24 to 48 hours of monitoring in the intensive care unit, the central venous pressure line, arterial line, and Foley catheter are removed and the patient returned to a routine patient care ward. Management of the remainder of the postoperative course does not differ significantly from that of patients undergoing a primary RPLND. The average hospital stay after a postchemotherapy RPLND is approximately 6 to 7 days.

Results of Surgery

Earlier reports of 123 patients who underwent postchemotherapy RPLND only, postchemotherapy thoracotomy only, or simultaneous RPLND and thoracotomy showed that the overall distribution of histologic findings in these patients was approximately one-third scar tissue, one-third teratoma, and one-third residual carcinoma (35,40,115,116). A more recent review at Indiana University of the histologic findings in RPLND after partial response to chemotherapy showed that the distribution of scar, including cystic necrosis, teratoma, and carcinoma, was 44%, 44%, and 12%, respectively, after primary chemotherapy, and 10%, 40%, and 50%,

respectively, after salvage chemotherapy (162).

Again, it should be pointed out that the previously described patients all had partial remissions after chemotherapy. In the patients who have achieved a complete remission with chemotherapy, surgery was not performed unless the patient had a subsequent relapse. The 10% relapse rate in those patients who underwent a complete clinical remission after primary chemotherapy corresponds very well to the findings of Richie, who noted a 10% incidence of residual carcinoma in those patients undergoing an RPLND after apparent complete clinical remission with primary chemotherapy (159a). At this time, the authors believe that the appropriate recommendation for treatment after complete remission with primary chemotherapy is observation only. Operating on the 90% of patients who would have negative findings does not seem justifiable. The 10% relapse rate that has been observed by the authors after patients are given four courses of primary BEP chemotherapy corresponds well with the 12% relapse rate reported by Vugrin and associates (199) after treatment with VAB-6.

Complications of Postchemotherapy Retroperitoneal Lymph Node Dissection

Two earlier reports in the literature have discussed the complications of postchemotherapy RPLND in sizable groups of patients (37,179). The rate of complications seems to be related proportionately to the bulk of disease present. This is evidenced by an overall combined complication rate of 12% in patients undergoing primary RPLND for stage I, IIA, or IIB disease versus an overall complication rate of 25% in those patients initially presenting with stage II or III disease who have undergone postchemotherapy RPLND. The death rate in the low-stage disease patients was 0.3%, while the death rate in the high-stage postchemotherapy node dissection patients was 3.0%. Of the complications, approximately half were minor. Only a small percentage of the major complications required reoperation. Virtually all of the deaths in the postchemotherapy node dissection group were related to complications of the previous chemotherapy, notably compromise in pulmonary function. This finding of compromised pulmonary function with a decrease in diffusion capacity and a restrictive defect as well has been noted by others (163).

A review of complications in postchemotherapy RPLND in 603 patients operated on at Indiana University from 1982 to 1992 was reported by Baniel and associates (3). The overall complication rate was 20.7% and the mortality rate was 0.8%. The most frequent severe complications were pulmonary, with six patients having adult respiratory distress syndrome, five of whom required prolonged ventilatory support. Additional procedures such as nephrectomy and bowel resections did not add to morbidity.

Although there is a significant complication rate and a mortality rate now of less than 1%, the benefit gained from reassessment of patients with partial remissions after chemotherapy far outweighs the risks. Reassessment of the patient's pathologic status at that point allows appropriate follow-up or additional treatment.

Follow-up of Postsurgical Patients

Usually, all patients who have had an RPLND are seen again at the medical center by the urologist and medical oncologist approximately 3 to 4 weeks after surgery. Beginning with this first checkup, chest roentgenograms and serum markers are obtained monthly for the first year. A physical examination, with particular emphasis on recurrent abdominal masses, and inguinal, axillary, or cervical adenopathy, is performed every other month. After the first year has passed, the testing and physical examination can be decreased in frequency. During the second year, the chest roentgenograms and serum markers are performed every other month and physical examinations every 3 to 4 months. At the end of 2 years, the patient can be followed on a semiannual or annual basis. The one exception to this is patients who have had teratoma in a specimen obtained at surgery after chemotherapy. In this group, there seems to be a subset of patients who are prone to late relapses for as long as 5 to 20 years after surgery. In this particular set of patients, prolonged follow-up is recommended. Because the teratoma often recurs at the margins of resection in the retroperitoneum, a CT scan on an annual basis is recommended for the first 2 to 3 years.

Interstitial Cell Tumors

Interstitial cell tumors of the testicle are uncommon and are usually a benign growth developing within the body of the testis; they consist of recognizable interstitial (Leydig) cells. In Pugh's series (154), interstitial cell tumors accounted for 1.6% of all testis tumors. Other series in the literature have quoted the incidence of interstitial cell tumors to be as high as 3% of all testis tumors (124). These tumors may or may not have endocrine activity.

Most of these tumors occur in persons aged 20 to 60 years. Dalgaard and Hesselberg (30) reported that 23 (24%) of their 94 cases of interstitial cell tumors occurred in patients who had not yet reached puberty. All patients in the prepubertal range had tumors that showed endocrine activity. Most of these patients had precocious virilization; feminization was present occasionally. Although interstitial cell hyperplasia has been noted frequently in the atrophic undescended testis, interstitial cell tumors in a cryptorchid testis have been reported only rarely (184). In some cases, testicular atrophy has been present. In cases of larger tumors, spermatogenesis often has been arrested or totally absent. Symington and Cameron noted that all but one of their patients had a palpable mass in the testis at the time of detection. These masses generally were described as being firm or hard and circumscribed, although some were irregular. Gynecomastia was the next most common finding. This occurred in approximately half of the patients. Regression of gynecomastia has been reported in some patients after orchiectomy (30,184). Other complaints include testicular pain, diminished libido, and morning vomiting before the development of gynecomastia.

In the series of Symington and Cameron (184), most of the interstitial cell tumors were located within the body of the testis, with an occasional tumor extending into the spermatic cord. Tumors usually were well circumscribed, rounded, and solid, with a striking yellow-brown color. The size in this series ranges from 0.7 to 10.0 cm, with most tumors being less than 6 cm. The same authors reported that 9% of the tumors were malignant. It is interesting to note that all of these tumors were large (6 to 10 cm) and that most displayed areas of necrosis within the tumor. The sites of metastasis were retroperitoneal and mediastinal lymph nodes, bone, and lung. As with other testicular tumors, occasionally the tumor is associated with a hydrocele.

Sertoli Cell Tumors

Sertoli cell nodules or tumors are associated most often with undescended testes. In these cases, the nodules are tightly packed, immature seminiferous tubules with little or no lumen. Interstitial cells are characteristically absent from these nodules. The aggregations of tubules, although usually microscopic in size, may be large enough to be seen by the naked eye when examining a cryptorchid testis. Similar findings may occur in the testes of patients with testicular feminization. In contrast to patients with cryptorchid testes, the nodules found in patients with testicular feminization not only have the aggregates of Sertoli cell–packed tubules, but also prominent areas of interstitial cells. The Sertoli cell nodules or tumors are present in approximately 25% of those patients with testicular feminization. Although the tumors are most frequently small and multiple, some masses as large as 24 cm have been noted. These most commonly occur in older patients with an intraabdominal gonad (133). No cases of metastasis have been reported in instances of Sertoli cell tumors. It is interesting to note, however, that this patient population has an increased incidence of other testicular tumors, particularly seminoma. Morris and Mahesh (123) noted a 22% incidence of seminoma in 50 cases of testicular feminization with Sertoli cell nodules or tumors. This may represent a falsely elevated incidence because in many of the patients, the presence of the seminoma led to the diagnosis of Sertoli cell nodules or tumors in reverse order.

Sertoli Cell Stromal Tumors

According to Pugh (154), Sertoli cell stromal tumors account for approximately 1.2% of all testicular tumors. The age range of patients at presentation varied from 2 months to 80 years. Most of the tumors occurred in patients under the age of 40 years. In 25 of 32 patients, the tumor was manifested by painless testicular swelling. Four additional patients had painful testicular swelling. Three patients had gynecomastia at the time of presentation.

All patients were treated with orchiectomy. Only two patients underwent an RPLND. Other therapy included radiotherapy and chemotherapy. Of tumors in these 32 patients, 7 (22%) were malignant. Of the malignant tumors, 4 of the 7 had local spread involving the rete testis, epididymis, or lower spermatic cord. All of the malignant lesions showed local invasion of lymphatics or blood vessels or both. Metastasis involved the retroperitoneal and mediastinal lymph nodes. Liver, lung, brain, and bone also were involved in some cases. Mostofi (124) noted a 10% incidence of malignancy of Sertoli cell stromal tumors in his series of testis tumors.

TUMORS OF THE TESTICULAR ADNEXA

Tumors of the Rete Testis

Carcinoma of the rete testis is rare. Approximately 25 cases in the literature are thought to meet the criteria for carcinoma of the rete testis. The first cases of presumed carcinoma of the rete testis were reported by Curling in 1853. Feek and Hunter (53) set forth criteria for the diagnosis of carcinoma of the rete testis. Shillitoe (175) emphasized that the parameters set out by Feek and Hunter were not absolute but formed a basis for making the diagnosis. In 1981, Jacobellis and

associates (89a) reiterated the criteria. According to these authors, the accepted criteria are (a) the tumor is located in the mediastinum of the testis rather than in the body of the testis proper; (b) a transition from normal epithelial structures to neoplastic structures is present in the rete testis; (c) no evidence of teratoma is present; (d) no primary tumor is present in another site; and (e) the parietal tunic is intact. Adenocarcinoma of the rete testis has been reported to occur in men ranging from 20 years (169) through 89 years of age (66).

Nochomovitz and Orenstein (139) noted that of the 21 cases they reviewed, 80% of the patients were older than 40 years and 70% were older than 60 years. Only two cases in this group were reported to occur in patients younger than 40 years of age. In both of these cases, the tumors developed in maldescended testes. Schoen and Rush (169) emphasize that tumors located in the posterior portion of the testis (rete testis) were likely to be missed unless the testis and surrounding structures were carefully palpated. They also noted that a hydrocele may easily conceal an underlying tumor of the rete testis. A scrotal mass is the most common initial finding. Other manifestations include scrotal pain, skin nodules, edema, and a draining sinus (139).

Once a tumor is suspected, the diagnosis is made by inguinal orchiectomy. Assuming that the aforementioned pathologic criteria are met, a metastatic workup must be performed to stage the disease. The workup is carried out similar to that in germ cell testis tumors. Survival from adenocarcinoma of the rete testis is inversely related to the amount of disease at presentation. Seven of 22 cases summarized by Nochomovitz and Orenstein (139) that had low-stage disease experienced survival from 4 to 42 months. Two of the seven patients underwent removal of localized metastasis, 1 and 42 months after orchiectomy. In general, patients who presented with advanced disease did poorly, with a mean survival of 8 months after the diagnosis.

Whitehead and associates (207) felt that radiation therapy had some benefit in patients with low- to moderate-volume disease. Occasional long-term survivals in patients who have had orchiectomy followed by radiation therapy have been reported. Skin recurrence in the incision, the scrotum, the perineum, or the shaft of the penis has been common. Management of the skin recurrences has been difficult.

According to Nochomovitz and Orenstein (139), four factors are important in dealing with adenocarcinoma of the rete testis: (a) early diagnosis of the neoplasm is important; (b) patients with tumor extending beyond the testis have a poor prognosis; (c) local skin recurrence is common; and (d) mechanical and inflammatory problems, such as epididymitis, hernias, and hydroceles, often mask the underlying tumor. The index of suspicion, particularly in older patients, should be high. An update on a total of 31 patients with this disease revealed similar findings as those reported before (139).

A review of 38 patients with adenocarcinoma of the rete testes by Sanchez-Chapado and colleagues shows that those with tumors 5 cm or smaller had a longer survival than patients with larger tumors. The overall 3- and 5-year disease-free survival rates were 49% and 13%, respectively (167).

Benign tumors of the rete testis are exceedingly rare and, to our knowledge, only four cases have been reported in the literature (71a,210,213). The pathologic findings of these lesions have been reported as papillary adenoma. Both of the patients described by Willis (210) were over the age of 50 years. The case reported by Yadav and associates (213) was in a patient aged 18 years. The fourth case, reported by Gupta (71a), was in a patient aged 12 years. In all of these cases, hydrocele was present at the time of initial examination, making the diagnosis of a mass of the rete testis more difficult. Despite the benign histologic appearance of these tumors, long-term clinical follow-up has not been reported.

Nistal and co-workers described another benign entity, cystic transformation of the rete testis in 38 patients. This was diagnosed by ultrasound in autopsy and surgical specimens and was associated with adjacent tumors in some patients. Other patients were noted to have evidence of chronic compression due to chronic epididymitis, traumatic hydrocele, ischemia, or cirrhosis (138).

Tumors of the Epididymis

Tumors of the epididymis are very rare. They consist of benign and malignant primary tumors, as well as metastatic tumors. Each of these is considered in the following sections.

Primary Tumors of the Epididymis

In 1951, Longo and associates published the first substantial review of primary neoplasm of the epididymis (113). In this study, the authors reviewed the world literature covering 134 cases of primary epididymal tumors, as well as 19 cases seen at Mayo Clinic. The authors pointed out that the average age at diagnosis of an epididymal tumor was 41.5 years. A scrotal mass was the chief complaint in 76% of the cases, while the finding was incidental on physical examination in 18% of the cases. Some patients had noted scrotal enlargement for as long as 30 years before seeking medical attention. Of the 134 cases reported in the world literature, 74% of the tumors were benign and 26% were malignant. Overall, 53% of the tumors were described as adenomatoid, terminology originally applied by Golden and Ash in 1945 (65a). This tumor apparently is a truly benign neoplasm. More than 200 cases have been reported in the world literature and no metastases have ever been observed (70). Although adenomatoid tumors can occur in females as well as in males, approximately 70% of all cases have occurred in males. The tumors are usually symptomless, small, and well circumscribed. Microscopically, the tumor has mixed epithelial and stromal elements. The cell that is the main component of the epithelial element is eosinophilic and has a vacuolated cytoplasm. Irregular, somewhat branched-appearing tubular structures appear within the tumor. These tubular structures are believed to represent coalescence of the vacuoles from the cells, forming a false lumen (32). Nistal and colleagues (137) supported the concept that these cells were of mesothelial origin by showing the presence of microvilli in the free surface of the cells and by demonstrating by histochemical techniques the presence of acid mucopolysaccharides in the lumen in the tubular structure.

Patients with adenomatoid tumors most frequently have a painless intrascrotal solid mass, which on examination is well circumscribed within the epididymis and is usually less than 2.5 cm in diameter. The globus minor is involved approximately four times more often than the globus major (70,113). Because truly malignant lesions of the epididymis are rare, when a well-circumscribed solitary mass is encountered during surgical exploration through an inguinal incision, excision of the mass or epididymectomy is the normal treatment. Rarely is an orchiectomy required. In more than 200 cases reported in the literature, no metastatic tumors have been noted; however, local infiltration has been observed (72).

According to Broth and associates (13), who reviewed 278 primary tumors of the epididymis, leiomyoma was the next most frequent benign lesion after adenomatoid tumors. The leiomyomas accounted for 6% of the overall tumors. The third most frequent benign tumor was the papillary cystadenoma, which accounted for 4% of benign tumors. Other benign tumors included vascular lesions, cystic embryomas, fibromas, cholesteatomas, teratomas, lipomas, hamartomas, dermoid cysts, and adrenal cortical adenomas.

In a summary of epididymal tumors, Elsasser (51) reported 40 cases of papillary cystadenoma in the literature. Kallie and associates (94) reported that the consensus is that the papillary cystadenoma arises from the efferent ductules of the epididymis. These ductules are mesonephric in origin. Cystadenoma resembles a spermatocele with respect to its location and lining epithelium (94). Most of the papillary cystadenomas occur in the globus major of the epididymis. The tumor may be bilateral and appears to be associated with von Hippel–Lindau disease. In an Armed Forces Institute of Pathology study, four of ten patients with known von Hippel–Lindau disease who underwent epididymal examination had papillary cyst adenomas (152). Local excision of the mass through an inguinal incision is usually satisfactory treatment. There are no reports in the literature of recurrence from metastasis. However because this is often a part of the von Hippel–Lindau syndrome, other manifestations of this disease must be kept in mind. Areas of particular interest in urology are the development of pheochromocytomas and manifestation of renal cysts or malignant renal lesions. Between 13% and 25% of patients with von Hippel–Lindau disease develop renal cell carcinoma (84).

Primary Malignant Tumors of the Epididymis

In addition to reporting the distribution of benign epididymal and cord tumors by tissue type, Broth and associates also reported the distribution of primary malignant epididymal and cord tumors (13). Of the 278 tumors reported, 56 (20%) were primary malignant tumors. Sarcomas were more common than carcinomas. In a more recent review by Elsasser, 50% of the paratesticular tumors were malignant (51). Virtually all of the tumors in this report were sarcomas. Rhabdomyosarcomas were the most common, accounting for half of the tumors. Following this were leiomyosarcomas, fibrosarcomas, and liposarcomas. With the exception of rhabdomyosarcomas in a young child, the majority of sarcomas occurred in middle-aged or older patients.

Often, hydroceles hamper the palpation and diagnosis of a paratesticular mass. Approximately 10% of benign tumors are masked by hydroceles, while a greater percentage of patients with malignant tumors of the epididymis have hydroceles. Painless swelling of the scrotum also should make the examiner suspect a tumor (51). If a tumor is suspected, the patient should undergo an inguinal approach for exploration of the testis and paratesticular structures. If a mass is found, a high ligation of the cord structures should be performed as in the case of a primary testis tumor. In general, the higher the tumor is located along the cord structures, the

more likely it is that the external inguinal lymphatics and the retroperitoneal lymphatics are involved.

In general, the prognosis of patients with primary malignant tumors of the epididymis is poor. In the series of extratesticular sarcomas reported by the Testicular Tumor Panel and Registry in Great Britain, many of which were primary lesions of the epididymis, over half of the patients died of disease within 2 years (69). Banowsky and Schultz (4) reported follow-up in 73 patients with extratesticular sarcomas. Two-thirds of these patients died of disease or developed metastases. Metastases were believed to have spread by lymphatics alone in 53% of these cases, by lymphatics and blood vessels in 37%, and primarily by hematologic means in 10%.

One exception to this poor outlook has been a multimodal therapy for treatment of rhabdomyosarcoma in children, reported by Ghavimi and colleagues (64). In this series, surgery, radiation therapy, and combination systemic chemotherapy were used in 11 children. Of the 11 children, 7 are free of disease 2 to 10 years after the initiation of treatment. Other more recent reports in the literature have shown mixed results using various forms of treatment for epididymal sarcomas. One review of fibrosarcomas of the epididymis by McCormack (117) noted that all patients who had recurrence other than local skin lesions overlying the original lesion were dead in less than 1 year.

At present, the optimal treatment for each type of primary malignant tumor of the epididymis is not clear. A radical orchiectomy through an inguinal approach is recommended. After the cell type of the lesion is documented, a careful review of the recent literature to seek advice on further therapy is recommended.

Metastatic Malignancies of the Epididymis

Solid tumor metastases to the epididymis are uncommon. Burger and Guthrie reported a case of metastatic colon carcinoma to the epididymis and summarized 15 cases in the literature (16). Of these 15, 9 of the lesions were from the gastrointestinal tract (7 stomach and 2 colon), 4 from the kidney, and 3 from the prostate (16). Most recently, Powell and associates reported 38 cases of secondary malignancies to the epididymis (150). In this series, urologic malignancies were the most common origin of the metastases. Of 38 total cases reported, 20 were from the urologic tract, with 14 originating from the prostate and 6 from the kidney. Of the remaining cases, 16 were from the gastrointestinal tract, with the stomach being the most common primary site, followed by colon and malignant carcinoid tumors of the ileum. Two cases of metastases from pancreatic tumors were reported. The prognosis of patients with metastatic tumors to the epididymis is most closely related to the prognosis of the primary disease. Often, the prognosis is poor because the metastases that are present represent an advanced stage of the primary disease. Some metastatic tumors of the epididymis have been discovered incidentally at the time of orchiectomy for carcinoma of the prostate. Others have been discovered because of pain or swelling of the scrotal contents. Four mechanisms that have been proposed to explain metastasis to the epididymis have been summarized by Powell and colleagues (150). These mechanisms include direct extension, retrograde venous extension, retrograde lymphatic extension, and arterial embolism. Eadie demonstrated retrograde lymphatic spread of a carcinoma of the stomach to the left testicle (42). This is the most likely mechanism of extension of metastasis from gastrointestinal tumors to the epididymis as well.

Tumors of the Cord Structures

Tabulations discussed in the previous section regarding tumors of the epididymis by Broth and associates (13) and Elsasser (51) included tumors of the cord structures as well as those of the epididymis. Approximately half of the tumors involving the cord structures are sarcomas. The majority of these are rhabdomyosarcomas and, particularly, embryonic sarcomas arising in children. Of the remaining sarcomas, the most common is leiomyosarcoma followed by fibrosarcoma, liposarcoma, and undifferentiated sarcomas. The incidence of tumor is highest distally in the cord structure near the testis. In this case, it is sometimes difficult to differentiate between a tumor of the cord structures and a tumor of the epididymis. The presence of a hydrocele often masks the presence of a tumor of the cord structures. The more proximally the tumor is located along the cord structures, the more likely it is that the external inguinal lymphatics will be involved. The retroperitoneal lymphatics are also commonly involved with these tumors. Finally, the treatment and prognosis of these tumors is essentially the same as previously outlined with epididymal tumors.

Tumors of the Scrotal Wall

Siegal and Goffey from the Mayo Clinic cited 182 cases that were identified as having lesions arising exclusively from the layers of the scrotal wall. Of these, 127 were available for histologic review. Nevi were the most common benign neoplasms, and squamous cell carcinomas (epithelioma) were the most common malignant lesions. Tumors have been reported that arise out of virtually any of the components of the scrotal wall, from the epithelium to the mesenchymal elements. In the case of benign scrotal lesions, such as leiomyomas, simple excision is curative (177).

Squamous cell carcinoma of the scrotum is now exceedingly rare. The incidence has been reported to be fewer than ten cases per year in the United States (33). However, squamous cell carcinoma of the scrotum is important from a historical perspective. In 1775, squamous cell carcinoma of the scrotum was the first cancer recognized as an occupational neoplasm. Pott reported on the disproportionate incidence in chimney sweeps in newly industrial England (149). Subsequently, other occupations with significant exposure to oils, such as cotton mule spinning (a primarily left-sided disease) (77); machine operators in engineering (27); petroleum wax pressman (110); screw-making industry (196); and automatic lathe operators (2) have been reported.

The prognosis for patients with malignant tumors arising from the scrotal wall seems to be linked most closely with the ability to completely excise a localized tumor. Tumors such as leiomyosarcoma arising from the scrotal wall appear in all respects to be similar to those tumors arising from smooth muscle in the skin and all other areas. A summary by Dahl and Angervall (29) noted no correlation between the spread of sarcomas and the size of the tumor or the mitotic rate of the tumor. The one important prognostic factor that they described was the ability to completely excise the lesion at the time of initial surgery. All of the patients who had a complete resection of the lesion remained free of metastases. At present, recommendation for treatment of lesions arising from the scrotal wall includes wide local incision with frozen section, when possible, to distinguish benign from malignant neoplasms. Lymphatic drainage of the scrotal wall is to the inguinal lymph nodes with considerable crossover (140). Ileoinguinal lymphadenectomy for scrotal cancer is controversial and generally reserved for patients with palpable disease, similar to penile carcinoma (17,156). Unfortunately, adjunctive therapy, such as radiation or chemotherapy or both, has not proved useful in these lesions.

The diagnosis and treatment of male sexual dysfunction were largely ignored by urologists until approximately 20 years ago. Successful therapy—primarily acceptable penile prostheses—preceded a surge in investigative efforts to better understand the physiology of penile erection. Several new therapies based on experimental advances in the neurophysiology and neuropharmacology of penile erection have evolved. The acquisition of new knowledge in this area has occurred so rapidly and so many new diagnostic and treatment methods, including oral therapy, have emerged that much of the clinical diagnosis and therapy of erectile dysfunction remains controversial.

THE PENIS

Anatomy

Penile erectile tissue is contained within three corporal bodies: two dorsally positioned corpora cavernosa and a ventrally positioned corpus spongiosum, which also contains the urethra (Fig. 42.1). Each of the three corpora is surrounded by tunica albuginea, a thick layer of fibrous tissue that separates the corpora from each other. Buck's fascia, a single fascial sheath that lies superficial to the tunica albuginea, envelops all three corporal bodies.

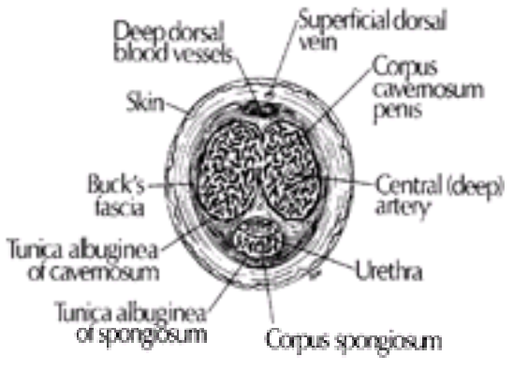

FIGURE 42.1. Cross-sectional anatomy of human penis.

The corpora cavernosa and the corpus spongiosum contain numerous cavernous spaces separated by trabeculae composed not only of smooth muscle but also of fibroblasts, collagen, and elastic fibers. The corpus spongiosum is composed of larger cavernous spaces and smaller trabeculae with fewer smooth muscle cells than found in the corpora cavernosa. When viewed with the electron microscope, the orientation and components of the trabeculae in the corpora cavernosa vary considerably. The surfaces of the trabeculae, the walls of the cavernous spaces, are covered by endothelial cells that resemble those found in blood vessels (26).

Arterial Supply

The penile arterial blood supply is derived from the paired internal pudendal arteries, which are terminal branches of the hypogastric arteries (Fig. 42.2). In the perineum, each pudendal artery gives off a perineal branch and then two arteries to the corpus spongiosum. The bulbar artery supplies the proximal corpus spongiosum; the urethral artery pierces the corpus spongiosum and then continues distally to the glans penis. Just outside the crus of the penis, each pudendal artery divides into the dorsal penile artery and the deep penile artery. The dorsal artery courses distally between the tunica albuginea of the corpora cavernosa and Buck's fascia. The deep penile artery penetrates the crus of the penis and then courses distally within the corpus cavernosum as the deep (central) artery. Arteriographic studies have demonstrated considerable variation in penile arterial supply (40).

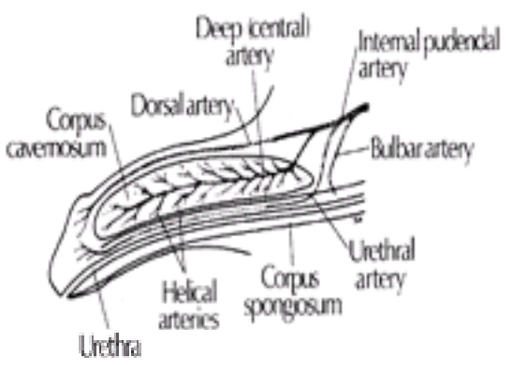

FIGURE 42.2. Arterial blood supply to human penis.

The deep (central) arteries supply nutrient vessels to the trabeculae, anastomoses that cross the septum to the opposite corpus cavernosum, and helical arteries. The helical arteries, which are more numerous in the proximal than in the distal corpora cavernosa, arborize into short end–arteries that then open directly into the cavernous spaces (259). In addition, numerous anastomotic channels interconnect all of the arteries of the penis (80,284). “Shunt arteries,” which connect the deep penile arteries with the arteries in the corpus spongiosum, also have been described (354).

Venous Drainage

The anatomy of penile venous drainage is complex and controversial, and the nomenclature is not standardized (345). Venous drainage is accomplished by at least three major pathways (259). The superficial dorsal vein lies superficial to Buck's fascia and is formed from multiple subcutaneous veins. The deep dorsal vein courses between Buck's fascia and the tunica albuginea of the corpora. Veins from the glans penis and emissary and circumflex veins from the corpora cavernosa drain into the deep dorsal system. The third major venous drainage system is composed of deep veins (venae profundae) of the corpora cavernosa. These relatively large vessels exit from the hilum of the penis (cavernosal veins) and from the penile crura (crural veins) and drain into the pudendal system. In addition to the aforementioned major drainage systems, bulbar and urethral veins drain the proximal corpus spongiosum.

An understanding of the venous drainage of various parts of the penis is further complicated by the recognition that numerous anastomotic connections exist between the major venous drainage systems just discussed (80,345). Furthermore, conflicting data make the resolution of significant questions difficult. For example, anatomically, the corpora cavernosa appear to drain into both the deep veins of the corpora cavernosa and through emissary veins, which penetrate the tunica albuginea and join the circumflex veins, which in turn empty into the deep dorsal vein. Deysach (80), however, found that the retrograde injection of India ink or cinnabar into the deep dorsal vein filled vessels of the glans penis and corpus spongiosum but did not penetrate into the corpora cavernosa. In addition, some clinical data also implicate the superficial dorsal vein as being important in the drainage of the glans penis and corpus spongiosum. In a clinical study of patients with priapism, cavernosograms demonstrated obstruction of the deep dorsal vein, and spongiosograms revealed that the superficial vein (lying above Buck's fascia) was patent (105). Furthermore, numerous small and large anastomotic connections have been described between the superficial dorsal vein and the deep dorsal vein (80).

A clearer understanding of the venous drainage of the penis in both normal and disease states is necessary for a more rational approach to clinical problems. Although the venous drainage of the corpora cavernosa probably is accomplished by both the deep dorsal and the venae profundae systems, the importance of each of these drainage systems in normal penile erection, priapism, and impotence secondary to “venous leaks” requires further anatomic definition.

Innervation

The innervation of the penis is derived from both divisions of the autonomic nervous system (sympathetic and parasympathetic) and from the somatic nervous system. Although cavernosal nerves have been recognized for years, recent investigation has significantly clarified our understanding of the gross and microscopic neuroanatomy of the penis and its vasculature.

Sympathetic nerves that originate in the low thoracic and upper lumbar regions of the spinal cord course retroperitoneally to condense into the superior hypogastric plexus (presacral nerve) located inferior to the aortic bifurcation. Sympathetic fibers then leave the superior hypogastric plexus as the right and left hypogastric nerves that fuse distally and contribute to the formation of the inferior hypogastric (pelvic) plexus (194) (Fig. 42.3).

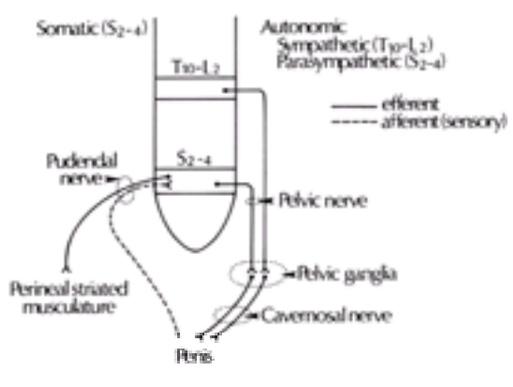

FIGURE 42.3. Innervation of penis.

The pelvic plexus also receives input from the parasympathetic nervous system, whose cell bodies are located in the sacral (S-2 to S-4) portion of the spinal cord (Fig. 42.3). Parasympathetic nerves enter the pelvic plexus by means of the pelvic nerve, which courses in the endopelvic fascia. In humans, the pelvic plexus is located retroperitoneally beside the rectum. Nerve fibers from the pelvic plexus innervate not only the penis but also the lower urinary tract and rectum. Anatomically, it is difficult (if not impossible) to ascertain the origin of nerves (parasympathetic or sympathetic, preganglionic or postganglionic) leaving the pelvic plexus. Walsh and Donker (357) demonstrated that the branches of the pelvic plexus that innervate the corpora cavernosa are situated between the rectum and urethra and penetrate the urogenital diaphragm near or in the muscular wall of the urethra. They then enter the dorsal medial side of the corpora cavernosa.

The somatic innervation to the penis is carried in the pudendal nerve, whose cell bodies, like those of the parasympathetic pelvic nerve, are located in the sacral (S-2 to S-4) spinal cord. The pudendal nerve does not course through the pelvic plexus; it travels with the internal pudendal vessels along the lateral wall of the ischiorectal fossa (357). The dorsal nerve of the penis is a terminal branch of the pudendal nerve, and penile sensation is carried by means of sensory fibers in the pudendal nerve.

The peripheral innervation of the penis has been studied extensively. Adrenergic nerves, whose neurotransmitter by definition is a catecholamine, have been identified by histofluorescent techniques at the light microscopic level. Although the distribution of catecholamine-positive nerve fibers was initially reported to be sparse (319), subsequent studies have demonstrated that the human corpus cavernosum contains numerous adrenergic nerves that course through the trabeculae and approach the walls of the cavernous spaces (26) (Fig. 42.4). Very few adrenergic fibers are demonstrable in the corpus spongiosum. Blood vessels within the corpora cavernosa also contain many adrenergic nerve varicosities in the outer tunic (Fig. 42.5). Nerves that contain small, highly electron-dense vesicles that are chrome positive by an electron microscopic glutaraldehyde dichromate technique and therefore thought to contain norepinephrine also have been identified (230).

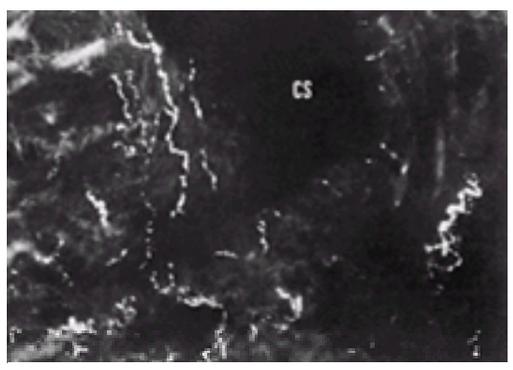

FIGURE 42.4. Micrograph of histofluorescent nerve fibers in the human corpus cavernosum. The brilliant fluorescence of the varicose catecholaminergic fibers near the cavernous space *(CS)* is easily differentiated from the dull glow of autofluorescent connective tissue located more peripherally (×80). (From Benson GS, McConnell JA. Erection, emission, and ejaculation: physiological mechanisms. In: Lipshultz LI, Howards SS, eds. *Infertility in the male,* 2nd ed. St. Louis: Mosby, 1991, with permission.)

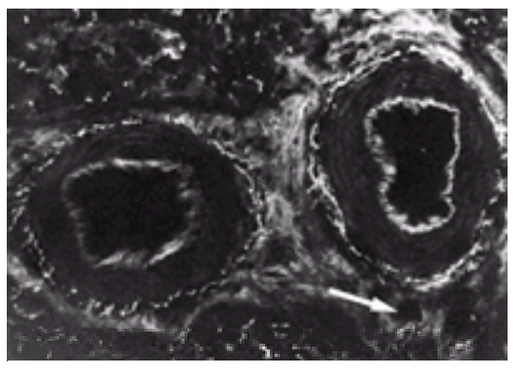

FIGURE 42.5. Fluorescent photomicrograph of paired central arteries in human corpus cavernosum (27-year-old man). Note the numerous adrenergic fibers at the periphery of these arterioles but the few fluorescent fibers near the small venule *(arrow)* (×200). (From McConnell JA, Benson GS. Innervation of human penile blood vessels. *Neurourol Urodynamics* 1982;1:199, with permission.)

Cholinergic nerves also are present within the corpora cavernosa. These nerves, whose neurotransmitter by definition is acetylcholine, have been identified classically at the light microscopic level by acetylcholinesterase staining. Controversy also exists as to the density of cholinergic innervation in the corpora. Some investigations have reported an abundant number of acetylcholinesterase-positive nerve fibers within the trabeculae of the corpora cavernosa (319). Other studies, however, have described a scant distribution of cholinergic nerves within the corpora cavernosa and even fewer of these fibers within the corpus spongiosum (26). Acetylcholinesterase-positive nerve fibers are contained within the outer tunic of most penile arterioles (Fig. 42.6).

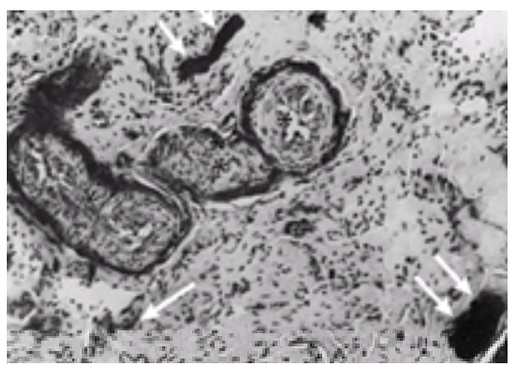

FIGURE 42.6. Photomicrograph of human corpus cavernosum (27-year-old man). Acetylcholinesterase-positive fibers are visible near each of the sections through the tortuous arteriole *(asterisks).* Nerve bundles containing acetylcholinesterase also are present *(arrows)* (×180). (From McConnell JA, Benson GS. Innervation of human penile blood vessels. *Neurourol Urodynamics* 1982;1:199, with permission.)

Nerves containing other putative neurotransmitters also have been identified anatomically within the penis of animals and humans. Using immunohistochemical techniques at the light microscopic level, vasoactive intestinal polypeptide (VIP) has been localized in nerve fibers near the trabecular smooth muscle of the corpora cavernosa, as well as around blood vessels (275) (Fig. 42.7). In addition, large VIP-immunopositive vesicles have been demonstrated in nerve terminals in penile tissues by electron microscopy (132). Various large vesicles that are not VIP immunoreactive also have been identified and are postulated to contain other peptides that may act as neurotransmitters (332).

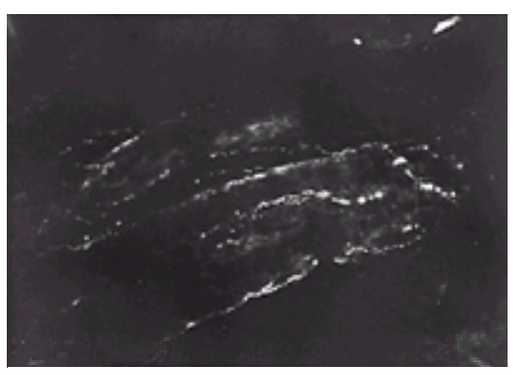

FIGURE 42.7. Monkey penile tissue demonstrating VIP fluorescent nerve fibers in trabeculae of corpus cavernosum (×100). (From Steers WD, McConnell JA, Benson GS. Anatomical localization and some pharmacologic effects of VIP in human and monkey corpus cavernosum. *J Urol* 1984;132:1048, with permission.)

Recently, much physiologic and pharmacologic evidence has been presented that implicates nitric oxide in the physiology of erection. Nitric oxide synthase, the enzyme that catalyzes nitric oxide production, has been identified in the pelvic plexus, cavernous nerves and their terminal endings within the corporal erectile tissue, branches of the dorsal penile nerves, and nerve plexuses in the adventitia of the deep cavernosal arteries in humans. In addition, these same nerves stain for reduced nicotinamide adenosine dinucleotide phosphate (NADPH) diaphorase. Because NADPH derives from nitric oxide synthase activity in neurons, this finding also supports the concept that nitric oxide is present in penile nerves (50). The significance of this finding is discussed in the following section.

PENILE ERECTION

Hemodynamic Aspects

Penile erection and detumescence are primarily controlled by hemodynamic events. Increased arterial inflow appears to be of primary importance; the contribution of increased venous resistance to the production of penile erection remains controversial. Furthermore, our understanding of precise anatomic details (including “shunts”) and the neural control of vascular events is not complete.

More than half a century ago, Semans and Langworthy (315) demonstrated the importance of arterial inflow in the production and maintenance of a penile erection. They found in cats that aortic occlusion prevented the development of penile erection produced by sacral nerve root stimulation. After an erection had been produced by nerve stimulation, aortic occlusion resulted in detumescence. Similar animal studies were refined and again demonstrated the importance of increased arterial inflow in the production of erection. With pelvic nerve stimulation in the dog, Dorr and Brody (83) demonstrated that the dorsal artery perfusion pressure fell while venous pressure rose. Blood flow through both the dorsal artery and vein greatly increased. In addition, no venous pressure gradient with erection could be demonstrated when venous pressure was recorded at multiple sites from the erectile tissue distally to the internal pudendal vein proximally. These data are consistent with the hypothesis that the primary hemodynamic event leading to erection is increased arterial inflow and that increased venous resistance plays a minor, or

insignificant, role.

Contradictory results have been reported in the canine model (209). With electrical stimulation of the cavernosal nerves, internal pudendal arterial flow was found to increase by 250% during the early phases of erection (Fig. 42.8). This was accompanied by a 20-mm Hg decrease in internal pudendal artery pressure. With erection, the flow rate gradually decreased to slightly above basal levels. A new equilibrium was established at full erection, with corporal pressure approximately 10 mm Hg below the systolic arterial pressure. At full erection, flow into and out of the corpus cavernosum, although present, was greatly reduced. Furthermore, with the aorta occluded and with saline solution infusing directly into the corpus cavernosum, an initial drop in intracorporal pressure and decreased venous flow during erection were demonstrated with cavernosal nerve stimulation. Thus these investigators have concluded that tumescence is the result not only of active arterial dilation and increased arterial flow but also of active relaxation of the corporal trabeculae and restriction of venous outflow. The decreased venous outflow is thought to be secondary to compression of venules located in the corpora cavernosa just beneath the tunica albuginea.

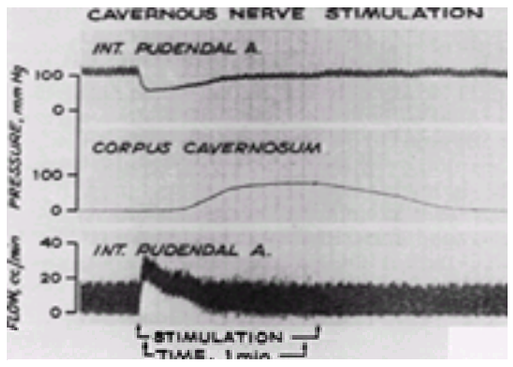

FIGURE 42.8. Changes in blood flow and pressure after cavernous nerve stimulation in the dog. (From Lue TF, Takamura T, Umraiya O, et al. Hemodynamics of canine corpora cavernosa during erection. *Urology* 1984;24:347, with permission.)

In animals, other data exist that implicate obstruction of venous return as an important mechanism in the production of penile erection (138). Anesthesia of the ischiocavernosus muscles produced by lidocaine injection often prevents goats, bulls, and stallions from copulating because of the inability to attain an erection (21,277). The highest pressures in the corpus cavernosum in the dog penis occur during intromission and coincide with contractile activity of the ischiocavernosus muscles measured electromyographically (277). Presumably, blockade of venous return secondary to skeletal muscle contraction may promote the development of penile erection. To the contrary, in the human, erection can occur without electromyographically measurable increases in bulbocavernosus, urethral sphincter, or deep transverse perineal muscle activity (178).

Although “venous valve mechanisms” and sphincteric-like smooth muscle structures surrounding penile veins have been described anatomically and hypothesized to contribute to the development of penile erection (60), physiologic investigation in humans is necessary to resolve the controversy concerning the possible role of increased venous resistance. Xenon washout techniques would appear to be an ideal method to resolve this question. In the flaccid state, there is minimum blood flow through the corpora cavernosa. If ^{133}Xe were placed into the corpora cavernosa and erection produced by visual stimulation, the rate of ^{133}Xe “washout” during erection should give valuable information concerning the importance of venous resistance to flow. This study has been done in humans by two groups of investigators with markedly conflicting results. Shirai and Ishii (318) reported an increase of disappearance of ^{133}Xe with erection and failed to show any significant increase in venous resistance. Wagner (355), however, described a decreased washout with erection, evidence that increased venous resistance and decreased venous flow occur with the development of an erection in humans. Primarily because of observations made by Lue and colleagues (209) and Aboseif and Lue (2), most investigators believe that penile erection is dependent not only on increased arterial inflow but also on relaxation of the corporal smooth muscle. Corporal smooth muscle relaxation and increased intracorporal pressure result in passive occlusion of corporal venous outflow.

Although active arterial dilation, corporal smooth muscle relaxation, and passive venous occlusion are generally considered the mechanisms of penile erection, other theories have been proposed. Venous “sluices” were hypothesized by Deysach (80) to open and close and thereby produce erection by altering venous outflow. For years, the most widely accepted hypothesis to explain penile blood flow was the “polster” theory advocated by Conti (68). In an anatomic study performed on cadavers, Conti described “polsters,” that is, columns of smooth muscle cells within the intima of penile arteries and veins. Although such structures had been described anatomically by earlier investigators, Conti proposed that contraction and relaxation of these polsters could divert blood into and away from the cavernous spaces and thus induce erection and detumescence. Calcification and fibrosis of polsters have been cited as causes for impotence in elderly diabetic patients (298). No data supporting a physiologic role for polsters, however, have been published, and the functional importance of these structures has been questioned. In addition, anatomic studies have demonstrated no innervation to polsters. Finally, evidence has been presented that suggests that polsters are actually atherosclerotic changes in penile blood vessels (27) (Fig. 42.9). Wagner and colleagues (354) proposed a mechanism of erection based on “shunt arteries.” According to their hypothesis, the helicine arteries that supply the corpora cavernosa are constricted during detumescence, resulting in blood being diverted to the corpus spongiosum by means of shunt arteries. Erection results when the helicine arteries dilate and the shunt arteries constrict. To date, all of the theories of various “shunt” mechanisms resulting in penile erection remain physiologically unproved.

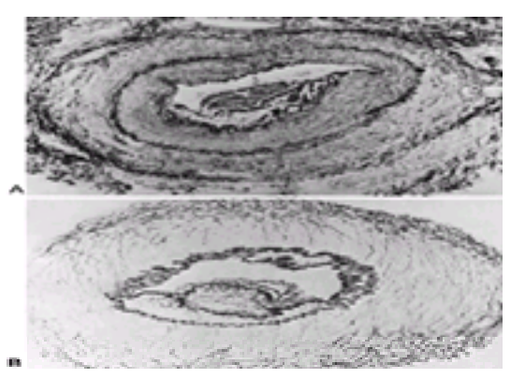

FIGURE 42.9. A: Atherosclerotic lesions from penile artery of 49-year-old man. **B:** Conti's drawing of penile polsters. (From Benson GS, McConnell JA, Schmidt WA. Penile “polsters”: functional structures or atherosclerotic changes? *J Urol* 1981;125: 800 and Conti G. L'erection du penis humain et ses bases morphologico-vasculaires. *Acta Anat Basel* 1952;14:217, with permission.)

Neurophysiology

The hemodynamic changes leading to penile erection and detumescence are clearly under neurologic control. One of the earliest investigations into the mechanisms controlling penile erection was Eckhard's demonstration that penile erection in the dog was produced by stimulation of the pelvic parasympathetic nerves, which he called the *nervi erigentes* (86). Eckhard was unable to produce an erection in the dog with stimulation of the hypogastric nerve, a sympathetic nerve. During the past century, investigators have attempted to understand and clarify Eckhard's findings.

In animals, the relative importance of the parasympathetic and sympathetic nervous systems in the control of erection was investigated by the classic studies of Muller (254) in the dog and Root and Bard (290) in the cat. In 1902, Muller observed that excision of the entire sacral and most of the lumbar spinal cord abolished reflex penile responses in the dog. Erection still developed, however, when the dog was placed with a bitch in heat. In addition, male dogs whose cords had been transected at a low thoracic level never exhibited erections in the presence of an estrous female; these animals, however, retained their ability to achieve full penile erection with penile stimulation. Forty-five years after Muller's study, Root and Bard performed similar, albeit refined, experiments in the cat. Excision of the sacral and lower lumbar

spinal cord abolished erections normally produced by manipulation of the penis but did not alter the ability of the male cat to achieve an erection in the presence of an estrous female. The addition of spinal cord transection between T-13 and L-1 or T-11 and T-12 in cats that had previously undergone ablation of the lower spinal cord resulted in the cessation of erectile response to both tactile and psychic stimuli. Resection of the inferior mesenteric ganglion and hypogastric nerves also abolished erectile responses in animals whose lower spinal cord had been resected. Finally, resection of the sympathetic nerves (inferior mesenteric ganglion and hypogastric nerves) had no effect on erection when the lumbosacral spinal cord was left intact. The results of the work of Muller and Root and Bard indicate that at least in the dog and cat, two peripheral neural pathways exist that control erection: (a) a sacral (parasympathetic) mechanism that responds to both tactile and psychic stimuli and (b) a lumbar (sympathetic) mechanism that responds to psychic stimuli.

Although these studies describe the contributions of the parasympathetic and sympathetic nervous systems in a straightforward manner, other animal data cast doubt on this relatively simplistic scheme. Sacral parasympathetic nerve or nerve root stimulation does produce erection in the dog, cat, and rabbit. Stimulation of sympathetic nerves, however, has achieved conflicting results, which may be explained at least in part by species variability. With hypogastric nerve stimulation, Eckhard observed erection in rabbits, but not in dogs. However, other reports have indicated that in the dog, hypogastric nerve stimulation results in a slight increase in penile volume (9). In cats, hypogastric nerve stimulation does not result in erection and, in addition, actually results in contraction of penile arteries and causes an erect penis to become flaccid (315).

Human data relating to the neurophysiology of erection are limited. Most of the information is retrospective and has been obtained by interview or questionnaire technique. In addition, the completeness of the neurologic lesion produced by spinal cord injury or neurosurgical ablative procedures is difficult to ascertain. A survey of sexual function in a large number of spinal cord–injured patients has been presented by Bors and Comarr (41). Patients with complete lower motor neuron lesions failed to achieve erection with genital stimulation. Of these patients, however, 24% reported erectile activity secondary to psychic stimuli. Most patients with upper motor neuron lesions (spinal cord lesions above the level of the sacral spinal cord) reported erections secondary to genital stimulation. The percentage of patients achieving erection with psychogenic stimulation depended on the level of the lesion: cervical (4%), thoracic T-1 to T-6 (0%), thoracic T-7 to T-12 (8%), and lumbar (57%). These human data are generally consistent with the feline data of Root and Bard and the canine data of Muller. Specifically, the development of penile erection secondary to genital stimulation appears to require an intact sacral reflex, whereas the sympathetic system appears capable of producing psychogenic erections through pathways that connect the cerebral cortex to the penis and its vasculature. Although patients who have undergone lumbar sympathectomy or extensive retroperitoneal lymph node dissection commonly develop symptoms consistent with sympathetic denervation (lack of seminal fluid emission or retrograde ejaculation), they do not report a disturbance in erectile function (166,179,291). Therefore, in humans, it would appear that the parasympathetic nervous system is of primary importance in penile erection and is probably capable of responding to both tactile and psychic stimulation. The sympathetic nervous system may be capable of producing erection secondary to psychic stimuli, but its role in sexual function is less clear and needs further definition.

Penile erection clearly is modified by supraspinal neurologic mechanisms. A better understanding of these mechanisms is necessary before we can rationally approach such problems as psychogenic impotence and the deleterious effects of drugs on erectile function. Animals have been studied to some extent with central nervous system (CNS) stimulation and ablation experiments. Human data consist primarily of case reports dealing with patients with CNS diseases or after ablative surgical procedures.

Hypersexual behavior in monkeys that had undergone removal of both temporal lobes, including the uncus and part of the hippocampus, was reported by Kluver and Bucy in 1939 (177). These animals exhibited frequent penile erections even under nonstimulated conditions. Stereotaxic electrical stimulation of specific parts of the brain, particularly the limbic system, is known to result in penile erection (84,218,219,288). In humans, impotence has been associated with temporal lobe lesions and after bilateral pallidofugal section for myoclonus (148,241).

Neuropharmacology

The neuropharmacology of penile erection has gained increasing attention in recent years, primarily because the introduction of intracorporal injection therapy, intraurethral therapy, and effective oral therapy has caused a resurgence of interest in the medical management of impotence. Numerous *in vitro* and *in vivo* animal and human experiments have been performed to study the responses of the penile vasculature and cavernosal tissue to pharmacologic stimulation. Because stimulation of the pelvic nerve produces erection and because the pelvic nerve has been classically thought to be made up primarily of a cholinergic nerve population, acetylcholine was previously thought to be the neurotransmitter responsible for penile erection.

However, several experimental observations cast doubt on a purely cholinergic mechanism. Although the erection produced by pelvic nerve stimulation can be abolished by pretreating animals with hexamethonium (a ganglionic blocking agent), atropine does not completely block the response (83,144). Studies in humans also are consistent with the concept that erection is an atropine-resistant phenomenon (353). In addition, the infusion of acetylcholine into animals does not produce an erection (82,83). Finally, strips of corporal smooth muscle in an *in vitro* muscle bath respond minimally, if at all, to stimulation with acetylcholine (26). Although it has been argued that, in these experimental situations, acetylcholine and atropine do not reach the vascular and corporal receptors, an equally plausible explanation is that penile erection is not a cholinergically (or exclusively cholinergically) mediated event. Evidence has been presented that corporal smooth muscle relaxation caused by acetylcholine is mediated by nitric oxide (300,301).

Efforts have been directed toward ascertaining whether a catecholamine could be responsible for initiating and maintaining penile erection. The penile vasculature and smooth muscle of the corpora cavernosa are generously supplied with adrenergic nerves, and high norepinephrine levels have been detected in the corpora cavernosa (237). In humans, the corpora cavernosa possess a high a-adrenergic receptor density determined by radioligand-binding studies (197). In the cat and rat, a portion of the sacral parasympathetic outflow is adrenergic (7,339), and these neurons conceivably could be responsible for the erection produced by pelvic nerve stimulation.

Strips of human corpora cavernosa relax when exposed to isoproterenol and salbutamol (b-adrenergic agonists) (4), and in the cat, erection has been produced by the intravenous infusion of salbutamol and phenoxybenzamine (an a-adrenergic antagonist) (82). Other data, however, do not support the concept that an adrenergic mechanism is responsible for penile erection. The infusion of norepinephrine does not cause erection in the dog (83) or cat (82), and in fact, epinephrine causes constriction of canine penile arteries (92). Stimulation of human corporal strips *in vitro* with norepinephrine results in a marked contraction, which can be blocked by pretreating the strips with phenoxybenzamine (26). In humans, the oral administration of large doses of a- and b-adrenergic blocking agents (phenoxybenzamine and propranolol) does not affect erections that result from mechanical or visual stimulation (353). The net effect of adrenergic stimulation therefore appears to promote penile detumescence (vascular constriction and corporal contraction) rather than erection.

It appears that the neuropharmacology of erection cannot be totally explained by classic cholinergic and adrenergic mechanisms (29). Numerous putative nonadrenergic, noncholinergic neurotransmitters have been investigated. Histamine, 5-hydroxytryptamine (serotonin), bradykinin, prostaglandins (PGE_1, PGE_2, and PGF_{2a}), and amino acids do not appear to be responsible for the production of penile erection (175,176). Likewise, no convincing evidence has implicated adenosine triphosphate (a putative purinergic neurotransmitter) to be important in the production of penile erection.

The search for a nonadrenergic, noncholinergic mechanism to explain the neuropharmacology of penile erection has included the evaluation of possible peptidergic mechanisms. The polypeptide most investigated to date is VIP. The anatomic localization of VIP in the penis at both light and electron microscopic levels has been previously described. VIP is known to have a vasodilatory effect (302,344) and has been demonstrated to cause relaxation of strips of rabbit, cat, monkey, and human corpora cavernosa (132,190,332,372). In other work using nonhuman primates, however, VIP had little or no effect on the corpora cavernosa urethra of the rabbit, guinea pig, dog, and cat and no effect on penile vessels in the bull (322). In human corporal strips, VIP causes a weak relaxant effect in tissue that previously has been contracted with norepinephrine stimulation and also has been reported to cause detumescence of the erect penis obtained by cavernous nerve stimulation in the monkey (332).

In the feline submandibular gland, VIP has been shown to be responsible for the atropine-resistant vasodilation seen with nerve stimulation (215). In this tissue, VIP and acetylcholine are present in the same neuron, and both are released with nerve stimulation. It is possible that a similar situation occurs in the penis and that VIP is responsible for some of the pharmacologic findings, such as atropine resistance, which at present are not well understood. It is equally possible that VIP and other polypeptides may act as neuromodulators to control the rate of release of acetylcholine at nerve terminals.

The recognition of the importance of nitric oxide in the physiology of vascular smooth muscle relaxation has led to new insights into the mechanisms responsible for penile erection. Nitric oxide is synthesized in many types of mammalian cells and is a modulator of several biologic activities, including endothelium-dependent dilation of blood vessels, inhibition of platelet aggregation, and macrophage cytotoxic activity (170,249). Nitric oxide synthase, located in nerves and endothelium, synthesizes nitric oxide and the amino acid citrulline from arginine and molecular oxygen (248). Nitric oxide does not interact with a receptor on the cell membrane,

but it crosses the cell membrane and interacts with the enzyme guanylate cyclase. Activated guanylate cyclase catalyzes the conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). The accumulation of cGMP induces a series of intracellular events that leads to smooth muscle relaxation. Phosphodiesterase type 5 inactivates cGMP. In strips of corporal smooth muscle from rabbits and humans, nitric oxide causes relaxation, which mimics electrical field stimulation. This relaxation occurs in the presence of guanethidine and atropine in the bathing media and is therefore thought to be mediated by nonadrenergic, noncholinergic neurons (52). Acetylcholine also is capable of causing endothelium-dependent relaxation by mechanisms that involve nitric oxide (301). Relaxant responses to nitric oxide are enhanced by pretreating the smooth muscle strips with a cGMP phosphodiesterase inhibitor. These observations support the hypothesis that stimulation of nonadrenergic, noncholinergic neurons in the corpus cavernosum cause corporal smooth muscle relaxation mediated by nitric oxide. In addition to cGMP, cyclic adenosine monophosphate (cAMP) may also be important in causing corporal smooth muscle relaxation. Both VIP and PGE_1 induce the formation of cAMP and cause corporal smooth muscle relaxation. In addition, VIP and neuronal nitric oxide synthase have been reported to be colocalized in the same nerves within the corpus cavernosum (88).

Valuable information concerning the neuropharmacology of erection has been obtained from the technique of intracorporal injection. Brindley's observation that the intracorporal injection of phenoxybenzamine (an a-adrenergic blocking agent) resulted in penile erection clarified to a large extent our understanding of the physiology of human corporal smooth muscle (42). Norepinephrine causes contraction of corporal smooth muscle, and this drug effect is blocked by phenoxybenzamine. Therefore relaxation of the corporal smooth muscle appears to be an important component in the development of penile erection. The intracorporal injection of the smooth muscle relaxant papaverine, an agent that does not act through neuroreceptors but rather directly on the smooth muscle cell, as well as the injection of multiple other agents also cause penile tumescence (43,350). The use of these drugs not only has created a new research approach to the understanding of erection but also has been a valuable addition to the clinical diagnosis and therapy of impotence (320,385).

The neuropharmacology of the CNS as it relates to penile erection is less well understood than our understanding of peripheral mechanisms. In the rat, serotonin inhibits and dopamine activates male sexual behavior (123). Some of these animal data may be applicable to humans. Levodopa, for example, is known to cause heightened sexual activity (15,154). In addition, trazodone, a widely used antidepressant, affects the actions of serotonin, and priapism is a known side effect of this agent (235).

Hormonal Factors

Although most physicians agree that a relationship between male hormones and penile erectile activity exists, the nature of this relationship and the mechanisms responsible for hormonal control of sexual activity remain unclear. The difficulties encountered in separating libido from erectile ability in clinical studies are well known. In addition, neither the mechanism of action nor the primary site of action (penis, spinal cord, or brain) of androgens in promoting penile erection is understood.

Clinical studies on the effects of castration and studies using testosterone replacement in hypogonadal men have been conducted. In a study of patients with carcinoma of the prostate undergoing either orchiectomy, estrogen therapy, or both, Ellis and Grayhack (93) found that a number of patients retained their potency after castration. Castration plus estrogen therapy appeared to more adversely affect sexual function in this small group of patients than did castration alone. Although an argument can be made that these patients did not undergo objective posttreatment evaluation, retained sexual potency after bilateral orchiectomy has been reported by others (141,231,289).

Androgen replacement in hypogonadal men has been analyzed in placebo-controlled clinical evaluations (74,214,323). In this group of patients, androgen increases sexual activity and interest. The relationship between androgen and penile erection, however, is less clear. Hypogonadal men demonstrate decreased erectile activity during nocturnal penile tumescence testing and report fewer spontaneous daytime erections. These abnormalities are corrected with testosterone replacement (72,189). Laboratory-tested erectile responses to erotic films and fantasy are not abnormal, however, in hypogonadal men. These observations are consistent with the hypothesis that the major effect of androgens on male sexual function is to enhance libido and not to directly control penile erection in a sexual setting. Nocturnal erection appears to be testosterone dependent (189). Therefore certain types of stimuli that promote erection appear to be androgen sensitive, and others do not (14).

There are no current data to suggest that serum testosterone levels in the normal laboratory range are correlated with sexual behavior in humans (74). Although a “threshold” serum level of testosterone for sexual activity probably exists, changes in circulating testosterone concentration do not correlate with sexual activity or interest. Furthermore, testosterone is no more effective than placebo in restoring sexual potency to impotent men without androgen deficiency. In a controlled study involving these patients, more than half of the men reported marked improvement in sexual potency, regardless of whether they received androgen or placebo (23).

Animal models have been used to study the effects of androgens on sexual function. In the rat, castration results in a rapid disappearance of circulating testosterone. Castrated animals exhibit diminished ejaculatory behavior, decreased number of intromissions, and finally, loss of mounting behavior. The administration of testosterone restores normal sexual activity (74). Although testosterone is known to affect spinal reflex activity (139), the primary site of testosterone action in controlling sexual function is probably the brain. The implantation of small amounts of testosterone into the hypothalamic preoptic area, but not into other parts of the brain, restores normal sexual behavior in castrated rats (74).

Hormones other than androgens also are proposed to be important in controlling sexual function. In addition to a loss of libido, most men with hyperprolactinemia are impotent (271). Although a small number of patients with hyperprolactinemia and a normal serum testosterone level have been reported, most patients, and in some series, all of the patients, with hyperprolactinemia have markedly depressed serum testosterone levels (58). The mechanism responsible for depressed testosterone levels in hyperprolactinemic states is unknown. Increased prolactin may inhibit the action of luteinizing hormone (LH) on Leydig cell function or decrease the secretion of LH either by inhibiting the response of the pituitary to LH-releasing hormone or decreasing the secretion of the latter from the hypothalamus (58). However, impotence associated with this syndrome is not solely related to low testosterone levels. Testosterone replacement does not correct the erectile dysfunction. The fact that sexual function improves when prolactin levels are lowered by bromocriptine therapy has led to speculation that hyperprolactinemia per se may be related to impotence (58). Evidence also exists that supports the concept that the primary effect of hyperprolactinemia is one of diminished libido and that the impotence is secondary or psychogenic (13,311).

Summary

The realization of the importance of the smooth muscle of the corpora cavernosum in the physiology of penile erection has led not only to a better understanding of the erectile process but also to innovative approaches, including oral therapy, to the patient with erectile dysfunction. Penile erection is produced by three interrelated processes: (a) relaxation of the smooth muscle of the corpora cavernosa, (b) arteriolar dilation, and (c) decreased venous outflow (probably from passive compression of venules just beneath the tunica albuginea). The sympathetic nervous system (acting through a-adrenergic receptors) causes contraction of corporal smooth muscles and arterioles and therefore promotes detumescence. Stimulation of parasympathetic nerves produces erection. The neurotransmitters that cause corporal smooth muscle relaxation appear not to be related to classic adrenergic, cholinergic mechanisms, and nitric oxide is an important mediator of this process. Major unanswered questions include the specific events leading to corporal smooth muscle relaxation, the influence of hormones on penile erection, and CNS control of the erectile process.

IMPOTENCE

Etiology

Various diseases have been associated with impotence. In many instances, a cause-and-effect relationship has not been demonstrated; in other instances, clinical observations have significantly contributed to our understanding of both erectile physiology and impotence. Causative processes are categorized as follows: (a) neurologic disorders, (b) vascular disorders, (c) endocrine disorders, (d) surgical and traumatic disorders, (e) drug-associated erectile dysfunction, and (f) psychogenic erectile dysfunction (346).

Neurologic Disorders

Neurologic causes of impotence can be viewed most conveniently as peripheral neuropathy, spinal cord lesions, or lesions of the cerebral hemispheres.

Peripheral Neuropathy

Diabetic Neuropathy. Diabetes mellitus is a common cause of impotence. This was first suggested as long ago as 1798 by Rollo (100). Diabetes has a profound effect on the vascular system, causing accelerated atherosclerosis and microangiopathy. This microangiopathy particularly affects the eyes, kidneys, and central and peripheral nervous systems. The incidence of impotence in diabetic men increases with age. In a study involving 198 diabetic men, impotence occurred in 7.5% of patients younger than 45 years of age, 23.2% at 50 years of age, 40.2% at 60 years of age, 58.4% at 70 years of age, and 80% at 80 years of age (295). These figures are two to five times higher than those found in healthy control subjects (39). The clinical course of impotence in diabetic men is most often gradual, beginning with decreased firmness or rigidity and progressively worsening.

The erectile abnormality associated with diabetes is thought by some to be primarily a neurologic rather than a vascular or endocrinologic problem. Ellenberg (90) identified peripheral neuropathy in 38 of 45 impotent diabetic patients, but others (226) have found a much lower incidence of neuropathy associated with impotence. Impotent diabetic men often have a peripheral neuropathy with diminished or painful sensation, muscle wasting and weakness, and trophic changes of skin and joints (39). However, impotence may be the first and only symptom of diabetes. Deutsch and Sherman (78) reported that up to 12% of impotent men have unrecognized diabetes mellitus. Masters and Johnson (227) suggest that there is a 200% to 300% higher incidence of abnormal glucose tolerance tests in men with impotence than in a representative cross section of the population. They also emphasize that careful maintenance of medical control often does not reverse the impotence once developed. Recent evidence suggests that the prevalence of impotence is lower in diabetic men who maintain good control of blood sugar, as measured by hemoglobin $A1_c$ (285). Libido is often preserved but may lessen as a result of frustration and other psychologic factors that occur because of lifestyle changes secondary to chronic disease. Impotence associated with diabetes cannot be assumed to be purely organic; psychologic factors also deserve attention.

The neuropathic changes associated with diabetes have long been considered one of the main causative factors in diabetic impotence. Somatic and autonomic neuropathy are more common in impotent than in nonimpotent diabetic men (54). A proportion of these patients complain of orthostatic hypotension and difficulty with micturition (91). Studies using instantaneous heart recordings have demonstrated that the onset of autonomic dysfunction may occur without evidence of peripheral neuropathy and may precede symptoms of autonomic dysfunction by a number of years (217). The association of autonomic neuropathy with diabetes mellitus is still not clear. Fairburn and colleagues (98) found no difference in cardiovascular autonomic neuropathy in impotent versus potent diabetic men. Ewing and associates (95) studied the vascular reflexes in 31 males with autonomic neuropathy. Of this group, 28 complained of impotence, and it was an isolated problem in 15. Vascular reflexes were studied by recording heart rate changes during the Valsalva maneuver and by measuring blood pressure response to sustained hand grip. Patients with abnormal vascular reflexes had greater evidence of peripheral neuropathy as measured by nerve conduction studies. There was a notable difference in responses of patients with impotence alone and the patients with other features of autonomic neuropathy with or without impotence. The vascular reflexes were less abnormal in those patients whose only manifestation of autonomic neuropathy was impotence. These investigators concluded that only when impotence is associated with other features of the disorder can it be attributed to autonomic neuropathy. Thus, if impotence is the only suggestion of autonomic neuropathy in the diabetic patient, other possible causes of sexual dysfunction should be sought.

Abnormalities of the sacral reflex in diabetic patients have been demonstrated by cystometric findings (90) and lengthened bulbocavernosus reflex latency times (156). Neuromorphologic changes can be seen by microscopic examination of the autonomic nerve fibers of the corpora cavernosa in impotent men (97). Ellenberg (91) reported the cystometric findings in 45 diabetic men who complained of impotence; only 8 had normal findings. The other 37 patients had increased bladder capacity (greater than 500 mL); 6 had residual urine with no cystoscopic evidence of bladder neck obstruction. Five of the diabetic patients had neither cystometric abnormalities nor involvement of the peripheral nervous system. Ellenberg concluded that impotence was psychogenic in 4 of these 5 patients as “indicated by the presence of morning erections and competence in extramarital situations in two and intermittent impotence in two.” Of note, only 3 of 30 diabetic patients without the complaint of impotence had abnormal cystometrograms (91).

Despite the fact that many accept autonomic neuropathy as the underlying disorder in impotent diabetic men, vascular factors may play an important role. Vascular changes in diabetic patients resulting in retinopathy and neuropathy are well known. These vascular lesions have been associated with impotence in the diabetic male (145). Ruzbarsky and Michal (298) reported on the morphologic changes in the arterial bed of the penis associated with aging. Microangiopathy occurred 10 to 15 years earlier in the diabetic man than in the nondiabetic man.

With Doppler studies, cystometrograms, and bulbocavernosus latency tests, Jevitch and associates (156) compared the vascular and neuropathic changes in a group of impotent diabetic men. Vascular obstructive changes occurred in 95% of the patients; 72% were severe and 23% mild. Abnormal neurologic studies were noted in only 34%. All of the patients with neurologic changes also had vascular abnormalities. In addition, 98% of the impotent diabetic men had normal antegrade ejaculation.

Hormonal abnormalities do not appear to play a prominent role in the sexual dysfunction of diabetic patients. In the prospective study by Ficher and colleagues (100), serum levels of testosterone, prolactin, LH, and follicle-stimulating hormone (FSH) were not significantly different in impotent diabetic patients when compared with impotent nondiabetic patients.

Uremic Neuropathy. Patients with chronic renal failure, particularly those undergoing dialysis, are frequently impotent, with complete impotence noted in 20% to 60% of patients (67). Even though uremic neuropathy may contribute to impotence, the hormonal abnormalities associated with uremia may play the predominant role (67). Holdsworth and colleagues (150) found significant elevations of LH and FSH in uremic patients. Serum testosterone levels were subnormal. Histologic examination of testes biopsy samples revealed severe spermatogenic damage. Bailey (11) concluded that testicular suppression was a result of the cellular toxic effects of retained uremic toxins. A more detailed discussion follows in the section describing endocrine causes of impotence. In addition to the neuropathy and endocrinopathy associated with uremia, the vascular effects of uremia have been studied objectively (165). Cavernous artery occlusive disease was found in 78% of patients with chronic renal failure. In addition, corporovenous leakage was found in 90% of these patients.

Amyloidosis. Amyloidosis with involvement of the autonomic nervous system can cause impotence. Neurogenic impotence appears to be particularly prominent in heredofamilial amyloidosis. Thus amyloidosis should be included in the causes of male sexual dysfunction. The clinical course of amyloidosis is slowly progressive, and patients usually die in renal failure. No specific therapy exists for amyloidosis (65).

Spinal Cord Lesions

Spinal Cord Injury. In 1960, Bors and Comarr (41) published their now classic study on sexual function in a large group of patients with spinal cord injuries. The degree and type of sexual dysfunction depend on the level and completeness of the cord lesion. Bors and Comarr found that 94% to 100% of men with upper motor neuron lesions that were incomplete maintained some erectile activity. These lesions may interfere with psychogenic erections, but spontaneous erections and reflex-stimulated erections are common (39). Lower motor neuron or lumbar spinal cord lesions produce a different clinical picture. Reflex-stimulated erections are absent, but psychogenic erections occur in up to 90% of patients (39,41) with incomplete lesions and in 27% with complete lesions. In a more recent study, Comarr (66) reported 20 patients with complete lower motor neuron cord lesions. Eight patients could obtain psychogenic erection, but none had reflex-stimulated erections. Seven had successful intercourse, and five achieved ejaculation with orgasm. It has been suggested that these phenomena are mediated by means of the sympathetic nervous system because those preganglionic fibers leave the spinal cord at the lower thoracic and upper lumbar level (39). Complete lesions of the sacral spinal cord have the worst prognosis with reference to sexual function. In Piera's study (273) of 100 patients with spinal cord injuries, the 15 patients with complete lesions of the sacral cord had no erections and no ejaculation.

Sexual function is a major concern of patients with acute spinal cord injuries, and physicians should be cautious about predicting the clinical outcome early in the patient's course. Spinal shock with complete or almost complete absence of reflex activity below the level of the lesion commonly occurs (6). Genital reflexes and rectal sphincter activity are profoundly depressed. This may last for many weeks. Thus, before prognosticating, the physician should wait until spinal shock is reversed so that the level and completeness of the spinal cord lesion can be assessed, thereby allowing for a more accurate prediction of the patient's future course.

Multiple Sclerosis. Multiple sclerosis is characterized by loss of myelin in the white matter of the brain, brainstem, and spinal cord. Its effect on potency is variable. Vas (349) reported 37 patients between 18 and 50 years of age. Forty-three percent were either totally or partially impotent. Cartlidge (59) reported that 7 of 20 patients with multiple sclerosis were impotent. The severity of the impotence was directly related to the duration of the disease, but in several patients, sexual potency tended to remit and relapse. Sacral-evoked response measurement has been recommended in the evaluation of impotence associated with multiple sclerosis (128). In a comprehensive study of 41 men with multiple sclerosis, sexual dysfunction was present in 29. Of these 29, 8 patients had prolonged sacral latency times. The authors concluded that abnormal sacral-evoked responses may imply neurogenic impotence. In this study, the authors also observed patients with a combination of abnormal perineal electromyography, abnormal sacral latency, and bladder detrusor hyperreflexia, which suggests spinal cord dysfunction at multiple levels.

Other Spinal Cord Diseases. Other spinal cord lesions that can affect potency include syphilis (tabes dorsalis), spina bifida, syringomyelia, amyotrophic lateral sclerosis, and compression from a herniated disc or tumor (346). Lateral cordotomies used to treat intractable pain also may result in impotence.

Idiopathic orthostatic hypotension (i.e., idiopathic autonomic insufficiency) is often referred to as *Shy-Drager syndrome.* This rare degenerative disorder of unknown cause is progressive, resulting in severe debility and death within 5 to 10 years of onset. It affects primarily middle-aged men, causing symptoms of autonomic dysfunction, such as loss of sweating, sphincter disturbances, orthostatic hypotension, and impotence (38).

Lesions of the Cerebral Hemispheres

Little information is available concerning the association of cerebral lesions and sexual potency. Frontal lobotomy, Parkinson's disease, Huntington's chorea, and electroshock therapy all may affect libido, but the effect on erectile function is unknown (39). Likewise, there is limited knowledge as to potency in men who have had strokes; presumably, the effect would be dependent on the site and severity of the lesion.

Vascular Disorders

Erection is essentially a hemodynamic phenomenon. Probably the most well-known cause of impotence is Leriche's syndrome, or thrombotic obliteration of the aortic bifurcation with resultant pain and claudication of the hips and thighs and impotence in males (196). Arteriosclerosis also affects the iliac, hypogastric, and pudendal vessels, as well as the small arteries of the corpora cavernosa. Fibrosis, calcification, and obliteration of the small cavernosal vessels occur with aging (298), and early changes can be identified in young men (27).

The role of vasculopathy in diabetic erectile dysfunction is not clear, and some investigators consider this dysfunction primarily neuropathic (90). This assumption may have developed from two suggestions: First, peripheral neuropathy most often occurs in the legs, it is common in diabetic patients, and it was believed that this peripheral neuropathy also would involve the pelvic and genital areas. Second, diabetic patients often have an enlarged bladder capacity, suggesting a relationship between neuropathy and impotence. However, peripheral neuropathy of the legs is rarely associated with disturbances of erection, bowel, or bladder function (287), and up to 30% of bladders with a capacity greater than 800 mL are urodynamically normal (365).

Vascular disease may be an important cause of erectile dysfunction in diabetic patients. As previously discussed, Jevtich and associates (156) found that vascular changes were more common than neurologic changes. More than 95% of the patients had evidence of penile arterial obstruction; 62% of the patients had penile arterial obstruction without any indication of peripheral neuropathy (156). The progressive nature of diabetic vascular changes should be expected to produce a gradual impairment of erectile function. Diabetes also may have an adverse effect on the smooth muscle of the corpora cavernosa. Impaired neurogenic and endothelium-mediated relaxation of penile smooth muscle from diabetic men with impotence has been demonstrated (301).

The “iliac artery steal syndrome” is an unusual manifestation of large-vessel arteriosclerosis (243). Initiation of penile erection occurs normally, but active pelvic movement quickly results in detumescence. It appears that there is collateral circulation in the pelvis to compensate for arteriosclerotic occlusion. During sexual activity, the blood flow is drawn away from the penis to supply the muscles of the hips and buttocks.

Abnormal venous drainage of the corpora also may contribute to the erectile insufficiency. It is well known that creating an artificial venous runoff to treat priapism results in detumescence, and Ebbehøj and Wagner (85) described spontaneously occurring “venous leaks.” Surgical correction led to erectile improvement. Tudoriu and Bourmer (343) subsequently studied 300 cadaver penises and found evidence that corpora cavernosal leakage is common and that the incidence increases with age. In a study of 49 impotent patients, cavernosography and papaverine-induced erection revealed abnormal venous drainage in 38 patients (206). The term *abnormal venous leakage* is, in the vast majority of cases, a misnomer. Although some cases of congenitally abnormal venous drainage undoubtedly exist, in most cases, venous leakage is not secondary to venous pathology but is caused by an abnormality of the smooth muscle of the corpora cavernosa. If the corporal smooth muscle does not efficiently relax and allow the cavernous spaces to fill with blood, the subtunical venules are not compressed and blood escapes from the corpora. A more correct term to describe this situation is *corporovenous leakage.*

Endocrine Disorders

In addition to diabetes mellitus, most other major endocrine abnormalities have been associated with impotence. However, the incidence of endocrine disorders in a population of impotent men is not clear. In a prospective study of 256 impotent men, an organic cause was found in 35.9%, a psychogenic cause in 38.3%, and a mixed or uncertain cause in 25.8%. The incidence of hypothalamic-pituitary-gonadal axis abnormalities in the entire group was 17.5%. However, in only 13 of those 45 patients could the impotence be directly related to the axis abnormality (262).

Testosterone is the primary androgen in humans and is secreted by the Leydig cells of the testis in response to LH. The secretion of LH is modulated by LH-releasing factor. These hormones interact in a negative feedback system. Lowering serum testosterone levels causes an increase in LH-releasing hormone, which leads to an elevation of LH. This increase stimulates the Leydig cells to restore the testosterone level to normal. FSH plays an integral role in inducing maximum Leydig cell sensitivity to LH during puberty. After puberty, however, the primary importance of FSH is its action on spermatogenesis.

Low levels of testosterone may result from abnormalities that exist at any point in the hypothalamic-pituitary-gonadal axis. Thus hypogonadism can be characterized as that caused by primary testicular disease or by hypogonadotropic hypogonadism. Testosterone is necessary to maintain male secondary sex characteristics, libido, and probably potency. Thus patients with endocrine abnormalities may present with a variety of symptoms. They may notice a change in body habitus or presence of gynecomastia. Commonly, they note a decrease in the size of the testicles. Physical examination may reveal a diminished size of the prostate and testes. It has been suggested that in adults, testicular size less than 4 cm in length is abnormal (265). A decreased serum total testosterone level confirms the diagnosis of hypogonadism. In cases of alcoholism, massive obesity, or thyroid dysfunction, a serum free testosterone level should be measured because decreased testosterone levels may be the result of low levels of testosterone-binding protein rather than endocrine abnormalities.

If testosterone is low, gonadotropin levels should be measured. Decreased or normal levels of LH and FSH indicate hypogonadotropic hypogonadism, whereas elevated levels of the gonadotropins in the presence of decreased testosterone levels indicate primary testicular dysfunction.

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism is caused by disorders of the pituitary and hypothalamus and may be part of a clinically recognized syndrome such as Kallmann's syndrome, Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, or cerebellar ataxia (265). Hypogonadotropism may be secondary to a mass lesion or other endocrine disease, such as Cushing's syndrome, acromegaly, panhypopituitarism, hyperthyroidism, or hypothyroidism. Evaluation of hypogonadotropic hypogonadism should include anatomic studies to rule out a mass lesion or brain tumor and a complete endocrine evaluation.

Hypergonadotropic Hypogonadism

Nickel and associates (262) found that 7% of impotent patients had hypergonadotropic hypogonadism or primary testicular failure. Hypergonadotropism can be associated with chromosomal abnormalities, or it can be secondary to infection, surgery, or trauma. In the 18 patients with hypergonadotropic hypogonadism described, 2 had previously undiagnosed Klinefelter's syndrome and 13 had a history of an acquired testicular disorder, small atrophic testicles, and/or a low serum testosterone level. The remaining three patients had psychogenic impotence.

Hyperprolactinemia

Prolactin is secreted by the anterior pituitary under hypothalamic control. Inappropriate elevation of serum prolactin in some patients with pituitary tumors has been associated with galactorrhea and hypogonadism. Hyperprolactinemia also may be secondary to drugs or renal disease. Franks and Nabarro (109) reported impotence as the presenting symptom in 8 of 21 patients with prolactin-secreting pituitary tumors. In male patients with pituitary tumors and normal prolactin levels, only 2 of 19 were impotent. They recommended that “serum prolactin estimations should be made in the course of investigation of all patients with impotence.” Other investigators have challenged this recommendation, and in a careful study of 30 impotent males and 11 potent control subjects, Miller and associates (244) found no significant

differences in serum prolactin levels among control, organically impotent, or psychogenically impotent patients. They concluded that impotence is not related to hyperprolactinemia per se and that the routine use of serum prolactin measurements in unscreened patients with impotence should be questioned.

Thyroid Dysfunction

The direct effect of thyroid disease on sexual function is unknown; however, occult hyperthyroidism has been implicated as a cause of impotence (329). Thyrotoxicosis is associated with increased testosterone levels but normal levels of unbound free testosterone. This is caused by the increased levels of testosterone estrogen–binding globulin associated with hyperthyroidism. Elevated levels of total free estradiol, as well as LH, have been noted (64) and may be associated with gynecomastia, impaired spermatogenesis, decreased libido, or erectile dysfunction (169). Whether the erectile dysfunction is caused by hormonal abnormalities or what the overall impact of the thyrotoxicosis is are both unknown.

Renal Insufficiency

Chronic renal failure and hemodialysis result in a dramatic decrease in male sexual function (304,341). Even though most impotent uremic men have evidence of peripheral neuropathy, endocrine changes also have been noted and associated with impotence in these patients. Sherman (317) evaluated 14 patients with chronic renal failure receiving hemodialysis with neurologic, psychiatric, and endocrine studies. Seven of the patients were impotent, and all seven had prolonged nerve conduction velocities and absent bulbocavernosus reflexes. However, these patients also had abnormally low serum testosterone levels. Uremia appears to affect Leydig cell function. Guevara and associates (133) noted decreased testosterone levels with increased LH and normal FSH levels in their study of 26 men receiving hemodialysis. Thurm (341) noted that patients with chronic renal failure who were receiving home dialysis maintained a higher level of sexual activity than those receiving hospital-based dialysis. Of 10 patients dialyzed at home, 8 maintained adequate sexual relations. Of 12 patients dialyzed at the hospital, 10 were completely impotent and 2 had little desire for intercourse.

The psychologic and physiologic milieu of patients with chronic renal insufficiency is complex. For instance, the treatment of chronic renal failure associated anemia with recombinant human erythropoietin improves not only the quality of life but also sexual function (263). In addition, many of the drugs used in their treatment, particularly antihypertensives and antidepressants, have been implicated as a cause of erectile dysfunction. After renal transplantation, most patients report a return to preillness levels of sexual activity (304). Successful renal transplantation results in restoration of low serum testosterone levels to normal and improved erectile function in 70% to 80% of patients (304). If impotence persists after transplantation, it is likely related to abnormalities of the blood supply to the penis. Often, the internal iliac artery is used in an end-to-end anastomosis to the transplant renal artery. If a second transplant is performed with the opposite internal iliac artery in a similar fashion, the problem of impotence is markedly increased (127). It is now recommended that second renal transplants be performed with an end-to-side technique on the external iliac or common iliac artery (127).

Traumatic and Surgical Disorders

Trauma to the lower urinary tract reportedly causes impotence in a high percentage of patients. Most patients with a fractured pelvis have multisystem injuries, and there is a high incidence of injury to the bladder and posterior urethra. Up to 50% of these patients may be impotent (125). The initial management of posterior urethral injuries appears to influence potency rates. Patients managed by initial suprapubic cystotomy and later reconstruction have a lower incidence of impotence than those managed by primary repair (70,228).

Many urologic surgical procedures can cause impotence. It is common knowledge that radical prostatectomy for carcinoma of the prostate frequently results in erectile dysfunction, and it has been presumed that damage to pelvic nerves and blood vessels is the cause. However, some patients retain erectile function after radical prostatectomy. Finkel and Taylor found that of 14 patients who claimed preoperative potency and normal sexual performance, 6 (43%) reported postoperative normal erections and sexual intercourse (101a). Walsh and Donker (357) concluded that impotence results from injury to the autonomic innervation of the corpora cavernosa most commonly during dissection of the prostatic apex and transection of the urethra or during division of the lateral pelvic fascia and lateral pedicle. Modifying the procedure to preserve the cavernosal nerves has reduced the occurrence of impotence, and 1 year after surgery, 86% of patients are potent (358). Others have reported lower rates of preservation of potency following radical prostatectomy. Catalona and Bigg (61) found that 63% of men who underwent bilateral nerve-sparing prostatectomy and 39% who underwent a unilateral nerve-sparing prostatectomy were potent postoperatively, with a minimum of 6 months of follow-up. Patient age, preoperative sexual function, and type of surgery (bilateral versus unilateral nerve sparing) are currently recognized as being important factors in determining postoperative sexual function (279). A modification of total perineal prostatectomy that preserves the periprostatic autonomic nerves has been described (366).

The assumption that radical prostatectomy causes impotence has led many urologists to recommend external beam radiation therapy as an alternative. However, this too has been reported to cause impotence in 40% to 60% of patients (10). Interstitial radiation therapy may be less deleterious. Herr (146) reported that 90% of patients treated with iodine-125 implantation retained potency.

The various types of prostatectomy for benign disease also may result in impotence: simple perineal prostatectomy, 29%; suprapubic prostatectomy, 13%; and transurethral resection, 5% (101). The mechanisms responsible for impotence after a simple prostatectomy, particularly a transurethral resection, are not clear. Although an organic cause cannot be totally excluded, a psychogenic cause is more likely. The myth that impotence is inevitable after prostatectomy is widely believed by patients and their spouses.

External sphincterotomy has been reported to cause impotence, but it appears that choice of technique may be an important factor. Kiviat (172) noted that 73% of his patients had some degree of erectile dysfunction after undergoing sphincterotomy at the 3 and 9 o'clock positions. Whitmore and associates (370) reported that of 28 patients who underwent lateral incisions of the external sphincter, 7% had a complete loss of erectile function and 14% had partial loss. They recommended that sphincterotomy be done at the 12 o'clock position and reported that, of 62 patients so treated, none had subsequent erectile dysfunction.

Leriche and Morel (196) first described impotence caused by infrarenal occlusion, and it is now known that approximately 80% of men who present with aortoiliac occlusive disease have significant erectile dysfunction (167). In men with reportedly normal preoperative potency, 21% to 88% have iatrogenic sexual dysfunction after aortoiliac revascularization (76). Ischemia secondary to diversion of pelvic blood flow and/or injury to the autonomic nerves during aortoiliac dissection have been proposed as the causes for postoperative impotence (106). A careful nerve-sparing aortic dissection and attention to preservation of improvement of pelvic blood flow have been reported to yield much improved results (76,299). Flanigan and colleagues (106) reported 110 men who underwent aortoiliac revascularization and whose sexual function was evaluated preoperatively and postoperatively; 30 patients (27%) were impotent both preoperatively and postoperatively, 67 patients (61%) had normal sexual function preoperatively and postoperatively, and 13 patients (12%) who were impotent preoperatively regained erectile function after surgery. No patient who was potent preoperatively was impotent postoperatively. The actual mechanism by which preservation of preaortic autonomic nerves preserves potency is unclear because it is known that complete preaortic retroperitoneal lymph node dissection with dissection of those nerves may result in ejaculatory incompetence because of absent seminal fluid emission or lack of bladder neck closure but does not cause erectile dysfunction (166,179). Also, the restoration of potency to preoperatively impotent men is most logically caused by reestablishment of pelvic blood flow because autonomic nerve function is unlikely to be enhanced.

The occurrence of erectile dysfunction after surgery for lower bowel disease seems to be dependent on the patient's age and the extent of the surgical resection (364,381). Watts and colleagues (361) noted that of 41 men who underwent rectal excision for ulcerative colitis, 8 were older than 50 years of age and 6 of these were impotent after surgery; of 33 patients younger than 50 years of age, only 1 was impotent postoperatively. Weinstein and Roberts (364) reported 24 men who had undergone colorectal resection (13 abdominoperineal resections and 11 anterior resections). None of the patients who underwent abdominoperineal resection were sexually active after surgery, whereas 8 of the 11 patients having an anterior resection remained sexually active. Two of the three who were not sexually active also had undergone a prostatectomy. The average age of these 24 patients was 64 years. In another review of 45 men undergoing rectal excision, all were younger than 50 years of age. Of 25 undergoing proctocolectomy, 1 (4%) was impotent postoperatively, and of 20 undergoing abdominoperineal resection, 3 (15%) were impotent (381).

Drug-induced Impotence

Medication may be the single most common cause of sexual dysfunction in our society. In a study of 1,180 men screened at one outpatient clinic, 401 were impotent. Of 188 who were more thoroughly evaluated, the most common cause of impotence was medication (324). The adverse effects of medication may be manifest as changes in libido, diminished erectile ability, or decreased ejaculatory capacity. Theoretic mechanisms for these drug effects include production of CNS sedation or

depression, drug-related hyperprolactinemia, direct antiandrogen effects, or anticholinergic and antiadrenergic effects (151).

Even though many classes of drugs may affect erectile function, the two most often implicated are antihypertensive and psychiatric or antidepressant compounds. Antihypertensives are categorized as diuretics, vasodilators, or sympatholytics. Most antihypertensives have been associated with some erectile impairment, but diuretics seem to cause relatively few side effects. Thiazides and spironolactone may depress libido, and spironolactone causes enough hormonal alteration to result in gynecomastia (151,269).

Spironolactone's sexual side effects have been attributed to endocrine dysfunction (202). Despite its innocuous reputation, hydrochlorothiazide may have significant effects on sexual function. It alone was implicated as the cause of impotence in 9% of 861 patients at the Naval Medical Center in Oakland, California (149). The Medical Research Council of Great Britain (236) reported that 36% of patients taking bendrofluazide were impotent. Bulpitt and Dollery (48) questioned 477 patients in a hypertension clinic and found that 31% of men taking diuretics alone complained of impotence.

Sympatholoytic antihypertensives often are associated with impotence. Guanethidine, an agent that blocks peripheral adrenergic nerve activity of postganglionic neurons, is reported to cause impotence. In addition, retrograde ejaculation occurs in nearly two-thirds of patients treated with guanethidine (282). Phenoxybenzamine, an a-adrenergic blocking agent, may inhibit emission and ejaculation, but erection is apparently unaffected (246). Prazosin, a selective a-adrenergic receptor blocking agent, is believed at present to cause few sexual side effects (379). At high dosages, the b-adrenergic blocking agent propranolol may impair libido and erectile function (269,282). Several studies have reported impotence associated with propranolol, with an incidence as high as 15% (269).

Centrally acting sympatholytic agents include methyldopa, clonidine, and reserpine. With these agents, impotence may be more common and ejaculatory dysfunction less so (234). Because these drugs have a central action, this pattern of dysfunction is not surprising (282). Methyldopa may cause erectile failure in 25% to 33% of patients (346). It causes increased serum levels of prolactin, and it also may cause sedation and depression (151). Twenty-six percent of patients receiving methyldopa have been reported to complain of sexual dysfunction, but these undesirable side effects disappeared within 2 weeks of discontinuing the drug and instituting propranolol and hydralazine (269). The sexual dysfunction associated with clonidine is dose dependent and appears to be caused by the central effects of the drug. Impotence occurs in up to 25% of patients taking clonidine (282), and decreased libido is common (266,269). Reserpine, an agent that may cause significant depression, has been associated with both impotence and failure of ejaculation (282). It remains unclear as to whether erectile dysfunction reported to be secondary to antihypertensive medications is caused by the medication per se or is simply the result of decreasing the systemic blood pressure.

Antidepressant agents, including tricyclic antidepressants and the monoamine oxidase inhibitors, have central and peripheral actions. The tricyclic antidepressants possess sedative and anticholinergic effects and have been associated with decreased libido and impotence. Monoamine oxidase inhibitors interfere with the metabolism of sympathomimetic amines and are reported to cause diminished libido, erectile dysfunction, and impaired ejaculation (233).

Various commonly used drugs have been implicated as being causative factors in erectile dysfunction. Many of the tranquilizers, including the benzodiazepines and meprobamate, have been reported to reduce libido and consequently cause impotence (346). Decreased libido and impotence have been reported to be the most common side effects in patients taking clofibrate, an agent used to treat hyperlipidemia. These symptoms were noted in 14.1% of 1,065 patients taking this drug (269). Cimetidine, a histamine (H_2) receptor agonist used in the treatment of duodenal ulcer disease, has been associated with diminished libido and impotence in up to 50% of male patients (155). The mechanism by which cimetidine adversely affects male sexual function is unclear. Cimetidine therapy has been associated with gynecomastia and elevated prolactin levels (55,135). Peripheral H_2-receptor blockade in penile corporal smooth muscle also has been suggested as a mechanism (5). Although numerous pharmacologic agents have been implicated in sexual dysfunction (313), few well-controlled studies using objective parameters of sexual function have been performed to evaluate the effects of drugs on libido and penile erection.

Masters and Johnson (227) reported that alcohol was the second most common cause of impotence in their patients. Alcohol has been reported to cause depression of serum testosterone levels in intoxicated male alcoholics and in nonalcoholic men who are given large amounts of alcohol for several days. No similar depression was seen in nonalcoholic males after an episode of acute intoxication (297). Even though increased sexual activity has been attributed to alcohol because of decreased inhibitions, high levels can depress sexual arousal (296) and result in transient impotence. Cannabis, cocaine, and opiates also have been implicated in sexual dysfunction (313).

Psychogenic

All types of male sexual dysfunction, including impotence, premature ejaculation, and ejaculatory incompetence, may have a psychologic origin. Kaplan (159) described the normal sexual response cycle as having two phases: the excitement phase and the orgasmic phase. The excitement phase is characterized by both the subjective (being “turned on”) and objective (erection) changes commonly associated with sexual arousal. The objective manifestations of the excitement phase are dependent primarily on parasympathetic stimulation. The orgasmic phase is postulated to be under both sympathetic and voluntary control.

Men with primary psychogenic impotence often come from sexually repressed or religiously orthodox family backgrounds where sex was not discussed or was treated as sinful and immoral (225). The pathogenesis of secondary psychogenic impotence is poorly understood, possibly because the causes are so varied, and it may be the endproduct of an admixture of temperamental, emotional, familial, affective, cognitive, cultural, maturational, and biologic factors (199). Secondary psychogenic impotence is characteristically rapid in onset and selective in nature, occurring in one set of circumstances but not in others. Performance anxiety is regarded by many as the final common pathway to psychogenic impotence. In the classic example, the initial episode of erectile dysfunction may have a specific and explainable cause, such as intoxication or depression or the fear of discovery in a clandestine encounter. If the man were to approach the next encounter with fear and apprehension, he is likely to fail again, thus entering a vicious cycle of performance anxiety and erectile failure.

Psychogenic impotence can be more narrowly defined as either deficiency of desire (desire inhibition) or inability to maintain excitement even though it is present initially (excitement inhibition) (199). This distinction is important because excitement inhibition, including performance anxiety, is treated more successfully than desire inhibition. Men with excitement inhibition often assume the “spectator role” (227) and remain vigilantly preoccupied with their erections and performance. These individuals often can be helped by sex therapy techniques. Most psychologically impotent men suffer from desire inhibition. Desire deficiency has many and varied causes, such as systemic illness, drugs, biologic disorders (e.g., Klinefelter's syndrome), and depression. Psychogenic desire deficiency tends to be situation specific or partner specific. This characteristic helps distinguish it from desire deficiency resulting from other causes.

Evaluation

Much of the interest in male sexual function and dysfunction can be traced to the work of Kinsey and associates (171). Public awareness of scientific advances in this field, particularly the introduction of acceptable and reliable therapy in the 1980s and 1990s, has resulted in increasing numbers of patients being evaluated and treated for impotence. Patients usually desire a quick remedy. The physician must remember that penile erection is a complex phenomenon and that the causes of erectile dysfunction are many, varied, and often interrelated. Education of the patient of this fact at the initial visit is often helpful; the patient needs to understand that organic impotence results in significant psychogenic overlay, just as primary psychogenic problems can result in impotence.

History and Physical Examination

At the initial visit, a careful history and physical examination are mandatory and are the most important part of the overall patient evaluation. The history should focus not only on medical problems that may relate to the patient's impotence but also on the specifics of the sexual dysfunction. Although almost any erectile dysfunction perceived or experienced by a given patient can be loosely defined as impotence, unrealistic patient expectations can be ascertained relatively easily. The duration and nature of onset of impotence often aid in differentiating a psychogenic from an organic cause. Patients with psychogenic impotence usually experience a rather abrupt onset of symptoms. Not uncommonly, this is associated with a traumatic event, such as a family death, job loss, or birth of a child with a congenital deformity. To the contrary, most causes of organic impotence result in a slow but progressive deterioration in erectile capacity. Changes in libido should be ascertained and, if present, may signify hormonal abnormality. The presence of morning erections and the occurrence of erections in situations apart from the usual sexual partner are important historical clues. A history relating to risk factors previously discussed should be obtained. Symptoms compatible with intermittent claudication should be sought. Specific questions related to systemic disease (e.g., atherosclerosis, diabetes), previous pelvic surgery, radiation therapy, bowel or bladder symptoms (indicative of neurologic disease), and cryptorchidism should be asked. The medications the patient is taking should be noted. As previously discussed, various drugs, but particularly those that act on the nervous or vascular systems, have been associated with erectile dysfunction. All unnecessary medications should be discontinued. Although it is reasonable to attempt to change dosages or medication in patients who require pharmacologic therapy for hypertension or psychiatric

disease, such efforts in our experience generally have not proved to be beneficial.

A physical examination should be performed with particular attention to identifying vascular, neurologic, hormonal, and genital abnormalities. The femoral and peripheral pulses should be palpated and the abdomen and femoral areas auscultated for bruits. A limited neurologic examination should be performed. Perineal sensation in the area of the sacral dermatomes to pinprick, as well as the quality of rectal tone, should be ascertained. The presence or absence of a bulbocavernosus reflex, elicited by simultaneously squeezing the glans penis and noting anal sphincter activity, should be noted. A rectal examination to evaluate the prostate gland and palpation of the penis to identify plaques suggesting Peyronie's disease should be performed. The size, position, and consistency of the testes should be noted. The physical examination also should include an assessment of the character and distribution of body and facial hair, as well as gynecomastia, which may indicate a hormonal abnormality.

Additional Evaluation

There is little agreement concerning the optimal evaluation of the impotent patient after the initial history and physical examination. We initially obtain a serum testosterone measurement and serum multiple analyses in addition to urinalysis. Serum prolactin is not routinely measured, but the level is determined when an abnormally low serum testosterone level is found or when a history of decreased libido is obtained. The need for any “routine” endocrine testing has been questioned. Performing hormonal screening on only those patients with clinical signs of hypogonadism, that is either decreased libido or bilateral testicular atrophy, has been advocated (157). Thyroid function tests are performed only if there is suspicion of thyroid disease from history or physical examination. We do not perform routine psychometric testing. In patients with low morning levels of testosterone, serum levels of prolactin, LH, and FSH are determined.

The evaluation of most patients can reasonably stop after the history, physical examination, and blood studies just discussed are complete. We do not routinely perform vascular studies. Therefore patients older than 50 years of age with significant vascular risk factors, such as previous myocardial infarcts, cerebrovascular accidents, hypertension, diabetes, or a strong family history of vascular disease, generally are not studied (129). Since the advent of successful medical therapy for erectile dysfunction, one can argue that initial vascular studies are rarely indicated. Neurologic testing, including measurement of sacral reflex latency time, is performed only in patients with suspected neurologic lesions and is rarely indicated or clinically useful. Urodynamic evaluation also may substantiate a suspected neurogenic component. Urodynamic evaluation also helps identify a patient requiring cystoscopy or transurethral resection of the prostate before the placement of a penile prosthesis. Finally, we do not routinely perform nocturnal penile tumescence testing.

The evaluation of patients presenting with impotence is not standardized and is controversial. Many of the methods currently used have been criticized because of the lack of standardization and normal control data.

Vascular Studies

For years, the most commonly used method for evaluating penile arterial blood flow was calculation of the penile-brachial index (PBI). These measurements are obtained with a 10-mHz Doppler probe positioned over the penile arteries. A pneumatic cuff is placed around the base of the penis and inflated until arterial flow ceases. The cuff is slowly deflated, and the point at which arterial flow is reestablished is the penile systolic blood pressure. The penile systolic blood pressure divided by the brachial systolic blood pressure yields the PBI. In general, a PBI of less than 0.60 is thought to be indicative of vasculogenic impotence (124). Most clinicians and investigators have abandoned the evaluation of the penile arterial supply with Doppler measured blood pressure indexes for several reasons. The Doppler signal is not specific, and the exact vessel being studied is difficult to ascertain. In addition, determinations are made with the penis in the flaccid state, and the findings may not be applicable to the erect penis. Finally, the study is operator dependent. Because of these shortcomings, measurement of the PBI has been largely abandoned.

Penile angiography should be reserved for patients who are potential candidates for a revascularization procedure. Suitable surgical patients are those with a demonstrable and surgically correctable arterial occlusion and patent distal flow. Even though a high proportion of organic impotence is vasculogenic, a relatively small proportion of patients are good candidates for angiography and revascularization (126,232).

Arteriography usually involves selective bilateral internal iliac visualization or selective pudendal arteriography. Some investigators recommend that the procedure be formed with the patient under general anesthesia. McDougal and Jeffrey (232) have found that these highly motivated patients often can be studied when liberal doses of intravenous diazepam and morphine are administered. Other investigators have stated that in unanesthetized patients, approximately 50% of apparent obstructions of the penile artery or its branches are functional in origin (40). In addition, visualization of penile arteries can be enhanced by the use of vasodilators injected either intraarterially or intracorporally.

Nocturnal Penile Tumescence

Erections during sleep were reported as early as 1940, but it was not until 1953 that Serinsky discovered rapid eye movement (REM) sleep and noted that the cycles of nocturnal penile tumescence (NPT) closely resembled the cycles of REM sleep (163). Subsequently, Fisher and associates (104) reported that in young males, nocturnal erections were definitely related to REM sleep and occurred five or more times nightly. Karacan and associates (163) found that NPT associated with REM sleep was most common in pubertal males and showed a steady decline in frequency and duration with aging. They also noted that the proportion of NPT associated with non-REM sleep increases with age. These early discoveries led to the development of transducers and recorders used to detect and measure engorgement of the penis, thus providing a reproducible and convenient means to measure NPT.

Karacan and associates (161) soon suggested that in impotent men, the presence of full, sustained erections during sleep was indicative of psychogenic impotence, and the absence of turgid nocturnal erections indicated organic impotence. NPT monitoring quickly became accepted as the only objective means to differentiate psychogenic and organic impotence and was routinely incorporated into the evaluation of erectile dysfunction at many centers. Some centers use elaborate sleep laboratories and monitor electroencephalographic activity and NPT activity and use video monitoring of erections. Other centers use simpler electronic measuring strain-gauge devices for in-hospital or at-home evaluation. The patient's time and financial considerations in performing NPT testing in a sleep laboratory are obvious.

Some limitations of NPT monitoring became apparent and included both technical problems with the strain gauges and monitors, as well as questions about the basic assumptions of NPT testing. The premise of NPT testing rested on the belief that normal penile tumescence detected by an average increase in circumference of 30 mm (15 to 45 mm) indicated that a rigid erection had occurred. Wein and associates (363) noted that 23 of 134 patients tested for nocturnal erections had significant penile expansion but did not achieve rigidity adequate for vaginal penetration. It became clear therefore that rigidity as well as expansion was an important parameter of penile erection.

To assess rigidity, the penile buckling pressure has been measured. When an erection is present, a pressure device is pressed against the glans penis and the pressure required to make the penis buckle is measured in millimeters of mercury. If the penis buckles at a pressure of less than 60 mm Hg, it is too soft for vaginal penetration. If the penis does not buckle at pressures of 100 mm Hg or more, it is rigid enough for intromission. Buckling pressures between 60 and 100 mm Hg are equivocal (162).

Part of the controversy surrounding NPT stems from uncertainty as to the validity of NPT testing. The basic presumption is that the absence of nocturnal erections indicates organic dysfunction. This premise is not universally accepted. A number of investigators have noted that dreams with high anxiety content may not be associated with NPT at all (160) or may cause rapid detumescence (104). Conversely, there are numerous cases of patients with abnormal NPT patterns suggestive of impotence who report normal coital activity (314). On the basis of NPT testing, certain organic conditions may be misdiagnosed as psychogenic. Patients with hyperprolactinemia or “pelvic steal syndrome” are in this category (314). NPT testing alone is not adequate to differentiate psychogenic from organic erectile dysfunction. The presence of rigid nocturnal erections strongly supports a diagnosis of psychogenic impotence. The significance of impaired or absent nocturnal erections is not known, and in some instances, men with psychogenic impotence may not have nocturnal penile tumescence. Because of these shortcomings, NPT testing is not indicated for routine use (257).

Intracorporal Injection, Cavernosography, and Cavernosometry

The hemodynamic changes associated with penile erection involve increased arterial inflow, sinusoidal relaxation, and decreased venous outflow. Histologic studies show that smooth muscle is present in the walls of the sinusoids, as well as the walls of the penile arteries (205,208). In 1982, Virag (352) reported the discovery that intracorporal injection of the vasodilating drug papaverine resulted in penile erection. Subsequently, other drugs, such as phenoxybenzamine, and drug combinations,

such as papaverine and phentolamine, have shown similar effects (42,385). Multiple other agents injected intracorporally, such as imipramine and verapamil, also have been reported to produce erection (43). PGE_1 alone or in combination with other agents (papaverine and phentolamine) is currently the most widely used drug for intracorporal injection (24,331). Maximum erection is usually evident within 10 to 20 minutes. Having the patient stand or kneel has been reported to enhance penile engorgement, and some patients require sexual stimulation to achieve maximum rigidity (385). Erection, or at least engorgement, lasts from a few minutes to several hours but in some cases may last much longer. Priapism is a significant complication associated with intracorporal injection and is discussed later.

The production of an erection with the intracavernosal injection of vasoactive drugs allows the penis to be evaluated in the erect state. In fact, the production of a rigid erection following intracavernosal injection has been interpreted to indicate that the penile vasculature (both arterial inflow and corporovenous occlusion) was intact. However, some evidence indicates that the production of an erection by this technique does imply normal corporovenous occlusive function but not necessarily normal arterial inflow. In 19% of cases with a rigid erection following intracavernosal injection, evidence of arterial occlusive disease existed (272).

Like low arterial inflow, abnormal or excessive corporovenous “leakage” from the penis causes impotence. Venous deterioration with increased leakage has been implicated as a cause of impotence in older men (343). The use of cavernosography and saline infusion techniques to determine venous outflow has been reported by a number of investigators (260,351,368). In these studies, however, there was no vasodilation or sinusoidal relaxation such as that pharmacologically induced by papaverine injection. Lue and associates (206) reported their findings with cavernosography during papaverine-induced erection. Because patients with arterial insufficiency would not benefit from cavernosography, they eventually selected patients who were unable to achieve or maintain a good erection but who had an excellent arterial response to papaverine as shown by pulsed Doppler analysis and sonography. In their study of 49 patients, 38 had evidence of abnormal venous drainage. They noted that an intracorporal pressure of 80 mm Hg almost completely stops venous outflow. If intracorporal pressure does not reach 80 mm Hg after papaverine injection, saline solution should be infused to produce further venous occlusion. Normal emissary veins should be occluded at this pressure, and only abnormally large veins remain open. If further infusion of 100 mL of saline at 80 mL per minute cannot increase the intracorporal pressure to 80 mm Hg, a large venous leak is diagnosed and can be localized with contrast cavernosography (206). The patients with excellent arterial dilation and blood flow after papaverine injection are the ones who are reported to benefit most from erection cavernosometry and cavernosography and are thought to be the most suitable candidates for venous ligation procedures.

The method used to diagnose venous leakage by cavernosometry and cavernosography is not standardized. It appears that cavernosometry after the intracavernous injection of vasoactive drugs provides more valuable information than cavernosometry performed with saline infusion alone (337). The best drug to use, optimal dosage, and best criteria to use to diagnose venous “leakage” are still unclear. The Society for the Study of Impotence has determined that a significant corporovenous leak should be diagnosed by either maintenance flow rate or by dynamic infusion cavernosometry and cavernosography (129). If the maintenance flow rate 10 minutes after 45 to 60 mg of papaverine or 10 µmg of PGE_1 injected intracorporally is greater than 30 mL per minute to maintain intracavernous pressure greater than 90 mm Hg or to produce a fully rigid erection, abnormal venous leakage is diagnosed (31). The clinical effectiveness of cavernosometry and cavernosography is limited by several factors, including lack of normative data, operator dependence, variable interpretation of results, and poor predictability of the therapeutic outcome of venous surgery.

Neurologic Testing

When the history or physical examination indicates a potential neurologic cause for impotence, neurologic testing can be performed, although it is rarely clinically useful. Two important points need to be remembered. First, the presence of a demonstrable neurologic lesion does not mean that the lesion is responsible for the erectile dysfunction. Second, the neurologic studies used do not directly measure the integrity of the autonomic nerves that control penile erection.

The integrity of neural pathways can be ascertained by measuring evoked potentials. Both sacral-evoked potentials and genitocerebral-evoked potentials can be used (134,184). These studies require sophisticated instrumentation and have significant limitations in the evaluation of impotence. The sacral-evoked potential (sacral latency) is essentially an electrophysiologic procedure that measures the bulbocavernosus reflex (184). When this test is performed, the penile skin is stimulated and recordings are made from a needle electrode placed in the bulbocavernosus muscle. The time from stimulation to the first response in the bulbocavernosus muscle (latency) is measured.

Penile erection is normally governed by a reflex arc consisting of pudendal afferent (sensory) fibers and parasympathetic efferent (motor) fibers. The sensory portion of the reflex that governs erection and the sensory portion of the reflex, which is measured by sacral-evoked potential studies, are therefore identical. This portion of the reflex arc also can be evaluated by performing dorsal penile nerve conduction velocity (122). At present, however, the efferent (parasympathetic) portion of the reflex controlling erection cannot be accurately evaluated. The sacral-evoked response measures reflex activity over pudendal sensory nerves and pudendal (somatic) motor nerves. This study provides information concerning some reflex activity through the sacral spinal cord, but it does not directly test penile innervation.

Similar problems are faced by urologists in attempting to ascertain whether the motor fibers to the urinary bladder are intact. A cystometrogram that demonstrates detrusor contractions indicates that the parasympathetic motor fibers to the bladder are intact. When no detrusor activity is elicited, however, one cannot conclude that the bladder is denervated. Cystometry has been used as a study of the parasympathetic motor fibers in impotent patients, but its usefulness is limited. Impotent patients with obvious neurologic disease and voiding symptoms often have abnormal cystometrograms, but this study adds little useful information to the overall evaluation. Cystometry is rarely helpful in patients with no significant neurologic or urologic disease and a normal neurologic examination.

The objective measurement of the status of the CNS as it relates to erectile dysfunction is even more limited. Genitocerebral-evoked responses can be measured. The penis is stimulated as in the sacral-evoked response study and recordings made from electroencephalographic leads on the scalp (134). As with other neurologic studies, an abnormal genitocerebral-evoked response must be interpreted with caution. Although a neurologic abnormality may be demonstrated, it may bear no relationship to the patient's complaint of impotence. Neurologic tests are rarely indicated in the evaluation of the patient with erectile dysfunction. No available neurologic study can determine whether penile innervation is intact, and neurologic testing adds little to information gained from the history and physical examination.

Management

Drug Therapy

Oral Drug Therapy

Yohimbine, an indolic alkaloid obtained from the yohimbine tree, currently is used in the treatment of erectile dysfunction. For many years, this drug has been considered an aphrodisiac. This agent, in combination with testosterone and nux vomica extract, was in widespread use for the treatment of impotence in the 1960s (224,245,328). Morales and colleagues (251) reported that 6 of 23 patients given this drug “reported the reappearance of full and sustained erections and resumption of satisfactory sexual performance.” A subsequent report (250) showed no statistical difference between yohimbine and placebo in treating patients with organic impotence. A well-known side effect of the antidepressant drug trazodone is priapism. For this reason, this antiserotoninergic drug has been advocated for the treatment of erectile dysfunction, particularly psychogenic impotence. Little data on this drug's efficacy exist, but preliminary data suggest that response to trazodone is significantly better than that to placebo (188).

A significant advance in the medical therapy of erectile dysfunction occurred with the U.S. Food and Drug Administration approval of sildenafil (Viagra) in 1998. This selective type-5 phosphodiesterase (PDE) inhibitor is approximately 4,000 times more selective for type-5 PDE than for type-3 PDE and 10 times more selective for type-5 PDE than for type-6 PDE (12). Nitric oxide released from nerves or endothelium causes an increase in cGMP, which results in smooth muscle relaxation. Type-5 PDE causes the breakdown of cGMP in corporal smooth muscle. The inhibition of type-5 PDE results in accumulation of cGMP and promotes cavernosal smooth muscle relaxation (335). *In vivo,* sildenafil increases intracavernosal pressure in response to cavernous nerve stimulation (57). The direct injection of sildenafil into the penis, however, does not produce a rise in intracavernous pressure (8). In addition, administration of sildenafil to animals that have undergone bilateral cavernous nerve transection and have been exposed to erectogenic central stimuli fails to increase intracavernous pressure (8). These data support the concept that an intact neural input is necessary for sildenafil to be effective.

Sildenafil has been reported to improve erections in patients with psychogenic, organic, and mixed factors. Many trials have shown that the success rate of sildenafil use is in the range of 65% to 80% (335). In a meta-analysis of data from 3,361 patients with predominately organic erectile dysfunction, sildenafil improved erections to a degree sufficient for intercourse always or almost always in 48% of patients with severe erectile dysfunction, defined as the inability to ever obtain or maintain an erection (334). Men with destruction of both cavernosal nerves would be unlikely to respond to sildenafil. Following radical prostatectomy, the efficacy of sildenafil appears to be greatest in men who have undergone bilateral nerve-sparing surgery, less with unilateral nerve-sparing surgery, and least with ablation of both

cavernosal nerves (384). Because many patients with erectile dysfunction, regardless of etiology or prior therapy, can potentially respond to sildenafil, this drug can be recommended as first-line therapy in the absence of a contraindication to its use.

An absolute contraindication to the use of sildenafil is the concomitant use of nitrates. The use of these two drugs in combination can lead to a precipitous drop in blood pressure. The use of sildenafil in patients with cardiovascular disease is controversial (62). Side effects with sildenafil use include nasal congestion, dyspepsia, and diarrhea. In addition, approximately 3% of men taking sildenafil experience blurred vision or a visual color tinge. These visual disturbances have been attributed to the fact that sildenafil is only ten times more selective for type-5 than for type-6 PDE, which is present in the retina.

Testosterone Therapy

The alkylated testosterone drugs methyltestosterone and fluoxymesterone have been widely used primarily because they can be given orally. Both agents have the significant disadvantage of poor gastrointestinal absorption and liver toxicity (375). For these reasons, their use has been replaced by the parenteral use of intramuscular esterified testosterone. The National Institutes of Health (NIH) Consensus Development Conference Statement on impotence (257) recommended that "oral androgens, as currently available, are not indicated." Significant side effects can occur with testosterone therapy. Despite the fact that hepatotoxicity has been markedly reduced when esterified rather than alkylated testosterone is used, evaluation of liver function studies before and periodically during therapy is prudent. No evidence exists implicating testosterone therapy as a cause of prostate cancer, but testosterone is contraindicated in the presence of prostate cancer. Patients receiving testosterone should be monitored with digital rectal examination and serum prostate-specific antigen determination. Androgen therapy also has been demonstrated to increase hematocrit and red blood cell volume by stimulating erythropoietin production. Patients with hematocrit values greater than 48% appear to be at risk from cardiovascular complications (187).

Intracorporal Injection Therapy

The use of intracorporal injection of vasoactive agents has been described previously. Initial clinical trials using intracorporal papaverine and combinations of papaverine and phentolamine in the treatment of impotence reported excellent results, particularly in the therapy of impotence secondary to neurologic causes (320,385). PGE_1 has been advocated as being superior to either papaverine or combinations of papaverine and phentolamine. PGE_1, like papaverine and phentolamine, causes relaxation of corporal tissue *in vitro* (140). In addition, enzymes that locally metabolize PGE_1 are present in penile tissue, and therefore the risk of priapism is at least theoretically reduced (294). Large clinical series have been reported, which attest to not only the efficacy but also the low complication rate (including priapism) with the use of this agent (153,331). The use of a drug combination of PGE_1, papaverine, and phentolamine also has been advocated (24).

Significant complications of the use of intracorporal papaverine alone, combinations of papaverine and phentolamine, and PGE_1 have occurred. The development of fibrotic penile lesions has been reported (69), and penile nodules have been reported to occur in up to 57% of patients who administer their own injections for 1 year (198). The acidic pH of papaverine may be related to the development of these fibrotic lesions. In animal studies, long-term use of intracorporal papaverine causes not only fibrosis in the area of the injection sites but also smooth muscle hypertrophy in other areas of the corpora (3). Hepatotoxicity is a known side effect of papaverine, but this has been an uncommon adverse effect of intracorporal papaverine use (198).

The most significant complication of intracorporal injection therapy for impotence is the development of priapism (136). The true incidence is unknown, but the number of patients who experience priapism is undoubtedly related to the patient population being treated and the type and dose of drug or drug combination being used. In large series, priapism has been reported to occur in less than 1% to 4% of patients (198,321).

The mainstay of therapy of drug-induced priapism has been the intracorporal injection of a-adrenergic agonists. Because erection has been induced artificially by drugs that relax corporal smooth muscle, the injection of agents (a-adrenergic agonists) that contract corporal smooth muscle is both theoretically sound and clinically efficacious (210). Several agents have been recommended, including epinephrine, norepinephrine, metaraminol, and phenylephrine (207,359). Phenylephrine appears to be particularly efficacious and results in fewer cardiovascular side effects than the other agents and has become the drug of choice to treat priapism (81). When treating priapism, the recommended dose of phenylephrine is 0.05 mg injected intracavernosally on each side (total dose of 0.1 mg) (359). The use of a-adrenergic agonists has been advocated for initial therapy of priapism of a variety of causes (207). Complications from the treatment of priapism with a-adrenergic agonists have occurred (207,211). Because of the potential for significant cardiovascular morbidity, these agents should be used with care.

Although intracorporal injection therapy is efficacious in a large number of impotent patients, both the patients best suited for this form of therapy and the best drug (and dosage) remain in doubt. For example, patients with neurogenic impotence tend to respond to lower dosages of vasoactive drug than patients with impotence secondary to other causes (321). Only approximately 40% to 50% of patients enrolled in at-home drug injection programs are still administering their own injections after 1 year (198).

Intraurethral Drug Therapy

The intraurethral administration of alprostadil through a novel delivery system designed to administer a pellet of PGE_1 was introduced in 1997. The drug is transferred through the urethral mucosa and corpus spongiosum to the corpora cavernosa. Alprostadil causes activation of adenylate cyclase, which leads to increased levels of cAMP and smooth muscle relaxation. After one pass through the pulmonary vasculature, between 60% and 90% of systemic PGE_1 is inactivated (292). The drug is available in 125-, 250-, 500-, and 1,000-µmg strengths to allow dosage titration. In the initial trials, symptomatic hypotension occurred in 3% of patients, dizziness occurred in 4% of patients, and syncope occurred in 0.4% of patients during in-clinic dosing. For this reason, titration should be carried out under medical supervision. The most common side effect is penile pain, which occurs in 36% of patients. Initial studies indicated that intercourse and erections sufficient for intercourse rates to be approximately 50% to 65% (142,268). Subsequent reports have indicated lower success rates (367).

Vacuum-constriction Devices

Vacuum-constriction devices provide effective and acceptable therapy for erectile dysfunction for some patients. The devices consist of a plastic cylinder, tubing connected to a handheld vacuum pump, and elastic constriction bands (Fig. 42.10). High patient acceptance and low morbidity have been reported (255,377). A survey of 1,517 users of the device revealed that 92% achieved erection with the device, and 77% had intercourse at least every 2 weeks (377). The successful use of this device in difficult clinical settings, such as with patients who have had penile prostheses removed, also has been reported (253).

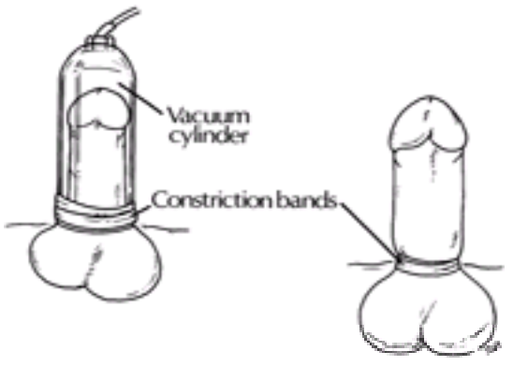

FIGURE 42.10. Vacuum-constriction device.

Penile Revascularization and Venous Ligation Procedures

Penile revascularization to treat vasculogenic impotence was introduced by Michal. The Michal I operation involved the direct anastomosis of the inferior epigastric artery to the corpus cavernosum. The procedure was abandoned because of many failures within the first months, and the initial success rates of 60% to 70% were

modified to 40% when patients were followed for 1 year (316). The Michal II modification involved the anastomosis of the inferior epigastric artery to the dorsal artery of the penis. In their initial series, 13 of 18 patients improved (242). Others have reported similar encouraging results. Of eight patients revascularized by McDougal and Jeffrey (232), four reported normal sexual function, and two reported markedly improved sexual function at least 1 year after the operation. The Michal II operation presumes that blood from the inferior epigastric artery flows into the dorsal artery of the penis and then retrograde to the pudendal artery where it bifurcates into the dorsal and profunda penile arteries. The ideal candidate for this operation is the patient in whom the arterial occlusion is located proximal to the bifurcation of the pudendal artery into the dorsal and deep penile arteries with patent vessels distally. A modification of the Michal II procedure has resulted in the restoration of coitus with improved erection in 80% of patients (129). Direct revascularization of the profunda penile arteries with the inferior epigastric artery also has been reported (216,261). Venous arterialization procedures as described by Virag also have been reported to be successful in a significant number of cases (25). These procedures consist of anastomosing the inferior epigastric artery to the deep dorsal vein of the penis with or without the creation of a fistula between the vein and the cavernous body.

Only a limited number of men with vasculogenic impotence are candidates for revascularization procedures. McDougal and Jeffrey (232) have outlined a careful evaluation to properly select patients. Of 44 patients thought to have organic impotence, 28 were found, by venous occlusion plethysmography, to have a penile blood flow measurement of less than 2 ml^3/100 cm^3 of tissue per minute. These 28 patients underwent pudendal angiography, which demonstrated significant arterial occlusive disease in 13, and 11 of those 13 underwent revascularization. In those patients in whom the penile arteries were demonstrated angiographically, the results of revascularization were successful. Angiographic visualization of the penile arteries indicates patency, and the use of tolazoline hydrochloride or another vasodilator may be necessary to avoid false-negative results. The key to successful penile revascularization appears to be careful patient selection.

After the demonstration that increased venous resistance is important in the physiology of normal erection, many investigators have sought the optimal surgical approach for patients with erectile dysfunction secondary to “venous leakage.” Venous ligation surgery was described in the early 1900s by Wooten (380). More recently, Ebbehøj and Wagner (85) reported successful restoration of potency after closure of a venous leak between the corpora cavernosa and the glans. Wespes and Schulman (369) reported an 80% success rate in patients with venous leakage by ligating the deep dorsal vein and its tributaries. Lue (213) has advocated including ligation of the cavernous and crural veins. The rationale for venous ligation surgery in most patients is questionable. Demonstrated “venous leaks” are almost always the result of inadequate relaxation of the corporal smooth muscle and are not primarily a “venous disease.” As reported success rates have fallen, enthusiasm for venous ligation surgery has waned (293). According to the 1993 NIH Consensus Statement on Impotence, “this has tempered enthusiasm for these procedures, which are probably therefore best done in an investigational setting in medical centers by surgeons experienced in these procedures and their evaluation.”

Penile Prostheses

Semirigid Prostheses

The concept of inserting a rigid rod inside the penis to facilitate coitus was a logical extension of the fact that various mammals (e.g., dogs, bears, raccoons, walruses) have a bone-os penis-in the penis. Loeffler and Sayegh (201) reported the first use of an artificial synthetic implant for the correction of organic impotence. They noted that reconstructive surgeons previously had favored autogenous grafts, but bone usually undergoes absorption when used as a free graft unless placed in contact with living bone. Autogenous cartilage often curled. These two characteristics made the use of autogenous grafts unsuitable in the penis. These investigators constructed a perforated penile implant from acrylic and surgically placed it in the groove between the corpora cavernosa. Absorbable sutures placed through the perforations held it in place until fibrous tissue formation fixed it in position permanently. They later modified these prostheses with silicone for construction (191,192,200,201).

In 1967, Pearman (270) described a silicone prosthesis developed from a mold formed by injecting hot paraffin in the space between Buck's fascia and the tunica albuginea of a cadaver's penis. The resulting prosthesis was a three-fifths circle on cross section and could extend from the corona to the suspensory ligament. Interestingly, one modification of the prosthesis included a metal spring, suggestive of the silicone–silver wire prosthesis introduced by Jonas and Jacobi (158) some years later.

Because of their placement between Buck's fascia and the tunica albuginea, these early implants were prone to instability, displacement, and even extrusion (256). Beheri (22) first suggested placement of prostheses within the corpora cavernosa in 1966. In 700 patients, he implanted paired polyethylene prostheses within the corpora and reported good stability and cosmesis (22). Lash (192) also eventually advocated intracorporal placement, with the prosthesis extending from midglans to pubis. Morales and associates (252) also used intracorporal placement, but the rigidity and narrow contour of the prosthesis caused problems with pain and perforation. Eventually, Small and associates (325) developed paired penile implants with an exterior of medical-grade silicone and a core of silicone sponge (called the *Small-Carrion prothesis*). The prosthesis provided adequate length and, more important, normal width to the penis. Even though firm, it had enough flexibility to keep the phallus inconspicuous while in the normal position or against the abdominal wall. The Small-Carrion prosthesis was introduced in 1975 and was widely used (164,239,240,258,326).

In 1977, Finney (102) introduced a hinged silicone penile implant. He noted that with the Small-Carrion prosthesis, it was not possible to preoperatively determine the appropriate sizing, thus requiring that several sizes be kept available. Also, the implant maintained the penis in an upright, erect state, sometimes requiring constrictive clothing to conceal it. Finney recognized that even though the earlier Lash prosthesis extended only to the pubis and allowed the penis to hang normally, it imparted adequate rigidity to the penile shaft. With these considerations in mind, he developed a prosthesis with a tail that could be trimmed to facilitate intraoperative sizing, a hinge section at the level of the penis to allow dependent positioning, a rigid shaft, and an anatomically correct conical tip to improve positioning under the glans.

Operative Techniques. The intracorporal prostheses introduced by Beheri (22) and Morales and associates (252) were inserted through a dorsal midline penile incision. To minimize trauma and scarring to the phallus, Small and associates (325) advocated a perineal surgical approach (Fig. 42.11). The patient was placed in a semilithotomy position and a Foley urethral catheter inserted to help identify the urethra during the procedure. A midline perineal incision was developed from the base of the scrotum toward the anus. Sharp dissection allowed identification of the bulbocavernosus muscle. The bulbocavernosus muscle and urethra were retracted to one side and the ischiocavernosus muscle and penile crus identified. Once identified, the crus was opened longitudinally with a 2- to 3-cm incision. The intracorporal space was developed with Hegar dilators proximal to the ischial tuberosity and distal to the end of the corpus cavernosum. Dilation was performed initially with a no. 5 Hegar dilator and advanced to a no. 10 or 11. The prosthesis of appropriate size was then inserted. The procedure was repeated on the opposite crus. Small and colleagues (325) noted that the 13.3-cm (medium) or the 14.5-cm (long) prosthesis was usually required, and they attempted to use the widest possible prosthesis. The wounds were closed with 3-0 chromic catgut; no drains were left. The Foley catheter was removed immediately after surgery, and broad-spectrum antibiotics were given postoperatively. For patients who were impotent after pelvic fracture or who had a perineal urethroplasty, Small and associates (325) suggested either making the skin incisions laterally directly over each crus or in the midline at the penoscrotal junction, thus avoiding scarred tissue.

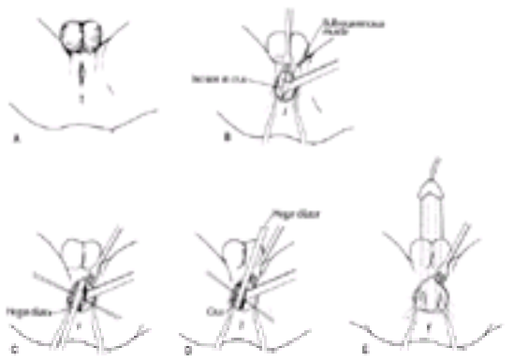

FIGURE 42.11. Perineal approach for placement of semirigid penile prostheses: through a midline perineal incision **(A);** the corpus spongiosum and penile crura are exposed and the crus incised **(B).** The corpus cavernosum is dilated distally **(C)** and proximally **(D).** A prosthesis is placed in each corpus cavernosum **(E).** (Redrawn from Small MD, Carrion HM, Gordon JA. Small-Carrion penile prosthesis: new implant for management of importance. *Urology* 1975;5:479.)

The penoscrotal approach was later popularized by Barry and Seifert (18) (Fig. 42.12). They emphasized that even in patients without trauma or previous surgery, there were inconveniences with the perineal approach, such as perineal fat incision and incision of the ischiocavernosus muscles. Damage to the dorsal neurovascular bundle was a possible complication of the dorsal penile approach.

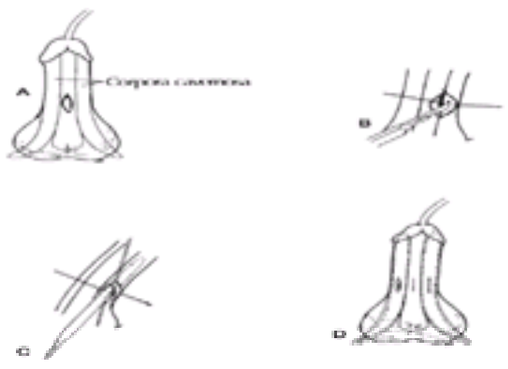

FIGURE 42.12. Penoscrotal approach for the insertion of paired semirigid penile prostheses: through a midline incision the corpus spongiosum (urethra) and corpus cavernosa are exposed **(A);** with traction sutures in the tunica albuginea the corpus cavernosum is incised longitudinally **(B);** the cavernosal space is dilated with the prosthesis or with dilators **(C);** and a prosthesis is placed in each corpus cavernosum **(D).** (Redrawn from Barry JM, Seifert A. Penoscrotal approach for placement of paired penile implants for impotence. *J Urol* 1979;122:325.)

The surgery was performed with the patient in the supine position. A Foley catheter was inserted. A 5-cm midline incision was made over the urethra at the penoscrotal junction. The tissues overlying the urethra were incised to the level of the corpus spongiosum, then dissected laterally to identify the tunica albuginea. The skin, subcutaneous tissue, and Buck's fascia were retracted laterally and stay sutures fixed in the tunica albuginea. A 5-cm longitudinal incision was made between the stay sutures. The corpus cavernosum was dilated with Hegar dilators. The procedure was repeated on the opposite side. The prosthesis was inserted, and the incisions in the tunica albuginea were closed with a running 3-0 polyglycolic acid suture. The subcutaneous tissues and skin were closed with 4-0 chromic catgut. During the procedure, a 1-g/dL neomycin sulfate solution was used as wound irrigant. An aminoglycoside or cephalosporin was used preoperatively, and the Foley catheter was removed 24 hours after the procedure (18).

In their introduction of the silicone–silver wire prosthesis, Jonas and Jacobi (158) described a dorsal subcoronal approach. This approach also has been used satisfactorily by others (29). A semicircular dorsal incision is made in the coronal sulcus. Buck's fascia is incised, and a 1- to 5-cm linear incision is made bilaterally in the tunica albuginea. The corpora cavernosa are then dilated with Hegar dilators, and the appropriate length of the prosthesis is determined with the sizer. The prostheses are then inserted, and placement in the distal corpora may be facilitated by the use of an eyelid retractor. The incisions in the tunica albuginea may be closed with absorbable or nonabsorbable suture. Most surgeons recommend the use of preoperative antibiotics, and some advocate use of a mild-pressure dressing (29,158,183). With all of the semirigid prostheses, an implant is placed in each corpus cavernosum. Gaur (117) has advocated in the placement of only one implant, claiming that results were satisfactory and significant cost savings could be realized.

Complications. Complications associated with the semirigid penile implants are usually related to pain, inappropriate size, or infection. Other serious problems include urethral or skin erosion, urinary retention, or skin necrosis secondary to pressure dressings.

Kaufman and associates (164) reviewed their experience with 1,207 cases, finding that major complications occurred in 7.8%. Before the introduction of antibiotics, the reported incidence of infection was 15%; however, this was reduced to less than 5% with the use of antibiotic protocols (306). Predictably, diabetic patients seem to be at highest risk for developing infection (164,182,306). Before surgery, care must be taken to find any possible source of infection, such as pustules, infected wounds, or infected urine. If such a source is found, surgery must be postponed until the infection has healed adequately. The patient should be shaved at the time of surgery, not the evening before, and should undergo careful preoperative skin preparation with an antiseptic soap. Systemic antibiotics are used routinely. Once an intracorporal infection is established, both prostheses should be removed; the two corpora cavernosa communicate freely, and it is unlikely that an infection will be isolated to one side. Pain lasting longer than 4 weeks is another major problem. It appears that diabetic patients are more likely than nondiabetic patients to have protracted, even incapacitating pain. In fact, diabetic patients may constitute 70% of this group (164).

Other complications are related to inappropriate sizing. If the prosthesis is too short, the patient may have an “SST,” or flexion deformity. This can be corrected by dorsal tacking sutures anchoring the glans penis back over the head of the prosthesis (Fig. 42.13). If the prosthesis is exceedingly short, there may be inadequate rigidity in the distal portion of the penis for intromission or disconcerting mobility of the prosthesis. A more subtle problem with more serious consequences is placement of a prosthesis that is too long. This results in persistent pain, bowing of the penis, and increased risk of eventual erosion.

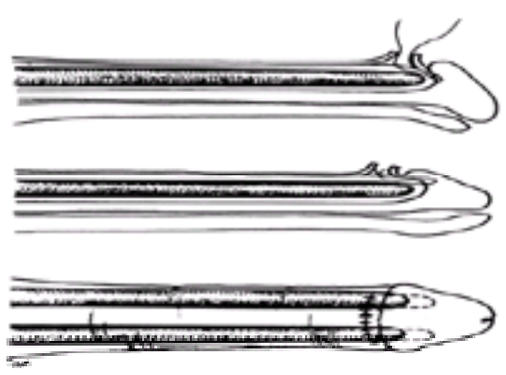

FIGURE 42.13. Correction of “SST” flexion deformity caused by inserting prostheses that are too short. Nonabsorbable horizontal mattress sutures are placed through the tunica albuginea and the substance of the glans. When tied, the sutures pull the glans back over the tips of the prostheses. (Redrawn from Kaufman JJ, Lindner A, Raz S. Complications of penile prosthesis surgery for impotence. *J Urol* 1982;128:1192.)

A tragic complication of implant surgery is penile gangrene. Two cases have been reported in patients who had pressure dressings applied after surgery, and four other cases occurred in diabetic patients, even though no pressure dressings were used (186,229,306).

Inflatable Prostheses

In 1972, Kothari and associates (180) described an implantable fluid transfer system that might be useful in the treatment of impotence. The next year, Scott and associates (312) revolutionized the management of impotence with their report of the implantable inflatable penile prosthesis. Since then, there have been many modifications in the design of the prosthesis and the technique of implantation.

The device consists of two inflatable cylinders: one of which is placed in each corpus cavernosum; a pump that is placed in the scrotum; and a reservoir that is placed extraperitoneally beneath the rectus muscle (Fig. 42.14).

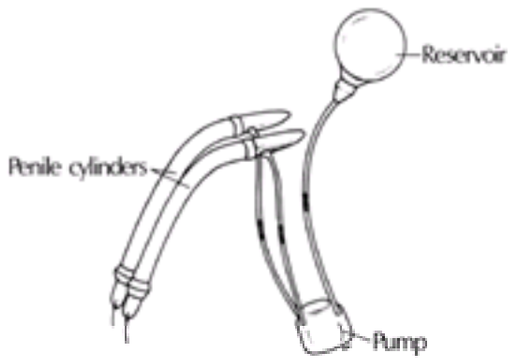

FIGURE 42.14. Scott multicomponent inflatable penile prosthesis. [Redrawn from Reimenschneider HS, Moon SG, Oliver WA, et al. Scrotal implantation of the inflatable penile prosthesis. *J Urol* 1981;126:747 (reference 283).]

Operative Techniques. The components can be implanted through either a dorsal incision extending from the proximal penis over the pubis or through a penoscrotal incision (Fig. 42.15). The patient is placed in the supine position, and a urethral catheter is inserted. A single midline incision is made in the scrotum just below the penoscrotal junction. The urethra and corpora cavernosa are exposed. Traction sutures are placed in each corpora cavernosum, and a longitudinal 1.5- to 2.0-cm incision is made through the tunica albuginea, exposing the cavernosal tissue. The incision is kept more proximal than distal. A space is developed within the corpus cavernosum extending from the distal subglandular extent to the proximal attachment to the ischium. The space is dilated serially with Hegar dilators. The appropriate penile cylinder length is determined with the Furlow inserter (112). A cylinder is then positioned in each corpus with the inserter. The corporal incisions are closed, and care is taken to have the cylinder tubing exit through the incision at the point at which cylinder and tubing are attached. In cases in which the tubing was juxtaposed with the cylinder under the tunica albuginea, erosion and leakage occurred. A subdartos scrotal pouch is bluntly developed, on the right for right-handed individuals and on the left for left-handed patients, for placement of the pump. A finger is then placed in the inguinal canal to retract the spermatic cord laterally and to identify the inguinal ligament and the pubic tubercle. Just above the inguinal ligament and adjacent to the pubic tubercle, the transversalis fascia is punctured with dissecting scissors or a right-angle clamp. The puncture site is widened and a space bluntly developed in the perivesical space medial to the epigastric vessels. The empty reservoir is positioned in this space and then filled. In patients who have had previous inguinal or pelvic surgery, such as cystectomy, it is best to place thereservoir in the preperitoneal space under direct vision, usually through a separate inguinal or abdominal incision.

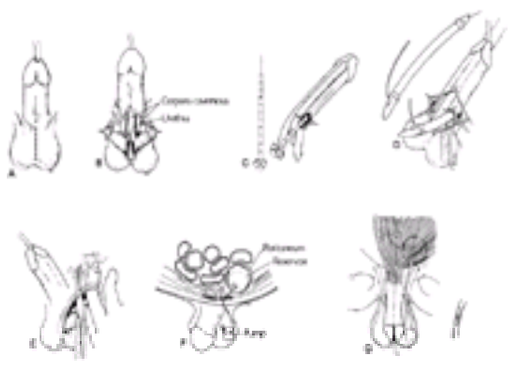

FIGURE 42.15. Placement of the Scott multicomponent inflatable implant. Through a midline scrotal incision **(A)**, the urethra and corpora cavernosa are exposed **(B).** Stay sutures are placed in the tunica albuginea. Through a longitudinal incision, the corporal tissue is dilated, and the corporal length is measured with the Furlow inserter **(C).** The inflatable cylinders are positioned within the corpora cavernosa with the Furlow inserter needle to pass the thread in the tip of the cylinder through the glans penis, providing a means to pull the cylinder into proper position. The corporal incisions are closed so that the cylinder tubing exits directly through the tunica and is not trapped against the cylinder **(D).** Through the inguinal canal, the spermatic cord is retracted laterally and the transversalis fascia is punctured just lateral to the pubic tubercle **(E).** The empty reservoir is pushed through the inguinal canal and through the opening in the transversalis fascia into the perivesical space. The reservoir is filled. The pump is positioned in the scrotum **(F).** The tubing connections are completed and the incisions closed **(G).** (Redrawn from Reimenschneider HW, Moon SG, Oliver WA, et al. Scrotal implantation of the inflatable penile prosthesis. *J Urol* 1981;126:747.)

The pump is situated low in the scrotal pouch so that the deflation valve is lateral, and it is held in place with an externally applied Babcock clamp. Tubing to the contralateral penile cylinder is passed through the scrotal septum to prevent torsion or retraction of the pump. The tubing to all components is then cut to the appropriate length and connected. The intrascrotal tissues just above the pump are closed with absorbable sutures to keep the pump position low in the scrotum. The scrotal incision is then closed with absorbable sutures. The cylinders are left partially inflated.

Antibiotic irrigation is used generously throughout the operative procedure, and systemic preoperative antibiotics are used routinely. The urethral catheter is removed within 1 day. The patients are taught how to operate the pump beginning 3 to 4 weeks after surgery, by which time most pain has disappeared.

Intracorporal Inflatable Prostheses

Intracorporal inflatable prostheses incorporate the advantages of both the semirigid and multicomponent inflatable prostheses. These inflatable implants are completely contained within the corpora cavernosa. These devices function on the principle of transferring a small amount of fluid from a distensible reservoir to a nondistensible chamber. When the fluid is transferred under pressure to the nondistensible chamber, it gives the implant rigidity. Flaccidity is regained by bending the prosthesis to override the pressure threshold of the release valve. The surgical technique for implantation of these devices is the same as that used for placement of the semirigid implants.

Two-piece Inflatable Prostheses

Two-piece inflatable prostheses consist of cylinders and a combination reservoir and pump. The reservoir–pump is placed in the scrotum (Fig. 42.16). These devices can be placed through either an infrapubic or a penoscrotal incision.

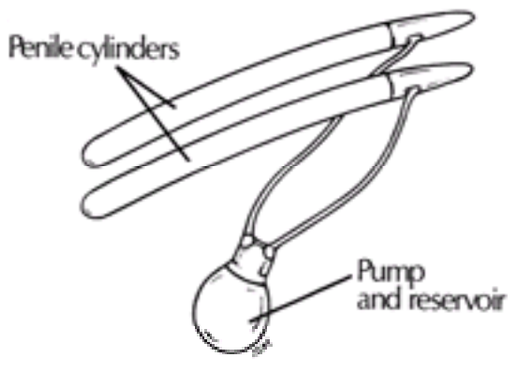

FIGURE 42.16. Two-piece inflatable prosthesis.

Complications. The inflatable penile implant offers a more physiologic result than the semirigid rod prostheses. Surgical revision rates of up to 43% have been reported (99). The mechanical malfunction rate increases as the length of follow-up is extended, but with continued modification of the devices, the mechanical failure rates have significantly lessened. There have been relatively few complications with the pumps and reservoirs. However, cases of reservoir erosion into the large bowel and bladder have been reported (193). Most problems have been related to cylinder leaks, aneurysms, or tubing kinks (99,164,168,222). Since the introduction of rear-tip extenders and careful attention to the exit site of cylinder tubing, the incidence of cylinder leaks has decreased (99,223). The incidence of nonmechanical complications, such as infection, is low, and problems with persistent postoperative pain are uncommon (17,168).

Patient and Partner Satisfaction. The first report on women's reactions to penile implants was published in 1978 by Kramarsky-Binkhorst (181), who interviewed 31 female partners of patients who had previously received a Small-Carrion semirigid penile implant. Less than half (42%) of the women reported that the couple was totally satisfied with the results of the operation; however, a most important observation was made. There seemed to be a direct relationship between perceived success and the level of preoperative consultation and education by the surgeon. In addition, Kramarsky-Binkhorst (181) recognized that the couple's interpersonal relationship was a critical factor in the outcome.

Priapism

Priapism has been clinically defined as a prolonged, painful, penile erection. The disease process is named for Priapus, a Greek god and symbol of good agriculture and hunting who is portrayed as having an enormous phallus. Historically, priapism has been considered to be a low-flow state. A prolonged, painful erection occurs because venous outflow is compromised. Dark blood (with an acidic pH and low Po_2) is typically found on corporal aspiration and therapy has consisted primarily of surgical shunting procedures designed to improve penile venous drainage. Although high-flow priapism was described more than 40 years ago (51), this second type of priapism has only recently been widely recognized. High-flow priapism is clinically recognizable because the erection is painless and corporal aspiration yields bright red blood. Priapism may be a spectrum disease (204), and the separation of priapism into purely low-flow and high-flow states may be artificial.

Etiology

Low-flow Priapism

Hematologic Causes. One or more priapistic episodes have been reported in 38% to 42% of patients with *sickle cell disease* (87,108). Theories to explain the pathophysiology of priapism in these patients include the relatively acidic state of the corpora during erection, mild acidosis accompanying hypoventilation during sleep, and abnormal endothelial adherence. Paradoxically, four cases of patients with sickle cell disease have been reported with high-flow rather than low-flow priapism (280,333).

The incidence of priapism in *leukemic* patients is less than 1%. Chronic granulocytic leukemia is responsible for 50% of leukemic priapisms (309,336). The cause of priapism in these patients is thought to be hyperviscosity and sludging secondary to high white blood cell counts.

Several reports have convincingly linked *total parenteral nutrition* (TPN) and priapism (89,173). This syndrome has been associated with infusions of 20%, but not 10%, fat emulsions.

Oral Medications. A variety of oral medications, particularly antidepressants and antipsychotic drugs, have been associated with priapism. The highest incidence of priapism is seen with the nontricyclic antidepressant trazodone. Phenothiazines, particularly chlorpromazine, have also been linked to priapism. Priapism has also been associated with several antihypertensive agents, including guanethidine, hydralazine, and prazosin (35). Heparin has also been implicated (174).

Intracavernosal Injection Therapy. Currently, the most common cause of priapism is probably the intracavernosal injection of vasoactive drugs. The incidence of priapism is less with the use of PGE_1 than with papaverine or combinations of papaverine and phentolamine, but priapism has been reported to occur after the injection of only 5 µmg of PGE_1 (308).

Malignant Penile Infiltration. Metastases to the penis may cause priapism. The most common primary tumors responsible for priapism are bladder (30%), prostate (30%), colon (16%), and kidney (11%) (276). The life expectancy of patients with priapism secondary to malignant disease is short.

Neurogenic Causes. Priapism may be seen immediately after high spinal cord injury. Priapism secondary to spinal cord injury usually resolves spontaneously and does not require therapy. Cerebrovascular accidents and other neurologic diseases have been mentioned as causes of priapism, but such cases are rare.

Idiopathic Priapism. Depending on the patient population, no cause of priapism can be identified in 30% to 50% of cases (274).

High-flow Priapism. The primary event leading to high-flow priapism is not venous occlusion, but rather high sustained arterial flow (378). The venoocclusive mechanism associated with normal erection is not activated, and the penis remains erect because of unregulated high arterial inflow. Because of high inflow and outflow, hypoxia and acidosis do not develop. The etiology of almost all cases of high-flow priapism is penile or perineal trauma. Injury to the cavernosal artery results in a cavernous artery to corporal tissue fistula (286). Arterial inflow bypasses the helicine arteries and is unregulated. Because the venoocclusive mechanism is not activated, high inflow and high outflow coexist. The number of reported cases of high-flow priapism is limited. In 1994, Bastuba and co-workers (20) added seven case reports to the twelve prior reports of arteriographically confirmed high-flow priapism. Although most reported cases are secondary to external penile or perineal trauma, laceration of the cavernosal artery during the intracorporal injection of vasoactive drugs is a recognized cause of high-flow priapism (20). Cases of high-flow priapism not associated with trauma have occurred. Three patients with sickle cell disease and no history of trauma who presented with high-flow priapism have been reported (280,333).

Evaluation. A history and physical examination should be performed. Historical findings consistent with a diagnosis of low-flow and high-flow priapism should be sought. Current medications, a history of sickle cell disease, and a history of penile or perineal are particularly important. With high-flow priapism secondary to trauma, there is often a delay from the time of injury to onset of priapism (20). Unlike patients with low-flow priapism, patients with high-flow priapism do not have significant penile pain. Physical examination should include a search for evidence of trauma. In patients with low-flow priapism, the corpora cavernosa are rigid while the glans penis remains soft. The penis in cases of high-flow priapism has been described as being 60% to 100% rigid (44). The patient should be examined for lymphadenopathy and abdominal masses. Initial laboratory studies should include a complete blood count and sickle preparation to rule out leukemia and sickle cell disease as possible etiologies.

Because therapy and the timing of therapy are dictated by whether the priapism is low flow or high flow, aspiration of the corpora should be performed after the initial evaluation. The finding of dark blood indicates low-flow priapism, whereas the finding of bright red blood indicates high-flow priapism. It has suggested that blood gas values of pH less than 7.25, Po_2 less than 30 mm Hg, and Pco_2 greater than 60 mm Hg define ischemic priapism (45). Color duplex scanning has also been advocated (44). This noninvasive study can determine the presence of high-flow priapism and provide information concerning the location of any injury. Angiography is not essential to make the diagnosis of high-flow priapism (20). In most cases, angiography is performed in conjunction with embolization to treat cases of high-flow priapism.

Therapy. The differentiation of low-flow from high-flow priapism is important because the treatment of the two conditions is markedly different. In low-flow priapism, therapy is directed at improving venous drainage, whereas in high-flow priapism, the goal is to decrease arterial inflow. Because histologic changes in the penis occur early in low-flow priapism (330), early therapy is indicated. The therapy of high-flow priapism is not an emergency; potency is usually restored after therapeutic intervention, even when the priapism has been present for weeks or months (20).

The therapy of three etiologies of priapism requires special mention. Patients with priapism secondary to metastatic infiltration should generally be managed expectantly. Patients with priapism secondary to leukemia should be treated with chemotherapy and/or penile radiotherapy. Priapism in patients with sickle cell disease is treated initially with hydration, alkalinization, analgesia, and hypertransfusion to increase the hemoglobin to greater than 10 mg/dL and reduce hemoglobin S to less than 30%. If these measures fail, corporal aspiration and instillation of an a-adrenergic agonist can be performed (108,137). Shunt procedures are performed

as a last resort in priapism secondary to sickle cell disease.

A diagnosis of low-flow priapism is made when corporal aspiration reveals dark blood. The corpora are then irrigated with saline and an a-adrenergic agonist instilled. The drug of choice is phenylephrine (359). From 100 to 200 µmg is injected (half into each corpora). This dose can be repeated several times with careful patient monitoring and particular caution exercised in patients with preexisting cardiovascular disease. If aspiration, irrigation, and intracorporal a-adrenergic agonist does not result in detumescence, a surgical shunt procedure should be performed. These shunts can be classified as (a) cavernoglanular, (b) cavernospongiosal, (c) cavernosaphenous vein, and (d) cavernopenile dorsal vein. Cavernoglanular shunts are the easiest and fastest to perform. The Winter shunt is performed by excising cores of tunica albuginea between the distal corpora and the glans penis using a Tru-Cut biopsy needle (376). If persistent detumescence is not achieved, an open surgical shunt is indicated. The Ebbehøj and Al-Ghorab procedures are also cavernoglans shunts. The Ebbehøj procedure consists of a stab wound incision with rotation of the knife blade to create a communication between the corpora cavernosa and the glans. In performing the Al-Ghorab operation, a 2-cm transverse incision is made in the glans penis 1 cm distal to the coronal sulcus (Fig. 42.17) (94). The ends of the corpora cavernosa are identified. and circular incisions are made and a portion of tunica albuginea removed from each corporum. The incision in the glans is then closed with running absorbable suture. Patients who do not achieve detumescence with a corporoglanular shunt require creation of another type of shunt. Grayhack described the use of the saphenous vein to shunt blood from the corpora (Fig. 42.18) (131). The saphenous vein is identified, transected distally, tunneled under the skin, and anastomosed end-to-side to a window created in the tunica albuginea. This procedure, as well as the cavernopenile dorsal vein shunt (19), is technically demanding, and the risk of pulmonary embolus exists. The Quackels cavernospongiosum shunt is performed through a perineal incision (Fig. 42.19) (278,360). The corpus spongiosum and corpus caverosum are exposed and incised. The shunt is created by suturing the two corpora together, first the inner edge and then the outer edge. This shunt can be performed either unilaterally or bilaterally. This shunt should be performed as far proximally as possible to lessen the chance of urethral injury. Despite early surgical intervention for low-flow priapism, postoperative erectile dysfunction is approximately 50% (33).

Evaluation and treatment of priapism. *J Urol* 1981;125:204.)

In high-flow priapism, the fact that the penis is well perfused argues against immediate intervention. In addition, spontaneous resolution has been reported to occur (44). Pharmacologic therapy has been attempted. a-Adrenergic agonists have been used in high-flow priapism in an attempt to decrease arterial flow. Typically, the penis becomes less rigid initially after the injection but then quickly resumes its priapistic state. Both cavernosal artery ligation and embolization have been used in the treatment of high-flow priapism. Ricciardi and co-workers (286) reported two cases of high-flow priapism secondary to trauma; one resolved spontaneously and the other was treated by surgical ligation of the involved cavernosal artery. Two of the four patients treated by Brock and associates (44) underwent an open surgical procedure. Most patients with high-flow priapism have been treated with arterial embolization. This therapy was initially described by Wear (362). The high-flow priapism in all seven cases reported by Bastuba and co-workers responded to this therapy. In two of the three cases reported by Brock, however, angiographic embolization was not successful and open surgical ligation was performed. The use of autologous clot for embolization has been advocated because it permits rapid restoration of blood flow after clot lysis, minimizes complications, and potentially allows for recovery of normal sexual function (356). Absorbable gelatin sponge also produces transient interruption of arterial flow through the lacerated vessels. Because of the small number of reported patients, the possibility of permanent erectile dysfunction should be explained to the patient prior to therapy.

Peyronie's Disease

Peyronie's disease is a sexually crippling condition of the penis that may result in penile pain, penile curvature prohibiting intromission, and impotence. The mean age of afflicted patients is 53 years, and the clinical course of the disease is variable. The penile curvature is caused by plaque formation secondary to fibrosis of the loose areolar tissue between the tunica albuginea and the corpus cavernosum (327). Light microscopic studies suggest that the plaque originates as a lymphocytic and plasmacytic infiltrate developing in the perivascular spaces of the areolar tissue. Electron microscopic studies corroborate these findings and support the suggestion that there is a process originating as a vasculitis in the tunica albuginea (348). Demyelination of nerve axons has been noted in specimens of plaque,

suggesting the potential of neuropathology even before surgery (348). Bacteria have been identified in vascular areas of the tunica albuginea, the vicinity of the urethra, and the periurethral glands, but this is an uncommon finding (36,327), and infection is not considered a primary cause of Peyronie's disease. The vasculitis and inflammatory infiltrates lead to gradual fibrosis that with longer duration eventually compresses the erectile tissue of the corpora cavernosa as the plaque develops. These findings have been confirmed by others who found that in patients with symptoms of less than 6 months' duration, the primary pathologic finding was vascular changes with perivascular infiltration by lymphocytes. In patients with long-term symptoms, biopsy specimens showed no acute vascular changes, but the tissue was rich in fibroblasts (53). Other findings include calcium deposits, bone, cartilage, and even bone marrow formation (327,347). In summary, Peyronie's disease begins as an inflammatory process and progresses to a fibrotic stage, eventually forming a plaque that may mature to bone or cartilage. The plaque is most often located on the dorsum of the penis and may involve the septum between the corpora cavernosa (340). Chesney (63) found multiple plaques in 22% of 250 patients. The plaques most commonly are 1 to 2 cm in width and 2 to 4 cm in length, and penile curvature occurs in 80% to 100% of cases (247).

Even though Peyronie's disease was first described in 1743, its cause is still unknown (75). Numerous factors have been implicated but none proved. Suspected causative factors have included arteriosclerosis, diabetes mellitus, trauma, phlebitis, medications, infections, heredity, or an immune reaction (71,264,267,347,373,382). Bivens and associates (37) reported that 2 of 6 patients with carcinoid syndrome had Peyronie's disease and suggested that elevated levels of serotonin were responsible for the fibrosis found in the retroperitoneum, endocardium, and penises of these men.

Approximately 10% of patients with Peyronie's disease have other types of fibromatoses, such as Dupuytren's contracture, plantar fibromatosis, and fibrosis of the auricular cartilage (36,63), suggesting that an immunologic factor may be involved. Vande Berg and colleagues (347) used scanning and transmission electron microscopy and demonstrated osteoblast-like cells and osteoid formation originating from vascular lumina in areas adjacent to calcified Peyronie's plaques. They suggested that this may result from an autoimmune stimulus associated with some form of vascular trauma. The association between Peyronie's disease and the histocompatibility antigens of the B7 cross-reacting group suggests that Peyronie's disease may be a pathologic response to an infective agent similar to the B7 antigen. The histocompatibility antigen HLA-B27 has been linked to a variety of fibrosing disorders, particularly ankylosing spondylitis. HLA-B27 also may be related to idiopathic retroperitoneal fibrosis and to the fibrotic changes associated with rotator cuff syndrome (47,374). Noting these relationships, Willscher and colleagues (373) tissue-typed eight patients with idiopathic Peyronie's disease; seven were found to possess an antigen of the B7 cross-reacting group. Citing the suspected immunologic cross-tolerance between HLA-B27 antigen and bacteria of *Klebsiella–Enterobacter* species in patients with ankylosing spondylitis, they suggest that Peyronie's disease may be a characteristic response to a yet unidentified agent that is similar to the B7 cross-reacting group antigens. Nyberg and associates (264) subsequently identified three families with an inherited form of Peyronie's disease associated with Dupuytren's contracture and the presence of HLA-B27 cross-reacting antigens. Leffell and associates (195) could not substantiate these findings. They phenotyped 28 men with Peyronie's disease for their HLA-A, HLA-B, and HLA-C locus determinants. There was no significant association of any individual B7 cross-reactive antigen or of the B7 antigens considered as a group.

The only reports documenting a specific antecedent agent noted that cessation of b-adrenergic blocking agents (propranolol and metoprolol) resolved the symptoms of Peyronie's disease in several patients (267,382). There is also much uncertainty as to the natural history of Peyronie's disease. The mean age of afflicted patients is 53 years, and the clinical course of the disease is variable. It is self-limited in up to 50% of cases (111) and may resolve spontaneously in 12 to 18 months (56). A retrospective study indicates that the spontaneous resolution rate may not be as high as that previously reported. In a retrospective review of 97 patients followed for 3 months to 8 years, 13% of the patients believed the disease to be one of gradual resolution, 47% believed there had been little or no change, and 40% believed that the disease pattern was one of gradual progression (120).

In 1949, Scardino and Scott (305) suggested vitamin E for the treatment of Peyronie's disease, noting that vitamin E deficiency interfered with the normal repair of connective tissue, resulting in contracture of scar tissue. Even though it has been widely used, the beneficial effects of vitamin E in the management of Peyronie's disease have not been proved. Potassium *para*-aminobenzoate has been a mainstay of therapy for many years, but it is difficult to ascertain any beneficial effect of this agent, and problems with hypoglycemia, nausea, and vomiting have occurred (247,383). In addition, patients find it inconvenient to take 24 tablets daily. Radiation therapy has been reported to be effective in providing pain relief (49,111,143,203,247). With orthovoltage, external radiation therapy complications are essentially nonexistent (111,247). Carson and Coughlin (56) administered doses between 600 and 1,600 rad over a 10- to 90-day period. The average radiation dose was 900 rad. Relief of pain was seen in 78.5%, improvement in the plaque was noted in 13.3%, and penile curvature improved in 6.2%. The average interval to improvement was 5.8 months.

Various other treatments have been used: ultrasound (147), steroid injection (77), topical b-aminopropionitrile (118), and collagenase injections (119). The plethora of treatments tried in this disease suggests that there is not one that is standard, widely accepted, or predictably efficacious. Also, the natural history is variable; some patients may improve with no therapy, and most authors believe that the results with nonsurgical treatment differ little from those with no treatment (46).

The role of surgery in the management of Peyronie's disease is determined by the severity of curvature or the degree of the patient's disability. A waiting period of from 18 to 24 months after the onset of symptoms until the disease has stabilized is advised (30). The reason why some patients with Peyronie's disease experience erectile dysfunction and others do not is unclear. Venoocclusive dysfunction occurring in the area of the plaque has been suggested (116). In the report of 106 patients by Bystrom and colleagues (53), only 18 were actually impotent but 55 found intromission difficult or impossible because of penile curvature. Early attempts at surgical correction focused on incision of the fibrous plaque (152), but this often resulted in an unstable erection. Subsequent efforts were directed to grafting of the surgical defect with various materials, such as fat, saphenous vein, dermis, or patches of synthetic graft (238).

In 1974, Devine and Horton (79) introduced the use of the dermal graft. After complete excision of the Peyronie's plaque, a dermal patch of exact size was removed from the abdominal wall and sutured into the penile defect with the fat on the inside. They reported good results, and their subsequent experience was also favorable (371). However, Melman and Holland (238) were less enthusiastic. All seven of their patients were completely impotent 1 year or longer after surgery. The cosmetic results of the dermal graft inlay technique were excellent, but they recommended placement of a penile prosthesis to restore a straight phallus and sexual function. Gangai and associates (115) reported that only 30% of their patients were sexually functional after plaque excision and grafting. They also recommended excision of the plaque and stenting with a penile implant. Raz and colleagues (281) advocated simple incision of the fibrotic plaques and placement of a stenting penile prosthesis. No attempt was made to graft the defect in the tunica albuginea. In their series of 12 patients, satisfactory function and cosmetic results were obtained. Use of the inflatable prosthesis also has provided good results (114,221,338).

In patients with Peyronie's disease and impotence, most authors advocate a penile-straightening procedure and placement of a penile prosthesis. There is still disagreement, however, as to the procedure of choice in patients with Peyronie's disease and adequate erectile function. If only a straightening procedure is performed, the patient must be made aware of the fact that he may develop impotence postoperatively. If the patient is willing to undergo further surgery for the placement of a prosthesis should he become impotent, the performance of only a penile straightening procedure is reasonable. The Nesbit procedure, which consists of excising a wedge of tunica albuginea on the side opposite to the plaque, provides a simple surgical correction in these men that obviates the need for a stenting implant and does not affect erectile function (71,130). This procedure, however, often results in penile shortening. The relationship between Peyronie's disease and impotence is not clear, so the primary treatment with penile prostheses is controversial. Several other surgical procedures have yielded excellent results in small series. Laser destruction of the plaque and placement of a deep dorsal vein patch graft resulted in retained potency in 8 of 8 patients (107). Incision of the plaque and placement of a polypropylene patch graft was successful in maintaining potency in 9 of 9 patients (96).

The views expressed are those of the author and not of the U.S. Food and Drug Administration.

Chapter References

In addition to infectious, inflammatory, and vascular lesions of the penis, a wide spectrum of benign, premalignant, and malignant neoplasms of the penis has been described. Although the majority of such lesions originate from the epithelium of the penis, other tumors also occur. A useful classification of penile neoplasms has been proposed and is modified in Table 43.1.

Primary Tumors	Nonepithelial
Epithelial	Lymphoma
Benign	Sarcoma
Condylomata acuminata	Mesenchymal
Molluscum contagiosum	Benign
Papilloma	Malignant
Hemangioma	Angiosarcoma
Nevi	Kaposi's sarcoma
Sebaceous cyst	Rhabdomyosarcoma
Premalignant	Leiomyosarcoma
Balantitis xerotica obliterans	Malignant schwannoma
Leukoplakia	Fibrosarcoma
Malignant	Histocytoma
Epithelial	Lymphohematogenous
Carcinoma *in situ*penile intraepithelial neoplasia	Lymphoma
Erythroplasia of Queyrat	**Metastatic Tumors**
Bowen's disease	Solid
Bowenoid papulosis	Prostatic carcoma
Verruciform tumors	Transitional cell cancer
Squamous cell carcinoma	Recosigmoid cancer
Basal cell carcinoma	Renal cancer
Melanoma	Testis cancer
	Lung cancer
	Lymphohematogenous
	Lymphoma
	Leukemia

TABLE 43.1. CLASSIFICATION OF PENILE NEOPLASMS

BENIGN PENILE TUMORS

Condylomata Acuminata

Condylomata acuminata, or venereal warts, are most commonly located on the corona of the glans, on the frenulum, and on the inner foreskin, but perianal, perineal, scrotal, and intertriginous involvement is not unusual (21,135). The penile shaft may also be involved. Grossly, condylomata appear as friable, papillary, multifocal, and multicentric cauliflower-like lesions; occasionally, they reach a large size or extensive distribution (152). The microscopic appearance is that of an undulating outer layer of keratinized tissue covering papillary fronds that are supported by connective tissue stroma. Other features (Fig. 43.1) include orderly rows of squamous cells in the epithelial pegs and the presence of a dermal lymphocytic infiltrate.

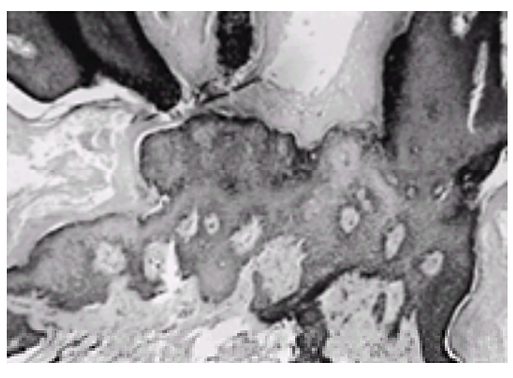

FIGURE 43.1. Condylomata acuminata. Note the papillary hyperplasia with multiple vacuolated superficial squamous epithelial cells. Focal parakeratosis is also present. (Hematoxylin-eosin, ×240.)

Condylomata acuminata are caused by infection with human papillomavirus (HPV), a double-stranded DNA virus containing approximately 8,000 base pairs. The use of DNA hybridization with specific HPV probes has identified more than 65 types of HPV that differ by more than 50% in the viral genome (266). In condyloma acuminata, HPV-6 and HPV-11 are most commonly detected and have been called *benign HPV types* (266). In malignant and premalignant lesions of the cervix and penis, however, HPV-16 and HPV-18, so-called oncogenic HPVs, are most commonly detected (253,266,291). Although there have been reports of penile cancers containing HPV-6 and HPV-11, these may coexist with the oncogenic viruses and the finding of different HPV types in condylomata and penile cancer suggests that condylomata acuminata are not premalignant lesions.

Sexual transmission of condylomata acuminata is widespread, with an estimated increase in incidence of 459% from 1973 to 1988. Rosenberg and associates (245) examined 199 male partners of women with HPV-associated disease of the lower genital tract and found evidence of HPV infection in 77%. O'Brien and associates (200) reported the results of DNA analysis of the lesions of 26 men with genital condylomata and found that 13 had infection with HPV-6, 2 with HPV-11, 2 with HPV-31, and 9 with infection that could not be identified with the hybridization procedure. The sexual partners of men with genital condylomata should be examined for the presence of both condyloma and cervical neoplasia. Detection of subclinical lesions is facilitated with 5-power optical magnification before and after application of 3% acetic acid. When dilute (3%) acetic acid is applied to the genital area with soaked gauze and left on for 5 to 15 minutes, the appearance of whitened patches is suggestive of HPV infection. However, biopsy is necessary to confirm the histologic diagnosis of condyloma.

Podophyllin/podophyllotoxin is widely used to treat smaller condylomata, but because podophyllin application may cause bizarre histologic changes that may be confused with cancer, a thorough biopsy should be performed on suspicious lesions before podophyllin therapy. Podophyllin is applied weekly for at least 6 weeks and washed off 3 to 4 hours after each application. Larger condylomata may require either excision, fulguration, electrodesiccation, cryotherapy, or laser vaporization, although the propensity for recurrence indicates that adjunctive, in addition to ablative, therapy is often necessary (21). The possibility of urethral involvement should also be considered based on history and careful inspection and palpation; if the urethra is involved, it can be managed by neodymium:yttrium-aluminum-garnet (Nd:YAG) laser and adjunctive intraurethral fluorouracil cream (38,97) or bacille Calmette-Guérin (BCG) (21).

Molluscum Contagiosum

Molluscum contagiosum is a venereally transmitted lesion that is increasing in incidence (204). Molluscum contagiosum has also been seen with increasing frequency in patients with AIDS, although cutaneous cryptococcal infections in this patient population may mimic molluscum contagiosum (129,181).

Molluscum contagiosum is caused by a virus of the paravaccinia group. After an incubation period of 8 weeks or longer, lesions develop that are initially smooth and papular and occurrence in epidermal cysts has been reported. If the lesions persist, they become pitted, slightly transparent, globular, and protuberant. With pressure, bleeding and the discharge of a firm granular mass, the “molluscum bodies,” may result (134). Histologic examination of these lesions reveals a mass containing large inclusion bodies showing eosinophilic degeneration of epithelial cells (Fig. 43.2). This condition may be self-limited and may not require specific therapy, although topical trichloracetic acid, liquid nitrogen, or cantharidin has been used (134).

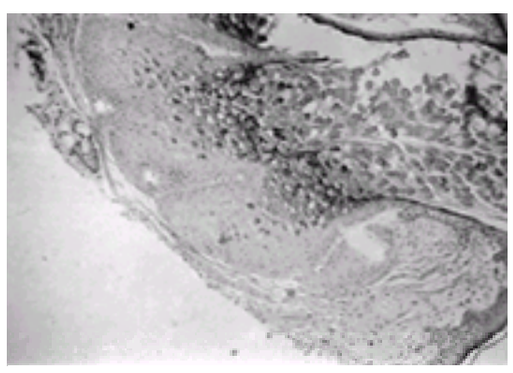

FIGURE 43.2. Molluscum contagiosum. This shows the typical inverted cuplike lesion of molluscum contagiosum. Also present are the classic intranuclei viral inclusion bodies (“molluscum bodies”) in the superficial and keratotic layers. (Hematoxylin-eosin, ×240.)

Hirsutoid Papilloma

Hirsutoid papillomas of the penis, also called *pearly penile papules,* have a reported incidence of 8% to 30% and occur in a circumferential distribution on the corona and sulcus of the glans (175). The lesions consist of one or more rows of whitish-yellow papules from 1 to 2 mm in diameter; the papules occur without symptoms or pathologic significance. Histologically, these papules represent epithelial thickenings consisting of a core of connective tissue covered by an acanthotic epidermis over a vascular network and are considered to be acral angiofibromas (155,222). The characteristic distribution and appearance of these lesions simplifies diagnosis, and the absence of HPV in these lesions has been confirmed by polymerase chain reaction (68). Treatment, although not essential, is often requested by the patient, and in such cases, CO_2 laser in continuous-wave (CW) mode or cryotherapy is effective (175,222).

Other Benign Lesions

Other benign lesions of the penis include angiomas, nevi, and sebaceous cysts. Hemangiomas appear as well-defined red papules that are commonly found on the glans. Generally, these lesions are self-limited and have a tendency toward spontaneous regression. Larger lesions or those that bleed may require excision, ligation, or sclerotherapy.

A variety of benign pigmented tumors may involve the penis, and their major importance is in distinguishing these tumors from malignant melanoma. Nevus cell nevi, or pigmented nevi, are the most common of these lesions and may be differentiated histologically on the basis of their location within the skin: (a) junctional nevi, which are seen only in childhood; (b) compound nevi, which are rare after puberty; and (c) intradermal nevus cell nevi, which are usually seen only in adults (135). A particularly conspicuous representative of the last-named type is the papillary and hairy nevus, also called the *bathing suit nevus* when advanced (134).

Sebaceous or inclusion cysts may occur wherever sebaceous glands are present and are commonly seen in the scrotum. There are no sebaceous glands on the glans penis, but ectopic sebaceous glands are found on the inner surface of the foreskin and on the shaft of the penis. These heterotopic glands look like small aggregates of white-yellowish grains that are either somewhat raised or are level with the surface of the skin.

PREMALIGNANT LESIONS OF THE PENIS

Premalignant lesions of the penis include balanitis xerotica obliterans and leukoplakia (169,219,228).

Balanitis Xerotica Obliterans

Balanitis xerotica obliterans (BXO), by definition, is lichen sclerosus et atrophicus limited to the glans and prepuce (36,61,299). The etiology of BXO is unclear, although autoimmune factors, chronic balanoposthitis, HPV-16 infection, hormonal, and because an association with HLA-29 and HLA-B44 has been shown, genetic factors have been proposed as causally related to BXO (229). The lesion usually, but not exclusively, occurs in uncircumcised patients and originates on the glans or prepuce as small erythematous areas that ultimately coalesce to form whitish plaques (197). The prepuce becomes thickened by a sclerosing and atropic process of the glans and foreskin with the development of glanular fissures and erosions leading to phimosis and/or meatal stenosis (263). Histologically, the lesion is characterized by hyperkeratosis, flattening of the dermal-epidermal interface, fibrosis of the upper dermis, and a lymphocytic infiltrate in the middermis (Fig. 43.3). Approximately 6% of patients with BXO will progress to squamous carcinoma *in situ* or frank invasive penile cancer (195,228); thus close follow-up and biopsy when

indicated is essential.

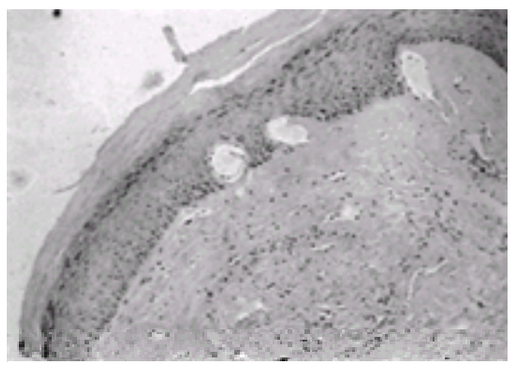

FIGURE 43.3. Balanitis xerotica obliterans. Marked hyperkeratosis and slight thinning of the epithelium, with sclerosis of the upper dermis and vascular dilation. (Hematoxylin-eosin, ×240.)

Therapeutic options in the treatment of BXO include high-potency topical corticosteroids (e.g., clobetasol 0.05%), 2% to 3% testosterone propionate ointment, antibiotics, and if unsuccessful, excision of the lesion or circumcision if the prepuce in involved (179,197). If meatal stenosis occurs, meatotomy or meatoplasty is indicated; if urethral stricture secondary to BXO develops, excision and staged free-graft urethroplasty using nongenital skin is recommended (293).

Leukoplakia

Leukoplakia of the glans penis is a rare lesion associated with either chronic irritation, inflammation, or diabetes (184). Clinically, the condition appears as one or more white plaques or scaly patches that tend to involve the meatus. The differential diagnosis includes BXO, lichen planus, and candidiasis (184). Histologically, the findings of leukoplakia include hyperkeratosis, parakeratosis, irregular acanthosis or atrophy of the malpighian layer, and disorderly arrangement of keratinocytes. Cellular atypia may or may not be marked.

The association of leukoplakia and squamous cell cancer is poorly understood, but leukoplakia is often found adjacent to or contiguous with squamous cell carcinoma. Initial management of suspected leukoplakia should include a thorough biopsy, particularly of any ulcerated areas, to rule out coexisting epidermoid cancer. Initially, less severe cases of leukoplakia may be managed by removing the source of irritation or inflammation (e.g., by circumcision). Persistent or progressive lesions require excision, with periodic follow-up, because recurrences have been reported after resection (184).

MALIGNANT LESIONS OF THE PENIS

Carcinoma *In Situ* of the Penis and Penile Intraepithelial Neoplasia

The term *carcinoma in situ* (CIS) *of the penis* is a descriptive histologic diagnosis encompassing the clinical entities of erythroplasia of Queyrat (Bowen's disease of the glans), Bowen's disease of the penile shaft, and bowenoid papulosis (81,89,179). In addition, because of the use of terminology in the literature, the term *penile intraepithelial neoplasia* (PIN) grade III has also been used for CIS (57,303,312). PIN is usually found on biopsy of suspicious penile lesions and has been classified into three grades (I to III) with the term *PIN* being restricted to grades I and II and the term *CIS* being reserved for grade III (37,312). Clarification of this ambiguity in terminology is provided by the recognition of oncogenic HPV-16 in 92% of patients with PIN III but in only 14% of patients with PIN I or II, while the nononcogenic HPV-6 or HPV-11 was found in 46% of PIN I and II but 0% of PIN III (57). Recent data support use of combinations of 5-flurouracil (5-FU) cream, interferon-a-2a, and CO_2 laser vaporization for PIN I and II and 5-FU plus CO_2 laser vaporization in PIN III (37).

Erythroplasia of Queyrat

Erythroplasia of Queyrat (EQ) is squamous cell CIS of the penile mucosa affecting the glans, inner surface of the prepuce, and/or the coronal sulcus of the penis. It is seen typically in elderly uncircumcised patients and presents with equal frequency as either solitary or multiple demarcated, nontender, shiny, bright red velvety plaques (86,230). HPV has been detected in EQ, and it has been suggested that coinfection of HPV-8 with oncogenic HPV (e.g., types 16, 39, or 51) lead to EQ (303). Progression of EQ to invasive squamous cell cancer of the penis occurs in 10% to 33% of cases, and if invasion occurs, regional node metastases are found in 20% (179). The differential diagnosis of EQ includes psoriasis, tinea, syphilis, BXO, circinate balanitis, candidiasis, and drug eruption. EQ demonstrates the same histologic changes as Bowen's disease, including acanthosis, loss of epidermal cell polarity, replacement of mature keratinocytes with basaloid cells showing nuclear atypia, and an infiltrate rich in plasma cells (Fig. 43.4).

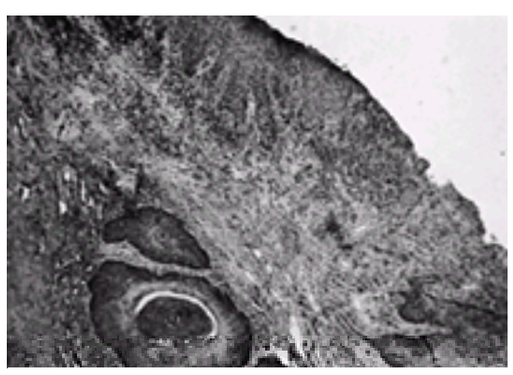

FIGURE 43.4. Erythroplasia of Queyrat. Note the full thickness of squamous epithelium composed of atypical cells with hyperchromatic irregular nuclei and loss of polarity. Marked vascularization and a dense chronic inflammatory infiltrate in the submucosa are apparent. (Hematoxylin-eosin, ×240.)

Topical therapy with twice daily 5% 5-FU cream for 3 to 4 weeks has been reported to be effective, although ulceration or nodularity suggesting invasion is a contraindication to this therapy and posttreatment biopsy is essential. When the lesion is limited to the prepuce, circumcision is recommended. Lesions that fail to respond to topical therapy should undergo either surgical excision or Mohs micrographic surgery (184). Interestingly, whereas Bowen's disease has a complete response rate of 89% to topical 5-aminolevlunic acid and photodynamic therapy, results in EQ are inconsistent and EQ does not at this time appear to be a legitimate target for photodynamic therapy (277).

Bowen's Disease

Squamous cell CIS of the mucocutaneous epithelium of the glans or prepuce is referred to as *EQ,* whereas CIS of the follicle-bearing skin (i.e., the penile shaft) is referred to as *Bowen's disease of the penis* (Fig. 43.5). Clinically, penile Bowen's disease appears as a solitary plaque, dull-red in color with crusting and oozing. Histologically, Bowen's disease strongly resembles EQ with parakeratosis, acanthosis, lack of maturation of surface epithelium, and replacement of keratinocytes with atypical basaloid cells (145,179). Both Bowen's disease of the penis and EQ are associated with HPV-16, although progression to invasive squamous cell cancer is more common in EQ (10% to 33%) than in Bowen's disease (5%) (179). Several therapies for Bowen's disease have been described, including topical 5-FU, Mohs micrographic surgery, laser treatment, cryotherapy, and aminolevulinic acid with photodynamic therapy. Recurrence is such that excision of the lesion with a 5-mm

margin is the most effective means to control the local lesion (284).

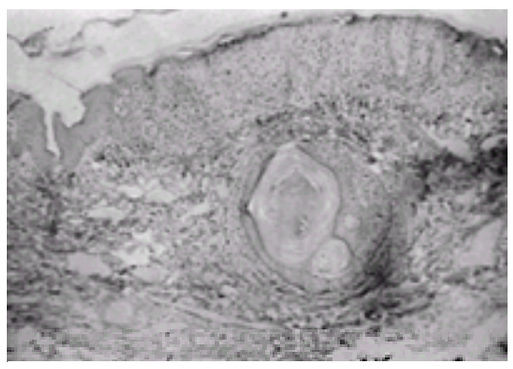

FIGURE 43.5. Bowen's disease. Abnormal epithelium composed of atypical squamous cells, with scattered, bizarre multinucleated cells. Note similar involvement in the wall of the ectopic hair follicle. (Hematoxylin-eosin, ×240.)

Bowenoid Papulosis

Bowenoid papulosis of the penis is a lesion of multiple red-brown or violaceous papules that may coalesce into plaques or into verrucous lesions ranging in diameter from 0.2 to 3.3 cm. These lesions occur primarily on the penile shaft but can also occur on the glans, prepuce, frenulum, or coronal sulcus of young, sexually promiscuous, circumcised males (133,258). Bowenoid papulosis is associated with multiple HPV subtypes, including benign subtypes and the oncogenic HPV subtypes 16, 18, and 33 (118). Histologically, dissociation between benign-appearing architecture and the cytologic features of malignancy, such as keratinocytes with crowded, large, pleomorphic hyperchromatic nuclei with atypical mitoses, is the most characteristic histologic feature of Bowenoid papulosis (214). Although Bowenoid papulosis may persist for years, regress spontaneously, or in immunocompromised or elderly patients progress to become invasive squamous cell carcinoma, recurrence after treatment is common (258). Treatment by surgical excision, CO_2 laser, cryotherapy, electrodesiccation, topical retinoic acid, or 5-FU is appropriate therapy, although periodic reevaluation is necessary because of the tendency to recur and/or progress (179).

Verruciform Tumors of the Penis

The classification of penile lesions has been somewhat controversial, and there exists a subtype of low-grade squamous cell carcinoma appearing grossly as an exophytic papillary lesion that has been classified as a “verruciform tumor of the penis” (44,242,264). The verruciform group of penile tumors includes the benign condyloma acuminatum described previously as well as the malignant verrucous carcinoma or Buschke-Lowenstein tumor, warty condylomatous squamous cell carcinoma of the penis, and papillary squamous cell carcinoma of the penis not otherwise specified (44). The latter two penile lesions are rare and have only recently been described; the reader is referred to Cubilla and associates for further discussion (44).

Although terminologic, pathologic, and clinical ambiguity has existed between the terms *verrucous carcinoma of the penis, Buschke-Lowenstein tumor,* and *giant condylomatosis of the penis,* it is now generally accepted that these are synonymous terms for an exophytic, well-differentiated, locally invasive variant of squamous cell carcinoma of the penis (3,117,257). The lesion typically originates from the glans, prepuce, or uncommonly, the shaft and has a propensity to infiltrate deeply and cause local destruction; however, it rarely exhibits nodal or visceral metastases.

Penile amputation, either total or partial, is currently the recommended treatment for this lesion, although CO_2 laser ablation has been shown effective in some cases (26). Treatment of verrucous carcinoma with chemotherapy (i.e., bleomycin and cisplatin) is generally ineffective, as is radiotherapy, which also may result in transformation of the lesion into a poorly differentiated metastasizing squamous cell cancer (159,300). Recently, the use of subcutaneous interferon-a 2×10^6 IU for varying schedules has shown promising results in patients unwilling to undergo amputation or who experience local recurrence (159).

Squamous Cell Carcinoma of the Penis

In the United States and in industrialized countries, squamous cell cancer of the penis is uncommon, with an incidence of 1 per 100,000 or less than 1% of all cancers and cancer deaths in men. On a global level, however, this lesion occurs more frequently and is associated with significant morbidity and mortality such that insight into its etiology, diagnosis, treatment, and possible prevention is important.

Incidence and Epidemiology

There is a marked social, economic, and geographic variance in the incidence of penile cancer, and in certain areas of the Indian subcontinent, Africa, and Latin America, this lesion accounts for at least 10% of all male cancers, in contrast to an incidence of 0.4% in the United States (Table 43.2).

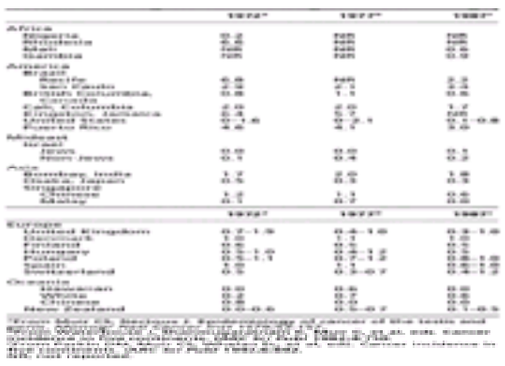

TABLE 43.2. AGE-ADJUSTED INCIDENCE RATES (CASES PER 100,000 MEN) OF PENILE CANCER OCCURRING BY CONTINENT FOR REPORTING PERIODS ENDING 1972, 1977, AND 1987

In Europe, the rates are low, but unlike in the United States or Japan, there is an urban preponderance in some areas. The relatively high incidence in India likely relates to the large Hindu population, who do not practice circumcision, and contrasts to the low frequency of this lesion among Muslims, who do so (124). Differences in incidence between various regions in Africa as well as between neighboring tribes has been noted. Among uncircumcised males in Uganda, the incidence of penile carcinoma is such that different tribes living in the same region have a similar incidence of this malignancy, whereas members of the same tribe living in different regions exhibit rates reflecting the area in which they live (254). Similarly, the incidence of penile carcinoma among migrants varies with their site of residence, rather than with their area of origin. The incidence of penile carcinoma among the Chinese of Singapore is lower than that of Chinese in general, but it remains elevated compared with the Japanese (Table 43.2). Interestingly, the incidence of penile carcinoma among Chinese living in the continental United States or Hawaii is lower than that for Chinese living in the Orient, further suggesting the relevance of geographic and environmental factors. The rarity of penile carcinoma in Israel reflects the rarity of this lesion among Jews in general and with the practice of neonatal circumcision. Finally, although penile carcinoma is uncommon in the United States, age-adjusted incidence figures suggest an increased frequency of this lesion in African Americans and Hispanics living in the United States as compared with Caucasians (188,212).

Time Trends and Relative Frequency

In the United States and Western Europe, the incidence of penile cancer has remained stable over the last 25 years, with an annual incidence of about 10 per 1 million (59,83,212). Using the surveillance, epidemiology, and end results (SEER) data, trends could not be detected within individual age groups and the age-adjusted rate for Caucasian males from 1984 to 1986 was 5.89 per million (83). Similarly, the incidence of basal cell carcinoma and of melanoma of the penis was unchanged over the same period (83).

In some regions where a high incidence of penile cancer had previously been noted, a decline is now apparent. In Hong Kong, the incidence fell from 3% during the period of 1930 to 1958 to 1.1% during 1961 to 1964 (22). In the Philippines, the relative frequency of penile cancer fell from 12% to 0.6% between 1925 and 1961, and in Puerto Rico, a 50% decline in the age-adjusted penile cancer incidence occurred between 1950 and 1977 (167,288). This trend toward a decrease in frequency in previously high-incidence areas may reflect improvement in environmental conditions, hygiene, and possibly an increase in the practice of neonatal circumcision.

Factors Associated with the Risk of Developing Penile Carcinoma

Various factors have been associated with the risk of developing penile carcinoma, including age, circumcision, racial factors, phimosis, smegma, venereal disease, trauma, socioeconomic status, occupation, tobacco use, ultraviolet radiation exposure, multiple sexual partners, and the presence of untreated premalignant lesions (153,188).

Age

Although penile carcinoma is rare in males younger than 25, the age-specific rate of this lesion increases with each decade thereafter (93,192); Table 43.3 shows the increasing incidence of penile cancer in the United States as a function of patient age. In addition, in those areas with a high incidence of penile carcinoma (e.g., Brazil), the age at onset of this lesion is lower and a higher proportion of cases occur in younger patients compared with those areas where the incidence of this lesion is low (e.g., New York State) (Table 43.2).

Age Interval (yr)	Whites	African Americans	Total
15–24	0.02	0.00	0.01
25–34	0.08	0.00	0.07
35–44	0.31	1.77	0.43
45–54	0.72	1.16	0.74
55–64	2.17	3.39	2.24
65–74	4.51	7.33	4.66
≥75	6.23	3.66	6.46

TABLE 43.3. AGE-RELATED INCIDENCE RATES (CASES PER 100,000 MEN) OF PENILE CANCER AMONG WHITES AND AFRICAN AMERICANS IN THE UNITED STATES

Circumcision

Squamous cell carcinoma of the penis is rare among populations that circumcise males in infancy, as illustrated by the virtual absence of this lesion in Jews and only a slightly higher incidence in Muslims, who undergo circumcision between the ages of 4 and 9 years (20,153). Further evidence for the preventive role of neonatal circumcision is seen in Uganda, where among tribes practicing circumcision, the rate of penile carcinoma is 0.5 per 100,000 males, compared with tribes not practicing circumcision, in whom the rate is 2.9 per 100,000 males (234). Other factors, however, must also be important among uncircumcised individuals because the incidence of penile cancer in uncircumcised males has been found to vary from 0.8 per 100,000 males in the Kigezi district of Uganda to 8.9 per 100,000 males in the Joru district (254). Similarly, when uncircumcised individuals migrate from an area of low incidence to an area of high incidence of penile cancer, and vice versa, the frequency of penile carcinoma reflects the area of residence rather than the region of origin.

Inadequate or incomplete circumcision or circumcision performed late in childhood, adolescence, or adulthood is much less effective in preventing the development of penile carcinoma than neonatal circumcision. Witness, for example, the equal frequency of this lesion among Mohammedans, who undergo delayed circumcision, with Chinese, who do not undergo circumcision (283). Delayed circumcision offers only slight protection against the development of penile carcinoma, as shown by South African Bantus, who undergo circumcision during or after puberty (101). Similarly, circumcision performed in adults is not protective, and in two large studies, 11% of cases of penile carcinoma occurred among patients circumcised in adulthood (121,164).

The medical consequences of circumcision have been debated, and a mortality of one death in more than 500,000 circumcisions described (29). Even though reports of severe disfigurement as a result of circumcision are extant, neonatal circumcision has a lower mortality and morbidity rate compared with the use of general anesthesia in adult circumcision; reports questioning the advisability of routine neonatal circumcision ignore its proven effectiveness in preventing penile carcinoma.

Racial Factors

Early studies suggesting that penile carcinoma was uncommon in African Americans compared with whites (140) may have reflected bias in reporting as well as in the accessibility to medical services. In contrast, recent comparisons of the incidence between African Americans and whites in various regions of the United States have indicated that the lesion is more common in African Americans (Table 43.3). It is unlikely, however, that racial or genetic factors alone account for differences in incidence, but rather that epigenetic, socioeconomic, or environmental factors determine the increased incidence of penile cancer in African Americans (93,256). In addition, and in contrast to whites, a 17% incidence of subsequent development of a second primary neoplasm (e.g., lung or prostate) was noted in African Americans an average of 7 years after diagnosis of the primary penile lesion, and of these patients, 70% died as a result of their second malignancy (113).

Phimosis

Phimosis is the most common coexisting anatomic abnormality found in patients with penile carcinoma and has been noted in 52% of patients with this lesion (10,65,250). Phimosis acquired during the growth of penile cancer has been reported in 15% of cases. Although control data are difficult to obtain, congenital phimosis was reported in 2.4% of Belgian army conscripts and in 2.3% of males in a report from the former USSR (261). Thus, although a far greater number of males have phimosis than develop penile carcinoma, phimosis is a risk factor in the development of this lesion. In histologic studies of the phimotic prepuce epithelial atypia, it was noted in 35% compared with 0% of patients without phimosis (240). Moreover, the phimotic preputial cavity provides optimal conditions for the action of carcinogens and for the early and undetected growth of this lesion (261). Smegma and phimosis are each independent risk factors for the development of penile cancer (103,153).

Hygiene and Venereal Disease

A correlation between venereal disease and subsequent development of penile carcinoma has been recognized, and a history of venereal disease has been reported in up to 22% of patients with penile cancer (94). Although a history of gonorrhea or syphilis may be obtained in patients with penile carcinoma, causation is unproven and may reflect the influence of coexisting HPV infection, sexual promiscuity, as well as multiple sexual partners, which correlates with risk of penile cancer (153,217).

Poor hygiene may be associated with, rather than a cause of, penile carcinoma, although Frish and colleagues (76) have concluded that improved personal hygiene accounts for the reduction in penile cancer in uncircumcised males. Among Ugandan tribes whose members do not undergo circumcision, the rate of penile carcinoma is lower among tribes with high, as compared with tribes with low, standards of personal cleanliness (254). Similarly, in Sweden, where circumcision is not routine but where standards of hygiene are high, penile carcinoma is uncommon (65). The importance of personal hygiene is further emphasized by the paradoxically high incidence of penile carcinoma in residents of northern Thailand, a population that bathes frequently (178). This bathing, however, is done in public, with the individual partially clothed and the genitalia therefore inadequately cleansed in the process.

Penile Trauma

Chronic trauma may be a risk factor for cancer of the penis, as evidenced by the high incidence of penile carcinoma among the Zulus, who practice routine circumcision but sustain chronic trauma by wearing protective devices over the glans (153). Interestingly, a history of recurrent small tears and abrasions of the penis has also been reported to be a risk factor in penile cancer (103,153).

Socioeconomic Factors

A direct correlation between the incidence of penile cancer and the patient's socioeconomic level has been noted (7,188). However, in a study from Denmark in which all patients with penile carcinoma from 1942 to 1962 were studied and selection bias was thereby minimized, a relatively even distribution among social class was reported (121). It was concluded that the incidence of penile cancer was relatively uniform among various social classes, and no definitive conclusions regarding socioeconomic class and penile carcinoma is possible at this time (93).

Occupation

Agricultural workers, as compared with men in mercantile or manufacturing occupations, are at increased risk of developing penile carcinoma (121). In a study in which less than 7% of the population was employed in agriculture, 12% of all deaths from penile carcinoma occurred among agricultural workers (93). In industrialized, as contrasted to agrarian, economies, however, farming may be associated with poverty and with a paucity of medical services, so farming itself may not be a risk factor (93).

Other potential occupational factors include asbestos exposure with subsequent development of squamous cell carcinoma of the glans or prepuce, as well as that of a house painter who developed squamous cell cancer of the base of the penis (231).

Other Factors

In a population-based case-control study, it was found that the risk of penile cancer among cigarette smokers was three times that of nonsmokers, and it was speculated that this may relate to the inhibitory effect of cigarette smoking on antigen-presenting dendritic or Langerhans cells (95,153). In patients with psoriasis who were treated with oral methoxsalen and then ultraviolet radiation, an increase in the risk of penile and scrotal cancer was observed (280). Additional investigations suggested that this increase was due to the combination of psoralen and ultraviolet radiation because increased exposure to ultraviolet radiation alone was not associated with an increased incidence of squamous cell cancer of the penis (83).

Squamous Cell Carcinoma of the Uterine Cervix in Sexual Partners of Men with Penile Cancer

There is no convincing evidence that the husbands of women with carcinoma of the uterine cervix are at increased risk of developing penile cancer, but there is evidence that wives of husbands with penile carcinoma are at increased risk of developing cervical carcinoma (215). Wives of men with penile cancer have at least a threefold higher incidence of cervical cancer compared with wives of men without penile cancer, and circumcision reduces the risk of both cervical cancer and penile cancer (78,158,283). The role of sexually transmissible agents in the etiology of tumors of the male and female genital tract is suggested by finding HPV in a variety of genital tumors, including squamous cell cancer of the penis, cervix, and vulva (12,171). Moreover, with the use of 5% acetic acid to screen for HPV infection in males, it was found that of male sexual partners of women with cervical carcinoma, 33% demonstrated intraepithelial neoplasia and 60% of these lesions contained HPV DNA sequences (12). Finally, epidemiologic studies of carcinoma of the cervix, vagina, and penis are consistent with the hypothesis that tumors at these sites have common or similar etiologies (i.e., sexually transmitted infections) (313).

Etiology

Various factors have been causally associated with the development of penile carcinoma, although only two—smegma and viruses—have received attention as specific etiologic agents (239,261,285).

Smegma

Smegma is thought to represent the debris of desquamated epithelial cells originating from epithelium of the glans or inner surface of the foreskin (261). It has been proposed that *Mycobacterium smegmatis,* present in the preputial sac of 50% of men, causes degradation of smegma into proximate carcinogens, such as hydrocarbons and sterols (211,226). Whether smegma derives solely from desquamating epithelial cells or from the secretions of Tyson's and other preputial glands at the coronal sulcus is unsettled. Some workers find no evidence of coronal glands opening into the preputial sac, whereas others note the presence of such structures (9,240).

Evidence for the carcinogenicity of smegma or its degradation products is persuasive and smegma placed in a buried skin tunnel of mice resulted in a 3% incidence of carcinoma (226). Topical application of carcinogens such as 7,12-dimethyl-benz(a)anthracene to the rabbit penis produced carcinoma only if phimosis (experimentally induced) was present (261). It is proposed that phimosis permits retention of smegma or its derivatives, both of which are carcinogenic, and that prolonged contact results in malignant epithelial transformation.

Viruses

A convincing association between HPV infection and penile carcinoma has been demonstrated (23,56,100,161,168,304). It is suggested that viral or virally induced factors either inactivate tumor-suppressor genes (p53 or Rb) or their products or activate cellular oncogenes such as c-rasHa (291). HPV DNA has been detected in malignant penile tissue in up to 70% of lesions studied and in patients with HPV-positive lesions, 84% to 100% show HPV-16, and 8% to 15% HPV-18 (45,100,292,314).

Approximately 50% of invasive penile cancers show HPV DNA, and 80% of early or *in situ* lesions do so (56,168). Interestingly, the foreskin of 0% to 4% neonates and 6% to 10% of otherwise healthy males also demonstrate HPV DNA (45,243). It has also been found that the lesions of 92% of patients with PIN, EQ, or Bowen's disease were positive for oncogenic HPV DNA and that none of the patients with verrucous carcinoma were positive for oncogenic HPV DNA (45). Finally, when the metastatic lymph nodes from patients whose penile carcinoma contained HPV-16 DNA were studied, it was found that more than 50% also showed HPV-16–positive nodes (259,304). Because the penile cancer tissue of a number of patients did not show HPV DNA, it has been suggested that penile cancer may develop in two distinct settings—HPV positive and HPV negative—and that separate mechanisms of carcinogenesis may be operative (100).

Pathology

Gross Pathology

Squamous cell carcinoma of the penis usually begins as a small nodular, papillary, or ulcerative lesion on the glans or prepuce, and origin from the shaft is rare. Typically, the prepuce is present and often phimotic, either primarily or secondary to tumor growth, thus obscuring the primary lesion until locally advanced. Ulceration eventually occurs in 85% of cases and secondary infection in 90%. This results in a discharge and an inflammatory infiltrate in the deep tissue that may simulate tumor extension. The clinically palpable inguinal lymph nodes often present at the time of initial diagnosis of penile cancer are, in about 50% of cases, due to an

inflammatory rather than a metastatic etiology, this inflammation being secondary to coexisting infection of the penile lesion. Although the size of the lesion bears no consistent relationship to prognosis, larger lesions are more often associated with a less favorable outcome and a higher incidence of nodal and visceral metastases than smaller ones (14); however, this is disputed (65).

In gross clinical appearance and pattern of growth, penile cancer has been classified as either exophytic (papillary, polypoid, or fungating) or endophytic (flat, infiltrating, or indurated), both occurring with approximately equal frequency (15,121,164). The rate of tumor growth, the tumor size at diagnosis, and its duration before diagnosis are the same for both patterns, although 5-year survival for patients with papillary lesions is somewhat higher than patients with endophytic lesions (14,165). Exophytic lesions appear as wartlike excrescences that ulcerate and metastasize relatively late in the course of their growth, whereas endophytic lesions tend to ulcerate and metastasize earlier and to grow laterally and infiltrate deeply.

Histopathology and Grading

Carcinoma of the penis typically arises from the squamous epithelium of the glans or mucosa of the foreskin and only rarely from the penile shaft. Squamous cell or epithelioid cancer is the most common histologic type of penile cancer, although other histologic variants of penile cancer, including basaloid squamous cell carcinoma, adenoid squamous cell carcinoma, spindle cell or sarcomatoid carcinoma, and squamous cell carcinoma with glandular component (either mucoepidermoid or adenosquamous carcinoma), have been described (298). Because of the rarity of these latter lesions and the paucity of clinical information concerning them, they are not discussed here (44,85,120,140).

Squamous cell cancer of the penis is typically composed of well- to moderately well-differentiated hyperchromatic cells that vary in cellular and nuclear size and shape with a loss of normal basal to superficial maturation and polarity (187). Figure 43.6 and Figure 43.7 show neoplastic cells invading the basement membrane and adjacent stroma with formation of keratinizing whorls and pearl formation. Lateral to the malignancy, the nonneoplastic epithelium becomes thickened, and deep to the lesion, the stroma shows capillary engorgement and an infiltrate of lymphocytes, mast cells, and polymorphonuclear leukocytes. Surface ulceration and secondary infection of the lesion increase the local inflammatory response, and despite the vascular nature of the penis, penile cancer is primarily a locoregional disease that metastasizes first to regional lymph nodes, with early hematogenous dissemination being distinctly uncommon.

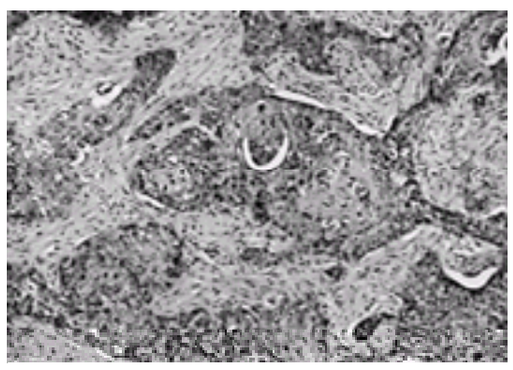

FIGURE 43.7. Penile carcinoma. General view of infiltrating component of penile squamous cell carcinoma involving the corpora cavernosa. (Hematoxylin-eosin, ×80.)

In addition to a classification of penile cancer based on gross clinical appearance as described earlier, classifications of penile cancer, based on various histologic criteria, are far more valuable (43,75,165). Frew and associates (75), as well as other investigators (66,250), have described a solid and a cord pattern with the 5-year survival rate of patients with the solid pattern (96%) being superior to that of patients whose tumor exhibits the cord pattern (76%). The solid pattern, which is believed to be less aggressive than the cord pattern, consists of large, rounded clumps and sheets of cells with cellular masses that tend to be smooth and rounded, each of which may show invasion. The cord pattern consists of a smaller cell mass irregular in outline, with small clumps and cords of cells invading underlying tissue in advance of the bulk of the tumor.

Marcial and co-workers (165), on the other hand, have identified five histologic patterns of growth, including intraepithelial, leukoplakia, verrucous, compact, and plexiform, with the plexiform type showing the highest degree of cellular anaplasia and the intraepithelial and leukoplakic varieties showing the least degree of anaplasia. The intraepithelial and leukoplakia patterns have the most favorable 5-year survival (67% and 72%, respectively), whereas the compact and plexiform patterns have the poorest (36% and 17%, respectively) (43,65).

Cubilla and associates (43) defined four distinct microscopic patterns of growth: superficially spreading epidermoid carcinoma (SS); vertical growth carcinoma (VG); verruciform (V), which includes Buschke-Lowenstein tumors and papillary carcinoma; and multicentric carcinoma (MC). The SS pattern was most commonly seen (42%) and, compared with VG, the second most common pattern (32%), had a lower histologic grade, incidence of perineural invasion, and frequency of inguinal node metastases. However, if patients with the SS pattern were treated by circumcision for preputial lesions or by limited resection for glanular lesions, there was a marked tendency for recurrence. The V pattern occurred only in 18% of cases, was of low histologic grade, and rarely showed vascular invasion; in addition, although corporal invasion occurred in two-thirds of cases, nodal metastases were not reported. Only 8% of the lesions were of the MC type, and because this pattern appeared similar in clinical behavior to the SS type, it was suggested that similar therapeutic recommendations for the two types were appropriate (43).

In contrast to classifications of penile cancer based on histopathologic patterns, the microscopic grading of penile cancer offers another important variable for tumor characterization (15). The classic grading criteria of Broders are based on cell and nuclear morphology, which differs from that of Maiche and associates (160), who proposed a new grading system based on four microscopic parameters, including the degree of keratinization, the number of mitotic cells, the extent of cellular and nuclear atypia, and the presence or absence of lymphocytes. Maiche and associates (160) concluded that this system correlated well with stage at diagnosis and with 5- and 10-year survival rates. Using various grading criteria, studies have shown a correlation between tumor grade and nodal status, with up to 15% of patients with low-grade tumors having nodal metastases and 40% of those with moderate- to high-grade lesions exhibiting nodal dissemination (14,65,131,250,294).

Survival correlates with tumor grade are summarized in Table 43.4. Low-grade tumors have better 5- and 10-year prognoses than moderate- to high-grade lesions (10,94,250,294), and two or three times as many patients with moderately to poorly differentiated or high-grade lesions die of their tumors, compared with patients with well-differentiated or low-grade lesions (75,121). Using Maiche and associates' grading system (160), the 5- and 10-year survival for patients with grade I tumors is 85%, whereas for grade III lesions, it is 55% and for grade IV lesions, 30%.

	Grade			
	Low		Moderate-high	
	No. of Cases	%	No. of Cases	%
5-yr survival	185/285	65	74/180	41
10-yr survival	43/91	47	27/76	35

TABLE 43.4. RELATION BETWEEN TUMOR GRADE AND SURVIVAL IN PATIENTS WITH PENILE CARCINOMA

Biochemical, serologic, chromosomal, and molecular studies of penile cancer are limited. However, elevation of the squamous cell carcinoma tumor-associated antigen TA-4 was found in the serum of 45% of patients with metastatic penile cancer, and TA-4 levels correlated with disease progression (307). The loss of chromosomes 13, 17 (site of the p53 gene), and 22, as well as structural chromosomal abnormalities, have also been reported in penile cancer (207,308). The p53 and p21 genes and/or their gene products are important factors in malignant transformation and in tumor progression, and deletion or mutation of these genes is found in many human tumors, including penile cancer (66,140). In 35 patients with squamous cell carcinoma of the penis, p53 was expressed in 89% of cancers and p21 in 39%; p21 expression was found to be either dependent or independent of p53 expression (140). However, all HPV-positive cases showed p53 expression, and expressions of p21, the proximate effector of p53, was found only in cases positive for HPV. Finally, and congruent with Higgins and co-workers (100), it has been proposed that penile carcinomas may result either from progression of lesions caused by oncogenic types of HPV (i.e., HPV-16) or through alterations of p53 unrelated to HPV infection.

Local Tumor Growth and Dissemination

As the tumor grows locally, progressive destruction of the prepuce, glans, and penile shaft occurs. Buck's fascia serves initially as a barrier to invasion, and the cancer is relatively slow to penetrate the corporal fascia (33). With invasion of the erectile tissue, the incidence of tumor dissemination increases, although despite the extensive venous sinusoids of the corpora, early dissemination is primarily lymphatic (121) and knowledge of the penile lymphatics is therefore relevant (Fig. 43.8).

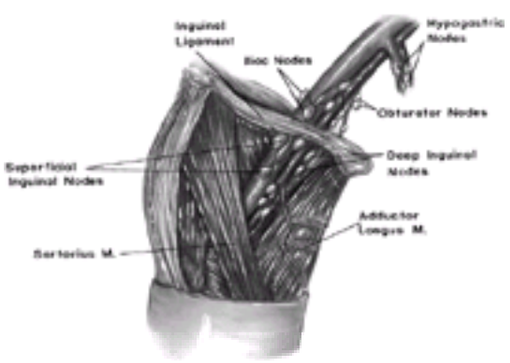

FIGURE 43.8. Unilateral view of relevant pelvic and inguinal lymph nodes. The regional lymph nodes of the penis are the superficial and deep inguinal nodes, the external iliac, hypogastric, and obturator lymph nodes. Although a unilateral view is shown for clarity, the lymphatic drainage of the penis is bilateral.

Lymphatic Anatomy

The regional lymph nodes of the penis, as defined by the American Joint Committee on Cancer (AJCC), are the superficial inguinal, the deep inguinal, the external and internal iliac, and the pelvic (including the obturator) lymph nodes (69,272). The efferent lymphatics of the superficial inguinal lymph nodes drain into the deep inguinal nodes located below the fascia lata, which then drain into the external iliac hypogastric or obturator nodes. For purposes of summarizing penile lymphatic drainage, three regions of the penis can be defined: (a) the prepuce, skin of the penile shaft, and subcutaneous tissue; (b) the glans, urethra, and corpus spongiosum; and (c) the corpora cavernosa.

The lymphatics of the prepuce drain toward the dorsum of the penis, merging with those of the skin of the penile shaft and with those of the subcutaneous tissue, forming lymph channels that drain into the superficial inguinal nodes (13,27,58).

The lymphatics of the glans converge toward the frenulum and join with the lymphatics of the urethra and corpus spongiosum. This combined system forms a collar of interconnecting channels at the base of the penis, which drain either into the deep inguinal nodes or through lymphatics traversing the inguinal canal directly into the external and internal iliac nodes. Indeed, this potential direct drainage into the deep pelvic lymph nodes explains why tumors of the glans or those invading the urethra or corpus spongiosum may exhibit pelvic metastases in the absence of inguinal lymph node involvement (237). The lymphatics of the corpora cavernosa drain into the superficial and deep inguinal lymph nodes, which drain into the iliac and pelvic nodes. Because the penile lymphatics anastomose freely and cross the midline along the shaft and at the base of the penis and because of the free communication between the right and left inguinal nodes via subcutaneous lymphatics, bilateral, and not unilateral, metastases may be expected. Therefore, when lymphadenectomy is indicated, bilateral, and not unilateral, resection should be performed (27).

Hematogenous dissemination with osseous, hepatic, or pulmonary metastases is uncommon, having been noted at initial diagnosis in only 1.2% of cases (121). Even in locally advanced lesions, lymphatics remain the principal mode of metastasis (13,27). Hematogenous spread occurs when tumor emboli reach (a) the pelvic veins and the inferior vena cava or (b) the dorsal vein of the penis, the prostatic plexus of veins, and then pass through the vessels of the lateral pelvic wall into the inferior vena cava (27,187). However, hematogenesis metastases also occur through extracaval routes, that is, through the lateral sacral veins, Batson's paravertebral plexus, and then into the systemic venous system (187). Finally, in locally advanced cases, direct extension of the tumor into the pubic bone, abdominal wall, or scrotum may occur and necessitate extensive resection to achieve at least local control.

Distribution and Significance of Nodal Metastases

At initial presentation, approximately 60% of patients will have palpable inguinal adenopathy, although in only 45% of cases of palpable adenopathy will metastases be found (33,53,66,75,94,250,311). In contrast, of those patients whose inguinal lymph nodes are clinically impalpable at diagnosis, 18% (reported range of 8% to 39%) will have unsuspected, usually unilateral, occult metastatic disease (11,14,33,206,235). Moreover, this incidence of occult disease correlates with the observation that approximately 14% of patients who have impalpable inguinal nodes at initial presentation subsequently manifest nodal metastases, and 95% of these patients do so within 18 months. Although a clinically negative lymph node examination has a negative predictive value of 82%, 83% to 94% of patients whose nodes are clinically negative on the initial examination and who subsequently develop palpable adenopathy will be found to have nodal metastases (14,66,123,206,236). Therefore, at the time of initial presentation, about 44% of all patients with penile cancer have nodal metastases, which in 26% of all cases are macroscopic and in 18% of all cases are microscopic (33,66,75,94,108,119,123,237).

Among patients with inguinal node metastases, lymphadenectomy may be curative, although the presence of pelvic lymph node metastases is associated with a 5-year survival rate of less than 5% (236,275). Importantly, the incidence of pelvic node metastases correlates with inguinal node status, because pelvic node

metastases in the absence of inguinal node metastases are rare. However, pelvic node metastases occur in 23% of patients with up to three positive inguinal nodes and in 56% of patients with more than three positive inguinal nodes (205,206,236,275).

Factors predictive of regional lymph node metastases in patients with penile cancer include invasion of the corpora, tumor grade, and the response of initially palpable inguinal nodes to definitive treatment of the primary lesion and to a 6- to 8-week course of antibiotics (106,206). The degree to which the primary penile lesion invades the corpora correlates with nodal status and is reflected by the fact that inguinal node metastases have been reported in only 13% of Jackson stage I lesions but in 48% to 66% of stage II lesions (94,173). Using tumor, node, metastasis (TNM) staging, inguinal node metastases were observed in 4% to 18% of stage T_1 lesions, in 47% to 64% of T_2 lesions, and in 71% of T_3 lesions (108,206,273). In contrast, the studies of Lopes and associates (147) and of Ravi (237) have failed to demonstrate that the extent of corporal and/or adjacent structure invasion (stages T_2 to T_4) is predictive of nodal metastases.

Tumor grade has also been correlated with nodal metastases, with 19% to 29% of grade I, 46% to 65% of grade II, and 82% to 86% of grade III lesions being associated with positive lymph nodes (62,106,273). In contrast, Lopes and co-workers (148) have reported that on multivariate analysis, only the presence of lymphatic or venous tumor emboli correlated with nodal metastases.

It has also been observed that if inguinal nodes remain palpable 6 to 8 weeks after definitive treatment of the primary lesion and a course of antibiotics, about 90% of such nodes will harbor malignancy. It has also been noted that if initially impalpable inguinal lymph nodes subsequently become palpable, there is a 94% likelihood that such nodes will contain metastases (207,237,275,294).

Paradoxically, the duration of symptoms before diagnosis (i.e., the delay in diagnosis) does not correlate with the incidence of nodal metastases (14,65,148). Moreover, with the exception of lesions confined to the prepuce, which show nodal metastases in less than 10% of cases, the site of origin of the primary lesion, its clinical T stage, size at diagnosis, and the presence or absence of corporal invasion, bear no consistent relationship to the presence or absence of nodal metastases (65,66).

Cause of Death

In patients diagnosed with penile carcinoma, approximately 50% to 60% will die of unrelated malignant or nonmalignant causes, emphasizing the competing mortalities that coexist in patients with this lesion (14,131,194,274). Overall, the 5- and 10-year disease-specific survival rates are 72% and 66%, respectively, and corresponding disease-free survival rates of 56% and 42%, respectively, have been reported (105,274). Of those patients in whom penile carcinoma is the proximate cause of death, mortality results from either regional recurrence with hemorrhage secondary to erosion of large vessels, sepsis secondary to infection of necrotic and/or malignant lymph nodes, the cachexia and inanition of malignancy, or local recurrence with invasion of the pubis, scrotum, and abdominal wall (148,274). Distant metastases may ultimately occur in up to 10% of patients and, when present, may be the immediate cause of death. Metastases are usually pulmonary, although osseous and hepatic lesions also occur.

Signs and Symptoms

The average age at diagnosis is 60.1 years (range of 15 to 92 years). Presenting symptoms consist of a penile mass, lump, or nodule in 47% of patients; a penile ulcer or sore in 35%; and an inflammatory lesion or bleeding from the external surface of the penis in 17%. It is of interest that in 0.7% of cases, carcinoma has been found incidentally during the course of an adult circumcision. Squamous cell carcinoma of the penis originates on the glans in 48% of cases, on the prepuce in 21%, in both loci in 9%, and in the coronal sulcus in 6% of cases. Although the penile shaft is a distinctly uncommon site of origin of squamous cell carcinoma of the penis and occurs in less than 2% of cases, involvement of the shaft by direct extension of tumors originating on the glans or prepuce occurs in 14% and tumors restricted to the prepuce or coronal sulcus only rarely are associated with nodal metastases. At diagnosis, approximately 60% of lesions are larger than 2.0 cm in maximum diameter, and penile carcinoma is noteworthy for the delay by patients in seeing a physician. The average interval between the initial perception of a penile lesion by the patient and his presentation to a physician is 10 months, with a range of 3 to 26 months. The biologic significance of this delay, however, is uncertain (147), and a large series reported a 46% rate of nodal metastases among patients with symptoms of less than 6 months' duration at the time of diagnosis and a 50% rate of nodal metastases among patients with symptoms of more than 6 months' duration at the time of diagnosis.

Diagnosis of the Primary Lesion

There are no unique physical characteristics diagnostic of penile cancer. Biopsies should be performed on suspicious lesions, and the use of salves, creams, ointments, or fulguration should be deferred until a definitive diagnosis has been established. Reports have noted physician delay in diagnosing this lesion, and a critical factor in its early diagnosis is an early index of suspicion “not only in patients with nodules, papillomas, or ulcerations but also in those with lesions which might be described as unusual or inflammatory” (27). Other penile lesions may resemble penile carcinoma, and the differential diagnosis includes EQ, BXO, tuberculosis, herpes progenitalis, gummatous ulceration, granuloma inguinale, and condyloma. Adequate biopsy and histologic study remain the diagnostic standard, although fine-needle aspiration cytology, if positive, is also effective (13,27,30,270).

If the prepuce can be retracted, a sore, pimple, or wart may be noted early in the disease, but in men with a new onset of phimosis, penile cancer should be excluded as a cause. With progression of the untreated lesion, ulceration, erosion, infection, fistula formation, hemorrhage, and urethral obstruction may occur. Because penile carcinoma may appear as or coexist with benign penile lesions, the need for a high level of suspicion in seemingly benign lesions is warranted and generous indications for prompt biopsy must be emphasized.

If phimosis precludes adequate visualization and biopsy, one or more longitudinal preputial slits can be made, with care taken to avoid the suspected lesion, thereby exposing the growth without risking dissemination. Biopsy is the definitive technique for diagnosing the type and extent of penile lesions, even though other techniques have been described (54). Corpus cavernosography is useful in detecting extension into the corpora, but noninvasive techniques, including computed tomography (CT) scan, ultrasound, or magnetic resonance imaging (MRI) of the penis, provide accurate assessment of local tumor extent (54,109,125,289). Moreover, in low-grade, clinically low-stage lesions for which nonsurgical therapy is contemplated, these techniques allow further precision in initial staging and posttreatment follow-up.

Staging of Penile Cancer

As summarized in Table 43.5, various systems for staging penile cancer have been used. At present, the TNM system of the International Union Against Cancer (UICC) and the identical classification of the AJCC, both in their most recent 1997 iterations, are in widest use (69,96,272). Each system recognizes clinical as well as histopathologic assessment, and the inaccuracies inherent in clinical staging attests to the importance of histologic confirmation. When clinical T stage (cT) is compared with pathologic T stage (pT), 74% of patients were staged correctly and 26% incorrectly (106,294). Of those staged incorrectly, 60% were overstaged and 40% understaged. Of all patients staged clinically, 16% were overstaged and 10% understaged (106). Among patients who clinically were believed to be free of inguinal node metastases (cN0), 30% to 40% were found to have metastases (pN+) and 20% to 30% of patients thought to harbor nodal metastases (cN+) were on pathologic study found to be free of metastases (pN_0) (98,106,294).

TABLE 43.5. COMMONLY USED SYSTEMS FOR STAGING PENILE CANCER

Historically, at the time of clinical diagnosis and using the staging system of Jackson (119), 56% of patients present with stage I disease, 14% with stage II disease, 27% with stage III disease, and 3% with stage IV disease (14,53,66,94,194). The pathologically confirmed stage at diagnosis in patients with penile cancer using Jackson's staging is as follows: stage I, 58%; stage II, 13%; stage III, 25%; and stage IV, 4% (53,66,119,131,250). The congruence between clinical and pathologic staging at diagnosis in the aggregate, despite the discordance between clinical and pathologic staging that occurs in individual patients, may relate to a 22% rate of clinical overstaging and a 14.6% rate of clinical understaging, with errors balancing in some of these studies. In addition, not all reports provide simultaneous clinical and pathologic staging; hence, reports from which clinical data were derived are not necessarily the same as those from which pathologic reports were obtained.

Based on the TNM system, 19% of all patients at diagnosis present with clinical stage T_1, that is, cT_1 disease (range of 15% to 53%), 49% with cT_2 (range of 32% to 56%), 29% with cT_3 (range of 13% to 43%), and 3% with cT_4 disease (range of 2% to 4%) (106,157,206,237). Comparison between clinical T stage (cT) and clinical node stage (cN) demonstrates that between 18% and 25% of cT_1 lesions are cN+, 47% to 56% of cT_2 lesions are cN+, and 69% to 71% of cT_3 lesions are cN+ (157,206). Finally, when the TNM system is applied to histopathologic findings, pT_{is} is found in 1%, pT_1 in 34%, pT_2 in 54%, and pT_3 in 11% (106).

Evaluation of Regional Lymph Nodes

Regional lymph node status is an important prognostic marker in penile cancer (236), and inguinal lymphadenectomy in patients with nodal metastases is of proven therapeutic value (174). However, diagnostic and/or prophylactic lymphadenectomy for patients with clinically negative lymph nodes remains controversial because this would expose a substantial number of patients who do not harbor metastases to the morbidity of inguinal lymphadenectomy. In addition, the reliability of the modified inguinal lymphadenectomy has been questioned (40,110,147,260). To limit morbidity, a variety of noninvasive or minimally invasive techniques have been used to evaluate the inguinal nodes, including lymphangiography, CT, MRI, percutaneous aspiration, fine-needle biopsy, modified superficial inguinal lymphadenectomy, and sentinel-node biopsy with or without lymphoscintigraphy and immunohistochemistry (34,40,110,151,289). In contrast to the inguinal nodes, pelvic node evaluation has, in addition to several of the aforementioned techniques, included laparoscopic node dissection and “open” pelvic lymphadenectomy (8). Attempts to identify noninvasive, yet accurate, predictors of regional node metastases have been unsuccessful, although patients with palpable inguinal nodes at diagnosis that persist after treatment of the primary lesion and a 6- to 8-week course of antibiotics are likely to harbor nodal metastases. In addition, inguinal nodes greater than 2 cm in diameter or inguinal node fixation is predictive of pelvic node metastases. Assessment of nodal status by CT or MRI is based primarily on nodal size, and neither technique is capable of defining internal nodal architecture (289). Because inflammatory and other nonmalignant processes may produce nodal enlargement, these techniques are insufficiently reliable for diagnosis. Despite this, CT and MRI are useful in the staging and follow-up of patients with penile cancer, particularly if observation, rather than lymphadenectomy, is elected.

In an effort to minimize the morbidity of inguinal lymphadenectomy while maximizing information on nodal status, the sentinel-node biopsy technique of Cabanas (34), and more recently, combined lymphoscintigraphic and immunohistochemical techniques (110), have been introduced. Based on penile lymphangiographic studies, a nodal basin including the so-called sentinel lymph node of the penis was identified (33). According to Cabanas, the sentinel lymph node of the penis is located at the anteromedial aspect of the superficial epigastric vein, medial and superior to the epigastric vein, medial and superior to the epigastric–saphenous junction (33). The sentinel node is believed to be the initial nodal site for metastases, and this concept has subsequently been extended to breast, vulvar, and colorectal cancer and to melanoma (186). In penile cancer, Cabanas (34) reported the absence of subsequent inguinal node metastases and a 5-year disease-free survival of 90% among sentinel node–negative patients. Others (71,72) concluded that despite a false-negative rate of up to 20%, sentinel-node biopsy identifies patients who will benefit from regional lymphadenectomy. Patients who still have palpable inguinal nodes (cN_{1-2}) after ablation of the primary lesion and a course of antibiotics and who then undergo sentinel-node biopsy have a twofold increase in the yield of positive nodes as compared with patients with clinically negative nodes (cN_0) (15.7% versus 7.5%) (71).

Subsequent studies demonstrated the development of deep inguinal and iliac node metastases following a negative inguinal node biopsy, with a false-negative rate of up to 22% illustrating the limitations of Cabanas' technique (301). Furthermore, among patients in whom bilateral inguinal node biopsy was carried out using a somewhat more extensive technique than that of Cabanas (average number of nodes removed, 6.8), it was found that in 20% of those patients in whom the sentinel node was negative for cancer, metastases to other inguinal nodes occurred (39,41,237). The limits of a negative inguinal node biopsy are that 12% of patients died of inguinal metastases despite a negative biopsy and that the 5-year disease-free survival for inguinal-node biopsy–negative patients was only 83% (218,236).

To improve the reliability of sentinel-node biopsy, a new technique that combines technetium-99m lymphoscintigraphy, and patent blue V dye for more precise node localization with immunohistochemistry for enhanced pathologic evaluation has been introduced (132). Although reports using this technique in penile cancer are limited, extensive studies in other cancers, including melanoma, breast, colorectal, and vulvar carcinoma, indicate that this is a very valuable technique that may eliminate unnecessary lymphadenectomy (51,110,186).

Similar results regarding the accuracy of even more extensive dissection of the sentinel node have been reported (218). Gallium-67 citrate scanning for detection of nodal metastases has been reported, but in view of the propensity of gallium to localize in neoplastic as well as in inflammatory nodes, gallium's specificity (and thus usefulness) is limited.

To enhance the accuracy of sentinel-node biopsy, preoperative lymphoscintigraphy using technetium-99m–labeled nanocolloid is injected 24 hours before biopsy and patent blue V dye is injected immediately before biopsy and followed by immunohistochemical staining of the resected node(s) (132). Use of a gamma probe facilitates localization of the sentinel node, the patent blue V dye facilitates dissection of the sentinel node (132), and immunohistochemistry enhances the accuracy of pathologic evaluation (110). Although studies of lymphoscintigraphic localization of sentinel nodes in penile cancer are limited (110,279), studies of other cancers suggest that this is a valuable technique that may preclude unnecessary lymphadenectomy with its attendant morbidity (51,186).

Treatment and Survival

The therapy of penile carcinoma involves several considerations, including treatment of the primary penile lesion, evaluation and treatment (if indicated) of the regional lymph nodes, and treatment of systemic metastases (if present).

Treatment of the Primary Lesion

The 3- and 5-year survival rates of patients in whom penile cancer remains untreated are 6.3%and 2.6%, respectively (14,15,94). Although many of these patients had clinically advanced disease when initially diagnosed, these figures provide some insight into the natural history of penile cancer. In contrast, the overall 5-year survival of patients treated for penile carcinoma irrespective of tumor stage, grade, or type of therapy used is summarized in Table 43.6. When the overall 5-year survival and the survival of patients either with or without nodal metastases in studies reported before 1984 are compared with survival rates in recent studies, improved results are noted. These statistics may reflect earlier diagnosis; improved staging; refinements in surgical technique; the availability of broad-spectrum antibiotics; and better preoperative, perioperative, and postoperative care. Moreover, the wide range of survival figures reflects factors associated with studies performed at disparate locations and time periods, inconsistent reporting practices and patient selection, and competing therapies.

	No. of Patients	Crude 5-year Survival: All Patients		Inguinal Lymph Node Status

TABLE 43.6. FIVE-YEAR SURVIVAL OF PATIENTS WITH CARCINOMA OF THE PENIS: COMPARISON OF RESULTS OF STUDIES PUBLISHED BEFORE 1984 WITH RESULTS OF STUDIES PUBLISHED AFTER 1984

When patients are stratified according to the status of their regional lymph nodes, the negative impact of nodal metastases on survival is apparent. Indeed, regional nodal metastases result in a survival rate approximately half that observed among patients free of such metastases (Table 43.6). The survival of patients with penile carcinoma in relation to tumor stage and to the results of surgical therapy (e.g., partial or total penile amputation) versus radiotherapy in the treatment of the primary lesion is presented in Table 43.7.

TABLE 43.7. FIVE-YEAR SURVIVAL RATES BY TUMOR STAGE IN PATIENTS WITH CARCINOMA OF THE PENIS TREATED BY EITHER RADIOTHERAPY OR SURGICAL AMPUTATION OF THE PRIMARY PENILE LESION

Surgery

The goal of treatment of the penile lesion is to eradicate the tumor, prevent local recurrence, and insofar as possible, preserve urinary and sexual function. A variety of therapies to achieve these goals have been used and are listed in Table 43.8. Surgical options include circumcision, local excision of the lesion, and partial or total amputation. The location and extent of the penile lesion determines which option is most appropriate, and for small, well-localized tumors restricted to the prepuce, circumcision is a legitimate option, although failure (i.e., penile recurrence) has been noted in up to 30% of cases (14,15,65,194,232,305). Of patients with preputial lesions, 70% are cured of their primary tumor, although 20% eventually develop regional lymph node metastases (Table 43.9) (14,53,194,232,267). Local excision of glanular lesions should be restricted to selected patients, and in these individuals, a 5-year survival rate of 82% has been noted, although 31% of patients treated by local excision experience recurrence requiring subsequent partial amputation (65,121).

TABLE 43.9. RESULTS OF VARIOUS THERAPIES FOR THE PRIMARY PENILE LESION IN PATIENTS WITH PENILE CARCINOMA

Partial or total amputation of the penis remains the most widely used surgical treatment of primary penile carcinoma (99,121,131,137,143). Traditionally, partial amputation is recommended to patients whose lesion involves the glans or distal shaft and when resection of tumor with a 2-cm tumor-free margin proximal to the malignancy can be achieved (172). Recently, however, a histologically tumor-free margin of 1.0 to 1.5 cm has been reported as being sufficient for local cure (102). If the tumor invades the proximal shaft or base of the penis or if the extent of the disease prevents performance of a partial amputation, then total penectomy with creation of a perineal urethrostomy is indicated (172). Innovative procedures for penile and urethral reconstruction that maintain function have been reported (18,60,87,149,251). Irrespective of nodal status, the 5-year survival rate of patients undergoing either partial or total amputation of the penis is 50%, with local control being achieved in about 90% of cases (Table 43.9) (131,137,138,194).

Local recurrence of tumor following partial or total amputation occurs in 10% of patients, with metachronous failure three times more common than immediate or synchronous failure (14,53,121,136,250). Among patients in whom regional lymph nodes are thought clinically to be free of metastases and who undergo either total or partial amputation, 14% subsequently develop nodal metastases, usually between 4 and 24 months after treatment of the primary lesion (53,131,137,311). Finally, of patients who are thought to be free of visceral metastases at diagnosis and who undergo penectomy, 11% subsequently develop visceral metastases, usually within 18 to 36 months after treatment of the primary lesion (136). Stricture of the newly created urethral meatus requiring dilation occurs in about 20% of patients, and in half of those with meatal stenosis, reoperation and revision of the stenotic meatus is needed (136,138,310).

Radiotherapy

To minimize the cosmetic, functional, and psychologic consequences of penile amputation, radiotherapy in the form of either teletherapy (external beam) or brachytherapy has been used (66,99,119,176,202,252). Brachytherapy may be either contact or pleisobrachytherapy using surface molds with iridium or radium sources or interstitial insertion of radioactive wires, usually iridium, directly into the lesion (5,80). External beam radiotherapy produces a complete response rate of up to 56%, and brachytherapy achieves complete response in up to 70% of patients (Table 43.9). Local failure (i.e., either persistence or local recurrence of disease) has been reported in 16% of patients treated with brachytherapy and in 40% treated with external beam therapy (55,235,247,252).

There is a modest increase in the 5-year survival rate among patients whose primary penile lesions are treated with external beam radiotherapy compared with those treated with brachytherapy; this is not due to differences in tumor stage or grade (Table 43.9). In patients receiving either brachytherapy or teletherapy and in whom the regional lymph nodes are clinically negative, a 5-year survival rate of up to 80% has been reported (32,55,176). Up to 20% of patients who are thought to have inguinal lymph nodes free of metastases on initial clinical examination and who undergo radiotherapy to the penile lesion subsequently develop inguinal metastases. This statistic correlates with the previously noted 14% incidence of subsequent inguinal node metastases in patients initially thought to be free of nodal metastases but who on prophylactic node dissection are found to harbor micrometastases (49,55,170).

The importance of tumor volume in patients being considered for brachytherapy as contrasted to external beam therapy or teletherapy is paramount because patients with tumor volumes greater than 8 cm^3 are poor candidates for brachytherapy (241). If either form of radiation therapy is ineffective, partial or total amputation is effective in 90% to 100% of cases, provided the recurrence is promptly diagnosed. Complications from therapy are more common with interstitial than external beam therapy and include meatal stenosis in 15% to 30% of cases, urethral stricture in 20% to 35%, penectomy for complications of radiation in the absence of recurrent malignancy in 5% to 15% of cases, and telangiectasia and catarrhal reaction in almost all cases (55,66,247,256).

Comparison of the survival of patients whose primary lesions were initially treated by radiotherapy (either teletherapy of brachytherapy) with those treated surgically shows little overall survival advantage between radiotherapy and surgery as long as local recurrence is diagnosed and treated promptly. Even though this conclusion is based on nonrandomized studies and the decision whereby a given patient received either radiotherapy or surgical amputation is unstated, there is, for a given tumor stage, little difference in ultimate survival between radiotherapy and surgery of the primary lesion (Table 43.9). Partial or total penile amputation represents the most common initial form of therapy, although among patients with limited penile lesions, radiotherapy is a legitimate therapeutic consideration. Survival depends less on the type of therapy of the primary penile lesion than on the stage of the lesion at diagnosis. If radiation of the primary lesion fails to sterilize the cancer or if subsequent recurrence develops, amputation can be performed without compromising prognosis. Clearly, patients treated with radiotherapy merit a posttreatment biopsy to ensure disease sterilization.

Chemotherapy

Because bleomycin tends to accumulate in the skin, patients with penile cancer have been treated with it (116). In a study of patients treated with bleomycin, there was a 50% survival rate for up to 5 years; when bleomycin was combined with either surgical extirpation, radiotherapy, or both, 80%, 73%, and 72% of patients, respectively, survived for up to 5 years (116). In another study of 15 patients treated with bleomycin, a complete response rate of 20%, a partial response rate of 73%, and no response rate of 7% was noted, but 64% of patients required subsequent penile amputation for local control (139). The optimal response to bleomycin occurred in tumors confined to the glans or prepuce, in tumors that were well differentiated, in older patients, and in patients who received a total bleomycin dose smaller than 750 mg (139).

Selection of bleomycin as the primary treatment of penile cancer remains a challenge, and bleomycin's definitive role in managing this lesion is unclear. When combined with surgery, bleomycin may enhance local control while potentially minimizing the extent of surgery necessary (116). Combination therapy using bleomycin and radiation achieved complete remission of the local penile lesion in 93% of cases (62). Indeed, this combination provided a local cure rate that compared favorably with surgery, did not compromise survival, preserved function, and resulted in a 5-year survival rate for stage T_1 to T_2, N_0 lesions of 95% (62,183).

Mohs or Micrographic Surgery

Other approaches permitting retention of penile function include microscopically controlled (i.e., Mohs) micrographic surgery (180,271,295) and cryotherapy (154). Micrographic surgery using either the fixed or fresh tissue technique involves local excision of the primary tumor in layers, with histologic tracking of residual neoplastic elements ultimately separating malignant from adjacent nonmalignant tissue (180,185). The overall 5-year cure rate was 74%, and using Jackson's staging system, the rate was 86% in patients with stage I disease, 62% in patients with stage II disease, and 0% in patients with stage III disease (185). A local failure rate of 6% has been reported for Mohs technique, and tumor stage and grade, size of the primary lesion, and the failure of prior surgical or radiation therapy were important factors in predicting the effectiveness of Mohs surgery. The ultimate assessment of the effectiveness of chemosurgery in treating penile cancer awaits evidence of its reproducibility by others, but in appropriately selected cases, this therapy provides excellent local control while retaining penile function.

Laser Therapy

The Nd:YAG laser is effective in treating penile cancer while maintaining penile integrity, although laser therapy is reserved for small *in situ* or only microscopically invasive carcinomas (107,244,248,287,306). Cure rates of up to 100% were achieved in patients with CIS, but only 66% of patients with T_1 lesions achieved cure and a local failure rate of 6% to 22% has been reported (107,162). It therefore appears that for low-stage lesions, the Nd:YAG laser, and perhaps cryosurgery, can provide high cure rates while avoiding the deleterious effects of amputation or radiotherapy (182,255). However, additional studies are necessary before the therapeutic indications for the use of these therapies can be assessed. In addition, obtaining adequate representative tissue for a definitive histologic diagnosis before destruction of the primary lesion is essential, as is posttreatment biopsy to ascertain cure.

Quality of Life After Therapy of the Primary Lesion

Of the various therapies for the primary penile lesion, partial or total penectomy is generally associated with the lowest incidence of local recurrence. However, the impact of this procedure on the patients' emotional, interpersonal, and sexual quality of life is of concern, and studies addressing this matter are of interest (48,201,202 and 203). Studies by Opjordsmoen and Fossa (201) concluded that patients undergoing amputation (partial or total) had a poorer outcome with regard to sexual function than patients undergoing organ-sparing procedures, while in other parameters of quality of life measured (e.g., well-being or social and mental symptoms), no differences were apparent. Moreover, mental symptoms, primarily anxiety and depressive disorders, have been well documented in patients with penile cancer, but it appears that this is due to the disease itself and not the type of therapy selected (201). In contrast, the study of D'Ancona and associates (48) found that sexual function in patients undergoing partial amputation was normal or slightly diminished in 64%, male self-image and relationships with their partners unchanged, sexual interest and satisfaction normal, and in 64%, frequency of intercourse unchanged. However, reasons for the difference in findings regarding sexual functioning between the studies of Opjordsmoen and Fossa and those of D'Ancona and associates are unclear.

Definitive Therapy of Regional Lymph Nodes

Therapeutic approaches to the regional lymph nodes in patients with penile cancer have included lymphadenectomy, external beam radiotherapy, and a combination of lymphadenectomy with either preoperative or postoperative radiotherapy (6,11,66,108,206,236).

Lymphadenectomy

Following definitive treatment of the primary lesion, lymphadenectomy should be deferred for 6 to 12 weeks, during which time a course of antibiotics is administered to permit coexisting inflammatory and/or infectious lymphadenitis to resolve. This approach has not led to any reports of clinically resectable lesions becoming unresectable and has the advantage of reducing the incidence of wound infection while providing opportunity for expectant management should the inguinal adenopathy resolve (75).

Patients in whom palpable nodes fail to resolve, in whom nodes enlarge while under observation, or in whom lymph nodes previously impalpable become palpable should undergo therapeutic lymphadenectomy.

The survival of patients with nodal metastases is about half that of patients free of such metastases, and when patients with node-positive disease are stratified as to the extent of nodal metastases, tumor burden correlates with survival (Table 43.10); early removal of microscopic nodal disease can improve survival (150,309). It has been shown that among patients with initially clinically negative nodes and in whom nodal metastases subsequently develop, a high cure rate is achieved by prompt lymphadenectomy, in contrast to patients in whom the treatment of nodal metastases is delayed (70,71). In comparison to therapeutic lymphadenectomy, the indications for prophylactic lymphadenectomy are less certain and the lymph nodes of up to 75% of patients undergoing prophylactic lymphadenectomy have been found to be free of metastases. The size of the primary lesion; its grade; and the presence or absence of venous, lymphatic, or corporal invasion are predictive of nodal status and identify potential candidates for prophylactic lymphadenectomy (1,2,42,108,147,174). Because the morbidity of even modified lymphadenectomy is not inconsequential, close surveillance of patients with clinically negative lymph nodes has been recommended (1,247,276).

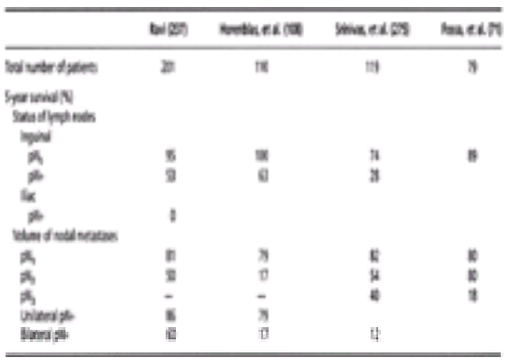

TABLE 43.10. EFFECT OF THE PATHOLOGIC STATE OF REGIONAL LYMPH NODES AND THEIR STRATIFICATION ON THE 5-YEAR SURVIVAL RATE OF PATIENTS WITH CARCINOMA OF THE PENIS

Paradoxically, the absence of nodal metastases in patients undergoing prophylactic lymphadenectomy does not ensure cancer-free survival, and the 5-year survival of such patients ranges from 71% to 95% (6,11,123,137,144,146). The reasons for failure in such cases include inguinal recurrence, perineal recurrence, or distant metastases (206,224,236,309). The interval during which lymph nodes initially thought to be benign subsequently manifest metastases is such that 50% occur within 16 months of treatment of the primary lesion and 75% within 34 months, with nodal metastases only rarely appearing beyond 5 years of initial diagnosis of the primary lesion (1,107,205,206,274). Of patients who die after treatment of penile cancer, 92% to 97% do so within 5 years (65).

The advantage of prophylactic inguinal lymphadenectomy in patients with clinically negative (cN_0) lymph nodes is that if nodes are found to be involved pathologically (pN+), survival is somewhat superior to that for patients in whom nodes initially are clinically negative but then become positive and in whom lymphadenectomy is then performed (206,237). In addition, prophylactic lymphadenectomy may identify a cohort of pN+ patients with a tumor burden lower than that of patients undergoing therapeutic lymphadenectomy. Patients who are found to have limited nodal disease appear to have a prognosis superior to that for patients with larger tumor burdens (Table 43.11). Patients who are poorly compliant with the close follow-up needed in expectant management regimens and patients whose inguinal areas are difficult to evaluate are better served by prophylactic lymphadenectomy.

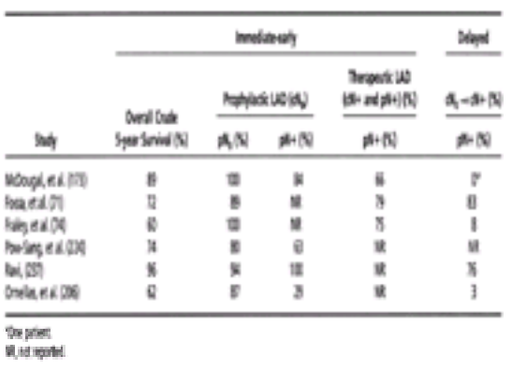

TABLE 43.11. FIVE-YEAR SURVIVAL OF PATIENTS WITH CARCINOMA OF THE PENIS STRATIFIED ACCORDING TO TIMING OF PERFORMANCE OF LYMPHADENECTOMY (LAD) AND NODAL STATUS

Radiotherapy

A 5-year survival rate of 30% among patients with penile cancer who were believed to have inguinal node metastases on clinical examination and who received radiotherapy has been reported. However, in patients treated by radiotherapy, the true histologic nodal status is unknown and nodes clinically suspicious for metastases may not in fact contain metastases. This results in a spuriously high cure rate for patients receiving nodal radiotherapy because an unknown number of individuals clinically thought to have nodal metastases (cN+) in fact do not (pN_0). Based on other studies, if we assume that only 50% to 60% of patients with clinically suspicious lymph nodes actually contain metastases, the ability of radiotherapy to control nodal metastases might actually approach only 15%. In addition, prophylactic radiation of the regional nodes in patients with clinically negative nodes (cN_0) did not prevent 25% of individuals with stage I disease from developing nodal metastases (65,190). This convincingly indicated that radiotherapy is of minimal therapeutic value in treating even low-volume nodal disease because 14% of patients with clinically negative nodes are known to develop nodal metastases and 18% of patients with clinically negative nodes who undergo prophylactic lymphadenectomy are found to have occult metastatic disease (15,53,94,237,297).

Systemic Chemotherapy for Metastatic Disease

Reports of systemic chemotherapy in treating metastatic penile carcinoma (Table 43.12) are generally based on relatively few patients; often involve a combination of therapies; lack controls, randomization, and statistical analysis; and have inconsistent follow-up (4,64,77,128,156,220,269). Despite these limitations, results of single-agent and combination chemotherapy have been reported using agents such as bleomycin, methotrexate, cisplatinum, vincristine, and 5-FU. Moreover, these agents have been used either in a therapeutic setting for established metastases, as neoadjuvant therapy in an attempt to increase resectability of nodal metastases, or as an adjunct following lymphadenectomy for pathologically proven metastases (Table 43.12).

Agent(s)	No. of Patients	Site of Metastases	Response (%)			Range of Response Duration (mo)	Reference
			Complete	Partial	None		
Single-agent Therapy							
Methotrexate	22	Nodes, bone, lung, skin	10	45	45	2–17	Ahmed et al., 1984; Garnick et al., 1979; Shirodkar and Sagdeo, 1979

TABLE 43.12. CHEMOTHERAPY IN THE TREATMENT OF METASTATIC PENILE CANCER

Table 43.12 indicates objective response rates for the single agents bleomycin, methotrexate, and cisplatinum and for a variety of combinations, including these agents and vincristine, although the reported duration of such responses varies. Paradoxically, bleomycin, shown to be effective in treating the primary penile lesion of squamous cell carcinoma of the penis, appears to be relatively ineffective when used alone in the treatment of metastatic disease, and development and use of other agents and of combinations of existing agents is warranted (91,116). Of note is the combination bleomycin, methotrexate, and either vincristine or cisplatinum in the neoadjuvant setting, rendering resectable 66% of patients with unresectable inguinal nodes (82). Also of note is the response of nodal metastases to the combination of methotrexate and bleomycin followed by radiotherapy (3). The combination of cisplatin, methotrexate, and bleomycin in a phase II study showed a response rate (complete or partial) of 32.5% (91). The intensity of this regimen, however, was such that 12.5% of patients died related to their treatment and 17% of patients had one or more life-threatening toxic episodes (91). Recently, a phase I study of several types of squamous cell carcinoma, including penile cancer, has been reported using etretinate and interferon-a based on the concepts of promoting differentiation of malignant cells as well as inhibiting proliferation (246).

When used as an adjuvant to ilioinguinal lymphadenectomy, the combination of vincristine, bleomycin, and methotrexate has produced a complete response rate of 92%, although duration of follow-up has varied. Even though cure has not been documented and a comparative group of patients undergoing only lymphadenectomy not studied, it is noteworthy that approximately 40% of the patients studied had positive pelvic nodes, a uniformly poor prognostic finding (220). Aggressive combination chemotherapy for metastatic disease appearing subsequent to lymphadenectomy, or in association with lymphadenectomy in patients at risk for dissemination (e.g., those with positive pelvic lymph nodes or with high-volume inguinal nodal disease), or in the neoadjuvant setting may be a legitimate therapeutic approach (64).

Technique of Ilioinguinal Lymphadenectomy

The term *inguinal lymphadenectomy* refers to removal of the superficial and deep inguinal and subinguinal lymph nodes, with the superior limit of dissection being approximately 2 cm above the inguinal ligament; the lateral margin of dissection being the sartorius muscle; the medial margin, the adductor longus; and the distal margin, the apex of the femoral triangle. Pelvic (iliac) lymphadenectomy includes extirpation of the common, external, and internal iliac lymph nodes and obturator nodes (111).

Preoperative Preparation

Ilioinguinal lymphadenectomy requires that the patient be in optimal metabolic condition, and the frequently coexisting regional lymphadenitis should have been treated with appropriate antibiotics before surgery. We suggest delaying regional lymphadenectomy for 6 to 12 weeks after excision of the primary lesion, during which time antibiotics are administered to sterilize any nodal infection because such infections at the time of lymphadenectomy will compromise wound healing.

Optimal preoperative hydration and nutritional status should be established before surgery and an infusion of Ringer's lactate solution and preoperative prophylactic antibiotics begun 12 hours before the procedure. In addition, the use of mini-dose heparin should be considered as a possible strategy to reduce embolic events and small-vessel thrombosis with consequent necrosis of skin flap margins.

Inguinal lymphadenectomy is initially performed, and because of crossed lymphatic drainage, bilateral dissection is preferred. Pelvic lymphadenectomy is not done prophylactically but is performed only if inguinal lymph nodes are positive for cancer.

Position

The patient is placed in the supine position with the legs abducted at the thigh, flexed at the knee, and externally rotated, with appropriate padding used. The scrotum and the penis are draped out of the operative field. To facilitate the pelvic dissection, a sacral roll may be placed.

Incision

A variety of incisions for ilioinguinal lymphadenectomy have been described, and these are outlined in Fig. 43.9. We currently favor a suprapubic midline incision for bilateral pelvic lymphadenectomy combined with bilateral curvilinear, somewhat oblique groin incisions 1 cm inferior to the inguinal ligament extending from below and medial to the anterior superior iliac spine and sufficiently medial to allow ample exposure of the femoral triangle (Fig. 43.10).

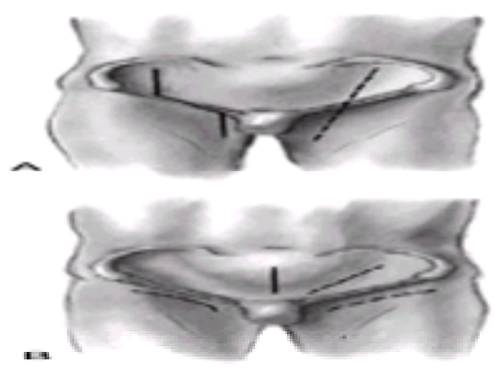

FIGURE 43.9. Incisions employed for ilioinguinal lymphadenectomy. **A:** Combined incisions for pelvic and inguinal lymphadenectomy. **B:** Skin bridge techniques. Lymphadenectomy should be deferred until all evidence of lymphadenitis has resolved. Irrespective of the incision selected, excessive thinning of the skin margins, and dessication of flaps should be avoided.

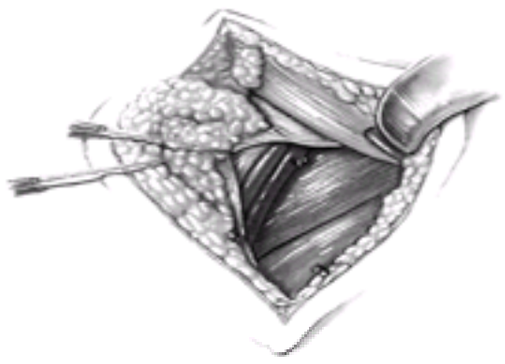

FIGURE 43.10. The skin flaps for the inguinal dissection have been developed and the medial margin of resection defined. The great saphenous vein has been ligated at its junction with the femoral vein, and the lymphatics emerging from beneath the inguinal ligament through the femoral canal are illustrated.

Inguinal Lymphadenectomy

After the incision has been made, skin flaps are raised and elevated laterally toward the sartorius, medially to the adductor longus, cephalad 2 cm above and parallel to the inguinal ligament, and caudally to beneath the apex of the femoral triangle. The skin flaps are made approximately 3 to 4 mm in thickness at their edges but can be thicker at their base in an effort to prevent flap necrosis. During dissection, the skin edges should be protected and kept moist, and the flaps should be handled atraumatically (Fig. 43.10).

The fascia lata is incised and reflected from the adductor longus and pectineus and sartorius muscles. Excision of the node-bearing tissue may be initiated superiorly and the fibrofatty node-bearing tissue dissected from under and above the inguinal ligament.

Superiorly, the adipose tissue is dissected off the surface of the external oblique aponeurosis down to the inguinal ligament and from the spermatic cord just distal to the superficial inguinal ring. As the dissection continues, the sheath of the femoral vessels is incised, the vessels exposed, and the surrounding node-bearing tissue resected. Approximately 2.5 cm below the inguinal ligament, at its junction with the femoral vein, the great saphenous vein is ligated and divided (Fig. 43.10). If possible, the great saphenous vein should also have been identified distally at the inferior aspect of the dissection and previously ligated and divided (Fig. 43.11).

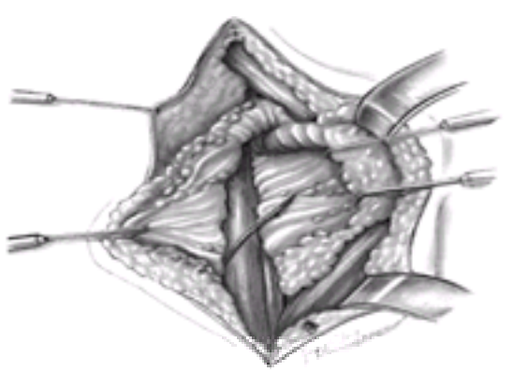

FIGURE 43.11. The lateral aspect of the inguinal dissection, the sartorius muscle, is shown. The fascia lata has been incised and reflected medially with the specimen, and the distal extent of dissection, the apex of the femoral triangle, is also shown. The lateral femoral cutaneous nerve should be preserved if possible. Dissection posterior to the femoral vessels is unnecessary and risks damage to the deep femoral vessels.

As the dissection of the femoral artery proceeds, the deep femoral artery should be identified and preserved, and particular care taken to prevent injury to the femoral nerve, which is lateral to the femoral artery. At the lateral aspect of the dissection, the lateral margin of the sartorius is exposed and the lateral femoral cutaneous nerve preserved as it emerges from under the inguinal ligament and courses anterior to the sartorius under the fascia lata (Fig. 43.11). The inguinal dissection should extend distally to the apex of the femoral triangle. Dissection posterior to the vessels is unnecessary and risks injury to the deep femoral artery.

Pelvic Lymphadenectomy

When, pelvic (iliac) lymphadenectomy is performed, en bloc nodal resection has been recommended; however, we believe this is not essential because such dissection is unnecessarily tedious and the pelvic and inguinal dissections can be completed separately, provided that all nodal tissue posterior to the inguinal ligament is excised (52).

Following retroperitoneal exposure of the iliac vessels and identification of the ureter, dissection is initiated at the origin of the common iliac vessels and extended distally to encompass the perivascular fibrofatty node-bearing tissue surrounding the common, external, and internal iliac vessels and the obturator vessels and nerve (Fig. 43.12). The pelvic lymphadenectomy performed in connection with penile cancer should extend somewhat more distally than that performed for prostatic or vesical carcinomas because of the importance of clearing the femoral canal of lymphatic tissue (Fig. 43.13). Indeed, relevant nodal tissue is located adjacent to the terminal portion of the external iliac vessels under the inguinal ligament, and in some cases, division of this ligament with subsequent repair lateral to the femoral artery is essential for adequate excision of nodal tissue. For closure, the sartorius muscle is separated from its origin, and the entire thickness of the muscle is reflected medially, with care taken to preserve its blood supply. The sartorius is then transposed to cover the femoral vessels by suturing it to the inguinal ligament over the femoral artery and vein (Fig. 43.14). In contrast, if extensive excision of a fixed mass results in a defect too large to close, primarily myocutaneous flaps, revascularized free flaps, or as recently described, use of a skin-stretching device is effective (177,286). The inguinal ligament and falx inguinalis are then sutured to Cooper's ligament laterally to close the potential hernia space in the femoral canal.

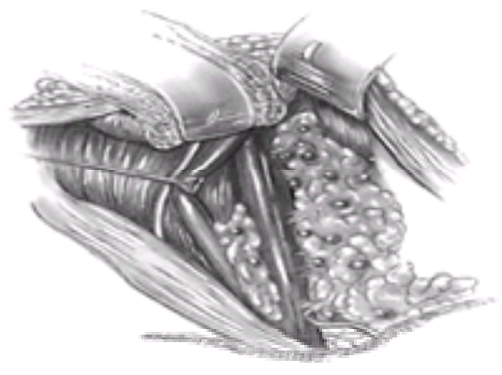

FIGURE 43.12. The area of the iliac vessels has been exposed retroperitoneally, the peritoneal contents retracted cephalad and medially, and the ureter identified and protected. Shown here is the fibrofatty node-bearing tissue being removed from the external and common iliac arteries, with the iliac vessels and obturator fossa yet to be exposed. Metal clips may be used to secure small vessels and lymphatics.

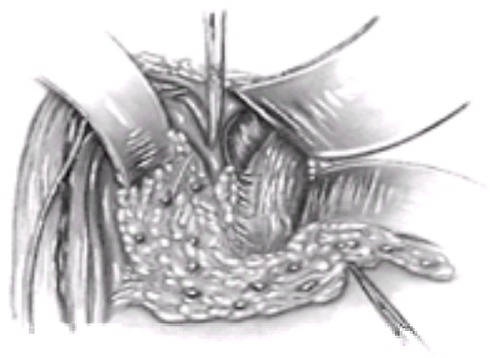

FIGURE 43.13. The node-bearing tissue is being dissected from the hypogastric vessels and the obturator artery thereby exposed. The dissection is continued and the obturator nerve isolated. At the conclusion of the pelvic dissection, the iliac vessels and obturator nerve are skeletonized.

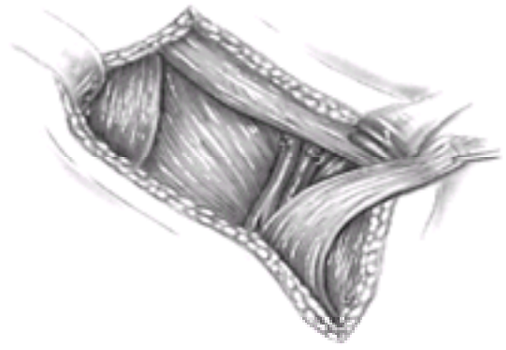

FIGURE 43.14. The sartorius muscle has been sharply detached from its origin, with care taken to preserve its vascular supply, which enters the muscle posteriorly and approximately 10 cm below its origin. The sartorius is mobilized only enough to allow it to be placed over the femoral vessels. The free end of the sartorius is sutured to the inguinal ligament over the femoral artery and vein with interrupted nonabsorbable sutures. Similarly, the lateral edges are secured to adjacent muscle.

The edges of the skin flaps are resected for approximately 3 to 4 mm because redundancy of the skin flaps often occurs as a result of dissection; the flaps are then anchored to the underlying muscle to close potential dead spaces. Hemostasis must be meticulous. Suction catheters are placed under the flaps to include both proximal and distal flaps, and the skin edges are approximated after excising any tissue of questionable viability.

Postoperative Care

Suction catheters are maintained until all drainage ceases, and the patient is kept at bed rest to facilitate this. Support stockings are valuable, and the recommendations of Karakousis and co-workers (126) should be followed to reduce the incidence of postoperative complications. The complications following inguinal or ilioinguinal lymphadenectomy and, in some cases, the debilitating long-term consequences of this procedure, coupled with less-than-unequivocal evidence for the therapeutic value of prophylactic lymphadenectomy, accounts for the hesitancy of some investigators to recommend “prophylactic” lymphadenectomy in patients with clinically negative nodes. Ilioinguinal lymphadenectomy has been associated with a mortality rate of 1% to 3% and a morbidity rate of 30% to 50%. Table 43.13 summarizes the types and incidence of complications following ilioinguinal lymphadenectomy based on several studies (15,27,122,138,142,302).

TABLE 43.13. INCIDENCE OF POSTOPERATIVE COMPLICATIONS FOLLOWING THERAPEUTIC LYMPHADENECTOMY IN PATIENTS WITH PENILE CARCINOMA

Use of the sartorius muscle to cover the femoral vessels has sharply reduced femoral vessel hemorrhage as a source of postoperative mortality (302). Of concern, however, is skin flap necrosis, which occurs in approximately 20% of cases, and incapacitating edema, which occurs in 11% (Table 43.13). Modifications in the surgical technique of inguinal lymphadenectomy, including use of selected incisions, careful flap development, trimming of flaps, prophylactic antibiotics, suction drainage, postoperative elastic support, and leg elevation, have produced a 50% reduction in the incidence of flap necrosis severe enough to require grafting and the elimination of severe incapacitating edema (40,126).

Prognostic Factors

Several factors have been evaluated as potential prognostic markers, including the presence or absence of inguinal or pelvic node metastases, vascular (i.e., lymphatic or venous) invasion, volume of nodal metastases, tumor size, depth of invasion, tumor grade, tumor ploidy, tumor growth pattern, S-phase fraction, location of lesion on penis, and patient age and symptoms (1,90,92,98,105,148,206,225,256,10). On univariate analysis, the prognosis for survival has been correlated with the size of the primary lesion, nodal status, tumor grade, and presence or absence of corporal invasion (104,274). Interestingly, on multivariate analysis, the size of the primary lesion was excluded but nodal status, tumor grade, and presence or absence of corporal invasion were found to be independent prognostic factors (105,274). Factors that show no consistent relationship to prognosis include duration of symptoms before diagnosis, patient age at diagnosis, and race (147,184).

Other Epithelial Malignancies of the Penis

Basal Cell Carcinoma of the Penis

Basal cell carcinoma is among the most common malignancies of humans, and because it typically occurs in areas exposed to ultraviolet radiation, it is not surprising that this lesion only rarely occurs on the penis and that only 0.25% of all basal cell cancers occur on the penis. The average age at diagnosis is 58 years, and circumcision has no influence on reducing the risk of developing this lesion. Of these lesions, 60% occur on the shaft, 23% on the prepuce, and 17% on the glans (84). The lesion usually presents as a nodule or scaly plaque, has a limited risk of metastases, and is usually only locally invasive. Indeed, in two-thirds of cases reported, local excision is curative, and in another 20%, radiotherapy appears to have been effective. However, in cases unresponsive to or unsuitable for

organ-sparing therapy, partial or total penectomy may be necessary (84).

Primary Melanoma of the Penis

Primary melanoma of the penis is rare and can arise on the glans, foreskin, or shaft. The average age at diagnosis is the sixth or seventh decade of life, which is older than the age at diagnosis of melanomas in other sites. Moreover, in contrast to squamous cell cancer, melanoma is rare in African Americans (163). The lesions vary in gross appearance from blue, black, or red to brown; they may ulcerate and most commonly arise *de novo,* although transformation of preexisting lesions has been noted (234,281). Because of the limited number of cases reported, a simplified staging system has been proposed: stage I, localized to the penis; stage II, metastatic to the regional lymph nodes; and stage III, distant dissemination (25). However, this staging system ignores two other critical prognostic factors in penile melanoma: (a) the thickness of the primary lesion, because lesions less than 1.0 mm in thickness have a more favorable prognosis than thicker lesions; and (b) the level of invasion of the primary lesion, although the thinness of the penile skin may facilitate early dissemination (191).

As in squamous cell cancer of the penis, diagnosis is often delayed and 40% to 60% of patients first present with nodal metastases (stage II or III disease) (16).

The rarity of this lesion is such that meaningful survival figures cannot be derived; indeed, therapy for the potentially most curable (stage I) lesion is subject to debate. Some investigators conclude that for clinical stage I lesions, particularly those less than 1.5 mm in thickness, partial amputation with a 3- to 5-cm tumor-free margin is appropriate and that prophylactic regional lymphadenectomy is of no value. If the primary lesion is greater than 1.5 mm in thickness, bilateral superficial inguinal lymphadenectomy is appropriate, even in the absence of palpable adenopathy (281). Others, however, have advocated performance of a total penectomy with perineal urethrostomy and radical ilioinguinal lymphadenectomy for all stage I lesions, although even with this approach inguinal recurrences have been reported (25,28). For clinical stage II disease, partial penectomy, if possible, and regional lymphadenectomy are appropriate; however, because of the high incidence of coexisting occult distant metastases and the fact that in melanoma, compared with squamous cell cancer, the regional nodes are less effective as barriers to dissemination, the prognosis is worse than that for similarly staged squamous cell cancer (281). Finally, in stage III disease, because of the absence of truly effective systemic therapy for melanoma, regional lymphadenectomy is recommended for palliation (281). The prognosis of primary penile melanoma is poor because of the occurrence metastatic disease.

Primary Lymphoma

Primary extranodal lymphoma of the penis, where the penis appears to be the sole site of lymphoma, is also rare. Because later nodal disease may develop and because the lesion is responsive to chemotherapy or radiotherapy, partial or complete amputation is rarely, if ever, indicated (166).

Primary Sarcomas of the Penis

Primary soft tissue or mesenchymal malignancies (i.e., sarcomas) of the penis are rare, with putative origin from one of several cell types: endothelial neural, muscular, or fibrous (50). Malignant neoplasms of endothelial origin consist of angiosarcomas (hemangiosarcoma, endothelioblastoma, and malignant hemangioendothelioma), which arise *de novo* or are radiation induced and which tend to occur on the penile shaft, and Kaposi's sarcomas, which occur most commonly on the glans (141,227,282,290). Sarcomas arising from neural elements of the shaft or glans consist of malignant schwannomas (neurofibrosarcomas) and clear cell cancers of neuroectodermal origin. Those of myogenic origin demonstrate features of either smooth muscle (leiomyosarcomas) (Fig. 43.15) or striated muscle (rhabdomyosarcomas), with the latter occurring in children (46,50). Finally, malignancies of fibrous tissue origin include fibrosarcomas, osteogenic sarcomas, fibrous histiocytomas, and epithelioid sarcomas (63,112,213,223). Although the rarity of the various sarcomas of the penis—with the possible exception of Kaposi's sarcoma, particularly in patients with AIDS—makes generalizations difficult, it seems that such lesions tend to occur at an earlier age and to present as a mass as either nontender (70%) or tender (30%) (50). Because many of these lesions may be only locally invasive and indolent in growth, assessment of their extent with ultrasound or MRI is reasonable because organ-sparing therapy may include excision, radiation therapy, or chemotherapy, although in some cases partial or total amputation is necessary (50,79,233).

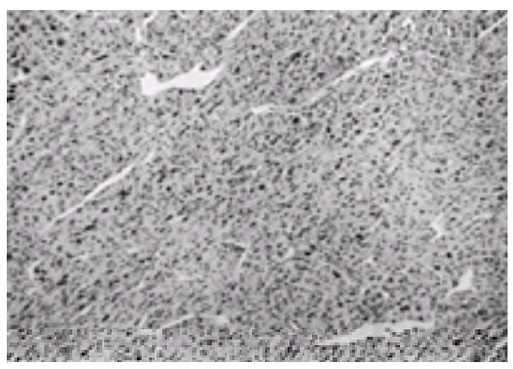

FIGURE 43.15. Leiomyosarcoma. Note the interlacing bundles of smooth muscle cells with cigar-shaped nuclei and elongated, wavy cytoplasmic processes (×240).

Metastases to the Penis from Other Primary Lesions

Although the penis is an unusual site for metastatic disease, metastases to the penis are well documented and those from other organs occur 50 times more commonly than those of lymphohematologic origin (19,216,223). Of metastatic neoplasms to the penis, approximately 30% arise from the prostate, 30% from the bladder, 16% from the rectosigmoid, 11% from the kidney (usually the left kidney), 4% from the testis, and the remainder from a diversity of other sites (30,117,249). Among patients with metastatic carcinoma to the penis, the diagnosis of penile metastases occurs simultaneously with that of the primary lesion in one-third of cases, within 2 years of diagnosis of the primary lesion in another one-third, and after 2 years in the remainder. In prostate and bladder cancer patients, the average interval between diagnosis of the primary prostatic or vesical lesion and that of the penile metastases is 33 to 36 months (17). In 80% of patients with metastases to the penis, evidence of additional metastatic sites is found, and in 20%, the penis appears at least initially to be the only site of metastases. Metastases to the penis have been reported to occur by either direct extension, by retrograde venous or lymphatic flow, or by embolization. Metastases are reported to occur, in order of diminishing frequency, in the corpora cavernosa (30%), the glans (20%), the corpora cavernosum and spongiosum together (10%), or in some combination of these sites (40%) (17,223). So-called malignant priapism, produced by neoplastic infiltration of the corpora cavernosa or by compression of the dorsal vein, may be complete, partial, or tumefactive (17,223). In addition, urinary retention secondary to invasion of the urethra occurs in one-third of patients, and swelling, multiple nodules, or a mass that might mimic Peyronie's disease occurs in another one-third (17). Diagnosis of metastases to the penis is based on history and physical examination and is confirmed by biopsy (core biopsy or fine-needle aspiration biopsy) (270). Although the extent of penile metastases may be determined by cavernosography, CT, ultrasound, or MRI is more effective.

The therapy for metastatic disease to the penis depends primarily on the nature and prognosis of the primary lesion and is generally palliative. Local resection or excision or, if this is not possible, partial or total amputation, is particularly effective in relieving symptoms, especially those of urinary obstruction or pain. However, radiotherapy, chemotherapy, and hyperthermia in combination with radiotherapy have been beneficial (19,189). In most cases, development of disease metastatic to the penis is a poor prognostic sign, with more than 50% of such patients dying within 6 months. However, 40% may live longer than 6 months and 20% longer than 12 months, with most of these patients having the primary lesion in the genitourinary tract (17,189,223).

Cutaneous Lesions of The Penis
Pearly Penile Papules
Angiokeratomas
Venous Lakes
Angiolymphoid Hyperplasia with Eosinophilia
Verruciform Xanthoma
Lichen Sclerosus Et Atrophicus
Psoriasis
Lichen Planus and Lichen Nitidus
Dermatitis Venenata
Balanitis
Fixed Drug Eruptions
Cysts of the Penis
Tuberculosis of the Penis
Elephantiasis of the Penis
Scabies
Penile Tumors
Pseudoepitheliomatous, Keratotic, and Micaceous Balanitis
Bowenoid Papulosis
Erythroplasia of Queyrat
Giant Condylomata Acuminata
Acknowledgment
Chapter References

A spectrum of benign premalignant and malignant lesions of the external genitalia, particularly the penis, has been reported. In the following section, the common cutaneous lesions of the penis are described. Benign, premalignant, and malignant lesions of the penis are presented in the succeeding section. Important, unusual dermatologic lesions also are presented.

CUTANEOUS LESIONS OF THE PENIS

Pearly Penile Papules

Pearly penile papules are asymptomatic dome-shaped papules on the coronal margin and sulcus (Fig. 44.1 and Fig. 44.2). Histologically, vascular networks are surrounded by dense connective tissue (2,67). No therapy is required.

FIGURE 44.1. Pearly penile papules are dome-shaped on the coronal margin and sulcus. See also Color Figure 44.1.

FIGURE 44.2. Dome-shaped pearly penile papules on the coronal margin.

Angiokeratomas

Traub and Tolmach (128) presented a comprehensive study of the literature in reporting a case of angiokeratoma of Mibelli, noting that “angioma plus keratosis does not constitute angiokeratoma of Mibelli, for an angiokeratoma of Mibelli is not an angioma; the condition is merely an alteration in the blood vessels associated with hyperkeratosis of the epidermis.” Although Mibelli's cases had a predilection for the hands, feet, and elbows and had a previous history of pernio, Fordyce reported cases of the scrotum; cases of angiokeratomas in atypical locations are reviewed by Traub and Tomach (128) (Fig. 44.3 and Fig. 44.4).

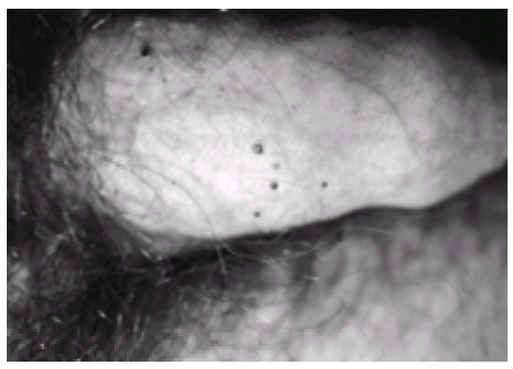

FIGURE 44.3. Violaceous and erythematous papules with variable scaling located on the scrotum. See also Color Figure 44.3.

FIGURE 44.4. *Candida albicans* as a secondary infection on moist papules on the glans penis. See also Color Figure 44.4.

Imperial and Helwig (61) reported the clinicopathologic findings in a review of 35 cases of angiokeratoma of Fordyce. The combined features of angiokeratomas are (a) marked vascular dilation of the papillary vessels, forming a large lacuna in the papillary region of the dermis; (b) acanthosis and elongation of the rete ridges encircling vascular lacunae, suggesting the formation of a blood cyst; (c) an intimate vascular and epidermal relationship; (d) moderate to marked hyperkeratosis; and (e) a direct communication between the vascular cystic paces in the dermal papilla and the dilated veins in the deeper dermis. The cause of angiokeratomas is unknown, but two-thirds of the patients reported had a history of venous obstruction (4,108).

Venous Lakes

Venous lakes have been reported on the glans penis (72). Clinically, these lesions are dark blue, but pressure removes most of the blood, leaving a reddish color. Histologically, the lakes have thin walls, little muscle tissue, and mostly, a single cell layer of endothelium. They lack elements that make them spontaneously contractile. Therapy can include local excision or destruction by desiccation (72). Sclerotherapy has been reported for other vascular blemishes but not specifically for venous lakes, and argon or tunable dye laser surgery has been used with success in the treatment of venous lakes (16). The differential diagnosis may include lymphangiomas (Fig. 44.5).

FIGURE 44.5. Lymphangioma resembling papules of Fox-Fordyce. Erythematous papules on the shaft and scrotum. See also Color Figure 44.5.

Angiolymphoid Hyperplasia with Eosinophilia

Wells and Whimster (134) first suggested angiolymphoid hyperplasia with eosinophilia as a distinct pathologic entity in a study of nine patients, and Rao and associates (105) first reported a case occurring on the penis. This is a benign condition that may persist for years. The nodules are predominantly in the subcutaneous tissue; however, some may enter into the dermis or underlying muscle fascia or muscle. They are unencapsulated masses of angiolymphoid hyperplasia with four components: (a) exuberant proliferation of capillary vessels, frequently canalized masses of endothelium; (b) massive infiltration of eosinophils and increased numbers of mast cells; (c) reticulin formation but little fibrosis; and (d) lymphoreticular hyperplasia, increasing with duration, and often lymphoid follicle formations in lesions of 1 year's duration or more.

Epithelioid hemangioma is probably a variant of angiolymphoid hyperplasia with eosinophilia (122). Ultrastructural studies and immunohistochemical analysis for factor VIII–related antigen and ulex europaeus agglutinin I demonstrated that the lesions were of endothelial origin.

The differential diagnosis may include eosinophilic granuloma, lymphocytoma and follicular lymphoma, atypical pyogenic granuloma, angiomatous lymphoid hamartoma, persistent reactions to insect bites, and eosinophilic lymphofolliculosis of the skin, or Kimura's disease (134).

Verruciform Xanthoma

Verruciform xanthoma was described initially as an oral lesion either normal or reddish in color or sometimes pale or “hyperkeratotic,” having a rough, pebbly surface with either a sessile or pedunculated base (114); however, this lesion also occurs on the penis (41,73,81). Verruciform xanthoma is a rare benign tumor. The differential may include verrucous carcinoma, wart, squamous cell carcinoma, and seborrheic keratosis. Serum triglycerides, cholesterol, and glucose determinations usually are normal. (33,91,92,129).

Histologically, the squamous epithelium reveals hyperkeratosis, acanthosis, and parakeratosis (73,110). The upper dermis contains a diffuse collection of round cells with abundant cytoplasm and a centrally located, small vesicular nucleus. Electron microscopic studies (110) reveal histiocytes distended with lipid vacuoles of various sizes and electron density (110). Treatment is usually by conservative excision.

Lichen Sclerosus Et Atrophicus

The characteristic lesion of lichen sclerosus et atrophicus (LSA) is an irregular, often polygonal, flat, ivory-colored lesion (Fig. 44.6). The lesion may be topped by whitish papules that can be slightly elevated, with a rosy or moderately pigmented zone around the lesion. These papules may coalesce to form a plaque, but in general the outline of the indurated papules can be determined. Each papule has on its shiny, smooth surface one to several black or dark, horny, comedo-like plugs, or minute, beadlike depressions, which show the former sites of horny plugs. As atrophy occurs, the keratotic plugs or central delling becomes more prominent. At times, keratotic plugging is formed only histologically, not clinically. At end stage, a white parchmentlike wrinkling may occur (Fig. 44.7).

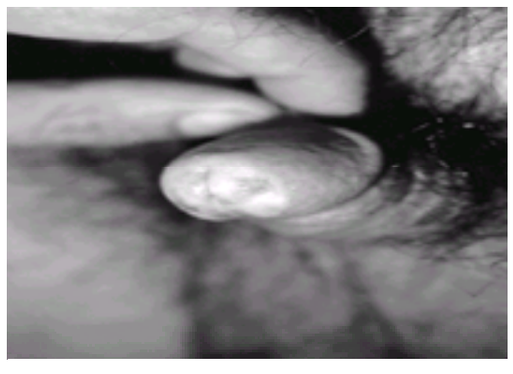

FIGURE 44.6. Progressive circumferential sclerosis at the meatus in lichen sclerosus et atrophicus (can lead to stenosis). See also Color Figure 44.6.

FIGURE 44.7. End-stage stenosis is present on glans with parchmentlike atrophy.

LSA occurs at any age, with the average age being 50 years, although it is reported to be associated frequently with phimosis in boys and in the elderly (9,24,27,36,55,107). All races appear to be affected (62). The cancer risk in childhood is low but is suggested to be 5% in women (79). LSA is less common in circumcised males (131) and is the most common indication for circumcision in children (107). Anal stenosis has been reported in association with LSA (118).

Histologically, the earliest lesions demonstrate papillary dermal edema, with flattening of the rete ridges and papillary bodies and separation of elastic tissue from the papillary bodies of the epidermis. There is a superficial perivascular infiltrate predominantly composed of lymphocytes, which may be sparse or dense. With progression, lesions may demonstrate a variable degree of inflammation in the middermis, at times bandlike in formation. The epidermis shows hyperkeratosis with atrophy and keratotic plugging of dermal appendages. There is increased papillary edema with vacuolar formation at the dermal–epidermal junction and, on occasion, liquefaction necrosis suggestive of lichen planus. There may be subepidermal bullae with edema of the papillary dermis.

Ultrastructure studies of lichen planus–like lesions show normal dermal collagen fibers in contrast to idiopathic lichen planus, in which fibers were referred to as *thin* or *beaded* (84).

LSA has been reported to occur following radiation therapy and also may occur as an isomorphic response (135). Organ-specific antibodies found in patients with LSA suggest an autoimmune process (47).

LSA of the penis may not induce malignancy but has been reported in association with penile malignancies (13,32,132). Early circumcision has been suggested to possibly prevent the development of LSA (39,77).

Therapy for LSA has included surgical excision (when feasible) with the involvement of the glans penis (138). Intralesional and sublesional injection of corticosteroids also may be effective (20).

Psoriasis

Psoriasis is a familial papulosquamous disease that frequently involves the glans penis, similar to lichen planus and lichen nitidus. Individual papules or coalescent plaques can be present (29,48) (Fig. 44.8). Most often, therapy is the use of less potent topical corticosteroids (29).

FIGURE 44.8. Typical erythematous psoriatic papules on the glans penis and sulcus. See also Color Figure 44.8.

Histologically, there is acanthosis of the epidermis with elongation of the dermal papillae, increased mitosis in the basal zone, an absent or diminished stratum granulosum, and microabscesses of polymorphonuclear leukocytes in the epidermis. The dermal infiltrate is composed primarily of lymphocytes and histiocytes.

Patients undergoing phototherapy for psoriasis with oral 8-methoxpsoralens and ultraviolet A radiation (UVA, PUVA) have been reported to have an increased risk of developing penile and scrotal tumors (119,123). There is a divergence of opinions comparing the European, Japanese, and American experience relating to the

development of cutaneous carcinomas (123).

A modified Goeckerman regiment using tar preparations before ultraviolet B radiation (UVB) has been suggested as a promoter of carcinogenesis initiated by coal tar (86,120). Other possible factors as cocarcinogens with PUVA are ionizing radiation, arsenic, history of skin cancer, methotrexate, and other immunosuppressives.

Appropriate shielding of the genitalia is recommended before PUVA therapy. UVB appears to have a lower carcinogenic potential in the series of psoriatics treated (123), but genitalia also should be shielded.

Lichen Planus and Lichen Nitidus

Lichen planus and lichen nitidus are papulosquamous diseases; their exact etiologies are unknown. They are worldwide in distribution, rare in childhood, and usually seen in the 30- to 60-year-old age group. Clinically, penile lesions can demonstrate individual papules and plaques (Fig. 44.9 and Fig. 44.10), which may be hypertrophic or atrophic.

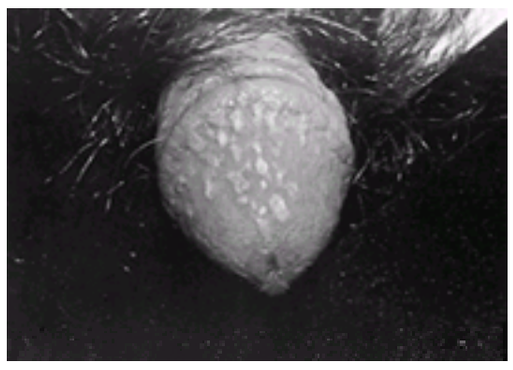

FIGURE 44.9. Polygonal violaceous papules with Wickham's striae on the glans penis.

FIGURE 44.10. Papules have coalesced to annular plaques at the sulcus.

In oral lichen planus, severe dysplasia associated with the concomitant lichen planus is associated with the development of precancerous lesions (95). Twenty-five percent of patients with lichen planus have genital lesions, yet the association with malignancy is rare (8,76). In addition, the loss of epidermal antigens associated with malignant changes occurs in lichen planus without that sequela (1). Phimosis has been induced by lichen planus (64). Therapy for lichen planus depends on the extent of disease and primarily includes topical or systemic corticosteroids.

Lichen nitidus is thought by some to be a variant of lichen planus, although histologically it is distinguished by the “clawlike” focal lichenoid infiltrate at the basement membrane zone (111). Clinically, tiny, flat-topped papules are seen on the glans penis; these are usually asymptomatic but are sometimes pruritic (Fig. 44.11). Generally, no therapy is necessary; corticosteroids are usually ineffective, although they may provide symptomatic relief.

FIGURE 44.11. Numerous flat-topped papules typical of lichen nitidus on the glans penis. See also Color Figure 44.11.

Dermatitis Venenata

Penile lesions can be induced by agents that may cause a contact dermatitis (e.g., poison ivy). Neomycin-induced contact allergies are common and can produce a contact dermatitis of the glans and shaft of the penis (Fig. 44.12). Condoms, contraceptive jellies, clothing, and industrial exposures can produce a contact dermatitis as well (Fig. 44.13). Therapy includes elimination of the allergen, local compresses, and topical corticosteroids.

FIGURE 44.12. Contact dermatitis of the glans and shaft of the penis and the scrotum. See also Color Figure 44.12.

FIGURE 44.13. Early contact dermatitis caused by a condom. Demonstrates erythema on the glans and shaft of the penis.

Balanitis

Balanitis refers to inflammation of the glans and may be caused by fungal infections, such as *Candida albicans* (Fig. 44.14) or tinea (Fig. 44.15). Candidiasis may be primary or a complication of another dermatitis (94). Some sexual partners may be allergic to the *Candida* organism. Circumcision may be necessary in resistant cases. Some cases are idiopathic (Fig. 44.16). Autodigestion of the glans penis and urethra by activated transplant pancreatic exocrine enzymes has been reported (127). Squamous cell carcinoma has been reported in association with chronic herpes simplex balanitis (37).

FIGURE 44.14. Satellite pustules typical of Candida extend throughout the groin, including the scrotum and penis.

FIGURE 44.15. Tinea involving the groin, scrotum, and penis.

FIGURE 44.16. A moist plaque found in nonspecific balanitis on the glans penis. See also Color Figure 44.16.

Zoon's balanitis (137) affects the glans and prepuce in middle-aged and elderly men. The surface is shiny and moist (Fig. 44.17). Histologically, there is an intense plasma cell infiltrate.

FIGURE 44.17. Zoon's balanitis occurs more typically on the glans and prepuce of the penis. See also Color Figure 44.17.

Fixed Drug Eruptions

Fixed drug eruptions are circumscribed lesions that recur persistently at the same site with ingestion of the inciting drug. Initially, an erythematous, elevated patch that may become bullous is present (Fig. 44.18). Fixed drug eruptions have been reported from tetracyclines (30), sulfamethoxazole-trimethoprim (Septra), and cotrimoxazole (6,125). Other drugs exacerbate fixed drug eruptions less frequently (26). Fixed drug eruptions can present with a hemorrhagic-appearing bulla on the glans penis (Fig. 44.19).

FIGURE 44.18. Fixed drug reaction to tetracycline with two nummular patches on the glans and shaft of the penis.

FIGURE 44.19. A bullous fixed drug reaction with subsequent denudation of the epidermis.

Cysts of the Penis

Median raphe cysts of the penis occur primarily on the ventral aspect of the penis in young men (46) (Fig. 44.20). The postcoital development of median raphe cysts has been reported (115).

FIGURE 44.20. This nodule on the ventral shaft is a median raphe cyst.

Cysts of the median raphe represent defects in the embryonal development of the genitalia (7,46,112,126). Asarch and co-workers (7) noted two theories regarding their origin: (a) they arise from epithelial nests incidental to incomplete closure of the urethral or genital fold, or (b) they develop from split-off outgrowth of epithelium after primary closure of the folds. Locally, irregularly shaped, empty cystic spaces are present in the cutis without connection to the overlying epithelium (7,46). They are lined by pseudostratified columnar epithelium. Surgical excision is the treatment of choice.

Serotonin-storing cells were detected in several varieties of median raphe cysts, suggesting that these cysts arise from the endodermal part of the urethra (38). The differential diagnosis includes apocrine cystadenoma (54), mucoid cyst (28), epidermal cyst, steatocystoma, glomus tumor, dermoid cyst, and urethral diverticula.

Mucoid Cysts

Mucoid cysts of the penis are rare lesions that usually present as small, superficial masses on the prepuce or glans penis (28). Although apparently cystic clinically, histologically the cystic nature is not always evident. The characteristic histologic findings of the cysts include a lining of stratified columnar epithelium often associated with mucous cells or mucous glands or both. These cysts probably arise from ectopic, urethral mucosa-entrapped remnants remaining in penile skin during

embryologic development.

Amyloidosis

Primary amyloidosis of the penis is rare (17,75,133). The penile lesions are painless, tan or yellow, rubbery nodules. Amyloidosis is characterized by an extracellular deposition of fibrillar proteins that demonstrate beta-pleated sheets on x-ray diffraction, a positive Congo red stain, and a green birefringence in polarized light. Secondary amyloidosis is associated with chronic granulomas, lymphomas, rheumatoid arthritis, and other chronic diseases (Fig. 44.21).

FIGURE 44.21. Secondary amyloidosis with papules in the groin.

Therapy for amyloidosis is contingent on the symptoms. Radical surgery with reconstruction of the urethra or glans penis may be necessary if symptoms of urinary obstruction are present (22,96). Other cases may not require therapy.

Epidermal Cysts

Epidermal cysts are common, although not frequently described. Most small epidermal cysts occur on the shaft (Fig. 44.22). They vary in size from 1 mm to several millimeters. Therapy is simple excision or marsupialization of the cyst wall.

FIGURE 44.22. Epidermal cysts at the base of the shaft of the penis.

Tuberculosis of the Penis

Tuberculosis of the penis is rare, and in a review of 110 cases, 72 were the result of ritual circumcision (78). Three modes of presentation occur: (a) a primary, usually ulcerative lesion of the glans; (b) secondary to a tubercle elsewhere in the urogenital tract, usually by extension from the urethra; and rarely, (c) by hematogenous spread. A number of authors have subsequently reported cases of tuberculosis of the penis (3,25,66,74,90,116).

Histologically, the epidermis may show an ulceration;however, the dermis contains tuberculoid granulomas with many giant cells and foci of caseation. Therapy is by antituberculosis drugs, with or without adjunctive surgery.

Elephantiasis of the Penis

Elephantiasis is characterized by a persistent and morbid enlargement of the affected parts (35). The cause of elephantiasis is an obstruction classified as (a) infectious, (b) noninfectious, or (c) idiopathic.

Infectious causes may include filariasis, erysipelas, lymphogranuloma inguinale, chancroid, syphilis, leprosy, and nonspecific skin infections (35,69,85). Noninfectious causes are all mechanical and include scars, constricting bands, and ablation of lymphatics, for example, surgical treatment of cancers. Idiopathic etiologies include Milroy's disease and a number of unclassified disorders.

Therapy is contingent on the cause and resultant deformity (31,35,69).

Scabies

Epidemics of scabies, occurring in 30-year cycles with a 15-year hiatus between the end of one epidemic and the beginning of the next, have been noted (98). The cyclic nature has been attributed in part to “prompting factors,” such as poverty, poor hygiene, sexual promiscuity, and other socioeconomic factors. There appear to be important immunologic factors in the pathogenesis of scabies. A functional, delayed hypersensitivity reaction is associated with partial immunity if cured after sensitization to the etiologic agent (23). Interdermal skin tests are positive after 6 months of disease. Further studies of Norwegian scabies demonstrates a predilection for the mentally retarded and physically debilitated (89). These patients may have a specific anergy to interdermal tests. Norwegian scabies occurs in recipients of renal transplants and in other immunosuppressed patients (100).

Orkin (98) describes several forms of scabies: (a) Scabies in clean persons shows minimal findings; burrows are difficult to find. This form often is misdiagnosed. (b) Scabies incognito follows the use of topical corticosteroids; the distribution and morphologic features may be atypical. When other concurrent skin diseases are present (e.g., psoriasis, mycosis fungoides), scabies can be overlooked. (c) Nodular scabies is manifested by pruritic nodules that occur predominantly on covered body areas, including the male genitalia, the groin, and axillary regions. Histologically, these nodules may stimulate lymphoma, cytosis, or arthropod bites. (d) Animal-transmitted scabies, of which the major source is dogs, has a greater ease of transmission but is usually self-limited unless the patient is reexposed to the canine source. (e) Scabies in children may appear as eczematous or papulovesicular with an atypical distribution including the head, neck, palms, and soles. (f) Scabies with syphilis coexists with other venereal diseases. (g) Norwegian scabies is highly contagious owing to the increased number of organisms; it usually is seen in institutional patients (the elderly and mentally retarded).

Scabetic papules localized to the penis may be erythematous, nodular, or excoriated (Fig. 44.23). Therapy may include the use of 1% lindane cream or lotion or 10% crotonotoluide in males (98). Permethrin 5% cream now is considered the treatment of choice in infants and small children because of its high efficacy and low risk of

side effects (99).

FIGURE 44.23. Scabies with papules on the glans and shaft of the penis. See also Color Figure 44.23.

Patients who are immunosuppressed may develop Norwegian scabies resistant to lindane (5,21). Multiple drug therapies have been intensively required. Oral ivermectin has shown promise as a systemic therapy for endemic scabies (58).

PENILE TUMORS

Penile tumors often create anxiety in the patient and may be seen early in their development, especially in the young or middle-aged man. Proper management is contingent on the recognition of benign, premalignant, and malignant neoplasms on both clinical and histologic criteria. However, there are entities whose clinical and histologic appearance defy easy characterization. This section presents and summarizes some of the more common skin tumors of the penis. Carcinoma of the penis is discussed in Chapter 43.

Pseudoepitheliomatous, Keratotic, and Micaceous Balanitis

Pseudoepitheliomatous, keratotic, and micaceous balanitis (PKMB) is a rare tumor characterized by thickened, scaly, and micaceous patches on the glans penis, and although considered benign, it is capable of becoming locally invasive and should be treated like other tumors of low-grade malignant potential (11). This condition occurs exclusively in older men and follows a prolonged course. Although some reports (11,82) note a history of phimosis, others do not (106).

Histologically, there is massive hyperkeratosis, acanthosis, and mild rete ridge hypertrophy. There may be mild dysplasia but no cytologic changes to suggest malignancy (50). However, with dermal invasion, some authors have suggested the appearance of early carcinomatous changes (12). An inflammatory infiltrate may be present in the dermis, but its severity is variable.

The histologic features and tendency toward recurrence are suggestive of verrucous carcinoma (14,65). The term *micaceous and verrucous malignant balanitis* has been suggested (14). PKMB has demonstrated chronicity and a benign pattern over years (63); however, there was an associated fatal fibrosarcoma occurring in the same patient.

The differential diagnosis of PKMB includes squamous cell carcinoma, keratoacanthoma, erythroplasia of Queyrat (Bowen's disease), penile horn, and giant condyloma (Fig. 44.24).

FIGURE 44.24. Condyloma acuminatum with hyperkeratotic papules on the glans penis and sulcus. See also Color Figure 44.24.

Conservative surgical management has been attempted, but local recurrences have been noted. Mohs' surgical excision appears to be the treatment of choice for PKMB, because the margins are well-controlled, ensuring tumor extirpation. Radiation therapy can be considered when surgical excision would be mutilating.

Penile horns have been associated with and are seen more frequently in circumcised men and have been associated with chronic irritation, verrucae, surgical trauma, keratoacanthoma, and squamous cell carcinoma (102,104).

Bowenoid Papulosis

Bowenoid papulosis probably has been recognized on occasion as a histologically malignant-appearing disease, usually with a benign course (40,71). The term *bowenoid papulosis* was coined to delineate this disease complex, which is characterized histologically by the features of Bowen's disease (squamous cell carcinoma in situ) but associated clinically with a benign course, because clinical impressions are those of benign diseases in prebiopsy diagnosis (42,52,55,68,71,113).

Clinically, the papules occur predominantly on the shaft rather than on the glans of the penis (Fig. 44.25), which may clinically suggest a diagnosis of papulosquamous diseases (psoriasis, lichen planus), a linear nevus, or more frequently, verrucae (124,130). Some present symptomatically as pruritus ani (121).

FIGURE 44.25. Papular Bowes's disease on the shaft of the penis. See also Color Figure 44.25.

Clinical features that distinguish bowenoid papulosis from Bowen's disease include early onset, occurrence in uncircumcised men, and multiplicity of lesions. The duration of the disease varies from less than 2 months to more than 10 years. It has been reported in women as well, with a frequency equal to that of males (130,136).

Histologically, there is hyperkeratosis with prominent parakeratosis; psoriasiform epidermal hyperplasia; a focally prominent granular zone, with crowding of epidermal nuclei; an increased number of mitotic figures at all levels of the epidermis; atypical keratinocytes with large hyperchromatic and pleomorphic nuclei; multinucleated keratinocytes; and atypical mitotic figures. The papillary dermis contains dilated vessels suggestive of verrucae with a superficial infiltrate of lymphocytes and histiocytes. Although initial electron microscopy failed to demonstrate viral particles, viruslike particles in bowenoid papulosis have been described.

The human papillomavirus (HPV) has been demonstrated with nick-translated, biotinylated DNA probes for HPV types 6, 22, 16, and 18 in giant condylomata, Bowen's disease, verrucae, and highly differentiated verrucous carcinoma (56,57,80,101), and HPV types 6 and 11 have a tendency to reflect a benign course compared with HPV types 16 and 18, which reflect a malignant trend. However, there are exceptions to the rule (43,44,80).

Bowenoid papulosis was suspected to be sexually transmitted (10,60) to a male sexual partner of a woman with squamous cell carcinoma and an HPV infection. Similarly, sexual partners of those with bowenoid papulosis are at increased risk of cervical cancer (93,109).

There have been reports of spontaneous regression of lesions, although bowenoid papulosis has progressed to Bowen's disease (34). No known cases have progressed to include squamous cell carcinoma or metastasis; however, some lesions may be locally aggressive, specifically with meatal involvement.

Therapy may include surgical excision, electrodesiccation with or without curettage, cryosurgery, CO_2, or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser surgery (70), topical fluorouracil, salicylic acid, topical steroids (130), and interferon (53).

Erythroplasia of Queyrat

Queyrat described erythroplasia of the glans penis, suggesting that this disease represented a precancerous process, although the histologic features were of Bowen's disease (103). Paget is said to have written the first report describing a similar case, which was also considered premalignant (87), and Brown (19) followed a case histologically for 5 years, reporting on its eventual outcome. Clinically, these lesions may appear as an erythematous patch, as papules similar to bowenoid papulosis, or as warts (Fig. 44.26,Fig. 44.27 and Fig. 44.28) (49).

FIGURE 44.26. Bowen's disease with an erythematous localized patch on the shaft of the penis. See also Color Figure 44.26.

FIGURE 44.27. Bowen's disease extends from the scrotum to the shaft of the penis. See also Color Figure 44.27.

FIGURE 44.28. Papular Bowen's disease suggestive of condyloma is on the shaft near the sulcus. See also Color Figure 44.28.

Therapy includes 5-fluorouracil (45), Mohs' micrographic surgery (15,88), and laser surgery (18,51).

Giant Condylomata Acuminata

Condylomata acuminata may extend to the glans, prepuce, and shaft of the penis or may be localized (97) (Fig. 44.29 and Fig. 44.30). Giant condylomata can have

the gross clinical appearance of cancer (83,117).

FIGURE 44.29. Condyloma acuminatum verrucous nodules extending from the rectum to the scrotum.

FIGURE 44.30. Early papules of condyloma acuminatum. See also Color Figure 44.30.

Histologically, giant condylomata may be benign or malignant; malignant condylomata can be distinguished microscopically from benign giant condylomata. In malignant lesions, the prickle cell layer is reduced and replaced by large, pale cells without cellular bridges; these cells may be vacuolated and multinucleated with occasional mitotic figures. The basal layer may contain pleomorphic nuclei. The central areas often contain keratohyaline material in addition to inflammatory cells. These features classify malignant condylomata as intermediate between squamous cell carcinoma and giant condylomata acuminata.

Treatment of giant condyloma includes conventional or Mohs' micrographic excisional surgery (59,88).

Chapter References

An understanding of the development of the genitourinary tract is essential in the diagnosis and management of congenital anomalies of the urinary tract. Embryologically, the genital and urinary tracts are intimately related. Although much is known regarding the morphologic development of the genitourinary tract (26,80,92,109), it is only during the last few years that some of the molecular mechanisms involved in these processes have been identified. This is largely a result of the identification of genes expressed during development and the use of techniques for single-gene disruption (62,65).

An error in any of a multitude of molecular steps can result in abnormal genitourinary development. Teratogens in early embryonic life can also affect the developing embryo. A maternal viral infection can increase the incidence of urologic anomalies (53), as can exposure to progestational (masculinizing) agents. Physical forces can also result in physical changes in the fetus even late in gestation (112).

The urogenital system is derived predominantly from the intermediate mesoderm of the early embryo. This mesoderm undergoes epithelial transformation to form the ducts and tubules that make up the urogenital tracts and kidneys (99) (Table 45.1). The mesonephric duct forms in the cervical region and progresses caudally toward the cloaca. This duct is important in the formation of the upper urinary tract, seminal transport system, and female reproductive tract.

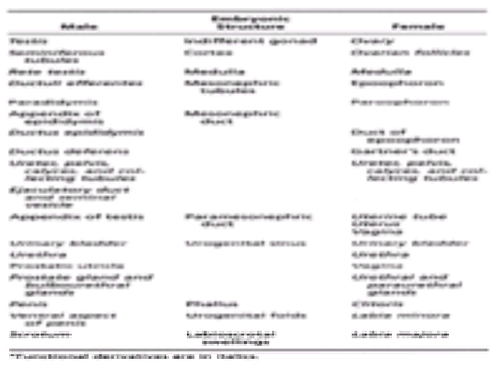

TABLE 45.1. ADULT DERIVATIVES AND VESTIGIAL REMNANTS OF EMBRYONIC UROGENITAL STRUCTURES

RENAL AND URETERAL DEVELOPMENT

The development of the kidney and ureter are intimately related. An abnormality of one structure is often associated with an abnormality in the other. Normal development of the kidney and ureter has been described using data derived from microdissection of fetal specimens (26,92). Renal development depends on the presence of the urogenital ridge that contains the nephric, gonadal, and genital duct primordia (Fig. 45.1B). The three distinct stages of renal development—the pronephros, mesonephros, and metanephros—develop sequentially and are found in the ridge (26,80,92,109).

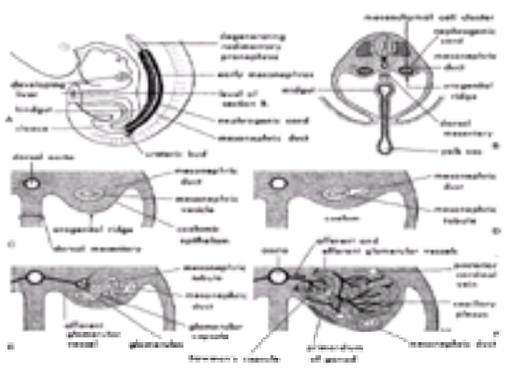

FIGURE 45.1. A: Sketch of a lateral view of a 5-week embryo shows the degenerating pronephros and the extent of the mesonephros. **B:** Transverse section through the embryo showing the urogenital ridge that contains the nephric, gonadal, and genital primordia. **C** to **F:** Transverse sections showing development of mesonephric tubule. The vesicle coalesces with the mesonephric duct and develops a cuplike outgrowth with a capillary ingrowth (a primitive glomerulus). The branching increases the surface area, enhancing the capacity for interchanging material with the blood. (From reference 80, with permission.)

The pronephros is the earliest stage in nephric development in humans. The pronephros is the mature excretory structure in primitive vertebrates but does not have function in humans. The nephrogenic cord undergoes epithelial transformation to form tubules that connect with paired pronephric ducts that extend caudally and empty into the cloaca. The pronephros completely disappears by the fourth embryonic week. If the pronephros or its duct do not develop, the mesonephros will not appear.

The mesonephros is present between the fourth and eighth weeks of gestation. The mesonephros is the permanent kidney in amphibians and may function transiently

in mammals until the metanephros develops. The mesonephros consists of glomeruli and tubules that drain into the mesonephric duct (Fig. 45.1D to Fig. 45.1F). As tubules are forming in the lumbar region, the thoracic tubules degenerate. By the ninth week, most of the mesonephros has disappeared, except for the duct and a few tubules that persist as genital ducts in males or vestigial remnants in females (see Table 45.1 and subsequent section on urogenital development).

The kidneys (metanephros) begin development in the fifth week, when the ureteral bud appears on the lower end of the mesonephric duct near its entry into the cloaca (Fig. 45.1A). The metanephros forms as result of a reciprocal epithelial-mesenchymal interaction between the ureteral bud and the metanephric blastema (38,62,65,99). Signals from the ureter induce metanephric mesenchyme in the caudal part of the nephrogenic cord to condense and proliferate. Reciprocal signals from the mesenchyme induce the ureteral bud to grow and branch (38). An abnormality in either the ureteral bud or the metanephric mesenchyme adversely affects renal development.

As the ureteral bud grows cephalad, the metanephros enlarges and rapidly differentiates. The cephalad end of the ureteral bud expands within the metanephros to form the renal pelvis. Outgrowths from the renal pelvis push radially into the metanephros and form primary collecting ducts. As the kidney grows, the tubules continue to branch into the peripheral zone of the kidney. The major calyces subdivide, and the tubules that drain into a minor calyx constitute a renal pyramid.

The nephron, which consists of the glomerulus, proximal convoluted tubule, loop of Henle, and the distal convoluted tubule, is derived from the metanephros. Vesicular masses that arise from the mesoderm adjacent to the ends of the collecting ducts develop a central cavity and become S-shaped. One end of the S develops into the distal convoluted tubule that connects with the terminal end of the collecting tubules. The other end becomes the glomerulus and Bowman's capsule.

Nephron development occurs at an exponential rate. More than 80% of nephrons have developed by the middle of the second trimester, and nephron formation is complete by 36 weeks (92). Urine formation begins at 8 weeks and continues throughout gestation. Fetal kidneys contribute urine to the amniotic cavity and maintain the appropriate volume of fluid that is essential for normal lung development. They play only a small role in salt and water balance, which is managed by the placenta. Oligohydramnios is associated with pulmonary hypoplasia and compression deformities of the head, thorax, and extremities.

The rate of urine production is substantial in the fetus and approaches 50 mL per hour (96). This urine is hypotonic compared with fetal and maternal serum, having a sodium concentration of less than 100 mEq/mL, chloride less than 90 mEq/mL, and osmolality less than 210 mOsm/mL (34,35).

Molecular Basis of Ureteral Budding and Metanephros Differentiation

The importance of a gene in development is shown if three conditions are met (62,65). First, the gene must be expressed where organ development is occurring. Second, the gene must be expressed during organ development. Third, if the gene is disrupted, normal organ development must not occur. There are now more than 250 candidate genes/proteins that are listed in the Kidney Development Database (19). This database was started in 1993 and is rapidly enlarging. There were 27 new entries between January 1999 and June 2000. Figure 45.2 shows genes that are clearly required for nephrogenesis, although clearly not completely defining the process. Excellent reviews cover renal and ureteral development (62,65). A flowchart of many mechanistic controls of nephrogenesis is shown in Fig. 45.2.

FIGURE 45.2. Flowchart indicating some of the critical genes involved in metanephric kidney development. Boxes summarize the steps in organogenesis. Listed genes are expressed during these periods and are grouped according to expression in the wolffian duct and ureteric bud *(W/UB)* or the metanephric mesenchyme *(MM).* Genes that are required primarily for certain steps in development are in boldface and underlined. The genes are listed in order of appearance. The expression pattern is recapitulated as renal development continues. Genes are discussed in the text. (From reference 62, with permission.)

Examination of ureteral bud development reveals the complexity of the multiple transcription factors, growth factors, receptors, and matrix proteins involved. Mice with targeted inactivation of RET have renal agenesis and hypodysplasia (100). The primary defect is a failure of the ureteric bud to emerge and respond to signals from the metanephric blastema. The receptor ligand is produced by the metanephric blastema and has been identified as glial cell line–derived neurotrophic factor (GDNF) (126). WT-1, the transcription factor that is the product of the Wilms' tumor suppressor gene, is essential for ureteric budding (60). In the absence of this factor, the metanephros condenses, but without the ureteral bud, it undergoes programmed cell death (apoptosis). The Wnt-11 gene is expressed only in that segment of the mesonephric duct adjacent to the metanephric blastema (58). As development continues, this is expressed only at the tip of the branching bud and not at the stalk.

Wnt-4 and BMP-7 are regulators of nephron maturation. Wnt-4 transcripts are found in aggregating mesenchymal cells adjacent to the growing ureter and its branches. Mice with disrupted Wnt-4 die at birth with renal agenesis. The mesenchyme is undifferentiated, and there is little evidence of epithelial formation. Bmp-7 is a member of the transforming growth factor-b (TGF-b) family of signaling molecules and is initially found in the mesonephric duct and later in the metanephros (71). Deficient animals show condensation and development of the mesenchyme but few glomeruli form, and there is increased interstitial and stromal tissue in the mutant kidneys. Thus nephron development requires both ureteric bud and mesenchymal signals for conversion of mesenchyme to epithelium.

Transcription factors coordinate the expression of differentiation programs. BF-2 is localized in stromal cells surrounding the ureteric bud and differentiating metanephros. This localization relates to the proposed function in regulating ureteral growth and differentiation of mesenchymal cells (44). WT-1 (see previous discussion) and Pax-2 (see following discussion) are two additional transcription factors important in renal development.

Renal Developmental Abnormalities

A number of puzzling features are associated with developmental renal abnormalities. Most are unilateral or asymmetric and have predominance in one gender, depending on the abnormality. Genetic analyses of syndromes of multiple organ anomalies that include the kidney show both autosomal (13) and X-linked inheritance (95). Multifactorial inheritance of vesicoureteral reflux (40% to 50% of siblings) has been reported (87). It is likely that most anomalies are the result of complex hereditary traits resulting from minor mutations in multiple specific genes involved in embryogenesis (Fig. 45.3) (91).

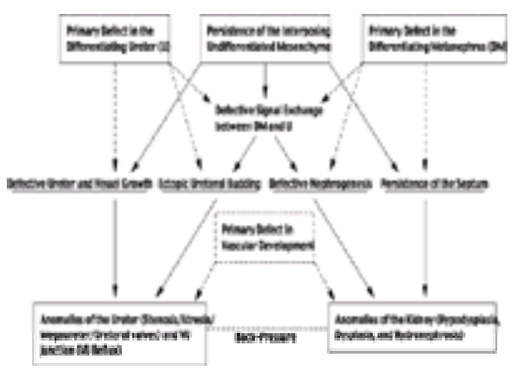

FIGURE 45.3. Potential mechanisms involved in formation of urinary tract malformations. A primary defect in the ureter or the metanephric mesenchyme can result in abnormalities of the ureter, kidney, or both structures. Persistence of undifferentiated mesenchyme disturbs normal development. Obstruction and elevated pressures imposed on the parenchyma may promote development of hydronephrosis or dysplasia. (From reference 91, with permission.)

The Pax-2 gene has been identified as a specific gene associated with renal anomalies (98). This gene is a transcriptional regulator that is widely expressed during development of both ductal and mesenchymal components of the urogenital system. In a homozygous mouse model, newborn mice lack kidneys, ureters, and genital tracts (123). Heterozygotes have kidneys that are reduced in size and hypoplastic. This is an interesting feature of this family of genes. This semidominant character of loss of function mutations is termed *haploinsufficiency.* The effect on development depends on the amount of product protein in the cell.

The renin-angiotensin system is important in renal development. The effects of angiotensin at the type 1 (AGTR1) and type 2 (AGTR2) receptors have been studied. AGTR1 is a proliferative receptor that influences hypertrophy, matrix deposition, cellular proliferation, and stimulation of growth factors. AGTR2 decreases cell growth, influences apoptosis, and stimulates antiproliferative substances (10). AGTR1 is localized to epithelial precursors in nephrogenic areas, and AGTR2 is expressed antenatally in the undifferentiated mesenchyme surrounding the ureteric bud and in the renal interstitium. Once nephrogenesis is complete, AGTR2 is no longer expressed in the upper urinary tract.

If AGTR1 is deleted, mice have progressive damage to the kidney shortly after birth. These kidneys are morphologically normal but develop progressive collecting system dilation consistent with obstruction. Histologically, the ureteral musculature and renal pelvis are poorly developed. AGTR1 allows normal development of the renal pelvis and ureter along with normal pacemaker and peristaltic activity (79).

The angiotensin type 2 receptor is important in programmed cell death. Studies show that the congenital anomalies are preceded by delayed apoptosis of undifferentiated mesenchymal cells surrounding the urinary tract during ureteral budding and expansive growth of the kidney and ureter.

AGTR2 null mutant mice display congenital anomalies of the kidney and urinary tract (86). The spectrum of renal pelvic dilation, ureteropelvic junction obstruction, multicystic dysplasia, megaureters, and nondilating reflux has been identified. As in humans, these renal abnormalities are not associated with other somatic anomalies and the inheritance does not follow a typical Mendelian pattern. Male pups are more commonly affected than females. AGTR2 is localized on the X chromosome, which may be important in the male predominance in these anomalies.

Dysplasia

Renal hypoplasia and oligonephronia mean a deficiency in the total nephron population. Fibrosis, cartilage, and immature renal tubules characterize renal dysplasia (6). This may involve the entire kidney (multicystic dysplastic kidney) or can be segmental in nature. Dysplasia is most commonly associated with obstruction (34,35) or reflux (72).

Controversy exists concerning the role of obstruction and reflux in the development of hypoplasia and dysplasia. Mackie and Stephens (72) proposed that the abnormalities resulted from defective induction by ectopic ureteral buds and deficiencies in the ectopic sections of the metanephros as opposed to being pressure related. Certainly, obstruction can have an additive effect on the abnormal induction. When dysplasia is an isolated finding, it is almost certainly the result of abnormal metanephric induction (see previous discussion).

Renal Ascent/Vasculature

While the kidney differentiates between the ninth and twelfth week, the metanephros ascends, rotates, and revascularizes (74). Ascent occurs from the fourth lumbar vertebra to the first lumbar or twelfth thoracic vertebra as a result of both cephalad migration and caudal growth of the fetus. While the kidney ascends, the renal pelvis rotates 90 degrees from an anterior position to a medial position. Arteries that are located higher on the urogenital ridge progressively supply the kidney. Failure of any of these steps to occur results in anomalies of number, volume, position, and form.

Lateral branches off the dorsal aorta progressively supply the mesonephros. As the mesonephros involutes, most of the lateral branches disappear; however, some persist as the inferior phrenic, adrenal, renal, and gonadal arteries. There are many variations of renal arterial supply that are largely dependent on the renal position. If the kidney is ectopic, the arterial supply arises from the branches of the aorta that would have atrophied if the kidney had ascended to a normal location.

The inferior vena cava forms between the sixth and eight weeks of gestation. Ventral subcardinal veins communicate with postcardinal veins that are sequentially replaced by the dorsally located supracardinal veins. Connections between subcardinal veins result in the common drainage of the left renal, adrenal, and gonadal veins. The right adrenal and gonadal veins drain directly into the vena cava because the right subcardinal vein forms the vena cava above the renal vein. Normally, the right supracardinal vein persists as the cava below the kidneys. If the subcardinal vein persists, a retrocaval ureter occurs.

EMBRYOLOGY OF THE URETER

The distal end of the mesonephric duct that is incorporated into the urinary system is called the *common mesonephric duct.* This expands in trumpet fashion into the urogenital sinus (future bladder and urethra) to form half of the trigone (114). This duct can be divided into caudal, middle, and cranial regions (Fig. 45.4). The attachment of the ureter to the mesonephric duct switches from a posterior to an anterolateral location. With expansion and absorption into the urinary tract, the orifices of the ureteral bud and mesonephric duct (wolffian) become independent and move away and settle in the bladder and urethra, respectively.

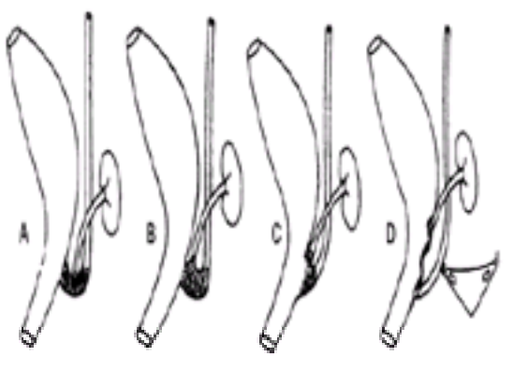

FIGURE 45.4. Embryologic rearrangement and migration of the orifices of the ureteric bud and ureters from the wolffian duct to the urinary tract and formation of the trigone. A single ureter arises from a normal position on the duct **(A)** *(middle black dot)* and migrates to the lateral cornu of the trigone **(D). B** and **C** show the expansion of the common excretory duct and wolffian duct into the urethra and bladder. (From reference 115, with permission.)

The more caudal section of the mesonephric duct ends up laterally positioned on the trigone, and the cranial position ends up in the urethra. For example, in ureteral duplication, the most caudal bud (lower pole of kidney) ends up in a more cephalad position on the trigone, and the cranial bud (upper pole of kidney) ends up at the bladder neck or urethra (ectopic) as defined by the Weigert-Meyer law (78). The location of the ureteral orifice can be related to renal development. Stephens (72) proposes that these abnormalities are programmed at the time of budding off the mesonephric duct. If the bud arises remote from the normal site, it projects into the caudal or cranial portion of the metanephric blastema and results in dysplasia. Based on this theory, abnormal ureteral budding results in the coexistence of high-grade reflux and renal dysplasia. Certainly, the previously mentioned bidirectional signaling between the bud and blastema also plays a role in these clinical

findings.

Ureteroceles

A single embryologic theory does not explain all ureteroceles. Chwalla (12) suggested that incomplete breakdown of the ureteral membrane that exists between the ureteral bud and mesonephric duct is an obstruction leading to the formation of a ureterocele. It is unclear in some anatomic studies whether this membrane truly exists. This theory would explain the majority of ureteroceles but does not explain the development of ureteroceles with patulous ureteral orifices in the urethra.

Stephens (113) and Tanagho (119) suggested that the distal ureteral segment is acted upon by the same stimuli that lead to expansion of the urogenital sinus to form the bladder. In ureteroceles with patulous orifices, obstruction of the orifice by the vesical neck might result in intravesical dilation. However, if this were always true, genitourinary ectopic ureters would have ureteroceles. To reconcile this, Tanagho (119) postulated that ureterocele formation results from delayed arrival of the bud into the bladder, with expansion occurring as part of the flaring of the common excretory duct.

Mitchell has suggested that a ureterocele is the result of an abnormal induction of the trigone by many of the genes and growth factors that are important in renal growth and development. Stephens' histologic studies (113) support this concept. Histologic analysis of the intravesical portion of ureteroceles shows deficiencies in the trigonal musculature of patients with ureteroceles that were not present in ectopic ureters without ureterocele formation (113). This field defect results in pseudodiverticulum (ureterocele eversion) and reflux into laterally displaced poorly supported ureters.

LOWER URINARY TRACT/ BLADDER FORMATION

The development of the lower urinary tract is closely related to that of the genital tract. The differential development of the urogenital sinus into male and female structures is discussed in a later section of this chapter.

The cloaca is the caudal extension of the hindgut. The cloacal membrane is the ectoderm that extends from the tail bud to the body stalk. The urorectal septum is a mass of mesodermal tissue at the notch between the allantois and hindgut that extends caudally. By the seventh week, the cloaca has been divided into the rectum and urogenital sinus (Fig. 45.5). At this point, the external genitalia are not distinguishable as male or female with labioscrotal swellings and urogenital folds on either side of the cloacal membrane.

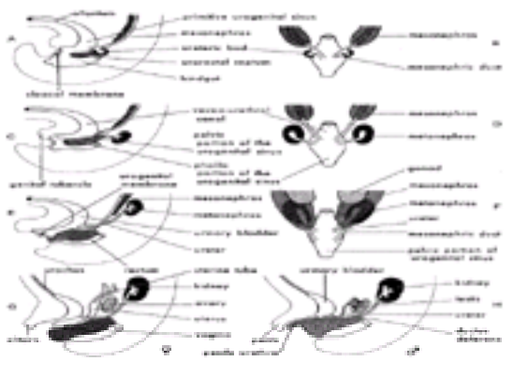

FIGURE 45.5. Division of the cloaca in the urogenital sinus and the rectum; absorption of the mesonephric ducts; and development of the urinary bladder, urethra, and urachus. **A:** Lateral view of the caudal half of a 5-week embryo. **B, D, F:** Dorsal views. **C, E, G, H:** Lateral views. Stages **G** and **H** are reached by about 12 weeks. (From reference 80, with permission.)

By the seventh week, the mesonephric ducts are absorbed into the dorsal aspect of the urogenital sinus (18). As described earlier, the ureters move cephalad and lateral while the mesonephric duct moves caudally. The trigone is initially mesodermal in origin. The epithelium is initially replaced by the endoderm of the urogenital sinus. The lamina propria, muscular layers, and serosa arise from the surrounding mesenchyme. The development of the bladder is the result of complex interactions between the epithelium and mesenchyme (21).

The bladder elongates as the abdominal wall forms below the umbilicus. The urachus (apex) is contiguous with the allantoic stalk. By birth, the urachus becomes a thick fibrous cord (the median umbilical ligament). Initially, the bladder is a cylindrical tube. The tubular bladder acts as a conduit and becomes a more spherical storage vesical later in gestation.

Bladder muscle appears by 7 weeks of gestation and shows significant orientation into layers by 21 weeks gestation (85). Animal studies show that bladder compliance is poor in early gestation and increases as gestation progresses (3,16). Both active smooth muscle tension and connective tissue matrix influence compliance and capacity. The ratio of type III to I collagen and the absolute amount of type III collagen correlate with bladder compliance with improved compliance associated with decreased quantities of type III collagen. The development of the detrusor layer is key because it seems to have the largest impact on bladder storage and emptying.

Mechanical distention of the bladder is made possible with development of a continence mechanism. The urethral sphincter encircles the urethra by 16 weeks (8,76,85). Because this occurs before the trigone is fully developed, the cyclic bladder expansion may aid in normal bladder development (14). Obstruction secondary to posterior urethral valves or absence of urine storage secondary to bilateral ectopia or exstrophy may lead to abnormal development of the trigone.

GONADAL DEVELOPMENT

The gender of the embryo is established at fertilization when the X chromosome of the ovum is united with a paternal Y or X chromosome. The genetic sex determines the gonadal sex, which in turn causes appropriate transformation of the internal ductal system and external genitalia. Although the genetic sex is determined at conception, the gonad is initially bipotential. Differentiation of the testis precedes that of the ovary and follows a critical sequence, or the female gonad will develop by default. In the past decade, considerable knowledge has been gleaned about the role of the Y chromosome and the molecular genetics of testicular determination.

The primitive (indifferent) gonads arise from the intermediate mesoderm medial to the mesonephros. Both testis and ovary arise from three different sources: (a) the mesodermal (coelomic) epithelium (or mesothelium) situated on the posterior wall of the abdomen, (b) the mesenchyme in this region, and (c) the primordial germ cells. During the fifth week after ovulation, the mesoderm on the ventromedial side of the mesonephros thickens. The underlying mesenchyme proliferates, producing a bulge—the genital ridge (Fig. 45.1B).

During the fifth week, primordial germ cells leave the posterior wall of the yolk sac and travel along the wall of the hindgut, through the dorsal mesentery into the genital ridge (Fig. 45.1B). Migration of the germ cells into the genital ridge is promoted by various chemotactic factors from the developing gonad that may exert long-range effects (36). Long cytoplasmic processes link many germ cells together as they actively move in an amoeboid fashion. Germ cell survival, proliferation, and migration are promoted by mast cell growth factor, encoded by the Steel locus gene (22). Mast cell growth factor is the ligand that binds to the tyrosine kinase receptor for protooncogene protein encoded by the c-kit protooncogene. The c-kit ligand exists as a soluble protein as well as in a membrane-bound form (49).

Simultaneously, fingerlike projections of the coelomic epithelium extend into the genital ridge to give rise to the primary sex cords. In the 46,XY mouse embryo, the basement membrane of the coelomic epithelium is temporarily discontinuous, allowing migration of epithelial cells into the gonad, which eventually give rise to Sertoli cells or potentially the granulosa cells of the ovary in the female (54). For the gonadal ridge to form, two genes are necessary: WT-1 and SF-1. WT-1 plays a key role in gonadogenesis: Mice of both sexes missing WT-1 fail to develop both kidneys and gonads (60). In the 6-week-old human male, SF-1 has been detected in the nucleus of cells in the coelomic epithelium and in the somatic component of the gonadal primordia, coinciding with WT-1 protein immunolocalization in the

undifferentiated gonad (20).

At this point, the bipotential gonad is composed of a cortical region containing somatic and germ cells as well as a medullary region consisting of primary sex cords. At the cranial end of the gonad, cords of epithelial cells extend into the core of the gonad, forming the rete, which also joins the mesonephric duct (105). Formation of the müllerian or paramesonephric duct begins at this stage.

Extensive research has allowed a better understanding of the molecular biology of sexual differentiation. The SRY (sex-determining region of the Y chromosome) gene, situated on the short arm of the Y chromosome is pivotal in this process, but multiple other X-linked and autosomal genes are also involved. SRY encodes a protein with a high mobility group (HMG) DNA-binding domain. SRY is believed to regulate downstream gene expression either in a positive or negative fashion and functions by changing chromatin structure (77). Changes in DNA configuration may alter transcription with SRY activating the process of sexual differentiation or inhibiting a repressor of male expression (23,59). In XX males and XX true hermaphrodites, SRY is often detected (82,120). The origin of this anomalous SRY gene may be translocation of the paternal SRY from the Y chromosome onto the paternal X chromosome (28,90). Mutations in SRY cause sex reversal in 46,XY individuals (11). Mutations in the SRY gene may alter the configuration of the HMG DNA-binding domain, and these distortions in the SRY protein affect DNA-binding characteristics (43).

Sertoli cells under the influence of SRY mediate differentiation of the male gonad (68,93). Human SRY in contrast to mouse SRY does not have a transcriptional activation domain, and intermediate cofactors are likely required to activate the Sertoli cells (43). Sertoli cells migrate into the bipotential primary sex cords and induce testicular formation. Once the Sertoli cells are committed, other key genes are activated and transcribed, such as SOX-9 (SRY HMG BOX–related gene 9), DAX-1 [dosage-sensitive sex reversal (DSS)], adrenal hypoplasia gene on XP_{21}, and müllerian-inhibiting substance (MIS) or anti–müllerian hormone (AMH) gene. SRY expression begins at 41 days after ovulation, and peak expression is detected at 44 days after ovulation, when the sex cords are first visible. As demonstrated by immunohistochemistry, SRY transcripts are demonstrable within human Sertoli cells of the sex cords at this stage (42).

SOX-9 situated on chromosome 17 plays a key role in gonadal and cartilage formation. Fourteen mutations with loss of SOX-9 function have been identified (11), and the majority of patients with 46,XY have sex reversal. SOX-9 acts as a transcription factor by its DNA-binding domain (11) and acts in conjunction with SRY to promote testis formation. Duplication of SOX-9, in the absence of SRY, can cause XX sex reversal (48). Sertoli cell differentiation is influenced by SOX-9, but minimal expression of SOX-9 is noted in the ovary (15). SOX-9 protein is demonstrable in the cytoplasmic compartment of somatic cells of male and female human gonads (20,57). During Sertoli cell differentiation and sex cord formation at 6.5 weeks, SOX-9 expression is found in the nuclei of Sertoli cells (20).

MIS or AMH causes regression of the female ductal system. The gene for MIS is located on chromosome 19 (16). In the human embryo, MIS has been demonstrated by immunohistochemistry in the cytosol of the Sertoli cell but is not found in the fetal ovary (20). SF-1 and WT-1 promote expression of MIS (81). MIS is a nonsteroidal glycoprotein that is split to enhance its activity on the müllerian duct. MIS may also be involved in testicular development and inhibits germ cell proliferation (73).

Absence of the DAX-1 gene situated on the short arm of chromosome 21 (Xp 21) results in adrenal hypoplasia and hypogonadotropic hypogonadism and cryptorchidism in males (128). In contrast, duplication of the DAX-1 gene with the 46,XY karyotype produces male-to-female sex reversal as well as testicular dysgenesis (DSS) (2). In the mouse, DAX-1 expression in the genital ridge occurs at the same time as SRY, and DAX-1 may antagonize SRY action (116). In the testis, as SRY expression declines, so does DAX-1; however, DAX-1 persists in the ovary. It has been postulated that SRY initiates differentiation of the testis, following which SF-1 and WT-1 act downstream (77). SRY may repress DAX-1, allowing normal testicular development in the mouse (37,77). In contrast, more recent research in the human embryo demonstrated a lower level of DAX-1 expression in the indifferent 46,XY gonadal ridge as early as 33 days after ovulation, coinciding with SF-1 expression, and before detection of SRY protein. This low level of DAX-1 expression persisted during and after testicular determination, raising questions about the true role of DAX-1 in testicular differentiation of the human compared with the mouse (42).

Sex differences are demonstrable in human gonads around 6 to 7 weeks of gestation as Sertoli cells in the primary sex cords induce formation of seminiferous tubules. In the outer portion of the testicular sex cords, germ cells migrate into the sex cords, become enclosed in tubules, and undergo mitotic arrest in the form of prespermatogonia (105). The seminiferous tubules remain solid until puberty. The inner portion of the sex cords gives rise to the rete testis, which ultimately connects to the efferent ductules, derived from mesonephric tubules. During the eighth week, Leydig cells develop from the mesenchyme of the mesonephros. The Leydig cells are partitioned outside of the tubules. MIS (4) may inhibit proliferation of the Leydig cells. The stromal cells and future vascular and peritubular myoid cells migrate from the mesonephros into the testis. Mesonephric cells migrate into XY but not XX gonads in response to a chemoattractant. These mesonephric cells give rise to the endothelial cell population, the myoepithelial cells surrounding the vasculature, and the peritubular myoid cells that separate the Sertoli cells from the Leydig cells (75).

The rapidly developing testis requires a more extensive blood supply compared with the ovary to import nutrients and to export testosterone and MIS. Synthesis of testosterone begins at 9 weeks, inducing differentiation of the wolffian duct. Testosterone production is stimulated by human chorionic gonadotropin (hCG), which reaches peak levels at 8 to 12 weeks. The testis becomes rounded and covered by a dense capsule—the tunica albuginea.

In the absence of SRY, the bipotential gonad differentiates into an ovary. The primordial germ cells remain in the cortical region of the ovary. SOX-9 is expressed later in the ovary compared with the testis (42) and the SOX-9 protein is demonstrable only in the cytosol of the future granulosa cells, but not in the nucleus (20), indicating a lack of DNA binding. The primary sex cords in the medulla regress, and the germ cells, oogonia, are concentrated in the outer cortical region. Viable germ cells are required for ovarian differentiation; otherwise, a streak ovary will ensue (68). The secondary sex cords of the ovary are derived from the mesothelium of the genital ridge. These extend into the underlying mesenchyme to envelop the primordial germ cells and ultimately form the follicular cells of the ovary. The oogonia replicate by mitosis to reach 7 million in number by the fifth month of gestation; they then enter meiosis to become primary oocytes arrested at the diplotene stage of meiotic prophase. At 16 weeks, primordial follicles begin to develop, containing primary oocytes surrounded by a monolayer of follicular or granulosa cells. Mesenchymal cells become flattened around the granulosa cells to form the theca (104). The cortex of the ovary contains the majority of the follicles, whereas the medulla is formed of connective tissue and blood vessels, predominantly from the mesonephros.

DESCENT OF THE GONADS

The testes and the ovaries are initially situated at the tenth thoracic level (31). From the gonad, a cordlike structure called the *gubernaculum* forms during the seventh week. This cylinder of embryonic mesenchyme extends from the gonad to the site of the inguinal canal. At the beginning of the third month, each processus vaginalis herniates from the lower portion of the peritoneal cavity obliquely through the abdominal wall, forming the inguinal canal (125). The gubernaculum extends through the inguinal canal, linking each labioscrotal swelling to the gonad. In the female, the processus vaginalis extends through the canal of Nuck into each labia and becomes obliterated by the eighth month. The gubernaculum connects the ovary to the developing ureterovaginal canal at its union with the future fallopian tube. The ovary descends due to elongation of the lumbar region and, by 12 weeks, is situated at the pelvic brim. The superior portion of the gubernaculum ultimately becomes the ovarian ligament, and the inferior portion forms the round ligament, between the uterus and the labia majora.

In the male fetus, the proximal end of the gubernaculum connects to the testis itself (25) or to the mesonephric duct/epididymis (40,70). The testis descends to the upper pelvis by 12 to 16 weeks but then ascends, potentially due to elongation of the gubernaculum (9). Testicular descent has been divided into two phases: (a) intraabdominal migration characterized by gubernacular outgrowth and (b) later transinguinal passage (67), due to gubernacular regression (64). Between 16 and 24 weeks, significant gubernacular growth occurs. The gubernaculum enlarges by producing extracellular matrix material that absorbs water (46). By 24 weeks, the gubernaculum is as wide as the testis, creating a potential passageway for the testis.

In the clinical arena, disorders of androgen metabolism such as 5a-reductase deficiency or androgen activity such as complete androgen insensitivity are typically associated with undescended testes, but the testes may be extraabdominal (124). Research into factors controlling gubernacular development and regression has involved rodents and various mammals as well as humans, with considerable variability in gubernacular morphology, timing of testicular descent, and the role of the cremasteric muscle. Testicular descent occurs before birth in the calf, pig, and human. Recent theories concerning testicular descent have included (a) activation of the hypothalamic-pituitary-gonadal axis with direct androgenic effect on the gubernaculum (24,108); (b) direct neural control of the gubernaculum and cremasteric muscle via the genitofemoral nerve with androgens acting indirectly at the spinal nucleus of this nerve (122); (c) stimulation of fetal androgen secretion by placental gonadotropins with additional modulation by maternal epidermal growth factor (EGF) (64), MIS (103), or placental estradiol (41); and (d) alternate control of descent by protein substances such as insulin-like hormone produced by the Leydig cells (83).

Different hormones may control the two phases of testicular descent, and controversy exists about whether gubernacular proliferation is independent of androgens or MIS. In the rat, which exhibits postnatal testicular descent, androgen receptors and peak 5a-reductase activity have been identified in the gubernaculum during the

outgrowth phase, when this structure is composed of dense mesenchymal tissue (32,50). Inhibition of 5a-reductase or androgen receptor blockage will result in cryptorchidism in the rat only if exposure occurs during gubernacular outgrowth phase (106,107).

In contrast, porcine 5a-reductase activity and androgen receptor binding were at a low level in the gubernaculum during testicular descent (45,47). Factors stimulating gubernacular growth include polypeptides such as EGF, insulin fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF). A low-molecular-weight extract of the fetal porcine testis produced the strongest effect on the gubernaculum, and this factor was named *Descendin* (27). Subsequently, the proliferation of fetal porcine gubernacular cells was demonstrated in response to a low-molecular-weight protein derived from the testis (127), but not from the ovary.

Leydig insulin-like hormone, also known as *insulin-3* (Insl3), is produced by the Leydig cells in response to SF-1 and regulates gubernacular outgrowth (129). Male mice with a knockout of the Insl3 gene demonstrated cryptorchidism with a female-type gubernaculum and testes situated below the kidneys. Development of the genitalia was otherwise normal, as was serum testosterone. At birth, heterozygous Insl3-deficient males had unilateral or bilateral testicular maldescent that corrected spontaneously, whereas males with homozygous deficiency of Insl3 remained cryptorchid and developed abnormal spermatogenesis and infertility (83). This model suggested that Insl3 acts in a dosage-sensitive fashion on the mouse gubernaculum and controls transabdominal migration of the testis.

The final phase of testicular descent—gubernacular regression and transinguinal migration—takes place between 24 and 32 weeks in the human fetus. This process occurs postnatally in the rat, rabbit, and dog and is associated with a rise in testosterone and dihydrotestosterone levels (24,55,97). Although 5a-reductase activity and androgen binding in the gubernaculum are low during testicular descent (27,45), androgen may act on the epididymis. In the human, the epididymis precedes the testis through the inguinal region (40). Higher testosterone concentration in the epididymis of the infant compared with that of the adult (7) may signify that the epididymis is the target organ for androgens and mediates testicular descent.

Alternatively, androgens may act indirectly via the genitofemoral nerve that innervates the gubernaculum and cremasteric muscle (122). Transection of the genitofemoral nerve results in cryptorchidism, and the spinal nucleus of this nerve is androgen sensitive. Boys with cryptorchidism show abnormalities of the cremasteric muscle suggestive of denervation.

Estrogens are known to impair testicular descent, and exposure to exogenous estrogens, such as DES, causes cryptorchidism (97). In newborn boys with cryptorchidism, the syncytiotrophoblastic region of the placenta demonstrated increased expression of estradiol compared with the placenta of normal boys (41). Research about intrauterine exposure to exogenous estrogens revealed that DES downregulated Insl3 expression in embryonic mouse Leydig cells, resulting in cryptorchidism and retention of müllerian ductal structures (84).

GENITAL DUCTS

Two pairs of genital ducts develop in both sexes: mesonephric (wolffian) and paramesonephric (müllerian) (Fig. 45.6). The mesonephric ducts drain the primitive kidneys but persist as the male genital ducts. The tubules of the rete testis become connected with 5 to 12 residual mesonephric tubules that give rise to the efferent ductules. The paramesonephric ducts develop as an invagination of the coelomic epithelium lateral and adjacent to the mesonephros (1). The funnel-shaped proximal end empties into the coelomic (peritoneal) cavity. They run parallel to the mesonephric ducts until they reach the region of the urogenital sinus. The lower segment of the müllerian duct crosses anterior to the mesonephric ducts and fuses into a Y-shaped ureterovaginal primordium. This projects into the urogenital sinus (Müller's tubercle). A mesonephric duct enters the urogenital sinus on each side of the tubercle.

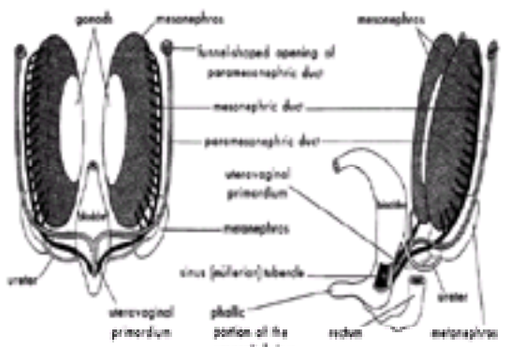

FIGURE 45.6. A: A frontal view of a 7-week embryo showing the paired genital ducts at the indifferent stage. **B:** Lateral view of a 9-week fetus shows the sinus (müllerian) tubercle on the posterior wall of the urogenital sinus. (From reference 80, with permission.)

Masculinization of the Ductal System

As noted, during the sixth to seventh weeks, the Sertoli cells produce MIS that causes regression of the müllerian structures by 8 to 10 weeks (52). SF-1 and WT-1 genes together promote MIS expression, and it has been proposed that the DAX-1 gene inhibits this synergistic effect (81). EGF enhances proliferation of the cells of the reproductive tract, and MIS blocks EGF activity (7). Remnants of the müllerian duct at the cranial end include the appendix testis, a small appendage of tissue on the superior aspect of the testicle. The sinus tubercle remains, forming the verumontanum (colliculus seminalis) on the dorsal wall of the future prostatic urethra. The caudal end of the müllerian duct may persist as the prostatic utricle, a diverticulum of the proximal urethra. At 8 weeks, the Leydig or interstitial cells produce testosterone with stimulation by hCG, causing proliferation of the mesonephric ducts, even as the mesonephros is involuting. EGF acts in a synergistic fashion with testosterone by enhancing the action of androgens due to an increase in receptor binding sites (39). Direct diffusion of testosterone down the lumen of the wolffian ducts is responsible for the stabilization of the epididymis, vas deferens, seminal vesicles, ampullae of the vas deferens, and ejaculatory ducts. The proximal end of each mesonephric duct becomes convoluted and transforms into the epididymis. The androgen receptor in the fetal epididymis is similar to the androgen receptors in the external genitalia and other locations (33). Distal to the epididymis, smooth muscle envelops the mesonephric duct, giving rise to the vas. The cephalic end of each mesonephric duct involutes, but a remnant may persist as the appendix epididymis. As noted, during the ninth week, mesonephric tubules connect the rete testis with the epididymis, forming the ductuli efferentes. At the inferior aspect of the testis, mesonephric tubules may persist as a small remnant—the paradidymis.

During the tenth week, a bud sprouts from the caudal end of each mesonephric duct near the urogenital sinus to form the seminal vesicle (61). The segment of each mesonephric duct between the seminal vesicle and the urogenital sinus is termed the *ejaculatory duct.* Development of the prostate begins in the tenth week under the influence of androgens, as endodermal buds from the urogenital sinus grow into the surrounding mesenchyme to form the glands of the peripheral zone. Acid phosphatase, which was detectable in the urogenital sinus as early as 7 weeks, could also be identified in the primitive prostatic glands at 11 to 14 weeks of gestation (56). The prostatic outgrowths form five or more groups of solid prostatic cords, which develop a lumen by 11 weeks (69). The mesenchyme surrounding these cords differentiates into smooth muscle and connective tissue. The glands of the median lobe develop later from the complex epithelium covering the verumontanum and may possibly be of mesonephric or paramesonephric origin (88). The median lobe demonstrates minimal acid phosphatase activity, confirming the different origin of this segment of the prostate (56). Urethral and paraurethral glands (of Skene) in the female correspond to the prostate.

Testosterone and dihydrotestosterone mediate these changes through binding to androgen receptors (5,63). Inferior to the developing prostate, the bulbourethral glands form during the same time frame. Paired epithelial buds grow from the urogenital sinus at the junction of the pelvic and perineal urethra. The ducts elongate and canalize, with lobular acini at the superior aspect (111).

Feminization of the Ductal System

In the absence of androgen effect, the mesonephric ducts regress (39). In the female, remnants of the mesonephric duct include the epoophoron and paroophoron in the ovarian mesentry (Gartner's cysts). The müllerian ducts are retained because MIS is not secreted in the female fetus. Even in the absence of ovaries, the female ductal system persists. The fallopian tubes differentiate from the cephalic segments of the müllerian ducts. Inferiorly, fusion of the müllerian ducts forms the uterovaginal primordium, from which the uterus and superior portion of the vagina are derived. After the ducts unite at 8 weeks, a central lumen is formed, extending caudally to the sinus tubercle where a solid tip is present initially (101). During this process, as the müllerian ducts are drawn toward the midline, peritoneal folds are

created on each side—the broad ligaments. The myometrium and endometrial stroma, as well as the parametrium, develop from the splanchnic mesoderm alongside the uterovaginal primordium.

Various theories have been proposed about the embryologic origin of the lower portion of the vagina. Paired endodermal outgrowths of the urogenital sinus, called the *sinovaginal bulbs,* develop in the region of the sinus tubercle. Evagination of the dorsal wall of the urogenital sinus in the region of the sinovaginal bulbs occurs at 9 weeks of gestation, to later form the lower vagina. Confirmation that the origin of this evagination is from the urogenital sinus has been documented by immunohistochemistry. Uroplakin, a membrane protein of the urothelium, has been demonstrated in the epithelium of the urogenital sinus as well as in the evagination of the 9-week-gestation human fetus. According to one theory, this region ultimately becomes the lower vagina (101). The lower end of the uterovaginal canal is temporarily occluded by a mass of tissue, termed the *cellular plate.* According to other views, the vaginal plate arises from the müllerian ducts, or a combination of the müllerian and mesonephric ducts (61). Subsequently, the vaginal plate elongates during the third to the fifth month, and a lumen develops by desquamation, so patency of the distal vagina is established. During remodeling of the vaginal plate, its junction with the urogenital sinus slides downward to the lowermost aspect of the sinus, with a partition remaining between the two structures. Ultimately, the distal most vagina becomes exteriorized from the urogenital sinus and differentiates into the vestibule of the vagina. Controversy exists about the origin of the vaginal epithelium—from the urogenital sinus, mesonephric duct, or müllerian duct. The origin of the hymen, which separates the vagina from the urogenital sinus, is also in question, and origins from the vagina, mesenchyma, or urogenital sinus have been proposed (89).

Buds arise from the urethra and extend into the mesenchyme to form urethral glands and paraurethral glands (of Skene). The vestibular glands of Bartholin are formed as outgrowths of the urogenital sinus itself.

GENITAL DEVELOPMENT

The external genitalia of the developing fetus are capable of developing either the male or female phenotype. Endodermal cells from the cloaca extend along the ventral midline surface of the tubercle to form the embryologic urethral plate beginning in the sixth week of gestation. The primordia of the external genitalia inherently feminize unless virilized by activity of dihydrotestosterone between the ninth and twelfth weeks of gestation. This hormone stimulation causes the tubercle to elongate, prompts fusion of the urethral folds, and tubularizes the urethral groove beginning proximally and continuing to the level of the glans. The anatomic development of the penis and hormonal control of this development are extensively covered in Chapter 52 and Chapter 53.

Chapter References

The last 25 years have brought about dramatic changes in the evaluation and management of urologic problems encountered in the neonatal period. Prenatal ultrasound has revolutionized the approach to congenital anomalies, in particular, those involving the genitourinary tract. Current technology allows the detection of urinary tract and renal lesions as early as 10 to 12 weeks of gestation and has provided insight regarding the natural history of these lesions before birth (468). A majority of pregnant women undergo sonographic screening, allowing the fetus to be evaluated before it becomes sick. The development and use of experimental animal models have further expanded our understanding of the pathophysiology of certain disorders, such as obstructive uropathy. Combined with refinements in surgical and anesthetic techniques, early prenatal diagnosis has provided the pediatric urologist with the opportunity to counsel parents and subsequently to offer specialized high-quality care for the newborn diagnosed prenatally with a congenital abnormality of the urinary tract (116).

This chapter presents an overview of the embryology and ontogeny of renal function, an understanding of which is paramount in the evaluation of the fetal urinary tract. Prenatal ultrasound screening is discussed as it pertains to the urologist. The urologic evaluation of the newborn with prenatally diagnosed genitourinary lesions is reviewed with special consideration to dilation of the upper urinary tract, the most common entity diagnosed on prenatal ultrasound screening (310). Finally, common urologic problems encountered in the neonatal period are discussed, including conditions that are being seen with increasing frequency in children who have been in the pediatric intensive care for prolonged periods.

DEVELOPMENTAL ASPECTS OF RENAL PHYSIOLOGY IN THE FETUS AND NEWBORN

Embryology of the Kidney

Until recently, little information was available regarding developmental renal physiology. With the survival of extremely premature infants and the study of fetal animal

models, a better understanding of the functional development of the fetal kidney has emerged (64). Although the placenta functions as the main hemodialyzer for the fetus, the fetal kidneys play a significant role in blood pressure regulation, fluid and electrolytes homeostasis, acid–base balance, and the synthesis of certain hormones.

Before attaining its functional status at about 14 weeks of gestation, the kidney has undergone three stages of morphogenic and physiologic development (73). The first stage of formation of the kidney is the pronephros, a nonfunctional organ, which involutes by 5 weeks of gestation. The mesonephros is the second stage of kidney formation, consisting of about 20 pairs of glomeruli and thick-walled tubules, which secrete urine. The mesonephros degenerates but contributes to the formation of the ureteral bud, which arises from the dorsal aspect of the mesonephric duct. During the fifth week of gestation, the ureteral bud elongates and penetrates the mesonephric blastema, an area of undifferentiated mesenchyme located at the caudal end of the nephrogenic ridge, causing differentiation into the excretory system of the kidney during the seventh week.

The molecular mechanisms regulating renal organogenesis currently are being studied in animal models and in cell–culture line systems (317). Metanephric organ culture systems have aided in elucidating the regulation of growth and branching of the ureteral bud, the changes in extracellular matrix composition, and the cell adhesion events that occur during nephrogenesis (409). Some of the growth factors controlling cellular proliferation and differentiation following induction also have been characterized (46,183). Branching of the ureteral bud, for instance, is regulated by the mesenchyme and by growth factors provided by other surrounding tissues. The specific mechanisms have not been clearly identified, but recent experimental data suggest that chondroitin sulfate proteoglycans may be important factors in branching morphogenesis (292). To date, few peptide growth factors have been identified as responsible for metanephric development (282). However, recent studies suggest that postinductive nephrogenesis is the result of a series of meticulously genetically programmed set of events that may be regulated by a finely tuned balance of local growth factors, transcriptional factors, and distal effector molecules such as epithelial growth factors (EGF) and tissue inhibitor of metalloproteinase-2 (TIMP-2) (222,586). In addition to cell differentiation and proliferation, it has become increasingly clear that renal organogenesis may also involve other important events, such as programmed cell death or apoptosis (528). Specifically, experimental data suggest that metanephric cells may undergo apoptosis if they are not induced by the ureteral bud (30,300). Abnormalities in renal development may also be the result of anomalous regulation of the apoptotic process as demonstrated genetically altered animals (414).

As the kidney develops under the influence of both the inductive process and under the influence of various gene products and growth factors, dividing branches of the ureteral bud penetrate the mesenchyme, compressing it and fragmenting it into separate aggregate islands of cells (409). These oval masses elongate to form tubular structures that become sinuous and establish connections with the ampullae of the ureteral bud. Subsequently, the ureteral bud undergoes a series of approximately 15 generations of divisions, always in two branches. As described, this branching process and its interaction with the developing mesenchyme is regulated by numerous factors, including specific genes such a Pax2 (539). Also involved are adhesion molecules that mediate the attachment of cells to one another and to the surrounding matrix (149). Early in nephrogenesis, the polar aspect of the ureteral bud divides more rapidly than its midportion. The first four or five polar and two or three interpolar branches coalesce to form the renal pelvis (Fig. 46.1A). The next three to five branches organize to form the major calyces (392). Further divisions of the ureteral bud result in the formation of the minor calyces. First-generation collecting tubules develop at the papillary ducts and represent branching distal to the minor calyces. The collecting tubules represent five to seven additional generations of tubules. By 20 weeks of gestation, approximately 30 million tubules have developed and differentiation of the renal collecting system is complete (416).

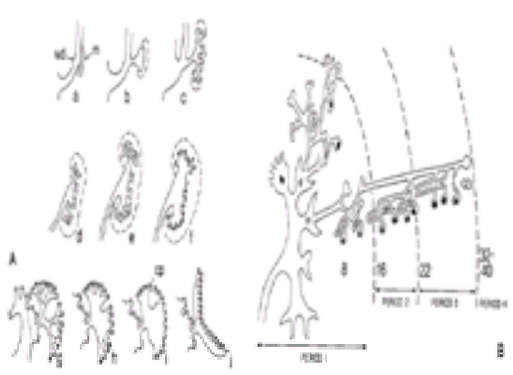

FIGURE 46.1. A: Embryology of the upper urinary tract: the ureteral bud. *a,* Bud arises from the wolffian duct *(wd)* and penetrates the metanephric mesenchyme *(m). b,* The mesenchyme caps the expanded end of the bud. *c,* The bud develops polar, hilar, and ampullary projections, which dichotomize. *d, e,* More dichotomous divisions. *f,* Confluence of the lumens of the divisions forming the pelvis and major calyces. *g,* Second series of ampullary divisions to form the minor calyx (shown in one only). *h,* Confluence of lumens except first division which forms the infundibulum. *i,* Expansion of the lumen to form rounded minor calyx with orifices of the papillary ducts in the convex cribriform plate *(cp). j,* Inversion of the plate to form the papilla. **B:** Embryology of the upper urinary tract: the nephronic components. The minor calyces are shown in the early spherical shape with cribriform plate *(solid arrow)* and later indented forming papilla *(open arrow).* Nephrons develop in periods according to the nature of ampullary activity. Period 1, 8 to 15 weeks, temporary nephrons induced by dichotomizing ampullae of branching collecting ducts; period 2, 16 to 21 weeks, the ampulla induces nephrons that are linked by a common duct to a collecting duct—the so-called arcades in the inner cortex. Period 3, 22 to 32 weeks, the ampulla advances toward the capsule, inducing nephrons that connect independently to its newly formed collecting duct in the outer cortex. Period 4, 32 to 40 weeks, the ampullae rarely divide, and the already established nephrons mature. (Courtesy of F. Douglas Stephens, M.D.)

The nephron arises from differentiated cells of the metanephric blastema, which becomes the glomerulus, Bowman's capsule, proximal and distal convoluted tubules, and loop of Henle (Fig. 46.1B). Simultaneously, the nephron becomes vascularized by an ingrowth of capillaries that arise from the middle sacral and common iliac arteries. Experimental evidence suggests that differentiation imparts angiogenesis-stimulating activity to the metanephric blastema. Recently, a specific heparin-binding angiogenesis factor has been isolated and characterized from the embryonic mouse metanephros (439). In addition, fibronectin has been found to have an important role in the guided migration of capillary endothelial cells into the primitive S-shaped tubules (469). Therefore formation of the renal unit (or nephron) is the result of close interaction between three distinct cell types brought together by organized migration and differentiation. These cell types are the epithelium of the wolffian duct–derived ureter, the mesenchyme of the metanephric blastema, and the endothelial cells (472). Further nephron development occurs at nearly an exponential rate as the ureteral bud continues to divide.

In summary, the ureteral bud forms the collecting system, namely the ureter, renal pelvis, calyces, papillary ducts, and collecting system, whereas the metanephric blastema forms the entire excretory system (i.e., the nephrons). By 20 weeks of gestation, the ureteral bud has completed its series of divisions and the ductal system is complete. At this point, approximately one-third of the ultimate number of nephrons are present; these nephrons form the juxtamedullary zone of the future renal cortex (387). Elaboration of the nephrons progresses along vertical extensions in the ends of the collecting ducts. Nephron formation is actually completed by 36 weeks of gestation (Fig. 46.2 and Table 46.1). From then, until the child is 2 to 3 years of age, the nephrons undergo maturation, and hypertrophy occurs through 12 years of age.

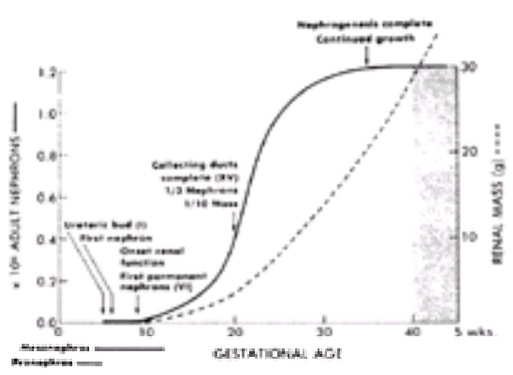

FIGURE 46.2. Fetal renal development. The branching of the collecting system is complete by 20 weeks, but the majority of nephrons and most of the functional mass form in the cortex after 20 weeks. TABLE 46.1. NEPHROGENESIS IN THE HUMAN

Morphology of the Kidney

The human kidney has multiple lobes, whereas the kidney in the rat, rabbit, and cat is unipapillary with a single calyx (416). At 10 weeks of gestation, three to four lobes have developed. As branching of the ureteral bud continues, the number of lobes gradually increases, and by the end of the fourth month, approximately 15 lobes are present. Each papilla forms a renal lobe, with one or two papillae opening into one calyx. The lobes are hemispheric, with the calyx in the center and the tubules radiating outward with their attached nephrons, capped by the residual undifferentiated blastema. As vascular development proceeds, large blood vessels in the papillae become fixed in position; in these areas, further peripheral growth is impaired. As a result, tubules lateral to the blood vessels may protrude from the surface of the kidney, forming secondary lobulation. At 36 weeks of gestation, when nephron formation is complete, approximately 30 lobes and lobulations may be seen (416) (Fig. 46.3). As renal maturation occurs and the nephrons increase in length and tortuosity, the demarcation of the surface of the kidney becomes less distinct. However, the lobar structure is permanent.

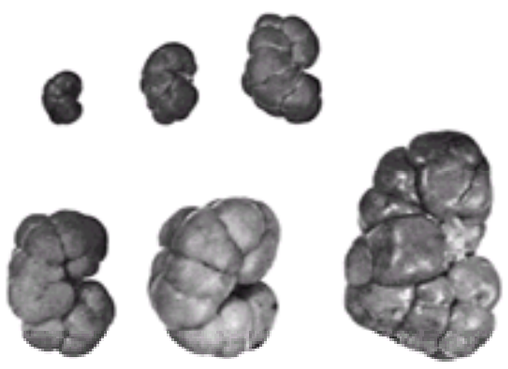

FIGURE 46.3. The lobes of the kidney gradually increase in number and size during fetal development. Weight of kidneys and fetuses from which they were removed: 0.4 g and 93 g, 0.9 g and 254 g, 1.6 g and 508 g, 3.7 g and 1,065 g, 7.5 g and 2,080 g, 11.2 g and 3,070 g. (From Potter EL: *Normal and abnormal development of the kidney*. Chicago: Year Book Publishers, 1972, with permission.)

Initial renal morphogenesis occurs at the level of the upper sacral segments. The vertebral column of the embryo straightens as it grows, and the kidneys undergo growth in a cranial direction. During the eighth week, the kidney comes into contact with the large fetal adrenal gland, and by the end of the eighth week, renal ascent is nearly complete. The renal pelvis initially forms on the ventral surface of the kidney. As the kidney ascends, the kidneys rotate medially 90 degrees.

In summary, several events appear to be crucial to the development of two normal kidneys: (a) development of a single ureteral bud from each mesonephric duct during the fifth week of gestation; (b) induction of the metanephric blastema by precise directional growth of the ureteral bud into the blastema; (c) branching of the ureteral bud; (d) formation of the nephrons in conjunction with vascular ingrowth in the renal mesenchyme; and (e) ascent of the kidneys during the sixth, seventh, and eighth weeks.

Renal Function in the Fetus

The developing fetal kidney is very different functionally from the newborn kidney (501). Throughout normal gestation, the placenta is the major regulatory organ of the fetal environment. Urine formation by the fetal kidney begins between 9 and 12 weeks of gestation. Evidence for early urine production is documented by distention of the renal pelvis (416). Hydrostatic pressure generated by the accumulation of urine in the collecting system in the early stages appears to be influenced by the development of Chwalla's membrane at the caudal end of the ureteral bud (352). This phenomenon may be responsible for the early canalization and dilation of the collecting system. Subsequent rupture of Chwalla's membrane at 9 weeks of gestation allows the urine to flow into the bladder. Others have demonstrated kinks and folds in the early ureteral development resulting from recanalization of the ureteral bud that may be precursors of obstructions at the ureteropelvic junction (UPJ) and ureterovesical junction (UVJ) (8,393).

Renal Blood Flow in the Fetus

Despite the fact that the kidneys constitute a larger percentage of body weight in the fetus than later in life, the fetal kidneys receive only 2% to 4% of the total cardiac output (10,197,461). Approximately 40% to 60% of the fetal cardiac output travels through the placenta.

Autoregulation, a phenomenon by which the kidney is able to preserve its blood flow at a constant level during major changes in perfusion pressure, may exist in the fetus (501). At birth, following clamping of the umbilical cord, the cardiac output increases, accompanied by a substantial rise in the renal vascular resistance, which maintains the intrarenal blood flow at rates similar to those late in gestation. As renal vascular resistance gradually decreases, an increasing proportion of the cardiac output is directed to the kidney for glomerular filtration, such that 15% to 18% of total output is received by the newborn kidneys. Renal blood flow, as estimated by *p*-aminohippuric (PAH) clearance, doubles by 2 weeks of age and reaches adult levels by 2 years of age (corrected for body surface area) (460).

Several factors are known to influence fetal renal hemodynamics. These include the renin-angiotensin system (RAS), arginine vasopressin, atrial natriuretic factor, certain prostaglandins, kallikrein-kinin, and the sympathetic nervous system (9,446). In the human fetus, renin has been localized in the mesonephros and in the metanephros by 8 weeks of gestation (79). A role for the RAS has been postulated in the process of angiogenesis because renin also has been identified in the mesonephric and renal arteries (273). In addition, the high serum renin level found in the human newborn may account for the high renal vascular resistance (21,205,301,526). The intrarenal distribution of blood flow in the fetus differs quantitatively from that of the newborn (447). In the latter stages of gestation, glomerular blood flow appears to shift toward the superficial cortex, whereas no change in the medullary nephron perfusion occurs. This trend continues after birth and reflects diminishing vascular resistance in the outer cortex (386). This centrifugal pattern of changing distribution of intrarenal blood flow appears to parallel the changes in glomerular maturation (Table 46.2). In the newborn, the volume of outer cortical glomeruli is proportionately less than that of the middle and inner cortical glomeruli, but in adulthood, the size of the glomeruli from these three regions is similar (174,509).

Age (Days)	Cortical[a] (nl/min)	Juxtamedullary[b] (nl/min)
1	0.9	17.2
15	4.1	43.2
30	19.3	42.1

TABLE 46.2. NEPHRON GLOMERULAR FILTRATION RATE IN THE GUINEA PIG

Throughout gestation, renal blood flow appears to be regulated by both humoral and neural factors. Changes in vascular resistance, after birth, allow greater perfusion of the kidney, which results in an increasing glomerular filtration rate (GFR). The decrease in renal vascular resistance might be due to decreases in circulating levels of vasoconstrictor catecholamines, vasopressin, and angiotensin or to concomitant increases in levels of vasodilator prostaglandins (103,200,373). Most of the increase in renal blood flow occurs in the outer zone of the cortex and is critical in urine production and glomerular filtration.

Glomerular Function in the Fetal Kidney

Urine is excreted by the fetal kidney as early as the fifth week of gestation, when the mesonephros is capable of making urine. Renal tubular function begins in the metanephric kidney between 9 and 12 weeks of gestation. By 14 weeks, the loop of Henle is functional and tubular reabsorption occurs. At term, urine flow rate average is more than 1 L per day (Fig. 46.4). Urine production in the fetus has been estimated by ultrasound measurements of bladder dimensions and frequency of fetal micturition (60).

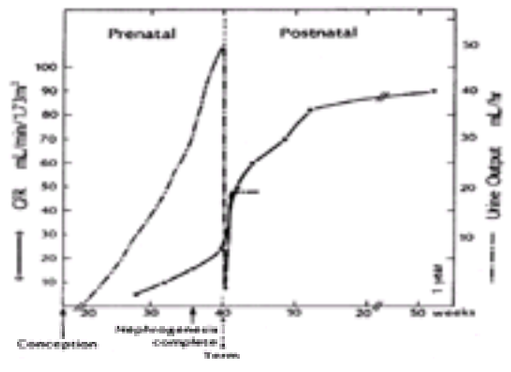

FIGURE 46.4. Changes in glomerular filtration rate *(GFR)* and urine output during fetal development and infancy. A report (Rabinowitz, et al. Measurement of fetal urine production in normal pregnancy by real time ultrasonography. *Am J Obstet Gynecol* 1989;161:1264) suggests that urine output at term may be 50 mL per hour.

GFR, which reflects the kidney's ability to filter blood, increases progressively with gestational age (500) (Fig. 46.4). Fetal GFR is dependent on several factors, including the permeability of the glomerular wall, the surface area available for filtration, and the ultrafiltration pressure, which depends on efferent arteriolar resistance, capillary blood flow, and the protein concentration in arterial plasma (221). However, relatively little information is actually available on fetal GFR (501).

Estimation of glomerular filtration in the perinatal period is based on determination of inulin clearance, which has been studied in neonate and premature, low-birth-weight infants (106,569). These methods are not entirely accurate and may vary, but they have been improved by the use of constant infusion techniques and by factoring in body weight as opposed to body surface area (105,569). GFR is dependent on the following factors:

1. Ultrafiltration pressure

   Hydrostatic pressure within the glomerular capillary (P_{GC})
   Oncotic pressure within the capillary (Onc_{gc})
   Hydrostatic pressure within the proximal tubule (P_{pt})
   Ultrafiltration pressure = $P_{gc} – (Onc_{gc} + P_{pt})$
2. Permeability of the glomerular wall
3. Surface area of the filtration membrane

Wilkins (569) confirmed that from gestational age 26 weeks to 40 weeks, GFR quadruples. After birth, GFR continues to mature slowly and progressively for about 4 months after birth. During the first 2 years of life, the rate of increase in GFR is much greater than that of somatic growth. It remains constant thereafter in the range of 90 to 100 mL/min/1.73 m^2. Studies in very-low-birth-weight infants have shown that as early as 26 weeks of gestation, the fetal kidney has the capacity to assume excretory function and that this capacity can be achieved 2 days after birth (569). The mechanisms responsible for the rapid increases in GFR are not well understood. Because 80% to 90% of nephrons are formed by 26 weeks of gestation, their functional potential may be stimulated by the redistribution of blood flow through the kidneys, which occurs after removal of the fetus from the intrauterine environment.

The ontogeny of the three primary parameters affecting GFR has been studied carefully in animal models. In the newborn guinea pig, it appears that a relatively small increase in the ultrafiltration pressure occurs, which can account for 10% of the increase in overall GFR (510). The permeability of the glomerular capillaries also increases causing a slight increase in GFR. Finally, there is a progressive increase in the filtering surface area (511). In the newborn kidney, the glomeruli are larger relative to the tubules when compared with their relative sizes in infants and children (174). With renal growth and maturation, there is a modest increase in glomerular size, but the capillary network within the glomerulus continues to develop, with a resultant increase in the total surface area for filtration. A twentyfold- to twenty-fivefold increase in capillary surface area has been demonstrated in various species (269,471), and it accounts for 85% of the rise in total GFR.

Renal development and maturation occur in a centrifugal pattern. Thus, at any stage, the most mature nephrons are located in the deep (juxtamedullary) cortex, and the most immature nephrons are in the outer cortex. Although the majority of nephrons are located in the outer cortex, at birth the blood flow is directed primarily to the deeper cortical nephrons, whereas in the adult kidney, blood flow to the inner and outer cortex is equal. Thus there is a similar changing pattern of distribution of glomerular filtration with an increasing ratio of outer cortical GFR to inner cortical GFR with age (386,531). Table 46.2 reflects the early centrifugal changes in glomerular filtration in the deep cortical and outer cortical nephrons.

Tubular Function

The proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting ducts are responsible for handling the filtrate from the glomerulus. Tubular functions include regulation of fluid volume, electrolyte balance, acid–base balance, and excretion of nitrogenous waste products. In the fetus, tubular function is reduced compared with that in postnatal life. Maturation of tubular function does occur in parallel to the increase in prenatal GFR (Table 46.3).

	Premature Infant	Term Infant	Adult	Age of Maturation (mo)
Glomerular filtration rate (mL/min/1.73 m²)	8–10	20–30	120	12–24
Renal plasma flow (mL/min/1.73 m²)		120–150	600	3–6
Filtration fraction (%)		30–40	20	6–36
T_m glucose (mg/min/1.73 m²)		35–100	300	12–24
Urinary dilution (mOsm/L)	50	50	50	—
Maximum urinary concentration (mOsm/L)	400–600	400–600	1,200–1,400	1
Maximum urine-to-plasma osmolar ratio	2.5		4	1
Ammoniagenesis	Lowered	Normal		
Urinary acidification	Normal*	Normal*		2
Hydrogen ion excretion	Normal or lowered	Lowered		

*Except in metabolic acidosis.

TABLE 46.3. FUNCTIONAL DEVELOPMENT OF THE KIDNEY

Transport of filtrate from the tubular lumen to interstitial fluid or peritubular capillaries is called *reabsorption,* and transport from the capillary to the tubular lumen is termed *secretion.* Transport may be active (against an electrochemical gradient and requiring metabolic energy) or passive (along an electrochemical gradient). Substances that are passively transported include water, certain organic acids, and urea. Substances that are actively reabsorbed include sodium, glucose, and amino acids. Other substances, such as organic bases and PAH, are secreted actively.

There are two types of active transport mechanisms in the kidney: systems that cannot be saturated and systems that are limited by a transport maximum (T_m). An example of a transport system that cannot be saturated is sodium transport. Characteristically, a relatively constant fraction of these substances is transported and excreted. In contrast, transport of glucose, bicarbonate, and PAH is limited. In systems limited by a T_m, all of the substance is reabsorbed or secreted until the maximum amount that can be transported, the T_m, is reached. The T_m for a substance must be distinguished from the plasma threshold for that substance. For example, the plasma threshold for glucose is the plasma concentration at which glucose first appears in the urine. In contrast, the T_m for glucose is the maximum amount that the tubules can reabsorb and is measured in milligrams per minute.

Although the plasma osmolality in humans is relatively constant at approximately 300 mOsm/L, the osmolality of the urine varies from 50 to 1,500 mOsm/L, depending on hydration, age of the patient, and state of maturation of the tubular system. Urine is concentrated as a result of a solute concentration gradient in the renal medulla. The solute concentration in the cortex and at the corticomedullary junction is isosmotic with arterial plasma, whereas at the tip of the papilla, solute concentration is extremely hypertonic compared with arterial plasma.

The concentration gradient is created by active transport of sodium out of the ascending limb of the loop of Henle. The extent of the gradient is directly proportional to the length of the loop of Henle. Blood flow through the medullary region of the kidney permits maintenance of the concentration gradient. The vasa recta loop up and down through the medulla, preventing dissipation of the concentration gradient created by active sodium transport out of the loop of Henle. As plasma travels down the descending limbs of the vasa recta, water leaves and solutes enter plasma because the plasma is going from a lesser to a more concentrated environment. As the plasma enters the ascending limb of the vasa recta, water enters and solutes leave the plasma passively because the plasma is going from a concentrated to a more dilute environment. The ultimate effect is that plasma leaving the vasa recta is slightly hypertonic compared with plasma entering the vasa recta, resulting in some dissipation of the concentration gradient. If blood flow through the medulla is slowed, the dissipation is lessened; if blood flow increases, dissipation is increased.

Approximately half of the concentration gradient is provided by active reabsorption of sodium. The additional solute that allows the mature kidney to concentrate urine to 1,500 mOsm/L is urea.

The concentration of solutes in the tip of the papilla of the mature kidney is approximately 1,500 mOsm/L. As urine traverses the collecting tubules and collecting ducts that run through the medulla, it becomes more concentrated. If the walls of the collecting tubule are permeable to water, the fluid in the collecting tubules has the same solute concentration as that in the deepest portion of the medulla; that is, it is quite concentrated. On the other hand, if the collecting duct and distal convoluted tubules are impermeable to water, the urine remains dilute. Antidiuretic hormone (ADH), produced by the posterior pituitary gland, regulates the permeability of the collecting duct and distal convoluted tubule.

In summary, urinary concentration depends on the ability of the ascending limb of the loop of Henle to transport sodium actively out of the tubular lumen into the interstitium, the length of the loop of Henle, permeability of the distal convoluted tubule and collecting duct to water, availability of ADH, ability of the kidney to respond to ADH, excretion of urea, solute load, and blood flow through the vasa recta.

All mammalian fetuses normally excrete urine hypotonic to plasma. Although the mechanisms for hypotonic urine in the fetus are not entirely understood, one reason is that fetal urea is cleared through the maternal circulation, preventing the development of a high concentration gradient. Thus urinary sodium and chloride concentrations are substantially lower than plasma levels.

At birth, the neonate is able to concentrate urine to a maximum osmolality of 400 to 600 mOsm/L. The neonatal kidney gradually increases its concentrating ability and achieves an adult level at approximately 3 to 6 months. The inability of the newborn to concentrate urine is related to an inefficient countercurrent multiplier system with diminished accumulation of urea in the medulla, increased medullary blood flow, decreased tubular responsiveness to circulating ADH, and a relatively short loop of Henle (587).

The major limitation in concentrating ability is the low rate of urea excretion, which results because the infant is in a substantially anabolic state and uses most of its dietary nitrogen intake for growth. Infants fed a high-protein diet demonstrated a rapid increase in urinary concentrating ability, with the increase being entirely attributable to increased urinary urea (146). In the normal infant, with increasing length of the loop of Henle and increasing blood flow to the outer cortex, higher concentrations of urea in the renal papilla result, allowing improvement in concentrating ability.

Another reason for the limited urine-concentrating ability of the newborn kidney is the low ADH activity. Bioassayable ADH is low or absent in infants younger than 2.5 months of age (264), and there is also evidence of a relative insensitivity of the distal tubule to ADH (473).

The newborn infant is able to dilute the urine as well as an adult, lowering urinary osmolality to 50 mOsm/L. Premature infants can decrease the osmolality to levels as low as 25 to 35 mOsm/L (18). Furthermore, infants from 3 weeks to 13 months have a better urine-diluting capacity than adults, but it diminishes with age (449).

However, the newborn is unable to excrete a water load as well as an adult. For example, infants given a water load of 3% of their body weight excrete only 10% of the load in the first 3 hours, whereas an adult excretes all of it during this time (17). Furthermore, the infant has a maximum urinary flow of 6 to 8 mL/min/1.73 m^2 compared with 12 mL/min/1.73 m^2 in the adult (31). Thus, although an infant's kidney is able to dilute urine as well as an adult's, its diuretic capacity is limited. Nevertheless, the immature kidney can double its urine output after administration of furosemide (303). In the rat, there is experimental evidence that there is an unelucidated factor in adult blood not present in infant rats that allows the kidney to generate a full diuretic response (507).

The ability of the infant to reabsorb and excrete sodium depends in large part on gestational age. The healthy term infant usually is in positive sodium balance regardless of the amount of salt in the diet (512). The fractional sodium excretion (Fe_{Na}) is determined by the following formula:

$$Fe_{Na} = (U_{Na}/P_{Na})/(U_{Cr}/P_{Cr})$$

where U_{Na} = urinary sodium concentration
P_{Na} = plasma sodium concentration
U_{Cr} = urinary creatinine concentration

P_{Cr} = plasma creatinine concentration

In very premature infants, serum sodium levels may be very low due to excessive urinary excretion (levels of sodium excretion up to 16% of filtered sodium load) and may result in significant hyponatremia. The exact cause of this is still being studied, but indications are that it may be due to failure of proximal tubular reabsorption (569). In the term infant, on the other hand, fractional sodium excretion is low, approximately 0.1% to 0.2% (495). This low sodium excretion is probably secondary to the high plasma renin and aldosterone concentrations that are five to ten times higher in the neonate than in the adult (21). It has been speculated that constant sodium removal is used for the development of new bone in the neonate and that the removal of sodium serves as a constant stimulus for renin release (353).

Although term infants retain sodium easily, they have a limited ability to excrete a salt load compared with adults (204). Because experimental aldosterone blockade does not alter the fractional sodium excretion in rats (159), it has been hypothesized that this limited ability to excrete a salt load may be secondary to an inability to elaborate natriuretic factors, such as oxytocin and kallikrein (522).

In contrast, premature infants less than 35 weeks of gestation have a natriuresis resulting in a negative sodium balance (527), with fractional sodium excretion varying between 0.8% and 6.0% (495). During this period, the premature infant reduces the high total body water content (approximately 80%) and extracellular fluid compartment (approximately 50%) (571). The negative sodium balance is probably secondary to multiple factors, including inefficient absorption in the gastrointestinal tract, short length of the proximal convoluted tubule in preterm infants, and a decreased sensitivity of the distal convoluted tubule to aldosterone (495). Appropriate recognition of this physiologic loss of sodium is important because aggressive replacement of the sodium loss can result in sodium and fluid retention, which could increase the risk of a symptomatic patent ductus arteriosus or necrotizing enterocolitis (40,41).

An important buffering mechanism in the maintenance of acid–base balance is the excretion of hydrogen ions by the kidney. The normal newborn has a relative metabolic acidosis. The urine in the neonate, and especially in the preterm infant, is alkaline during the first week of life and becomes acidic during the second week (147). Furthermore, premature newborns are unable to acidify their urine as well as term infants. Urinary pH often is more than 6 in premature infants (527). The early production of alkaline urine is normal, and evaluation for renal tubular acidosis need not be undertaken (22).

Although term newborns ultimately excrete an acidic urine, they have a diminished capacity for excreting hydrogen ions compared with adults (525). One explanation for this limited capacity may be that the renal excretion of ammonia is less, particularly in the premature infant (495).

In addition, the renal threshold for bicarbonate reabsorption in the fetus and neonate is lower than in the adult and is altered by changes in the extracellular fluid volume (ECFV) (445). The expanded ECFV in the normal fetus and neonate depresses proximal tubular bicarbonate reabsorption. However, as the ECFV falls during the first few weeks of life, increasing bicarbonate reabsorption occurs, resulting in a rise in plasma bicarbonate and serum pH and a decrease in urine pH. Thus, although the infant is able to excrete usual acid loads, in the presence of a metabolic acidosis, the newborn may require supplemental bicarbonate.

Another example of tubular immaturity is glucose excretion. Urinary glucose concentrations in premature infants less than 34 weeks of gestation are significantly higher than in older infants. Similarly, fractional excretion of glucose is high before 34 weeks of gestation (19). Thus sick premature infants less than 34 weeks of gestation receiving hyperalimentation for maintenance of sufficient caloric intake may be at risk for significant glycosuria. If unrecognized, this situation could result in an osmotic diuresis and dehydration. Consequently, infants receiving solutions of 10% dextrose should have their urine monitored frequently for the presence of glucose, particularly if they are less than 34 weeks of gestation.

Determination of Renal Function in the Fetus

Evaluation of GFR is important in infants with structural or functional abnormalities of the urinary tract or if nephrotoxic medications are being used. Traditionally, GFR has been based on a determination of creatinine clearance by the following formula:

$$C_{Cr} = [(U_{Cr} \times V)/P_{Cr}] \times (1.73/SA)$$

where C_{Cr} = creatinine clearance (mL/min/1.73 m^2)
U_{Cr} = urine creatinine concentration (mg/dL)
V = urine volume (mL/min)
P_{Cr} = plasma creatinine concentration (mg/dL)
SA = surface area (m^2)

The GFR in infants and children is compared with adult levels by using a correction factor; that is, the GFR is expressed as milliliters per minute per 1.73 m^2.

Creatinine is filtered, as well as reabsorbed and secreted. Using creatine may overestimate the GFR compared with measurements using inulin, which is neither reabsorbed nor secreted. However, although inulin clearance is a more precise method of determining GFR, it is impractical. In children between 1 and 12 years of age, a simple formula has been derived that estimates GFR from the plasma creatinine and a child's length (480):

$$GFR = (0.55 \times L)/P_{Cr}$$

where L = length (cm). This formula is similar to the one derived earlier by Barratt (32) and also applies to females between 13 and 21 years of age. However, in males between 13 and 21 years of age, the formula results in a significant underestimation of GFR, and in this group, a more accurate formula (479) is as follows:

$$GFR = 1.5\ (\text{age in years}) + 0.5\ (L/P_{Cr})$$

A third formula is used for determination of GFR in term infants between 1 week and 1 year of age is as follows (478):

$$GFR = (0.45 \times L)/P_{Cr}$$

The third formula is not applicable to infants younger than 1 week of age because serum creatinine during this period is a reflection of the maternal renal status and it takes approximately 1 week for the term newborn with normal renal function to reach a baseline creatinine level. In addition, the formula has not been verified in premature infants.

Another technique of measuring renal function in infants uses a radionuclide, such as technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc DTPA), which is cleared by glomerular filtration:

$$GFR = Vd \times (0.693/T_{½})$$

where Vd = volume of distribution
$T_{½}$ = half-time of disappearance of the radionuclide

When this system is used, it is possible to determine the GFR by drawing a single specimen of blood at a specified time after injection of the radionuclide.

Although formulas using serum creatinine and body weight or height are relatively accurate in children with normal renal function, they are not very accurate in children with renal insufficiency.

In a preliminary report, Chandhoke and colleagues (83) presented a newer and presumably more accurate method of assessing GFR using iothalamate that is infused subcutaneously with an insulin pump. After 24 to 48 hours of infusion, the distribution of the iothalamate reaches an equilibrium and serum and urine samples are obtained, making it possible to derive the GFR. The technique has been compared with inulin clearance in adults with normal and abnormal renal function and has

been extremely accurate. Extensive trials in children are under way.

Periodic determination of GFR in the sick neonate, particularly the premature infant, is important when the dosages of drugs that are excreted primarily by the kidney are calculated. When nephrotoxic drugs such as aminoglycosides are used, serial measurements of serum creatinine and trough drug levels should provide sufficient information to be certain that dosage is appropriate. Furthermore, in infants born earlier than 34 weeks of gestation, serum creatinine concentration often remains unchanged from maternal levels until 34 to 35 weeks of conceptional age is reached because the GFR is too low to clear creatinine from the plasma. The contribution to serum creatinine by maternal creatinine, ongoing creatinine production, rate of creatinine excretion, conceptional age, hemoconcentration or hemodilution associated with postnatal weight loss or fluid therapy, and the influence of nonrenal factors on GFR vary independently in any given infant (20). However, regardless of renal or conceptional age, if the serum creatinine rises, the clinician should be alerted to renal dysfunction secondary to a structural or functional renal abnormality or to nonrenal factors, such as mechanical ventilation, that may alter the GFR in the neonate (544).

With the ability to image the fetal urinary tract came the opportunity of assessing renal function before birth. At present, direct measurement of renal function *in utero* is not technically feasible. However, fetal renal function can be inferred from (a) measurements of fetal urine outputs, (b) sonographic appearance of the kidneys, and (c) analysis of fetal urine composition after percutaneous aspiration. Newer modalities, such as magnetic resonance imaging (MRI), may also be on the horizon (565).

Fetal urine output has been studied in a variety of animal models. In 1964, Chez and associates (88) studied urinary flow *in utero* in rhesus monkeys using indwelling catheters placed in the urethra or bladder. They demonstrated that average urine flow was 5 mL/kg per hour.

In 1973, Campbell and co-workers (74) studied human fetal urine output by measuring the size of the bladder in three dimensions by ultrasound (bladder size = 4/3 × p × length × width × breadth ÷ 2) and determining the number of times the fetus voids per hour. In a series of patients between 32 weeks of gestation and term, the fetal bladder cycle varied from 50 to 155 minutes, with a mean of 110 minutes. The bladder volumes were noted to increase from 11 mL at 32 weeks to 40 mL at term. Rabinowitz and colleagues (422) have shown that fetal urine output increases from 5 mL per hour at 20 weeks to 51 mL per hour at term. Data from other studies have shown that (a) in the small fetus, urine output is lower, corresponding to fetal size rather than gestational age; (b) the fetus of a diabetic mother has an increased urine output; and (c) the fetus with anencephaly and polyhydramnios has a normal urine output (303,580,581). In addition, administration of intravenous (IV) furosemide to the mother during the last trimester doubles fetal urine output (303,582). Therefore it appears that the volume of amniotic fluid is not a reliable indicator of fetal renal function except at the extremes of oligohydramnios.

The sonographic detection of cortical cysts and increased cortical echogenicity has been associated with irreversible renal damage in the fetus (329). Normal fetal kidneys beyond 30 weeks of gestation exhibit an echotexture similar to that of liver, with an internal architecture showing a differentiation between cortex and medulla. The medulla containing tubules and fluid appears darker. In contrast, a dysplastic kidney exhibits no internal architecture and may have increased echogenicity caused by a disruption in normal histology. The dysplastic fetal kidney is characterized by the presence of disorganized metanephric structures surrounded by fibrous tissue, which may be associated with cortical cysts (246). More than 90% of dysplastic kidneys with cortical cysts are associated with an obstructive process occurring during nephrogenesis. Mahoney and associates (329) studied the kidneys of 49 fetuses with obstructive uropathy and found that the presence of cortical cysts had 100% specificity and a positive predictive value of 100% for the presence of renal dysplasia. However, the absence of cortical cysts cannot ensure the absence of renal dysplasia. Of the dysplastic kidneys, only 44% had cortical cysts. Increased echogenicity of the kidney's alone also was shown to be less specific and to have a lower positive predictive value than the presence of cortical cysts. The evaluation of renal function solely on the basis of renal echogenicity is further limited by the subjective nature of this feature. Ultrasonographic examination of the fetal kidneys may provide prognostic information if cortical cysts and increased echogenicity are detected, but it is less specific in their absence (113). Furthermore, when seen in conjunction with oligohydramnios and fetal bladder distention, increased renal echogenicity is highly predictive (87%) of bladder outlet obstruction (279).

Fetal urine is an ultrafiltrate of fetal serum. Glick and co-workers (201) observed that fetuses with congenital hydronephrosis and normal renal function produce hypotonic urine, whereas those with poor function made isotonic urine. In this initial study from the fetal treatment program in San Francisco, 20 fetuses with bilateral hydronephrosis were evaluated, 18 of which had percutaneous drainage of fetal urine before birth. In an attempt to determine prognostic criteria of renal function, urine electrolytes were studied. Prognostic features for “good” renal function included urinary sodium less than 100 mEq/L, chloride less than 90 mEq/L, osmolality less than 210 mOsm/L, and urine output greater than 2 mL per hour. Other reported prognostic criteria for good renal function were normal to moderately decreased amniotic fluid and a normal echogenic appearance of the kidneys. These criteria were established as a possible means to select those fetuses with sufficient renal function to have a favorable postnatal outcome if *in utero* decompression of an obstructive process was carried out early enough to prevent the sequelae of obstructive uropathy. These criteria have been challenged by several groups because normal controls in normal fetuses were not provided. In addition, these criteria failed to take into account variation in urine electrolytes during gestation (153,376,570). More recently, Johnson and associates (271) have recommended sequentially sampling fetal urine to establish patterns of progressive improvement or worsening of values so as to provide a better assessment of renal damage.

Subsequent to the 1985 study, Crombleholme and associates (113) evaluated a subsequent series of 40 fetuses with bilateral hydronephrosis and found that the prognostic criteria accurately predicted a good outcome after intervention, showing a statistically significant difference in survival in the good versus poor prognosis group (81% versus 12.5%). In addition to measuring the levels of fetal urine sodium, chloride, and osmolarity, other groups have evaluated urine Ca^{2+}, PO_4, and b_2-microglobulin to assess fetal renal function (369,376). Nicolini and colleagues (375) found that fetal urinary calcium and sodium were significantly elevated in fetuses with renal dysplasia compared with those fetuses noted to have lower urinary tract obstruction but normal renal histology and normal clinical outcome. Urinary calcium levels were reported to be the most sensitive indicators of renal dysplasia (100%), but they lacked specificity (60%). Urinary sodium was slightly less sensitive (87%) but was found to be the most specific (87%). Urinary PO_4, creatinine, and urea were not helpful in confirming renal dysplasia. Muller and co-workers (369) found that b_2-microglobulin levels were significantly elevated in patients with an elevated creatinine (greater than 0.56 mg/dL at 1 year of age) and recommended its use as a predictor of renal function at 1 year of age. The same group of French researchers have further published reference values for fetal urine markers (369).

FETAL MEMBRANES

The extraembryonic or fetal membranes include the chorion, amnion, yolk sac, and allantois (213,365,542). These membranes are intimately related to the placenta, which develops from (a) the chorion (fetal portion) and (b) the endometrium (maternal portion). The fetal membranes and placenta are essential to fetal growth and development by providing several important functions, such as protection by cushioning, nutrition, respiration, and excretion.

Implantation of the blastocyst on the uterine wall begins on the sixth or seventh day after fertilization. The trophoblast rapidly proliferates and differentiates into the cytotrophoblastic and syncytiotrophoblastic layers of the placenta. In addition, lacunar networks develop, creating a primitive uteroplacental circulation. Finally, primary villi form on the outer surface of the chorionic sac. By the end of the second week, the conceptus is completely embedded within the endometrium. Concurrently, the yolk sac and the amniotic cavity develop (Fig. 46.5). The allantois appears during the third week.

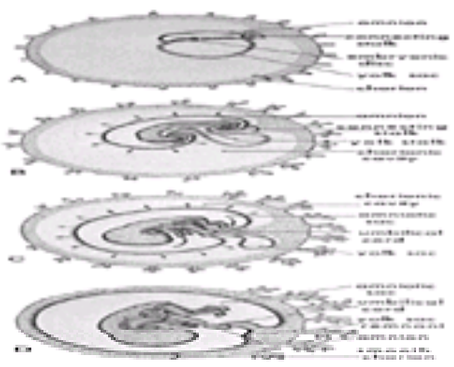

FIGURE 46.5. Drawings illustrating how the amnion becomes the outer covering of the umbilical cord and how the yolk sac is partially incorporated into the embryo as the primitive gut. At 3 weeks **(A),** 4 weeks **(B),** 10 weeks **(C),** and 20 weeks **(D).** (From Moore KL. *The developing human. Clinically oriented embryology,* 3rd ed. Philadelphia: WB Saunders, 1982, with permission.)

The yolk sac serves several important functions during embryogenesis. First, it appears to provide nutrients to the embryo during the second and third weeks while the uteroplacental circulation is being established. Second, angiogenesis begins in the yolk sac during the third week and persists until hematopoietic activity in the liver begins in the sixth week. Furthermore, germ cells form in the yolk sac and subsequently migrate to the gonadal ridge. Finally, the dorsal aspect of the yolk sac is incorporated into the embryo during the fourth week as an endodermal tube—the primitive gut. This structure gives rise to the epithelium of the gastrointestinal tract, trachea, bronchi, and lungs. By 12 weeks, the yolk sac is quite small but may still be identified. The stalk of the yolk sac usually is detached from the gut during the fifth week; persistence of the yolk stalk results in a diverticulum from the ileum, known as *Meckel's diverticulum,* with an incidence approximating 2% (365).

The allantois appears during the third week as a small fingerlike diverticulum from the caudal wall of the yolk sac. Although this structure functions as a reservoir for excretory products or as a respiratory chamber in some vertebrates, in humans it does not function. However, hematopoiesis occurs on its walls during the first 2 months, and its blood vessels become the umbilical vein and arteries. The allantois itself connects the urinary bladder to the umbilicus. As the bladder increases in size, the allantois becomes much smaller and forms the urachus. After birth, the urachus becomes the median umbilical ligament and extends from the dome of the bladder to the umbilicus.

The amnion, the innermost of the fetal membranes, is derived from the cytotrophoblast adjacent to the dorsal aspect of the germ disc. As the amnion grows, it gradually obliterates the chorionic cavity, concurrent with ventral longitudinal folding of the embryo. The primary junction of the amniotic cavity with the embryo is on its ventral surface. The amnion provides the epithelial covering for the umbilical cord. The amnion therefore lines the expanding amniotic cavity, which holds increasing volumes of fluid. Early in pregnancy, the amniotic fluid appears to be a transudate of maternal plasma. During the first trimester, amniotic fluid production results from the active transport of electrolytes and other solutes across the amnion, which is composed of a single layer of cells. There is passive diffusion of water along the osmotic gradient thus generated (556). As the fetal kidneys start to produce urine and as flow through the urinary tract occurs, fetal urine is the major source of amniotic fluid. It is also likely that before keratinization of fetal skin at about 17 weeks, some of the amniotic fluid may be derived from water transport across the highly permeable fetal skin (5,400).

The volume of amniotic fluid increases at a relatively constant rate during pregnancy until the end of the second trimester. Regulation of amniotic fluid volume depends not only on urine production by the fetus but also on fetal swallowing, which starts between 8 and 11 weeks of gestation (538). By the end of the second trimester (24 weeks), the volume of amniotic fluid has increased steadily to approximately 800 mL, with this volume remaining relatively constant throughout the remainder of gestation. A mild decrease in volume is seen just before term (Table 46.4). Normally, amniotic fluid volume ranges from 500 to 2,000 nil (237,418). During the first half of gestation, the amniotic fluid has an electrolyte composition and osmolality similar to that of fetal and maternal blood (326). Later, amniotic fluid osmolality progressively decreases with advancing age, reaching values of 250 to 260 mOsm/kg H_2O near term. The amniotic fluid composition of various electrolytes parallels the variations in osmolality. Later in gestation, sodium and chloride concentrations decrease, and urea and creatinine concentration increase (556). Regulatory mechanisms of amniotic fluid volumes have not been completely studied, but there are three possible mechanisms involved: (a) water and solute transport across fetal membranes, (b) regulation of excretion and absorption by the fetus, and (c) maternal influences via the placenta over the fetus' fluid status.

Gestation (wk)	Volume (mL) Fetal	Urine Output (mL/24 hr)
14	100	—
16	185	—
18	360	—
20	380	—
24	450	—
28	800	230
32	850	293
36	850	439
40	800	655

Data from Haswell GL, Morris JA. Amniotic fluid volume studies. *Obstet Gynecol* 1973;42:725; and Queenan JT, Thompson W, Whitfield CR, et al. Amniotic fluid volume in normal pregnancies. *Am J Obstet Gynecol* 1972;114:34, with permission.

TABLE 46.4. AMNIOTIC FLUID VOLUME DURING PREGNANCY

The amniotic fluid provides several functions; it (a) allows symmetric growth and development of the fetus, (b) allows the fetus to move freely, (c) cushions the embryo and fetus against external forces, (d) aids in maintaining body temperature of the embryo and fetus, and finally (e) may have a role in lung development (59).

An excessive amount of amniotic fluid (more than 1.5 to 2 L) is termed *polyhydramnios* (or hydramnios) and a significantly diminished fluid volume is termed *oligohydramnios* (less than 0.5 L). Throughout gestation, the circulation of amniotic fluid is a very dynamic event. The fetus swallows up to 500 mL per day as the urine output increases (470). The placenta also may play an important role in the turnover of amniotic fluid, and the biologic half-life of water in amniotic fluid has been reported to be as low as 90 minutes (258,484).

Obstetric evaluation of the fetus by ultrasound includes an assessment of amniotic fluid volume, particularly in the second and third trimesters. Several methods have been proposed. These include subjective assessment, measurement of the single, deepest pocket of fluid seen, amniotic fluid index, planning metric measurement of total intrauterine volume, and several mathematical formulas. In clinical practice, variability for all of these methods is low and is too similar to provide a basis for choosing one over the other (140,366). Currently, the amniotic fluid index seems to be the most widely used criterion to evaluate amniotic fluid volume.

Polyhydramnios

As previously noted, *polyhydramnios* refers to the presence of an excessive amount of amniotic fluid. It occurs in 0.25% to 0.67% of pregnancies. Greater than 2,000 mL of amniotic fluid during the third trimester constitutes polyhydramnios. The diagnosis may be suggested by maternal symptoms including excessive abdominal pressure, a protuberant or rapidly increasing size of the abdomen, excessive uterine contractions, or dyspnea. Physical signs include evidence of a disproportionate increase in uterine fundal height, abdominal girth, weight gain, and abdominal striae. Although the fetal head may be balloted, the extremities often are difficult to identify with certainty. In addition, it may be difficult to hear the fetal heart tones.

In 2% of patients with polyhydramnios, the excessive amniotic fluid accumulates acutely, usually by 23 to 25 weeks of gestation, resulting in a very tense and tender uterus (419). Chronic polyhydramnios is much more common and is diagnosed during the third trimester by abdominal examination or abdominal ultrasound.

Other conditions and fetal malformations associated with polyhydramnios are shown in Table 46.5 (39,417). Approximately one-third are idiopathic. In women with diabetes mellitus, polyhydramnios is more common when the diabetes is severe. The most common associated congenital anomaly is anencephaly; approximately half of pregnancies associated with anencephaly have polyhydramnios. In addition, abnormalities of formation of the upper gastrointestinal tract, such as tracheoesophageal fistula or esophageal or duodenal atresia, also have a high incidence of hydramnios.

Polyhydramnios (% of Total)	Oligohydramnios
Diabetes mellitus (25)	Bilateral renal agenesis
Anencephaly (20)	Posterior urethral valves
Erythroblastosis fetalis (11) usually associated with hydrops fetalis)	Prune-belly syndrome
	Urethral atresia
	Bilateral renal dysplasia
Multiple gestation (8)	Pulmonary hypoplasia
Meningocele or encephalocele	Growth retardation
Tracheoesophageal fistula	Amnion nodosum
Esophageal or duodenal atresia	Amniotic fluid leak
Pyloric stenosis	Limb defect
Klippel-Feil syndrome	Fetal demise
Cleft palate, cleft lip, or both	Abdominal pregnancy
Achondroplasia	
Diaphragmatic hernia	
Multiple anomalies*	
Trisomy 18	
Idiopathic (34)	

*Not central nervous system.

TABLE 46.5. ASSOCIATED CONDITIONS AND FETAL MALFORMATIONS ASSOCIATED WITH DISORDERS OF AMNIOTIC FLUID VOLUME

The prognosis in a pregnancy complicated by polyhydramnios is poor. Perinatal mortality is 35% to 40%, and the incidence of stillborn infants is 10% to 20%. Perinatal mortality associated with twin gestations, erythroblastosis fetalis, and diaphragmatic hernia is quite high.

Recently, a small number of mothers with polyhydramnios have been treated with indomethacin, which reduces fetal urine output and consequently diminishes amniotic fluid volume considerably. This treatment has been reported to result in significant neonatal renal dysfunction in a few cases (498).

Oligohydramnios

Oligohydramnios occurs in approximately 0.4% to 5.0% of pregnancies, depending on the sonographic criteria and source of patients, and carries an increased risk of fetal abnormality and morbidity (357,404). Because the daily turnover of amniotic fluid depends in large part on adequate fetal urinary output, oligohydramnios often is associated with obstructive lesions of the urinary tract. Usually, the diagnosis is made during prenatal ultrasound examination. In some cases, the diagnosis is subjective and may require serial ultrasound examinations to assess more accurately the true amniotic fluid volume.

If oligohydramnios is found or suspected and an associated urinary tract abnormality is suspected, one of two patterns generally is seen. In bilateral renal agenesis, neither the kidneys nor bladder are identified. The sonographic diagnosis of this condition is highly accurate (450). Bilateral renal agenesis usually results in oligohydramnios, but cases of normal amniotic fluid volume associated with this condition have been reported (534). On the other hand, if oligohydramnios results from bladder outlet obstruction secondary to posterior urethral valves (PUV) or prune-belly syndrome, characteristically a distended bladder is seen associated with bilateral hydronephrosis. Small cysts in the kidneys may be detected by ultrasound and indicate renal dysplasia. The fetal mortality rate for pregnancies complicated by oligohydramnios is high, particularly when it is detected before 27 to 30 weeks of gestation (357,499). Further discussion of the diagnosis and management of these conditions is presented elsewhere in this chapter.

When the urinary tract is normal in the presence of oligohydramnios, fetal growth often is retarded. Other associated conditions include amnion nodosum and a chronic amniotic fluid leak (377) (Table 46.5).

Because amniotic fluid normally cushions the fetus, oligohydramnios often results in compression abnormalities. When oligohydramnios is secondary to bilateral renal agenesis, the phenotypic condition is referred to as *Potter's syndrome* (Fig. 46.6). Characteristically, such a fetus has external features suggestive of intrauterine compression, including a flattened nose, a recessed chin, low-set aberrantly folded ears, spadelike hands, talipes equinovarus, and hypoplastic lungs. Currently, it is thought that amniotic fluid is important in allowing normal lung development, largely by its cushioning effect. Support for this hypothesis is provided by reports of monozygotic twins, one of whom had renal agenesis (345,534). Both fetuses were cushioned by the normal amniotic fluid and were born with normally developed lungs and without the secondary features of Potter's syndrome. The possible role of amniotic fluid in directly stimulating pulmonary development is unclear at this time.

FIGURE 46.6. Infants with Potter's syndrome. **A, B:** Infant with renal agenesis in intrauterine position and with legs extended showing how intrauterine fixation causes bowing of legs. Note low-set ears. **C:** Bowing of legs and deformity of chest from intrauterine fixation resulting from oligohydramnios. **D:** Excessive amount of skin causing enlargement of the hands often associated with renal agenesis. All infants appear remarkably senile. (From Potter EL. *Normal and abnormal development of the kidney.* Chicago: Year Book Medical, 1972, with permission.)

Umbilical Cord

The site of attachment of the umbilical cord to the placenta is determined at implantation and is usually near the center of the placenta. If the blastocyst does not attach to the placenta at the embryonic pole, the connecting stalk (i.e., the umbilical cord) attaches to the placental margin or to the chorion. The cord is usually 55 cm in length and 1 to 2 cm in diameter. Excessively long or short cords are uncommon (360,371). Usually, there are two arteries and one vein encased in a mucoid substance called *Wharton's jelly,* which is rich in mucopolysaccharides. The umbilical vein is longer than the arteries, and the vessels are longer than the cord, resulting in significant tortuosity of the cord vessels and looping of the cord itself.

Approximately 1% of newborns have only one umbilical artery, which is associated with a variety of fetal anomalies, including the urinary tract (58). In the past, it was believed that such neonates deserved routine radiographic imaging of the genitourinary tract. A recent study of screening renal ultrasound in 27 infants with a single umbilical artery showed that 5 (19%) had a renal anomaly (318). Consequently, imaging of the urinary tract by ultrasonography is advisable if there is a single umbilical artery.

Fetal circulation differs from postnatal circulation. In the fetus, well-oxygenated blood is provided by the placenta through the umbilical vein. Approximately half of this blood travels through the portal sinus and hepatic sinusoids, and the other half bypasses the liver, passing through the ductus venosus into the inferior vena cava. After passing through the heart, which has its own unique fetal circulatory pattern, blood of medium oxygen saturation travels down the aorta. Blood that is to return to the placenta travels through the umbilical arteries, which are large branches of the hypogastric arteries. The umbilical arteries have a branch, the superior vesical artery, at the level of the bladder, and then continue on to the umbilicus adjacent to the urachus. At birth, following the development of the neonatal circulatory pattern, the umbilical vein fibroses and becomes the ligamentum teres. The umbilical arteries distal to the branch of the superior vesical artery become the lateral umbilical ligaments. Near the base of the bladder, the obliterated umbilical artery is an important landmark in the identification and dissection of the distal ureter.

ENDOCRINE FUNCTION OF THE PLACENTA

The placenta represents the site of exchange between maternal and fetal circulation. In addition to its filtering role, the placenta appears to have an active metabolic role and an important endocrine function, which contributes to the maintenance of the pregnancy and growth of the fetus (Fig. 46.7) (76,274,385). Furthermore, it serves as an immunologic barrier, allowing the fetus to grow and develop with the maternal autogenically different environment. The trophoblast that forms the epithelium through which the exchanges occur possesses the important property of allowing the passage of certain macromolecules. Active transports, as well as exchanges, over concentration gradients also are known to occur. Interestingly, it appears that the intimate relationship between trophoblast and fetal capillaries is due to the influence of the trophoblast itself on fetal capillary growth. The exact controls that the placenta exerts on fetal growth are unknown, however. Certain influences, such as that of human chorionic gonadotropins (hCG), are recognized with regard to sexual differentiation and adrenal gland development. Fetal hCG plasma levels influence fetal testosterone secretion from the testis. Peak secretion of fetal testosterone occurs at about 12 weeks of gestation concomitantly with wolffian duct development and differentiation of the external genitalia (96). In addition, hCG may have a role in maintaining the fetal zone of the adrenal gland early in

gestation.

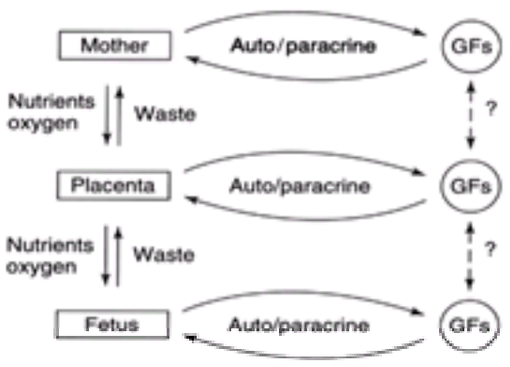

FIGURE 46.7. The transfer of substrates and waste between mother and fetus is, for the most part, unidirectional. Adequate transfer of substrates (nutrients and oxygen) from the mother to the fetus via the placenta, and efficient removal of waste from the fetus to the mother are essential for normal fetal growth. Growth factors *(GFs)* are synthesized in the maternal reproductive tissues, placenta, and fetus and act locally in an autocrine/paracrine manner. Endocrine transfer of growth factors between the mother, placenta, and fetus has not been shown to occur. (From Growth factors in fetal growth. In: Thorburn GD, Harding R, eds. *Textbook of fetal physiology.* Oxford: Oxford University Press, 1994, with permission.)

The placenta has a very important endocrine role and throughout pregnancy secretes certain hormones, such as placental I-lactogens, progesterone, and estrogen, the regulation of which is poorly understood. Later in pregnancy, glucocorticoids produced by the fetus induce placental estrogen production, which in turn induces parturition. The placenta may influence fetal growth early, but later the fetus appears to become more autonomous and have a role in regulating placental function. Fetal growth factors originate from the fetus, but fetal growth itself depends on the normal development and function of the uterus and placenta. Placental growth factors also have been identified, but their role on the fetus is unclear (385). The placenta is known to contain a high concentration of EGF receptors. EGF is a direct stimulator of DNA synthesis and may regulate fetal growth mainly by its influence on placental development. For fetal growth to occur, different cellular processes, specifically proliferation and differentiation, are regulated by intercellular communications. There appears to be no central regulatory process but rather an integrated system where cell-to-cell and cell-to-matrix interactions are mediated by effector molecules within the extracellular matrix, by peptide growth factors, and by intercellular recognition molecules. The exact role of the placenta with regard to fetal growth remains to be determined precisely. The weight of the placenta has been demonstrated to increase with gestational age, and fetal weight is directly correlated to placental weight (364).

PRENATAL ULTRASOUND OF THE URINARY TRACT

Since its introduction in the 1950s, ultrasonographic evaluation of the fetus has undergone significant improvement. Technological advances have allowed for earlier and more precise identification of congenital anomalies. The safety of ultrasound has been studied extensively, leading to the American Institute for Ultrasound in Medicine (AIUM) Bioeffects Committee to conclude that, with judicious use of ultrasound screening in pregnancy, the benefits outweigh any potential risks (16).

The first report of the use of ultrasonography in pregnancy was published in 1958, and the first reported ultrasound diagnosis of a fetal urologic anomaly was published in 1970 (138,190). The introduction of this diagnostic modality heralded in a new era in medicine, an era in which a noninvasive diagnostic technique could reveal congenital anomalies in the fetus, thus allowing for prenatal counseling, early management, and possible intervention should the lesion be amenable to treatment. Availability of sonographic screening in the fetus has increased dramatically, such that several European countries have instituted programs for routine prenatal screening. Controversies do exist with regard to the indications and extent of use of ultrasound in pregnancy, as well as to when it should be administered (189). Prenatal ultrasonography has become an important component of the fetal evaluation. Suspected anomalies can be precisely delineated, and a team of specialists can offer expert advice and counseling. Options in the management and treatment can be discussed in order to plan for delivery and care of the newborn under optimal conditions (325).

With the increasing availability and use of ultrasonography, indications for screening of the fetus have been better defined: determination of gestational age by biparietal head diameter, suspicion of a gestational abnormality, and strong family or maternal histories of prior congenital anomalies. Practice guidelines have been formulated and proposed by the American College of Obstetrics and Gynecologists (15).

Although routine prenatal ultrasound has been advocated (160), a recent multicenter, randomized study of screening ultrasound in more than 15,000 low-risk pregnant women failed to conclusively demonstrate a significant difference in adverse outcome as defined by fetal death, preterm labor and delivery, significant neonatal morbidity, and neonatal death (168). Unfortunately, studies such as this one, designed to evaluate the efficacy of ultrasound as a diagnostic tool that is possibly helpful in improving clinical outcomes, fail to take into account the fact that the natural history of certain congenital anomalies has not been investigated fully and that, in turn, standardized management protocols do not exist for these prenatally diagnosed conditions. At present, current recommendations are to offer the options of a routine ultrasound to any pregnant patient following in a discussion of the potential risks and benefits (189).

The overall incidence of detectable fetal anomalies is approximately 1%. The diagnostic accuracy depends on the expertise of the ultrasonographer, the quality of the equipment, the extent of the malformation, and timing of the study. The type of institution reporting rates of congenital anomaly diagnosed prenatally influences the reported incidence of fetal anomalies: Tertiary centers may include anomalies that have been referred from obstetricians and radiologists, significantly increasing the frequency of various anomalies.

The incidence of urologic anomalies detected *in utero* is approximately 1 in 500. In addition, a wide spectrum of dilation of the urinary tract can be seen, making hydronephrosis the most commonly detected congenital condition that is observed by prenatal ultrasound. It may represent up to 50% of all abnormalities detected by prenatal ultrasound. By pooling a number of reports, it has been calculated that the incidence of detectable urinary tract dilation *in utero* is 1 per 100 pregnancies, but of these, only 1 in 500 is believed to represent a significant urologic problem (533). Thus the urologist must be familiar with prenatal ultrasound diagnoses and with the information one should expect to obtain at different times in gestation, as well as the accuracy of ultrasound in detecting urogenital abnormalities.

Table 46.6 lists the primary structural anomalies and conditions of urologic significance that may be revealed during a prenatal ultrasound examination. In all of these conditions, with the exception of primary vesicoureteral reflux (VUR) and cloacal exstrophy, prenatal ultrasound usually demonstrates an abnormality, although a specific diagnosis can be made only on postnatal evaluation. Most of the obstructive anomalies occur primarily in males.

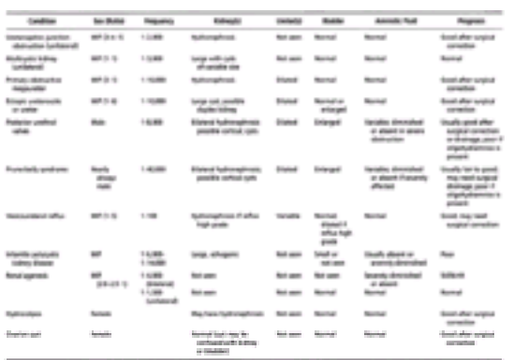

TABLE 46.6. GENITOURINARY ANOMALIES DETECTABLE BY PRENATAL ULTRASONOGRAPHY

- Anomalous UPJ
- UPJ obstruction

- Ectopic ureter
- PUV
- Prune-belly syndrome
- Urethral atresia
- Hydrocolpos
- Pelvic tumor
- Cloacal abnormality

The long-term renal function in the affected renal unit is variable. In cases in which the degree of hydronephrosis is significant (greater than 15 mm) with caliectasis and renal parenchymal thinning from longstanding obstruction, renal function in the involved kidney may be severely compromised. If the obstruction has occurred before 24 weeks of gestation, dysplastic changes may be identifiable by an increase in the echogenicity of the kidney or the presence of cortical cysts (329).

The prenatal diagnosis of unilateral hydronephrosis may be suggestive of obstruction, but VUR also can be identified, especially during the cycles of filling and emptying of the fetal bladder. VUR is associated with changes in the degree of ureteral and pelvic dilation (238,372,593). Prenatal ultrasonographic identification of VUR requires follow-up in the postnatal period in the form of a postnatal ultrasound and voiding cystourethrogram (VCUG). Recent studies suggest that the natural history of prenatally diagnosed VUR differs from postnatally diagnosed VUR because it affects a higher percentage of males; it is more severe and is associated with a higher incidence of coexistent anomalies (593).

UVJ obstruction most commonly is found unilaterally. Dilation of the ureter may be identified also with varying degrees, but massive renal pelvic dilation is not usually seen. The dilated ureter can be confused with the bladder, pelvic cysts, or a dilated loop of bowel. Duplication of the upper urinary tract should be suspected when hydronephrosis is seen in conjunction with cystic dilation of the upper pole of the kidney or the presence of a ureterocele in the bladder (185).

If the amniotic fluid volume is normal and the fetus has no other anomalies before 30 weeks of gestation, one ultrasonographic evaluation will be necessary before birth to determine progression or regression of the hydronephrosis (194) (Fig. 46.12).

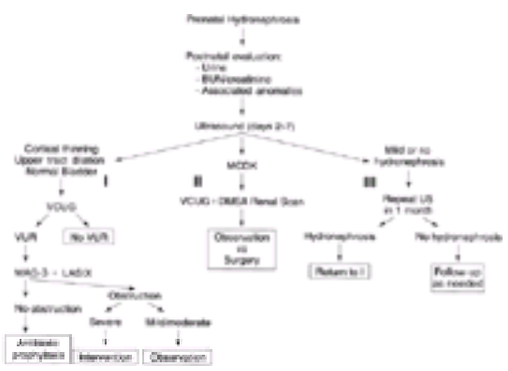

FIGURE 46.12. Algorithm for the postnatal evaluation of fetal hydronephrosis. Prenatal diagnosis and management of the fetus with hydronephrosis. *Semin Perinatol* 1994;18:163, with permission.)

When bilateral hydronephrosis is identified early in gestation, of greatest concern is the possibility of a urinary tract obstruction. Bilateral hydronephrosis attributable to obstruction is most often infravesical but also may occur at the level of the UVJ or UPJ. The most common cause of infravesical obstruction is PUV, which occurs in approximately 1 in 5,000 to 1 in 8,000 boys, with a wide spectrum of severity (240).

It is thought that high intravesical pressure is transmitted to the upper urinary tracts, which contributes to the maldevelopment of the kidneys. The fetus may respond to bladder outlet obstruction by several popoff mechanisms, including bladder diverticula, massive VUR, or urinary ascites (91,575).

The fetus that presents with bilateral hydronephrosis should be evaluated for degree of dilation and whether or not the criteria for minimal pyelectasis versus pathologic hydronephrosis are met. The fetus with significant bilateral hydronephrosis and dilated bladder should undergo a complete diagnostic evaluation (Fig. 46.13 and Fig. 46.14). This evaluation should include a complete ultrasound survey to identify any associated anomalies and a genetic amniocentesis because the incidence of associated chromosomal anomalies is approximately 10% (343,575). The fetus with high-grade bladder outlet obstruction and decreasing amniotic fluid or oligohydramnios should undergo bladder tap for fetal urine sodium, chloride, osmolality, Ca^{2+}, PO_4, and b_2-microglobulin (201,369). The fetal kidneys should be examined carefully to exclude cortical cysts or increased echogenicity (329). If renal function is preserved as indicated by a favorable prognostic profile, fetal treatment should be considered. The treatment selected depends on the gestational age. Those at 32 weeks of gestation or later can be considered for early delivery and immediate postnatal decompression. Those fetuses at 28 to 32 weeks may be considered for short-term decompression *in utero* with vesicoamniotic shunts. The fetus diagnosed before 28 weeks of gestation should be considered for open vesicostomy or fetoscopic vesicocutaneous fistula to provide long-term decompression (112,114,165,230).

Postnatal Evaluation by Ultrasound

Newborn ultrasonography is the initial step in the evaluation of the newborn urinary tract. It has even been proposed as a screening test that would complement prenatal ultrasound evaluation. Indeed, in a recent prospective study of 437 healthy infants between 2 and 10 months of age who underwent a screening ultrasound, 6 (1.4%) had a significant urologic anomaly (517). At present, its use is confined to the follow-up of fetuses diagnosed *in utero* with hydronephrosis and in the initial evaluation of newborns suspected of harboring congenital anomalies. These include babies with multiple congenital anomalies such as the CHARGE association, chromosomal abnormalities, congenital heart disease, malformations of the ears, severe hypospadias, intersex conditions, myelodysplasia, single umbilical artery, family history of duplex systems or VUR, and exposure to various teratogens or cocaine (216,318,425,485).

A renal ultrasound examination in babies usually begins with the bladder because the cold gel often stimulates a bladder contraction. Supine longitudinal views of the pelvis are performed to determine bladder volume and thickness and extravesical or intravesical masses, as well as to follow the course of a dilated ureter. A transverse scan is then performed to aid in determination of bladder volume. In females or in a newborn with ambiguous genitalia, the uterus may be visualized. In a neonate with suspected PUV, posterior urethral dilation occasionally may be appreciated both in transvesical and perineal images (94).

Next, the kidneys are imaged. The kidneys are studied with longitudinal scans, with particular attention to the upper poles (to detect the presence of duplication) and kidney size. Neonatal kidneys normally range from 4 to 6 cm in length, 2 to 3 cm in width, and 1.5 to 2.5 cm in diameter (356). The best view of the right kidney is obtained through a supine longitudinal scan through the liver, whereas the left kidney is more likely to be visualized optimally by a prone longitudinal scan through the spleen. In infants with VUR or infection, renal scarring may be detected but calyceal morphology may not be distinct.

Attention also should be directed to identification of the adrenal glands. These structures are imaged optimally in the positions used to identify the upper poles of the kidneys. In the newborn, significant adrenal enlargement is suggestive of CAH. In such patients, the size of the adrenal glands may be compared with reported normal values (388).

The echogenicity of the kidneys should also be assessed. Organs with a uniform parenchymal composition, such as the liver and spleen, produce a homogeneous echo pattern that provides an excellent acoustic window for examining the adjacent kidney. In infants up to 6 months of age, cortical echogenicity may be equal to that of the liver. Another important feature is the prominent hypoechoic pyramids, which may be mistaken for dilated calyces or cysts.

Timing of the neonatal ultrasound is important to the interpretation of its clinical relevance. The renal pelvis may be moderately dilated on antenatal sonography, yet appear normal in the first few days of life despite significant obstruction because oliguria during the first 24 to 48 hours of life may cause a distended renal pelvis to shrink transiently (306). If the neonatal ultrasound is normal, a VCUG should be obtained to determine whether reflux is present and a renal ultrasound should be repeated in 3 weeks. Dejter and Gibbons (124) reported on 49 dilated renal units detected antenatally, 9 of which were normal on the postnatal evaluation done in the first few days of life. In follow-up, one had a UPJ obstruction, one had a UVJ obstruction, two had VUR, and three had nonobstructive dilation of the collecting system necessitating continuing radiologic evaluation. Thus 50% of neonates with antenatal hydronephrosis and a normal postnatal sonogram within 48 hours of birth required reconstructive surgery or had VUR.

The severity of hydronephrosis has been standardized by the Society for Fetal Urology (SFU) (332) (Table 46.10). The hydronephrotic grade is based on the severity of renal pelvic and calyceal enlargement, as well as the presence of renal cortical atrophy. In general, only those kidneys with grade 3 or 4 (out of 4) hydronephrosis secondary to suspected obstruction require surgery (331).

Grade of Hydronephrosis	Central Renal Complex	Renal Parenchymal Thickness
0	Intact	Normal
1	Slight splitting	Normal
2*	Evident splitting, complex confined within renal border	
3	Wide-splitting pelvis dilated outside renal border and calices uniformly dilated	Normal
4	Further dilation of renal pelvis and calices (calices may appear convex)	Thin

*An extrarenal pelvis extends outside the renal border, yet because the calices are not dilated hydronephrosis is grade 2. When the major calices are imaged but are not dilated, hydronephrosis is also grade 2.

TABLE 46.10. SOCIETY FOR FETAL UROLOGY GRADING OF HYDRONEPHROSIS

Voiding Cystourethrography

Any newborn with a prenatal diagnosis of hydronephrosis should undergo a VCUG, even if the postnatal ultrasonogram is normal. Usually, the study is obtained before the baby leaves the hospital because if VUR is present, antimicrobial prophylaxis should be started. Furthermore, in newborn male infants, infravesical obstruction must be excluded, even if sonography or isotope renography indicates probable upper tract obstruction.

In a boy with hydronephrosis, a radiographic VCUG should always be obtained to evaluate the lower urinary tract to exclude urethral and bladder disease. However, in girls, in whom these abnormalities are less common, it may not be so important to obtain a radiographic cystogram. A nuclear cystogram confers approximately 1% to 2% of the radiation exposure of a standard radiographic study, but the anatomic detail from the nuclear cystogram is considerably less than with the standard radiographic VCUG. Furthermore, the grading system for the nuclear cystogram has not been established, and the two studies are not always comparable. In addition, reflux associated with a duplication anomaly demonstrated on the radiographic VCUG might not be apparent on a nuclear study. Most children's hospitals have digital fluoroscopy units, which result in significantly less radiation exposure during a VCUG. Consequently, the clinician must decide which of the tests should be done.

Indications for VCUG in the newborn include the following conditions: prenatally diagnosed hydronephrosis, unilateral multicystic dysplastic kidney to rule out contralateral reflux (485), suspected bladder outlet obstruction (e.g., PUV, urethral anomalies), and suspected duplicated upper collecting system with or without ureterocele (267). If the neonate has ambiguous genitalia, contrast material should be injected into all genitourinary cavities, allowing the anatomic definition of the bladder and other genital cavities; this procedure is termed a *genitogram.*

What If the Initial Sonogram Is Normal?

A common dilemma is whether a full evaluation is necessary if the initial renal sonogram is normal. Assuming a significant degree of fetal renal pelvic dilation (i.e., 4 mm AP pelvic diameter at less than 33 weeks at gestation, 7 mm after 33 weeks) (104) was present, the child may have VUR. For example, Bouachrine and colleagues (57) reported that 17 of 42 (40%) infants with prenatally diagnosed reflux had mild antenatal renal pelvic dilation as the only sign of a urinary tract abnormality. Tibballs and de Bruyn (535) reported that of 982 children referred for treatment of antenatal hydronephrosis, among 255 renal units with reflux, the postnatal sonogram was normal in 177 (70%). Furthermore, in children with dilating grades of reflux, renal sonography often is normal. For example, Blane and colleagues (54) reported that 12% of children with grade V, 31% with grade IV, and 80% with grade III reflux had a normal renal sonogram. Because reflux may cause intermittent renal pelvic dilation, theoretically these babies may have reflux, and early diagnosis and medical treatment of reflux may reduce the likelihood of developing reflux nephropathy (156). On the other hand, others have advocated performing a VCUG only if the postnatal sonogram was normal (145,557); however, in their reports, neonates with a normal postnatal renal sonogram were not systematically evaluated to determine the real incidence of reflux in this group. Consequently, we generally recommend performing a VCUG even if the postnatal renal sonogram is normal.

Nuclear Medicine Studies

In the newborn with a suspected structural urologic anomaly, nuclear medicine studies play an important role in diagnosis and in helping to direct treatment or assess results of therapy. Radionuclide studies of the kidneys (renograms) may be used to assess renal perfusion, glomerular function of each kidney, structural anomalies, and the presence or absence of obstruction (244). The advantages of radiopharmaceuticals include the absence of systemic pharmacologic effects or allergic reactions, lower radiation exposure than conventional urography, and no need for fasting or special preparation of the bowel. If there is renal failure or significant renal insufficiency, the images with radiopharmaceuticals are inferior.

Two radiopharmaceuticals are used primarily for assessing functional of the kidney and whether obstruction is present (diuretic renogram): technetium (Tc)-99m MAG-3 (mercaptoacetyltriglycerine) and Tc-99m diethylenetriaminepentaacetic acid (DTPA). When the clinician is interested primarily in assessing whether a particular moiety of a duplicated collecting system is functioning (e.g., with an ectopic ureter or ureterocele) or whether reflux nephropathy is present in a neonate with VUR, Tc-99m dimercaptosuccinic acid (DMSA) is preferred. At times, DMSA is unavailable; in these instances, Tc-99m glucoheptonate (GHA) is used, although the images are inferior to those obtained by DMSA. DTPA is cleared almost entirely by glomerular filtration (95%), without significant retention by the renal parenchyma. The remainder of the radionuclide is protein bound.

MAG-3 is secreted by the renal tubules and has a rate of excretion more than three times that of DTPA, with 73% normally excreted by 30 minutes (164,465). The images obtained are similar to those obtained with DTPA in older children, but in the neonate, there is less background activity with MAG-3, making it a superior radiopharmaceutical. The disadvantages of MAG-3 is that its shelf life is short and it is more expensive than DTPA. Differential renal function is computed in an identical manner to DTPA (406). DTPA is excreted primarily by glomerular filtration.

The renal handling of MAG-3 and DTPA can be divided into three phases: (a) radionuclide uptake by the kidney, (b) transit through the renal parenchyma, and (c) washout into the collecting system. Estimation of glomerular filtration is determined by the activity recorded in the kidney between 1 and 3 minutes after injection of the radionuclide corresponding to parenchymal transit time. Differential renal function is computed by comparing differential uptake from 1 to 3 minutes. Accumulation of radionuclide within the kidney is proportional to GFR. In the later phase of the study, the high urinary concentration of MAG-3 or DTPA with normal or near-normal renal function can provide excellent visualization of the upper urinary tract and bladder. Renal anomalies, such as pelvic kidney, crossed fused ectopia, horseshoe kidney, or urinary extravasation, can be delineated easily.

^{99m}DMSA is retained by the renal tubules and the most sensitive radiopharmaceutical for imaging the renal parenchyma in the absence of obstruction. It is often used to assess renal scarring or to compare the relative function of the upper- and lower-pole moieties of a duplicated collecting system. The study will not demonstrate whether upper urinary tract obstruction is present. In the neonate or premature infant, however, uptake of DMSA may be low due to renal functional immaturity, low plasma flow, and reduced bulk of tubular tissue. DMSA scanning provides functional information about the kidneys and demonstrates areas of decreased function, such as focal dysplasia, scarring, or acute infection (51,440,462). After the injection of DMSA, renal images are obtained 2 to 3 hours later. GHA is secreted, and some of the radiopharmaceutical is retained by the renal tubules, providing similar but lower-quality images compared with those obtained by DMSA.

Renal scanning usually is performed in the following situations (532):

1. Assessing whether upper tract obstruction is present in a neonate or infant with hydronephrosis (diuretic renogram-MAG-3 or DTPA)
2. Confirming that a multicystic kidney has no function (MAG-3, DMSA, or DTPA)
3. Determining whether the upper pole of an obstructed duplex system (ureterocele or ectopic ureter) functions (MAG-3, DTPA, DMSA, or GHA)
4. Confirming that a kidney is absent in a neonate in whom the ultrasound demonstrates renal agenesis (MAG-3, DMSA, or DTPA)
5. Demonstrating a fusion anomaly of the kidney (horseshoe kidney or crossed renal ectopia; MAG-3, DMSA, or DTPA)
6. Determining whether a child has acute pyelonephritis (DMSA) or evidence of renal scarring from previous infection (DMSA or GHA)

Diuretic Renogram

Diuretic renography is a provocative method of evaluating patients found to have dilation of the upper urinary tract in whom an obstructive process is suspected. The theoretical basis of this test is twofold: If an obstructive lesion is present, then (a) renal function, more specifically glomerular filtration, may be impaired, and (b) a dilated upper urinary tract will retain a larger amount of radionuclide that will not wash out if increased urine flow is generated by the administration of a diuretic (97). Two radionuclides tracers are used for diuretic renography: DTPA and MAG-3. Imaging is superior with MAG-3 compared with DTPA because of a smaller volume of distribution and faster clearance.

The technique for the diuretic renal scan is critical to its correct interpretation and requires attention to detail to ensure reliability and reproducibility. In general, neonates and young infants are placed supine for the study; mechanical restraint usually is necessary. At some institutions, infants are placed prone, however, because this may affect better upper tract drainage. Ideally, the child should be well hydrated because relative dehydration prolongs parenchymal transit and delays urinary excretion. MAG-3 or DTPA is injected intravenously as a bolus. Subsequently, 4-second posterior images are recorded with a high-resolution collimator. One minute after injection, images of the kidneys are obtained each minute. Normally, the renal parenchyma is well visualized during the first minute; by 2 to 3 minutes, activity is seen in the collecting system, and by 6 to 9 minutes the bladder is visualized.

The differential renal function of each kidney is calculated between 60 and 180 seconds after injection of the radiopharmaceutical, which represents parenchymal transit and reflects glomerular function. On computer images, regions of interest are selected from each kidney and background activity is subtracted. The activity within each kidney is expressed as a percentage of the total renal counts, and this differential activity is used to compute differential renal function. In a kidney with a duplex system in which there is upper-pole obstruction, the regions of interest of the affected kidney may be broken down further and used to determine relative function of the upper and lower segments.

To determine whether significant obstruction is present, furosemide is administered intravenously, with a recommended dose of 1 mg/kg when the hydronephrotic system shows maximal accumulation of radionuclide, but not later than 30 to 60 minutes. It is important to distinguish hydronephrosis secondary to suspected UPJ obstruction from UVJ obstruction, in which the ureter should contain a large amount of radionuclide before furosemide is given. The activity over each kidney is measured and the half-time clearance determined. The half-time ($T_{½}$) represents the number of minutes required for half of the radiopharmaceutical to drain from the collecting system after administration of furosemide. O'Reilly and colleagues (389) have defined several types of responses to furosemide (Fig. 46.15). Compared with drainage in the older child, in the newborn, drainage typically is delayed, primarily because the GFR is low. A nonobstructed system should have a $T_{½}$ of less than 10 to 15 minutes, whereas a $T_{½}$ of greater than 20 minutes is consistent with but not necessarily diagnostic of obstruction. If the $T_{½}$ is between 15 and 20 minutes, the results are indeterminate. The $T_{½}$ is computed from the peak of renal activity, not the actual time of diuretic administration, because if the hydronephrotic system is not completely filled when furosemide is administered, the radionuclide may continue to accumulate for several minutes in the collecting system before it begins to drain. If a normal drainage pattern begins, then levels off, the slope of the drainage curve should be used to extrapolate $T_{½}$. If the collecting system does not fill completely within 1 hour after injection of MAG-3 or DTPA or if the kidney has less than 20% of total renal function, the diuretic washout curve may be prolonged, even if the

system is not obstructed.

Normal response **(A),** dilated nonobstructed system **(B),** dilated obstructed collecting system **(C),** and equivocal response **(D).** (From Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology,* 2nd ed. Philadelphia: WB Saunders, 1985, with permission.)

Technical Considerations Affecting Interpretation of Diuretic Renogram

Numerous variables may affect the interpretation of the diuretic renal scan, particularly in the newborn (Table 46.11) (156).

Renal maturity	Volume of urine in bladder
Renal function	Outlined regions of interest
Hydration status	Patient position
Type and dose of radiopharmaceutical	Patient movement
	Capacity of upper tract
Dose of diuretic	Severity of obstruction
Timing of diuretic administration	Site of obstruction
	Method of data interpretation
Vesicoureteral reflux	

TABLE 46.11. FACTORS AFFECTING DIURETIC RENOGRAPHY IN THE NEONATE

Renal Maturity

In the newborn, there is temporary but significant renal functional impairment that may confuse the diagnosis of obstruction by renography, because there is no readily available measurement to determine when renal function is too immature for diuretic renogram accuracy. Koff and associates (296) studied the diuretic response of the normal kidney in 33 infants with unilateral hydronephrosis caused by either multicystic kidney or UPJ obstruction. These infants were not formally hydrated, nor was a bladder catheter used. In neonates younger than 1 month of age, 68% of the normal kidneys had a $T_{½}$ of greater than 9 minutes; of the infants studied between 1 and 4 months of age, 33% had a prolonged $T_{½}$; and all infants older than 4 months had a normal $T_{½}$ in the normal kidney. Prematurity was a significant factor as well. Of 9 term infants younger than 1 month of age, 5 (55%) had a $T_{½}$ of less than 9 minutes in the normal kidney, whereas none of the 8 premature infants had a $T_{½}$ of less than 9 minutes. Consequently, when the neonate is studied with a diuretic renal scan, drainage of the normal kidney must be assessed carefully. If the normal contralateral kidney shows impaired drainage, the study is invalid and cannot be used to provide a satisfactory indication of whether obstruction is present. In these cases, other clinical information must be used to assess the kidney with suspected obstruction. If the hydronephrotic kidney is functioning as well as the nonhydronephrotic kidney, the renal scan should be repeated 6 to 12 weeks later.

Renal Function

In a kidney with significantly reduced renal function secondary to a UPJ obstruction or PUV, or with a primary renal functional abnormality, the diuretic renogram may be difficult or impossible to interpret. In general, if the differential renal function is less than 20% or if the kidney has not reached its peak intensity by 60 minutes after administration of MAG-3 or DTPA, the diuretic phase cannot be used to provide an indication of definite obstruction.

Hydration Effect

State of hydration has an important effect on the diuretic response. Dehydration prolongs parenchymal transit and the diuretic response. In a study by Howmann-Giles and co-workers (254), of 12 patients with a prolonged $T_{½}$, in 10 the $T_{½}$ decreased to the normal range with infusion of 360 mL/m^2 normal saline solution over 30 minutes before the study. Although forced hydration is not physiologic, it reduces the likelihood that prolonged $T_{½}$ is secondary to prolonged parenchymal transit. In many centers, the family is asked to feed the infant immediately before the study.

Dose and Timing of Diuretic Administration

Although O'Reilly and colleagues (390) recommended an administered dose of 0.5 mg/kg furosemide, in children, and in particular the newborn, 1 mg/kg provides a stronger and more reliable effect. If the infant is well hydrated, significant dehydration is unlikely to result. Children with renal insufficiency may require as much as 4 mg/kg furosemide to stimulate satisfactory diuresis. If a catheter is used to drain the bladder during the diuretic study, urine output can be measured to determine whether diuretic response is adequate.

The timing of diuretic administration is controversial. O'Reilly (391) recommends administration at 20 minutes in all patients. However, in a nonobstructed hydronephrotic or poorly functioning kidney, the radionuclide might not accumulate maximally in the collecting systems by 20 minutes. If furosemide is administered too soon, the radionuclide will continue to accumulate in the kidney for a variable period before drainage occurs, potentially simulating an obstructed kidney.

Bladder Effect

Approximately 15% of children with a UPJ obstruction have VUR (248). Consequently, if the VCUG demonstrates reflux, bladder catheterization during the diuretic renogram is mandatory. Whether bladder catheterization should be done in all cases, however, is controversial. A full bladder impairs drainage of the upper tracts. Thus a nonobstructed kidney may begin to drain after furosemide is given, but the drainage response may be blunted as the bladder fills, spuriously prolonging the $T_{½}$. It can be argued that bladder catheterization is not a normal physiologic situation. Furthermore, infants often void during furosemide diuresis, and there may be some risk of causing iatrogenic urinary infection in the hydronephrotic kidney with placement of a urethral catheter. On the other hand, if the bladder is not catheterized, it may be difficult to determine whether impaired upper tract drainage is secondary to a distended bladder or obstruction. The ideal diuretic renal scan should include a continuously drained bladder, although this is not routinely done by most pediatric nuclear medicine departments at present.

Outlined Regions of Interest

Differential renal function is computed by comparing the differential uptake for 1 minute, between 1 and 3 minutes after injection of the radiopharmaceutical. The renal images that are analyzed, or “regions of interest,” are extremely important to this analysis. Background activity from the liver or spleen may affect the number of counts, and this activity must be subtracted. In reality, the computed uptake of a kidney may be altered significantly by changing the region of interest. In some institutions, the regions are drawn outside the area of perceived renal activity; at other institutions, the region of interest is drawn tightly to the edge of the kidney. Recognition of this variable is important because often the decision of whether to operate on a hydronephrotic kidney is based largely on whether the differential glomerular function is affected significantly.

Position of the Infant

In some cases, drainage of urine from the kidney may be improved by placing the child in the prone or upright position rather than supine during the study because the bladder becomes more dependent.

Site of Obstruction

If the neonate has a megaureter, ideally the renal pelvis and ureter should be filled with the radionuclide before furosemide is administered. If the diuretic is administered prematurely and renal pelvic drainage is impaired, the study probably should be repeated before deciding on a diagnosis of obstruction. If the diuretic is administered at the appropriate time, currently it is unresolved whether to assess drainage from the renal pelvis and ureter separately or as one entire system.

Interpretation of Diuretic Renogram

The diuretic renogram does not actually measure obstruction; rather, it monitors the ability of the kidney to respond to a volume challenge. Thus accuracy of the study depends on a number of biologic factors that influence this response. The clinician should never rely on the written report to determine whether an obstructive lesion is present. The study should always be reviewed by the urologist to assess specifically which of these variables might have adversely affected the outcome of the test and whether it should be repeated under modified conditions or when renal function is better.

Another important aspect in evaluation of the study deals with the interpretation and comparison of follow-up examinations. For example, how does one assess stability or deterioration of renal function or obstruction? If the differential renal function remains stable but the $T_{½}$ becomes prolonged, is there deterioration of function, is there worsening obstruction, or is this simply a difference in technique between the two studies?

Recommended Protocol for Diuretic Renogram in the Neonate

Because the method of diuretic renography varies among nuclear medicine practitioners, and recognizing the limitations of the diuretic renogram in the neonate with hydronephrosis, the SFU and the Pediatric Nuclear Medicine Club developed a standardized method for the diuretic renogram in the neonate (97). Ideally, infants should be older than 1 month at renography to reduce the likelihood that renal function is immature, and premature infants should be even older before the initial renogram. Oral hydration is offered as desired, beginning 2 hours before the study. The bladder is catheterized to ensure that it is empty, and the catheter is left to continuous open drainage or intermittent syringe evacuation of the bladder via the catheter. Urine output of 4 to 5 mL per minute is expected during the active diuresis in a well-hydrated infant. Prophylactic antiseptic therapy is adinistered during the study and for 3 days afterward. Before the study, a dilute normal saline solution is administered at a rate of 10 mL/kg over 15 minutes, before injection of MAG-3 or DTPA, and is continued for 15 minutes after injection. The renogram should be recorded in the supine position. After injection of MAG-3 or DTPA, the regions of interest encompass the entire kidney, including the dilated renal pelvis, with a region of interest for background subtraction defined as 2 pixels wide around the entire outer perimeter of the kidney. The percent differential renal function is determined by measuring the total counts of the renogram curve for each kidney minus background between the intervals of 90 and 150 seconds after the appearance of the abdominal aorta. Furosemide is administered at a dose of 1 mg/ kg after 20 to 30 minutes or when the dilated pelvis or ureter is thought to be filled on the scintigram images. It may be necessary to place the patient in the prone position to allow the radioactive agent to be distributed evenly throughout the entire dilated pelvis and ureter. Methods used to monitor $T_{½}$ clearance include (a) $T_{½}$ from the time of furosemide injection, (b) $T_{½}$ from the peak of the curve, and (c) $T_{½}$ of the extrapolated slope of the primary response to furosemide. Most likely, one of the latter two will prove most accurate.

Other Imaging Studies of the Upper Urinary Tract

In select situations, such as with severe hydronephrosis and a renal fusion anomaly or an ectopic kidney, imaging studies other than ultrasonography, VCUG, and renal scintigraphy are necessary for diagnosis and to plan management.

A computed tomography (CT) scan of the urinary tract often provides useful information. It outlines the urinary tract and is extremely sensitive in assessing whether a kidney is functioning. The test generally is done with sedation. In recent years, MRI also has been studied, although it has not come into widespread use (380,435). The advantage is that there is no exposure to ionizing radiation and it provides anatomic detail, but the study does not provide sufficient functional information and it requires general anesthesia.

The indications and use of intravenous urography (IVU) to assess the newborn urinary tract have decreased steadily over the last 20 years because of the increased availability of sonography and isotope imaging. The anatomic resolution of the IVU can be excellent, but at birth, renal function may be too immature to allow for adequate concentration of the contrast material within the collecting system, thus preventing satisfactory visualization, which may be further obscured by copious bowel gas. However, 2 to 3 weeks after birth, visualization of the kidneys and collecting system can be obtained following administration of 2 to 3 mL/kg of contrast medium.

The IVU provides excellent anatomic delineation of the upper urinary tract and can be used to identify specifically an area of obstruction, as well as to determine whether the patient has a duplex collecting system (163). In addition, renal scarring from VUR may be identified. However, its use for follow-up has diminished because radionuclide imaging can provide reliable quantitative estimation of relative renal function.

Retrograde Pyelography

With the radiologic studies currently available, retrograde pyelography rarely adds important diagnostic information in the evaluation of hydronephrosis in the newborn, even with a UPJ obstruction (464). In a neonate, urethral or ureteral injury may occur from the study. If ultrasound, IVP, and the renal scan do not provide sufficient visualization of the upper tract, antegrade pyelography usually is preferable to retrograde pyelography.

ANTEGRADE PERFUSION STUDIES OF UPPER URINARY TRACT

Another method to evaluate the hydronephrotic kidney is the Whitaker test, in which fluid is infused into the kidney at a constant rate and the differential increase in pressure in the kidney, compared with the pressure in the bladder, is measured. A variant of this is the constant-pressure perfusion test, in which fluid is infused at a constant pressure to assess the change in output.

Constant Volume Perfusion (Whitaker Test)

The Whitaker test generally is performed when other diagnostic tests, such as sonography, excretory urography, and diuresis renography, either do not agree or are inconclusive in establishing a diagnosis (567). The test is much more invasive than the other procedures because it requires insertion of a needle or small nephrostomy tube into the kidney, with the patient under general anesthesia.

After administration of general anesthesia, the child is placed in the prone position. Access to the hydronephrotic collecting system is obtained percutaneously, either using sonography or after injecting a bolus of contrast medium intravenously and imaging the kidney fluoroscopically. Spinal needles of 22 or 20 gauge are commonly used, although we have selectively used a pigtail nephrostomy tube. The needle resistance is subtracted from the renal pressure to determine intrapelvic pressure. If

the kidney is extremely hydronephrotic, a second needle may be inserted into the kidney to measure the pressure continuously. A urethral catheter is inserted as well. A Harvard pump or similar apparatus is used to deliver a constant flow through the kidney at a set rate. Usually, the bladder catheter is left open and allowed to drain during the procedure, except in situations of suspected secondary UVJ obstruction. Each institution has its own protocol for performing the study. In some centers, the study is initiated by infusing 5 mL per minute for 5 to 10 minutes and checking the renal pressure with a manometer or pressure transducer every 5 minutes. If the pressure remains within a physiologic range, the inflow is increased to 10 mL per minute for another 5 to 10 minutes. In some cases (generally in older children), the fluid infusion is increased to 15 mL per minute. This study also allows infusion of contrast medium to examine the upper urinary tract fluoroscopically, which often is as helpful as the pressure readings.

A maximum renal relative pressure (renal pelvic pressure minus needle resistance minus bladder pressure) less than 15 cm H_2O indicates absence of obstruction, pressure greater than 22 cm H_2O is indicative of resistance to urinary flow, and maximum pressure between 15 and 22 cm H_2O is considered indeterminate.

The Whitaker test measures only drainage, not function. The implication is that the kidney that has impaired drainage by the Whitaker test is likely to develop renal functional impairment.

Numerous technical variables may influence the Whitaker test, including the concentration of contrast medium (if used), the gauge and length of the perfusion needle, temperature of the solution, and flow rate (537). For example, as the temperature of contrast increases, its viscosity decreases. Diminished viscosity of the infusate results in diminished resistance by viscous drag. Not surprisingly, viscous drag was greater using a 9-cm-long needle, compared with a shorter needle. In these studies, the greatest intrinsic resistance resulted with high rates of infusate flow using 25% contrast, with the maximum pressure difference 5.0 cm H_2O at 11.5 mL per minute.

Although the Whitaker test was developed in children, there are no reports of its use in large series in neonates and infants. Because the kidneys and ureters are smaller, we can speculate that the desired maximum rate of flow should be lower in an infant than in an older child or adult. However, no one is certain what the appropriate infusion rate should be. Is a dramatic rise in renal pressure at 10 mL per minute significant? Assuming a two-kidney system, this infusion rate would be equivalent to 1,200 mL per hour, which is a greater volume than the urinary output in most infants over 24 hours. Consequently, an infusate rate of 10 mL per hour is not physiologic. Furthermore, standards for abnormal renal pressure in neonates have not been established, although these should be similar to those in older children. In an unpublished report, Ransley noted that in neonates and infants with a UPJ obstruction, using a second needle to measure renal pressure, intrarenal pressures between 100 and 300 cm H_2O have been obtained in some patients, even at infusate rates of only 5 mL per minute (427). More data are required to clarify this issue.

Constant Pressure Perfusion

The Whitaker, or constant volume perfusion test, assesses the compliance of the renal pelvis (and ureter in hydroureteronephrosis) with suspected upper tract obstruction. Upper tract obstruction is characterized by the necessity for increased renal pelvic pressure to cause urinary flow to the bladder. As a result of dissatisfaction with the Whitaker test, the study has been modified to use constant pressure perfusion rather than constant flow (585). Constant-pressure perfusion is independent of upper tract compliance, uses low fixed pressures in the renal pelvis, and measures the rate of flow out of the upper tract into the bladder at various pressures. In a pig model, one kidney was isolated and a nephrostomy tube was inserted into the renal pelvis. A bag of saline solution served as the constant pressure reservoir, and the height of the bag was adjusted to achieve the desired intrarenal pelvic pressure. The contralateral ureter was clamped, and fluid outflow through the ureter was measured with a urethral catheter. The authors found that in the normal pig, flow should always occur with renal pelvic pressures less than 5 cm H_2O, with a flow rate of approximately 5 mL per minute. At 10 cm H_2O renal pelvic pressure, drainage was 12 mL per minute. When partial obstruction was created, the flow rate from the kidney was more than 3 standard deviations below the normal curve. When the Whitaker model of continuous flow is used in the same animals, an inflow of 5 mL per minute yielded an equivocal pressure rise and at a flow rate of 10 mL per minute the system demonstrated obstruction.

In theory, the constant-pressure perfusion technique is advantageous over constant flow in that it measures flow out of the upper tract at various renal pelvic pressures. Furthermore, the results were more reproducible and had less overlap with normal or equivocal values. In the human, however, an obvious limitation in a patient with two kidneys is the difficulty in determining the outflow from the single obstructed kidney. The authors speculated that this might be accomplished by using radionuclide perfusion and assessing outflow by scintigraphy. Further work on this important model is under way.

MANAGEMENT OF THE NEWBORN WITH GENITOURINARY ANOMALIES

Parental Issues

Prenatal diagnosis of congenital anomalies not only has permitted counseling and early management but also has introduced significant stress during pregnancy, especially if invasive procedures are recommended (236,548). This stress can be managed adequately by providing the parent(s) with adequate information and nondirective counseling (262). Difficult management decisions should be handled with a multidisciplinary approach coordinated by a genetic counselor who acts as the liaison between the parent(s), referring physician, and the perinatal team. The counseling should ensure comprehensive and compassionate care in cases in which termination is considered or in which the outcome of the pregnancy is poor.

Postnatally, the mother–child interactions are especially important in establishing bonding.

Bonding

Bonding refers to the strong emotional and affectional relationship that occurs between a mother and father and their newborn infant. Although bonding has been demonstrated to occur at the time of prenatal ultrasound (179), most important are the first few days or weeks of an infant's life (344). The classic references on this subject are by Klaus and Kennell (289,290). The long-term significance of bonding is controversial, and there is extensive discussion in the literature regarding the importance of the extensive early mother–newborn contact and its effect on the subsequent parent–child relationship and behavior (291,299,307,308). Early mother–infant contact has been associated with improved speech between mother and child at 2 years (438), and at age 5, such offspring have been reported to have higher intelligence quotients and better scores on language comprehension tests than those with limited mother–infant contact in the neonatal period (437). Furthermore, following neonatal illness and hospitalization, there is a significantly increased incidence of child abuse and neglect (327,381) and failure to thrive in the absence of organic causes (487).

Anesthesia

In general, neonatal surgery is quite safe from an anesthetic standpoint when the patient is healthy and a staff with extensive experience in pediatric anesthesia is available (250). However, in the transition from fetus to neonate, there are important circulatory and hematologic considerations. In addition, newborn infants may be at risk for retrolental fibroplasia or postoperative apnea under certain circumstances.

Retrolental fibroplasia (RLF; retinopathy of prematurity) is a major cause of blindness or impaired vision in low-birth-weight infants on ventilators. When the retinal vasculature is immature, elevated inspired oxygen concentrations result in a Pa O_2 higher than normal, with the potential for significant arterial narrowing and the destruction of newly formed capillary endothelium. A vasoproliferative process results, leading to RLF. There have been cases of RLF developing in infants in whom the only supplementary oxygen received was during anesthesia (48,358). At a conceptional age of 40 weeks (i.e., term), approximately 40% of newborns have an immature retina. However, this incidence decreases to 0% at 45 weeks (420). The risk of RLF developing in a child with an immature retina during anesthesia may be minimized by maintaining the Pao_2 at less than 90 mm Hg (14).

There is a subgroup of newborn infants that may develop an apneic episode following general anesthesia (564). The primary group at risk consists of prematurely born infants who have had a previous episode of apnea, whether idiopathic or otherwise (323). Such infants less than 55 to 60 weeks of conceptional age (15 weeks after term) appear to be at particular risk (305). Reasons for this higher risk are unclear. However, apneic episodes in prematurely born infants have been attributed to immaturity of the respiratory system (489,490). In infants with a history of neonatal apnea, alveolar hypoventilation during sleep and an abnormal response to hypercapnia and hypoxia have been demonstrated (257,488). It is postulated that inhalational anesthetics as well as narcotics affect the ventilatory control mechanism and predispose to postoperative apnea for 48 hours (323). Infants born at term who have not experienced apnea do not appear to have an elevated risk for ventilatory

complications following general anesthesia.

At birth, the ductus arteriosus constricts but has the potential to reopen during the first week of life under certain conditions. For example if Pao $_2$ falls to fetal levels within the first few days of life, the ductus arteriosus may reopen with right-to-left shunting of blood away from the lung, referred to as *persistent fetal circulation syndrome* (118). This phenomenon could be caused by a very brief episode of hypoxia, as potentially could occur during induction of anesthesia.

Finally, the red blood cells (RBCs) in the neonate are undergoing qualitative and quantitative changes. In the first few months of life, fetal hemoglobin predominates in RBCs and differs from adult hemoglobin in its inability to bind 2,3-diphosphoglycerate. This inability results in oxygen binding more efficiently to hemoglobin, making it more difficult to release oxygen to the tissues. Furthermore, during the first 3 to 4 months of life, the total hemoglobin concentration decreases to its lowest level. Thus, at 3 months of age, the infant's oxygen-carrying capacity may be compromised quantitatively and qualitatively (118). This effect is compensated for by an increase in cardiac output. However, the effects of many anesthetic agents include reduction of the cardiac output, increase of the intrapulmonary shunt (decreasing Pao_2), and decrease in peripheral oxygen consumption. The margin for error is reduced, and the risk of anesthesia may be increased in the first few weeks of life, particularly if hypovolemia, hypoxemia, or anemia is present and undetected.

The preceding discussion is not meant to exaggerate the anesthetic risks of neonatal surgery. With the skills of a pediatric anesthesiologist, general anesthesia may be administered safely to practically any infant, but the potential risks must be understood by the surgeon.

Abdominal Masses

An abdominal mass in the neonate demands urgent evaluation (424,562). Table 46.12 shows the distribution of abdominal masses based on a collation of five large series. Excluded are babies with distended bladders without hydronephrosis, isolated splenomegaly, pyloric stenosis, pelvic tumors palpable only by rectal examination, and babies with hydrocolpos in whom the diagnosis was obvious because of a bulging imperforate hymen. Nearly two-thirds of abdominal masses detected within the first month of life arise from the urinary tract, and 10% occur in the female genital system. Half are secondary to either hydronephrosis or multicystic kidney. It has been reported that during the first 2 days of life, an abdominal mass is more likely to be a multicystic kidney, whereas beyond 2 days of age, hydronephrosis is more common (219).

TABLE 46.12. DISTRIBUTION OF ABDOMINAL MASSES OF 280 PATIENTS IN THE NEONATAL PERIOD[a]

Nearly all neonatal masses arising from the genitourinary tract may be diagnosed accurately based on history, physical examination, ultrasound, and nuclear renal scan (574).

The history may provide important clues to the source of the abdominal mass. One should inquire whether prenatal ultrasonography was performed and, if so, at which week of gestation. Ideally, these films should be obtained and reviewed. As has already been detailed, prenatal ultrasonography is extremely sensitive in identifying a variety of obstructive urologic lesions (Fig. 46.16). Normal prenatal ultrasound late in gestation in which the fetal urinary tract was visualized would tend to exclude hydronephrosis and multicystic kidney as etiologic factors (187).

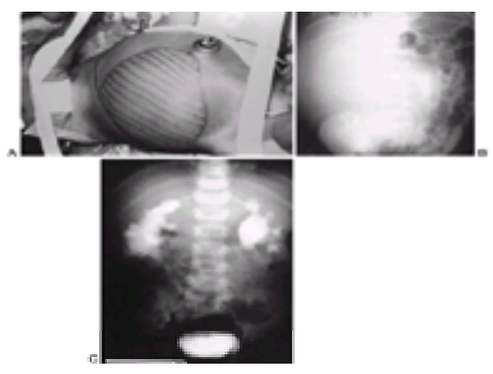

FIGURE 46.16. Neonate with large abdominal mass discovered on prenatal ultrasonography and found to have bilateral hydronephrosis. **A:** Extent of palpable right abdominal mass is marked out. **B:** Preoperative intravenous pyelogram (IVP) showing large right abdominal mass and left hydronephrosis. The right kidney was found to be severely hydronephrotic secondary to a ureteropelvic junction obstruction, and a right pyeloplasty was performed. A left pyeloplasty was performed subsequently. **C:** Postoperative IVP demonstrating excellent function bilaterally.

A history of fever developing in the neonatal period suggests an obstructive lesion because febrile illnesses in the neonate are rare. Persistent vomiting in the first few days of life may be indicative of a gastrointestinal disorder. In a boy, the stream should be visualized because most boys with urethral valves have a weak urinary stream. Infants with severe dehydration and those with diabetic mothers have an increased incidence of renal vein thrombosis (RVT).

Family history is important as well. Infantile polycystic kidney disease is an autosomal-recessive disorder, and infant deaths are often noted in the family history. Duplication of the urinary tract often is hereditary and has a polygenic mode of inheritance. Consequently, if there is a family history of duplication of the urinary tract, one might suspect an ectopic ureterocele or ureter as the diagnosis. Similarly, multicystic kidney has been observed to recur in family members.

Physical examination is important. In the first few days of life, the newborn is particularly easy to examine. The kidneys are nearly always palpable in the newborn. If the lower poles of the kidneys are positioned close to the midline, one should suspect a horseshoe kidney. In such circumstances, palpation along the anterior aspect of the spine may detect the isthmus. The lower quadrants are examined in the customary manner. By compressing the abdomen from both sides, one may detect a mobile abdominal mass, such as an intestinal duplication or ovarian cyst.

Another important aspect of examination is transillumination (139). This technique helps distinguish between masses that are solid and those that are filled with fluid or air. In addition, in the neonate, it may aid in identifying the liver edge, stomach, bladder, and gallbladder. Bladder massage may be a helpful diagnostic aid. Rather than forcefully expressing the bladder (Credé method), one gently massages the bladder between the index finger and thumb. Within 1 to 2 minutes, if the bladder is moderately full, voiding will commence. One may judge the stream, assess residual urine, note bladder thickness, and obtain a clean urine specimen in this manner.

A complete examination also includes blood pressure measurement, respiratory tract and genitalia assessment, and a rectal and bimanual examination. Hypertension

may occur with neuroblastoma or infrequently with hydronephrosis. Respiratory distress in the newborn often is associated with bladder outlet obstruction and may be indicative of hypoplastic lungs. In a female infant, a bulging interlabial mass is suggestive of hydrometrocolpos. Rectal examination may help disclose the origin of a solid lower abdominal tumor, such as a sacrococcygeal teratoma.

After the physical examination, ultrasonography is the next diagnostic step. In most cases, an experienced ultrasonographer is able to demonstrate the location of the mass and whether it is cystic or solid. A multicystic kidney has characteristic sonographic features that usually distinguish it from hydronephrosis. If it appears that the mass is either a hydronephrotic or multicystic kidney, a VCUG should be performed to assess whether there is VUR and, in males, whether bladder outlet obstruction (i.e., PUV) is present. If a tentative diagnosis of unilateral UPJ obstruction, UVJ obstruction, or multicystic kidney is made, the newborn may be discharged with its mother and allowed to return after 3 or 4 weeks for a renal scan. A scan should be performed urgently, because if the renal mass is a hydronephrotic kidney secondary to a UPJ obstruction, early pyeloplasty probably will be necessary.

If a solid tumor is suspected, a sonogram or CT scan should be performed. It is likely that the mass represents a mesoblastic nephroma, and a nephrectomy should be performed before discharge from the hospital. Wilms' tumors rarely occur in the newborn period. The management of RVT is discussed later in this chapter. Other urologic problems that may require immediate treatment include PUV, hydrocolpos, and an ovarian cyst.

The list in Table 46.12 should not be construed as a complete list of all neonatal abdominal masses. Other masses that have been encountered include focal renal dysplasia manifested as a unilateral solid renal mass (152) and oxalosis and neonatal leukemia (210), both of which were diagnosed after the detection of bilateral renomegaly.

Multicystic Kidney

The multicystic kidney is the second most common cause of an abdominal mass in the neonate (Table 46.12) and is the most common cause of an abdominal mass in the first 2 days of life (219). It represents a severe form of renal dysplasia and is associated with ureteral atresia. The etiology is uncertain, although Stephens (518) suggests that during migration of the developing kidney from the sacral to the lumbar level, the normal arterial cascade providing vascularity to the kidney may not occur, resulting in an ischemic insult, producing the multicystic kidney and associated ureteral atresia. Before the era of antenatal ultrasound, nearly all multicystic kidneys were detected in the newborn after detection of an abdominal mass. However, the widespread use of antenatal ultrasound has resulted in the majority of multicystic kidneys being detected before birth. However, at times, a multicystic kidney cannot be distinguished from an obstructed hydronephrotic kidney prenatally (98). Therefore prompt postnatal evaluation is necessary. The multicystic kidney is almost always unilateral, with the left side being more commonly involved. Bilateral multicystic kidney is incompatible with life. A few cases of autosomal-dominant inheritance of multicystic kidney have been reported (513).

Diagnosis

Most multicystic kidneys detected by antenatal ultrasound are not palpable unless the cysts are quite large. In one series, only 13% were palpable. When the kidney is palpable and enlarged, examination usually reveals a unilateral firm mass that has an irregular surface caused by the cysts and which may feel like a bunch of grapes. Transillumination demonstrates the mass to be lucent. Although the kidney usually is in a lumbar location, it may occur in a pelvic kidney, crossed fused ectopia (454), or a horseshoe kidney (Fig. 46.17). Ultrasound is usually diagnostic, but occasionally strikingly resembles a kidney with a UPJ obstruction, termed the *hydronephrotic variant* (467). Thus the diagnosis must be confirmed by renal scan, which should demonstrate a photopenic area with less than 1% differential function. A few multicystic kidneys, have been reported to demonstrate significant function or renal scan in the neonate, leading to uncertainty about the diagnosis (75). Because the contralateral kidney has a 20% chance of being abnormal (551), careful imaging of this kidney with an ultrasound is mandatory. In addition, a VCUG should be performed because there is a significant incidence of lower urinary tract anomalies and 15% have reflux (486).

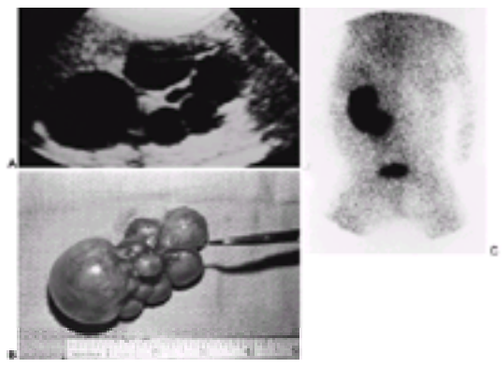

FIGURE 46.17. Infant born with palpable right abdominal mass. **A:** Sonogram of right kidney demonstrating multiple echolucent cysts of varying sizes with no discernible cortex. **B:** DTPA renal scan demonstrating absence of flow and function on the right side. The infant also has a horseshoe kidney with a ureteropelvic junction obstruction of the left kidney on the left side of the image. **C:** Multicystic kidney, gross specimen.

Management

Left untreated, most multicystic kidneys become smaller relative to total body size, and some regress completely (551). In a registry of children with a multicystic kidney, 23% of those managed nonoperatively until 3 years of age showed complete regression (553). With a mean observation period of 4.9 years, John and co-workers (270) reported that 48% showed complete regression, 33% were reduced in size, 15% showed no change, and 4% increased in size.

Complications associated with multicystic kidneys include gastric outlet obstruction and respiratory depression (540); hypertension (504); malignancy (33,49,121,134,235,362,382,423); nodular renal blastema, which is a precursor to Wilms' tumor (134); and focal nephroblastomatosis (551).

Because of the occult nature of these potential problems, annual follow-up with ultrasonography and blood pressure measurement is recommended. If the kidney causes symptoms because of its large size or if any cysts enlarge, the stromal core increases in size, or hypertension develops, nephrectomy is recommended (561). It should be noted, however, that cyst regression does not mean that the multicystic kidney poses no risk because the tumor elements are thought to arise from the stromal component, not the cystic component. Alternatively, in lieu of follow-up screening, nephrectomy may be performed as an outpatient through a 3-cm incision when the child is 3 to 12 months old (151). The Section on Urology of the American Academy of Pediatrics has ongoing registry to determine the long-term “risks” of nonoperative management of multicystic kidneys.

Ureteropelvic Junction Obstruction

Congenital hydronephrosis secondary to UPJ obstruction is a common disorder of childhood, with an incidence approximating 1 in 1,000. In the past, approximately 75% of children with this anomaly were diagnosed beyond 1 year of age (505). However, with increasing use and improved sophistication of prenatal ultrasound, 30% to 50% of children with UPJ obstruction are diagnosed prenatally, before they become symptomatic. Currently, less than 15% of neonates with a UPJ obstruction present with an abdominal mass. Other typical presentations include urinary tract infection (UTI), VATER (*v*ertebral defects, *a*nal atresia, *t*racheoesophageal fistula with *e*sophageal atresia, and *r*adial and *r*enal anomalies) screening, urinary ascites, and as an incidental finding during cardiac catheterization for congenital heart disease.

In most series, the sex incidence and left-sided preponderance are similar to those described in older children (Table 46.13). Approximately two-thirds of newborns with UPJ obstruction are boys, and in 60%, the obstruction is on the left side. Approximately 5% to 10% have bilateral involvement (Fig. 46.16). Approximately 15% have VUR (248). In children with unilateral UPJ obstruction, contralateral renal anomalies are common, including agenesis, duplication of the collecting system, malrotation, ectopia, and multicystic kidney. The etiology of UPJ obstruction is uncertain. The most attractive proposed theory is failure of recanalization of the metanephric cord between the fifth and sixth week of fetal development (459).

Series	No. of Patients (Time Period)	Bilateral	M:F	L:R	Prenatal Diagnosis	Nephrostomy	Reoperation Rate

TABLE 46.13. INFANT PYELOPLASTIES

Without ultrasound, the most common sign leading to diagnosis of UPJ obstruction in the newborn is the presence of an abdominal mass. Other associated symptoms and signs include fever (secondary to UTI, more common in girls), hematuria, vomiting, and failure to thrive. In contrast, in older children, abdominal or flank pain and UTI are the most common presentations (151,505).

A spectrum of abnormalities is seen pathologically in UPJ obstruction (223,224). The UPJ may show reduced muscle bulk, muscular malorientation, thickened adventitia, and infiltration by inflammatory cells. Approximately 20% are normal by light microscopy (223). By electron microscopy, abundant collagen fiber is in the obstructed UPJ and between the muscle cells just proximal to the UPJ. In the renal pelvis, there is variable muscle cell damage with increased collagen and ground substance deposition and disrupted nexuses. An accessory lower pole renal artery is present in 10% to 20% of patients and usually is anterior to the obstructed UPJ (464,505). However, in most patients, the obstruction produced is due to a stenotic or dysfunctional UPJ that does not allow normal propulsion of urine from the renal pelvis to the ureter (396). When an accessory lower-pole artery is present, a distended pelvis may pull the ureter up such that it drapes over the vessel and kinks the ureter, further obstructing the system. The vessel usually is an associated finding and not the primary cause of obstruction. There is a group of patients who appear to develop intermittent obstruction at the UPJ. In such patients, there appears to be a borderline functional obstruction, and during high rates of urine flow, the renal pelvis decompensates, resulting in severe abdominal pain and vomiting (Dietl's crisis). When the pelvis finally drains sufficiently, the pain resolves. This situation exists more commonly in older children and adults and is rare in neonates; often, there is a crossing accessory lower-pole vessel.

Evaluation

In a newborn with hydronephrosis detected by prenatal sonography, a UPJ obstruction often is suspected if the ureter is nondilated and the bladder is normal. In some cases, there is an abdominal mass, but in most cases, the examination is normal and the perinatal finding is incidental (Fig. 46.18, Fig. 46.19, and Fig. 46.20). If there is an abdominal mass, a solitary kidney, or bilateral hydronephrosis, prompt evaluation is suggested. Otherwise, the workup does not need to be as urgent. Renal function should be assessed with serial serum creatinine levels, recognizing that it may not become normal (0.4 mg/dL) until 1 week of age. The radiologic evaluation consists of a renal ultrasound, VCUG, and diuretic renogram.

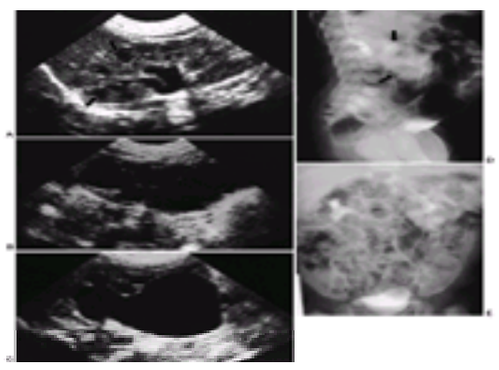

FIGURE 46.18. A: Normal neonatal renal ultrasound. Note prominent intrarenal pelvis and corticomedullary junctions *(arrows).* **B, C:** Renal ultrasounds in newborn with left ureteropelvic junction obstruction. Note large renal pelvis communicating with clubbed calyces. Cortex is quite thin. **D:** Intravenous pyelogram (IVP) performed at 1 week of age. Film was taken 1 hour and 45 minutes after injection. Note large left renal pelvis *(arrows)* of the left kidney. Patient underwent pyeloplasty in the neonatal period. **E:** IVP 2.5 months postpyeloplasty, a 15-minute film. Visualization of the left kidney was prompt. Note persistently clubbed calyces.

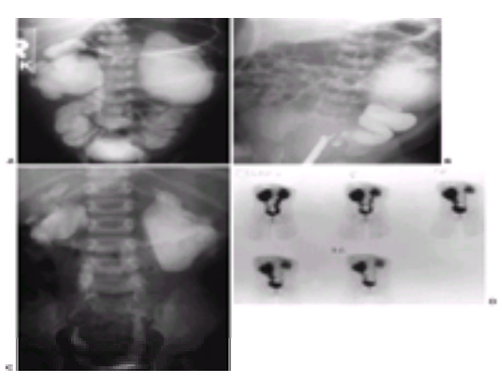

FIGURE 46.19. Example of bilateral hydronephrosis that is apparently nonobstructive. As newborn, a large abdominal mass was palpable. Serum creatinine was 0.3 mg/dL. **A:** Intravenous pyelogram (IVP) performed at 3 days of age 5.5 hours after injection demonstrating marked bilateral hydroureteronephrosis with multiple transverse folds in the ureters. **B:** Left retrograde pyelogram performed at 2 months of age. Child was followed nonoperatively and maintained on antimicrobial prophylaxis. Serial IVPs and renal scans were obtained. **C:** IVP at 2.5 years of age demonstrating nearly complete resolution of hydronephrosis. Renal units are dysmorphic. **D:** DTPA diuretic renogram at 3.5 years of age. Left kidney is on left side of image. Percent uptake: left, 3.2%. Differential function: left, 46%; right, 54%. Cortical transit time: left, 3.5 minutes; right, 2.5 minutes. After administration of furosemide, $T_{½}$; left kidney on left side of image, 9 minutes; right, less than 5 minutes.

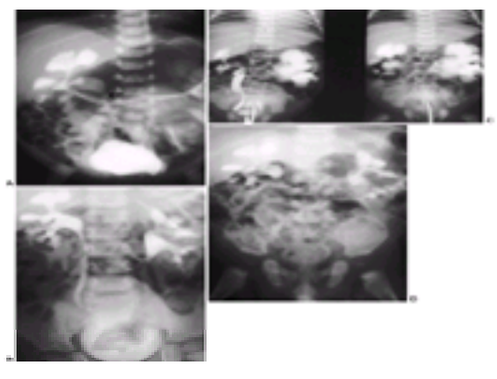

FIGURE 46.20. Example of Ostling's valves or ureteral folds. **A:** Intravenous pyelogram (IVP) showing bilateral hydronephrosis. Note tortuous upper ureter on right side *(arrow).* **B:** Right retrograde pyelogram again demonstrating tortuosity of upper ureter. **C:** IVP 1 year later. The child has undergone left pyeloplasty. Note diminished calycectasis on the right side. **D:** IVP 2 years after initial study. Ureteral folds persist but are straightening out.

If the initial ultrasound is normal, the finding may be secondary to oliguria, which occurs immediately postnatally (306), and a repeat study should be performed in 3 weeks. Hydronephrosis should be graded according to the SFU grading scale, from 0 to 4 (332). If there is severe hydronephrosis with marked parenchymal thinning, generally seen in neonates with an abdominal mass secondary to a UPJ obstruction, or if there is bilateral hydronephrosis, a prompt VCUG and diuretic renogram should be done. In most cases, the evaluation may be delayed until the infant is 4 to 6 weeks of age to allow renal maturation with an increased GFR, which will enhance the accuracy of the diuretic renogram (97). In such cases, the infant should be discharged on oral amoxicillin 50 mg daily. In addition, in boys with hydronephrosis, circumcision is recommended to diminish the risk of UTI. An IVP generally is not performed because the diuretic renogram provides much more information regarding function of the hydronephrotic kidney and severity of obstruction. Furthermore, visualization of the kidney is likely to be suboptimal because of insufficient concentration of the contrast media and overlying bowel gas.

A VCUG is necessary to ascertain that the male urethra is normal and to determine whether there is VUR, which is present in as many as 15% of children with a UPJ obstruction (248). At times, the reflux may be high grade (315,333) (Fig. 46.21). Performing a pyeloplasty in a child with reflux may subject the repair to high pressures and result in an anastomotic leak.

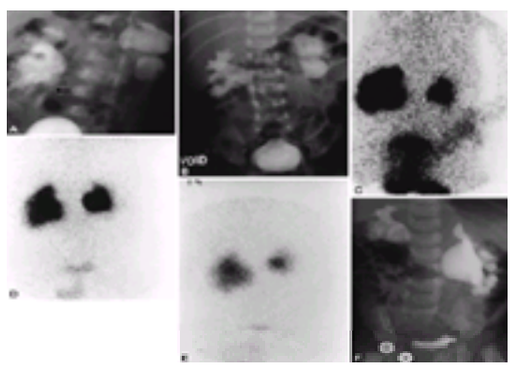

FIGURE 46.21. Example of left ureteropelvic junction obstruction and bilateral vesicoureteral reflux. **A, B:** Voiding cystourethrogram demonstrating bilateral grade III-IV reflux. Note Ostling's valve or ureteral fold *(arrow).* **B:** Postvoid film. **C:** Delayed image after DTPA renal scan performed at 3 weeks of age showing stasis in left kidney. $T_{½}$ normal on right, prolonged on left side. Percent uptake: left side, 1.2%; right side, 1.5%. Differential function, left, 45%; right, 55%. Because of excellent function in the left kidney on the left side of the image, it was decided not to perform a pyeloplasty at this time. **D, E:** DTPA diuretic renogram at 4 months of age. Left kidney is on the left side of the image. **D:** Prefurosemide image. **E:** Image 15 minutes after administration of furosemide. $T_{½}$ on right side, 7 minutes; 40% washout of radionuclide at 20 minutes on the left side. Percent uptake: left, 2.7%; right, 2.1%. Differential function: left, 56%; right, 44%. **F:** Intravenous pyelogram performed at 5 months of age. Pyeloplasty has not yet been performed. Case demonstrates continued growth of left kidney despite obstruction on furosemide washout curve.

The most important diagnostic study is the “well-tempered” MAG-3 diuretic renogram. This study is covered in detail previously in this chapter in the section on nuclear medicine studies. In general, extrapolating the drainage slope from the point of maximal activity, a $T_{½}$ greater than 20 minutes is consistent with obstruction. However, if the first study shows significant drainage after diuretic administration and the differential renal function in the hydronephrotic kidney is at least 35% to 40%, the infant generally may be followed nonoperatively and the “well-tempered” diuretic renogram repeated 3 months later because the obstruction often reduces in severity or disappears with time. Exceptions to this approach include an infant with a solitary kidney, bilateral hydronephrosis, reduced renal function, an abdominal mass, or the rare infant with nearly constant abdominal pain which has been attributed to colic.

With current methods of diagnosis, percutaneous nephrostomy and antegrade pyelography rarely are necessary. Antegrade pyelography may aid in distinguishing a UPJ obstruction from a multicystic kidney. However, the renal scan is likely to be as accurate, if not more accurate, because a congenital UPJ obstruction almost always demonstrates at least 5% function in the newborn, whereas a multicystic kidney demonstrates minimal or no flow or function. If the diagnosis is in doubt, an antegrade study of a multicystic kidney generally demonstrates that the cysts do not communicate.

It may be worthwhile to place a percutaneous nephrostomy temporarily if the salvageability of an obstructed kidney is in doubt or in the presence of respiratory distress compounded by abdominal distention secondary to a tremendously dilated obstructed renal pelvis. Although percutaneous nephrostomy in the newborn is safe and generally successful, it may result in edema, inflammation, infection, or hemorrhage in the pelvis that can result in a very difficult pyeloplasty.

Immediate Versus Delayed Surgical Arrangement

In the human, nephrogenesis is completed by 36 weeks of gestation. At birth, blood flow is redistributed, with an increasing proportion directed to the peripheral nephrons. During the first 6 months of life, the GFR increases rapidly and the ability of the kidney to concentrate and acidify urine improves. Chronic urinary tract obstruction can result in decreasing GFR and renal blood flow, and impaired concentrating ability (186). Unfortunately, there is no reliable method to predict recovery of renal function following relief of obstruction (555).

In the newborn rat (corresponding to the human fetus in the last trimester), when partial ureteral obstruction is created, the GFR on the hydronephrotic side is variably affected, being 10% to 43% less than the contralateral side, with compensatory hypertrophy of the normal side (276,277,278 and 279). Furthermore, the single-nephron GFR may be elevated on the hydronephrotic side, with minimal redistribution of glomerular filtration (276). The alterations in GFR appear to stabilize over time, as do the changes in renal morphology (92,279). Similar studies have been performed in the newborn guinea pig, which correspond to the human in that nephron formation is complete at birth. In this model, neonatal ureteral obstruction results in variable hydroureteronephrosis, with the intraureteral pressure inversely proportional to a reduction in GFR (86). These studies suggest that although partial ureteral obstruction may cause diminished kidney function, the changes may not progress over time. In UPJ obstruction, there is partial obstruction that is variable in severity. Accordingly, one might infer from these studies that with a mild UPJ obstruction a mild diminution of renal function is likely to remain stable, whereas with high-grade obstruction, progressive deterioration of renal function is likely.

To better understand the natural history of apparent UPJ obstruction in infants, Ransley and associates (428) performed a study in which selected newborns with hydronephrosis and a suspected UPJ obstruction and satisfactory differential renal function were followed nonoperatively. Their management plan separated patients into three groups based on the “function” of the “obstructed” kidney on DTPA diuretic renogram.

Group I:Normal function: normal uptake curve (parenchymal transit time) with greater that 40% of overall function

Group II:Moderately reduced function: delayed uptake curve with 10% to 40% of overall function

Group III:Severely reduced function: flat uptake curve with less than 10% of overall function

Group I was managed expectantly. The concept was that if the kidney had good function despite a long period of antenatal obstruction, surgical intervention might not be necessary in an asymptomatic child. In those with moderately reduced function (group II), it was assumed that the partial obstruction was severe enough to warrant early surgical therapy. If the renal function was severely affected, it was distinguished from a multicystic kidney either by antegrade pyelogram or temporary

percutaneous nephrostomy.

Of a total of 142 kidneys, 106 were group I, 27 were group II, and 9 were group III (428). Of the 9 group III patients, 3 (33%) underwent pyeloplasty and 6 (67%) had a nephrectomy because of poor function. Of the 27 group II patients, 23 underwent early pyeloplasty. Of these, 9 (39%) had marked improvement in differential function, 5 (22%) had moderate improvement, and 9 (39%) had no change. Of the group I patients, 6 underwent early pyeloplasty. Of the 100 patients who were followed nonoperatively, 23 (23%) eventually required a pyeloplasty, 19 (83%) requiring it by 3 years of age. Reasons given for pyeloplasty included deteriorating differential renal function in 14 (61%), UTI in 3 (13%), pain in 1 (4%), concentrating defect in 1(4%), and “other” in 4 (18%). Of the 14 patients with deteriorating renal function, only 5 (36%) returned to the original level of differential function. Mean follow-up was less than 3 years. Of the 66 kidneys with a renal pelvic diameter of more than 12 mm, 23 (35%) eventually underwent pyeloplasty, whereas none of 34 with a pelvic diameter of less than 12 mm required surgical intervention.

This report was the first study of a large group of patients with suspected UPJ obstruction followed nonoperatively. In retrospect, there were significant problems with the methodology of the diuretic renograms used to diagnose obstruction. For example, only 0.2 mg/kg of furosemide was administered 20 minutes into the study, rather than 1 mg/kg at peak activity in the renal pelvis, as is currently recommended. Consequently, the diuretic stimulus was minimal. In addition, hydration before the diuretic renogram was not monitored. Furthermore, a catheter was not used to drain the bladder (209). Finally, using a liberal definition of obstruction (decrease in activity to 75% within 10 minutes or to 50% of activity within 20 minutes), 27% of the group I patients never showed an obstructive pattern. Therefore this study is not ideal for documenting the natural history of suspected UPJ obstruction.

Cartwright and associates (77) studied 97 newborns with suspected UPJ obstruction. Of 39 with at least 35% differential renal function followed nonoperatively, only 6 (15%) underwent pyeloplasty, with average follow-up of 18 months (range of 6 to 48 months). All three of the patients with differential renal function of less than 40% who underwent pyeloplasty because of decreasing renal function returned to their initial levels. One might question whether early pyeloplasty in these three patients would have allowed renal function to improve to 50%, which would have been ideal. In those followed nonoperatively, all maintained differential functions greater than 40% with follow-up as late as 48 months.

Takla and associates (530) studied 51 patients with SFU grades 2, 3, and 4 hydronephrosis initially managed nonoperatively and found that 4% of those with grade 2, 56% with grade 3, and 71% with grade 4 hydronephrosis ultimately underwent pyeloplasty. In the remaining patients, the hydronephrosis resolved, usually by 18 months of age.

In contrast, Ulman and co-workers (545) reported 104 infants with SFU grade 3 or 4 hydronephrosis initially managed nonoperatively a mean of 6.5 years. Of the patients followed nonoperatively, hydronephrosis resolved in 69% and improved in 31%. However, 33% still had a $T_{½}$ of greater than 20 minutes on their most recent diuretic renogram. Of the infants, 23% underwent pyeloplasty. All were younger than 18 months of age and showed progressive hydronephrosis and/or reduction in differential renal function. In these kidneys, postoperative differential renal function exceeded the predeterioration level in all kidneys.

Palmer and colleagues (394) reported the initial results of a prospective randomized trial comparing observation to pyeloplasty in infants with SFU grade 3 or 4 hydronephrosis. All had differential renal function greater than 40% on their initial renal scan and a prolonged $T_{½}$. Of the 32 infants studied, in the observation group, 25% had significant deterioration in renal function and underwent pyeloplasty. The remaining observation patients were stable. Those undergoing pyeloplasty had less hydronephrosis and a shorter $T_{½}$ drainage curve at follow-up compared with the observed group.

These observations may be interpreted in several ways. First, it may be that some partially obstructed kidneys have significant functional impairment at birth but that the capacity for renal maturation, with increasing GFR secondary to redistribution of blood flow to cortical nephrons, during the first year of life is maintained. Another explanation is that the early diuretic renogram is erroneous and that during the period of transitional nephrology the differential renal function and capacity for washout in these kidneys is different than in older children. This position was vigorously disputed by Chung and co-workers (90), who performed well-tempered diuretic renograms and found no significant differences in renal function or washout in neonatal and follow-up studies in patients managed nonoperatively. Finally, it must be remembered that all of these studies base “renal function” on the results of the differential renal function, which has significant potential for variability.

Elder and colleagues (154) reported the results of renal biopsies performed in 55 children undergoing pyeloplasty. Overall, 63% showed minimal or no obstructive histologic changes. However, of those with differential renal function greater than 40%, 21% showed significant histopathology (reduced glomerular number, glomerular hyalinization, interstitial inflammation). In contrast, of those with a differential function less than 40%, 33% showed minimal or no obstructive changes. Consequently, in 25% of the patients, the findings on renal biopsy did not correspond to the computed differential renal function and suggest the need for more sensitive markers of obstruction.

The critical question in patients with suspected UPJ obstruction is what is obstruction? Koff and Campbell (295) define obstruction as identifying “evidence of obstructive injury, such as a failure of expected improvement in renal function, compensatory hypertrophy in the contralateral kidney or progressive hydronephrosis.” By this definition, no neonate with unilateral hydronephrosis would undergo pyeloplasty until follow-up studies confirmed evidence of obstructive injury. Allen (12), on the other hand, has stated “it makes no more sense to wait for evidence of progressive renal damage before making diagnosis of obstruction than it does to wait for a tumor to metastasize before calling it a cancer.” Peters defines obstruction as “a condition of impaired urinary drainage that if uncorrected will limit the ultimate functional potential of a developing kidney.” Woodard (584) stated “to delay surgery...until measurable deterioration in renal function has occurred seems to deny the patient the benefit of state-of-the-art management.” Unfortunately, no one knows how many of these children later will become symptomatic with abdominal or flank pain. Although there are many viewpoints on the indications for pyeloplasty and appropriate timing (136,297,340), the physician managing these infants nonoperatively must be able to provide assurance that no permanent injury will occur.

Our approach to neonates with a perinatal diagnosis of suspected UPJ obstruction is as follows. In children with unilateral hydronephrosis, no abdominal mass, and a normal contralateral kidney, the hydronephrosis is graded (1 to 4). Those with grade 3 and 4 hydronephrosis are most likely to require pyeloplasty. A VCUG is obtained during the first few weeks of life, the child is placed on prophylactic amoxicillin or cephalexin, and circumcision is recommended for boys. At 6 weeks, a well-tempered renogram is performed. If differential renal function is greater than 35% to 40% and any significant drainage is noted after administration of furosemide, even if the $T_{½}$ is greater than 20 minutes, the child is managed nonoperatively and kept on prophylaxis with trimethoprim-sulfamethoxazole, which is safe to administer after 2 months of age. A follow-up renal sonogram and diuretic renogram are performed 3 months later. If there is deterioration in differential function, worsening of the diuretic washout curve, or worsening hydronephrosis, pyeloplasty is recommended. If these parameters remain stable or improved, however, follow-up 3 to 6 months later with another diuretic renogram is performed and management is individualized. If there is an abdominal mass, a solitary kidney, bilateral hydronephrosis, or impaired renal function, pyeloplasty is performed any signs of obstruction are present.

On occasion, urography of the fetal or neonatal urinary tract may disclose mild to moderate hydronephrosis and a dilated ureter a few centimeters distal to the UPJ. In many of these patients, the apparent dilation is secondary to *Ostling's valves,* which represent transverse folds of the upper ureter (393). They are usually nonobstructive and resolve over time (Fig. 46.20).

Pyeloplasty: Technical Points

The infant is admitted to the hospital on the day of surgery, and rooming in by one of the parents is encouraged. Preoperatively, the anterior or posterior location of the extrarenal pelvis is determined because it may help in determining the surgical approach. Lateral or oblique views on the urogram or ultrasound are helpful in this regard. The anterior muscle-splitting approach clearly is indicated if the pelvis is anterior (142), but because the pelvis is posterior in most infants, a lumbotomy incision may be preferred.

If a flank incision is used, the infant is placed with the appropriate flank elevated 30 degrees, with the opposite side flexed over a rolled towel. The peritoneum should be mobilized widely and retracted medially. In general, the kidney does not need to be mobilized.

We have found the posterior lumbotomy to provide an excellent surgical approach to the kidney in the neonate (206). The infant is placed in the supine position, and a towel is placed under the abdomen to push the kidney further posteriorly. A 45-degree incision is made in the costovertebral angle. This approach is minimally traumatic because no muscles are cut. The exposure is optimal (except when the renal pelvis is anterior), and opening and closing the incision is rapid.

In general, a dismembered Anderson-Hynes pyeloplasty is performed. The pelvis is exposed completely by dissecting bluntly in the plane just superficial to its intrinsic blood supply. The dissection of the upper ureter should be minimal, just enough to permit resection of the narrow segment and spatulation. The ureter is not elevated or placed on traction with umbilical tape or vessel loop. Following these precautions results in the preservation of maximal blood supply to the anastomosis. When a

large redundant pelvis is present, the pelvis is resected to 1 cm from the edge of the renal parenchyma. If a decompensated large-capacity floppy pelvis is left unresected, the likelihood of an unanticipated kink at the ureteropelvic anastomosis when filling occurs is increased.

Holding sutures are placed to help position the tissues for precise approximation and to avoid the need for handling the tissue with forceps. Optical magnification (×2.0 to 3.5) is beneficial in ensuring precise suture placement and a watertight anastomosis. The pelvis is closed with a running 6-0 polyglycolic acid (PGA) suture. The ureteropelvic anastomosis is performed with 6-0 or 7-0 PGA sutures. Between three and five interrupted sutures are placed at the apex, allowing more precise alignment of this critical portion of the anastomosis. The remainder of the anastomosis is performed with a running stitch, allowing a watertight closure. The anastomosis is performed over a small feeding tube passed a few centimeters down the ureter. Passage of a catheter into the bladder is avoided because it may cause edema of the UVJ, resulting in mild obstruction, increased intrapelvic pressure, and possible breakdown of the anastomosis. The renal pelvis should be irrigated before closure to remove any blood clots.

There is no consensus as to whether a nephrostomy or a ureteral stent should be used. Numerous series have demonstrated that a pyeloplasty in a neonate may be performed safely without proximal drainage (457). However, several points must be considered. It may be more difficult to produce a perfect anastomosis in a small ureter. Edema may make coaptation of the walls of the anastomosis more likely, leading to the postoperative synechiae, obstruction, or both. These considerations would encourage the use of a nephrostomy and possibly a stent (25). When a nephrostomy is not used, leakage of urine is common during the first few postoperative days. Although extravasation of urine without drainage induces an inflammatory tissue reaction, a minor amount of leakage is not problematic if the area is drained adequately. Therefore proper management of the drain is essential. One other option is to use an internal double-J stent for several weeks postoperatively. The disadvantage of the indwelling stent is that is must be removed 4 to 6 weeks later under anesthesia. Another alternative is the Salle stent (Cook), which is a double-J stent with a proximal end that is brought out through the renal parenchyma and flank; this stent drains into a bag.

Ipsilateral VUR or a full bladder may subject the anastomosis to high intraluminal pressure and may result in excessive leakage from the fragile anastomosis. Cystoscopy or intraoperative urethral catheterization may cause sufficient irritation in a newborn to allow unwanted bladder distention and probably should be avoided, as should retrograde ureteral catheterization. If a nephrostomy is not used, the infant should be checked carefully during the first 24 hours and catheterized every 4 to 6 hours if the child does not void to prevent a significant increase in the intrapelvic pressure.

Proximal drainage (e.g., nephrostomy) generally is recommended with a solitary kidney, a bilateral pyeloplasty, or an unusually small or thin-walled ureter. In general, a 12-Fr Malecot catheter is used as a nephrostomy, with two of the wings excised. In a patient whose kidney has been demonstrated postoperatively to have little or no function, a nephrostomy provides a way of demonstrating postoperatively that no obstruction is present. The catheter is placed in a lower-pole calyx. Because there is a theoretical advantage in urine transversing the anastomosis immediately postoperatively, when a nephrostomy is used, an option is to clamp it immediately and use it as a backup only if there is significant drainage from the anastomosis, obstruction, or urinary infection. When the nephrostomy is left open, it may be allowed to drain into a double diaper. Such drainage eliminates twisting, kinking, and inadvertent removal of tubes that may occur when the infant moves about the crib with the nephrostomy tube attached to a drainage bag. The infant may be discharged with an indwelling nephrostomy as soon as feeding is progressing satisfactorily and the clinical situation is stable.

Delayed opening of the anastomosis protected by a nephrostomy is common in the infant pyeloplasty. The drainage tubing may be elevated (hump the tube) 30 cm to increase the intrapelvic pressure and encourage the anastomosis to open. Gravity drainage may be reinstituted if the baby is fussy and to check for residual urine.

A reoperation rate of 8% to 10% in infant pyeloplasties has been reported, similar to series of older patients, although with greater experience there have been lower complication rates. The technical failures may be secondary to traumatic dissection, devascularization of the ureter, excessive traction on the ureter resulting in ischemia or creation of an anastomosis that is too tight, or extravasation from an undrained anastomotic leak with subsequent fibrosis.

Follow-up studies include an ultrasound and diuretic renogram.

Megaureter—Nonrefluxing

In a child with a megaureter, the condition may be obstructive or nonobstructive and refluxing or nonrefluxing (158). In most cases, there is no reflux.

Nonrefluxing megaureter results from an aperistaltic segment of the distal ureter that does not allow normal propulsion of urine. In this condition, sonography shows a dilated ureter and renal pelvis with variable renal parenchymal atrophy. VCUG shows no reflux in most cases. Before the era of antenatal ultrasound, most patients with this condition presented with flank pain, a flank mass, pyelonephritis, hematuria, or stone disease. Approximately 70% of individuals with this condition are male and two-thirds are on the left side.

Although severe hydronephrosis may be present, the natural history of this condition is that there is a tendency to gradual reduction in hydronephrosis over a period of several years. For example, in one series of 35 neonates with a primary nonrefluxing megaureter, 10 underwent early repair, whereas 25 were followed nonoperatively (37). With a mean follow-up of 7.3 years, none of the 25 exhibited deterioration in differential function or demonstrated signs of obstruction. In another series of 21 patients with nonrefluxing megaureters with obstruction on the initial scan, 6 underwent early reconstruction, whereas 15 were observed (436). Of the patients who were managed nonoperatively, two showed functional deterioration and three, who were not receiving antimicrobial prophylaxis, developed UTIs. Finally, Liu and colleagues (322) found that 11 of 67 (17%) neonatal megaureters managed nonoperatively ultimately needed repair because of deteriorating renal function in 8 and breakthrough UTIs in 3. Consequently, it appears that most of these patients may be followed nonoperatively on antibiotic prophylaxis and serial monitoring of renal function and drainage.

In these neonates, a VCUG and renal sonogram should be obtained before discharge. Early management is identical to that of neonates with a suspected UPJ obstruction. If an abdominal mass, solitary kidney, or bilateral hydroureteronephrosis is present, a well-tempered diuretic renogram should be obtained promptly. Otherwise, the study is deferred until 6 to 8 weeks of age. If the differential renal function is at least 35% to 40%, the child is managed nonoperatively and follow-up diuretic renograms and/or renal sonograms are obtained every 3 to 6 months. Circumcision is recommended for boys, and all are administered antimicrobial prophylaxis. As long as the child remains asymptomatic and the severity of hydronephrosis remains stable or decreases, nonoperative management may continue. On the other hand, if the differential renal function is low or is diminishing, the $T_{½}$ is prolonged, the child is symptomatic, or the hydronephrosis worsens, repair is indicated.

When repairing a megaureter, one must be certain to remove the narrowed distal ureteral segment and part of the redundant ureter. Although Hendren's (239) technique of extensive ureteral excisional tapering has stood the test of time, ureteral plication has been demonstrated to be a reliable method of repair if the ureter is not too wide, with a low incidence of postoperative obstruction. Two techniques have been used: ureteral plication (514) and ureteral folding (148,281). The tailoring needs to be performed only up to a few centimeters proximal to the intramural segment. In general, we have stented these tailored ureters for 3 weeks with a small double-J stent that is connected to a small suture that is brought out through the urethra and taped to the lower abdomen.

Early repair of megaureter has a higher complication rate than in older children. For example, Peters and associates (403) reported on megaureter repair in 42 infants operated on at a mean age of 11.8 months. In that series, early complications occurred only in those younger than 6 weeks of age and included transient apnea in three, UTI in one, hyponatremia in one, and meningitis in one. Six had postoperative reflux, and none had obstruction. Greenfield and others (214) reported on repair of 11 megaureters in infants younger than 6 months old. Of these children, two had transient ureteral obstruction immediately after stent removal and persistent grades I and II reflux in two children.

Posterior Urethral Valves

The most common cause of bladder outlet obstruction in the newborn is PUV. The embryology, clinical features, and long-term management are described in Chapter 50. Although Young (590) described three types of valves in 1919, presently only type I and type III valves are thought to be clinically significant. Type I valves are represented by leaflets or sails that extend distally from either side of the verumontanum to the anterior urethral wall at the level of the urogenital diaphragm. More than 90% of valves are type I. A type III valve is a diaphragm just distal to the verumontanum that has a small central perforation. Patients with type III valves tend to have more severe bladder and upper urinary tract obstruction.

A recent study suggests that most congenital posterior urethral obstructions are similar. Dewan and co-workers (129) performed antegrade voiding cystourethrography in boys with suspected valves. Subsequently, cystoscopy demonstrated that all had a “type III” urethral membrane. After passing the cystoscope

into the bladder and then withdrawing the cystoscope back into the urethra, all had the appearance of a type I valve. This report suggests that the catheter used for VCUG disrupts the valve membrane, giving it a type I appearance.

The incidence of PUV is approximately 1 in 5,000 to 1 in 8,000 boys. There is a wide spectrum in the presenting symptoms and long-term prognosis following treatment. Because of the high-grade bladder outlet obstruction throughout gestation, many children with valves have severely compromised renal function secondary to renal dysplasia.

Diagnosis

The newborn with urethral valves may have an abdominal mass (48%), failure to thrive (10%), urosepsis (8%), or urinary ascites (7%). When the bladder is empty, most will have a walnut-size firm mass in the pelvis, which corresponds to the trabeculated bladder muscle. In as many as half, the diagnosis of valves is suggested by prenatal ultrasonography (Fig. 46.10). Prognosis is significantly better if ultrasound studies performed before 24 weeks of gestation were normal; more than half detected by 24 weeks died or were in chronic renal failure (135,260,261). In addition, dyspnea at birth associated with pneumothorax or pneumomediastinum may be the initial sign of severe urethral obstruction. A normal urinary stream is an uncommon finding.

When the diagnosis of urethral valves is suspected, a VCUG should be performed. A thick trabeculated bladder with a very distended posterior urethra and valve leaflets is seen. Other finds include detrusor hypertrophy, often with cellules or diverticula; bladder neck hypertrophy; and a thin stream distal to the valve leaflets. Half of these patients have VUR, with 25% having bilateral and 25% having unilateral reflux (Fig. 46.22). The radiographic appearance of urethral valves is not confused with prune-belly syndrome, although both of these conditions can cause significant bladder and upper urinary tract dilation.

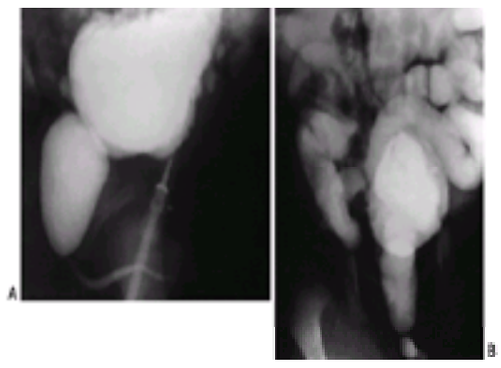

FIGURE 46.22. A, B: Examples of voiding cystourethrogram demonstrating typical posterior urethral valves. Note dilated posterior urethra, hypertrophy of bladder neck, and trabeculated bladder. Bilateral vesicoureteral reflux demonstrated in **B.**

The other important radiographic study is a renal and bladder sonogram. It is critical to obtain baseline views of the renal collecting systems to assess pelvic and calyceal dilation, as well as cortical echogenicity, which may be indicative of the presence of dysplasia. Sonographic presence of the corticomedullary junction in newborns with urethral valves is an important prognostic indicator of good renal function following drainage of the urinary tract (Fig. 46.23). Conversely, if the corticomedullary junction is not visualized and does not appear on subsequent ultrasound examinations, most develop renal insufficiency (256). Suprapubic or perineal ultrasound may demonstrate the dilated posterior urethra, and thus one might establish the diagnosis of valves on the basis of an ultrasound before the VCUG is performed (94) (Fig. 46.24).

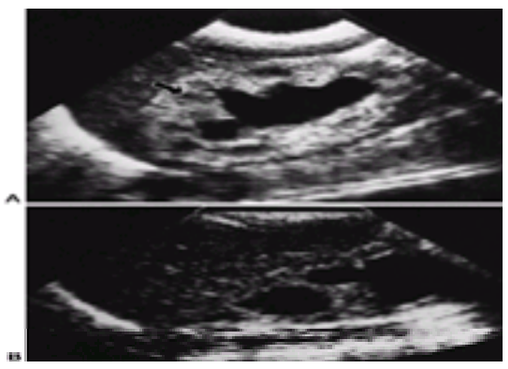

FIGURE 46.23. Sonograms of kidneys from infants with posterior urethral valves. **A:** Corticomedullary junction is present *(arrow).* At birth, creatinine rose to 2.8 mg/dL but fell to 0.6 mg/dL following valve ablation. **B:** Corticomedullary junction absent. The infant progressed to chronic renal failure.

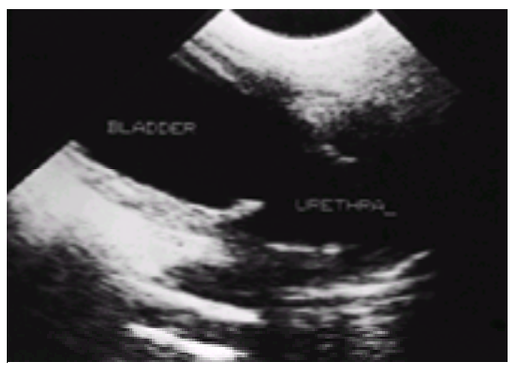

FIGURE 46.24. Suprapubic ultrasound demonstrating dilated bladder and posterior urethra strongly suggestive of posterior urethral valves.

Management

After the diagnosis of urethral valves is made, the bladder should be drained with a 5- or 8-Fr pediatric feeding tube. A Foley balloon catheter may not drain satisfactorily because the balloon has a tendency to occlude the ureteral orifices or it may cause severe bladder spasm and prevent normal drainage of the upper urinary tracts (275). When passing the ureteral catheter, there is a tendency for the tip of the tube to bump on the bladder neck and coil in the dilated posterior urethra, compromising effective drainage. In this circumstance, most of the urine tends to drain around the feeding tube. If there is a question, the appropriate position should be confirmed either by sonography or when the VCUG is done. Repeatedly adjusting the tip of the catheter increases the likelihood of a secondary infection of the urinary tract.

Broad-spectrum antibiotics are given intravenously to minimize the chance of developing a nosocomial bacterial infection. The serum creatinine is monitored, and electrolyte abnormalities, including acidosis and hyperkalemia, need to be managed before surgical treatment of the lesion is undertaken. In addition, repeat

sonography of the upper tracts may be performed to assess the response to bladder drainage.

Initial treatment of the valves depends on the age at presentation and the size and condition of the child. The goal of therapy is to provide optimal upper tract drainage and preserve bladder cycling to allow satisfactory bladder growth with maximal compliance (93,144,502). In the past, use of inappropriately large endoscopic instruments for valve ablation resulted in urethral strictures. With improvement in the optics of the 8-Fr pediatric cystoscope, fulguration can be performed in most small infants safely. In the newborn, the 8-Fr cystoscope is used to examine the bladder, with assessment of the degree of trabeculation, the presence of diverticula, and the position of the ureteral orifices, as well as examination of the valves. In most cases, the 3-Fr Bugbee electrode may be inserted through the operating channel of the 8-Fr cystoscope. The valve leaflets should be ablated at the 5 and 7 o'clock positions, and on occasion at the 12 o'clock position.

Complications with transurethral valve ablation are rare; the most common is incomplete valve ablation. Urethral stricture may occur if the cystoscope is too large for the urethra or if the diathermy current comes into contact with the metal of the cystoscope (491). If the water used for intraoperative irrigation is too high, the elevated pressure may be transmitted to the kidneys and result in forniceal rupture with urinary ascites (122).

Before the availability of miniature endoscopic equipment, a method of valve ablation was a modified crochet hook. Subsequently, Whitaker and Sherwood (566) redesigned the hook (Fig. 46.25) such that it engages only valves and not the bladder neck, verumontanum, or external sphincter. Except for the crotch of the hook, the entire instrument is insulated to prevent spread of diathermy current. It is important to use low-cutting current with the device. It may be used under fluoroscopic guidance in the radiology suite without the necessity for general anesthesia. A cystogram in the operating room confirms adequate relief of obstruction. Experience with this technique has confirmed its effectiveness in relieving bladder outlet obstruction, although some patients have required secondary valve ablation (84). Unfortunately, the Whitaker hook is no longer made, although some centers still have it in available in their inventories. Its most appropriate use may be in countries where miniature endoscopic equipment is unavailable.

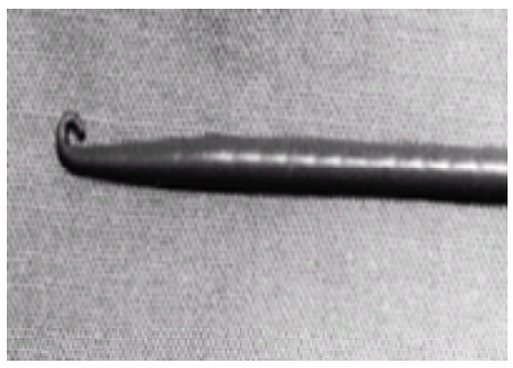

FIGURE 46.25. Tip of insulated crochet hook developed by Whitaker and Sherwood (566). Tip of hook engages only the valve leaflets. Crotch of hook is not insulated allowing diathermy ablation of valves.

Cromie and colleagues (117) reported using a venous valvulotome to incise the valve leaflets at the 12 o'clock position under local anesthesia. Of the ten patients, two underwent later resection of small nonobstructive valve leaflet remnants.

Other techniques for valve ablation also have been described. Zaontz and Gibbons (592) reported antegrade ablation of valves through an established vesicostomy. The technique also has been used percutaneously in neonates (591). The technique involves distending the bladder and performing a percutaneous cystotomy with a 12-Fr trocar midway between the symphysis and umbilicus in the midline. The obturator may be removed, leaving the 12-Fr sheath in the bladder. The 11.5-Fr resectoscope then may be passed through the sheath with visualization of the valves through a 0-degree lens. Visualization has been reported to be quite good. Following this procedure, neither a suprapubic tube nor a urethral catheter was necessary postoperatively.

If the urethra is too small to accommodate the pediatric cystoscope and miniature Bugbee electrode, cutaneous vesicostomy is an alternative form of management (143,259). The dome of the bladder should be brought to the skin at a level such that the posterior bladder wall will not prolapse into the stoma (Fig. 46.26). The vesicostomy should calibrate to 24 Fr.

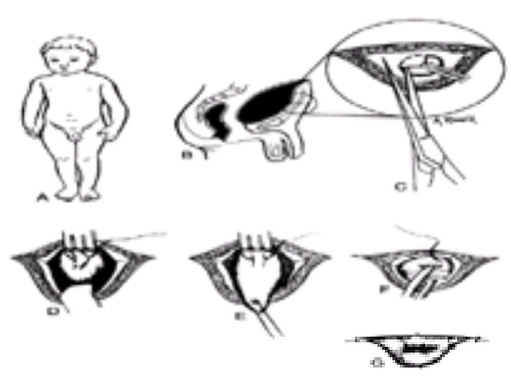

FIGURE 46.26. A–G: Diagram of cutaneous vesicostomy. Incision is made halfway between the pubic symphysis and umbilicus. Holding sutures are placed through the bladder wall for traction, and the bladder is mobilized superiorly until the dome is reached. The dome of the bladder is then exteriorized.

Following definitive therapy, the child should be monitored closely by ultrasound to be certain that the upper urinary tracts are decompressed satisfactorily. A high serum creatinine should decrease gradually. In a newborn who has undergone only valve ablation, however, if the serum creatinine remains unchanged or does not decrease at least to 1.0 to 1.2 mg/dL, proximal diversion by vesicostomy. In the past, cutaneous pyelostomy was thought by some to be a superior form of upper tract diversion compared with cutaneous vesicostomy. However, supravesical diversion does not seem to prevent progression to end-stage renal disease in many of these children because of underlying renal dysplasia (93,192,536). Furthermore, proximal diversion results in the absence of urine going to the bladder and thereby prevents bladder cycling, which may result in poor bladder compliance (i.e., the “valve bladder”) (144,408), although this theory is not universally accepted (265). An alternative is to insert a percutaneous nephrostomy tube for temporary diversion and identify those few patients who might benefit from cutaneous pyelostomy (192). An alternative is the Sober-en-T temporary high diversion for urethral valves, in which a cutaneous ureterostomy is performed, and the distal ureter is sutured to the upper ureter just distal to the renal pelvis (320,506). The advantage of this approach is that the upper urinary tract is diverted, but some of the urine drains to the bladder, which preserves long-term bladder cycling. In select cases, cutaneous pyelostomy may be necessary if a child has urosepsis secondary to pyonephrosis. If upper urinary tract diversion is performed, concurrent renal biopsy should be done to assess renal morphology.

The long-term prognosis for infants with PUV depends on multiple factors (443) (Fig. 46.27). Among the most important are the serum creatinine level 1 month after urinary drainage and whether a pop-off valve, such as unilateral VUR associated with a nonfunctioning kidney (VURD syndrome), a large bladder diverticulum, or urinary ascites is present. If the serum creatinine level falls below 0.8 to 1.0 mg/dL 1 month after treatment, renal function usually remains sufficient to prevent the need for dialysis, particularly if the renal corticomedullary junction is intact on sonography (256). More recently, a serum creatinine less than 0.8 mg/dL 4 to 5 days after bladder drainage is predictive of satisfactory long-term renal function (127). Attempts to identify biochemical parameters, such as transforming growth factor-b1, that might be useful in predicting long-term response to therapy have been unsuccessful to date (126).

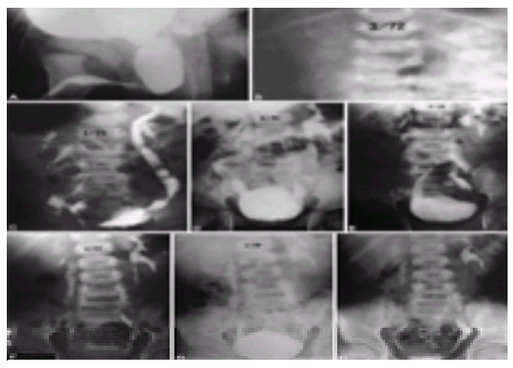

FIGURE 46.27. Example of long-term follow-up in a patient with posterior urethral valves. Infant was born with urinary ascites. Child underwent primary resection of urethral valves. **A:** Voiding cystourethrogram with typical posterior urethral valves. **B:** Initial intravenous pyelogram demonstrating bilateral hydronephrosis. **C–H:** Initial improvement was observed, and long-term follow-up shows good results. Vesicoureteral reflux of the right kidney ceased within 3 years. Note the straightening of the ureters with time. (**A–G** from Duckett JW, Snow BW. Disorders of the urethra and penis. In: Walsh PC, Gittes RF, Perlmutter AD, et al, eds. *Campbell's urology,* 5th ed. Philadelphia: WB Saunders, 1986, with permission.)

In patients with unilateral VUR associated with nonfunction, the prognosis has been quite good. It has been called the *VURD* (valves, unilateral reflux, and dysplasia) *syndrome* (252). The refluxing ureter acts as a pop-off valve, preventing the deleterious effects of high vesical pressure on the opposite kidney. A similar phenomenon occurs when a giant vesical diverticulum is present (Fig. 46.28). In five patients with this entity, all have good renal function and some have surprisingly normal upper urinary tracts (443). Finally, the presence of urinary ascites in newborns with PUV has been recognized as another protective factor, with an upper or lower urinary tract leak allowing the kidneys to develop without the deleterious effects of high pressure (Fig. 46.29).

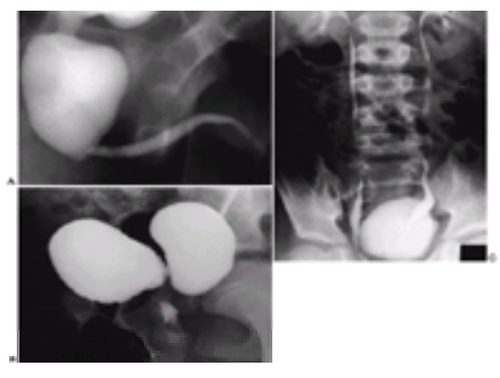

FIGURE 46.28. Example of bladder diverticulum as a protective feature in a child with posterior urethral valves. **A:** Voiding cystourethrogram showing typical posterior urethral valves. **B:** Lateral image on cystogram showing large vesical diverticulum. **C:** Intravenous urogram before valve ablation showing normal collecting systems and medial deviation of lower left ureter secondary to large diverticulum.

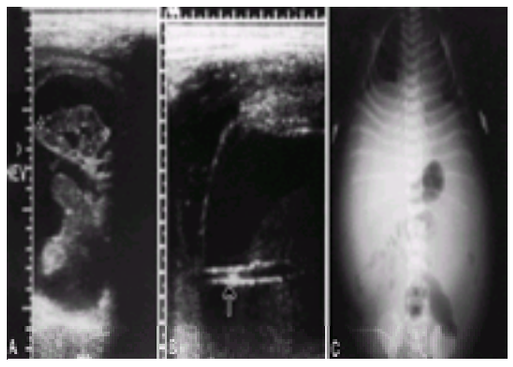

FIGURE 46.29. Urinary ascites secondary to posterior urethral valves. **A:** Prenatal ultrasound, 38 weeks of gestation, showing right kidney and ascites. **B:** Massive ascites, resulting in stretching of umbilical vein *(arrow).* L, liver. **C:** Abdominal film at birth, showing characteristic appearance of ascites. Note umbilical artery catheter.

In one series of 71 boys with valves and long-term follow-up, 20 (28%) had one of the protective mechanisms. Of these, only one (5%) had a serum creatinine greater than 1.0 mg/dL. In contrast, of the 51 boys without a pop-off mechanism, 20 (39%) had an elevated creatinine and 7 (14%) were on dialysis or had undergone renal transplantation (443). However, Cuckow and colleagues (119) reported that only 25% of boys with the VURD syndrome had a normal GFR at 5 to 8 years of age.

The risk of end-stage renal disease in boys with PUV is significant. In a series of 98 boys with follow-up between 11 and 22 years, Parkhouse and colleagues (398) reported that 31 (32%) had poor renal function; 10 (10%) had died of renal failure, 15 (15%) had endstage renal failure, and 6 (6%) had chronic renal failure but were not yet receiving dialysis. Adverse prognostic factors included presentation before 1 year of age, bilateral VUR, and diurnal incontinence after 5 years of age, the last being the most important factor. The association of diurnal incontinence and poor renal function in these patients most likely is related to detrusor instability and detrusor sphincter dyssynergia, which many of these boys develop, resulting in elevated upper urinary tract pressures and gradual deterioration in renal function.

When urethral valves are discovered in the newborn, it is likely that the infant will have high urine output resulting from a renal concentrating defect. Consequently, the parents of these infants should be advised that their child is much more likely than other infants to become severely dehydrated with viral gastroenteritis or other febrile infections that might increase the child's fluid requirements.

Anterior Urethral Valve

Another form of urethral obstruction that may be apparent in the newborn is the anterior urethral valve (Fig. 46.30). This anomaly is rare, and its embryologic origin is uncertain. Usually, the valve is a filamentous cusp on the ventral aspect of the urethra, resulting in the development of a diverticulum that by virtue of its size may obstruct the distal urethra. Nearly all occur in the bulbous or pendulous urethra. If the diverticulum is large, it may be visualized as a cystic mass on the ventral aspect of the penoscrotal junction, which increases in size when the infant voids. In addition, a prolonged dribbling stream is noted. If obstruction is severe, the neonate may develop renal insufficiency. Diagnosis is confirmed by VCUG. In addition, a renal ultrasound to assess the upper urinary tracts should be performed.

FIGURE 46.30. Example of anterior urethral valve. **A:** Infant born with cystic firm mass at penoscrotal junction. **B:** Voiding cystourethrogram showing huge ventral diverticulum secondary to anterior urethral valve. Note distal anterior urethra. Infant also had bilateral vesicoureteral reflux. **C:** Neonate underwent primary open resection of valve and diverticulum. Intraoperative view demonstrates large diverticulum *(solid white arrows)* and anterior urethral valve *(black arrow).* **D:** Postoperative photograph. A 6-Fr Silastic stent is used for bladder drainage.

Treatment is based on the size of the diverticulum and renal function. If the diverticulum is small, the cusp may be ablated by transurethral resection. Another technique is incision with a venous valvotome (117). However, if the diverticulum is massive or if there is significant VUR and poor bladder emptying, open surgical resection of the diverticulum and valve cusp is necessary. A 6-Fr silastic urethral stent may be left in place to drain continuously into the diaper for 10 to 14 days. If renal function is impaired, temporary catheter drainage of the bladder may be necessary to stabilize the infant and correct electrolyte abnormalities. If the serum creatinine fails to decrease to a satisfactory level, resection of the diverticulum and valve and perineal urethrostomy provide reliable drainage. Alternatively, cutaneous vesicostomy should be considered in these patients (463). In one recent series of 17 patients, 1 underwent supravesical diversion, 5 underwent temporary vesicostomy, 5 had open urethroplasty, and 6 underwent transurethral fulguration (549). All had continence and minimal or no hydronephrosis at follow-up.

Gross Hematuria

Gross hematuria in the neonate is an uncommon event but requires emergency diagnosis (63). The unusual nature of hematuria in this age group is exemplified by the report by Emanuel and Aronson (162) in which only 35 cases were encountered at a busy children's hospital over a 27-year period. In that series, seven patients (20%) had RVT, seven (20%) had obstructive uropathy, and six (17%) had infantile polycystic kidney disease. In 11 (31%) of the patients, the cause of the hematuria was unknown.

Another cause of neonatal hematuria is stone disease, which occurs with some frequency in premature newborns receiving parenteral furosemide therapy and which is discussed later in this chapter.

Other potential causes of hematuria in the newborn include endocarditis (383) and peripheral venous air embolus (573); it can also occur secondary to indomethacin therapy for patent ductus arteriosus (102). Although renal disease is a common cause of hematuria in the older pediatric age groups, glomerulonephritis is rare in the newborn.

Renal Vein Thrombosis

RVT is a common cause of neonatal hematuria. The neonatal kidney seems to be particularly vulnerable to RVT because of low renal perfusion pressure. RVT occurs primarily in conditions associated with dehydration and polycythemic sludging. For example, infants of diabetic mothers experience osmotic diuresis and have a substantially increased incidence of RVT. In addition, it may occur following diarrhea, perinatal stress, sepsis (fever with increased fluid requirements), cyanotic congenital heart disease (with resultant polycythemia), acute hypoxia, sickle cell disease, cytomegalovirus infection, hypotension, or seizures, and it is associated with polyhydramnios, toxemia, and maternal diuretic use (434). There is a moderate male predominance. Sludging in the renal venules results from low perfusion pressure, whereas contracture of the extracellular volume leads to increased blood viscosity and further diminishes renal blood flow, with predisposition to thrombosis. RVT is thought to originate in the arcuate and interlobar veins at the corticomedullary junction. The thrombotic process extends along the venous tributaries to the cortex, as well as centrally along the interlobar veins to the main renal vein (324). Following RVT, severe renal congestion occurs, leading to further impairment of arterial perfusion with thrombosis.

Among cases of RVT in childhood, almost 65% occur during the neonatal period, whereas 30% occur after the age of 1 year (324). In addition, RVT has been recognized prenatally and may even cause fetal distress (110,130). Evidence for the latter includes the finding of organized RVTs with calcification in the newborn period. An early postnatal renin-mediated hypertension may result.

Diagnosis

The classic features of neonatal RVT include palpable renal mass (60%), gross hematuria (70%), thrombocytopenia (90%) less than 75,000/μmL, consumptive coagulopathy (prolonged clotting time, elevated fibrin split products), leukocytosis, proteinuria, and anemia (32%). Other features in some cases include hypertension and renal failure.

If there is edema of the lower extremities, one should suspect thrombosis of the inferior vena cava. In RVT, the blood pressure is usually normal or low. With bilateral RVT (20% of cases), the blood urea nitrogen (BUN) and serum creatinine levels usually are elevated. The prognosis of bilateral RVT is ominous compared with unilateral RVT.

As in the evaluation of other renal masses, ultrasonography is the initial procedure of choice for the diagnosis of RVT (434). The findings depend on the stage at which the examination is performed and extent of the thrombus. Initially, the interlobular and interlobar thrombus appears as highly echogenic streaks. These streaks commence in a peripheral, focal segment of the involved kidney and persist for only a few days. In the first week, the affected kidney swells and becomes echogenic with prominent echo-poor medullary pyramids. Later, the swelling increases and the kidney becomes heterogenous with loss of corticomedullary differentiation. Thrombus within the renal vein or veins and possibly the inferior vena cava is seen also. In the early stages of RVT, color Doppler may demonstrate absent intrarenal and renal venous flow. Adrenal hemorrhage is a recognized association and may be identified also. Ultimately, the kidney may recover, show focal scarring, or become atrophic.

Management

Initial therapy is directed at correction of the fluid and electrolyte abnormalities and prevention of propagation of the venous thrombus. Careful attention must be paid to correcting dehydration and electrolyte abnormalities and to restoring acid–base balance. In addition, underlying conditions such as cardiac disease must be treated. In the presence of acute renal failure, peritoneal dialysis may be necessary. Operative management rarely is necessary on an emergency basis.

The extent of the venous thrombus must be assessed. If the ultrasound demonstrates unilateral involvement, no therapy may be necessary. A baseline renal scan should be obtained to assess function of the involved kidney, and CT may be used to provide a baseline for the extent of venous involvement. With bilateral RVT, the prognosis is more ominous, particularly if the thrombus involves the vena cava as well (208).

Definitive therapeutic options include prevention of propagation of the thrombus, thrombolysis, and formal thrombectomy. Systemic heparinization may be used to prevent thrombus propagation, although the risk of propagation occurring with restoration of fluid and electrolyte balance is low. There is no consensus regarding the efficacy of heparin therapy for unilateral RVT (324).

The development of thrombolytic agents such as urokinase (208) and streptokinase (71) has provided the physician with a more definitive way of stimulating resolution of the thrombus, but these drugs should be reserved for bilateral RVT. Whether to perform thrombectomy is controversial. With vena caval thrombosis, the

vena cava may remain permanently occluded, but collateral venous channels generally develop and provide satisfactory drainage.

The overall survival rate is high (324). Most deaths are related to the underlying disease, not renal infarction. Long-term sequelae include (a) a nonfunctioning, completely fibrosed, shrunken kidney; (b) a partially fibrosed kidney with impaired function; (c) renovascular hypertension; (d) nephrotic syndrome; (e) chronic renal infection; and (f) chronic renal tubular dysfunction. Often, the prognosis may be inferred based on the DTPA scan performed during acute stages of the disease.

In unilateral RVT, the most serious complication is hypertension, which usually results from an atrophic kidney. In such cases, renin-mediated hypertension is present, and nephrectomy is curative (503). Jobin and co-workers (268) reported that 5 of 6 patients followed 21 months to 12 years after neonatal RVT were hypertensive. However, only three had an atrophic kidney. Furthermore, not all patients with small scarred kidneys following RVT developed hypertension. If significant return of renal function is going to occur, visualization on the renal scan may be expected within 4 to 6 weeks. In some small kidneys labeled as “congenitally hypoplastic,” unrecognized RVT is the probable underlying cause.

Renal Failure

With the expertise of neonatal intensive care units for premature neonates, acute renal failure probably is occurring with increasing frequency. Acute renal failure should be suspected in any infant who has a sustained decrease in urine output to less than 1 mL/kg per hour, a persistent serum creatinine level greater than 1 mg/dL (in newborns beyond 34 weeks of gestation), or hematuria. Although renal failure may be associated with normal or even increased production of urine, most neonates with acute renal failure have oliguria or anuria.

Because 92% of term newborns pass urine within 24 hours of birth and 99.4% do so within 48 hours (493), renal failure should be suspected in any infant who fails to void within 48 hours after delivery.

In the neonate, as in the older child and adult, renal failure is characterized as prerenal, renal, or postrenal (Table 46.14). In prerenal and in many patients with intrinsic renal failure, the kidneys are basically normal, although the renal insult may result in permanent impairment of function. In contrast, many patients with postrenal failure have irreversible renal damage, often from congenital abnormalities.

Prerenal	Intrinsic	Postrenal
Hypotension secondary to:	Congenital anemias	Posterior urethral valves
Sepsis	Cystic dysplasia	Anterior urethral valves
Maternal antepartum hemorrhage	Hypoplasia	Prune-belly syndrome
Twin-to-twin hemorrhage	Agenesis	Urethral atresia
Intrinsic neonatal hemorrhage	Polycystic kidney disease	Ectopic ureterocele
Cardiac surgery	Inflammatory	Ureteropelvic or ureterovesical obstruction
Congestive heart failure	Congenital syphilis or toxoplasmosis	Extrinsic tumor compressing bladder outlet
Asphyxia neonatorum	Pyelonephritis	
Dehydration	Metabolic	
Intermittent positive pressure breathing	Oxalosis	
Continuous positive airway pressure	Vascular Renal vein thrombosis Renal artery thrombosis Hemolytic uremic syndrome Disseminated intravascular coagulation Cortical necrosis Perinatal asphyxia Sepsis Shock Acute tubular necrosis Nephrotoxins Maternal use of nonsteroidal anti-inflammatory medication Dehydration Transient renal dysfunction	

TABLE 46.14. MAJOR CAUSES OF RENAL FAILURE IN THE NEONATE

The most common cause of acute renal failure in the newborn is prerenal failure, whereas the most common cause of intrinsic renal failure is perinatal asphyxia (283,521). Prerenal failure may also result from perinatal asphyxia when blood is shunted away from the kidneys to improve circulation to the brain and heart.

Renal development in the fetus whose mother is azotemic progresses normally. Often, these infants are born prematurely. Interestingly, renal size at birth in these cases has been reported to be at the upper limits of normal (62), raising the possibility that compensatory growth might be occurring *in utero.*

Prerenal Failure

There are numerous causes of diminished renal perfusion that may result in renal failure in the neonate (Table 46.14). Hypotension may result from sepsis, fetal and perinatal hemorrhage (e.g., twin–twin transfusion, complications of amniocentesis, abruptio placenta, birth trauma), neonatal hemorrhage (severe intraventricular hemorrhage, adrenal hemorrhage), necrotizing enterocolitis, perinatal asphyxia, and hyaline membrane disease. Furthermore, renal blood flow may be compromised in patients with congestive heart failure or in those with a patent ductus arteriosus. In these patients, total blood volume may be normal or increased. In addition, newborn infants have a higher ratio of body surface area to body mass than older children and adults, and this may result in increased insensible and sensible fluid loss through the skin, especially when the baby is under a radiant warmer. Hypovolemia and shock in the newborn may occur secondary to RVT. Finally, diarrhea in the neonate may result in prerenal azotemia and acute renal failure. When it is severe, prerenal failure may result in cortical necrosis.

Intrinsic Renal Failure

Intrinsic renal failure implies that inadequate kidney function is secondary to inherent kidney damage. All of the conditions that cause prerenal failure may result in intrinsic renal damage if the insult is severe. Some of these infants may have renal failure secondary to congenital renal anomalies. In most of these patients, the diagnosis can be made rapidly from a history of oligohydramnios, features of Potter's syndrome, or both.

Vascular complications are an important cause of neonatal renal failure. Sick neonates with umbilical artery catheters may develop aortic thrombosis or bilateral renal artery thrombosis. RVT and renal artery thrombosis are covered elsewhere in this chapter. Disseminated intravascular coagulation may result from sepsis or necrotizing enterocolitis.

Acute tubular necrosis (ATN) may result from the same insults as cortical necrosis but only if the insult is less severe. Often, it is secondary to nephrotoxic medication. For example, aminoglycosides are potent nephrotoxic agents that have been studied much more in adults than in newborns. Because the GFR in the newborn is low, it is important to measure peak and trough drug levels when these agents are used. Although the blood flow distribution in the newborn kidney, which favors the juxtamedullary nephrons, might make aminoglycoside nephrotoxicity less common in the neonate (109), toxicity has been demonstrated. Indomethacin, a prostaglandin synthesis inhibitor, is used in the pharmacologic closure of the ductus arteriosus in premature infants. Its major toxicity is renal, and Vert and associates (550) reported transient oliguria in 16 of 18 infants treated with indomethacin. The toxic effect of indomethacin appears to be diminished considerably by the administration of concomitant furosemide (588). Nonsteroidal antiinflammatory agents, such as indomethacin, also have been administered to diminish amniotic fluid volumes in women with polyhydramnios, presumably by diminishing fetal urine output. In a recent report, three premature infants with prenatal exposure to indomethacin developed renal failure, which was fatal in one case (498). Angiotensin-converting enzyme inhibitors taken by women for control of hypertension may have an adverse effect on renal development, particularly if taken during the second and third trimesters (225,589).

Another cause of intrinsic renal failure is transient oliguric renal failure with enlarged kidneys and echogenic medullary pyramids (245). In these patients, there was no apparent cause, and all eventually had a normal serum creatinine; none required dialysis.

Postrenal Failure

There is a discussion of these entities elsewhere in this chapter, as well as other chapters in the text. In general, oligohydramnios is present if the obstruction is severe enough to cause renal failure in the newborn. Whether relief of obstruction may allow satisfactory renal function to occur depends on a number of factors, including the severity and duration of obstruction.

Diagnosis

The most important sign of acute renal failure in the neonate is oliguria, with a urine output of less than 1 mL/kg per hour. Measurement of urine output in premature infants may be inaccurate while they are in an incubator or isolette because significant evaporation occurs within 15 minutes (98). In infants, the newer highly absorbent diapers that contain a gel-based absorbent also may absorb ambient moisture, spuriously elevating recorded urine output.

Often, the history and physical examination provide important clues to the diagnosis. For example, respiratory distress syndrome, hypoxia, shock, congestive heart failure, and sepsis, as well as dehydration, may cause renal failure. Enlarged kidneys may be secondary to RVT, hydronephrosis, infantile polycystic kidney disease, or multicystic kidneys. Urinary ascites may be secondary to PUV. The presence of edema usually indicates volume overload. In most of these conditions, treatment of the underlying condition will allow resolution of satisfactory renal function. However, until renal function does resolve, careful monitoring of electrolytes and volume status is necessary.

If the cause of renal failure is not readily apparent from the initial clinical evaluation, a battery of studies is in order, including complete blood cell count with RBC morphology and platelet count; prothrombin time; partial thromboplastin time; serum electrolyte, BUN, creatinine, uric acid, calcium, phosphorus, glucose, total protein, and albumin concentrations; blood pH, P_{O_2}, and P_{CO_2}); urinalysis; urine culture; urinary sodium concentration; creatinine clearance; osmolality; electrocardiogram (ECG); chest x-ray film; and renal ultrasound.

Postrenal causes of acute renal failure are apparent from the ultrasound examination. Using the studies shown in Table 46.15, Mathew and co-workers (347) found that the fractional excretion of sodium and the renal failure index were of greatest value in distinguishing prerenal from intrinsic renal failure. Practically speaking, once volume overload and urinary obstructive causes are excluded, a fluid challenge may be given. In general, 20 mL/kg of normal saline or Ringer's lactate may be administered intravenously over 1 to 2 hours. If oliguria persists, furosemide in a dose of 1 mg/kg of body weight is administered. If there is still no response, the dose of furosemide should be increased to 2 mg/kg. If no further increase of urine output is observed during the following hour, intrinsic renal failure should be suspected and fluid administration reduced. Although furosemide may protect the kidney during recovery from renal ischemia, after intrinsic renal failure has developed, repeated doses of furosemide may cause ototoxicity.

	Prerenal	Intrinsic
Urine osmolality (mOsm/kg H_2O)	>400	<400
Urinalysis	Normal	>5 RBCs/HPF
Urine sodium (mEq/L)	31 ± 19	63 ± 35
Urinary (U)/plasma creatinine (P_{Cr})	29 ± 16	10 ± 4
Fe_{Na} %	<2.5 (x = 0.9)	>2.5 (x = 4.2)
RFI	<3.0 (x = 1.3)	>3.0 (x = 11.6)

Fe_{Na}%, fractional sodium excretion; HPF, high-power field; RFI, renal failure index [(U_{Na}/U_{Cr}) x PG].

TABLE 46.15. DIAGNOSTIC INDICES IN NEONATAL ACUTE RENAL FAILURE

Management

After the cause of renal failure is determined, attention must be directed to the volume status and electrolytes of the infant while the underlying condition resolves.

Because acute renal failure is nearly always oliguric, fluid intake must be monitored carefully. A 5- or 8-Fr pediatric feeding tube should be inserted into the bladder to monitor urine output. Fluid intake should be restricted to insensible water loss plus other nonrenal losses, such as gastrointestinal. If the infant is normovolemic, urine losses should be measured and replaced with an equal volume each hour. In the presence of volume overload, the desired amount of weight loss should be subtracted from the total replacement fluids. In the newborn, daily insensible water loss is 40 mL/kg per 24 hours, although it may be higher in low-birth-weight infants (521). Insensible water loss is increased if the infant is under a radiant warmer or is febrile; it is decreased if the neonate is on a respirator. Insensible water loss should be replaced as electrolyte-free water in a 10% dextrose solution. Urinary losses should be replaced with a solution containing the same concentration of sodium as is present in the urine. The neonate should be weighed at least every 12 hours to monitor fluid balance. A daily loss of 0.5% to 1.0% of body weight is to be expected (521).

Hyponatremia may result from fluid overload with dilution of extracellular sodium. If the infant is asymptomatic, fluid and sodium restriction is adequate. If the infant is symptomatic or the sodium concentration is less than 120 mEq/L, 3% saline should be administered in a dose of 6 mL/kg over 1 to 2 hours, which should increase the serum sodium concentration by 5 mEq/L.

Hyperkalemia may be severe in the presence of acute renal failure and can be fatal if untreated. Accordingly, the potassium level should be monitored frequently and promptly treated if significantly elevated. However, before treatment, one must check to be certain that the specimen was not hemolyzed. If the potassium concentration is 7 mEq/L or less, it may be managed with cessation of potassium intake and administration of sodium polystyrene sulfonate (Kayexalate), which exchanges 1 mEq of potassium for 2 to 3 mEq of sodium. Sodium polystyrene sulfonate 1 g/kg body weight is mixed with 10% sorbitol or 10% dextrose in water (1 g/4 mL) and given rectally as a retention enema. It should be retained for 3 to 4 hours to have maximal effect. This dose of sodium polystyrene sulfonate should reduce serum potassium approximately by 1 mEq/L. Repeated doses of sodium polystyrene sulfonate may cause hypernatremia. If the serum potassium is greater than 7 mEq/L or ECG changes are present, more aggressive therapy is necessary. If only peaked T waves on the ECG are present, IV sodium bicarbonate 2 mEq/kg and sodium polystyrene sulfonate enemas may be used. If widening of the QRS complex is seen on ECG, 0.5 mL of 10% calcium gluconate should be given slowly intravenously, with constant ECG monitoring. It should be followed by sodium bicarbonate 2 to 3 mEq/kg. The duration of effect of these agents is short, and dialysis should be instituted. Another effective treatment is glucose 2 g/kg (administered as 25% dextrose) plus insulin 0.5 U/kg.

Metabolic acidosis usually is present in acute renal failure and may be managed with IV sodium bicarbonate 1 to 3 mEq to maintain the serum pH between 7.25 and 7.35.

Serum phosphorus and calcium may be abnormal in renal failure. The serum phosphorus concentration may be maintained within normal range by administering aluminum hydroxide 20 mg/kg per day three times daily orally to maintain a serum phosphorus level between 5 and 6 mg/dL. If hypocalcemia develops, 500 mg per day of calcium gluconate or carbonate should be started once the phosphorus concentration is normal and the gastrointestinal system allows normal intake. Intestinal absorption of calcium may be enhanced by using 0.1 to 0.4 mg per day of dihydrotachysterol.

The nutritional status of infants with renal failure is important because improved nutrition may diminish the metabolic complications of renal failure. If the infant is able to tolerate feedings, breast milk is optimal, although PM 60/40 is satisfactory. If the infant is unable to tolerate enteral feedings, peripheral or central hyperalimentation should be used.

Indications for dialysis include severe fluid overload, hyperkalemia, electrolyte abnormalities that cannot be corrected medically, or severe central nervous system (CNS) depression secondary to uremia. Peritoneal dialysis generally is performed (82,298). The catheter may be placed at the bedside in the intensive care unit under sedation or general anesthesia.

Prognosis

The prognosis of infants with acute renal failure depends largely on the etiology. Chevalier and associates (86) reviewed 16 neonates with acute renal failure and determined significant prognostic factors. Nine had renal failure secondary to perinatal asphyxia, and three were secondary to congenital heart disease. Half were

oliguric. All of the nonoliguric infants survived, whereas half of the oliguric patients died, usually from renal failure. Of the eight oliguric patients, the three that were anuric 3 days or less and had demonstrable renal perfusion by renal scan survived. In contrast, all four infants who had anuria 4 days or longer and had no perfusion on renal scan died. Thus anuria lasting 4 days or more and lack of visualization by renal scan are poor prognostic signs. Another adverse prognostic sign is significant prematurity. For example, Meeks and Sims reported 30 neonates with a mean gestational age of 31 weeks; mortality was 90%.

More recently, with improved neonatal intensive care unit (NICU) care, the prognosis for babies with acute renal failure seems improved, particularly if the baby is term (13,411).

Urinary Tract Infection

In the newborn, UTI often presents with symptoms and signs of sepsis, including fever (50%), weight loss (75%), and cyanosis (40%) (576). Other findings include a distended abdomen, jaundice, and symptoms referable to the CNS, such as irritability and seizures. Thus, if a newborn is not growing satisfactorily and seems ill, a UTI should be suspected. In a series of infants younger than 3 months of age with fever, 11% were secondary to UTI (302). In 75% of newborns, *Escherichia coli* is the etiologic agent, with *Klebsiella* accounting for approximately 10% (199).

In contrast to older age groups, between 70% and 80% of newborns with a UTI are boys (199). Beyond the neonatal period, the incidence of UTI in males drops considerably. The vast majority of newborn boys with symptomatic UTIs who do not have obstructive abnormalities are uncircumcised (199,577). Pathogenic bacterial organisms colonize the newborn prepuce (188), conferring a greater risk of UTI in uncircumcised boys until 3 to 6 months of age, when the foreskin usually begins to retract. In females, the highest incidence of UTI also is in the newborn period.

Diagnosis

The method of obtaining the urine specimen must be assessed before one decides that an infant has a UTI. For example, if a plastic bag is used to obtain the specimen, the genitalia must be washed thoroughly, the bag must be removed within a few minutes of voiding, and the urine either must be refrigerated or cultured immediately. Urine cultures obtained with a plastic bag are most informative if the culture is negative. If the culture from the plastic bag is a single organism with a colony count greater than 100,000/mL and the infant is symptomatic, a UTI may be presumed, as long as the specimen was obtained by the previous guidelines. The presence of significant pyuria also provides confirmation that the neonate has a UTI.

On the other hand, in asymptomatic infants or uncircumcised boys, if the culture grows a mixed group of organisms or the colony count is less than 100,000/mL, the urine specimen should be obtained in another manner. A catheterized specimen may be obtained by sterilely passing a 5- or 8-Fr pediatric feeding tube into the bladder. If a urethral abnormality or preputial contamination is suspected or if one has difficulty identifying the infant female urethra, a suprapubic aspirate (SPA) should be done (Fig. 46.31). Before an SPA is performed, the bladder should be palpable. In the newborn, the bladder is an abdominal organ, and it is relatively easy to obtain a suitable specimen to culture. An SPA should not be attempted if the bladder is not palpable because complications may result. The procedure is performed after cleaning the suprapubic area with an antiseptic solution. A 22-gauge needle then is inserted periappendicular to the lower abdominal wall in the midline one fingerbreadth above the pubic symphysis. A local anesthetic generally is not necessary.

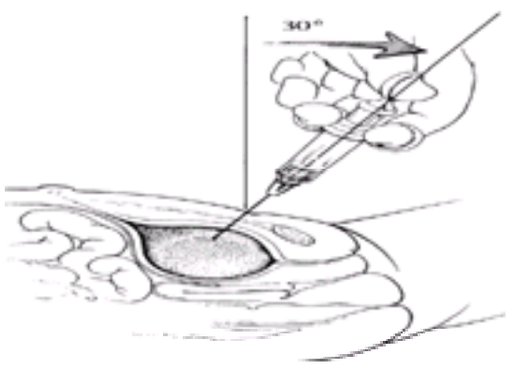

FIGURE 46.31. Suprapubic aspiration for collection of bladder urine with a full bladder. The needle is inserted 2 cm cephalad to the pubic symphysis perpendicular to the axis of the child.

Management

Because most neonates with a UTI have evidence of sepsis and broad-spectrum parenteral antibiotics are necessary, these children should be hospitalized. Generally, IV gentamicin and ampicillin are given until the culture and sensitivities are available. Fever and vomiting may increase the infant's fluid requirements substantially, and urine output must be monitored closely. IV antibiotics should be continued until the infant has been afebrile for 48 hours, at which time a suitable oral agent may be used. However, if the child has a positive blood culture as well, parenteral antibiotics may need to be given for a longer period. Because the newborn's renal function is low, peak and trough aminoglycoside levels must be obtained regularly.

Two antimicrobial agents that are used commonly in older children and adults should not be used in the newborn. Trimethoprim-sulfamethoxazole is a combination medication that interferes with bacterial folic acid metabolism and in the newborn also may interfere with bilirubin excretion and cause jaundice. Nitrofurantoin interferes with the bacterial Krebs' cycle but is contraindicated in the newborn because of potential hepatotoxicity and a risk of hemolytic anemia.

If a newborn has a symptomatic UTI, he or she should continue to be given oral antibiotics until a radiographic evaluation has been obtained. This evaluation should include a VCUG to study the lower urinary tract and either a renal ultrasound, IVP, or renal scan, depending on the child's age and findings of the VCUG. The evaluation should be performed while the child is still in the hospital. An ultrasound does not provide sufficient visual evidence of the presence or absence of reflux (593).

A renal ultrasound should be used to study the upper urinary tracts and the bladder. If either the ultrasound or VCUG is abnormal, a renal scan should be obtained. The specific type of scan to order depends on whether reflux, hydronephrosis, a duplex collecting system, or PUV is identified (532).

In a study of 100 patients less than 8 months of age with a UTI, 45% of the girls and 7% of the boys had a urinary tract abnormality. The most common finding was VUR (199). In another study of newborns with UTIs, nearly half demonstrated varying degrees of reflux (44). Thus radiographic evaluation of these infants is important.

Even if reflux or an obstructive anomaly is not found, the child clearly is at risk for developing pyelonephritis. Because the kidneys are most likely to develop scarring secondary to reflux and infection during the first 2 years of life, a course of antimicrobial prophylaxis with nitrofurantoin or trimethoprim-sulfamethoxazole should be used until the child is at least 1 year old. In addition, a follow up IVP or DMSA scan should be performed at 1 year of age to detect renal scarring.

Adrenal Hemorrhage

Because of its large size and hypervascularity in the newborn, the adrenal gland is susceptible to spontaneous hemorrhage or to trauma with subsequent hemorrhage. Small unilateral or bilateral adrenal hemorrhage is a common finding at postmortem examination of infants and the incidence by ultrasonographic screening is 1.9 per 1,000 births (172), but clinically significant neonatal adrenal hemorrhage is much less common.

The relatively large size of the newborn adrenal glands, their hyperemia, and any condition that causes venous congestion or stasis within the adrenal tend to make the adrenal gland more susceptible to trauma (503). Traumatic delivery seems to be an important factor (503), but asphyxia, sepsis, hemorrhagic disorders, and hypoprothrombinemia also are predisposing conditions (286). Adrenal hemorrhage is reported to occur more commonly on the right side (53), probably because

venous engorgement caused by temporary vena caval occlusion or compression is dampened by the renal vein on the left side, whereas the right adrenal vein drains directly into the vena cava. In approximately 10% of patients, the condition is bilateral.

Diagnosis

A triad of findings is usually present with adrenal hemorrhage: (a) flank mass (more than 85%), (b) jaundice (more than 80%), and (c) mild anemia (approximately 50%) (286). Jaundice is secondary to reabsorption of blood from the retroperitoneum and depends on the degree of hemorrhage and rapidity of reabsorption. Another presenting sign in boys may be scrotal hematoma, with blood from the adrenal bed dissecting along the fat tissue in the inguinal canal or through a patent processus vaginalis (255,359). Most clinically significant cases become apparent by the time the patient is 1 week of age.

As in the diagnosis of many adrenal masses, ultrasound is extremely useful (Fig. 46.32). Usually, a well-defined echo-free area superior to an inferiorly displaced kidney is identified, but in other cases, the adrenal hemorrhage may have a solid appearance. If clots and necrotic tissue are present in the hemorrhagic area, a mixed pattern is encountered. The differential diagnosis includes congenital neuroblastoma, in which the adrenal gland has a solid appearance and demonstrates blood flow by power Doppler sonography, whereas blood flow will not be present in adrenal hemorrhage (123). Following complete liquefaction, the mass becomes completely echo free (402). Ultrasound is the best method to use to follow these infants because it demonstrates the progressive decrease in size and resolution of the hemorrhagic area, as well as subsequent calcification (402).

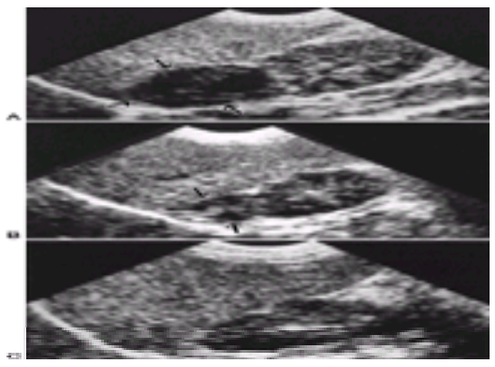

FIGURE 46.32. Patient at 17 days of age, ultrasound of adrenal hemorrhage. **A:** A 4.0-by-3.7-by-2.7-cm complex mass *(arrows)* in region of right adrenal gland. Echolucent areas suggest liquefaction. **B:** Patient at 1 month of age. The mass *(arrows)* has diminished in size, measuring 2.0 by 1.5 cm. **C:** Patient at 2 months of age. Adrenal gland is normal. Adrenal hemorrhage has resolved completely.

In addition to serial hematocrits, serum bilirubin, and abdominal ultrasound, other studies should be performed. Measurement of the 24-hour urinary excretion of vanillylmandelic acid, homovanillic acid, and catecholamines is important because an increase in these substances, particularly vanillylmandelic acid, is virtually diagnostic of neuroblastoma. In addition, a CT scan may demonstrate the lesion, confirm that it is not a neoplasm, and demonstrate that the ipsilateral kidney is functioning. Simultaneous RVT and idiopathic adrenal hemorrhage have a recognized association (314) and probably explain reports of nonvisualization of the kidney on IVP in a small proportion of infants with adrenal hemorrhage (286).

Management

In most patients, adrenal hemorrhage is self-limited, particularly when the hematoma remains intracapsular. Rarely, with extensive hemorrhage, capsular rupture with retroperitoneal bleeding may occur. Ultrasonography is useful in following resolution of the hematoma, and serial hematocrit and serum bilirubin levels should be obtained. The adrenal typically calcifies following adrenal hemorrhage. Calcification may occur as early as 7 days and usually may be visualized radiographically about 2 weeks after the hemorrhage. Initially, a thin rim of calcification is seen surrounding the mass. As reabsorption of the hematoma occurs, the calcified area condenses and takes the shape of the adrenal gland. In contrast, the calcification that frequently occurs in neuroblastoma typically is stippled throughout the mass.

Adrenal Abscess

An unusual complication of adrenal hemorrhage is adrenal abscess. Theories regarding the etiology of adrenal abscess have included (a) hematogenous bacterial seeding of a normal adrenal gland with subsequent abscess formation and (b) bacterial seeding of neonatal adrenal hemorrhage with formation of an abscess (195). In a review of reported cases of neonatal adrenal abscess, Atkinson and co-workers (24) found that maternal infection at the time of delivery and forceps or breech delivery were common. Clinical findings included palpable mass, fever, leukocytosis, and jaundice. Most cases have been diagnosed at 1 to 4 weeks of age.

Ultrasound has been extremely useful in demonstrating the character and extent of the abscess. The abscess is identified as a suprarenal fluid-filled mass, and layered debris is frequently noted with changes in position. The differential diagnosis includes an obstructed upper-pole duplication anomaly, adrenal hematoma or pseudocyst, upper-pole hydrocalyx, neuroblastoma with hemorrhage and necrosis, and cystic Wilms' tumor (24). Failure of a suspected adrenal hemorrhage to resolve or evidence of a gradual increase in the size of the mass with evidence of systemic disease should raise suspicion.

Ideally, the diagnosis can be made before the suppurative process extends to adjacent organs; in almost one-third of reported cases, the kidney has been removed (24). Treatment of a neonatal adrenal abscess consists of excision of the abscess, incision and drainage, or percutaneous aspiration and antibiotics (195,313).

Scrotal Mass

In most cases, a firm testicular mass in the newborn male represents testicular torsion. Anatomically, testicular torsion in the newborn is extravaginal with twisting of the entire spermatic cord (Fig. 46.33). In contrast, in pubertal boys, testicular torsion is intravaginal, that is, within the tunica vaginalis. In the perinatal period, extravaginal torsion is speculated to result from loose or absent connections between the gubernaculum and the scrotal wall.

FIGURE 46.33. Neonatal extravaginal testicular torsion, left side. Inguinal approach is preferable.

In most neonates with testicular torsion, the event occurs *in utero.* Consequently, the mass is hard, is painless, and does not transilluminate. The scrotal skin may be

discolored and edematous.

Other diagnoses to consider include scrotal hematoma (which could be secondary to adrenal hemorrhage), incarcerated inguinal hernia, testis tumor, idiopathic testicular infarction, meconium peritonitis, and testicular strangulation secondary to an inguinal hernia. If the scrotal swelling transilluminates, it usually represents either a hydrocele or, less commonly, an inguinal hernia. The other diagnosis of concern in the newborn is testicular tumor (319). However, testicular neoplasms are extremely rare in the neonate, and most are benign lesions. Given these considerations, the diagnosis of testicular torsion in the newborn usually is straightforward, but imaging is recommended. Color Doppler ultrasound demonstrates an inhomogeneously hypoechoic testis surrounded by a slightly echogenic rim with absent intratesticular blood flow (29,78,523).

Whether to perform immediate or even elective surgical exploration is controversial. The likelihood of salvaging a torsed testis that is detected at delivery is remote. Nevertheless, there is a significant risk that the contralateral testis may undergo extravaginal torsion, and this risk is present until at least 8 weeks beyond term (69). However, the long-term risk for contralateral intravaginal torsion seems low. In a survey of 67 pediatric surgeons and urologists in Great Britain, only 6 cases of torsion of a solitary testis were identified (363). Another possible long-term complication of leaving an atrophic neonatal testis in place is the risk of antisperm antibody formation, but there is no evidence that a newborn necrotic testis stimulates such antibody formation.

We are not aware of any cases of testicular torsion discovered at delivery that have been salvaged. Consequently, we do not advocate routine immediate surgical exploration in which unilateral testicular torsion is recognized at delivery.

Because the main risk of unilateral testicular torsion noted at birth is the chance of contralateral extravaginal torsion (99), one should perform prompt exploration of the involved side to establish the diagnosis and then pex the contralateral normal testis, or advise the parents of the issues and have them monitor the scrotal appearance closely for the first 2 to 3 months of life for signs of contralateral torsion. If the baby is healthy and pediatric anesthesia coverage is available, prompt elective exploration of the involved side is recommended, and assuming torsion is found, contralateral scrotal orchiopexy is advocated (141,407). This form of management was advocated in a survey of pediatric urologists.

Whether to perform testicular exploration through the inguinal canal or scrotum is controversial. The inguinal approach allows definitive treatment if a hernia or hydrocele needs correction or radical orchiectomy if a tumor is encountered. For most cases, a scrotal approach is satisfactory. For contralateral scrotal orchiopexy, suture fixation of the testis is not advised. Instead, placing the testis in a dartos pouch will provide optimal permanent fixation and avoid the risk of damage to the testis from a suture. A transverse scrotal incision should be made, a dartos pouch created, and then the tunica vaginalis opened and the testis placed in the dartos pouch.

Ascites

Ascites refers to an abnormal accumulation of fluid in the peritoneal cavity. In the neonate, ascites are uncommon and typically are secondary to extravasation from the urinary tract, accounting for 25% of cases. Other causes of neonatal ascites include gastrointestinal disorders (e.g., bowel obstruction), cardiac disease, liver disease, toxoplasmosis, ovarian cyst, and chylous ascites. In addition, ascites has been observed in association with persistent cloaca in girls secondary to intraperitoneal reflux through the genital system (6). In 15% of patients, the diagnosis is unknown (218).

As many as 70% of newborns with urinary ascites have PUV (483) (Fig. 46.29). Other etiologies include urethral atresia, VUR, neurogenic bladder, ureterocele, ureteral stenosis, and bladder perforation (218,541). In most patients with urinary ascites, the site of extravasation is unknown. When extravasation from a fornix or the renal pelvis occurs, urine may accumulate within the retroperitoneum with subsequent rupture into the peritoneum. In other patients, there may be rupture of the distended pelvis directly into the peritoneal cavity. In cases of bladder perforation, the dome of the bladder ruptures into the peritoneal cavity.

Earlier reviews emphasized the significant mortality associated with urinary ascites, as high as 70% (218,483). More recently, with improved neonatal care, mortality has been considerably lower, now reported at approximately 12% (215).

In some neonates with ascites, the condition may not be evident until 1 or 2 weeks of age. In such patients, poor feeding, vomiting, and progressive abdominal distention are reported.

In most cases, neonates with ascites should be evaluated initially by abdominal ultrasound, which confirms the presence of ascitic fluid and may demonstrate dilation of the upper urinary tracts or a distended, thick-walled bladder in the presence of obstructive uropathy. However, if the kidneys are decompressed because of forniceal rupture, the dilation may be minimal. A VCUG should be performed to determine whether PUV are present, to aid in detecting whether the site of extravasation is the bladder, and to detect reflux. A peritoneal tap may be necessary, particularly if severe abdominal distention is present or if respiratory function is compromised. In other cases, it is performed for diagnostic purposes. In patients with urinary ascites, one would expect to find an elevated BUN concentration and creatinine in the ascitic fluid. However, because the ascites equilibrate with serum rapidly, it is not a valid study. Because of their ineffective excretion, serum BUN concentration and creatinine usually are elevated.

Management

Parenteral antibiotics should be instituted. Following stabilization of the infant, adequate urinary diversion should lead to resolution of the ascites, because the reduced pressure on the upper urinary tracts will allow the leak to close. An 8-Fr pediatric feeding tube placed into the bladder should achieve this. If it does not, cutaneous vesicostomy or possibly even cutaneous pyelostomy may be necessary. Once the child has been stabilized sufficiently, operative ablation of the valves may proceed.

Urinary ascites may be secondary to a problem other than urethral valves. For example, a ruptured bladder is present in 25% of newborns with urinary ascites. Although the most common cause is urethral valves, it also may be secondary to neurogenic bladder (341) or iatrogenic during umbilical artery cutdown (241,430). In nearly all patients, it has been discovered within the first day or two of life. Management has consisted of suprapubic cystostomy or cutaneous vesicostomy, with a survival rate of 94% (541).

Ultimately, many have surprisingly normal-appearing upper urinary tracts (215,397). The upper or lower leak from the urinary tract seems to act as a pop-off valve and allows renal development to proceed more normally (443).

Related to urinary ascites is the *isolated perirenal urinoma* (Fig. 46.34). In some patients, it is secondary to urethral valves, whereas in others, it is secondary to UPJ obstruction. Interestingly, when the urinoma is contained within Gerota's fascia, the kidney usually is severely dysplastic. Presumably, severe obstruction has occurred, and if the leaking urine is contained within Gerota's fascia, there is insufficient decompression of the urinary tract to allow satisfactory renal development. When this condition occurs bilaterally in the absence of ascites, the outcome is always fatal.

FIGURE 46.34. Neonate with right perirenal urinoma secondary to posterior urethral valves. Simultaneous cystogram shows left vesicoureteral reflux.

Vesicoureteral Reflux

Some neonates with medium- and high-grade vesicoureteral reflux are detected by the finding of hydronephrosis on prenatal sonography (156). Approximately 80% of such patients are boys (156,170). The male predominance is thought to be secondary to transient urethral valvelike urethral obstruction *in utero* that resolves before birth (27). The high intravesical pressures generated seem to destabilize the UVJ. Infants with reflux have had abnormal urodynamic patterns including low bladder capacity in combination with extremely high detrusor pressure levels (hypercontractility) and high-capacity bladder with normal or low detrusor pressure levels (496,497).

A complication of bilateral high-grade reflux is the *megacystis-megaureter syndrome* (68,338) (Fig. 46.35). This syndrome primarily affects boys. Most of the voided urine refluxes into the upper urinary tracts, resulting in a weak urinary stream, a large bladder, and significant residual urine mimicking bladder outlet obstruction. However, the bladder is smooth walled, and no obstructive component is demonstrated on VCUG. This pattern of constant recycling of large volumes of refluxing urine has been termed *aberrant micturition.* Ureteral reimplantation with tapering is necessary to correct the condition, although cutaneous vesicostomy is a temporizing procedure that may allow the ureters to diminish in caliber, which may facilitate later ureteral reimplantation (Fig. 46.36). Reduction cystoplasty is not necessary or effective.

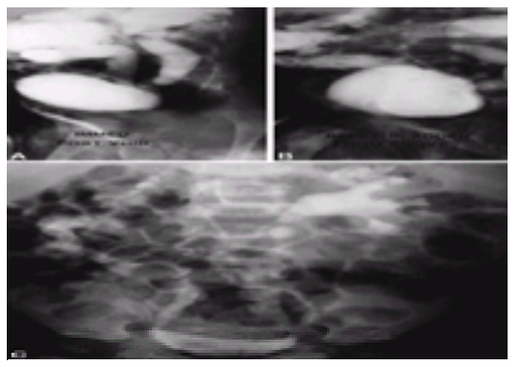

FIGURE 46.35. Newborn with bilateral grade V reflux and congenital heart disease. **A:** Voiding cystourethrogram demonstrating severe reflux. The infant was placed on a program of clean intermittent catheterization to decompress the upper urinary tracts during recovery from corrective heart surgery. **B:** Intravenous pyelogram 6 weeks after bilateral transtrigonal ureteral reimplantation. Tapering was not necessary.

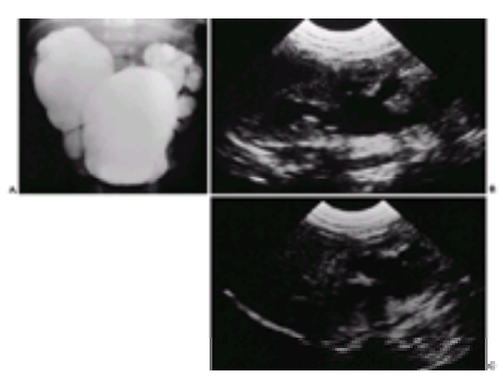

FIGURE 46.36. Newborn with distended abdomen and renal insufficiency. **A:** Voiding cystourethrogram shows huge smooth-walled bladder with bilateral grade V reflux, the typical picture of megacystis-megaureter syndrome. **B, C:** Following cutaneous vesicostomy, renal function improved, with serum creatinine clearance dropping to 0.7 mg/dL. Ultrasound at 9 months of age shows nicely decompressed upper urinary tracts. Cortex is quite thin. **B:** Left kidney. **C:** Right kidney.

If the neonate has grade III or higher reflux, consideration should be given to obtaining a DMSA renal scan to determine the baseline differential renal function. Often, the affected kidney shows significant reduction in differential renal function, even though no infection has occurred (410).

Initially, neonates with reflux are usually managed medically. They are placed on antimicrobial prophylaxis with amoxicillin or cephalexin for 2 months and then switched to trimethoprim-sulfamethoxazole or nitrofurantoin. Circumcision is recommended for male neonates to decrease the risk of UTIs (243). They undergo a follow-up sonogram every 6 to 12 months and follow-up cystography every 12 to 18 months.

Neonates with reflux are more likely to show spontaneous resolution than older children with similar reflux grades. For example, 20% to 35% of ureters with grade IV and V reflux have reflux resolution with 2 years (57,170,243). However, as many as 25% have a breakthrough UTI, and ureteroneocystostomy is recommended in these cases (214). The success rate for surgical correction of reflux in infants can be high (321,546). Although these patients have been reported to have abnormal urodynamic patterns, late follow-up of operated patients demonstrates that nearly all have a normal voiding pattern and bladder capacity (546).

Other Neonatal Urologic Conditions

Megacystis-microcolon-intestinal hypoperistalsis syndrome was described in 1976 (43). The condition is characterized by abdominal distention, lax abdominal musculature, a huge bladder, incomplete intestinal rotation, bilious vomiting, and diminished or absent intestinal peristalsis. Approximately 80% of patients are female (429). All patients have microcolon and small bowel dilation. The cause of this condition is unknown. Unfortunately, some infants die within the first few years of life because of an inability to obtain sufficient nutrition through their abnormal gastrointestinal tracts. VUR usually is present, but it generally is low or moderate in grade. Bladder emptying may be ineffective, and clean intermittent catheterization may be necessary to ensure vesical drainage.

A nonlethal variant of this syndrome has been termed *chronic intestinal pseudoobstruction*, *hollow visceral myopathy*, and *pseudo-Hirschsprung's disease*, in which there is megacystis and colonic dilation without aganglionosis. In this disorder, there is a slight male predominance, usually there is poor bladder emptying and many have hydronephrosis (193,211). In a report of 24 patients, 9 patients died from extensive gastrointestinal involvement, and of the remaining 15, all but 1 were performing clean intermittent catheterization or had a cutaneous vesicostomy (193).

Prune-belly syndrome probably represents a transient congenital urethral membrane obstruction at 8 to 10 weeks of gestation, resulting in severe dilation of the upper urinary tract. The urethra recanalizes and decompresses the system, leaving the stigmata of prune-belly syndrome, with a severely dilated bladder and upper urinary tract, bilateral cryptorchism, and the characteristic wrinkled abdomen. Some of these neonates have severe renal dysplasia and associated pulmonary hypoplasia. The prognosis probably depends on how soon the urethra recanalizes.

The newborn with *classic bladder exstrophy* usually is otherwise healthy and has normal renal function. Associated anomalies of other organ systems are uncommon. We believe that primary closure within 48 hours of birth is ideal in nearly all cases because the bony pelvis usually can be brought together anteriorly without the need for iliac osteotomies because of residual circulating maternal relaxin. Early closure is recommended even if the bladder is small.

In contrast, *cloacal exstrophy* represents the most devastating urologic congenital anomaly. These infants are likely to have anomalous upper urinary tracts and defects in the spine and gastrointestinal tract.

Hypertension in a premature infant affects as many as 0.8% of babies and is most common in babies with bronchopulmonary dysplasia, patent ductus arteriosus, intraventricular hemorrhage, or an indwelling umbilical artery catheter. In term babies, hypertension is much less common and is most often secondary to a renovascular abnormality or renal parenchymal disease (181). The blood pressure varies with gestational age at birth and weight (594). In the normal term male newborn, blood pressure is 72 mm Hg systolic and 47 mm Hg diastolic and the ninety-fifth percentile is 92/72 mm Hg. The blood pressure tends to be lower in female neonates. The most common etiologies are coarctation of the aorta and *renal artery thrombosis* secondary to umbilical artery catheter complication. Causes of urologic significance that may be encountered in the newborn include renal artery stenosis, RVT, polycystic kidney disease, MCDK, UPJ obstruction, mesoblastic nephroma, and the 11-hydroxylase deficiency form of CAH (35,181,361). Initial evaluation includes serum electrolytes, BUN, creatinine, calcium, plasma renin, complete blood count and platelet count, urinalysis, chest radiograph, and renal sonogram with Doppler. In select cases with a urologic etiology, renal scintigraphy is necessary. In patients who are resistant to medical therapy, the cause is often surgically correctable (426).

Micropenis is a small penis that is structurally normal but more than 2.5 standard deviations below the mean in stretched penile length (4). In a term newborn, the critical length is 2.5 cm. Many of these patients have a cerebral abnormality involving the hypothalamic-pituitary axis. Early evaluation of the etiology followed by testosterone stimulation should be performed (155). In the past, if no demonstrable penile growth occurred with androgen stimulation, gender reassignment was often recommended. However, this philosophy is currently being reconsidered (431).

Circumcision

In pediatrics, few topics generate as much controversy as whether a newborn male should undergo circumcision, mostly because indications for neonatal circumcision have been obscured by factors such as cultural prejudices; parental preferences; presumption about medical necessity and health benefits; physicians' biases; and aesthetic choices of the family, physician, and society (456). Although it is the most common surgical procedure performed in the United States, circumcision is seldom performed in European countries, China, and South America.

It has been estimated that approximately one-sixth of the world's population practices circumcision for religious reasons (85,374). The practice goes back to as early as 2300 B.C. in Egypt, and it has been suggested that it may have derived from the practice of mutilating prisoners of war while retaining them capable of laboring as slaves (70).

Circumcision as a means of preventing disease was strengthened by the two World Wars and the increased belief in the United States, Canada, and Australia that circumcision provided an additional measure of hygiene (191). By the 1960s, the indications for neonatal circumcision came under increased scrutiny and three reports by the Task Force of Neonatal Circumcision from the American Academy of Pediatrics (AAP) have tried to define guidelines for the procedure. In 1975, the conclusion was that routine neonatal circumcision had no valid medical indications. However, in 1989, as several published reports had suggested that uncircumcised infants were at increased risk for UTI, the AAP concluded that “newborn circumcision has potential medical advantages, as well as disadvantages and risks. When circumcision is being considered, the benefits and risks should be explained to the parents and informed consent obtained” (2). In 1999, the AAP updated its policy statement (1). Its position was essentially unchanged, with the exception that it emphasized the importance of local anesthesia for the procedure.

There are several nonreligious justifications supporting neonatal circumcision to ensure good hygiene. These include the prevention of UTI, penile cancer, venereal diseases, cervical cancer, and phimosis, as well as lessening the risk of balanoposthitis.

Reports linking the presence of an intact foreskin and UTIs in the first 6 months of life have been responsible for the resurgence of the sentiment in favor of neonatal circumcision. Subsequently, epidemiologic studies have shown a tenfold increase in the incidence of UTIs among uncircumcised male infants, and a higher risk of serious sequelae, such as bacteriemia and meningitis (199,579). The increased risk of UTI is presumed to be secondary to the presence of uropathogens under the prepuce (578). There was also an increased risk for UTIs in prepubertal males (111) and young adult uncircumcised males (median age of 30) (508). Although uncircumcised boys are at increased risk for UTIs, routine neonatal circumcision may prevent UTIs in only 1% to 2% of all newborn males.

Squamous cell carcinoma of the penis is extremely rare in males circumcised at birth (476). Penile cancer occurs much more frequently in areas where circumcision is not practiced and poor hygiene is prevalent. For example, in Brazil, the rate of penile cancer is ten times higher in poor regions as compared with the more developed parts of the country. The incidence of penile cancer in the United States is reported to be between 0 and 2.1 per 100,000, representing less than 1% of all cancers in men (559). This incidence is similar to that of Denmark (1.1 per 100,000) and Japan (0.3 per 100,000), countries where neonatal circumcision is not practiced routinely.

Whether circumcision reduces the risk of sexually transmitted diseases (STDs) has been controversial. An increased risk has been attributed to minor frenular injuries during intercourse and to the larger surface area of the penis in uncircumcised men. In some studies, however, an increased incidence of STDs in uncircumcised men has been attributed to demographic factors. Nevertheless, in a recent report, Lavreys and associates (311) studied 746 HIV-1–seronegative men and found that uncircumcised men were 4 times more likely to become HIV-1 positive and 2.5 times more likely to develop genital ulcers compared with circumcised men. However, there was not an increased incidence of genital warts in uncircumcised men. Other studies have achieved with similar findings (475).

Because circumcision is so prevalent in the United States, education regarding hygiene of the uncircumcised penis has lapsed, and benign neglect may have contributed to an increased rate of balanoposthitis and phimosis in boys who have not been properly instructed to retract their foreskin and wash their penis. A better understanding of the relationship between glans and prepuce can help illustrate the care of the uncircumcised penis. In the newborn, physiologic adhesions of the inner aspect of the prepuce to the glans prevent retraction and serve to protect the glans. Desquamated cells may accumulate and form smegma beads, which are benign.

If circumcision is carried out, a careful review of the potential complications should be given to the parents and informed consent obtained (230). Various instruments and procedures can be used, including a Gomco clamp, Bronstein or Mogen clamp, and Plastibell (456). None have a significant advantage over the others.

When neonatal circumcision is performed, local anesthesia is recommended. Available options include the topical application of a cream containing eutectic mixture of local anesthetic cream (lidocaine and prilocaine; EMLA), dorsal penile nerve block, and a penile ring block (227,288). Randomized controlled trials have demonstrated that a dorsal penile nerve block is more effective than EMLA cream (253,529). In addition, the prilocaine in EMLA cream poses a risk for methemoglobinemia (100), although the risk is quite low. Consequently, a dorsal penile nerve block or ring block at the base of the penis with 1% lidocaine is preferred.

Circumcision should not be performed in neonates with hypospadias, chordee without hypospadias, a dorsal hood deformity, a webbed penis, or a small penis. In addition, many neonates with a large hydrocele or hernia are more likely to develop secondary phimosis and a buried penis if circumcision is performed. In a report by Williams and others (572), 8% of boys referred for initial circumcision had an inconspicuous or hidden penis.

The complication rate after circumcision ranges between 0.2% and 3% (36,89). Immediate complications include pain, hemorrhage, removal of insufficient or excessive penile skin, trapped penis from scarring of the skin edges over the glans, infection, and urinary retention from a tight bandage. Late complications include meatal stenosis, which may require meatoplasty; formation of a synechia or skin bridge between the residual prepuce and glans; chordee; inclusion cyst at the circumcision line; urethrocutaneous fistula; removal of a portion of the glans; and slough of a portion or the entire penis from excessive use of cautery. Recently, the U.S. Food and Drug Administration (FDA) issued a warning regarding malfunction of some Gomco and Mogen clamps that had resulted in 105 circumcision injuries between 1996 and 2000 (171).

Bleeding usually results from oozing from the frenulum or occasionally from a large arterial or venous vessel on the penile shaft. Bleeding usually can be controlled with compression, but occasionally, cautery with a silver nitrate stick or ophthalmic cautery is necessary; in some cases, hemorrhage must be controlled with a suture. If cautery is used, ventrally one must be careful not to injure the urethra. Wound infection is rare and usually is prevented by applying antibiotic ointment to the circumcision wound. Another potential complication is severe penile vasoconstriction secondary to inadvertent injection of concentrated epinephrine instead of lidocaine. Treatment of this unusual problem is either local infiltration with 0.4 mg of phentolamine or insertion of a caudal catheter to induce a sympathetic block (7).

Many of the other problems with healing can be managed in the office if the baby is seen 2 or 3 weeks after the circumcision. Filmy penile adhesions are common and have been reported to be present in 71% of infants, 30% of 1- to 5-year-olds, and 2% of children older than 9 years of age (413,547). These adhesions usually cause no problems and will come apart on their own over time. Occasionally, epithelial debris will accumulate and helps separate the adhesion. In some cases, dense skin

bridges form between the penile shaft and glans—these will never come apart and need to be excised. This procedure can be performed as an office procedure under local anesthesia, or if the adhesions are extensive, excision under general anesthesia is necessary. If too much penile shaft skin is removed, application of antibiotic ointment and adherent gauze to the open wound usually yield a satisfactory result. Typically, most of the skin will grow back and bridge the defect. Immediate skin grafting rarely is necessary and may result in a disfigured penis and graft site. In addition, suturing the skin edges together to bridge the gap is not recommended because the penile shaft may end up with insufficient skin. If too much skin is left, revision of circumcision may need to be considered. In some babies, the penis retracts into the suprapubic fat pad or scrotum. This situation is most common if the baby had a large hydrocele or hernia or in babies born with a webbed penis. A cicatricial scar may result, resulting in a trapped penis, which can cause urinary retention and/or UTI in the most severe cases. If this situation is recognized early, the cicatrix may be opened bluntly in the office. Alternatively, application of a topical corticosteroid cream may loosen the scar tissue. If the problem is not corrected satisfactorily, correction of hidden penis under anesthesia will be necessary when the child is older.

The most serious circumcision complications include urethral injury and removal of part of the glans or part or all of the penile shaft. Partial glans removal has been reported to occur with a Mogen clamp; in these cases, the excised tissue should be preserved and immediately sutured back to the penis (492). A microscopic repair is unnecessary. When repair is performed within 8 hours of the injury, most penises heal nicely. In extremely rare cases, penile necrosis may result from thermal injury. One way a thermal injury can occur is if a metal clamp is applied to the foreskin and the cautery is used to excise the foreskin; if the cautery comes into contact with the metal clamp, an electrical/thermal injury to the shaft can result. Thermal injury to the penis also can result from inappropriate use of the YAG (yttrium-aluminum-garnet) contact laser in performing a circumcision. When an ablative penile injury occurs, the optimal therapy is unresolved at this time. One option is to reassign the baby to a female gender and perform bilateral orchiectomy (61). Unfortunately, these children may grow up with a male identity, presumably from androgen imprinting *in utero* and shortly after birth (132,133,431). On the other hand, current efforts for penile reconstruction in such cases have suboptimal cosmetic and functional results. These cases should be referred immediately to a tertiary center with a team approach including pediatric urology, endocrinology, plastic surgery, child psychiatry, and ethics for definitive management.

UROLOGIC PROBLEMS IN THE NEONATAL INTENSIVE CARE UNIT

Candidiasis

With improvement in the respiratory, nutritional, and antimicrobial management of preterm infants, increasing numbers of extremely premature neonates are surviving. However, these neonates often are intubated for weeks and receive long-term IV hyperalimentation with the resultant risk of bacterial superinfection.

As many as 40% of nosocomial UTIs that develop in NICUs are secondary to *Candida* (405). Nearly all infants who develop renal candidiasis have a variety of predisposing features, including treatment with broad-spectrum antibiotics and prolonged fluid therapy with central or peripheral (or both) intravascular catheters or needles. Approximately half weigh less than 1,500 g at birth. The most common clinical manifestation is the development of oliguria or anuria, which occurs in 85% of patients. Physical findings also may include hypertension, a palpable flank mass or abdominal distention, and subcutaneous abscesses. The serum creatinine often is elevated.

The diagnosis is made by urine culture obtained by suprapubic bladder tap or percutaneous renal aspiration. Renal candidiasis is confirmed by the presence of more than 10,000 colonies of *Candida albicans* per milliliter of urine, isolating *Candida* in the sediment obtained from 10 mL of suprapubic urine centrifuged for 3 minutes at 3,000 rpm, or growth of *Candida* in urine obtained from the kidney.

Early in the disease course of systemic candidiasis, the urine culture may be positive, although the blood cultures may be negative. In such cases, primary renal candidiasis is excluded by the absence of pathologic changes on renal ultrasonography and by the presence of *Candida* from other sources, such as the endotracheal tube or IV catheter. A positive urine culture for *Candida* should prompt an arterial (not venous) blood culture, followed by antifungal therapy. Systemic candidiasis can be detected early and possibly avoided by routine urine cultures by suprapubic bladder aspiration in the neonatal intensive care unit (ICU). With current antifungal therapy, few infants die from either systemic candidiasis or its treatment, but rather from complications of its predisposing factors.

Radiographic evaluation may demonstrate unilateral or bilateral hydronephrosis associated with an intrapelvic filling defect that represents a fungal ball. Renal scan generally demonstrates that the involved kidney or kidneys exhibit poor function.

The treatment of renal candidiasis involves IV antifungal therapy in conjunction with local instillation of antifungal agents, surgical removal of the fungal balls, or both. At present, 5-flucytosine and amphotericin B are the drugs of choice for primary IV therapy. When used in combination, these drugs are synergistic and prevent the emergence of a resistant strain. An adverse effect of 5-flucytosine is bone marrow suppression, and amphotericin B may cause nephrotoxicity, hypotension, and thrombocytopenia; however, amphotericin B has been reported to have less toxicity in very-low-birth-weight infants (287). The latter drug has been well tolerated in infants by gradually increasing the dosage of 0.25 to 1.0 mg/kg per day. Furthermore, by combining these two agents, the therapeutic doses of the individual drugs are smaller, diminishing the risk of toxic effect (242). The imidazole derivatives miconazole and ketoconazole, which have been used to treat fungal infections in adults, have not been used widely in the treatment of infant renal candidiasis.

IV antifungal therapy may be necessary for 4 to 6 weeks. In general, the endpoint of therapy is the inability to isolate *C. albicans* from specimens of urine sediment obtained 1 week apart. Alternatively, the *Candida* antigen mannin may be found in the sera of patients with disseminated candidiasis (477). If mannin is detected, antifungal therapy should be continued until the antigen is no longer detected. For persistent candidemia, fluconazole has been reported to be effective (448).

When a large fungal ball is present, medical management often is not sufficient. Most cases will require a percutaneous nephrostomy to be placed in the involved kidney so that irrigation with a solution of amphotericin B (1 mg in 100 mL of normal saline daily) may be performed. The irrigant provides a high concentration of antifungal agent, allows the bezoar to dissolve gradually, and provides a flushing effect. Percutaneous removal of the fungal ball may be achieved under anesthesia. Alternatively, open surgical removal of the bezoar or nephrectomy may be necessary.

Nephrolithiasis

One of the more common urologic problems encountered now with the improved care of the premature neonate is the development of renal calcifications secondary to furosemide administration (198,378). The overall incidence of nephrolithiasis in infants treated in the NICU is approximately 2.5% (198) and was 11% in those weighing 1,250 g or less (198). Furosemide is used extensively in the management of infants with patent ductus arteriosus and to mobilize interstitial water in respiratory distress syndrome secondary to bronchopulmonary dysplasia; it results in substantial hypercalciuria. Filtered calcium, in large part, is resorbed in the proximal tubule in the loop of Henle. Furosemide further increases the excretion of calcium, as well as sodium and potassium.

The development of urolithiasis in these preterm infants appears to be multifactorial: (a) high dosages of furosemide necessary to control the bronchopulmonary dysplasia, (b) prolonged half-life of furosemide in premature infants, and (c) development of secondary hyperparathyroidism. Other contributing factors include excessive calcium intake, phosphate depletion, chronic corticosteroid therapy, distal renal tubular acidosis, excessive glucose intake, and immobilization. Furthermore, nephrocalcinosis is more common in low-birth-weight neonates with a family history of stone disease and in white neonates (284).

Essentially all of the reported infants developing renal calcifications or calculi have received furosemide 2 mg/kg per day or more for at least 2 weeks, with a mean duration of therapy of approximately 4 weeks before calcification was noted. Many of the affected infants have received furosemide at dosages substantially higher than 2 mg/kg per day. Importantly, long-term use of furosemide in the premature infant is associated with ototoxicity and secondary hyperparathyroidism (198).

The half-life of furosemide in the premature infant is prolonged. In the normal adult, the plasma half-life of the drug is between 33 and 100 minutes, compared with values between 4 and 44 hours in neonates. In adults, slightly more than half of total plasma clearance of furosemide is accounted for by renal clearance, with the remainder excreted through the biliary and intestinal tracts. However, in the premature infant, the GFR is low, hepatic function is immature, and furosemide is excreted unchanged almost entirely in the urine (543). Thus the prolonged half-life of furosemide also contributes to the development of hypercalciuria.

All of the infants who developed nephrolithiasis had a gestational age of 34 weeks or less at birth. In these preterm infants with stone disease, the spot urine calcium-to-urine creatinine concentration ratio (mg/mg) has been significantly elevated, greater than 3.0 (normal is less than 1.24) (379). The total urinary excretion of calcium has varied from 15 to 30 mg/kg per day of calcium compared with a normal level of less than 4 mg/kg per day of calcium.

Most of the infants developing nephrolithiasis have been asymptomatic, although in one series, 6 of 10 had a UTI and 3 had associated sepsis. It is likely that the

infections were related to colonization of the catheterized urinary tract.

Preterm infants in ICUs often have frequent radiographic evaluation, and the renal calculi may be detected by a careful radiologist. At times, the stones may continue to grow undetected, and a few staghorn calculi have been reported. In patients with suspected renal calculi, ultrasonography will provide confirmation of the suspected diagnosis and may demonstrate other areas of nephrocalcinosis.

The treatment of renal calculi in these infants generally is nonoperative. Administration of 20 mg/kg per day of chlorothiazide concurrently with furosemide has resulted in radiographic diminution or disappearance of most calculi. A few infants have undergone early surgical removal of the calculus. Extracorporeal shock wave lithotripsy has been used in only a few of these patients.

The mortality rate has been high because of the severity of the bronchopulmonary dysplasia. Postmortem examination of affected kidneys has demonstrated the calculi to be composed of calcium oxalate and calcium phosphate. In general, the microscopic renal involvement is bilateral, even if only one side is involved on x-ray film. Calcium deposits have been found in the collecting tubules and interstitial areas of the renal papillae. Ezzedeen and co-workers (169) reported on the follow-up between 9 and 56 months of nine neonates with renal calcification. Total resolution was noted in four patients and improvement in one with medical management. Renal length was normal in 17 of 18 kidneys, but GFR was reduced in four patients. The need for continued urologic management in such patients is apparent.

The differential diagnosis of intrarenal calcification in the premature infant is limited. In addition to renal calculi, renal calcification following renal cortical necrosis and RVT has been reported. In renal cortical necrosis, peripheral linear calcifications are found, whereas following RVT, lacelike and reticular calcifications are suggestive of an intravascular location (198). Nephrocalcinosis in association with metabolic disorders, such as primary hyperoxaluria, has not been reported in infants younger than 2 months of age.

In summary, the urologist should recognize that preterm infants are at risk for the development of renal calculi when they are receiving high dosages of furosemide and that, in most cases, the problem may be managed by administration of concurrent chlorothiazide.

Umbilical Artery Catheter Complications

Another condition of urologic significance related to improved intensive care management of premature neonates is complications of umbilical artery catheterization. These catheters have been used for more than 20 years and have become standard in the treatment of sick newborn infants. Usual indications include the need to gain arterial access for reliable monitoring and blood pressure, frequent blood sampling for blood gas and pH values, exchange transfusion, cardiac catheterization, and infusion of fluid and nutrients. It is estimated that approximately 2% of all infants have an umbilical artery catheter. Until recently, polyvinyl chloride catheters impregnated with barium in sizes 3.5 and 5 Fr have been used. The overall incidence of major complications is approximately 3% (524).

Small infants appear to be at greater risk for thrombotic complications from an umbilical artery than larger infants, but the size of the catheter does not appear to play a role. The level of catheter placement is controversial. Although catheters placed at the level of the thoracic aorta have a significantly lower incidence of complications, when complications do occur, they tend to be much more devastating.

One of the most serious complications associated with the use of such catheters is occlusion of the distal aorta secondary to thrombosis. The diagnosis is suggested by the development of congestive heart failure, hypertension, and lower limb ischemia. Involvement of one or both renal arteries is suggested by the development of anuria. Often, patients have had demonstrable low-flow states, hypoxia, hypercoagulable states, and sepsis. Placement of the umbilical artery catheter below the thoracic aorta and frequent replacement or manipulation predispose to thrombosis. Persistent hypertension in infants with aortic thrombosis strongly suggests renal involvement and must be managed aggressively.

Other umbilical artery catheter complications of urologic significance include vesicoumbilical fistula (554) and urinary ascites (137,552).

ANOMALIES OF NUMBER

Renal Agenesis

Embryologic Considerations

For the kidney to develop properly, a normal ureteral bud must penetrate a normal metanephric blastema at the proper time. These events typically occur between the fifth and the seventh week of gestation. Major factors that alter the morphology or sequence of these events, such as absence of the nephrogenic ridge or failure of ureteral bud formation, prevent the kidney from developing. Although the kidney obviously will not form in the absence of metanephric tissue, it is genuinely unclear in renal agenesis which is the primary developmental abnormality, the nephrogenic ridge or the ureteral bud. Studies by Potter (98) on the fetus and infant suggest that the primary abnormality rests in failure to develop a normal ureteral bud; she observed that if any portion of the ureter was present, some identifiable renal tissue usually existed. In contrast, an extensive review of autopsy material by Ashley and Mostofi (7) disclosed that in many cases of renal agenesis there was partial or complete formation of the ureter and wolffian duct structures. They also observed examples of renal dysgenesis occurring without a formed ureter. Although these findings are to some extent conflicting, they do support a theory that the ureteral bud directly stimulates the differentiation of the renal parenchyma, and they also indicate that the potential for renal differentiation rests in the nephrogenic ridge itself. This potential suggests that the stimulus for ureteral bud formation resides, at least partly, in the developing metanephros.

The embryologic basis for renal agenesis appears to be an early insult to the developing ureteral bud, which prevents normal renal organogenesis from progressing. The ultimate clinical expression of this teratogenic event depends on its severity and extent (unilateral or bilateral renal agenesis) and on the sex of the fetus because wolffian duct derivatives are much less commonly affected than müllerian duct structures. Also, even though there is close proximity between the renal and gonadal anlage on the nephrogenic ridge, injuries to the developing gonads are rare in this condition.

Bilateral Renal Agenesis

Bilateral renal agenesis is a rare anomaly, with an incidence of approximately 1 in 4,000 births. It occurs much more often in males than in females (72%), and most affected infants are of low birth weight (less than 2.5 kg). Amniotic fluid is characteristically absent in all cases, although no other feature of pregnancy or maternal state is abnormal. Approximately one-third of births are stillborn; the survivors usually succumb to the effects of severe pulmonary hypoplasia within a short time.

The kidneys and renal arteries are usually completely absent, although dysgenetic vestiges may at times be noted. The ureters are completely absent in approximately half of the infants, as is the bladder, which often is absent or hypoplastic. The adrenal glands usually are present but typically ovoid because they are not compressed by the kidneys and fail to assume their characteristic shape (7). The infant with bilateral renal agenesis is characteristically deformed. The face is prematurely senile, with a flat nose, large flattened and lowered ears, and a depression below the lower lip. A prominent skinfold covers the inner canthus of each eye. In addition, the legs are often bowed and clubbed. This constellation of features, along with pulmonary hypoplasia, has been termed *Potter's syndrome* (Fig. 47.1 and Fig. 47.2). However, these features are not pathognomonic or specific for bilateral renal agenesis. Elegant experimental studies on the fetal rat subjected to repeated amniocentesis (27); observations by Bain and associates (8) on infants with leakage of amniotic fluid; and documentation of Potter's syndrome in babies with polycystic kidney disease, bilateral renal dysplasia, and urethral atresia or obstruction indicate that all of the features of Potter's syndrome are attributable to the mechanical effects of insufficient amniotic fluid volume.

FIGURE 47.1. Characteristic Potter's facies in an anephric child who survived only hours. Note flat nose, large flattened and lowered ears, depression below lower lip, and inner canthal skinfolds.

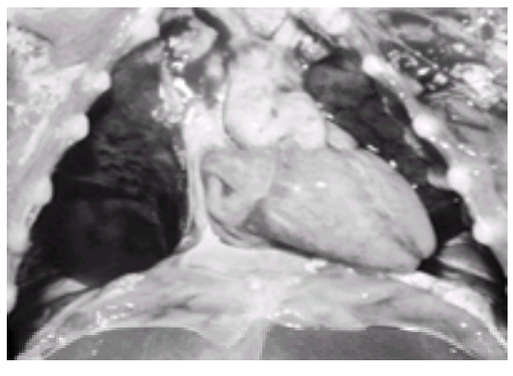

FIGURE 47.2. Bell-shaped chest and pulmonary hypoplasia in stillborn child with bilateral renal agenesis.

Bilateral renal agenesis is incompatible with life, and thus its clinical significance is limited. With characteristic body features and associated oligohydramnios, the diagnosis should be readily apparent and can be easily confirmed by ultrasonography, renal scintigraphy, and if necessary, umbilical artery catheterization with aortography. In addition, the diagnosis of Potter's syndrome can be made prenatally. This raises important controversies and implications in fetal therapeutics (48).

Unilateral Renal Agenesis

Because of the potentially asymptomatic nature of this anomaly, its reported incidence varies according to the population surveyed. Necropsy studies suggest an occurrence of approximately 1 in 1,000, whereas clinical presentation may be 1 in 1,500 (33,127). Males dominate in a ratio of 1.8:1 (30).

The clinical significance of solitary kidney relates to associated genitourinary tract abnormalities and to its potential for pathologic complications. Genital anomalies occur commonly and are three to four times more frequent in females than in males. In girls, partial or complete nonunion of the müllerian ducts is the most commonly occurring embryologic defect. This defect is usually expressed clinically as an obstructed hemivagina and uterus didelphis, which produces lower abdominal pain after menarche. These signs and symptoms are often diagnosed incorrectly because hematocolpometra is seldom considered as a likely diagnostic possibility in an otherwise healthy menstruating young woman (120,143) (Fig. 47.3). Magnetic resonance imaging (MRI) is particularly useful in defining müllerian duct anomalies and establishing a correct diagnosis in this setting (124). A spectrum of renal anomalies including unilateral agenesis may occur in certain patients with the Mayer-Rokitansky-Kuster-Hauser syndrome, which is defined by congenital absence of the vagina and uterus. Two forms of this condition occur in otherwise normal genotypic and phenotypic females who have a shallow pouch replacing the vagina. In the typical form, complete absence of the vagina is associated with bilateral symmetric rudimentary uterine anlagen (noncanalized muscular buds) and normal ovaries and fallopian tubes. In the atypical form, the uterine remnants are asymmetric (aplastic or enlarged), the fallopian tubes are abnormal (aplastic or hypoplastic), and the ovaries may be cystic and anomalous. Interestingly, the ovarian and renal anomalies occur almost exclusively in the atypical form of this syndrome (96,122,125).

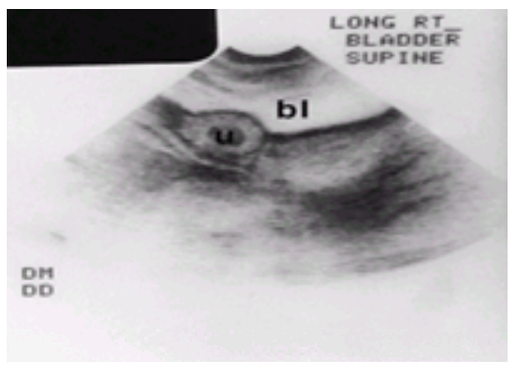

FIGURE 47.3. Pelvic ultrasonogram demonstrates right-sided partially fluid-filled pelvic mass in a 15-year-old girl with solitary left kidney and menstrual irregularity. The mass proved to be an obstructed duplication of the uterus and vagina with hematometrocolpos. u, uterus; bl, bladder.

Genital anomalies are much less common in males, although hypospadias, undescended testes, hypoplastic or absent vas deferens, and seminal vesicle and prostatic cysts have been reported (57,136). In both sexes, patients with ipsilateral renal agenesis (or severe dysplasia) may develop cystic dilations within the pelvis. In males, these typically represent seminal vesicle cysts, whereas in females, Gartner's cysts occur. Sheih and others (115) performed screening renal ultrasound studies on 280,000 children and found 235 with a congenital solitary kidney. Of these, 13 had seminal vesicle or Gartner's cysts, an incidence of 0.005%. The embryologic connection between renal agenesis and pelvic cystic disease was made more obvious in those cases in which dilated ureters were identified entering the cysts.

Except as previously noted, the gonads are usually normal, although urologic anomalies may be associated with and lead to the diagnosis of unilateral renal agenesis. These include vesicoureteral reflux and obstruction at the ureterovesical and ureteropelvic junctions (18). The ipsilateral adrenal gland would be expected to be normal because of its separate embryologic development. Interestingly, the adrenal has been reported to be absent in approximately 10% of cases of renal agenesis (85). Associated nongenitourinary tract anomalies occur in up to 25% of affected individuals and commonly involve the cardiovascular, gastrointestinal, and skeletal systems.

The diagnosis of unilateral renal agenesis is often made during an evaluation for urinary symptoms or as part of an investigation in patients with abnormalities of the external genitalia or other organ systems. Females are often identified at puberty during an evaluation for menstrual irregularities or a mass. In males, the external genitalia may give a clue to diagnosis, but finding an absent vas deferens or hypoplastic epididymis does not necessarily indicate that there will be an absence of the kidney (20,130). Likewise, absence of the kidney does not signify absence of the testis in those instances when the testis is undescended and impalpable. The clinical diagnosis of unilateral renal agenesis and its relationship to multicystic renal dysplasia becomes confusing and even more significant when fetal ultrasound studies are considered. Mesrobian and co-workers (81) reported on the occurrence of unequivocal unilateral multicystic renal dysplasia detected in three fetuses during maternal ultrasound examination, which completely disappeared during fetal development so that no trace of a kidney or cystic structure was seen on subsequent ultrasonograms performed after birth. It is thus apparent that some solitary kidneys may not result from a lack of induction of the metanephric blastema, but rather reflect an acquired insult to the developing kidney. The incidence and significance of this finding requires further clarification, but it does help explain certain embryologic findings such as cystic dilations of the seminal vesicle or Gartner's duct associated with renal agenesis. Some of these cases may represent ureteral ectopia with early and total obstructive renal injury.

Investigations used to make the diagnosis of unilateral renal agenesis can include excretory urography, ultrasonography, radionuclide imaging, computed tomography (CT), and MRI. Cystoscopy is usually not helpful, even though it may reveal an asymmetric or absent hemitrigone typically without visualization of a ureteral orifice. However, these cystoscopic findings are not pathognomonic of renal agenesis. They merely indicate that the ureter does not enter the bladder normally; it may be ectopic. Consequently, cystoscopy is not used to confirm the diagnosis of renal agenesis.

Although the susceptibility of a solitary kidney to pathologic complications is now recognized to be no greater than that of a normal kidney, early studies suggested that solitary kidneys were predisposed to disease and carried an increased mortality. In recent times, such a potential has not been observed, and unilateral renal agenesis is compatible with normal longevity. Beginning *in utero,* the solitary kidney shows evidence of compensatory hypertrophy (80). By adulthood, the solitary kidney associated with renal agenesis develops a hemodynamic response to protein challenge that is no different from other types of acquired solitary kidney as occurs in renal donors and other uninephrectomized patients, which indicates normal renal reserve (28). However, in following the clinical course of 157 patients with

unilateral renal agenesis, Argueso and associates (6) did observe that while survival data was the same as for age-matched controls, the risk of developing proteinuria, hypertension, and renal insufficiency was increased. Prolonged follow-up of these patients thus appears warranted.

Hereditary Renal Adysplasia

Most cases of renal agenesis and renal dysplasia generally have been considered as isolated findings, occurring sporadically and not part of any inherited syndromes. Recent reports suggest alternatively that because of a common pathogenesis, renal agenesis, small kidneys with solid dysplasia, and large kidneys with solid or cystic dysplasia should be viewed as a spectrum of disease that includes multicystic renal dysplasia. In addition, familial renal agenesis and dysplasia have been shown to occur together and to be inherited along autosomal-dominant lines with variable inheritance (10,84,103,118).

Hereditary renal adysplasia was first described by Buchta (13) in 1973 as the occurrence of renal agenesis and hypoplasia/dysplasia in two kindreds where a predominantly autosomal-dominant inheritance pattern with variable penetrance was suggested. Roodhooft (103) clarified the familial nature of bilateral renal adysplasia and found that 9% of parents and siblings of afflicted individuals had asymptomatic renal abnormalities. Recent evidence by Murugasu (84), who studied three kindreds with hereditary renal adysplasia where two or more children in each family were affected, indicated that (a) at least one family member had a clinically silent anomaly; (b) normal kidneys in parents did not protect offspring from developing anomalies; and (c) empiric risks for offspring and first-degree relatives were 50% and 25%, respectively. These findings suggest that the strong genetic predisposition is along the lines of a dominant gene with variable expression. Because of this higher-than-expected incidence of silent genitourinary tract abnormalities as well as the increased risk to parents of having another infant so affected, there is a strong need for careful and complete genetic screening of the proband's family, pregnancies, and subsequent children. Although the risks of recurrence of the different forms of hereditary renal adysplasia have generally applied only to the renal components, Battin (9) has identified a kindred in which müllerian duct abnormalities (vaginal atresia or anomaly) were inherited in an autosomal-dominant pattern.

Supernumerary Kidney

The supernumerary kidney is a rare condition in which a free accessory renal organ exists as a distinctly separate parenchymatous mass and blood supply associated with two usually normal kidneys. It is generally distinguishable from the normal ipsilateral kidney by its smaller size and abnormal position. Typically, the supernumerary kidney is located caudal to the normal kidney. When in this position, the supernumerary ureter is usually a bifid branch of the normal ureter. This contrasts with the cranially placed supernumerary kidney whose ureter is characteristically completely duplicated and separate from the normal ureter and may empty ectopically (86). Pathologic conditions such as calculus disease and hydronephrosis have been reported in more than 50% of patients. However, it may not indicate a true increased susceptibility, but rather may merely be an indication for their recognition (108). When it is diagnosed, therapy for supernumerary kidney should be directed toward and reserved for pathologic processes affecting the kidney rather than simply its abnormal position or apparent redundancy.

ANOMALIES OF POSITION

Embryologic Considerations

During normal embryologic development, the permanent kidneys are initially positioned in the pelvis opposite the sacral somites, with their pelves facing anteriorly. Through a combination of axial trunk lengthening, elongation of the ureter, intrinsic renal growth, and rotation, the metanephros ascends to a higher position (Fig. 47.4). By the eighth week of gestational life, migration has been completed, and the kidney resides in the upper retroperitoneum opposite the second lumbar vertebra with the hilum facing medially. During ascent, the vascular supply to the kidney is locally derived until it reaches its final position, where the main renal arteries and veins develop. Because of the interdependence of renal ascent, rotation, and vascular supply, anomalies of renal position often are associated with bizarre and at times puzzling alterations in morphology and function that become interpretable and subject to classification only on the basis of these embryologic processes.

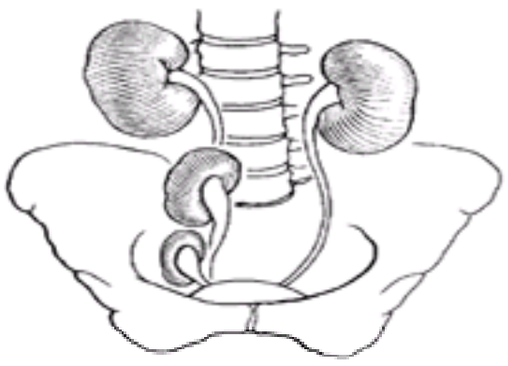

FIGURE 47.4. Ascent of kidney is associated with medial rotation.

Malrotation

Malrotation may be unilateral or bilateral and may affect a normally positioned or ectopic kidney. The kidney is commonly rotated around its vertical axis, and in most cases the pelvis is aimed somewhat anteriorly somewhere between the fetal and normal adult positions (Fig. 47.5). Rarely, this situation can be reversed, with the pelvis pointing posteriorly. The renal vessels are usually normal when the kidney is malrotated but in its normal retroperitoneal position, which excludes a vascular cause for the anomaly.

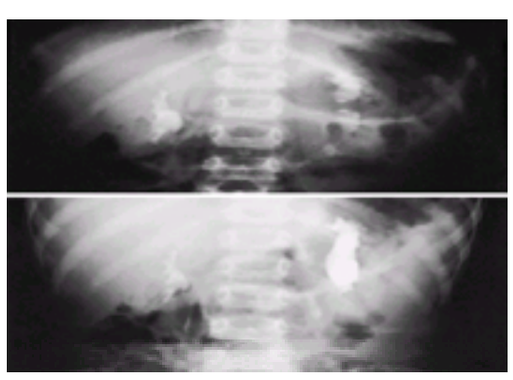

FIGURE 47.5. Excretory urogram of malrotated left kidney with pelvis pointed anteriorly demonstrates normal calyces **(top)** and slightly dilated pelvis **(bottom).**

Although the malrotated kidney is generally no more predisposed to pathologic conditions than is the normal kidney, malrotation is often accompanied by dysmorphism of the pelvis and calyces, especially in the presence of renal ectopy and fusion. Consequently, the malrotated kidney and pelvis may look hydronephrotic or deformed or may have a bizarre shape that suggests extrinsic compression or the presence of tumor (Fig. 47.6). In most instances, these appearances are illusory. However, at times, special diagnostic studies may be needed to exclude obstruction and to establish a correct diagnosis.

FIGURE 47.6. Excretory urogram of malrotated left kidney demonstrates dysmorphic renal pelvis and hydronephrosis, proved to be nonobstructive by diuretic radionuclide studies.

Renal Ectopy

When the kidney occupies a position outside of its normal retroperitoneal location, it is termed *ectopic.* Ectopy may be acquired, as in ptosis, where the renal vasculature and ureteral length are normal. In contrast, congenital renal ectopia usually represents a developmental arrest during renal ascent so that the kidney occupies a pelvic, iliac, or abdominal location (Fig. 47.4), having a shorter-than-normal ureter and an abnormal vascular supply. Malrotation is a usual accompaniment, with the pelvis typically directed anteriorly (Fig. 47.7).

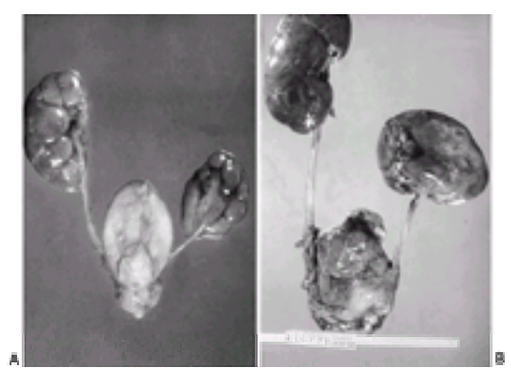

FIGURE 47.7. A: Ectopic left kidney shows incomplete rotation with renal pelvis aiming anteriorly. **B:** Ectopic left kidney, which has ascended higher than **A,** has completed normal medial rotation but has an abnormal axis.

Pelvic Kidney

In most cases of simple (ipsilateral) renal ectopy, the kidney is located within the confines of the bony pelvis and is often termed a *pelvic kidney* (Fig. 47.8). In this position, it overlies the pelvic bones and lumbosacral vertebrae, which makes its visualization on urography difficult even when renal function is well preserved. Diagnostic difficulty may be further compounded by poor renal function and by the renal pelvis and calyces assuming an abnormal and often unexpected attitude (Fig. 47.9). Many ectopic kidneys display a characteristic ultrasonographic appearance with absent or eccentric renal sinus echo patterns that reflects this altered calyceal anatomy and the presence of an extrarenal pelvis.

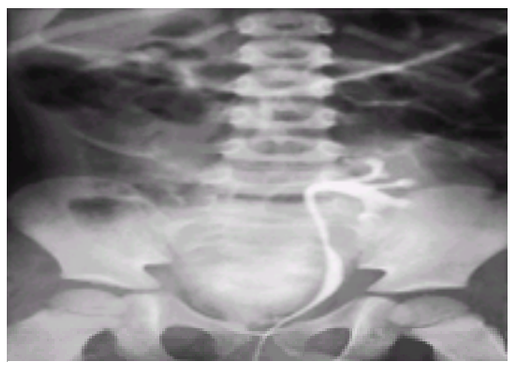

FIGURE 47.8. Retrograde study of normally rotated and formed pelvic kidney with short ureter.

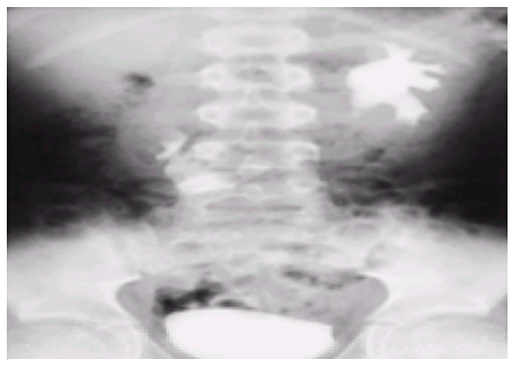

FIGURE 47.9. Right pelvic kidney overlies the lumbosacral spine and is difficult to visualize on excretory urogram.

Pelvic kidneys are more susceptible to calculus formation than normal ones. They are also more frequently observed to be hydronephrotic, the cause of which may be true obstruction or nonobstructive dilation due to vesicoureteral reflux, dysmorphism, malrotation, and so on. Because nonobstructive dilation occurs in over 50% of cases (41), careful assessment must be made before the dilated kidney is assumed to be obstructed and treatment is initiated. If reconstructive surgery is necessary, angiography occasionally may be helpful to characterize an unpredictable renal vasculature (Fig. 47.10). Also, the presence and status of the opposite kidney must be determined in case nephrectomy is required (3). In general, the prognosis in renal ectopia is primarily related to the presence of any associated urologic disease and not related directly to ectopia alone (41).

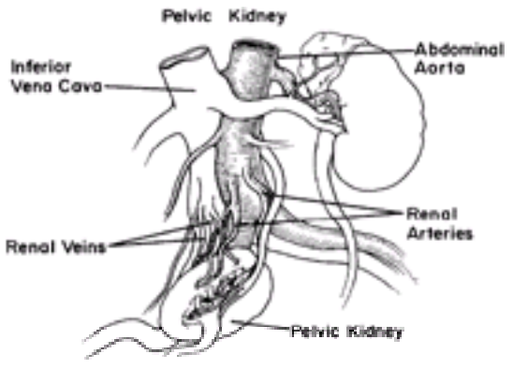

FIGURE 47.10. Unpredictable renal vasculature to pelvic kidney is derived from surrounding major vascular trunks.

In clinical series, ectopic kidneys are frequently symptomatic in up to 40% to 50% of patients (31). Symptoms are generally on the basis of urinary infection, abdominal mass, or pain simulating gastrointestinal disease. The autopsy incidence of this condition, 0.14% (17), is much greater than is the clinical expression, 0.008%, based on hospital admissions (61). This finding suggests that in many cases the anomaly is asymptomatic and remains unrecognized. Prognosis ultimately depends on whether the pelvic kidney is solitary and whether the contralateral kidney is normal, as reflected in the series by Downs and co-workers (31) in which renal disease developed in 40% of patients with a solitary ectopic kidney (representing approximately 10% of patients with pelvic kidney) and 15% did not survive early adulthood. The clinical significance of ectopic kidney is reinforced by the fact that in up to 50% of patients, the contralateral kidney may be abnormal (77).

Prognosis also depends on the severity of associated anomalies, which are particularly common with renal ectopy, and may coexist in up to 85% of patients (77). In addition to the high incidence (15% to 45%) of genitourinary tract anomalies, such as hypospadias, undescended testis, and vaginal agenesis, associated anomalies typically include the skeletal, cardiovascular, and gastrointestinal systems. This high incidence of associated abnormalities requires thorough investigation, particularly in young children found to have renal ectopy. Similarly, the presence of skeletal and especially vertebral anomalies should raise the level of suspicion for coexisting renal abnormality (29). Maizels and Stephens (75) have identified and defined an embryologic explanation for this close relationship between renal ectopy and vertebral anomalies in a series of elegant experiments. By deforming the developing caudal trunk of the chick embryo, they could regularly induce scoliosis, which, when present, was associated with a 62% incidence of renal ectopia. Equally important was the relatively high incidence of associated anomalies of the mesonephros, mesonephric duct, and müllerian duct comparable with that reported in the clinical literature. As a result of these studies, they have proposed that an environmental teratogen affecting the hind end of the embryo at a critical period of approximately 5 to 7 weeks' gestation may lead to abnormal growth of the spine. This abnormal growth of the spine in turn would limit renal ascent to produce ectopia and deflect the mesonephric duct away from the cloaca, leading to abnormalities of these structures or of the müllerian duct system. Such studies and their clinical correlates clearly indicate that the development of the lower end of the embryo is a highly complex process with multisystem interdependence. Therefore the clinician must keenly recognize the interrelationships between renal anomalies and other genitourinary and somatic abnormalities to provide the thorough investigation necessary to uncover their presence and to interpret their significance.

Thoracic Kidney

Thoracic kidney is a rare form of renal ectopy where the kidney protrudes or projects, at least in part, above the diaphragm. It is distinguishable from diaphragmatic hernia in which other abdominal viscera occupy the chest cavity as well. Embryologically, it is uncertain whether the kidney ascends before the diaphragmatic leaflets close normally or whether delayed diaphragmatic formation enhances the exaggerated renal ascent (16).

Because the thoracic kidney is typically asymptomatic and otherwise normal except for position, the diagnosis is usually made on routine chest roentgenogram. The ureter is longer than normal to reach the bladder, but unlike the pelvic kidney, the renal vasculature is not anomalous and typically arises as a single renal artery and vein. Once a diagnosis has been confirmed (Fig. 47.11), therapy is usually not required because neither the ectopic thoracic kidney nor its contralateral mate are predisposed to pathologic disturbances.

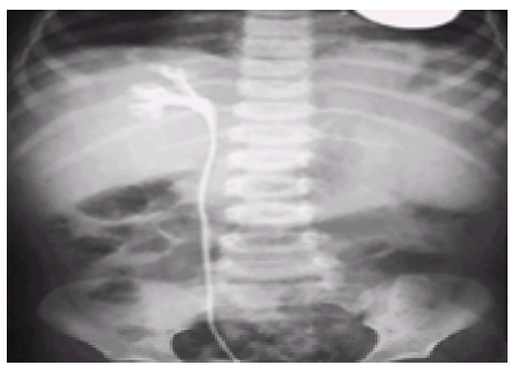

FIGURE 47.11. Thoracic kidney, evaluated by retrograde pyelography, is entirely normal but abnormally positioned.

ANOMALIES OF POSITION AND FUSION

Embryologic Considerations

Anomalies of position and fusion include kidneys that have migrated to become contiguous or fused with their contralateral mate and is subdivided clinically on the basis of whether both or only one kidney moves toward or crosses the midline. In horseshoe kidney, the most common fusion abnormality, both kidneys have migrated, whereas in crossed ectopia, usually only one kidney has crossed the midline. In both situations, the blood supply is unpredictably abnormal, arising from multiple sources, and the kidneys are malrotated to some degree because fusion usually prevents normal rotation from being completed.

Numerous eclectic embryologic theories have sought to provide an explanation for these different events, which occur very early in gestation. These explanations include faulty ureteral bud development, abnormalities of renal vasculature limiting ascent, and other teratogenic factors (61,79). More recently, Cook and Stephens (24) have proposed a more unified theory that relates the position and fusion anomalies to abnormal variations in growth or flexion of the hind end of the developing embryo and to the subsequent induction of one or two nephrogenic cords. They propose that horseshoe kidney and its variants may be due to midline fusion of the two renal blastemata while they are still confined to the true pelvis. This fusion results from excessive ventral flexion of the hind end of the embryo, which pushes the kidneys together (Fig. 47.12). Alternatively, a combination of exaggerated ventral as well as lateral flexion with rotation of the tail might carry the cloaca and its attached ducts across the midline to allow the development of a fused kidney from a single nephrogenic cord that has been intercepted by ureteral buds from both wolffian ducts.

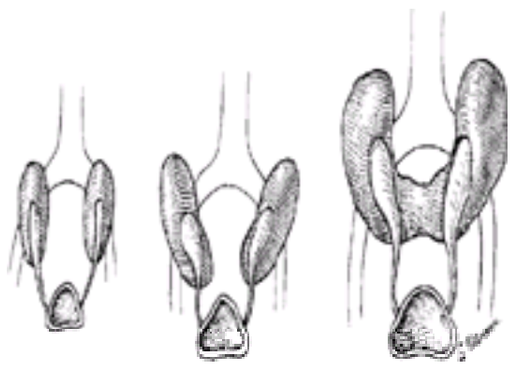

FIGURE 47.12. Presumed embryologic sequence in the formation of horseshoe kidney.

Crossed Renal Ectopy

Crossed renal ectopy is an uncommon condition with an autopsy incidence of approximately 1 in 2,000 and a slight male predominance (1,79). It occurs when the ureter occupies its normal position in the bladder but crosses the midline to join an ectopic kidney, which, in 90% of patients, is fused to its mate. In their comprehensive study, McDonald and McClellan (79) subdivided this condition into four groups: (a) crossed ectopia with fusion, (b) crossed ectopia without fusion, (c) solitary crossed ectopia, and (d) bilateral crossed ectopia (Fig. 47.13). Crossed renal ectopia with fusion, the most common of these entities, was further classified into six categories based on morphologic appearance (Fig. 47.14). Of these, the most common form appears to be fusion with the ectopic kidney placed inferiorly.

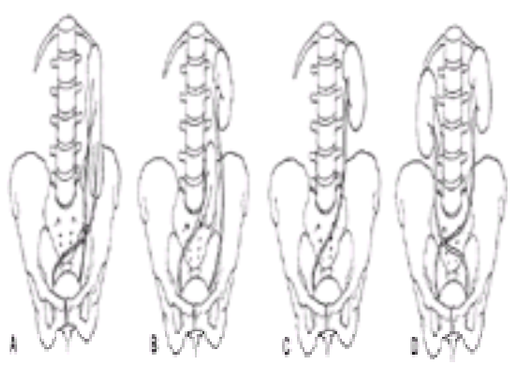

FIGURE 47.13. Types of crossed renal ectopia. **A:** Fused. **B:** Nonfused. **C:** Solitary. **D:** Bilateral. (Modified from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995, with permission.)

Six types of crossed renal ectopia with fusion. **A:** Ectopic kidney superior. **B:** Sigmoid or S-shaped kidney. **C:** Lump kidney. **D:** L-shaped kidney. **E:** Disk kidney. **F:** Ectopic kidney inferior. (Modified from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995, with permission.)

Although both urinary and nonurinary anomalies can be associated with this condition, their incidence is low and they are not as frequently seen as in unilateral agenesis or pelvic kidney. However, various abnormalities, including sacral agenesis, scoliosis, and cardiovascular and gastrointestinal anomalies, have been reported (61,79).

Many patients with crossed renal ectopia remain entirely asymptomatic. However, because of associated malrotation, a significant proportion of these kidneys displays pelvocalyceal dysmorphism that simulates hydronephrosis. In some instances, an abnormal ureteropelvic junction (UPJ) position and aberrant blood vessels may actually interfere with pelvic emptying to produce obstruction and predispose to urinary infection and calculus formation. Also, reflux is commonly observed to be associated with this anomaly.

Although crossed ectopia can be appreciated by ultrasonogram, excretory urography is often required to precisely characterize the anatomy of the crossed ectopic moieties, especially if function or morphology is not normal (Fig. 47.15 and Fig. 47.16). However, because of the high incidence of reflux, voiding cystography and radionuclide studies that evaluate the functional significance of collecting system dilation are recommended. If surgery is required, angiography may occasionally be helpful because, as Rubinstein and associates (106) have shown, the vascular supply to both the ectopic and nonectopic kidney may be anomalous.

FIGURE 47.15. L-shaped crossed fused renal ectopia with renal pelvis overlying spine is visualized by excretory urography. Note malrotation of left kidney.

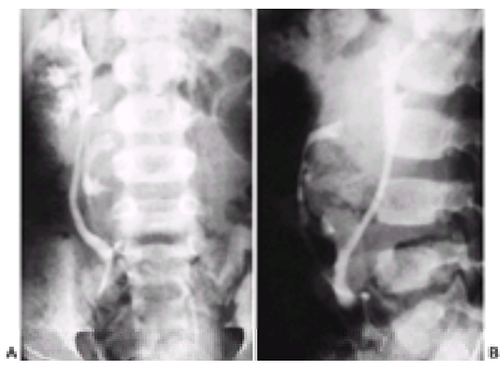

FIGURE 47.16. A: Crossed renal ectopia with crossed kidney fused inferiorly is demonstrated on excretory urogram. **B:** Lateral film shows orientation of collecting systems to be anterior for inferior ectopic kidney and posterior for superior kidney.

Horseshoe Kidney

Horseshoe kidney is the most common fusion anomaly, with an incidence of approximately 1 in 400 births and a male predominance (42,112). It presents great variability in morphology, position, and vascular supply. In more than 90% of cases, there is true fusion of the lower poles, which form an isthmus and become medially directed (Fig. 47.17). The site of fusion may lie over the midline or may be asymmetrically positioned to one side. Depending on the degree of fusion, the isthmus may be composed of thick functioning parenchyma or merely be a fibrous band that serves to tether the lower poles. In most instances, the kidneys are located in their proper retroperitoneal positions, with the isthmus placed anterior to the great vessels at approximately the level of L-4 or L-5. The ureters typically course in front of the isthmus, descending from anteriorly facing renal pelves. Blood supply to the horseshoe kidney is variable, with the fused segment receiving a particularly unpredictable blood supply from branches of the common iliac, aorta, and at times, the hypogastric and middle sacral arteries (11). If large portions of the renal parenchyma fuse, the resulting kidney may lose its horseshoe shape and become a flattened disc or lump kidney, which often has a pelvic location (Fig. 47.18).

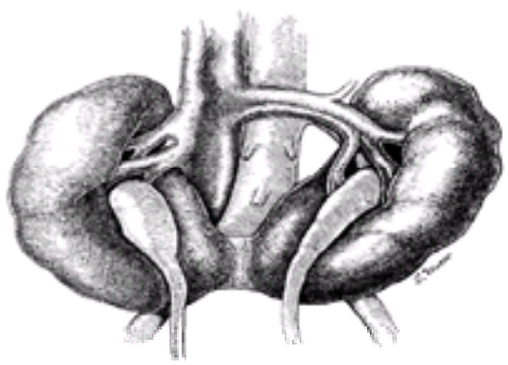

FIGURE 47.17. Classic features of horseshoe kidney. Fusion of lower poles produces an isthmus and shifts the axis of the kidneys toward the lumbosacral vertebrae.

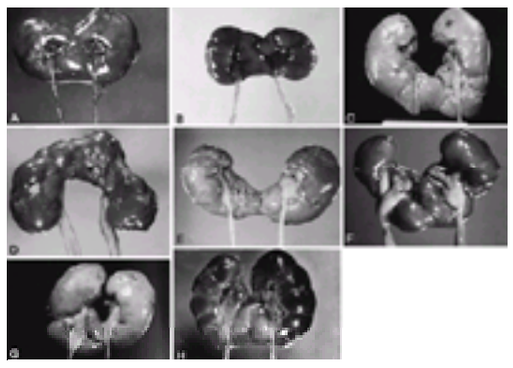

FIGURE 47.18. Horseshoe kidney. Specimens **(A-H)** show wide variation in degree of fusion, thickness of the isthmus, ureteral morphology, renal axis, and horseshoe appearance. Note fusion of upper poles in **D**.

Associated anomalies occur in at least one-third of patients regardless of whether the horseshoe kidney is itself symptomatic. These anomalies include multisystem disturbances of the skeletal and cardiovascular systems and gastrointestinal tract as well as genitourinary abnormalities. It appears that horseshoe kidneys are more common in infants succumbing to multiple congenital anomalies, but the kidney itself is rarely the cause for their deterioration. Boatman and colleagues (11) documented an increased incidence of male and female genital anomalies with this condition. Also, an increased frequency of ureteral duplication with obstructive sequelae (e.g., ureterocele) and reflux has been reported (97,112).

A large proportion of patients with horseshoe kidney remain entirely asymptomatic. When symptoms are present, they typically relate to calculi, hydronephrosis, infection, or hematuria. A high incidence of calculus disease has been attributed to a combination of partial obstruction and stasis; however, Evans and Resnick (36) found that metabolic causes for kidney stone disease were no less frequent in patients with horseshoe kidney than in the general population. The treatment of calculi in a horseshoe kidney requires special consideration with regard to shock wave lithotripsy (SWL) therapy and endourologic techniques (25,35,113).

Hydronephrosis was present in approximately 80% of the children with horseshoe kidney (88,112). Hydronephrosis may be due to UPJ obstruction, which is commonly associated with a high insertion of the ureter into the pelvis as well as displacement by the fused isthmus. However, hydronephrosis also may be consequent to vesicoureteral reflux or to pelvocalyceal dysmorphism consequent to malrotation, ectopy, and parenchymal distortion. Differentiation between obstructive and nonobstructive conditions is obviously essential for effective therapy (Fig. 47.19).

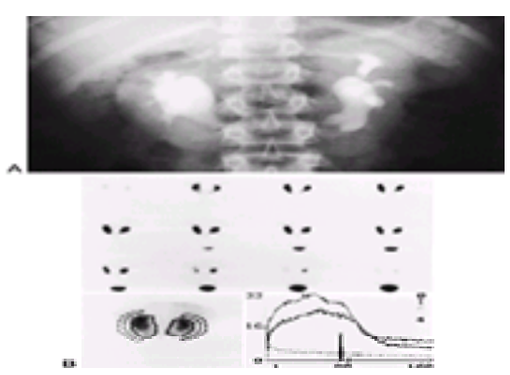

FIGURE 47.19. A: Excretory urogram shows horseshoe kidney with bilateral hydronephrosis greater on the right side. **B:** Diuretic radionuclide study indicates that

isthmus has no appreciable blood flow *(bottom left).* Also, scintiscans *(above)* and histogram curves *(bottom right)* illustrate rapid nonobstructed tracer transit and exclude mechanical obstruction.

Dysplasia and neoplasia have been reported to occur in horseshoe kidney. Wilms' tumor, angiomyolipoma, teratoma, and transitional cell carcinoma all have been documented (19,37,39,109). Also, the incidence of transitional cell carcinoma appears to be increased (100).

The radiographic diagnosis of horseshoe kidney, although difficult with ultrasonography if the isthmus is not detected, usually can be made with excretory urography if the renal segments function well; the vertical line of axis through the kidneys will point toward the lumbosacral spine, and there will be ureteral deviation by the isthmus. However, in children with spina bifida and a thoracolumbar gibbus deformity, the axis of the kidneys may be distorted to simulate a horseshoe kidney (78).

The addition of diuretic radionuclide imaging may be helpful in patients with horseshoe kidney because it reliably establishes whether the isthmus contains functioning parenchyma (52), and it distinguishes true obstructive hydronephrosis from nonobstructive dilation (128) (Fig. 47.19). To these studies, voiding cystography should be added because of the predictably high incidence of vesicoureteral reflux. If surgery for a diseased horseshoe kidney is contemplated, angiographic study may be required to characterize the variable arterial supply to the kidney.

Treatment and prognosis for horseshoe kidney, particularly for associated hydronephrosis, have changed considerably over the years, reflecting both conceptual evolution and technologic advance. Historically, Smith and Orkin (116) believed that a horseshoe kidney was almost always diseased and in need of surgical therapy, especially division of the isthmus. Later, Glenn (42) provided evidence that nonoperative follow-up of horseshoe kidneys was compatible with a symptom-free course; fewer than 25% of patients required surgery for calculus or obstruction. Also, no patient required division of the isthmus for pain relief, a practice that has since lost favor. Division of the isthmus, however, was often thought to be necessary and was performed in conjunction with pyeloplasty or alone to improve drainage. However, symphysiotomy is not commonly performed today because the position of the kidneys and course of the ureters are not appreciably altered nor is the drainage pattern of the kidney improved by this maneuver (97). Standard pyeloplasty techniques are easily adaptable to the horseshoe kidney despite the presence of the isthmus whose division is not required for excellent surgical result (111). With the absence or elimination of obstruction many large series have reported a very favorable prognosis for these patients (42,97). The presence of a horseshoe kidney can significantly affect the management of other disease conditions involving the kidney and retroperitoneum such as renal and testicular neoplasm, aortic aneurysm, and renal transplantation. Special considerations and alterations in therapy may be required (51,89,99).

ANOMALIES OF THE RENAL COLLECTING SYSTEM

Calyx

Calyceal Diverticulum

A calyceal diverticulum is a cystic cavity located peripheral to an otherwise normal minor calyx with which it communicates through a narrow channel. It is lined by transitional epithelium, may be multiple, and can occur anywhere in the kidney, although the upper calyx is most frequently affected. Because the incidence in children and adults is approximately the same, it is considered to be a defect in embryogenesis, although the embryology is unclear. One plausible explanation is based on persistence of later generations of the dividing ureteral bud that fail to degenerate and persist as calyceal diverticula, enlarging because of backflow of urine (82,129).

Diagnosis is usually suspected on ultrasonography and confirmed if necessary by excretory urography, although the neck of the diverticulum is best outlined on retrograde study (Fig. 47.20). In the evaluation, they must be distinguished from other acquired abnormalities such as cortical abscess, papillary necrosis, and tuberculosis. Calyceal diverticula may be entirely asymptomatic, but there is an increased incidence of milk of calcium and stone formation within the poorly draining cavity, which in turn may cause clinical symptoms and secondary complications of pain, infection, and hematuria (142). Percutaneous surgery may be required to treat the contents of the diverticulum, and if required, eradication can be achieved by dividing the calyceal neck and marsupializing the cyst.

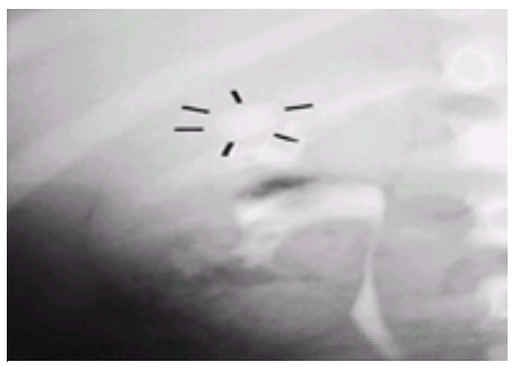

FIGURE 47.20. Excretory urographic demonstration of a calyceal diverticulum.

Megacalycosis

In this nonobstructive condition, the calyces are dilated, malformed, and often increased in number in the absence of UPJ obstruction or enlargement of the renal pelvis. Megacalycosis or megacalyces are much more common in males, and the usual presenting symptoms in children are urinary tract infections, which are not necessarily related. In adults, megaureter is associated in 10% to 20% of patients and must be proved to be nonobstructive before a diagnosis of megacalycosis can be made with certainty (40). Histologically, the renal cortex is normal, but the medulla is underdeveloped, which correlates with malformation of the renal papillae and an almost universally present defect in tubular concentrating ability.

The diagnosis of megacalycosis can be made only when there is no anatomically or functionally definable site of obstruction in the urinary tract. However, the etiology may involve a transient obstruction in fetal life during the period of early parenchymal development (40,55). The observations on transient fetal hydronephrosis and the similarity between megacalycosis and the postoperative appearance of successfully corrected UPJ obstruction give credence to this theory. Occasionally, the clinical features and radiographic findings of these two conditions appear to overlap, which leads to diagnostic confusion (93).

Megacalycosis must be differentiated from true obstructive uropathy and from acquired conditions that produce infundibular scarring and calyceal dilation. As a nonobstructive anatomic deformity, the overall prognosis is excellent.

Infundibulopelvic Stenosis

Infundibulopelvic stenosis is a rare form of congenital hydrocalycosis in which the narrowed and at times distorted infundibula drain variably dilated calyces into a small, nonobstructed renal pelvis (Fig. 47.21). Although the cause of this condition is unknown, it may have embryologic significance as a link in the spectrum of congenital upper urinary tract obstructive anomalies, which ranges from infundibulopelvic dysgenesis, hydrocalycosis, and calyceal diverticulum through UPJ obstruction to severe multicystic renal dysplasia (60,132). Clinically, infundibulopelvic stenosis must be differentiated from renal malignancy as well as from the more recognizable and correctable forms of hydronephrosis. Unless it is associated with significant renal parenchymal dysplasia, this abnormality rarely progresses (73,110).

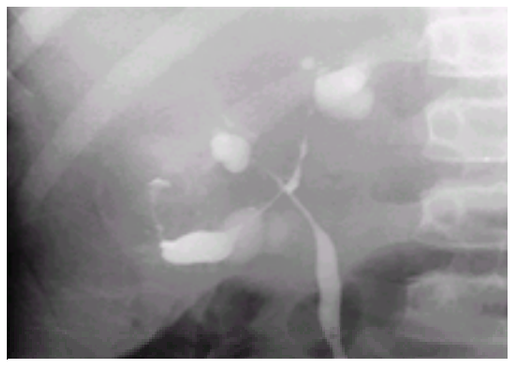

FIGURE 47.21. Infundibulopelvic stenosis. Excretory urogram demonstrates dilated calyces and narrowed, elongated infundibula, which fuse to form narrowed upper ureter; renal pelvis although almost nonexistent is not obstructed.

Ureteropelvic Junction Obstruction

Before the era of ultrasonography, hydronephrosis caused by obstruction at the UPJ was considered a common cause of hydronephrosis in children and adolescents. Although its overall incidence was difficult to estimate, presentation was often in younger children; 25% of cases were diagnosed within the first year of life and 50% recognized before the age of 5 years (56,139,140). With the use of routine perinatal ultrasonography, hydronephrosis suspected of being caused by UPJ obstruction is now recognized in nearly 1 in 500 live births (5,44). This condition occurs more commonly in males, especially neonates, with left-sided lesions predominating. Bilateral obstruction has been reported to occur in 10% to 40% of patients and, again, is more common in infants (71,135,140). Occasionally, true UPJ obstruction occurs in a duplicated kidney and usually affects the lower pole moiety (Fig. 47.22).

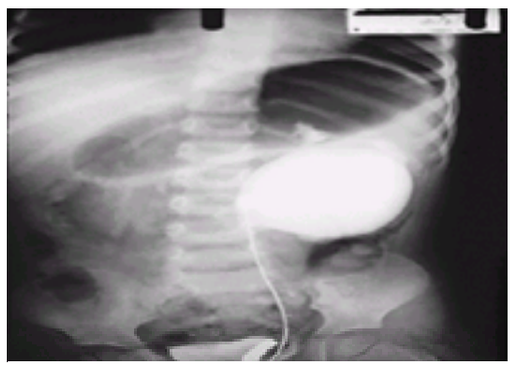

FIGURE 47.22. Sequential retrograde pyelograms of each moiety of a duplicated kidney demonstrates ureteropelvic junction (UPJ) obstruction affecting the lower pole.

Pathophysiology

Hydronephrosis may be caused by a variety of anatomic lesions or functional disturbances of the UPJ, which restrict urinary flow across this region either by compression of the UPJ and/or by interference with peristalsis. Because complete obstruction to the UPJ causes relatively rapid renal destruction, most clinical cases of hydronephrosis are thus suspected of being caused by a partial rather than a total obstruction. Although hydronephrosis associated with partial UPJ obstruction has a potential to cause progressive dilation and renal deterioration, such does not necessarily occur. In some instances, a state of equilibrium will occur, whereas in others improvement may even be spontaneous. These phenomena are recognized clinically both in patients with lifelong UPJ-type hydronephrosis who have no measurable reduction in renal function (Fig. 47.23) and in those adults and children followed nonoperatively who develop neither loss of renal function nor progressive urinary tract dilation (12,134). Also, the clinical observations that as many as 40% of patients show no measurable radiographic improvement after pyeloplasty for UPJ obstruction suggests that partial obstruction was not functionally significant (32,49,56,140). Experimental studies support these clinical observations. Application of a ligature to the UPJ or burying the ureter in the psoas muscle in dogs produces initial hydronephrosis, but thereafter, not all kidneys progressively dilate; some reach an equilibrium, dilate no further, and maintain stable renal function (65,90).

FIGURE 47.23. Incidentally discovered bilateral congenital UPJ-type hydronephrosis in a 72-year-old woman who had normal renal function and no symptoms attributable to the urinary tract.

The potential for progression or equilibration in hydronephrosis appears to be determined by several physiologic factors. These include (a) urinary output and flow rates during diuresis, (b) the anatomy and function of the UPJ, (c) glomerular and tubular renal function, and (d) pelvic compliance. Experimental pelvimetric studies have helped clarify the relative importance and interrelationship among these factors. Pelvimetric study of the renal pelvis involves temporarily occluding the UPJ while infusing saline into the pelvis and simultaneously measuring renal pelvic pressure and volume (63,65,91). This is analogous to a cystometric examination in which a pressure volume curve is generated that describes the visceroelastic properties of the renal pelvis. The results of numerous pelvimetric studies have shown that all kidneys, whether normal, obstructed, dilated but nonobstructed, or previously obstructed, are characterized by a similar shaped pelvimetric curve: Low-pressure filling or accommodation occurs until a critical pelvic volume, unique for each pelvis is reached—the “capacity volume” of the renal pelvis. This capacity volume is analogous to bladder capacity and represents the volume above which low-pressure accommodation is no longer possible and overstretching of pelvic smooth muscle and elastic and connective-tissue components occurs. Above this volume, pressures rise rapidly as volume expands further (Fig. 47.24). As the size of the pelvis increases, two important pelvimetric changes take place, which determine the likelihood for progressive hydronephrotic dilation and renal damage: (a) The pelvis stretches, and its “capacity volume” and compliance increase, causing (b) the slope of the pelvimetric curve above the “capacity volume” to flatten (Fig. 47.25). As a result, large hydronephrotic kidneys require proportionately greater volumes of urine to overdistend their pelves and to develop high intrapelvic pressures, and once the pelvis is overdistended, intrapelvic pressures rise at a much slower rate in kidneys with large pelves than in those with small pelves. These findings explain (a) why kidneys with a small intrarenal pelvis are more vulnerable to renal damage from obstruction (they will rapidly develop high intrapelvic pressures) and (b) why kidneys with large pelves are seemingly protected from obstructive injury (they can accept larger volumes of urine before pressures begin to rise and once overdistended, pressures rise at a much more gradual rate). Consequently, once kidneys develop a large extrarenal pelvis with relatively increased compliance as a

result of partial obstruction, they may reach a state of hydronephrotic equilibrium and deteriorate no further (14,65).

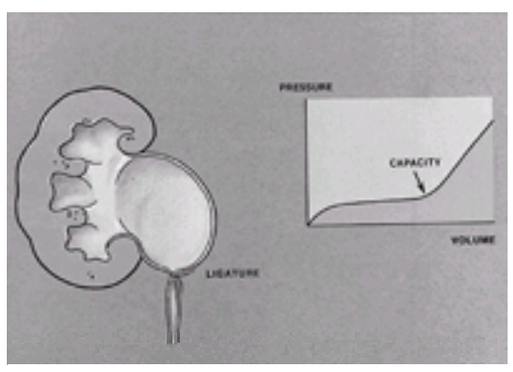

FIGURE 47.24. Pelvimetric study of the renal pelvis displays characteristic pelvimetric tracing, which defines the capacity of the renal pelvis and the slopes of the accommodation and filling phases below and above capacity.

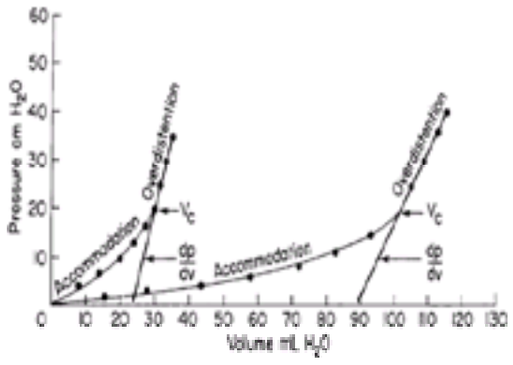

FIGURE 47.25. During progression of hydronephrosis, pelvimetric studies demonstrate an increase in pelvic capacity (V_c) and a decrease in the slope of the overdistention portion of the curve (dp/dv). (From Koff SA. the diagnosis of obstruction in experimental hydronephrosis: mechanisms for progressive urinary tract dilation. *Invest Urol* 1981;19:85, with permission.)

Experimental studies also have shown that a partial UPJ obstruction that is capable of causing a normal kidney to initially dilate and become significantly hydronephrotic may not be significant enough to cause the now dilated kidney to develop progressive hydronephrosis or renal injury. The kidney may no longer be able to induce a diuresis sufficient to overfill the renal pelvis and to cause intrarenal pressures to rise. In this setting because of acquired changes in pelvic size, compliance, renal function, and nephron mass, hydronephrosis may have become a beneficial compensatory mechanism that protects the kidney from further injury (65,69). These interrelationships and observations have special importance in neonatal hydronephrosis, where the combination of a disproportionately large, stretchy, highly compliant renal pelvis, immature renal function, and reduced urinary output tend to minimize or eliminate completely the potentially harmful effects of partial UPJ obstruction and, in some cases, allow hydronephrosis to spontaneously improve. Witness the fact that reviews of the natural history of nonoperated UPJ-type hydronephrosis in newborn infants indicate that only approximately 25% of infants will actually be found to have an obstruction or display any evidence of renal deterioration or progression of hydronephrosis and require pyeloplasty (21,66,67,134).

Ureteropelvic Junction Anatomy

Various anatomic abnormalities can affect the UPJ to cause restriction of flow and obstruction. *Intrinsic* lesions are easily recognized during radiographic evaluation and at the time of surgery. Although true strictures at the UPJ are rare findings, the upper segment of the ureter is often visibly narrowed and thinned but probe-patent (Fig. 47.26 and Fig. 47.27). This narrowing may represent an arrest in development (2) which can be explained embryologically by the fact that during fetal life the ureter undergoes a continuous process of obstruction and recanalization, which, if incomplete, may produce narrowing and obstruction (105). The fetal ureter also may show intraluminal muscular invaginations, folds or valvelike structures, which can persist postnatally; ordinarily these are nonobstructive and disappear with time. However, if these folds become overdeveloped, they may produce obstruction to the upper ureter or UPJ (54) (Fig. 47.28).

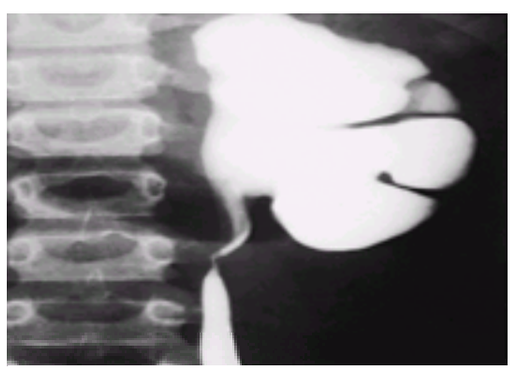

FIGURE 47.26. Ureteropelvic junction obstruction due to narrowed segment of upper ureter.

FIGURE 47.27. Anatomic appearance of intrinsic ureteropelvic junction obstruction caused by narrowed upper ureteral segment.

FIGURE 47.28. Ureteropelvic junction obstruction associated with prominent ureteral folds.

Although there is no histologic difference between the normal UPJ and the remainder of the upper urinary collecting system (62), histologic differences have been identified in cases of obstruction by several authors, but their findings and interpretations have differed. Abnormalities include a preponderance of longitudinal muscle fibers, excessive collagen fibers in and around muscle bundles, and compromised or attenuated muscle bundles (34,47,58,83,119). All of these changes can, to some extent, interfere with normal ureteral peristalsis and urine transport, but it remains genuinely unresolved as to whether these changes better represent the cause or are merely a histologic effect of the obstruction.

Extrinsic mechanical abnormalities at or below the UPJ may produce morphologic alterations and functional disturbances that impair pelvic emptying. This type of obstruction is commonly caused by an aberrant or accessory renal artery or early branching vessel to the lower pole of the kidney or a similarly positioned fibrous band that typically passes anterior to the pelvis and ureter to produce kinking, compression, or both. Although this type of ureterovascular hydronephrosis has been reported to occur in up to 40% of patients, not all observers are convinced that the crossing vessel or band is the sole or inciting cause of the obstruction (56). Interestingly, in contrast to older children and adults, crossing vessels are rarely encountered in young children with prenatally detected hydronephrosis (104). This suggests that the mechanism for hydronephrosis and obstruction in the fetus and young child may be altogether different than for the older patient. In many instances, an underlying primary intrinsic disturbance of the UPJ may exist or coexist to produce obstruction, which results in pelvic overdistention and rotation. This rotation may then distort the normal anatomy and give the illusion that vessels or bands are the primary cause of obstruction. Stephens' (121) observations on ureterovascular hydronephrosis support this view by indicating that transient or permanent defects in medial rotation of the renal pelvis predispose the UPJ to vascular obstruction. Insertion of the ureter high onto the pelvis instead of in a dependent position may produce a similar type of mechanical obstruction that combines a deficiency in UPJ funneling with pelviureteral adhesions that can angulate and/or compress the ureter against the expanding pelvis (Fig. 47.29 and Fig. 47.30). Extrinsic obstructions of this type have important clinical implications, especially at the time of surgical repair. It must not be assumed that apparent extrinsic compressions or mechanical disturbances are the sole cause of impaired pelvic emptying and that their correction will relieve obstruction. The possibility that a coexisting intrinsic disturbance at the UPJ also exists must be considered, assessed intraoperatively, and if present, treated appropriately. In addition, it has been hypothesized that in some cases, UPJ obstruction may be caused entirely by a functional disturbance in the ability of the pelvis and upper ureter to function synchronously to initiate, form, or conduct peristaltic waves across the UPJ (23,138). This concept is obvious in those cases when no other cause for the obstruction is apparent, but it also may be operative in certain cases when after release of an obvious extrinsic obstruction, the now normally appearing UPJ does not function properly and resection of an adynamic UPJ segment is required for complete relief of obstruction.

FIGURE 47.29. Ureteropelvic junction obstruction associated with high insertion of the ureter into the pelvis.

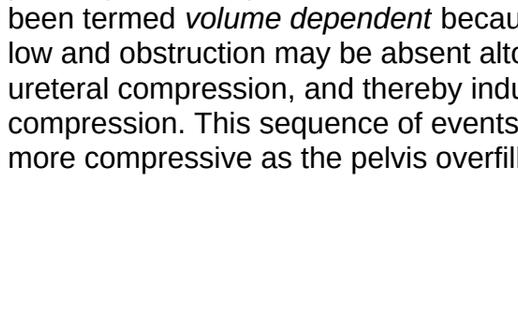

FIGURE 47.30. Anatomy of extrinsic ureteropelvic junction obstruction demonstrates adventitial tissue compressing the upper ureter against the overdistended renal pelvis.

Ureteropelvic Junction Function

The different forms of pathologic anatomy of the UPJ, intrinsic and extrinsic, not only produce dissimilar degrees of static compression and obstruction at the UPJ, but also they produce altogether different patterns of dynamic urinary flow across the UPJ, which has important clinical implications. These distinctive flow patterns determine to a great extent the potential for progression or equilibration of hydronephrosis and influence the accuracy of diagnostic tests that aim to assess obstruction in hydronephrosis (68). Intrinsic obstructions, such as ureteral narrowing or an adynamic segment tend to be fixed in severity, produce a constant degree of obstruction, and are characterized by a linear pressure-flow curve in which the rate of flow across the UPJ is determined and driven primarily by increases in intrapelvic pressure. This flow pattern has been termed *pressure dependent.* In contrast, extrinsic UPJ obstructions such as kinks, angulations, or compressing bands or vessels tend to vary in severity, produce a changing degree of resistance, and are characterized by a nonlinear pressure-flow curve in which flow rate depends primarily on renal pelvic volume and is determined by how tightly the ureter is kinked by or compressed against the overdistended renal pelvis. This flow pattern has been termed *volume dependent* because even at high pressures, flow may be low or absent. With this pattern, when pelvic volumes are small, resistance is usually low and obstruction may be absent altogether. However, during a diuresis when the pelvis enlarges to a sufficient volume, obstruction may be activated, produce ureteral compression, and thereby induce self-perpetuating progression of obstruction by causing further pelvic enlargement, which increases obstructive compression. This sequence of events may be recognized clinically and at surgery in cases in which adventitial bands bind the pelvis and ureter together and become more compressive as the pelvis overfills and the bands are drawn taut (Fig. 47.31).

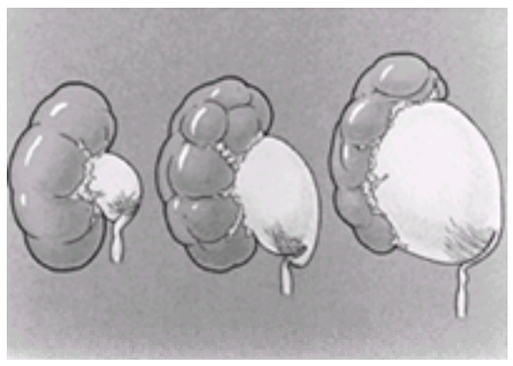

FIGURE 47.31. Representation of the sequence of events involved in activation of an extrinsic volume dependent obstruction by diuresis, which causes renal pelvic volume expansion and overdistention. This allows adventitial bands to tightly compress the ureter against the dilating renal pelvis.

In trying to relate the anatomy and function of the UPJ to its clinical behavior, it appears that intrinsic or extrinsic obstructions with pressure and volume-dependent flow patterns can explain many of the differences observed in the way kidneys respond to partial obstruction and the difficulties encountered in trying to diagnose obstruction. These discrepancies are related primarily to the intermittency of the obstruction. Intrinsic obstructions are almost always present, whereas extrinsic obstructions are not active at all times, but instead fluctuate depending on the renal pelvic volume. Renal function and the ability of the kidney to initiate and sustain a diuresis are thus major factors in determining the timing and extent of pelvic overdistention and if obstruction becomes activated.

The diagnosis of obstruction can be particularly difficult in cases of intermittent obstruction, especially if the pelvis is minimally or not dilated between episodes of overdistention because diagnostic tests may simply report that urine flows freely across the UPJ. In this setting, successful diagnosis often requires provocative testing during ultrasound or excretory urography with fluid loading to induce a diuresis; dynamic studies such as diuretic renography or Whitaker's pressure-perfusion test also may be particularly helpful in provoking or sustaining pelvic overdistention (68). Occasionally, testing must be performed during an episode of pain because this is the only way to actually prove the diagnosis (76).

Presentation

In cases of symptomatic UPJ obstruction, the presenting signs and symptoms depend on the age of the patient. Pain, hematuria, or urinary infection is more common in older children, whereas infants usually present with a palpable abdominal mass (56,117,139). The pain often simulates gastrointestinal disease, especially if it is intermittent and associated with vomiting. Hematuria, which often occurs after mild abdominal trauma, is particularly significant because it reflects an increased susceptibility of the already dilated kidney to injury. Episodic intermittent flank pain associated with increased fluid intake is another recognizable presentation pattern that suggests sudden overdistention of the renal pelvis associated with diuresis. Congenital anomalies are commonly associated with UPJ obstruction and may occur in up to 50% of patients (71,102,135); however, genitourinary tract abnormalities usually are seen in only 10% of patients (56,117).

Diagnostic Evaluation

Most cases of perinatal hydronephrosis are not symptomatic and are detected initially by ultrasonography. UPJ obstruction is suspected when the pelvis is enlarged and the ureter is not dilated. In this age group, a voiding cystogram is required to exclude vesicoureteral reflux, which can produce renal pelvic and calyceal dilation indistinguishable from obstruction. In older patients, an excretory urogram is often the first study to identify hydronephrosis. The pattern of hydronephrosis caused by UPJ obstruction has a characteristic radiographic appearance; the pelvicalyceal system is dilated, contrast transitions abruptly at the UPJ and the ureter is either nonvisualized or of normal caliber (Fig. 47.32). These diagnostic findings also may be produced by (a) obstruction at the ureterovesical junction with incomplete visualization of a dilated ureter, (b) lower urinary tract obstruction, or (c) vesicoureteral reflux. To exclude these other causes, one should obtain delayed filming (during excretory urography) and perform voiding cystography. However, visualization of a normal ureter on delayed films does not exclude significant urinary obstruction, nor does identification of reflux or a dilated ureter exclude coexisting obstruction at the UPJ.

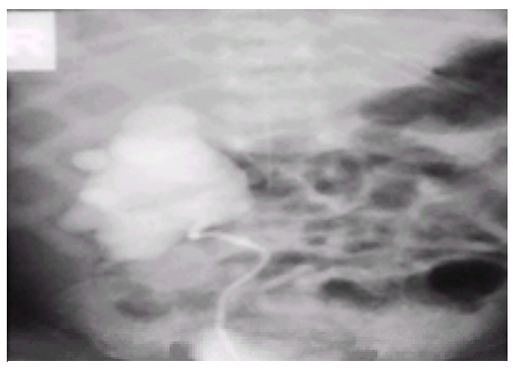

FIGURE 47.32. UPJ obstruction demonstrated by retrograde pyelogram illustrates characteristic features. Pelvicalyceal dilation and abrupt transition at ureteropelvic junction to normal-caliber ureter are noted.

Reflux associated with hydronephrosis may present particular diagnostic difficulty (Fig. 47.33). If there is trapping of urine in the pelvis following voiding and pelvic dilation persists, UPJ obstruction may coexist. In this setting, a diuretic renogram may be able to determine if primary UPJ obstruction also exists, but it must be performed using a continuously draining bladder catheter to allow the UPJ to be analyzed independent of the reflux by eliminating any reflux-induced pelvic overdistention. The use of diuretic renography and constant perfusion pressure flow testing also are required whenever the diagnosis of UPJ obstruction is equivocal (64,94,138). A more detailed discussion of the application of diagnostic tests in the diagnosis of hydronephrosis is presented in Chapter 48B.

FIGURE 47.33. When mild reflux is associated with pelvic hydronephrosis, ureteropelvic junction (UPJ) obstruction may coexist even though refluxed urine crosses the UPJ. A postvoiding study is required. If hydronephrosis persists, diuretic renography performed with a continuously draining bladder catheter is required.

Before surgical treatment of UPJ obstruction, it is necessary to prove that the ureter is normal in caliber and not obstructed. In some cases this information can be obtained by visualization of a normal ureter on excretory urography or noting normal ureteral transport and size at renography. When required, precise anatomic delineation of the ureter, pelvis, and UPJ before surgery may be obtained by retrograde or antegrade pyelography.

Prognosis

The prognosis for kidneys obstructed at the UPJ is generally good when surgery is performed in childhood. Anticipated renal recoverability generally correlates inversely with the age of the patient and with the duration and severity of obstruction and the extent of renal injury. Because of the unpredictably great potential for renal recoverability in young children, reconstructive surgery is almost always performed in childhood with nephrectomy reserved for only the most hopelessly damaged and dysplastic specimens.

RENAL VASCULAR ANOMALIES

Aberrant and Accessory Vessels

Normal vascular anatomy of the kidney and its variations are described and discussed in Chapter 1. In addition to normal variations, two anomalies of blood supply must be recognized: aberrant and accessory renal vessels. The term *aberrant* should be reserved for arteries that originate from vessels other than the aorta or main renal artery (43). True aberrant vessels are rare except in association with anomalies of renal position and fusion such as renal ectopia and horseshoe kidney, in which they may arise from a number of nearby major arterial trunks.

Accessory renal arteries are multiple arterial branches supplying the same renal segment. They occur rather frequently (23%) and are more common on the left side (Fig. 47.34). Accessory arteries enter the lower pole twice as frequently as the upper pole and typically pass caudal to the main renal artery (4).

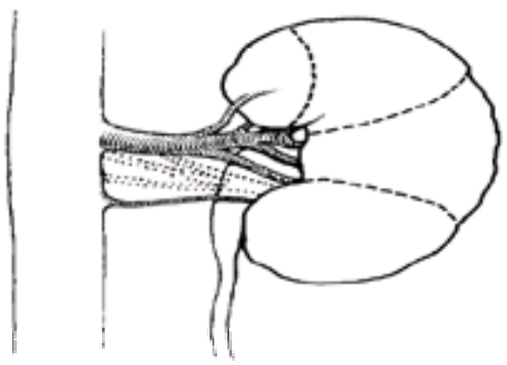

FIGURE 47.34. Accessory renal arteries more commonly supply lower pole of left kidney.

Vascular anomalies typically become clinically significant only when they interfere with urinary drainage to produce symptoms or to create unexplained filling defects on the excretory urogram. Characteristic vascular-induced patterns include UPJ obstruction due to an aberrant or accessory vessel to the lower pole and superior infundibular compression producing calyceal enlargement and pain.

Renal Arteriovenous Malformation and Fistula

Arteriovenous malformation (AVM) and fistula (AVF) of the kidneys are direct communications between the renal arteries and veins via enlarged, tortuous vascular spaces (123). AVF is most common and is usually acquired as a result of renal biopsy or trauma (Fig. 47.35). Congenital AVM of the kidney is rare and usually presents in adulthood, more commonly in women (3:1) and in the right kidney (133). Two types have been described: (a) *cirsoid* (resembling varices) with multiple vascular communications (38) and (b) *aneurysmal* with a single cavernous channel and a well-defined arterial and venous element (141). Congenital AVM accounts for 25% to 30%; the rest are acquired secondary to arteriosclerosis, neoplasia, fibrodysplasia, or trauma, especially renal biopsy (53,74,123). Although many AVM remain asymptomatic, their presentations reflect the local and system disturbances caused by each lesion. Hematuria is common and is probably related to the proximity of the anomaly to the pelvicalyceal wall. As the lesion enlarges and shunting increases, the perfusion of renal parenchyma decreases, leading to renin-mediated hypertension. In addition, large fistulae can produce high output cardiac failure, an abdominal mass, or flank pain (74). On physical examination, a loud bruit is often heard in the abdomen. Some lesions have been reported to affect renal function and cause polyuria and electrolyte abnormalities (141).

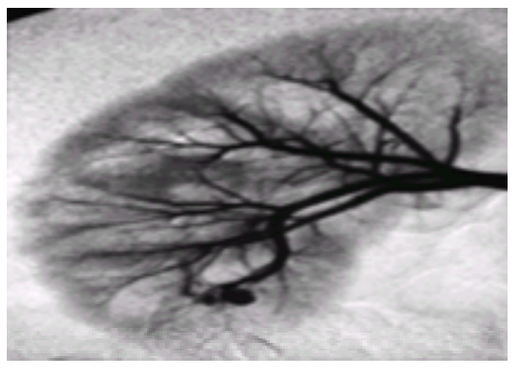

FIGURE 47.35. Selective renal arteriogram performed after renal biopsy demonstrates an arteriovenous fistula in the lower pole of the right kidney.

Intravenous urography may be normal in up to 50% of patients. In others it can show characteristic findings such as a segmental or generalized reduction in renal function, distortion of calyces or pelvis by an enlarging mass, and filling defects caused by clots. Renal ultrasonography of these lesions typically reveals anechoic structures located within the kidney in association with an enlarged renal vein (22). Ultrasound with color Doppler (USD), CT, and MRI also may suggest the diagnosis; however, arteriography remains the gold standard for diagnosis (74,123). The diagnosis of renal AVM is typically made by selective angiographic studies (137). Tortuous vascular channels, shunting with early filling of venous vessels, and an enlarged renal vein are pathognomonic (137,141) (Fig. 47.36). Visualization of the inferior vena cava within seconds of the arteriogram phase is considered the hallmark of renal AVM. Importantly, arteriography provides the opportunity not only to diagnose but also to simultaneously treat the lesion with transcatheter embolization (137).

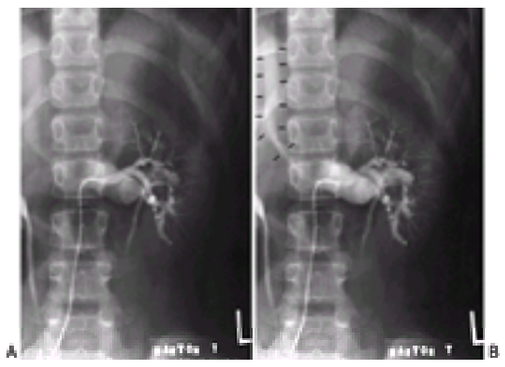

FIGURE 47.36. Arteriovenous fistula involving lower pole of left kidney visualized by selective arteriography. **A:** Early injection film shows tortuous vascular channels and early filling of enlarged renal vein. **B:** Later film shows prominent, dilated renal vein and contrast in inferior vena cava.

Treatment of renal AVM depends on the etiology, symptoms, size and location, and presence of associated renal artery disease (137). Small asymptomatic lesions can be managed nonoperatively, especially because angiographic evidence of spontaneous closure has been reported. Nonoperative management is especially suited for postrenal biopsy AVF, with embolization usually reserved for excessive bleeding requiring multiple transfusions. Medium and large symptomatic fistulae have been treated successfully with percutaneous transluminal embolization or surgical resection requiring partial or total nephrectomy (123,137). Recent reports with long-term follow-up of transcatheter embolization of cirsoid AVM describe excellent results (123). Excision may be more appropriate for large lesions with associated arterial disease, those that fail embolization, or if a malignancy is suspected.

Renal Artery Aneurysm

Renal artery aneurysms (RAAs) occur with equal frequency in both sexes and have been reported in all age groups (1 month to 82 years). Approximately 80% are unilateral, 17% are intrarenal, and in 30% of patients, the lesions are multiple. Two morphologic types of RAA are commonly described: saccular (most common type) and fusiform.

The clinicopathologic classification of pediatric aneurysms suggested by Sarkar and associates characterizes aneurysms into two broad categories, true aneurysms and false aneurysms (107). True aneurysms contain all three layers of the arterial wall and may be congenital or acquired. In false aneurysms, the wall contains fewer than the three normal layers, usually none (45). This classification is appropriate for RAAs when true RAA can be further classified into aneurysms associated with (a) arterial infection, (b) giant cell aortoarteritis, (c) autoimmune connective-tissue disorders, (d) Kawasaki's disease, (e) Ehlers-Danlos and Marfan syndromes, (e) arterial dysplasia, (f) other forms of noninflammatory medial degeneration, and (g) congenital or idiopathic factors. The second main category, false aneurysms, are those associated with extravascular events causing vessel wall injury or disruption (107).

The incidence of RAA in children is less than in adults (15). Congenital RAA are usually recognized in children younger than 5 years of age. The presence of all three layers of the vessel wall without arteritis is necessary to confirm the diagnosis. However, most RAAs in children are of the acquired type and specifically represent renal artery dysplasia (45). This condition affects only the renal arteries and usually is associated with renal artery stenosis and hypertension. It is typically diagnosed by arteriogram performed to evaluate hypertension and is treated by surgical excision. Trauma and infection are also common causes of pediatric RAA, and even in children, some of these aneurysms can reach a large size (8 cm) (45,87).

The presentation of children with RAA is dependent on the size and location of the lesion. Most aneurysms are small and silent; however, when they are symptomatic they may be associated with hematuria, abdominal pain, or most commonly, hypertension. Arteriography remains the diagnostic test of choice for RAA, especially if surgical intervention is considered (72,87) (Fig. 47.37). However, because of the size and character of these lesions, less invasive imaging using USD, CT, and MRI is useful in the initial investigation of RAA because of the better sensitivity and specificity (15,87). USD typically shows a cystic (hypoechoic) lesion near the renal artery with arterial pulsation (59). CT findings include a cystic lesion that enhances simultaneously with the aorta.

FIGURE 47.37. Selective renal arteriogram in a 12-year-old girl with severe hypertension reveals saccular renal artery aneurysms.

Treatment of RAA depends on symptoms, etiology, size, and location of the aneurysm as well as associated renal artery disease. Several authors recommend nonoperative management for asymptomatic RAA because the risk for rupture is extremely small and spontaneous cure (thrombosis) has been reported (50,70). In a study of more than 36,000 autopsies in Sweden, Tham and associates (126) found no case of death due to ruptured RAA. Small RAA due to vasculitis may be treated medically (45). Also, small intrarenal aneurysms have been treated with transcatheter embolization even in children (72). Most other types of RAA are usually treated by surgical resection using standard vascular techniques (15,87,107).

Renal Artery Stenosis

Renal artery stenosis (RAS) in children is one of the most common causes of pediatric renovascular hypertension (RVH), can have either a congenital or acquired etiology, and may occur as an isolated lesion or be part of a systemic disease. Neurofibromatosis and Williams syndrome are examples of systemic conditions that can be associated with congenital RAS (92). Acquired lesions include fibromuscular dysplasia, anastomotic stenosis, and renal artery trauma, whereas Takayasu's arteritis, Kawasaki syndrome, Marfan syndrome, Alagille syndrome, and midaortic syndrome (MAS) are systemic conditions associated with RAS (26,92,101).

The signs and symptoms of children with RAS reflect hypertension with headache, palpitation, irritability, epistaxis, encephalopathy, retinopathy, and congestive heart failure. An abdominal bruit may be heard on examination (101). Although no laboratory tests are specific for the diagnosis of RAS, selective renin sampling may be useful if the patient is hypertensive. Determination of the erythrocyte sedimentation rate (ESR) may help guide the timing of operative intervention in children with arteritis because it is recommended that surgery not be performed during the active inflammatory phase of the disease (92).

In hypertensive children with suspected RAS, several different imaging studies can be used initially, including USD, captopril renography, MRI, and CT with and without angiographic phases and arteriography (92). Currently, reports on the accuracy of captopril renography and color Doppler in diagnosing RAS in children are insufficient to draw conclusions. We recommend ultrasound initially because it is noninvasive, can detect other urologic anomalies, and in experienced hands, suggests the diagnosis of RAS in the majority of patients (46). However, the gold standard for the diagnosis of RAS is selective renal arteriography, which has a sensitivity of 98% (92) (Fig. 47.38). A large percentage of children with RAS have involvement of segmental or distal branches that are better defined with an angiogram. Angiography also allows for simultaneous transluminal balloon angioplasty (dilation) of nonostial lesions.

FIGURE 47.38. Arteriogram of a hypertensive child with proximal right renal artery stenosis.

In cases of medial fibrodysplasia producing arterial stenosis and hypertension, the treatment of choice is percutaneous transluminal angioplasty (PTA) or surgical bypass, depending on the specific arterial anatomy. The results of angioplasty are best when the lesions are in the midportion of the main renal artery or in its segmental branches. Angiography should be attempted when the lesion is in this favorable location. However , many children have lesions affecting the ostia, a location that is better treated with surgery (92,101). Angiography should be attempted when the lesion is in a favorable location or when associated with nonspecific aortoarteritis (114). Tyagi and co-workers (131) reported a 91% success rate in 35 children with renovascular hypertension treated with PTA.

Midaortic Syndrome

Midaortic syndrome (MAS) is a relatively rare condition that involves segmental narrowing of the distal thoracic and/or abdominal aorta, including the visceral and renal arteries. Other names have been given to this condition, including subisthmic coarctation, abdominal coarctation, mesenchymal disease of neurofibromatosis, and aortoarteritis (95). Typically, these patients present in their second decade of life with severe hypertension, an abdominal bruit, and absent or diminished femoral pulses (101). Diagnosis requires arteriography, and renal revascularization is required (Fig. 47.39).

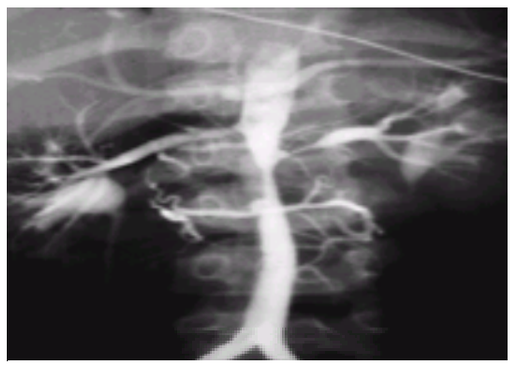

FIGURE 47.39. Preoperative aortogram in a child with midaortic syndrome demonstrates segmental narrowing of the infrarenal aorta and left renal artery stenosis.

TERMINOLOGY

A standard set of definitions used to describe ureteral duplication anomalies was established by the Urologic Section of the American Academy of Pediatrics Committee on Terminology, Nomenclature, and Classification (64). A *duplex (duplicated) system* refers to a kidney with two pelvicalyceal systems. If this kidney has two ureters that empty separately into the bladder (double ureters), it is considered a *complete duplication.* A duplex system may also have a partial or incomplete duplication, in which case a single ureter enters the bladder. A *bifid system* is a form of duplication with two pelvicalyceal systems joining at the ureteropelvic junction (bifid pelvis) or before emptying into the bladder (bifid ureters).

The *upper* or *lower pole ureter* describes the ureter draining the upper or lower pole of a duplex kidney. The orifice associated with the ureter draining the upper or lower pole is known as the *upper* or *lower pole orifice,* respectively. A *laterally ectopic* ureter inserts lateral to the normal position and a *medially* or *caudally ectopic ureter* inserts medial and distal to the normal position on the trigone. An *ectopic ureter* drains to an abnormal site and generally refers to an orifice located medially or caudally.

A ureterocele consists of a cystic dilation of the intravesical submucosal ureter. Ureteroceles contained entirely within the bladder are called *intravesical ureteroceles*. *Ectopic ureteroceles* contain a portion permanently situated at the bladder neck or urethra. A *single-system ureterocele* is associated with a kidney with only one ureter. A *duplex-system ureterocele* is associated with the upper pole of a kidney with a complete ureteral duplication. Ureteroceles can be characterized further as stenotic, sphincteric, sphincterostenotic, cecoureteroceles, blind, and nonobstructive, as suggested by Stephens (163).

EMBRYOLOGY AND PHYSIOLOGY OF THE URETER
