Advances in molecular biology have aided our understanding of the immunobiology of organ transplantation and rejection. A *locus* is the location of a gene on a chromosome. *Alleles* are alternative forms of a gene at a given locus on homologous chromosomes. The *major histocompatibility complex* (MHC) is a series of cell surface antigens encoded by closely linked genes. A *haplotype* is the sum of genetic material or unit of inheritance contributed by each parent. Each individual inherits a distinct haplotype from each parent. The *phenotype* is the total histocompatibility antigens expressed by an individual without distinguishing which antigens are maternally or paternally derived. The *genotype* is the total of histocompatibility antigens expressed by an individual, designating the maternal and paternal contributions.

Many of the basic observations on transplant rejection were made through research into the mechanisms of tumor resistance. Following is a brief historical review of some of the investigators who have advanced our current knowledge of transplant immunobiology. In 1902, Carrel and Guthrie, during the development of vascular suture techniques, performed canine kidney autotransplants (same individual), allotransplants (members of same species), and xenotransplants (between species) (40). They observed that the autografts survived indefinitely, whereas the allografts and xenografts were rejected. Landsteiner (148) described the ABO blood group antigens. Haldane (103) theorized that transplanted tissues were rejected due to differences in alloantigens that were similar to differences in blood group antigens. Little and Tyzzer (156) noted that tumors survived when transplanted between mice of the same strain, but rejected when transplanted to other strains. Gorer (96), noting these observations, correlated these findings with the existence of an allelic blood group antigen that was able to be serologically detected. This important observation demonstrated that tumor rejection is not dependent on tumor-specific antigens, but on antigens present in normal tissues.

Snell (259) confirmed that it was the histocompatibility loci, and their encoded antigens, that account for both tumor and skin graft rejection. He reasoned that the distribution of these “transplantation antigens” followed a Mendelian pattern. Medawar (176) demonstrated that the rejection response was primarily a reaction rather than humorally mediated hypersensitivity. He performed full-thickness rabbit skin grafts and a few weeks later regrafts using the same donors into the same recipients, and demonstrated the phenomenon of accelerated rejection. Billingham and associates (22), expanding on the observations of Medawar, demonstrated the phenomenon of second set or accelerated rejection in recipients sensitized by prior exposure to the donor alloantigen (i.e., the more rapid rejection of a second graft from the same donor from which a first graft had been rejected).

Through the work of these and many other investigators, the field of clinical organ transplantation has evolved. However, the success of clinical renal transplantation currently rests on the use of drugs to achieve nonspecific immune suppression to prevent allograft rejection. The ultimate goal of organ transplantation is to induce the development of *donor-specific tolerance* (defined as the state of immune unresponsiveness to the donor MHC antigens, but the host maintains the ability to respond to other foreign antigens). Several hypotheses exist regarding mechanisms of tolerance induction, which has been observed primarily in animal models, but also anecdotally seen in transplant recipients who were taken off immunosuppressive medications for medical reasons or occasionally in noncompliant patients who stopped taking their medications. These include *clonal deletion*–elimination of immunoreactive T cells; *clonal anergy*–prevention of activation and proliferation of donor antigen–specific T cells; *suppression*– inducing other cells or mechanisms to prevent the triggering of a donor-specific immune response; and *chimerism*–persistence of a small number of hematopoietic cells of donor origin in the recipient (10). Although presently not a clinical reality, tolerance induction remains the goal of transplant research worldwide.

THE HUMAN MAJOR HISTOCOMPATIBILITY COMPLEX

The immune response of a patient when exposed to the “foreign” tissue of an organ transplant continues to represent the major barrier to success in spite of the many advances that have been made in immunosuppression. The human major histocompatibility complex is the primary target of immune-reactive cells that make up the rejection process. The MHC describes a region of genes that encode proteins that are responsible for the rejection of tissues between different species or between members of the same species. More important, these cell surface proteins serve as identity markers on cells interacting with T lymphocytes carrying out specific immune functions. The cell surface MHC markers are called human leukocyte antigens (HLAs) because they were first identified on white blood cells.

The HLA gene complex is found on the short arm of chromosome 6 (Fig. 22.7). Two classes of antigens, class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP), can be differentiated by their molecular structure and their tissue distribution. The class I HLAs consist of a 44-kDa, transmembrane glycoprotein a-chain that is noncovalently associated with b $_2$-microglobulin on the cell surface. These molecules are found in varying densities on essentially all cells in the body. HLA class II molecules are made up of two transmembrane glycoproteins, an a-chain of approximately 34 kDa and a b-chain that is slightly smaller (28 kDa). Their tissue distribution is much more restricted than that seen with class I. The B lymphocytes, which express both class I and class II, are commonly used to identify class II antigens in the laboratory. The involvement of HLA class II in transplant rejection results from the presence of these molecules on the surface of vascular endothelial cells of the graft, as well as on “passenger leukocytes” that are present in the organ.

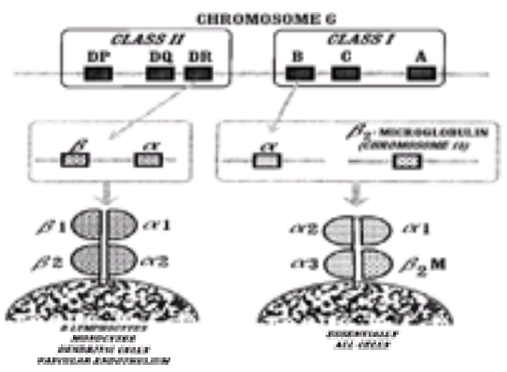

FIGURE 22.7. A simplified illustration of HLA genes and molecules.

The MHC genes are codominantly expressed, meaning that each individual expresses the HLAs that are inherited from either parent. What makes this system unique is the degree of polymorphism that is found, resulting in a great many alleles or variants of these antigens that have been identified in the population. Table 22.2 illustrates the HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ antigens that can be identified using standard lymphocytotoxicity methodologies. Using polymerase chain reaction (PCR)–based DNA-level testing, it is becoming abundantly clear that the degree of polymorphism is much greater than was previously thought. In 1994, the numbers of alleles that had been identified at the DNA level included 50 at HLA-A, 97 at HLA-B, 34 at HLA-C, 106 at HLA-DR, 26 at HLA-DQ, and 59 at HLA-SP (24). All of the class I polymorphism is found in the a-chain, b $_2$-microglobulin being invariant, and the number of class II alleles given are for the b-chains, which are much more polymorphic than the class II a-chains.

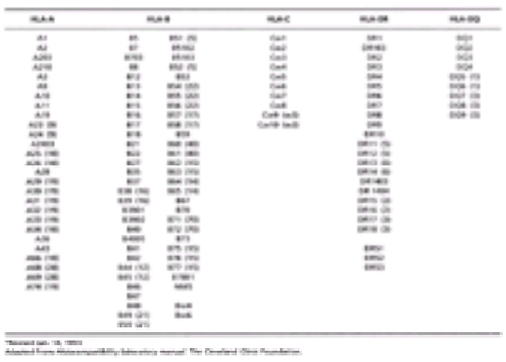

TABLE 22.2. LISTING OF RECOGNIZED HUMAN LEUKOCYTE ANTIGEN SPECIFICITIES*

One other system that plays a major role in histocompatibility is the ABO blood group antigens. Incompatibility at ABO can result in hyperacute rejection of a transplanted organ. The same general rules that apply for transfusion are relevant for transplantation (i.e., type O is the universal donor, type AB is the universal recipient, and so on), and confirmation of ABO compatibility should always be performed before transplantation of an organ.

HISTOCOMPATIBILITY TESTING FOR TRANSPLANTATION

Three areas of histocompatibility testing are relevant for organ transplantation: (a) the typing of patient and donor to determine the degree of *match;* (b) assessment of the level of *sensitization* to HLAs in patients who have been exposed to foreign antigens via pregnancies, transfusions, or transplant; and (c) *crossmatching,* in which the serum of the patient is examined for the presence of preformed antidonor antibodies that would be potentially harmful to the graft. By examining all of these factors, it is possible to assess the degree of risk for rejection in a particular donor–recipient combination.

The mainstay of histocompatibility testing is the complement-mediated, lymphocytotoxicity assay (285). This technique involves the incubation of lymphocytes with antibodies that react with HLAs, addition of a source of complement that results in lysis of the cells if antibody is bound to their surface, and the scoring of cell death using a vital stain. T lymphocytes, which express HLA-A, HLA-B, and HLA-C, are used only for class I typing, and B lymphocytes, which express class II, are used to identify HLA-DR, HLA-DQ, and HLA-DP. The sources of HLA reagents include allosera obtained from sensitized individuals as a result of pregnancy, transfusion, or transplant rejection, and in some cases monoclonal antibodies specific for HLA. Because individuals are seldom exposed to a single mismatched HLA, a considerable amount of screening of sera is required to obtain reagents appropriate for HLA typing. HLA typing at the DNA level is a rapidly developing technology that holds much promise (204). Here it is the nucleotide sequences of the DNA that are identified, rather than the epitopes found on the HLA molecules that recognized using antibodies. Once the DNA sequence of an HLA molecule is determined, it is relatively simple to produce reagents that can identify the polymorphic sequences. This general approach has almost unlimited potential for the identification of the many HLA alleles.

Individuals inherit one set, a haplotype, of HLAs from each of their parents. Therefore matching for HLA involves two antigens each at three HLA loci. Most data regarding HLA matching have included antigens at the HLA-A, HLA-B (class I), and HLA-DR (class II) loci, including anywhere from zero to six antigens matched. However, for solid organ transplantation, the concern is to avoid mismatched antigens that the patient would recognize as foreign. Therefore assessing the number of mismatches is the more appropriate method for determining compatibility at HLA in solid organ transplantation. Sometimes fewer than six antigens are identified, which may result from an individual who inherits the same antigen at a particular locus from each parent (homozygous).

Presensitization to HLAs is the major obstacle faced by many kidney transplant candidates. The same events that provide potential sources of HLA reagents in some individuals, such as pregnancy, transfusion, and transplant rejection, may sensitize a potential transplant candidate. To assess the degree of presensitization, a patient's serum is tested against a panel of lymphocytes from individuals of known HLA type, using essentially the same lymphocytotoxicity assay used for HLA typing. A value is obtained, the percent panel reactive antibody (PRA), that represents the percentage of the population that the patient's serum would be expected to react against. Many laboratories take this a step further, identifying HLA specificities of the antibodies, as well as identifying HLAs that the patient does not have antibodies

against and therefore would be “acceptable” mismatches for the patient. In general, sera are obtained and screened on a monthly basis for patients waiting for a kidney transplant. The PRA may vary from month to month, necessitating frequent antibody screening to provide current information should a donor become available. Patients not previously exposed to HLAs may be screened at longer intervals, assuming that it is possible to document changes in their status (e.g., transfusion).

Perhaps the most important activity of the histocompatibility laboratory is performing the crossmatch test. It has been known for years that the presence of antidonor antibodies, particularly IgG, anti–T cell (class I) reactions, is associated with a significant risk of hyperacute rejection (209). The class of antigen recognized by the antibodies (class I or II) by using T and B cells as targets can be determined, as can the class of antibody (IgG or IgM) using a variety of permutations of the lymphocytotoxicity technique. Not all types of antibody reactions are associated with a high degree of risk of rejection, so characterization of the reaction can assist in determining compatibility between patient and donor. Sometimes reactions may also be due to an autoantibody, which can be removed by absorption with “self” lymphocytes.

Standard crossmatching techniques have made hyperacute rejection a rare occurrence. However, the observation that a number of transplants resulted in grafts that never functioned and that this was more likely to occur in presensitized recipients has led to the development of more sensitive crossmatching techniques. Two approaches use antibody reagents that bind to human IgG to enhance the sensitivity. In the antiglobulin crossmatch, a second anti-IgG antibody is used, allowing the detection of weak reactions and those involving noncomplement-binding IgG using lymphocytotoxicity. The flow cytometry crossmatch uses a fluorescent-labeled anti-IgG reagent, and the binding of the patient's antibodies, not the donor lymphocytes, is measured using a flow cytometer. Both the antiglobulin approach (137) and the flow cytometry technique (51) can be used to identify patients who are at high risk of graft loss, and these techniques are especially effective in cases involving retransplants.

Using the information provided by the degree of mismatch, the PRA information and the crossmatch allow an assessment of the degree of compatibility between patient and donor. In general, an extremely well-matched graft, such as an O-A, B, DR antigen mismatch, can be expected to do well. An antibody specificity against a donor antigen found in a recent serum is of more concern than one from months or years before the transplant, particularly if there is crossmatch activity (115). In terms of crossmatch reactivity, IgG is of more concern than IgM, T cell (class I) more than B cell (class II), and recent serum more than historical (114); reactions involving autoreactive antibodies, which are often IgM, do not appear to be deleterious. Essentially all transplants involve some degree of risk of rejection, but using the histocompatibility results can help avoid recipient–donor combinations at the greatest risk.

MECHANISMS OF IMMUNOLOGIC RESPONSE—ANTIGEN RECOGNITION; CELLULAR AND HUMORAL RESPONSE

The purpose of the immune system is to protect the host by identifying and eradicating potentially harmful invaders and foreign substances. The cells and molecules responsible for immunity constitute the immune system, and their collective and coordinated response to the introduction of foreign substances is called the immune response. The immune response can be divided into nonspecific-innate immunity and specific-adaptive immunity. The nonspecific arm includes cells such as neutrophils and macrophages, which can phagocytose pathogens, and inflammatory molecules such as complement, which can directly kill cells. The specific arm of the immune system by contrast is able to selectively identify foreign molecules and respond and adapt to only those foreign cells. Furthermore, the specific arm exhibits memory, such that reexposure prompts a more rapid and vigorous response. It is the specific arm of the immune system that is most important in transplant rejection (296).

Adaptive immunity can be further divided into humoral (antibody) and cellular components. The humoral response derives from B cells that recognize foreign antigens via antibody receptors on the B-cell surface. When activated, the B cell matures into a plasma cell, which secretes a large quantity of its specific antibody. When a pathogen is coated by these specific antibodies, cell death can occur by complement activation or phagocytosis by other cells that recognize and bind to the “tail” of the antibody (opsonization). In organ transplantation, the presence of “preformed” antibodies in the recipient that are specific for the donor organ results in the rapid destruction of the organ (hyperacute rejection). These antibodies bind immediately to the vascular endothelium of the graft and trigger complement-dependent cytotoxicity, eventually leading to complete vascular thrombosis.

The T lymphocyte is the central component of the cellular arm of the immune response (298). T cells recognize protein antigen through their T-cell receptor only after an antigen has been processed into peptide fragments and presented on carrier MHC molecules by antigen-presenting cells (APCs). Intracellular antigens are usually presented to T cells by class I MHC molecules. Extracellular antigens, however, must first be phagocytosed by a specialized APC such as a macrophage or dendritic cell, which presents peptides bound to class II MHC molecules. The result is that the T cell must recognize both MHC and peptide in a particular arrangement for antigen-specific activation to take place (Fig. 22.8). The types of responses are also controlled by the specificity of the MHC antigens on the APCs themselves. Those T cells bearing CD8 that are programmed to be cytotoxic require APCs to present antigen in context of MHC class I molecules; those T cells bearing CD4 that are programmed to become helper T cells require antigen to be presented in context of MHC class II molecules (178).

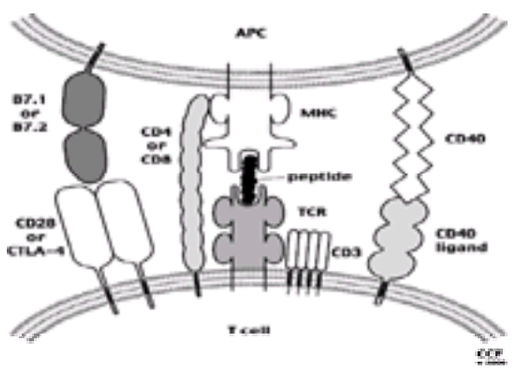

FIGURE 22.8. Presentation of foreign peptide antigen to host T cell. Signal 1 delivered as peptide is processed and presented in MHC groove of APC to T-cell receptor. Signal 2 is delivered by APC costimulatory molecule B7 or CD40 to T-cell ligand CD28 or CD40 L, respectively. T cell CD4 or CD8 molecule stabilizes the interaction.

The overall scheme of allograft rejection can be divided into five stages:

1. Antigen recognition
2. T-cell activation—requires two signals
3. Signal transduction and cytokine release
4. Cellular differentiation and proliferation
5. Target cell destruction

Graft alloantigens provide a unique potential for host T-cell activation because they themselves serve both as immunogens and as components of the activation mechanism. When a kidney is transplanted into a recipient, it brings with it an array of tissue-bound class I and II MHC molecules, as well as antigen-presenting cells. These APCs are included in the group of donor-derived white cells referred to as *passenger leukocytes,* which can be adherent to blood vessels or within the interstitial tissues. The activation of recipient T cells requires two distinct signals. Signal 1 requires the presentation of the peptide–MHC complex on an APC to the T-cell receptor of a resting T cell. Signal 2 is a costimulatory signal that is transmitted by surface glycoproteins on the APC, which interact with their ligand on the T-cell surface. The most important costimulatory signals are the B7 or CD40 molecules on an APC binding to their T-cell surface ligands CD28 (or CTLA-4) or CD40 ligand (CD154), respectively. The triggering of the T-cell receptor by signal 1 alone leads to anergy or nonresponsiveness. An APC that provides both signals 1 and 2 leads to activation of protein kinase C and other signal transduction pathways in the T cell. The resting T cell then progresses through the cell cycle from the “G_0” phase to clonal proliferation.

The immune response is provided two distinct pathways for allorecognition (99). A *direct presentation* pathway is provided by *donor APCs,* which present peptide–MHC complexes to recipient T cells. The foreign MHC molecules presented to the recipient can be a myriad of alloantigens, including the allogenic MHC molecule itself plus the many different peptides derived from endogenous proteins. Direct presentation is thought to be responsible for early acute rejection episodes.

The recipient can also engage alloantigens through the *indirect presentation* pathway dependent on *recipient APCs.* Indirect presentation requires the uptake and processing of donor MHC molecules (to form peptide fragments) by recipient APCs, which present peptide–MHC complexes to the recipient T-cell receptor. Peripheral recipient APCs migrate to the graft to pick up soluble donor MHC molecules for processing. The actual site of indirect pathway T-cell activation occurs in recipient lymph nodes and is thus “self” MHC restricted. The indirect route becomes more important with time as donor APCs (required for direct recognition) diminish by senescence. The indirect pathway is thought to be more important for the development of chronic allograft rejection.

Once the recipient immune system is activated, the allograft can be attacked by several mechanisms. Recipient CD8 T cells that recognize foreign MHC class I molecules can directly damage donor cells by drilling holes in their cell membranes with a class of molecules called perforins (133). Some cytokines released by CD4 T cells can damage the allograft directly, such as tumor necrosis factor-a. Natural killer (NK) cells, which are not MHC specific but which are attracted during the immune response by opsonins, can also cause direct cell damage. Antibodies produced by B cells can fix complement, attract platelets, and destroy the organ through vascular rejection.

MODIFICATION OF THE IMMUNE RESPONSE—PREVENTION OF REJECTION

Blood Transfusion Effect

For more than 30 years, the effect of blood transfusions in renal transplantation has been investigated and debated. As clinical transplantation has developed, the policies and practices regarding the avoidance or use of blood transfusions has changed dramatically on several occasions. Before 1973, transfusions were avoided in dialysis patients awaiting transplantation because of concern that they would develop deleterious antibodies (sensitization), which would have an adverse impact on success (16). Opelz and colleagues (205) described improved results in a large number of recipients who had received transfusions compared with those who had not been transfused. Subsequently, numerous reports revealed a 10% to 20% improvement in graft survival in transfused patients and a near-uniform policy of all patients receiving at least two to five transfusions before transplantation was adopted. However, over the ensuing years, refinements in HLA typing and crossmatching, as well as the development of new immunosuppressive medications, especially cyclosporine, appeared to diminish the transfusion effect. As Fig. 22.9 indicates, no discernible difference has been seen between transfused and nontransfused recipients of first cadaver transplants since 1988 (286).

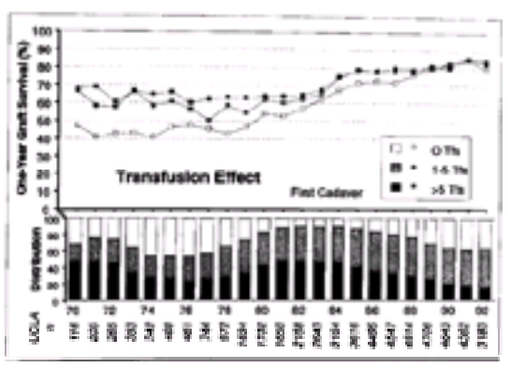

FIGURE 22.9. Effect of blood transfusions in recipients of first cadaver transplants by year, 1970–1992, demonstrating no benefit since 1988. (From Terasaki PI, Yuge J, Cecka DW, et al. Thirty year trends in clinical kidney transplantation. In: Terasaki PI, Cecka JM, eds. *Clinical transplants, 1993.* Los Angeles: UCLA Tissue Typing Laboratory, 1994, with permission.)

Similar results have been reported relative to the use of transfusions in recipients of living-related renal transplants. Salvatierra and colleagues (243) demonstrated that donor-specific (blood from the intended donor) transfusion greatly improved results in recipients of 1-haplotype–matched kidneys. This benefit was substantiated as donor-specific transfusion (DST) protocols became commonplace. Again, however, the transfusion benefits appeared to wane with the introduction of newer immunosuppressive medications (77). The major disadvantages of transfusions include the possible transmission of viral diseases and sensitization of the patient to disparate HLA phenotypes. In addition, the availability of synthetic erythropoietin (66) has led to a substantial reduction in the number of centers currently using pretransplant transfusions.

Immunosuppressive Agents

As the molecular events in the alloantigen processing pathways have become more apparent, so has the nonspecificity of long-standing immunosuppressive therapy whose toxicities have derived from the broad impact on the body's immune system (“overimmunosuppression”). Although the ideal immunosuppressant that selectively targets only specific steps in allograft rejection while sparing all other immunologic components is not yet available, numerous promising agents are being investigated. The chemical structures of agents in current clinical use, as well as newer ones being studied, are depicted in Fig. 22.10, Fig. 22.11 and Fig. 22.12. Their proposed mechanism of action, available results, and toxicities are reviewed next; several more comprehensive reports are available (106,279,293,296).

Chemical Immunosuppression

Corticosteroids

Since the initial observations more than 35 years ago that corticosteroids could prevent and treat renal allograft rejection (120), they have become the cornerstone of immunosuppressive therapy. Corticosteroids have numerous effects on the immune system (294), and their effect on T lymphocytes appears greater than that on B lymphocytes. Sequestration of lymphocytes in lymph nodes and the bone marrow results in the often observed lymphopenia. Glucocorticoids become bound to intercellular receptors, and conformational changes in the steroid–receptor complex allow for genetic interference with cytokine production. The primary immunosuppressive affect of corticosteroids is inhibition of production and monocyte release of interleukin (IL)-1with subsequent inhibition of IL-2 and interferon-g, thus interfering with lymphocyte activation and production of effector cells.

Systemic toxicities of corticosteroids, including cushingoid features, hypercholesterolemia, hyperlipidemia, hyperglycemia, weight gain, aseptic necrosis of bone and osteoporosis, poor wound healing, growth retardation, psychiatric disturbances, and increased susceptibility to infection, are known to all clinicians and have resulted in intense efforts to reduce steroid dosage. Alternate-day steroid dosing appears beneficial for growth in children (283), but complete steroid withdrawal appears more problematic. There have been several trials attempting to withdraw steroids form stable transplant patients (2,245). The benefits include lower blood pressure, improved lipid profiles, and diminished physical side effects attributed to steroids. However, early graft stability is often followed by acute rejection in about one-third of the patients. If attempted, withdrawal should be entertained in well-matched recipients, 1 year or more after transplant, with no prior episodes of rejection. Living-related recipients who demonstrate *in vitro* hyporesponsiveness to the donor can usually be safely withdrawn (77).

Antiproliferative Drugs

Azathioprine

Initial efforts with immunosuppression in renal transplant recipients occurred using 6-mercaptopurine and its imidazole derivative azathioprine (185). Azathioprine is metabolized *in vivc* to 6-mercaptopurine, and the antimetabolites block DNA synthesis by inhibiting purine synthesis and metabolism via competitive enzyme inhibition. Early proliferation, especially in rapidly dividing cells (lymphoblast), is inhibited, although there is no effect against activated lymphocytes (effector phase). As such, azathioprine is most effective if given immediately after antigen presentation to prevent rejection and is ineffective in treating ongoing rejection.

Adverse effects of azathioprine include myelosuppression with leukopenia and thrombocytopenia, alopecia, hepatotoxicity, cholestatic jaundice, and increased risk of infection and neoplasia. Toxicity from azathioprine will usually respond to dose reduction, although occasionally drug substitution is required. When compared directly with another antiproliferative agent, mycophenolate mofetil, azathioprine is not as potent in rejection prophylaxis. Therefore its use has been diminishing rapidly over the past few years.

Cyclophosphamide

Cyclophosphamide has historically been used in place of azathioprine, although it is much less commonly used today. It is an alkylating agent that is biotransformed by the hepatic microsomal oxidase system to active alkylating metabolites. It inhibits DNA replication and, like azathioprine, affects rapidly dividing cells and is most effective immediately after antigen presentation. Xenotransplants have renewed interest in cyclophosphamide's ability to block B-cell proliferation (268). Cyclophosphamide has a narrower therapeutic-to-toxic ratio than azathioprine, and adverse effects include myelosuppression with leukopenia, fertility disorders, and hemorrhagic cystitis.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF), developed specifically as an immunosuppressant, is a semisynthetic morpholinoethyl ester derivative of the fungal antibiotic mycophenolic acid (5). It is a noncompetitive inhibitor of the enzyme inosine monophosphate dehydrogenase, resulting in the inhibition of purine biosynthesis. MMF has markedly increased oral bioavailability compared with the parent compound mycophenolic acid, and it inhibits the proliferation of activated T and B cells and blocks antibody formation (225). It is thought to be more specific for lymphocytes, which rely primarily on *de novo* purine synthetic pathways. In experimental models, MMF prolongs the survival of skin, kidney, heart, and pancreatic islet allografts, as well as reversing ongoing rejection (183). Its role would seem to be as a substitute for azathioprine due to a decreased incidence of significant myelosuppression or hepatotoxicity. MMF is well tolerated at dosages up to 2,000 to 3,000 mg/day, with dose-related gastrointestinal (GI) disorders being its major toxicity. Initial multicenter trials comparing MMF with azathioprine in addition to cyclosporine and steroid maintenance therapy demonstrated a marked decrease in acute rejection episodes during the first year, from approximately 50% to 35% (107,262). However, patient and graft survival were not statistically different. Nevertheless, the diminished acute rejection rates translate into less clinical morbidity, and this agent has replaced azathioprine in many centers. *In vitro* MMF is a more potent inhibitor to B-cell responses than azathioprine, and it is hoped that this may have a beneficial effect on the development or severity of chronic rejection. Longer follow-up will be needed to confirm this hypothesis.

Antilymphocyte Drugs

Cyclosporine

One of the most significant advances in clinical transplantation was the isolation of cyclosporine from *Tolypocladium inflatum Gams,* a soil fungus, and the demonstration by Borel and colleagues (25) of its immunosuppressive properties, which were lymphocyte specific. Cyclosporine is a cyclic peptide that is soluble only in lipids or organic solvents. Detailed accounts of cyclosporine's proposed mechanisms of action, pharmacokinetics, results, and toxicities have been summarized (129).

Significant insight into mechanism of action was gained with the identification of immunophilins (cytosolic binding proteins). Cyclosporine binds to its specific immunophilin, cyclophilin, resulting in conformational changes and subsequent binding of calcineurin (105). Ultimately, the inhibition of calcineurin prevents the downstream gene transcription of IL-2 and other cytokines required for T-cell activation and proliferation (279). Thus cyclosporine is the prototype of a class of drugs now referred to as calcineurin inhibitors. Cyclosporine's actions are directed primarily toward T helper (CD4+) cells with less effect on other T-lymphocyte subsets,

and although the blockade occurs early in the lymphocyte activation pathway, it is slightly later than corticosteroid activity, thus allowing for synergistic therapy.

Initial clinical results with cyclosporine revealed significantly improved 1-year allograft survival in cadaveric recipients compared with conventional therapy with prednisone and azathioprine (37), and this improved 1-year allograft survival has withstood the test of time. Improved results led to enthusiasm to investigate cyclosporine monotherapy without steroids, although problems similar to those discussed previously for steroid withdrawal, including increased rejection and graft loss, have been experienced (282). Therefore the agent is most commonly administered in combination with steroids and an antiproliferative agent.

Despite the marked improvements seen and broad experience gained with cyclosporine, difficulties with its use continue to be encountered. Diminished bioavailability, especially in the immediate posttransplant period, and variable patient pharmacokinetic profiles have resulted in numerous dosing strategies (129), with both 12- and 24-hour schedules widely used. Cyclosporine is metabolized by the hepatic P-450 cytochrome system, and drugs that inhibit or stimulate this enzyme system can significantly affect cyclosporine blood levels, thus making it imperative for clinicians to be informed of drug changes and their interactions (147). Primarily related to the cost of cyclosporine, drugs with more pronounced inhibition of the P-450 system, including diltiazem and ketoconazole, have been used to increase cyclosporine blood levels, thus reducing the required dosage (89). The introduction of an oral encapsulated cyclosporine has improved patient compliance (56), and a new oral cyclosporine microemulsion appears promising in addressing these concerns. Neoral is a microemulsion formulation that has been demonstrated to have more consistent absorption (increased bioavailability) and diminished pharmacokinetic variability (256).

However, the most distressing component of cyclosporine has been its toxicity, especially acute and chronic nephrotoxicity. Acute cyclosporine nephrotoxicity is mediated by pronounced vascular and, to a lesser degree, tubular alterations (239) and is manifested by oligoanuria and azotemia, clinically indistinguishable from acute rejection, and severe acute tubular necrosis in the immediate post–cadaveric transplant setting (81). Associated hyperkalemia, hyperuricemia, hypertension, hypomagnesemia, and renal tubular acidosis can also occur. A dose-dependent reduction in renal blood flow and glomerular filtration rate occur in acute cyclosporine nephrotoxicity, and although data are somewhat confusing, it appears to be mediated through an imbalance of the prostaglandin-thromboxane system rather than the renin-angiotensin system (48,141). Unfortunately, the findings of cyclosporine-induced decreased levels of vasodilating prostaglandins and elevated levels of the potent vasoconstrictor thromboxane A_2 have not resulted in the identification of specific agents effective in ameliorating cyclosporine nephrotoxicity. A number of prostaglandin analogues have been evaluated, and although some have resulted in improvement in renal function, this has not been universal. A large, multicenter, prospective, randomized, double-blind study failed to demonstrate any difference in cyclosporine toxicity in patients receiving placebo or Enisoprost (1). Similar conflicting results have been reported with the use of thromboxane synthetase inhibitors (239), and further studies will be needed to assess the potential benefit of these agents.

A number of theoretic and observed properties render calcium channel blockers ideal candidates for the treatment of cyclosporine nephrotoxicity. In addition to reducing the dosage requirement, they are effective in treating the associated hypertension. The cyclosporine-induced renal mesangial cell uptake of Ca^{2+} and resultant enhanced contractility and vasoconstriction may well be blocked by calcium antagonists, which also reverse afferent arteriolar vasoconstriction. In addition to reducing cyclosporine nephrotoxicity, verapamil administration has been associated with fewer rejection episodes, possibly related to direct immunosuppressive actions (58).

Chronic nephropathy with progressive renal deterioration was encountered in early experiences with higher doses of cyclosporine. Fortunately, fears related to high rates of graft loss have not been realized, and stable renal function has been demonstrated with long-term cyclosporine use (153). Similarly, higher incidences of lymphoproliferative disorders, including non-Hodgkin's lymphomas, appear related to excessive dosages (212). Other adverse effects of cyclosporine include hepatotoxicity, hyperglycemia, hyperlipidemia, hirsutism, gingival hyperplasia, myalgias, arthralgias, and neurotoxicity (131). Dosage reduction will often mitigate against these effects, although it must be done carefully to avoid increased risk of rejection. Cessation of cyclosporine therapy, like steroid withdrawal, has been accompanied by increased rejection and even late graft loss (244).

Tacrolimus

Tacrolimus is a fungal macrolide antibiotic isolated from *Streptomyces tsukubaensis* with very similar effects on T-cell function as cyclosporine, and it is also classified as a calcineurin inhibitor. Like cyclosporine, it binds to a cytosolic receptor protein (FKBP, a distinctly separate immunophilin class), which leads to the inhibition of a transcription activator, necessary for lymphokine (e.g., IL-2) gene expression. These events result in the inhibition of T-cell activation and proliferation (292). *In vitro,* tacrolimus is 10 to 100 times more potent than cyclosporine on a per weight basis, permitting diminished dosing. In multicenter trials, tacrolimus was found to be comparable in immunosuppressive efficacy to cyclosporine in kidney transplantation (172,222). However, the agent has a similar toxicity profile to cyclosporine. In particular, it may be just as nephrotoxic and requires careful dosage adjustments. Interestingly, histopathologic findings similar to those ascribed to cyclosporine toxicity have been seen in biopsies of tacrolimus-treated patients (231). Tacrolimus may permit a lower maintenance dosage of steroids, but it has been associated with an increased incidence of posttransplant diabetes (125). Trials of tacrolimus to reverse chronic rejection in patients initially given other agents were not successful, although (surprisingly, given the mechanism of action) it has been effective in “rescuing” ongoing rejection refractory to steroids and antilymphocytic therapy (128).

Rapamycin (Sirolimus)

Rapamycin is a macrolide antibiotic derived from *Streptomyces hygroscopicus* with potent immunosuppressive activity. It has similar molecular structure to the calcineurin inhibitors (Fig. 22.12) and binds to the same cytosolic receptor protein (FKBP) as tacrolimus. However, its mode of action appears to be distinct from the other agents (254). Although it is a potent inhibitor of lymphocyte responses to cytokines such as IL-2, IL-4, and IL-6, it has no direct effect on the synthesis of these lymphokines. The rapamycin–FKBP complex appears to block a distinct p70 kinase called mTOR (molecular target of rapamycin). The inhibition of mTOR blocks IL-2 signal transduction pathways that prevent cell-cycle progression from G_1 to S phase in T cells. In experimental animals, rapamycin prolonged the survival of skin, heart, kidney, pancreas, and small bowel allografts. It also produced synergism with cyclosporine, which suggests an initial approach to its clinical use (although it appears antagonistic with tacrolimus). In initial clinical trials, rapamycin did not cause nephrotoxicity, unlike cyclosporine and tacrolimus. It is not hepatotoxic, nor does it induce hyperglycemia. However, it can induce thrombocytopenia and causes significant hyperlipidemia in approximately 20% of patients (27). Significant increases in cholesterol and triglycerides usually require the use of both dietary control and statin drugs. Rapamycin was first used in combination with cyclosporine and steroids in doses of 2 and 5 mg, and it was compared with cyclosporine, steroids, and azathioprine in the pivotal multicenter trials. With 2 years of follow-up, there was no significant difference in patient or graft survival between the groups. However, the incidence of acute rejection at 6 months was less, 23% versus 43%, in the patients given sirolimus (130). This exciting new agent may offer effective immunosuppression without nephrotoxicity, and it is currently being evaluated in combination with other agents.

Antilymphocyte Antibodies

Polyclonal Antibodies

Polyclonal antibodies directed against human lymphoid cells were initially used in renal transplant recipients more than 30 years ago (269). Antibodies are produced by injecting (immunizing) animals such as horses, goats, sheep, or rabbits with cells from human lymphoid tissue. Immune sera from several animals is usually pooled and the gamma globulin fractions extracted. Desired antibodies are recovered, and unwanted antibodies are removed. Minnesota antilymphoblast globulin (MALG) and antithymocyte globulin (ATGAM, Upjohn Co.), both equine derived, have been most widely used in clinical transplantation, although the former is no longer available. Recently, a rabbit-derived antithymocyte antibody (thymoglobulin, Sangstat) has been introduced.

Once injected, the antibodies bind to lymphocytes, resulting in a rapid lymphopenia. Although the exact mechanism is not known, it is probably related to complement-mediated cell lysis with clearance by the reticuloendothelial system, or the antibody may mask T-cell surface antigens, thus blocking the cell's function. A prolonged immunosuppressive effect may be the result of suppressor cell inhibition of proliferation. Polyclonal antibodies have been used primarily in cadaveric renal transplantation for the prevention and treatment of rejection. In a meta analysis including thousands of patients who received antilymphocyte induction therapy, there appeared to be both short-term advantages and long-term improvements in graft survival (280). In randomized trials, the rabbit product thymoglobulin was shown to be more effective than the equine product ATGAM in reversing acute rejection (88% versus 76%) and for rejection prophylaxis during induction therapy (30).

Because of their strong immunosuppressive effects, polyclonal antibodies are limited to short courses and other immunosuppressive agents are significantly reduced during polyclonal antibody administration. Adverse effects include fever, chills, and arthralgias related to the injection of foreign proteins and possibly the release of cytokines. These effects can be minimized by pretreatment with corticosteroids and antihistamines. There is a significant “batch-to-batch” variability, and pretreatment

is required before each administration. More serious adverse effects include increased susceptibility to infections (especially viral), serum sickness, and anaphylaxis.

Monoclonal Antibodies

The introduction of hybridoma technology has opened the door for the development of more highly specific antibodies directed against single elements at the molecular level (144). Mice are generally used for the production of monoclonal antibodies after immunization with human lymphocytes. Antibody-producing B cells are recovered from the spleen and fused with an immortal murine myeloma cell line. The resulting hybrid cells (hybridomas) are isolated and grown in culture. The desired clones are then chosen for the specific antibody production. Numerous monoclonal antibodies are currently being investigated for possible use in transplantation (250). These antibodies, like polyclonal antibodies, exert their effects through a variety of mechanisms. In addition to complement-mediated lysis, blockade and inactivation of cell surface molecules, and opsonization with phagocytosis, these antibodies can induce cytotoxicity and modulation of cell surface molecules on target tissues.

OKT3 (Orthoclone)

OKT3 was the first commercially available monoclonal antibody used in transplantation. It is a murine (mouse) antibody directed against the CD3 antigen complex, a component of the T-cell receptor, which exists on the surface of all T cells. The CD3 molecule plays an important role in signal transduction and subsequent T-cell proliferation and activation. After a standard 5-mg dose, OKT3 inhibits the CD3 complex with resultant lymphocyte inactivation and results in depletion of CD3-positive T cells from the circulation via opsonization. After a few days, lymphocytes reappear but are modulated with the CD3 complex internalized or shed from the cell surface. OKT3, like polyclonal antibodies, has been used to delay the initiation of cyclosporine and for prophylaxis and treatment of rejection episodes (181).

Adverse effects of OKT3 include a first-dose response that simulates a severe flulike syndrome, consisting of fever, chills, nausea, vomiting, diarrhea, myalgias, headache, general malaise, and in severe cases, aseptic meningitis and pulmonary edema. These symptoms are caused by initial activation of resting T cells by OKT3, which is a xenoantibody, and the release of cytokines such as tumor necrosis factor and interferon-g (43). Many of these symptoms can be diminished by pretreatment with corticosteroids (219). The use of OKT3 for induction therapy has been shown to diminish early acute rejection episodes and improve long-term graft survival (111,193). A recent randomized trial using a low-dose (2.5-mg) regimen for induction, with mycophenolate mofetil and timed doses of corticosteroid pretreatment, demonstrated that a 16% rate of acute rejection and diminished side effects could be achieved (84).

Anti–Interleukin-2 Receptor Antibodies

Another selective site for monoclonal antibody targeting of the immune response is the IL-2 receptor or Tac (CD25), present on the surface of activated immune-competent T cells. Previous studies in animals demonstrated the utility of CD25 blockade for immunosuppression using murine-derived monoclonal antibodies. However, the rapid translation of this model to the clinic has come about due to the development of humanized and chimeric forms of anti–IL-2R antibody through the use of recombinant DNA technology. Both a chimeric anti-CD25 (basiliximab) and a humanized anti-CD25 (daclizumab) bind to different epitopes on the a-chain of the T-cell IL-2 receptor, preventing further signal transduction and T-cell proliferation. The chimeric form is genetically engineered to combine human heavy and light chain constant regions with murine heavy and light chain variable regimens, which contain the antibody binding sequences. The humanized form uses multiple amino acid substitutions of human for mouse sequences to produce a more “humanlike” IgG antibody. The net effect is to produce a hybrid IgG that retains the specific anti-CD25 binding characteristics with a less xenogenic backbone. In clinical trials, each agent was shown to produce excellent antirejection prophylaxis with a diminished side effect profile (309). We have recently compared basiliximab to OKT3 for induction therapy and found comparable rates of acute rejection, 16% versus 12%, *p*= NS, and less cytokine release with basiliximab (82). These newer drugs appear easier to use than previous anti–T cell agents, and they are becoming the preferred agents for induction therapy presuming these results will be durable over several years.

Costimulatory Blockade

As previously mentioned in the section on immune activation, a new and exciting area of investigation is the role of costimulation in immune responsiveness. Blocking the costimulatory signal 2 prevents T-cell activation from occurring. Future clinical trials are anticipated to test the efficacy and safety of this approach. Agents such as the fusion protein CTLA-4 Ig, which blocks the B7–CD28 interaction, and anti-CD154, which interrupts CD40–CD40 ligand interaction, may provide a new avenue for control of allograft rejection.

Additional Agents Under Investigation

15-Deoxyspergualin

15-Deoxyspergualin is an antitumor antibiotic extracted from *Bacillus laterosporus* that has shown immunosuppressive activity in animal models. Its mechanism of action has not been elucidated, although it appears to decrease cytotoxic T-lymphocyte proliferation and inhibit antibody production by preventing lymphocyte maturation. It also may downregulate the expression of class II antigens on immune-competent cells. In experimental animals, 15-deoxyspergualin prolonged survival and reversed rejection in skin, pancreatic islet, heart, liver, and kidney allografts (234). The drug has been used clinically in Japan as part of induction therapy in living related and cadaveric renal transplantation. Although a number of reports appeared promising, in one study the drug was not as potent as steroids in reversing acute rejection, and its precise role is currently under consideration. Side effects were significant, including leukopenia and thrombocytopenia (199).

Mizoribine

Mizoribine is an imidazole antibiotic that has been available for clinical use in Japan. Like azathioprine, it inhibits purine biosynthesis and abrogates both cell-mediated humoral immune responses. Although it may posses less immunosuppressive potency than other agents, it apparently does not cause significant myelosuppression or hepatotoxicity. In clinical trials of mismatched living related renal transplants, mizoribine was used in combination with cyclosporine and prednisone. When compared with other patients treated with cyclosporine, azathioprine, and prednisone, there was no difference in outcome (301). Data among recipients of cadaveric kidneys are not yet available. GI toxicity was reported to be related to the blood levels of the drug, which must be adjusted in patients with diminished renal function (101). It is recommended that the agent not be given to significantly oligoanuric patients, which may limit its use in cadaveric transplantation.

RECIPIENT SELECTION AND PREPARATION

The increasing demand for transplantation is a natural trend that parallels the improved results enjoyed by current recipients compared with previous generations of transplanted patients (42,68). Diminished morbidity, coupled with improved graft survival, have encouraged more and more patients to seek the transplant option. At the same time, improved results have expanded the pool of potential recipients for which transplantation can be safely performed. Absolute criteria that in the past would render a patient too old, too young, too small, too debilitated, too atherosclerotic, or diabetic have been liberalized or even eliminated by most transplant centers. The primary indication for transplantation today is the patient-driven desire to return to preillness levels of activity, well-being, self-image, employment status, and sexual performance. Although a functioning renal allograft is not a cure for renal failure, renal transplantation provides the best opportunity to achieve these goals (45,68,78). However, the proper evaluation of every potential recipient and donor is of critical importance to ensure the best clinical outcome and the best use of a limited resource.

The option of renal transplantation should be entertained by any patient with permanent renal failure, even though not every patient would be medically suitable or desire a surgical form of therapy. In addition, the unique risks and responsibilities required of an individual receiving chronic immunosuppression would not be appropriate for all patients. Nevertheless, a complete discussion of treatment options can be useful to permit patients the opportunity to participate in treatment planning.

The timing of renal transplantation may also have a significant impact on outcome. Some renal physicians advocate a mandatory period of dialysis before transplantation so that patients can “get used to” their diagnosis of ESRD. In some circumstances, this may be psychologically beneficial, especially when renal function has been waxing and waning or when the etiology of renal failure is unknown. Clearly, transplantation should not be performed as an emergency, and patients who first present in florid uremia may require acute dialysis and stabilization. However, for those with slowly progressing renal failure, many highly motivated individuals have requested that the transplant be performed before the need for chronic dialysis (86,179). These patients see elective or preemptive transplantation as less disruptive to their lives, and they can avoid or delay the additional surgery required to create vascular access. Such an approach in carefully screened and selected patients can be done successfully, especially when a living donor is available. Therefore the patient with ESRD has several options to consider in the choice

and timing of renal replacement therapy (Fig. 22.13).

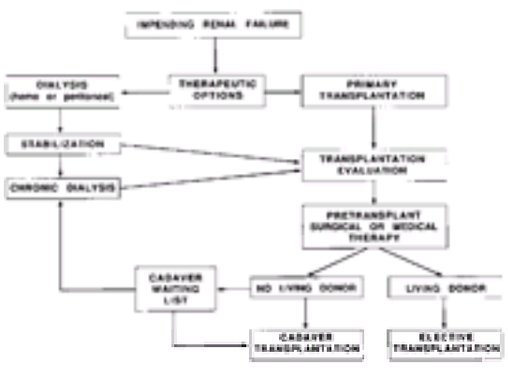

FIGURE 22.13. Patient options with end-stage renal disease.

The ever-increasing worldwide shortage of donor organs necessitates a strategy of donor allocation that provides for the best possible outcome among a given ESRD population. The altruism of donor families, which is the engine that drives organ donation, depends on the doctrine that needy recipients will have equitable access to organs and that recipient selection will be based on sound medical criteria. Therefore the option of renal transplantation should not be entertained when the risks of the surgical procedure and attendant lifelong use of immunosuppressive drugs outweigh the benefits of a functioning kidney. Each individual must be carefully evaluated for any coexisting medical or psychosocial problem that would lead to a poor outcome if left uncorrected (300).

Primary Renal Diseases

The diagnoses listed in Table 22.3 represent the most commonly encountered causes of ESRD. This large spectrum includes both congenital and acquired renal disease, those isolated to the kidney, as well as systemic diseases with renal complications. With few exceptions, patients with any of these primary diagnoses have been successfully transplanted with either a cadaveric or living-related kidney. According to data among U.S. residents reported to the Health Care Financing Administration at the end of 1991, more than 58% of the individuals receiving dialysis were older than age 50 and 46% were female (302). In addition, nearly 30% of the transplants done that year were in individuals older than age 44 and nearly 40% were female (302).

Glomerular disease	Neurogenic bladder
Membranoproliferative glomerulonephritis	Congenital (meningomyelocele)
Rapidly progressive glomerulonephritis	Acquired
Anti-glomerular basement membrane disease	Hereditary diseases
Membranous nephropathy	Polycystic kidney disease
IgA nephropathy (Berger's)	Medullary cystic disease
Focal segmental glomerulosclerosis	Alport's syndrome
Diabetic nephropathy	Nephrolithiasis
Arteriolar nephrosclerosis	Infection stones
Essential hypertension	Hyperoxaluria
Malignant hypertension	Cystinuria
Bilateral renovascular disease	Systemic diseases
Interstitial disease	Lupus erythematosus
Chronic pyelonephritis	Hemolytic uremic syndrome
Analgesic nephropathy	Amyloidosis
Toxic nephropathy	Scleroderma
Congenital disorders	Polyarteritis nodosa
Renal agenesis	Henoch-Schönlein purpura
Renal dysplasia	Infections
Posterior urethral valves	Tuberculosis
Vesicoureteral reflux	Schistosomiasis
Prune-belly syndrome	Surgical nephrectomy
Ureteropelvic junction obstruction	Trauma
	Renal malignancy

TABLE 22.3. MOST COMMON FORMS OF CHRONIC RENAL FAILURE LEADING TO RENAL TRANSPLANTATION

There has also been a shift in the most commonly encountered renal failure diagnoses among those patients eventually receiving a kidney transplant. Although all forms of glomerulonephritis are still the most common etiology (26%), diabetes is now the second most commonly encountered diagnosis (21%), followed by hypertension (14%), cystic disease of the kidney (8%), other causes (8%), urologic disorders (previously obstructive uropathy) (6%), cause unknown (7%), and missing information (9%). It is not unusual for patients to seek medical attention after they are in far advanced stages of chronic renal failure and have small, shrunken kidneys. At such a late stage, it is often impossible to determine the true cause of renal failure with a biopsy, hence the unknown etiology category. Interestingly, more than 11,000 new patients entering dialysis for the first time each year enter into this category.

As might be predicted, patients with primary glomerular diseases may develop recurrent disease in the transplanted kidney. Recurrence rates as high as 50% have been reported on posttransplant biopsies in some patients with anti–glomerular basement membrane (anti-GBM) disease, IgA nephropathy, focal sclerosis, and membranoproliferative glomerulonephritis (11, 21, 98, 171, 175). It has been postulated that the continuous use of immunosuppressive drugs after transplant may significantly slow the progression of recurrent disease. This may be true because the actual rate of graft loss from recurrent disease is quite small (218). *De novo* glomerular disease, such as membranous nephropathy, has also been reported (253, 272). Although the fear of recurrence should not alter the decision to proceed with transplantation, the timing of the transplant should be considered carefully. Patients with a very rapid and aggressive course to renal failure, such as those with focal segmental sclerosis, rapidly progressive glomerulonephritis, or high titers of anti-GBM antibody, should probably wait 6 to 12 months on dialysis until the disease is quiescent.

Insulin-dependent diabetic patients make up a steadily increasing percentage of the ESRD population (302). Although not a cure for diabetes, patients with uremic diabetes often experience dramatic improvement in exercise tolerance, mobility, and well-being after renal transplantation. Much of this improvement is due to a reversal of uremic neuropathy, which often compounds the peripheral neuropathy of diabetes (200). Diabetic patients with severely compromised vision often experience a similar degree of rehabilitation as sighted patients and should not be excluded from transplantation (102). Unfortunately, progressive vasculopathy continues after transplant, which leads to a higher rate of myocardial infarction, stroke, and amputation than in the nondiabetic transplant population (151). For this reason, it is important to screen diabetic patients for correctable coronary artery, carotid, and peripheral vascular lesions before transplantation. The improving results with simultaneous pancreas–kidney transplantation may provide an additional opportunity for selected patients to slow the progression of diabetic vasculopathy (135, 190).

Arteriolar nephrosclerosis, often associated with malignant hypertension, is another common cause of renal failure, especially in young African American males. Although some patients have a dramatic improvement in blood pressure control with the onset of dialysis, others may require nephrectomy to prevent cardiovascular and cerebrovascular accidents. It should be noted that control of blood pressure with medication may significantly improve renal function in previously untreated patients as well (164). Such patients should not be transplanted until irreversible renal failure has been established. The successful transplantation of patients with metabolic, hereditary, and systemic diseases can usually be accomplished. However, patients should be advised that recurrences have been reported. An especially troubling group are those patients with primary oxalosis. Oxalate deposition and stone formation in the new transplant kidney has been observed frequently, with nonimmune graft loss as a result of recurrent disease (242). For this reason, there has been increasing enthusiasm for the simultaneous transplant of both a liver and a kidney to correct the metabolic abnormality. The transplantation of patients with a previous history of self-destructive behavior leading to renal failure, such as those with analgesic abuse nephropathy, intravenous drug abuse nephropathy, and similar behaviors, must be carefully screened and evaluated. A period of observation with required compliance to the medical regimen and random drug screens may be appropriate in certain situations. It may be helpful to seek the input of various family, community, social service, and religious support services (91, 316).

Age

Chronologic age has often been a barrier to transplantation, with arbitrary cutoffs established for upper and lower age ranges in many centers. In the past, the ideal candidate may have been between 15 and 45 years of age, but improved transplant practice and delivery of immunosuppression has permitted the transplantation of

small children less than 10 kg in weight and older patients in their sixties and seventies. The physiologic age of the patient is a more significant determinant of outcome (122,162). Older candidates should be aggressively screened for active cardiovascular disease. Posttransplant myocardial infarction, stroke, and peripheral vascular disease remain the most common causes of morbidity and mortality in these patients, whether they are transplanted or remain on dialysis (117). Therefore careful history and physical examination and the liberal use of noninvasive and invasive (angiography) studies, when indicated, best determine suitability for transplantation (62). The older-age patient with atherosclerotic disease should have realistic goals regarding rehabilitation and physical activity. Those patients with severe, noncorrectable atherosclerotic disease and little expectation for physical rehabilitation are probably best served by chronic dialysis, regardless of their chronologic age. On the other hand, patients with identifiable atherosclerotic lesions should have them repaired by surgery or angioplasty before transplant (61).

Small children less than 20 kg in weight have been considered high-risk recipients because of the technical difficulties associated with surgery and dialysis in this group (180). In addition, many small babies with progressive uremia are severely malnourished and have somatic and neurologic growth retardation. Refinements in pediatric anesthesia, intensive care practice, and surgical technique have substantially improved transplant outcome, and size alone should no longer be considered a contraindication (49,174,188). Although some have advocated the transplantation of small infants on an urgent basis, such practice is rarely, if ever, indicated. Small uremic children can be safely stabilized with peritoneal dialysis (72). During this time, they can be nutritionally repleted. The use of small nasogastric tubes for enteral hyperalimentation during continuous peritoneal dialysis has been a major advance. Because many such children have willing parental donors, the once high-risk endeavor of transplanting small children can now proceed in an orderly, elective fashion.

Urologic Evaluation

The purpose of the urinary tract evaluation is to uncover any functional or anatomic abnormalities that would predispose the recipient to posttransplant complications. An initial history should address the onset of renal failure and its presentation, in an attempt to identify such problems as recurrent urinary tract infection, pyelonephritis, stone disease, gross hematuria, and the presence of irritative or obstructive voiding symptoms or incontinence. Routine evaluation should include a urinalysis, urine culture, 24-hour urine collection for volume, creatinine clearance, protein excretion, and a voiding cystourethrogram. Some studies may be limited in patients with oligoanuria, and others may be required only for those with specific complaints. Patients with hematuria, filling defects, incontinence, significant prostatism, or a history of previous lower urinary tract pathology should undergo cystoscopy. Retrograde pyelograms may be required in certain patients. Selected urodynamic studies may be used for those with incontinence or suggestion of a neurogenic bladder. It should be noted that virtually all ESRD patients with a defunctionalized bladder (less than 200 mL per day urine output) demonstrate high voiding pressures, uninhibited contractions, and low flow rates. These findings invariably resolve when normal voided volumes are restored after transplantation. Men older than age 50 should have a prostate-specific antigen (PSA) blood test to screen for occult prostate cancer (41). Posttransplant prostate cancer was detected in 5.8% of men after kidney transplant in a previously unscreened recipient population (163). This suggests that the disease will become more prevalent in men as older-age patients are referred for transplant.

The increase in the number of men older than age 55 who elect the option of transplantation includes many with symptoms of prostatism. Those who produce more than 1 L per day of urine should undergo standard evaluation, and if significantly obstructed, undergo transurethral (electroresection or laser-assisted) prostatectomy. However, patients who produce small urine volumes are difficult to evaluate and have a propensity to develop bladder neck contractures and strictures after a resection (23). Such patients should await definitive management until urine volumes return to normal after transplantation. The role of pharmacotherapy for prostatic obstruction is currently evolving. Patients who develop posttransplant retention can be successfully managed by intermittent clean catheterization until definitive therapy is instituted. Patients with urethral stricture disease should be treated by direct-vision internal urethrotomy. More complete reconstructions should be completely healed before transplant. If stricture patients produce small urine volumes, daily self-catheterization of the urethra may be required to prevent recurrent stricture disease.

The adequacy of the bladder to both store and empty can usually be elicited by history and voiding cystourethrogram, although an occasional patient may need a more detailed urodynamic assessment. If unresolved, bladder filling, emptying, and continence can be reliably tested before transplant by the placement of a small percutaneous suprapubic tube and graduated saline irrigation (143). Patients with large flaccid bladders (some diabetics) that empty poorly can be managed after transplant using intermittent catheterization if their continence mechanism is intact (76). Most small defunctionalized bladders (even those less than 50 mL) will dilate nicely after transplantation, even when anuria has been present for many years (255). However, a few patients may have contracted noncompliant and fibrosed bladders most often secondary to tuberculosis, radiation, schistosomiasis, or severe interstitial cystitis. The bladders in such patients, as well as those with total incontinence or high-pressure neurogenic bladders, are not suitable for transplantation and will require the use of intestinal segments (191,291).

If the patient has a noncompliant, high-pressure, small-capacity bladder with an intact continence mechanism, bladder augmentation with a segment of large or small bowel can be performed. If no satisfactory urethral continence mechanism remains, an abdominal reservoir with a continent stoma (a Kock pouch or variation thereof) may be considered. For many, the standard ileal loop conduit may be the procedure of choice (110). The implantation of an artificial urinary sphincter for incontinent patients can be safely performed in selected patients (201). Reconstructive bowel surgery should be performed at least 4 to 6 weeks before transplantation to permit complete healing.

PRELIMINARY SURGERY

The use of continuous chemical immunosuppression after transplant increases the risk of complications for elective or emergency surgical procedures. For example, wound healing is impaired, sutured anastomoses have a greater tendency to leak, and wound hematomas are more frequently encountered. Otherwise, minor postoperative complications such as pulmonary problems or urinary tract infections may become more difficult to resolve in the immunosuppressed patient. For this reason, it is preferable to perform any necessary elective surgery before transplantation. This includes more common procedures such as hernia repair, hemorrhoids, cosmetic surgery, skin biopsies, extensive dental work, and orthopedic procedures. The following major surgical procedures may also be required to prepare a recipient for transplantation and should be completed and healed before the introduction of continuous immunosuppression.

Nephrectomy

Routine bilateral native nephrectomies are no longer considered a prerequisite for transplantation. The intended indication, removal of the stimulus that triggered immune-mediated renal injury, has been superseded by improved immunosuppression. Another common indication, hypertension, has been made more manageable by the introduction of new classes of antihypertensive agents such as a- and b-adrenergic blockers, vasodilators, calcium channel blockers, and converting enzyme inhibitors. For dialysis-dependent patients, the retention of native kidneys has distinct advantages. They contribute to red cell production and calcium homeostasis and provide an additional source of fluid and potassium loss. A number of specific indications remain for pretransplant nephrectomy, which is required in approximately 10% to 15% of patients. These indications include recurrent bacterial pyelonephritis, infected renal cysts, active stone passage, high-grade vesicoureteral reflux with residual urine, hypertension refractory to oral agents, renal tumors, and patients with severe proteinuria causing malnutrition and edema. On occasion, patients may have massive polycystic kidneys that cause abdominal symptoms, gross hematuria, or cyst infection, or become so large that they preclude placement of the graft in the iliac fossa, and must be removed. In patients with reflux, tuberculosis, hydronephrosis, or other ureteral pathology, a nephroureterectomy may be required.

Splenectomy

Surgical removal of the spleen for the purpose of augmenting immunosuppression was once thought to be an integral component of pretransplant preparation, especially for those recipients undergoing retransplantation. Earlier reports of improved graft survival were no doubt the result of a greater tolerance for azathioprine in splenectomized patients (90). Leukopenia, which often limited the use of antiproliferative agents such as azathioprine in patients with intact spleens, is now less common in cyclosporine-treated patients. In addition, splenectomized patients are known to have a greater long-term risk of sepsis, which has further diminished the enthusiasm for this procedure (3). The rare patient may benefit from splenectomy if pancytopenia secondary to massive hypersplenism is present. More recently, recipients of ABO-mismatched kidneys have been salvaged by the combination of splenectomy, plasmapheresis, and antilymphocyte preparations (4). The spleen is apparently an essential site for the production of anti-ABO isohemagglutinins.

Parathyroidectomy

Most ESRD patients suffer from secondary hyperparathyroidism, which can be managed with oral phosphorus binders and is readily reversible with a kidney transplant. However, a few develop tertiary hyperparathyroidism often accompanied by peptic ulcer disease, metastatic calcification, pancreatitis, itching, and severe bone mineral reabsorption. Many of these patients have serum calcium levels at the upper limit of normal, but radioimmunoassay parathormone levels are elevated 10

to 100 times. These patients should undergo subtotal parathyroidectomy before transplantation.

GASTROINTESTINAL DISEASE

Transplant recipients with active peptic ulcer disease are at high risk for bleeding or perforation in the early posttransplant period when doses of corticosteroids are highest (277). Therefore patients with active disease, recurrent ulcers, and a history of significant bleeding requiring transfusion should have an acid-reducing procedure before transplant. The selective vagotomy has become the preferred procedure. It is prudent to document complete healing by endoscopy before the introduction of immunosuppression.

The mortality rate associated with acute cholecystitis in transplant recipients has been reported to be up to 30%. Therefore patients with active gallbladder disease, as well as those with asymptomatic cholelithiasis, should undergo cholecystectomy before transplant (157). Laparoscopic techniques have revolutionized the management of this disease, permitting a more rapid recovery time (8). The laparoscopic approach has also been used successfully in ESRD patients who are treated with peritoneal dialysis.

The presence of colon diverticula in patients older than age 45 is of concern. Those patients with a well-documented history of diverticulitis should have a prophylactic colectomy (usually on the left side) if they are to be immunosuppressed. The mortality rate of posttransplant colon perforation has been reported to be as high as 50% (46,202). Patients with scattered diverticula and no history of bowel symptoms need to be appraised of the possibility of perforation and its consequences. Although prophylactic colectomy in these patients seems hard to justify, the decision to proceed with transplantation should not be taken lightly. If possible, these patients should have the renal allograft placed on the right side.

GENERAL MEDICAL EVALUATION

It is imperative that each potential recipient undergo a complete evaluation before transplantation by the team responsible for the patient's surgery and immunosuppression (Table 22.4). The majority of this evaluation can be done as an outpatient; in a few specific instances, some tests may require hospitalization to complete. The main purpose of this evaluation is to uncover any preexisting medical or psychosocial conditions that could lead to increased posttransplant morbidity or mortality. Any such condition, if identified, should be corrected before transplant surgery and the administration of immunosuppressive therapy. The absolute list of studies performed may vary from center to center based on different practice philosophies and the distribution of various groups of ESRD patients (230). Whatever the circumstance, it is incumbent on all transplant practitioners to ensure that patients are thoroughly prepared and can therefore maximize their opportunity for a successful outcome (121).

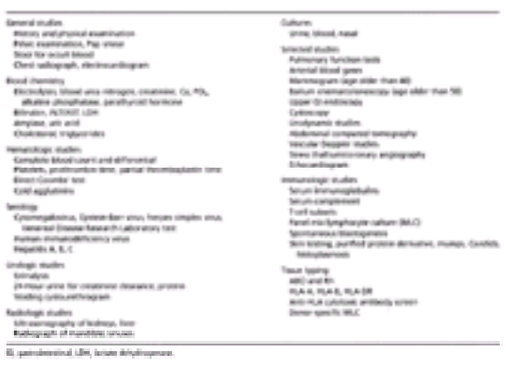

TABLE 22.4. PRETRANSPLANT EVALUATION FOR POTENTIAL RECIPIENTS

History

The initial history should address the onset of renal failure and its presentation. Hypertension, proteinuria, edema, fever, or weight gain may have resolved or may remain active. The cause of the disease and any available biopsy material should be reviewed. Associated problems, such as recurrent urinary tract infections, pyelonephritis, stone disease, or gross hematuria, should be explored. If a patient still produces urine, voiding patterns should be ascertained in an effort to diagnose bladder outlet obstruction. Symptoms related to vascular disease should be elicited, specifically looking for coronary or carotid artery disease and peripheral vascular disease. A careful GI history is important to uncover gallbladder, pancreatic, liver, or peptic ulcer disease symptoms. The family history may uncover a pattern of cancer, bleeding disorders, or inherited renal disease. Previous use of immunosuppressive drugs and any complications should be noted. The quantity and time of administration of blood products should be recorded.

Physical Examination

The initial physical examination may reflect patient compliance with dialysis and with medical therapy. Fluid overload and edema may represent intentional noncompliance. The eyes may reveal lipid abnormalities or cataracts, and the fundi can demonstrate the degree of diabetic retinopathy or arterial pathology. The cardiac examination may reveal new murmurs that have an infectious origin. All major blood vessels from the carotids to the dorsal pedis should be palpated. Diminished pulses or bruits should be evaluated further. Sources of occult infection such as otitis, dental abscesses, genital or perirectal abscesses, and the lower extremities of diabetics should be carefully inspected. The presence of lymphadenopathy in the inguinal, cervical, and axillary regions should be identified. A pelvic examination in females should include a Papanicolaou smear if not previously done, and the rectal examination should screen for occult blood.

Laboratory Tests

Blood chemistry and serology studies are important to uncover any abnormalities or exposure to infectious agents that could complicate the transplant procedure or subsequent immunosuppressive therapy. The goal should be to normalize metabolic balance and nutrition for each potential recipient. All potential recipients should be tested for antibody to the HIV virus using confidentiality procedures and Western blot confirmation as appropriate (136). Prior or current exposure to cytomegalovirus (CMV), Epstein-Barr virus, herpes simplex virus, and hepatitis A, B, or C virus should be ascertained. Patients with positive blood or urine cultures should be treated after the source of the infection is identified. Cultures should be repeated after treatment to ensure complete response. Patients with an autoimmune etiology for kidney failure such as those with systemic lupus erythematosus, anti-GBM disease, or rapidly progressive glomerulonephritis should be screened for low complement levels, high titers of anti-GBM antibody, or circulating immune complexes. If any are present, these patients should wait 6 to 12 months on dialysis before proceeding with transplantation, to diminish the risks of recurrent disease.

Radiographic Studies

In addition to a chest radiograph, the native kidneys should be examined by ultrasound to rule out stones, tumors, acquired cystic disease, hydronephrosis, and so on. Ultrasound of the gallbladder and pancreas is necessary to screen for stones or pancreatic disease. Patients with a history of peptic ulcer disease or current symptoms should have an upper GI series or endoscopy. Patients older than 50 who may harbor diverticula or polyps or those with occult blood in the stool should have a barium enema or colonoscopy. Plain films of the sinuses, mandible, and teeth can uncover small microabscesses.

Selected Studies

Patients with extensive smoking history are instructed to stop before transplantation. Such patients, as well as those with a history of frequent pulmonary infections, should have pulmonary function tests and blood gases. Reversible bronchospasm should be corrected medically if identified. Coronary artery disease is a significant cause of morbidity and mortality after transplant, especially in older-age patients and diabetics (75,151). Patients older than 50 with any cardiac symptoms should initially be screened with a treadmill or exercise-induced stress thallium scan (7). However, these tests are often inconclusive in diabetics and patients who fail to

produce a maximal-effort heart rate (116,168). Therefore, in sedentary patients and diabetic patients, a screening coronary angiogram is strongly recommended (158,165). Potential recipients with critical coronary artery lesions should have them repaired either by angioplasty or bypass surgery before transplantation (166). Doppler studies are useful to screen for carotid and peripheral vascular lesions, especially in symptomatic patients or those with audible bruits.

LIVE DONOR EVALUATION AND PROCUREMENT

Donor Evaluation

Healthy, willing, and highly motivated living relatives of the recipient such as siblings, parents, and children make up approximately 20% of the kidneys transplanted. More distant relatives such as aunts, uncles, grandparents, or cousins may also be suitable donors in certain circumstances. A second source of live donor kidneys comes from non–biologically related individuals. A healthy spouse is the most likely representative of this group, but unusually motivated “friends” of the recipient have been used in highly selective circumstances. The use of a living-related donor (LRD) in human renal transplantation has created a unique ethical dilemma for those involved with the daily care of transplant patients. In no other area in medicine is an otherwise healthy individual asked to subject himself or herself to the potential morbidity or mortality of major surgery for no apparent physical benefit. There are two basic reasons why LRD transplants are done, and each presents a variable degree of significance for a given donor recipient pair. First, LRD kidneys work better and last longer (42). This fact has been continuously observed using virtually all combinations of nonspecific chemical immunosuppression during the past 30 years. Second, there is a global shortage of cadaver kidneys (67,266). Therefore LRD transplantation will expedite the process for some recipients and may permit transplantation to be done in some patients who have been unable to secure a crossmatch-negative cadaver kidney while waiting for an extended period. These benefits, solely to the recipient, must be balanced against the potential short- and long-term harm to the donor. If more than one donor is available to a particular recipient, donors are selected based on their degree of histocompatibility, assuming that medical and psychosocial parameters are equal. Table 22.5 lists, in descending order, the degree of tissue similarity among potential donors and suggests the order of preference for a specific recipient.

Monozygotic twins
HLA-identical siblings
Haploidentical siblings, parents, children, relatives
Less than haploidentical siblings, parents, children, relatives
Distant relatives
Unrelated living donors (e.g., spouse)
Cadaveric donors

TABLE 22.5. DONOR SELECTION BY IMMUNOLOGIC SIMILARITY

Despite compelling arguments for the use of living donors, such procedures should not be done if significant morbidity or mortality were to be experienced by the donor. The concept of self-sacrifice and organ donation has been extensively examined by the medical, ethical, and legal professions. Postdonation analyses have consistently found that the donor experience was an overwhelmingly positive one, although sometimes tempered by recipient outcome (126,249). Clearly, renal donation is not an innocuous procedure; all donors experience some degree of anxiety, physical pain, and disruption of their employment schedule, schooling, and home life. In addition, a degree of pressure and coercion can be present among family members that is not readily apparent to health care professionals. For this reason, each donor must be given the opportunity to give his or her independent, informed consent to this decision. We have found that it is very important to counsel the spouse of the potential donor and to permit his or her input into the process as well. It is also helpful to allow the potential donor to determine the pace of the evaluation. Some may truly be undecided and may require more time to evaluate their commitment or desire to opt out of the process. These complex social interactions make it difficult to consider minors younger than age 18 as potential donors in all but the most unusual circumstances.

What then is the potential risk to the renal donor? Although the number of donor deaths worldwide is quite low, they have occurred. It has been reported that the 5-year life expectancy of a unilaterally nephrectomized 35-year-old healthy male donor is 99.1%, as compared with 99.3% for a matched control with two kidneys (177). Another estimate is that the mortality rate for donor nephrectomy is less than 0.1% (150). The long-term risk by actuarial methods has been calculated to equal that of commuting in a car 16 miles each working day. Fortunately, major postoperative complications such as life-threatening cardiopulmonary events or infections are rare, but minor complications such as atelectasis and urinary tract infections are reported to occur in 10% to 20% of cases (314). A flurry of concern has been generated from the findings of Brenner and colleagues (31) that rats who underwent renal ablation were subject to hyperfiltration in the remnant kidney. This process led to glomerular sclerosis and deterioration of renal function, which was related to protein intake and time. However, several studies of renal donors with more than 20 years of follow-up failed to identify this problem in humans (238,308). Progressive renal deterioration is not observed, and the incidence of hypertension was consistent with that of the population at large. Some uninephrectomized donors did have an increased urinary protein excretion, but the implications of this are presently unknown. In an interesting comparative report, adult kidney donors followed for more than 20 years were compared with their siblings who did not donate for other than medical reasons (187). Both groups had similar renal function at the time of kidney donation. There was no significant difference in serum creatinine, creatinine clearance, blood urine nitrogen, blood pressure, or proteinuria between the kidney donors or their siblings with two kidneys. Proper informed consent and risk appraisal should continue to be the cornerstone of live donor evaluation.

The use of kidneys from living unrelated individuals, primarily a spouse, has increased in recent years. The enthusiasm for using living unrelated donors comes from three general observations. First, the continued increase in the number of waiting potential recipients and a stagnant supply of suitable cadaver organs continues to drive efforts to expand the organ donor pool (152,266). Second, the bond between two individuals, such as husband and wife, is arguably as firm as that between blood relations. The same satisfaction in helping a loved one that is attributed to living-related donation can be conveyed by spousal donation. Third, as the results of transplantation continue to improve, the expectations for success with living unrelated donors has never been better. In fact, 1-year patient and graft survival in excess of 90% has been reported using living unrelated donors (287,318). The elimination of warm ischemic injury and preservation injury to the live donor kidney, similar to that enjoyed with the LRD kidney, improves transplant outcome. One underlying concern and criticism of living unrelated transplantation relates to the possibility of commercialization and coercion of the donor. Precisely these considerations have made the sale and trafficking of human organs and tissues illegal in the United States (public law 98-507) and have been decried by virtually every transplantation organization (39,52). The decision to use living unrelated donors is not a trivial one and should be carefully individualized by any transplant unit considering this approach (317).

The purpose of the donor evaluation is to uncover any preexisting renal disease or predilection for renal disease in the potential donor. In addition, patients are screened for risk factors that would preclude major surgery and general anesthesia. Certain conditions may be identified that will not only lead to exclusion of the donor, but may require medical or surgical therapy for the donor's benefit. Therefore, before evaluation, every potential donor must be informed as to the nature of these studies and how the information will be used. It is important to maintain a strict doctor/patient relationship with donors and to accede to their requests for confidentiality. Table 22.6 lists the most commonly encountered problems that lead to exclusion of a potential donor.

Age younger than 18 and older than 65 years
Hypertension, >140/90 mm Hg, long-standing use of medications
Diabetes, abnormal GTT, HbA_{1c}, islet cell antibody
Proteinuria, >250 mg per 244 hr
Stones
GFR <80 mL/min
Significant renal abnormalities, horseshoe, fused ectopia, etc., resulting in a solitary normal kidney
Obesity >30% ideal body weight
Psychosocial problems

GFR, glomerular filtration rate; GTT, glucose tolerance test.

TABLE 22.6. EXCLUSION CRITERIA FOR LIVING DONORS

History and Physical Examination

Potential donors should be adults (age 18 or older) who are competent to give their own informed consent for renal donation. It is unusual that potential donors older than 65 would be suitable candidates (12). Donors should not have unexplained fevers, urinary tract infections, pyelonephritis, hematuria, or stone disease. Any history of urologic surgery should be documented. In general, donors with hypertension, diabetes, cerebrovascular disease, or systemic illnesses involving the kidneys are excluded. Daily medications, nonprescription drug use, and allergies should be noted. The sexual history of the donor is recorded. Donors should be reassured that donation will not alter present sexual performance (34).

Laboratory Tests

Screening chemistry and hematologic studies should be consistent with a normal physiologic state. Abnormalities such as elevated liver transaminases or prolonged coagulation profiles should be further evaluated. Serologic studies and cultures are necessary to identify present or past exposure to transmissible diseases. Donors with a previously unknown history of exposure to venereal disease should be completely treated before consideration for renal donation. Potential donors who are infected with hepatitis B or C virus or HIV should not donate organs or tissues (64,240). However, some have advocated the use of hepatitis C–positive donor organs in recipients with prior hepatitis C infection. Donors with previous exposure to CMV may place recipients at increased risk for primary CMV disease, which will require appropriate prophylaxis.

Renal function studies are essential and should be performed in triplicate. Although no absolute criteria have been established, renal donors should have a creatinine clearance in excess of 80 mL per minute. It is not uncommon to find donors with a serum creatinine less than the laboratory-suggested 1.5 mg/dL who have a creatinine clearance under 80 mL per minute. Such donors, often thin, middle-aged women, may require an inulin clearance or radionuclide determination of the glomerular filtration rate for confirmation. The 24-hour urinary protein excretion should be less than 250 mg in adults. Patients with crystalluria on urine analysis require metabolic stone evaluation.

Radiographic Studies

The final piece to the donor evaluation confirms the anatomic integrity of the donor kidneys. An excretory urogram is performed initially to document two functioning renal units of generally normal size, shape, and position. Abnormalities, such as a solitary kidney, severe atrophy or scarring, stones, obstruction, horseshoe kidney, or tumors would exclude renal donation. If the urogram is normal, an angiogram is done to identify the abdominal aorta; determine number, position, and patency of renal vessels; and further delineate the renal parenchyma. This can be done by either standard catheter angiography or the somewhat less invasive digital subtraction techniques (79,265). Spiral computed tomography (CT) imaging is currently under evaluation as a noninvasive method to identify renal vascular and parenchymal anatomy.

DONOR NEPHRECTOMY TECHNIQUE

If one kidney has a minor abnormality on radiographic studies, such as a renal scar, a single small simple cyst, or an abnormal calyx, it is considered prudent to remove that renal unit, leaving the donor with the more anatomically normal one. If both renal units are normal, the left kidney is preferred by most transplant surgeons because the left renal vein is longer, making recipient transplantation easier to perform. Multiple renal arteries exist in approximately 20% of potential donors, and removal of the kidney with a single renal artery is preferred. If a kidney with two renal arteries is necessary for transplantation, *ex vivo* bench surgery techniques can be used to facilitate transplantation in the recipient. However, the use of kidneys with more than two renal arteries of substantial size is generally not recommended. Kidneys with duplicated collecting systems have been used successfully for live donor transplantation, if care is taken to remove the ureters in a common sheath with the blood supply protected.

The surgical technique for live donor nephrectomy should in principle use the minimum surgical insult required to remove an anatomically intact and physiologically maintained kidney for transplantation. An extraperitoneal and extrapleural flank incision is suitable in most cases. The nephrectomy can be done in most cases without removing a rib. A Turner-Warwick supracostal twelfth rib incision is preferred (299). A transperitoneal nephrectomy may occasionally be used if multiple renal vessels are involved. However, this incision has been associated with an increased rate of morbidity, such as bowel obstruction and splenic injury.

During the last few years, several centers have begun to remove donor kidneys using laparoscopic methods. The left kidney is usually removed by placement of intraperitoneal ports, and a second counterincision is made for the surgeon to place a hand in the abdomen to remove the intact kidney. Those who perform the procedure state that it causes less pain and provides for a more rapid recovery (87). The kidneys removed by laparoscopy are anatomically and physiologically inferior to those removed by open nephrectomy, but appear to function normally after a short period (85). The procedure requires a dedicated team of skilled laparoscopists so as to avoid technical complications such as ureteral necrosis (192). Randomized comparative trials are lacking to compare the open and the laparoscopic approach, but the procedure is becoming more popular, especially in centers that have invested in laparoscopic equipment.

The goal of donor nephrectomy is to remove the kidney without sustaining any ischemic injury. A well-preserved kidney, when transplanted into the recipient, should function promptly and avoid posttransplant dialysis requirements.

Four things can be done by the transplant surgeon to minimize the ischemic damage to the live donor kidney. First, ischemic injury can be minimized by decreasing the energy-requiring oxidative metabolism of the kidney. Glomerular filtration is passive, driven by cardiac output, but the tubular reabsorption of the kidney requires energy expenditure, primarily by the mitochondria. Flooding the kidney with salt and water diminishes tubular reabsorption. This is done with intensive preoperative hydration of the donor, usually 150 to 200 mL per hour of intravenous fluid, which will result in a urine specific gravity less than 10.010. During the surgical procedure, diuresis can also be maintained with use of a hyperosmolar agent such as mannitol.

Second, renal ischemia can be minimized by avoiding vasospasm of the renal circulation. This is most often caused by traction on the kidney during the surgical dissection. If the kidney becomes soft or dusky in color during dissection, it is best to stop and allow the spasm to break. The application of local vasodilator drugs such as papaverine or lidocaine may be useful. Dissection can commence when the kidney becomes full and pink in color. The same problem can occur if the renal artery is surrounded with a vessel loop that is secured by a weighted metal clamp.

Third, warm ischemic injury to the kidney can be minimized by cooling the kidney after it is removed from the donor. Iced saline or perfusate at 40°C will retard mitochondrial oxidative metabolism.

Fourth, the kidney when removed is subject to cellular swelling due to the paralysis of the oxygen-dependent Na^{+}-K^{+}-ATPase pump. By perfusing the *ex vivo* kidney with a hyperosmolar solution that mimics the intracellular ionic concentrations of sodium and potassium, cellular swelling can be minimized.

It is also important during surgical nephrectomy to remove the kidney when it is in an active state of diuresis. Therefore the previously mentioned techniques to avoid spasm should be used when the kidney is removed.

The integrity of the blood supply to the ureter is essential to avoid ureteral necrosis and fistula formation in the recipient. This is done by removing a wide area of periureteral tissue with the specimen. It is generally satisfactory to transect the ureter at the pelvic brim, which will provide adequate length for transplantation.

A small rent in the peritoneum should be oversewn with absorbable suture. After the kidney is removed, the incision should be filled with water or saline and the lungs inflated to check for a rent in the pleura. A small tear can usually be oversewn around a 16-Fr Red Robinson catheter. The wound can then be closed in layers around the catheter. When closure is complete, the lungs should be expanded by the anesthesiologist, and the air in the chest can be evacuated by placing the end of the catheter under a water seal. Air bubbles will cease when the lung is fully expanded. If there is a very large hole in the pleura or the pneumothorax is not diagnosed

until the patient is in the recovery room, a chest tube will have to be placed temporarily for expansion of the lung. A Foley catheter, which is placed during the induction of anesthesia, can be removed on the first postoperative day as the patient is encouraged to ambulate. We have found that the use of a patient-controlled analgesic delivery system is useful for some patients to control pain. The use of an epidural catheter for postoperative pain control and the use of intravenous ketorolac for up to 48 hours are also helpful, and decrease narcotic use (which predisposes to ileus). Donors should remain on nothing-by-mouth status for 1 to 2 days to avoid an ileus. They can generally be discharged 2 to 3 days after surgery and can return to full activity in about 3 to 4 weeks.

CADAVER DONOR EVALUATION AND PROCUREMENT

Most renal transplant recipients will not have a willing family donor, and therefore they must rely on an organ from a cadaver. A well-functioning cadaveric kidney will provide the same opportunity for rehabilitation from ESRD as a live donor organ. However, a number of complicating factors in cadaveric transplantation arise from the fact that organ availability is both a limited and random event, which makes the surgical procedure nonelective in nature. Cadaver kidneys are preferably transplanted within 24 hours of recovery, but they can produce acceptable results after up to 48 to 60 hours of preservation. During this period, a previously evaluated and waiting recipient is identified and prepared for surgery. This may include dialysis or metabolic adjustments for the recipient, as well as transport of the recipient or the kidney across the country. As mandated by UNOS with some local variance, the kidney is usually placed by using a weighted system encompassing ABO blood type, tissue type, length of wait, and possibly other medical or local criteria (304).

Donor Evaluation and Maintenance

Potential renal donors generally come from individuals who have suffered irreversible head trauma, cerebrovascular accident, or anoxic brain injury (57). They should preferably be between 5 and 60 years of age. There should be no history of systemic diseases that involve the kidneys, such as nephrolithiasis, hypertension (longstanding with drug therapy), diabetes mellitus, or autoimmune disease. Patients with a history of malignant tumors other than localized brain or nonmelanoma skin cancer should not be used as organ donors. There should be no history of transmissible infectious disease or active untreated infection. A history of longstanding use of analgesics may indicate chronic renal injury. It is best not to consider individuals with high-risk behavior for HIV disease such as documented intravenous drug users, active homosexuals, hemophiliacs requiring blood transfusions, or those with known infected sexual partners (64,241). One of the great uncertainties associated with cadaver renal transplantation relates directly to the adequacy of the medical history of the cadaver donor. Many posttransplant recipient problems can be minimized or even avoided by an accurate donor history. This can be a special problem when the mortal injury occurs far from the patient's home. It is always important to obtain a medical history from someone who has had close recent contact with the individual, not merely a relative or friend.

Organs for transplantation cannot be removed until the surviving family gives specific permission for this act and brain death has been declared. The act of donation is therefore completely dependent on the good will and altruism of the public at large. The use of a signed donor card on the back of a driver's license is not sufficient consent and has been of marginal value in increasing the donor supply. Interestingly, one of the greatest impediments to identifying donors and obtaining family consent has been delayed referral or nonreferral to local organ procurement agencies by hospital personnel. It is hoped that increased local and national education policies, as well as “required request” legislation, will expand the pool of potential donors through greater public awareness (221).

Donor Management

The process of organ procurement can begin only when an individual has been declared brain dead and family consent has been obtained. In most states, the diagnosis of brain death requires strict medical criteria to be met, and a signed declaration must be made by two physicians, neither of whom can be a member of the transplant team. Brain death remains a clinical diagnosis (Table 22.7), but it can be supported by other objective tests (208). To be declared brain dead the patient should be comatose, be unable to breathe without mechanical assistance, and have absent cranial nerve function and reflexes. The absence of perfusion of the brain on an isotopic cerebral blood flow scan is a useful confirmatory test due to its ease of performance and reliability (252). The absence of flow is not compatible with the return of brain function. It is important to make this diagnosis after ruling out hypothermia, drug intoxication, metabolic encephalopathy, and shock as confounding diagnoses.

I. Clinical criteria
a. Unresponsiveness to external stimuli (pain, sound, light, noxious, ice water calorics)
b. Absence of spontaneous breathing
c. No cranial nerve function
d. Above findings present with body temperature >90°F
e. Absence of CNS-depressant drugs
II. Clinical criteria can be supported by
a. Isoelectric electroencephalogram
b. Lack of cerebral perfusion by angiogram or radiographic flow scan
c. Absence of evoked potentials

CNS, central nervous system.

TABLE 22.7. DIAGNOSIS OF BRAIN DEATH

Once declared brain dead, the donor should be kept in a state as close to normal homeostasis as possible. Appropriate ventilatory support is required, and normothermia should be maintained. Maintenance of pulmonary care, nasogastric suction to prevent aspiration, lubrication and protection of the eyes, removal of all intravascular catheters placed without sterile technique, monitoring of vital organ function with a central venous and arterial pressure catheter, and a Foley catheter are usually required. Blood transfusion is not routinely necessary, except in cases of ongoing hemorrhage. Often, donors are volume contracted and dehydrated (the appropriate management for brain injury) and must be resuscitated with fluids. Ringer's lactate is usually sufficient. Deterioration of brain function and loss of central neurohumoral regulatory control may result in severe systemic hypertension (Cushing's reflex) due to elevated circulating catecholamines and sympathetic activity. b-Blockers can be useful to protect the myocardium when this occurs. In some donors, brain herniation may result in bradycardia, hypotension, and diminished organ perfusion. Adequate systolic blood pressure, usually more than 100 mm Hg, is recommended. The use of vasopressors such as dopamine, which maintains renal blood flow, can be helpful. Urine output in adults should be maintained at more than 1 mL/kg per hour. Frequently, donors may develop massive urine output (more than 500 mL per hour) as a result of central diabetes insipidus, due to low levels of circulating antidiuretic hormone from the destroyed hypothalamic-pituitary axis. The resulting excessive free water loss can lead to hypokalemia, hypernatremia, hypocalcemia, and hypophosphatemia. This condition can be treated with exogenous vasopressin, which can be delivered intranasally.

The serum creatinine in the cadaver donor should be less than 2.0 mg/dL. A rising creatinine may be due to prolonged hypotension, which may cause irreversible renal ischemia. A rising serum creatinine, coupled with a markedly diminished urine output of less than 30 mL per hour before removal of the kidneys, is associated with permanent renal injury. The maintenance of the donor before surgical nephrectomy is one of the most important factors that contribute to immediate graft function after revascularization and the diminished need for posttransplant dialysis (160). Older donor kidneys, older than age 60, are especially susceptible to adverse prerecovery donor function, and every effort should be made to normalize physiologic parameters in these patients.

Donor Procurement Technique

The goals of cadaver kidney removal are to recover two anatomically intact kidneys with good physiologic function. The kidneys are removed en bloc with the midportion of the aorta and vena cava so as to preserve the origins of the renal blood vessels. Currently, most organ donors have an extra renal organ removed at the same time. If multiple organs are to be removed, the preferred sequence is the heart or lungs first, liver or pancreas second, and then the kidneys. It is important to keep the donor hemodynamically stable as long as possible during organ recovery. Most cadaver donors are given a large dose of corticosteroids to deplete circulating donor lymphocytes. Intravenous mannitol in doses of up to 1 g/kg is useful to ensure diuresis and provide some ischemic protection. A large dose of systemic heparin (10,000 to 20,000 units) is given just before organ removal. Some have advocated the use of a-blockers, calcium channel blockers, or dopamine to diminish renal vasospasm secondary to surgical manipulation.

In multiple organ recoveries, the procedure begins with a long incision from the sternum to the pubis. In kidney-only procurement, this may be modified with a

xiphoid-to-pubis incision that may be widened with a cruciate extension. The right colon and duodenum are mobilized, exposing the great vessels. The aortic bifurcation is isolated and a cannula is placed for cooling. A similar cannula is placed near the bifurcation of the vena cava. The suprarenal aorta is mobilized above the celiac trunk, as well as the suprarenal vena cava. If liver or pancreas procurement is to be done, this is more easily accomplished after the abdominal organs are removed. The ureters are divided deep in the pelvis with a generous amount of periureteral tissue intact. Once the superior mesenteric and celiac arteries are ligated, the kidneys can be flushed with ice-cold preservation fluid and circulatory arrest can ensue. Iced slush can be placed around the kidneys for additional surface cooling. At this point, wide excision of the kidneys with Gerota's fascia and the great vessels can be done, with care being given to avoid any dissection in the hilum of the kidney or posterior to the great vessels without direct visualization.

The entire en bloc specimen with aorta vena cava in both kidneys is then removed from the patient and placed in a pan of ice-cold perfusate for further dissection on a back table (Fig. 22.14). A large amount of Gerota's fat and fascia should be removed, confirming the complete flushing of all renal segments. This is rarely a problem if the return perfusate from the vena cava is clear while the organs are *in situ.* The kidneys should always be separated first by dividing the aorta on its posterior surface and then anteriorly, to leave a generous cuff of right or left aortic wall with the renal arterial circulation. This will include multiple renal arteries if present. The left renal vein can be divided flush with the vena cava and the left kidney removed separately. The right renal vein should always be kept intact with the vena cava to permit renal venous extension procedures if required in the recipient.

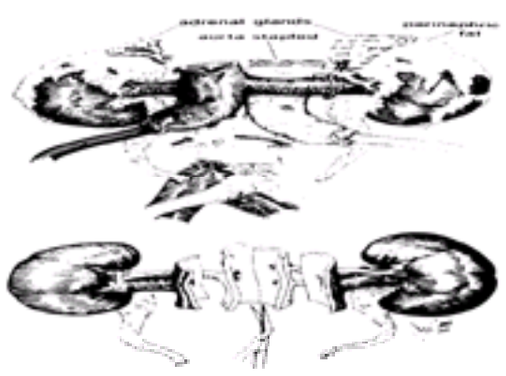

FIGURE 22.14. Technique for cadaver kidney removal. Specimen should include midaorta and vena cava with attached renal vessels. Once removed, the great vessels should be divided on their posterior surface to identify the number and location of the renal vessels. (From Barker CF, et al. Renal transplantation. In: Sabiston DC, ed. *Textbook of surgery.* Philadelphia: Saunders, 1986, with permission.)

Organ Preservation

The clinical practice of a cadaver renal transplantation requires the ability to store and preserve the kidney *ex vivo* for hours or even days. Because the acquisition of a renal donor is random, may occur at any hour, and must permit the transport of the organ over great distances, organ preservation techniques must be relatively simple, mobile, and inexpensive. In most circumstances, the process of tissue typing, crossmatching, and identification and preparation of a recipient takes at least 10 to 12 hours. In larger UNOS regions, and factoring in mandatory sharing of phenotypically identical donor–recipient pairs, this process may take up to 48 hours. In unusual circumstances, up to 60 hours of *ex vivo* time has been required. The goal of organ preservation is to provide an organ that will be protected from ischemic hypoxic damage and will function promptly in the host when revascularized.

Diminished blood flow and oxygen delivery to an organ results in ischemic injury (73). In kidney transplantation, there are two clinicopathologic consequences of ischemic injury. The first, due to a milder degree of ischemia, is acute tubular necrosis (ATN), which is reversible and results in delay of graft function after transplant. Pathologically, ATN results in sloughing and regeneration of the renal tubular epithelium with intact basement membranes. Blood flow is maintained, although glomerular filtration rate is minimal. The kidney may produce a filtrate (nonoliguric ATN) but does not remove waste products. The second form of ischemic injury is more severe and irreversible, termed *cortical necrosis.* Pathologically, necrosis of the entire renal cortex is found. Such kidneys never function (primary nonfunction), have poor blood flow characteristics, and ultimately fibrose. These pathologic findings are similar to the renal injuries suffered by patients who experience massive cardiogenic or hemorrhagic shock.

Kidneys can suffer ischemic injury at several points during organ recovery and preservation (18). *In situ* ischemia can occur in the cadaver donor during the terminal phases of brain death and organ retrieval. Hypotension is the proximate cause. Warm ischemia occurs from the time of circulatory arrest until the kidney is cooled and flushed. A human kidney can tolerate up to 20 to 30 minutes of warm ischemia, although current methods of organ procurement attempt to keep this time to zero. Beyond this time, irreversible injury ensues. Cold ischemic time refers to the period of *ex vivo* cold storage before reestablishment of the renal circulation in the recipient. A variable period of ambiothermic (room temperature) ischemia can occur during the surgical time required for anastomosis of the kidney blood vessels, although this can also be minimized by surface cooling with iced slush.

On a cellular level, ischemic injury renders the tissues hypoxic and retards oxidative, energy-requiring metabolic functions, often found in the mitochondria. One such function is the formation of high-energy phosphonucleotides such as adenosine triphosphate (ATP), required for the plasma membrane–situated Na-K and Ca pumps. Hypoxic cells lose the intermediate purine substrates required for ATP formation through degradation by xanthine oxidase. Loss of these pump functions leads to cellular swelling due to the influx of sodium and water into the cell and efflux of potassium across strong diffusion gradients. In addition, anaerobic glycolysis predominates, which produces lactic acid and hydrogen ions with resultant cellular acidosis. Acidosis is responsible for activation of lysosomal enzymes that lead to mitochondrial and cell membrane lysis. Another destructive process is the formation of superoxide anions during ischemia. These so-called oxygen free radicals can cause tissue injury during reperfusion of the kidney if they have accumulated.

Therefore solutions for organ preservation have been developed that attempt to counteract the metabolic consequences of hypoxia and anaerobic metabolism (Table 22.8). An essential ingredient in organ preservation is hypothermia. Rapid cooling at the onset of organ removal is done with iced saline slush. Perfusion and storage of the kidney at 4° to 10°C will minimize ischemic injury. Hypothermia reduces oxygen demand, slows metabolism, conserves energy in the form of adenine nucleotides, and retards catabolic enzyme activity. In addition, the ideal preservation solution would prevent acidosis, provide substrate for regenerating high-energy phosphate compounds (ATP), prevent reperfusion injury due to oxygen free radicals, and minimize cellular swelling.

Collins Solution	UW Solution
Potassium chloride	Hydroxethyl starch
Potassium phosphate	Lactobionate
Glucose	Potassium phosphate
Sodium bicarbonate	Magnesium sulfate
Magnesium sulfate	Raffinose, glutathione
Osmolality 360 mOsm/L	Allopurinol, adenosine, insulin
	Osmolality 320 mOsm/L

TABLE 22.8. MAJOR COMPONENTS OF KIDNEY PRESERVATION SOLUTIONS

The most commonly used preservation solution for kidneys was first developed by Collins more than 20 years ago. Its essential constituents mimic the intracellular rather than the extracellular fluid compartment with high K and low Na concentrations. It is made hyperosmolar with sugars to diminish the intracellular uptake of

water, which causes cellular swelling. Similar preservation solutions have been made using either mannitol or sucrose as the primary osmotic agent. Each can produce adequate cold storage for up to 48 hours.

However, the advent of extrarenal organ transplantation in the 1980s required further refinements. The liver, which can metabolize glucose under preservation conditions more efficiently than the kidney, was not well maintained by the Collins solution. Therefore researchers at the University of Wisconsin (UW) developed a perfusate more suitable for the liver and pancreas, which may also provide better preservation for the kidney (226). The UW solution uses lactobionate in place of glucose as an impermeable anion to prevent cellular swelling. Raffinose and hydroxymethyl starch provide additional osmotic and colloid support for the extracellular space. The absence of glucose diminishes anaerobic glycolysis and subsequent acidosis, and adenosine provides substrate for regenerating ATP during reperfusion. Allopurinol may help reduce the formation of oxygen free radicals. The use of UW solution may extend renal preservation up to 72 hours (264).

Once cooled and perfused through the renal artery, kidneys are generally kept in a container filled with the perfusate on ice. A container with each kidney is then transported to the transplant center. This technique (so-called simple cold storage) is used by the majority of transplant centers worldwide. Some have advocated the use of machine pulsatile perfusion to preserve kidneys, which may provide for lower rates of delayed graft function with extended preservation times. The machine pulsatile perfusion method can allow the determination of perfusion pressures, resistance to flow, pH, and metabolic products, which some have suggested correlate with renal viability. Although it is more cumbersome and expensive, the machine preservation technique may be most helpful for kidneys preserved beyond 48 hours.

RENAL TRANSPLANT OPERATION

Renal transplant recipients are particularly susceptible to poor healing and infection because of the complications of uremia and the altered host responses induced by immunosuppressive therapy. These considerations demand meticulous attention to detail in performing transplantation surgery, with careful handling of tissues and strict adherence to basic operative principles of asepsis and hemostasis.

In most cases, the renal allograft is implanted into one or the other iliac fossa (197). In determining which iliac fossa to use for transplantation, one should consider both the anteroposterior relationships of the renal vessels and the anticipated method of arterial anastomosis. When end-to-side arterial anastomosis to the hypogastric artery seems likely, as in performing single-artery transplantation in young patients, it is customary to place the right kidney in the left iliac fossa, and vice versa. When end-to-end arterial anastomosis to the external or common iliac artery is expected, as in older patients or when using a Carrel aortic patch with multiple donor arteries, the right kidney will lie more comfortably in the right iliac fossa and the left kidney in the left iliac fossa. These are only relative considerations, and with proper positioning of the graft and renal vessels, either kidney may be inserted into either iliac fossa. A relative advantage of using the right iliac fossa is that the right iliac vein has a more horizontal course than the left and is more accessible for the venous anastomosis. This may assume clinical significance when transplanting a kidney with an unusually short renal vein.

In patients with a history of lower extremity thrombophlebitis, silent thrombosis of the iliac veins may have occurred and transplantation should be performed preferentially into the opposite iliac fossa. If ipsilateral transplantation is being considered, preoperative venography should be done to verify iliac venous patency. In patients with a prior failed renal transplant, the second graft is always placed in the unoperated contralateral iliac fossa.

When the recipient is anesthetized, a 20-Fr urethral catheter is inserted in the bladder. A urine specimen is sent for culture, or if the patient is anuric, the bladder is irrigated with saline and this fluid is cultured. The bladder is filled by gravity with 100 to 200 mL of 1% neomycin sulfate solution, and the catheter is clamped and connected to a closed drainage system. Shaving of the operative site is done in the operating room, and the skin is prepared with an iodine solution for 10 minutes. Before commencing the operation, a single intravenous bolus of broad-spectrum antibiotics is given.

A lower-quadrant transverse semilunar skin incision is made, extending from the midline to just above the anterior superior iliac spine (Fig. 22.15). Throughout the operation, care is taken to achieve absolute hemostasis and to minimize blood loss. The external oblique, internal oblique, and transversus abdominis muscles are divided in line with the incision. The inferior epigastric vessels are identified lateral to the rectus muscle and are then secured and divided. The rectus muscle is either retracted medially or, if exposure of the bladder is not adequate, divided at its tendinous insertion into the symphysis pubis. The round ligament in the female is ligated and divided. The spermatic cord in the male is mobilized and retracted medially to obviate postoperative hydrocele formation, which commonly occurs following high cord ligation.

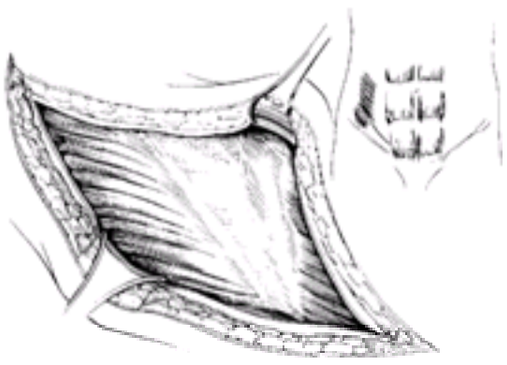

FIGURE 22.15. Lower quadrant transverse semilunar incision is used to perform renal transplantation. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

Extraperitoneal exposure of the iliac fossa is obtained by reflecting the peritoneum superiorly to the common iliac artery and medially to the bladder. A self-retaining ring retractor is then inserted to maintain exposure of the operative field (Fig. 22.16). The lateral blade of the retractor is doubly padded to avoid injury to the lateral femoral cutaneous nerve. The superior retractor blade is positioned to avoid compression of the common iliac artery, which may interfere with allograft perfusion following revascularization.

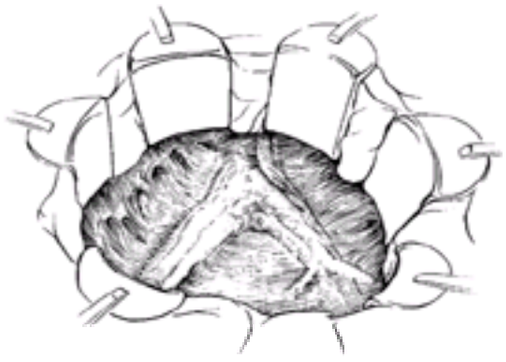

FIGURE 22.16. Extraperitoneal exposure of the iliac fossa is maintained with a self-retaining retractor. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

The external iliac vein is mobilized from the internal iliac origin to the femoral junction. To avoid postoperative lymphatic complications, all overlying lymphatic tissue is ligated and divided. If the donor kidney has a short renal vein, the internal iliac vein is divided to allow elevation of the external iliac vein and thereby facilitate the venous anastomosis. End-to-end anastomosis of the renal artery to the hypogastric artery is preferred, and the latter vessel is then mobilized from its origin to the

major anterior and posterior branches. Again, all overlying lymphatic vessels are ligated and divided. In such cases, it is unnecessary to mobilize the common and external iliac arteries (Fig. 22.17).

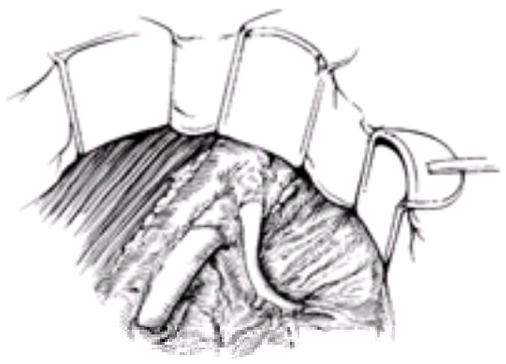

FIGURE 22.17. The external iliac vein and hypogastric artery are mobilized. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

Vascular clamps are placed proximally and distally on the external iliac vein. A venotomy is performed by excising a narrow longitudinal ellipse from the anterolateral aspect of the vein. The hypogastric artery is temporarily occluded proximally, the major branches are ligated distally, and the artery is divided proximal to the ligatures. If mild atherosclerosis of the hypogastric artery is present, endarterectomy is performed to render this vessel suitable for anastomosis to the renal artery. Heparin solution is instilled into the lumen of the hypogastric artery and external iliac vein.

The kidney is then brought into the operative field and the artery and vein are examined. Any residual tissue surrounding the origin of these vessels is removed and, if the renal vein appears short, this is mobilized from the renal sinus to obtain greater length. The kidney is lowered into the incision and end-to-side anastomosis of the renal vein to the external iliac vein is performed with a continuous 5-0 vascular suture. End-to-end anastomosis of the renal artery to the hypogastric artery is performed with interrupted 6-0 sutures after aligning these vessels carefully to avoid angulation or kinking. After the arterial anastomosis is completed, all vascular clamps are removed and circulation to the kidney is restored (Fig. 22.18).

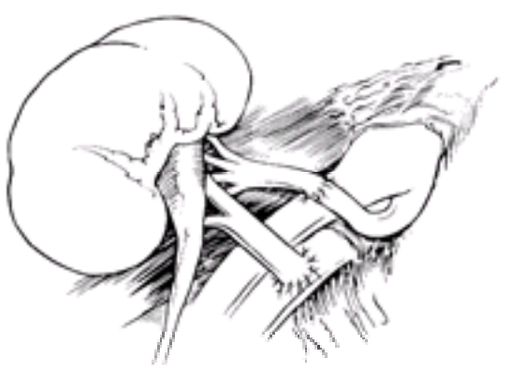

FIGURE 22.18. The renal vein is anastomosed end-to-side to the external iliac vein; the renal artery is anastomosed end-to-end to the hypogastric artery. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

The indications for end-to-side arterial anastomosis to the common or external iliac artery are extensive atherosclerosis of the hypogastric artery, significant discrepancy in size between the renal and hypogastric arteries, or multiple donor renal arteries encompassed by a Carrel aortic patch. In such cases, the external iliac artery and a contiguous segment of the common iliac artery are mobilized. Vascular clamps are placed across the common iliac, hypogastric, and external iliac arteries, and an arteriotomy in the recipient vessel is performed. In general, our preference is to perform end-to-side arterial anastomosis to the common iliac artery because of its larger caliber. This may not be possible when renal arterial length is insufficient or when there is significant atherosclerosis of the common iliac artery. In such cases, arterial anastomosis is to the external iliac artery, which lies in closer proximity to the renal hilus and is less often diseased than the common iliac artery. An interrupted-suture technique with 6-0 sutures is used unless anastomosis of a Carrel aortic patch is performed, in which case a continuous 5-0 suture is used (Fig. 22.19).

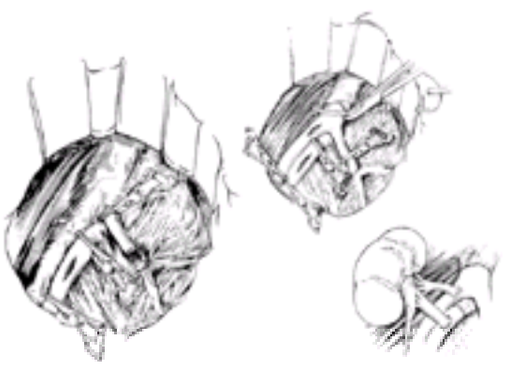

FIGURE 22.19. The renal vein is anastomosed end-to-side to the external iliac vein, and the renal artery is anastomosed end-to-side to the common iliac artery. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

After completion of the vascular anastomosis, urinary tract reconstruction is achieved by ureteroneocystostomy. This method is preferred over ureteroureterostomy or ureteropyelostomy because of a lower incidence of postoperative urinary fistulae. In performing ureteroneocystostomy, one should use the shortest length of ureter that will reach the bladder without tension because the allograft ureter receives its blood supply exclusively from branches of the renal artery. Since 1983, we have preferentially used the extravesical ureteroneocystostomy technique originally described by Lich (Fig. 22.20).

FIGURE 22.20. Extravesical ureteroneocystostomy technique. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

A 3-cm incision is made on the posterolateral aspect of the bladder. The perivesical fat, adventitia, and muscle of the bladder wall are incised to expose the mucosa over the entire length of the incision. The edges of the bladder muscle are undermined by pushing the mucosa away from the muscle. The distal end of the allograft ureter is spatulated for a short distance. A small opening is made in the bladder mucosa at the distal end of the incision, and mucosa-to-mucosa anastomosis is done between the ureter and the bladder, using interrupted or continuous 4-0 chromic sutures. At the distal aspect of the suture line, one or two bites are inserted through the entire bladder wall to anchor the ureter and prevent it from pulling out of the tunnel. The bladder muscle then is reapproximated loosely over the ureter with interrupted 3-0 chromic sutures.

As an alternative to this method, a transvesical ureteroneocystostomy technique may be used. The bladder is opened through an anterior cystotomy and a stab incision is made in the posterolateral bladder wall. The donor ureter is brought through the stab incision, and a 2- to 3-cm submucosal tunnel, directed toward the bladder neck, is fashioned. The ureter is then brought through the tunnel, taking care to avoid torsion on its longitudinal axis. The ureter is spatulated and anastomosed to the bladder with interrupted 4-0 or 5-0 chromic sutures. The sutures fixing the distal aspect of the ureter to the bladder are inserted deeply into the muscularis, while the remaining sutures are placed only through the bladder mucosa. The mucosa overlying the stab incision is closed with a continuous 5-0 chromic suture. The cystostomy incision is closed in three separate layers, with the second and third layers slightly overlapping the immediately underlying layer, to ensure a watertight repair.

The transvesical ureteroneocystostomy technique is preferred for transplantation of kidneys with a double ureter. The two ureters are left in their common adventitial sheath and are brought through the posterior bladder wall and submucosal tunnel together, as with a single ureter. Both ureteral ends are spatulated, the medial ends are sutured together, and the lateral and distal aspects are anastomosed to the bladder as with a single ureter (Fig. 22.21).

FIGURE 22.21. Transvesical ureteroneocystostomy technique for donor kidney with double ureter. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

After all anastomoses have been completed and adequate hemostasis has been achieved, the wound is irrigated with 2,000 mL of normal saline solution. This is an important local measure both in debriding the wound of small nonviable pieces of tissue and in minimizing the influence of inadvertent intraoperative contamination. The transplant incision is always closed without drainage in two separate musculofascial layers. The subcutaneous layer and the skin are also closed separately, and a pressure dressing is then used to cover the wound.

In the early postoperative period, fluid and electrolyte balance is maintained by monitoring central venous pressure, blood pressure, pulse rate, urinary output, and body weight. When oligoanuria is present despite normovolemia, 12.5 g of mannitol and 40 mg of furosemide are given intravenously. The amount of furosemide may be doubled to a maximum dose of 160 mg. Some cadaver allograft recipients remain oliguric following these measures due to vasomotor nephropathy. This diagnosis can be established only after excluding hyperacute rejection or technical problems by examining the incision for drainage, ensuring a patent urethral catheter, and obtaining an ultrasound study and an isotope renal scan. In contrast, living related allograft recipients often experience a profound postoperative osmotic diuresis, which necessitates vigorous fluid and electrolyte replacement.

Within the first 24 hours postoperatively, a technetium renal scan is routinely done to verify the patency of the transplanted renal artery. If uptake of isotope by the allograft is lacking or questionable, renal arteriography should be performed to evaluate the possibility of arterial thrombosis or hyperacute rejection. The initial surgical dressing is removed 24 hours postoperatively and is changed daily thereafter, using strict sterile technique. Systemic antibiotic therapy is administered only to patients with documented infection. A urethral catheter is left indwelling for 3 to 7 days, and the sutures from the transplant wound are removed 10 days postoperatively.

MULTIPLE RENAL VESSELS

Multiple renal arteries occur unilaterally and bilaterally in 23% and 10% of the population, respectively. Important prerequisites to successful transplantation of kidneys with multiple arteries are proper techniques of organ procurement, thorough arteriographic evaluation of potential living donors, and selection of an appropriate method of arterial revascularization. When such kidneys are transplanted, failure to recognize and preserve an accessory renal artery may eventuate in ureteral necrosis, graft rupture, segmental renal infarction, postoperative hypertension, or calyceal fistula formation. A variety of techniques are available for performing multiple artery renal transplantation (195).

Anastomosis of a Carrel aortic patch encompassing all renal arteries to the recipient common or external iliac artery is the preferred method for arterial anastomosis of cadaver kidneys with multiple arteries (Fig. 22.22). This requires that cadaver donor nephrectomy be performed en bloc with the aorta and vena cava. Use of such an aortic patch is not possible when kidneys are harvested separately, when polar vessels are injured inadvertently during removal, when there is significant atherosclerosis of the perirenal aorta, or when the renal arteries are widely separated on the aorta. Likewise, in live donor renal transplantation, a cuff of aorta should never be taken because of the increased risk to the donor.

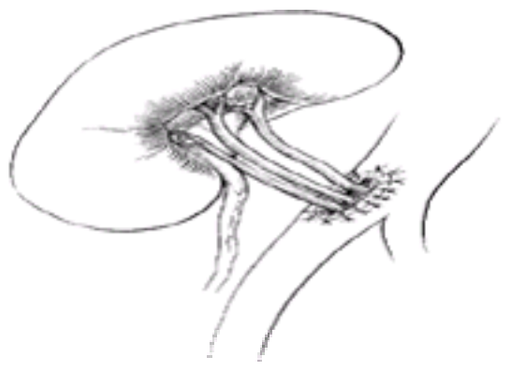

FIGURE 22.22. End-to-side anastomosis of the Carrel aortic patch with multiple renal arteries to the common iliac artery. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

When two adjacent renal arteries of comparable size are present, our preferred method is extracorporeal side-to-side anastomosis of the two vessels to create a common ostium (Fig. 22.23). This is done just before implantation, with the kidney cooled in ice saline solution. Continuous 6-0 or 7-0 vascular sutures are used for the repair, with optimal magnification provided by 3.5× loupes. Revascularization in the recipient involves only a single arterial anastomosis, preferably end-to-end to the hypogastric artery, with no increase in the warm renal ischemia time. This method is technically simple and, hemodynamically, yields less resistance to flow than do separate vascular anastomoses because of the greater cross-sectional area of the coapted vessels.

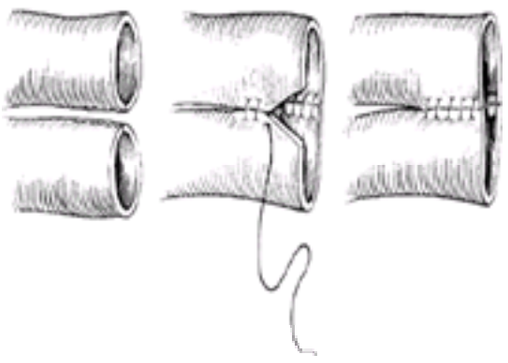

FIGURE 22.23. Side-to-side conjoined anastomosis for two renal arteries of equal caliber. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

When two renal arteries of disparate caliber are present, our preferred technique is end-to-side reimplantation of the smaller artery into the larger one (Fig. 22.24). A short linear arteriotomy is made in the side of the larger artery, without removing any of the vessel wall, to obviate narrowing of the arterial lumen. The smaller artery is spatulated, and end-to-side anastomosis to the larger vessel is done with interrupted 7-0 vascular sutures, using microvascular instruments and 3.5× loupes for magnification. A small catheter or probe may be placed through the suture line during its construction to prevent accidental entrapment of the back wall. The completed anastomosis is tested for patency and integrity by gentle perfusion of the main renal artery. The transplant operation is then done as with a single renal artery. The advantages of this method are that it is technically simple, it involves anastomosis of vessels that are similar in thickness, only one arterial anastomosis is required in the recipient, and warm renal ischemia time is not prolonged. This technique can also be used for transplant kidneys supplied by more than two renal arteries of varying caliber.

FIGURE 22.24. End-to-side reimplantation of small renal artery into larger one. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

Another method for transplanting kidneys with multiple renal arteries involves fashioning these into a single artery before implantation with a branched graft of autogenous hypogastric artery (Fig. 22.25). If atherosclerosis is present in the hypogastric artery, this can be removed after its procurement using the eversion endarterectomy technique. Donor arterial repair is done extracorporeally under surface hypothermia with end-to-end anastomosis of the graft branches of the distal renal arteries. The kidney is then transplanted as with a single renal artery, with no added warm ischemia time. This technique is particularly useful to transplant kidneys with more than two renal arteries or when insufficient arterial length is present to permit use of the previous two methods described. Should extensive calcification of the hypogastric artery render it unsuitable as a reconstructive graft, a branched saphenous vein graft can be used alternatively in the same fashion.

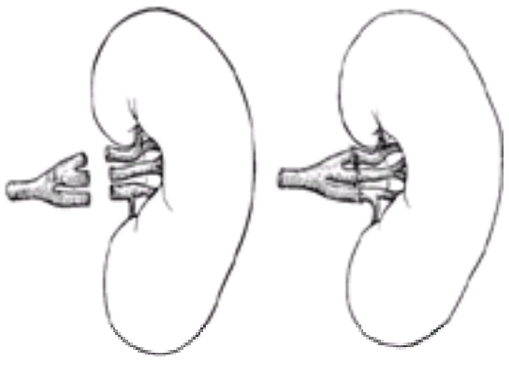

FIGURE 22.25. Use of branched autologous vascular graft to reconstruct multiple renal arteries. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

Additional techniques for performing multiple artery transplantation include arterial anastomoses to the branches of the hypogastric artery, separate arterial anastomoses to the external or common iliac arteries, separate arterial anastomoses to the hypogastric and external iliac arteries, and polar artery anastomosis to the inferior epigastric artery. These techniques all require performance of multiple arterial anastomoses *in situ* that result in a prolonged warm ischemia time. Therefore, when a Carrel aortic patch is not available, we prefer extracorporeal arterial reconstruction using one of the three methods described previously. These latter techniques have proven to be readily applicable, either individually or in combination, to most anatomic variants presented by kidneys with multiple arteries.

Multiple renal veins are less common than multiple arteries and more frequently involve the right kidney. Small renal veins can be ligated without risk. When double renal veins of equal size are present, both of these must be preserved to avoid increased intrarenal venous pressure after revascularization. The optimal method involves implanting these together with a cuff of vena cava obtained at the time of nephrectomy. When this is not available, extracorporeal venous reconstruction is performed as described for multiple arteries with either a conjoined or an end-to-side anastomosis of the two veins.

TRANSPLANTATION IN CHILDREN

There are special surgical considerations when renal transplantation is performed in young pediatric patients. In children weighing less than 20 kg, the iliac fossa is too small to accommodate a kidney from an adult donor. In this event, the graft must be inserted in a more cephalad location.

A midline transperitoneal incision is made, and the cecum and ascending colon are reflected medially to expose the aorta, the vena cava, and the common iliac vessels. The graft is placed retrocecally with end-to-side anastomosis of the renal vein either to the vena cava or to the right common iliac vein. The renal artery is anastomosed end-to-side to either the aorta or the right common iliac artery (Fig. 22.26). Immediately after revascularization of the allograft, 300 mL of albumin is administered as an intravenous bolus to replenish the suddenly depleted intravascular volume and to ensure adequate renal perfusion. The ureter generally reaches the bladder easily, remaining retroperitoneal throughout its course, and a ureteroneocystostomy is performed. An alternative surgical approach for performing transplantation in children involves the use of extraperitoneal incision extending from the tip of the twelfth rib to the symphysis pubis. This method is particularly helpful in children who have been managed with peritoneal dialysis. Very small children, weighing less than 8 kg, require transplantation of a pediatric cadaver graft.

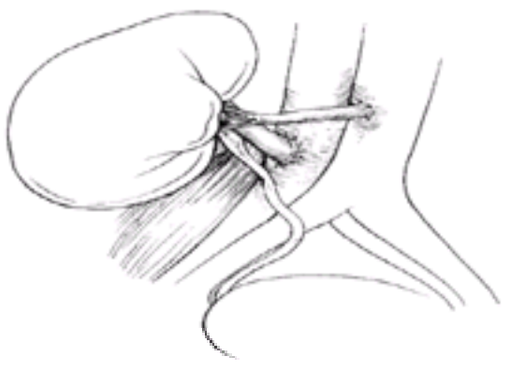

FIGURE 22.26. Technique of retrocecal renal transplantation for placement of adult donor kidney into small child. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

TRANSPLANTATION WITH URINARY DIVERSION

In some patients, the bladder may be unsuitable for transplantation due either to severe neurogenic disease or to postinflammatory contracture. In such cases, renal transplantation must be performed in conjunction with supravesical urinary diversion. The most common technique involves the creation of an intestinal (generally ileal) conduit with a lower quadrant stoma at a separate operation before transplantation; 4 to 6 weeks later, the transplant operation is performed (161).

The preferred method for performing transplantation into an ileal conduit is to place the allograft retrocecally, as in pediatric transplantation, with anastomosis of the renal vessels either to the aorta and vena cava or to the common iliac vessels. This allows gravity-dependent urinary drainage and a more direct ureteroenteric anastomosis than when transplantation into the iliac fossa is done (Fig. 22.27).

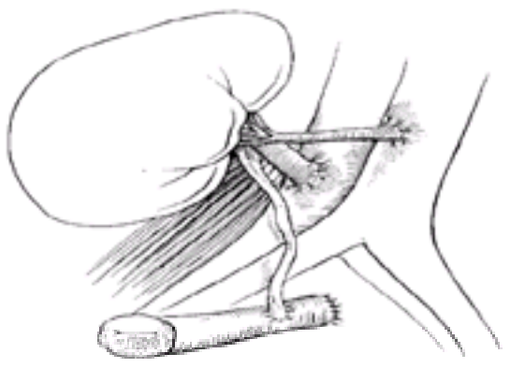

FIGURE 22.27. Technique of renal transplantation into an intestinal conduit. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989, with permission.)

In some patients with ESRD, diversion with cutaneous ureterostomy has been performed previously and a well-functioning stoma is present. In such cases, the stoma and a short contiguous segment of distal ureter can be preserved at the time of bilateral nephrectomy. Transplantation is then performed with anastomosis of the allograft ureter to the retained native ureter just below the abdominal wall, thus obviating the need for an intestinal segment (Fig. 22.28). Using this method, satisfactory urinary drainage is achieved through the normal peristaltic ability of the allograft ureter, and the retained dilated ureter functions solely as a short conduit and stoma (161).

FIGURE 22.28. Technique of renal transplantation using existing cutaneous ureterostomy stoma. (From Novick AC, Streem SB, Pontes JE, et al, eds. *Stewart's*

operative urology. Baltimore: Williams & Wilkins, 1989, with permission.)

RENAL ALLOGRAFT REJECTION

Preventive Immunosuppressive Protocols

Immunosuppressive protocols using the agents discussed previously can be divided into two phases: induction and maintenance. *Induction* describes initial high-dose immunosuppression designed to prevent a primary immune response during the first 7 to 10 days of engraftment. Numerous factors (e.g., patient selection, organ quality) can influence immunosuppressive decisions, and transplant physician experience and judgment are key determinants of patient management. Currently, induction therapy involves either polyclonal or monoclonal antilymphocyte agents. As previously mentioned, these agents are often used as sequential therapy with a delay in the institution of a calcineurin inhibitor drug until the kidney has sufficiently recovered from ischemic preservation injury. In general, if preservation times are short, under 12 to 18 hours, calcineurin agents can be introduced earlier without an increased risk of delayed graft function. However, when preservation times are 24 hours or longer, delayed graft function rates of 30% or more can occur, and the duration will be prolonged by the immediate introduction of calcineurin inhibitor drugs. Another consideration in induction therapy is the choice between polyclonal and monoclonal agents. Most studies have found these two classes of agents to be equally effective with respect to rejection prevention and allograft survival. The polyclonal agents are usually administered for 7 to 14 days and require central venous access due to the high protein load and vein sclerosis that occurs. The monoclonal agents can be given peripherally and are more suitable for early hospital discharge. The newer anti–IL-2 receptor blocking agents have longer half-lives and can be given only on days 0 and 4 with prolonged immunosuppression present for several weeks.

Maintenance therapy describes the lowest doses of immunosuppressive drugs necessary to prevent rejection. Unfortunately, this is often arrived at by trial and error and results in much interpatient variability. The principles of drug interactions and synergism that have been developed from multidrug protocols for cancer chemotherapy also apply to rejection prophylaxis. Multiple drugs with different mechanisms of action can be used together to permit lower dosages and less toxicity than would be obtained from higher dosages of single agents. Most centers have arrived at triple-drug maintenance regimens consisting of a calcineurin inhibitor drug (cyclosporine or tacrolimus), an antiproliferative agent (mycophenolate mofetil or azathioprine), and corticosteroids. Rapamycin is being evaluated either in combination with a calcineurin drug or as a replacement.

The following is a description of current immunosuppressive protocols used at The Cleveland Clinic Foundation and a brief review of their rationale.

Live Donor Recipients

HLA-identical siblings receive corticosteroids and cyclosporine. Cyclosporine is begun at 6 to 8 kg per day in divided doses approximately 36 hours before transplantation and subsequently adjusted to maintain trough blood levels at about 200 ng/mL. One gram of intravenous methylprednisolone is given perioperatively, and prednisone is begun at 2 mg/kg per day in divided doses from postoperative day 1. Prednisone is tapered to 30 mg per day by day 8, to 25 mg at 1 month, and lowered by 2.5 mg per month to 7.5 mg per day. Steroids are sometimes tapered off by 1 year.

Mismatched live donor recipients (1-haplotype, 0-haplotype, and live unrelated) recipients are managed with cyclosporine-based triple-drug therapy. Again, cyclosporine is begun 36 hours before transplantation at 6 to 8 mg/kg per day and adjusted by trough blood level monitoring. Steroids are given in doses similar to those described for HLA-ID recipients. Mycophenolate mofetil is begun on day 1 at 1 g twice daily and left at this dose unless specific toxicity necessitates dosage reduction. We have recently experienced a fall in acute rejection rates to single digits in mismatched live donor recipients with the addition of basiliximab (82). The IL-2 receptor blocking antibody has now been incorporated into our protocol.

Cadaveric Recipients

Our initial concerns of cyclosporine's potentiation of ischemic injury in kidneys with prolonged preservation times were confirmed by a randomized study in which kidneys from a single donor were transplanted separately into one of two groups, the first receiving initial cyclosporine therapy while the second received sequential therapy with a delay in initiation of cyclosporine (194). Patients receiving cyclosporine had an increased incidence of delayed graft function and primary nonfunction, resulting in a diminished overall allograft survival. This was further substantiated in an experimental model in which cyclosporine was administered to rats subjected to varying times of renal ischemia (132). A protocol using sequential, quadruple therapy (MALG plus prednisone, azathioprine, and cyclosporine) was instituted at that time. Subsequent to the availability of OKT3, we initiated a randomized, prospective comparison of OKT3 versus ALG in patients with acute renal failure following cadaveric renal transplantation (270). The results revealed no difference in patient or allograft survival or rejection rates, although there was a slight increase in side effects in the OKT3 group. We subsequently demonstrated that OKT3 side effects could be diminished using lower doses and steroid pretreatment (84).

Currently, cadaveric recipients receive steroids and mycophenolate mofetil in a manner similar to that for live donor recipients. Basiliximab is given at 20 mg on days 0 and 4. The T-cell activation marker CD25 is obtained to confirm efficacy. Cyclosporine is begun after return of adequate renal function (serum creatinine 4.0 mg/dL or lower) at approximately 6 mg/kg per day and adjusted to keep trough levels at 200 to 250 ng/mL the first month. In cases of prolonged ATN, cyclosporine is delayed until day 8 to 10 and advanced more slowly.

DIAGNOSIS OF REJECTION

The prompt diagnosis of rejection as the cause of allograft dysfunction is imperative to minimize irreversible damage to the kidney. Depending on the time from transplantation and the preceding level of renal function, the diagnosis can be obscure. The more classic findings of fever; a swollen, painful kidney; and diminished urine output are often absent in patients receiving cyclosporine. Differential diagnoses include ATN, nephrotoxicity, urinary obstruction or fistula, and vascular complications. A renal ultrasound (see Surgical Complications) will assist in assessing the latter causes. The findings resulting in the diagnosis of rejection are those related to renal nuclear scanning and a renal allograft biopsy.

Renal Scan

The value of sequential renal scans in the evaluation of renal transplant recipients has long been established (71). Technetium 99m diethylenetriamine pentacetic acid (^{99m}Tc DTPA) (173) and iodine-labeled orthoiodohippurate (I-OIH) (319) have been the most widely used radiopharmaceuticals. However, we now use technetium 99m mercaptoacetyl-triglycine (^{99m}Tc MAG3) to image renal transplant recipients (38,198). MAG3 is a primarily tubular-excreted compound; it shares equivalent physiologic properties with OIH that, in combination with its availability as a technetium-labeled agent, make it a preferable alternative as the radionuclide pharmaceutical. Images obtained with MAG3 are distinctly superior to those previously seen with DTPA and OIH.

Representative MAG3 scans for various clinical scenarios are depicted in Fig. 22.29, Fig. 22.30, Fig. 22.31, Fig. 22.32, Fig. 22.33, Fig. 22.34, Fig. 22.35 and Fig. 22.36. Figure 22.29 is that of the allograft of a living-related recipient immediately after transplant and demonstrates excellent perfusion and function. There is prompt uptake of the radiopharmaceutical with early peak accumulation and a rapid excretion and clearance from the allograft. Episodes of renal function deterioration will be demonstrated in the scan, primarily manifested as a delay in uptake with the failure to reach peak accumulation (the allograft continues to accumulate throughout the duration of the study) and diminished excretion and clearance. Figure 22.30 demonstrates an immediate posttransplant cadaveric recipient with acute tubular necrosis. Figure 22.31 reveals significant improvement in the scan 1 week later as the acute tubular necrosis has resolved. Failure of the scan to demonstrate improvement in this setting or a sudden deterioration in the appearance in the scan would implicate other causes of renal failure. Figure 22.32 is a 24-hour posttransplant scan in a living-related recipient with excellent function. One month after transplant, the patient experienced an acute rise in his serum creatinine with associated deterioration of the scan (Fig. 22.33). A percutaneous renal biopsy revealed acute cellular rejection. He underwent antirejection therapy with improvement in renal function (Fig. 22.34). Figure 22.35 is that of an immediate posttransplant living-related recipient; Fig. 22.36 was obtained approximately 4 days later associated with a rise in the patient's serum creatinine. The patient was noted to have elevated cyclosporine levels, and his dosage was reduced with improvement in his renal function.

FIGURE 22.29. Renal scan in living related recipient 1 day postoperatively demonstrating excellent perfusion and function with rapid uptake and time to peak accumulation and prompt excretion and clearance.

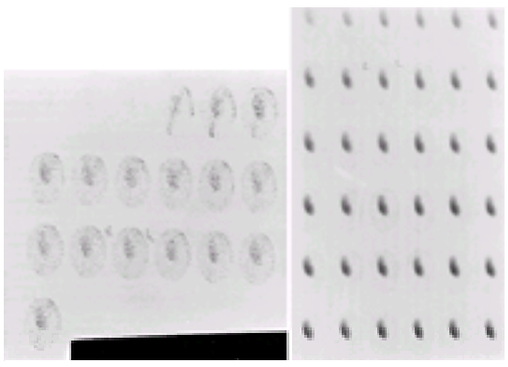

FIGURE 22.30. Baseline renal scan in cadaveric recipient with acute tubular necrosis illustrating a delay in uptake with persistent accumulation throughout the study and diminished excretion and clearance.

Percutaneous Renal Allograft Biopsy

Although clinical and radiographic clues can arouse suspicion, the certainty of rejection requires histopathologic examination of allograft tissue. A percutaneous needle biopsy of the kidney is often easily performed; including in the outpatient clinic, especially under ultrasound guidance. We currently perform approximately 80% of biopsies in this setting. Although the potential for significant complications, including bleeding, exists, a core biopsy can be performed safely with a high likelihood of providing needed information (140). A proposed standardized classification (Banff schema) was developed based on the premise that some findings (including tubulitis and intimal arteritis) are specific for rejection, whereas others (e.g., a cellular infiltrate) are nonspecific (Table 22.9) (261). A more recent update of the schema focused on so-called borderline cases of interstitial inflammation and severe vascular rejection (228).

Biopsy Findings	Banff Classification	Possible Clinical Approach
Normal; minor changes, or infiltrates without tubular invasion	Normal or "other" (nonspecific changes)	No treatment, or treat other entity
Mild lymphocytic invasion of tubules (tubulitis)	Borderline changes	No treatment, or treat other entity
Widespread interstitial infiltrate with moderate invasion of tubules	Mild acute rejection (grade I)	Treat for rejection if there are clinical signs
Widespread interstitial infiltrate with severe invasion of tubules and/or mild or moderate intimal arteritis	Moderate acute rejection (grade II)	Treat for rejection; consider ALG or OKT3 if refractory to steroids
Severe intimal arteritis and/or "transmural" arteritis, fibrinoid change, and medial smooth muscle cell necrosis often with patchy infarction and interstitial hemorrhage	Severe acute rejection (grade III)	Treat for rejection unless clinical course suggests rejection cannot be reversed, in which case consider abandoning the graft
Hyaline arteriolar thickening (new onset, not present in implantation biopsy), and/or extensive isometric vacuolization of tubules, smooth muscle degeneration, thrombotic microangiopathy	"Other," cyclosporine toxicity	Reduce cyclosporine therapy
Tubular cell loss and necrosis, regenerative changes	"Other," acute tubular necrosis	Await recovery
Interstitial fibrosis, tubular atrophy (new-onset arterial fibrous intimal thickening supports chronic rejection)	Chronic transplant nephropathy	Temporize

TABLE 22.9. THE BANFF SCHEMA SIMPLIFIED

TREATMENT OF REJECTION

Pulse Corticosteroids

As they have been for more than three decades, increased (pulse) doses of corticosteroids are the initial antirejection therapy in most programs. There are few data to support any given dose (0.5 g versus 1 g per day) or a particular route of administration (intravenous versus high-dose oral) (59). Currently, rejection episodes at our center are initially treated with 0.5 g of methylprednisolone (Solu-Medrol) per day for 3 days (271). If the rejection has not been reversed after 3 days of corticosteroid therapy or if more ominous findings are present in the biopsy (e.g., severe vasculitis), more aggressive therapy is initiated with antilymphocyte agents. Corticosteroids are administered before a biopsy is performed, and all patients undergo a biopsy before receiving antilymphocyte preparations to ensure that rejection is the cause of allograft dysfunction, as opposed to other etiologies such as acute tubular necrosis or cyclosporine nephrotoxicity.

Antilymphocyte Preparations

Both polyclonal (MALG) (274) and monoclonal (OKT3) (206) antilymphocyte preparations are extremely effective in reversing rejection when compared with corticosteroids. Although reported as primary therapy by some centers (289), we have generally reserved the use of these agents for steroid-resistant rejection episodes because of the toxicities mentioned previously. Both agents have been extremely effective with reversal rates of 70% to 90% for steroid-resistant rejection (193), although there is a slightly higher rate of re-rejection following treatment. Interestingly, approximately 50% of these rejection episodes occurring after treatment with antilymphocyte preparations for steroid-resistant rejection will respond to a course of steroids. Before re-treating with OKT3, the patient must be checked for the presence of antibodies to OKT3.

Although direct comparative studies are few, results with ALG and OKT3 for steroid-resistant rejection appear to be similar. A prospective, randomized, although small, study found slightly improved results in patients treated with OKT3 for steroid-resistant rejection compared with those receiving ALG (113). MALG is given at dosages of 15 to 20 mg/kg per day for 10 to 14 days, and OKT3 is given at a dosage of 5 mg per day for 7 to 14 days.

Plasmapheresis

Although OKT3 has been shown to be of benefit in some patients with “vascular” rejection (251), there currently exists no universally effective treatment for

antibody-mediated rejection. As plasmapheresis had been shown to be successful in treating various immunologically mediated renal diseases (211), attempts were directed at using it for humoral rejection. Initial anecdotal reports indicated that plasmapheresis would be efficacious in treating antibody-mediated rejection; however, more in-depth reviews (59,211) of available data including controlled studies have failed to confirm its role in this setting. More sensitive posttransplant monitoring, such as flow cytometry crossmatches (50), may allow for antibody production detection before organ damage and thus potentially enhance the effectiveness of plasmapheresis. Additional applications of plasmapheresis have included the removal of anti–blood group antibodies in patients undergoing ABO-incompatible transplants (297). Backman and colleagues (14) reported on the use of plasmapheresis to remove anti-HLA antibodies from highly sensitized patients, thus allowing 14 of 17 patients to undergo transplantation who otherwise would have remained on dialysis. However, numerous logistical problems (e.g., waiting time before a cadaver kidney becomes available, necessity for availability of plasmapheresis at any time) have limited this potential application of plasmapheresis.

MEDICAL COMPLICATIONS

Medical complications experienced by renal transplant recipients are manifestations of underlying systemic diseases (e.g., diabetes), medication-specific adverse effects, or the result of acquired immunodeficiency. Complications encompass essentially all organ systems, and virtually every recipient will require therapeutic intervention for management of medical diseases. These complications can occur at any time in the posttransplant course (early or late), and thus lifelong surveillance of the transplant recipient is necessary.

Infection

Broad-spectrum antimicrobials and prophylactic protocols aimed at more serious infectious agents (including viral) have diminished but not eradicated the significant morbidity and mortality rates suffered by immunocompromised renal transplant hosts. More than half of renal transplant recipients will experience at least a single episode of infection in the first year after transplant (240), and septicemia is second only to cardiovascular events as the leading cause of death in the posttransplant setting (302). Immunosuppressed patients are at risk not only for the usual bacterial infections experienced by the immunocompetent host, but opportunistic infections as well. Pulmonary infections have been the leading contributor to the morbidity and mortality rates seen in renal transplant recipients, and causative agents include bacterial *(Pseudomonas, Mycobacteria, Listeria monocytogenes, Legionella,* and *Nocardia asteroides),* viral (CMV, herpesvirus), and fungal *(Candida, Pneumocystis carinii, Aspergillus,* and *Cryptococcus)* (240). Significant morbidity is associated with a delay in the accurate diagnosis, which is often not possible based on sputum specimens and may require transtracheal or transbronchial aspiration or biopsy or even percutaneous or open lung biopsy. Improvements in immunosuppressive strategies (especially decreased corticosteroids) have been associated with a reduction in the incidence of and death from pneumonia in renal transplant recipients (182), which are approximately 10% and 2%, respectively, in the cyclosporine era (112). Morbidity from *Pneumocystis carinii* pneumonia, which occurs in 5% to 10% of transplant recipients, has been virtually eliminated with trimethoprim-sulfamethoxazole prophylaxis (169), which also protects against *Nocardia asteroide*s and *Listeria monocytogenes.*

Urinary tract infections are by far the most common bacterial infection occurring in the renal transplant recipient, with an incidence of 35% to 79% in the nonprophylaxed patient. Approximately 60% of episodes of Gram-negative sepsis in renal transplant patients originate from the urinary system (240). The morbidity of urinary tract infections is closely linked to the timing from transplantation, with those infections in the first few months more often being associated with pyelonephritis, bacteremia, and frequent relapses, compared with those infections occurring more than 6 months after transplant, which are usually more benign. Risk factors for urinary tract infection include indwelling Foley catheters, lower urinary tract anatomic abnormalities, stones, ureteral stents, and neurogenic bladder. In addition to the described pulmonary benefit, trimethoprim-sulfamethoxazole significantly reduces the incidence of urinary tract infection and resultant bacteremia in this patient population (88). We currently administer one single-strength trimethoprim-sulfamethoxazole tablet daily in the posttransplant period. In patients with an allergy to sulpha drugs, low-dose quinoline (norfloxacin or ciprofloxacin) may be substituted, although this results in a loss of the pulmonary prophylaxis.

Chronic liver disease occurs in 10% to 15% of renal transplant recipients and is the cause of death in 8% to 28% of survivors greater than 10 years after transplant (28). Viral hepatitis is the major cause of morbidity. Much has been learned with regard to hepatitis B virus (HBV) in this setting, and numerous questions regarding hepatitis C virus (HCV) have emerged as major considerations. The presence of a specific, sensitive, and rapid screening test for hepatitis B surface antigen (HBsAg) has rendered the transmission of hepatitis B by transplantation (with the associated risk of fulminant hepatitis), as well as the transplantation of chronically infected individuals destined to do poorly, relatively uncommon (240). A study of several thousand cadaveric organ donors revealed a prevalence of HCV by antibody testing to be approximately 5% compared with approximately 1% for healthy blood donors (215). The prevalence of virus as detected by polymerase chain reaction (PCR) was 2.4%, suggesting that half of the donors would not have transmitted virus. However, PCR is not currently available as a screening tool. A separate study from the New England Organ Bank identified 29 recipients of organs from 13 HCV antibody donors (216,217). One hundred percent of the recipients had detectable virus by PCR, although only 62% seroconverted. Forty-eight percent of the recipients developed hepatitis, including 12 with chronic liver disease and 1 with subfulminant hepatic failure. The development of chronic liver disease in posttransplant HCV disease appears more indolent than that of HBV. Rao and Andersen (232) reported a higher incidence of chronic progressive hepatitis, chronic active hepatitis, cirrhosis, and death from hepatic failure in patients 10 years after renal transplant with chronic hepatitis B compared to those with non-HBV chronic liver disease, thought to represent HCV. Until the risks are better defined, it appears that a policy of avoiding the use of HCV antibody–positive donors is appropriate, whereas the presence of HCV in a potential recipient does not represent an absolute contraindication to transplantation.

CMV is the most frequently encountered infection in renal transplant recipients, and risk factors include the serologic status of donor and recipient, as well as the immunosuppressive regimen used (240). CMV infection is reported to occur in 20% to 70% of renal transplant recipients. CMV infection occurs via one of three mechanisms. Primary infection results from the transmission of virus form a seropositive donor to a seronegative recipient; reactivation occurs when a seropositive recipient experiences reactivation of latent virus; and superinfection is a result of the transmission of a different strain (serotype) from a seropositive donor to a seropositive recipient. The term *CMV infection* is used to describe the growth of CMV in the blood or urine of the recipient. Symptomatic CMV disease describes viral growth accompanied by clinical symptoms. The most common is a clinical syndrome of fever and leukopenia. However, tissue-invasive disease involving the lungs, liver, GI tract, bone marrow, or central nervous system can occur. Approximately 60% of recipients at risk for primary infection will develop symptomatic CMV disease.

The nucleoside analogues acyclovir and ganciclovir have been used to treat CMV infection. High-dose acyclovir (800 mg four to five times a day) (15) and CMV hyperimmune globulin (260) have been used to diminish the incidence or severity of primary disease. They appear to be somewhat less effective when donors are seropositive or when antilymphocyte preparations, especially OKT3, are used. Intravenous ganciclovir at doses of 5 mg/kg twice a day for 2 to 3 weeks has proven effective in the treatment of CMV infection, as well as for preemptive therapy in patients receiving antilymphocyte preparations (210).

An oral preparation of ganciclovir has been introduced for CMV prophylaxis, although it has significantly decreased bioavailability compared with the intravenous blood levels achieved. We performed a randomized trial of oral ganciclovir versus oral acyclovir for CMV prophylaxis in renal transplant recipients considered at high risk due to induction with OKT3 (83). Only 2% of ganciclovir-treated patients compared with 36% of acyclovir-treated patients developed CMV infection. Most acyclovir failures occurred when donors were seropositive for CMV. We now administer oral ganciclovir for 90 days for all recipients of CMV-seropositive donors.

Malignancy

Renal transplant patients experience an increased susceptibility to malignancy, and the Cincinnati Tumor Registry reports a higher incidence of lymphomas, lip cancer, Kaposi's sarcoma, carcinomas of the kidney, carcinomas of the vulva and perineum, and hepatobiliary tumors as compared with the general population (214). Skin cancers are the most common and occur with similar frequency in both groups, although squamous cell predominates in the transplant patients and basal cell is more common in the general population. Lymphomas account for 20% of all cancers in transplant patients, compared with 5% of all cancers in the general population. Posttransplant lymphoproliferative disorders (PTLDs) represent a serious threat to the transplant patient. PTLDs differ from the lymphomas in the general population in that the overwhelming majority (94%) are non-Hodgkin's lymphomas and arise predominantly (86%) from B lymphocytes. Extranodal involvement is more common in PTLDs (70%); approximately 25% involve the central nervous system and 20% involve the allograft itself. Although initial reports suggested a higher incidence of PTLDs in OKT3-treated patients, it is probably a result of overall overimmunosuppression rather than a single immunosuppressive agent (214) and appears to be related to the induction of B-cell proliferation by Epstein-Barr virus (EBV) infection in the immunosuppressed patient. These relationships were demonstrated dramatically in a small series of patients in which a 12.5% incidence of PTLD was noted in patients receiving MALG induction followed by OKT3 for rejection (47). In the same study, patients at risk for primary EBV infection had a 23.1% of incidence of PTLD compared with 0.7% for EBV-seropositive patients. Polyclonal B-cell PTLD appears to be more responsive to therapeutic measures including reduction of immunosuppression (189) than monoclonal B-cell PTLD, which appears to have a more malignant course (possibly representing progression in the continuum of the disease). The role of ganciclovir in the treatment of PTLDs is unknown at present.

Hypertension

In the cyclosporine era, 60% to 70% of patients experience hypertension following transplantation, compared with 40% to 50% before the introduction of cyclosporine, with a significant impact on patient and allograft survival (53,74). Not only has cyclosporine altered the prevalence of hypertension in the posttransplant patient, but it has also changed the mechanism and nature, and thus the treatment, of hypertension in this setting (53,74). Although the causes of posttransplant hypertension are numerous, before the introduction of cyclosporine renin-mediated causes appeared to be primarily responsible, often related to native kidney contributions or chronic rejection in the allograft. Currently, direct effects from cyclosporine predominate as the etiology of hypertension in most patients. Discussed previously (see section on cyclosporine), calcium channel blockers have emerged as the antihypertensive treatment of choice in these patients, assuming that corticosteroids and cyclosporine have been reduced to as low a dose as possible without risking rejection. Angiotensin-converting enzyme (ACE) inhibitors should be used with extreme caution because they can induce renal insufficiency, even in the absence of renal artery stenosis, as well as exacerbate existing hyperkalemia. However, the observation that posttransplant patients treated with ACE inhibitors were experiencing unexplained anemia has lead to a therapeutic benefit (310). Approximately 10% to 15% of posttransplant patients experience erythrocytosis, and through mechanisms poorly understood (although possibly related to alterations in erythropoietin production), judicious use of ACE inhibitors has been proven effective in lowering the hematocrit without creating the adverse effects mentioned previously, thus obviating the need for frequent phlebotomies, which had been the mainstay of previous treatment for posttransplant erythrocytosis (92). Provided rejection, recurrent disease, and renal artery stenosis in the allograft have been excluded, patients whose hypertension does not respond to medical therapy should be considered candidates for bilateral native nephrectomies (54).

Hyperlipidemia

Hyperlipidemia occurs in 50% to 80% of renal transplant recipients and, like hypertension, is the result of multifactorial causes, occurs with at least the same if not greater frequency since the introduction of cyclosporine, and serves as a potential risk factor for significant cardiovascular-related patient morbidity and death (119,167). Posttransplant hyperlipidemia appears to be more closely related to corticosteroid dose than cyclosporine dose (307), although unfortunately a reduction or withdrawal of steroids does not ameliorate the hyperlipidemia, and a concomitant reduction in high-density lipoprotein cholesterol with total cholesterol raises considerable doubt with regard to the cardiovascular benefit (119). Dietary management, exercise, and optimization of steroid and cyclosporine dosing constitute primary therapy for posttransplant hyperlipidemia. Persistent hyperlipidemia despite these measures requires drug intervention, and 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors have become the preferred treatment in this setting. Although adverse effects, especially rhabdomyolysis, have been observed with higher doses of HMG-CoA, especially with higher cyclosporine doses, the cautious use of lower doses and proper monitoring of liver function test and creatinine phosphokinase levels appears to be safe and effective (44).

Hyperparathyroidism

Posttransplant hypercalcemic hyperparathyroidism occurs in approximately 30% of patients despite the normalization of urinary phosphate excretion and renal synthesis of calcitriol, defects seen in uremic hyperparathyroidism (127). Patients with a longer duration of dialysis and larger hyperplastic parathyroid glands appear to be at greater risk because glandular involution after transplant is size and time dependent. However, most patients who have spontaneous resolution and parathyroidectomy, necessary in approximately 6% to 10%, should be reserved for patients experiencing significant complications such as marked or symptomatic hypercalcemia and progressive bone disease, especially osteonecrosis (55). Transient hypocalcemia can be seen following parathyroidectomy, although long-term calcium supplementation is usually not required.

SURGICAL COMPLICATIONS

Surgical problems following renal transplantation are predominantly related to either vascular or urologic complications. Improvements in surgical technique and meticulous attention to both the donor and recipient operations has led to a significant decrease in the surgical complication rate. Equally important in minimizing the morbidity associated with renal transplantation are anticipation of surgical complications and their prompt treatment when they occur (196). Surgical complications continue to occur in 10% of transplant recipients but, fortunately, are rarely the cause for allograft loss today.

Hemorrhage

Acute postoperative hemorrhage can result from disruption of a vascular suture line. Additional causes include inadequate preparation of the graft bed, an undetected or poorly ligated branch of the hypogastric artery, inappropriately ligated epigastric vessels, an unrecognized vessel in the renal pelvis, abnormal coagulation mechanisms of the recipients, and spontaneous graft rupture. The incidence of postoperative hemorrhage is increased when hemodialysis is required in the immediate postoperative period. The diagnosis of postoperative hemorrhage is usually evident on clinical grounds. The patient complains of excruciating pain around the kidney, in the back and flank. Hypovolemic shock can develop rapidly. Perinephric hematoma formation can cause functional allograft impairment by compression of the renal parenchyma, renal vessels, or ureter. Emergency exploration is usually necessary. If vascular repair or reconstruction cannot be accomplished within a reasonable time, allograft nephrectomy is indicated. Evacuation of the hematoma is important to prevent bacterial infection.

Late hemorrhage, arising months or years after transplantation, is rare but can occur as a result of rupture of a pseudoaneurysm at the anastomotic site. Hemorrhage as a result of percutaneous needle allograft biopsy has also been reported (313). The use of smaller-gauge automated needle biopsy under real-time ultrasound guidance should decrease this complication (65). Rupture of a mycotic aneurysm is another disastrous event that is fortunately rare (145). It is usually the result of a deep wound infection with secondary involvement of the vascular suture line. Transplant nephrectomy with ligation of the iliac artery and drainage of the area is the most expeditious and effective procedure (97). Salvage of the ipsilateral limb is possible with an extraanatomic revascularization procedure such as a femoral-femoral or axillofemoral bypass.

Renal Artery Thrombosis

Arterial thrombosis is a rare (less than 1%) complication that may occur as a result of hyperacute rejection, postoperative hypotension, faulty technical performance of the anastomosis, trauma to the intima of the donor artery during harvesting or perfusion, severe atherosclerosis in the recipient vessels, or wide disparity in the calibers of the donor and recipient vessels. Cyclosporine toxicity has been implicated in some cases of renal artery thrombosis on the basis of a hypocoagulable state (237). If the transplant recipient is anuric postoperatively and there is no uptake of isotope with a technetium renal scan, renal arteriography should be performed immediately. In most cases, the kidney is beyond salvage by the time the diagnosis is made, and transplant nephrectomy is the treatment of choice.

Renal Vein Thrombosis

Renal vein thrombosis is a rare (less than 1%) complication. It may result from a technical error in performing the venous anastomosis, ipsilateral femoroiliac thrombosis, external compression of the iliac or renal vein by perinephric fluid collection, or compression of the left common iliac vein between the right common iliac or aorta and the sacral promontory (silent iliac compression syndrome) (263). Additional causes in pediatric recipients include extrinsic compression in the iliac fossa (26) and kidneys from young donors less than 5 years old (109). An increased incidence of venous thromboembolism has also been noted in the cyclosporine era (306).

Venous thrombosis should be suspected when a transplant recipient has oliguria, graft enlargement, heavy proteinuria, and ipsilateral lower extremity edema. Renal flow scan shows delayed uptake with little or no excretion of the isotope. Renal venography is diagnostic and is useful in delineating the extent of the thrombus. Graft survival with renal vein thrombosis occurring within 1 month of transplantation has been poor. Early diagnosis and prompt thrombectomy occasionally have resulted in graft salvage, but more commonly, prolonged venous stasis will lead to a nonviable graft when surgical exploration is undertaken and nephrectomy is then performed. Renal vein thrombosis occurring more than 1 month after transplantation is best treated with systemic anticoagulation because, by that time, established collateral venous channels are adequate to prevent graft loss.

Renal Artery Stenosis

Hypertension following renal allotransplantation is common and may be secondary to rejection, ischemic allograft damage, retained native kidneys, steroid therapy, cyclosporine therapy, recurrence of primary renal disease in the allograft, or renal artery stenosis. Renal artery stenosis has been reported in 1% to 12% of transplant recipients and can occur at the site of anastomosis, in the donor renal artery, or in the recipient hypogastric artery (207). The causes include faulty suture technique, damage to the donor arterial intima during perfusion, intimal damage from rejection, improper apposition of the donor and recipient vessels with torsion, excessive length of the renal artery leading to angulation, or atherosclerosis in the recipient artery. An increased incidence of renal artery stenosis has been observed following

transplantation of small pediatric cadaver donor kidney.

Renal arteriography is indicated whenever an allograft recipient has severe hypertension or unexplained deterioration in renal function (104). Renal vein renin measurements and captopril renography are of limited diagnostic value in this setting. Revascularization of the allograft is indicated when arterial stenosis is considered the cause of intractable hypertension or renal dysfunction. Percutaneous transluminal angioplasty has yielded satisfactory results in these patients and is an appropriate initial option (100,233) (Fig. 22.37). Secondary surgical revascularization is indicated if angioplasty cannot be done or is unsuccessful.

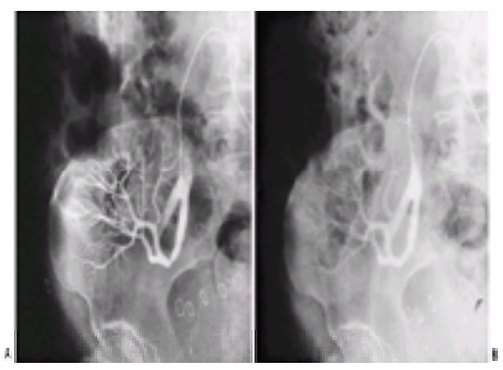

FIGURE 22.37. A: Transplant arteriogram demonstrates significant stenosis at the site of anastomosis of the recipient hypogastric artery to the donor artery. **B:** Following percutaneous transluminal angioplasty, a repeat transplant arteriogram shows complete resolution of the arterial stenosis.

A variety of techniques have been described for performing secondary arterial revascularization of a renal allograft. These include segmental arterial resection with end-to-end anastomosis, saphenous vein bypass for the proximal common iliac artery or aorta, direct reimplantation into the common or external iliac artery, patch angioplasty, or anastomosis to the hypogastric artery if this vessel is available. These are technically complex operations due to the frequent presence of dense scar tissue around the allograft; the renal vein and ureter are also often adherent to the renal artery. The results of surgical revascularization in these patients are generally satisfactory but less so than those obtained with primary revascularization of the native or transplant kidney (Table 22.10) (60,63,146,296). These operations should be performed through a transabdominal incision, which facilitates identification of the transplant renal artery. We have found that a saphenous vein bypass graft from the common iliac artery or aorta to the distal disease-free transplant renal artery is a relatively straightforward, versatile, and effective technique (Fig. 22.38). Occasionally, with a long renal artery and a short focal area of stenosis, segmental resection with reanastomosis is a satisfactory option.

Renal Artery Pseudoaneurysm

Renal arterial pseudoaneurysm formation is a potentially devastating complication of renal transplantation that occurs in less than 1% of patients (94,145,235,236). Pseudoaneurysms may result from infection, injury to the renal artery during procurement or preservation, ischemic damage from excessive stripping of the artery and its vasa vasorum, faulty suture technique, or external traumatic injury. These mechanisms produce disruption of the arterial wall, usually at the site of arterial anastomosis, leading to the development of a communicating sac lined by fibrous and adventitial tissue.

The natural history of transplant renal artery pseudoaneurysm is not known, although it is clear that rupture can occur even if the aneurysm is not affected. Hypertension and deterioration of renal function also can result from pseudoaneurysm formation, usually through extrinsic compression of the renal vessels with consequent diminished allograft perfusion. Transplant nephrectomy generally has been performed to prevent rupture (94,145,235), while *in situ* reconstruction and allograft salvage have only rarely been described (236).

We recently treated a transplant recipient with stable graft function and a 6.5-cm renal artery pseudoaneurysm causing severe hypertension and sciatic pain. Excision of the pseudoaneurysm and reconstruction were indicated to prevent rupture, reduce hypertension, and maintain stable allograft function. At surgery, extensive fibrosis was observed around the pseudoaneurysm, which enveloped the external iliac artery and renal vessels. The renal allograft together with the pseudoaneurysm and a segment of the external iliac artery were removed en bloc, and the allograft was quickly flushed with cold Collins solution. The excised segment of external iliac artery was replaced with an interposition synthetic graft. Extracorporeal renal vascular reconstruction was performed, and the repaired graft was autotransplanted into the contralateral iliac fossa (Fig. 22.39). This approach allowed allograft revascularization to be done in a previously unoperated area using healthy recipient vessels. Extracorporeal reconstruction and autotransplantation of a renal allograft has not previously been reported but can be an effective salvage technique for selected patients with complex vascular lesions involving the transplant kidney (35).

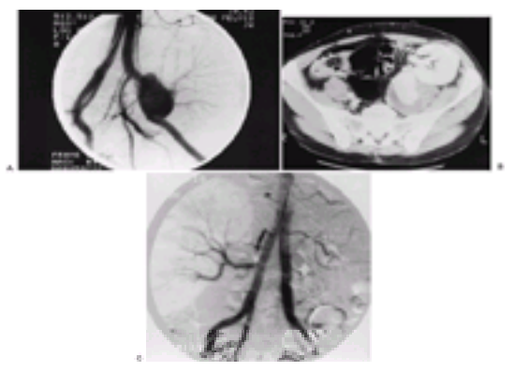

FIGURE 22.39. A: Arteriogram reveals large pseudoaneurysm arising near arterial anastomosis between renal artery and left external iliac artery. Intrarenal vasculature can be seen lateral to pseudoaneurysm. **B:** Pelvic computed tomography scan shows large renal artery pseudoaneurysm extending posteriorly in left iliac fossa. **C:** Following extracorporeal revascularization and autotransplantation, arteriogram shows patent anastomosis of reconstructed renal artery to right common iliac artery. (From Campbell SC, Gill I, Novick AC. Delayed allograft autotransplantation after excision of a large symptomatic renal artery pseudoaneurysm. *J Urol* 1993;149:361, with permission.)

Allograft Rupture

Spontaneous allograft rupture is an uncommon complication that usually occurs within the first month after transplantation (196). Graft rupture is most often seen in transplant recipients undergoing an acute rejection episode. Although this complication was formerly observed in 1% to 10% of patients, it is now only rarely encountered (less than 1%) because patients on cyclosporine maintenance therapy do not generally experience severe graft enlargement during acute rejection. Trauma, ureteral obstruction, and recent open renal biopsy are additional predisposing factors for graft rupture. Routine capsulotomy at the time of transplantation does not obviate postoperative graft rupture. The clinical picture includes sudden pain and swelling of the graft, a palpable flank mass, oliguria, and vascular collapse.

If the graft is functionally salvageable and it is technically feasible, the laceration should be repaired. If the graft has been irreversibly damaged by rejection or if multiple areas of rupture preclude a satisfactory repair, nephrectomy provides the optimum treatment.

Ureteral Fistula

Ureteral fistulae most often manifest early in the posttransplant course and may be heralded by pain or swelling over the allograft. Unilateral leg edema may also be present; occasionally, fluid will egress from the wound. A definitive diagnosis can be made by determination of electrolyte, urea, and creatinine concentrations in any fluid collected from the incision or from fluid aspirated percutaneously. This will help differentiate urine from serum or lymph. Diagnostic radiographic studies include intravenous pyelography (Fig. 22.40), ultrasound, and CT (33,220). When renal function is adequate, intravenous contrast can be given during CT scanning to differentiate urine from other fluid collections. A plain film can be taken immediately after the CT to obtain anatomic information equivalent to that with intravenous urography. As is the case for patients with transplant ureteral obstruction, however, the level of function at the time the urinary extravasation is diagnosed may not be adequate to allow administration of intravenous contrast. Retrograde studies can be difficult and have often been replaced by routine percutaneous nephrostomy placement and antegrade pyelography. In this setting, the percutaneous nephrostomy allows early proximal diversion and access for subsequent follow-up studies. It also allows precise delineation of the level of extravasation to plan further management.

FIGURE 22.40. Intravenous pyelogram shows extravasation of contrast material from a distal ureteral fistula. (From Novick AC, Straffon RA, eds. *Vascular problems in urologic surgery.* Philadelphia: WB Saunders, 1982, with permission.)

Ureteral fistulae almost always result from compromise of ureteral vascularity, the result of which is ureteral necrosis and sloughing. As such, the distal ureter is most commonly involved, although the necrosis can involve the entire ureter. Less often, the ureteral fistula is a result of a local technical factor associated with the ureteroneocystostomy that then results in a distal ureteral leak. In any case, standard intervention for a ureteral fistula is immediate open operative intervention (196,248). For fistulae limited to the distal ureter or ureteroneocystostomy itself, a repeat ureteral reimplant can be performed and a stent temporarily left indwelling. If viability of the more proximal transplant ureter is in question, repeat ureteroneocystostomy is not appropriate. In these cases, the ureter is resected back as far as necessary to ensure that it has an adequate blood supply. Options for reconstruction then include ureteroureterostomy with anastomosis of the native ureter to the proximal transplant ureter or, when the entire allograft ureter is nonviable, a ureteropyelostomy (Fig. 22.41). In all cases, an internal stent is left indwelling for these secondary reconstructive procedures (20). If associated infection is also a factor, externalized drains should be placed near the anastomosis, and in some cases, nephrostomy drainage should be implemented (95).

FIGURE 22.41. A: When ipsilateral native ureter is available, ureteral fistula can be repaired with ureteroneocystostomy *(top)* or ureteropyelostomy *(bottom)*. **B:** When ipsilateral native ureter is absent, ureteral fistula can be repaired with ureteroneocystostomy *(top)* or pyelovesicostomy *(bottom).* (From Novick AC, Straffon RA, eds. *Vascular problems in urologic surgery.* Philadelphia: WB Saunders, 1982, with permission.)

Percutaneous nephrostomy drainage has gained a role for adjunctive and at times definitive management of ureteral fistulae (154,275). When a ureteral fistula is

diagnosed, institution of percutaneous nephrostomy drainage allows early proximal diversion and access for radiographic studies that allow precise delineation of the site of extravasation. Such antegrade studies are especially important when compromised renal function does not allow administration of intravenous contrast for urography or CT. When a percutaneous nephrostomy has been placed for diagnostic purposes, it can be left indwelling during the postreconstructive period to allow proximal urinary diversion and access for postoperative radiographic evaluation.

In some cases, percutaneous techniques can be used to obviate entirely the need for secondary operative reconstruction. Successful endourologic management of ureteral fistulae is a likely result only in select patients in whom antegrade studies suggest extravasation limited to the distal ureter and in whom contrast enters the bladder during antegrade pyelography. Proximal extravasation or failure of contrast to enter the bladder suggests extensive ureteral loss, and in such cases, percutaneous treatment will rarely prove definitive. When percutaneous management is selected, the optimal approach involves placement of a guidewire, and subsequently a stent, across the site of extravasation into the bladder. Ultimately, the patient should be left with an internal stent and a nephrostomy tube for drainage or an internal-external stent for external drainage. Percutaneous management can be continued as long as the patient remains stable clinically and serial radiographic studies show the fistula to be resolving. Separate percutaneous drainage of a urinoma should be performed if it is infected, particularly large, or in any way symptomatic.

Although percutaneous techniques can provide long-term definitive management for some transplant ureteral fistulae, success rates will be limited. As such, we believe the primary roles of percutaneous techniques in this setting are for diagnosis and as therapeutic adjuncts before definitive operative reconstruction. In our experience, definitive percutaneous management of transplant ureteral fistulae has had a success rate of only 36%, even in highly selected patients (36).

Calyceal Fistula

Calyceal fistula is now a rare complication of renal transplantation that is essentially always the result of segmental renal infarction. Contemporary vascular techniques for management of multiple renal arteries have relegated this to a rare cause of urinary fistula. Standard intervention historically involved open exploration with debridement and drainage, along with primary closure of the involved collecting system. Unfortunately, such management was associated with unacceptably high rates of graft loss and mortality. Improved results were subsequently reported with operative placement of nephrostomy tubes and institution of external drainage. More recently, calyceal fistulae have been shown to resolve with external drainage alone. The contemporary management of this uncommon complication should consist of institution of percutaneous catheter drainage at the site of extravasation. If there is any degree of urinary obstruction associated with the fistula, percutaneous nephrostomy drainage or internal stenting should also be instituted. With adequate percutaneous drainage, calyceal fistulae should resolve without the need for open operative intervention.

Bladder Fistula

The incidence of bladder fistulae has decreased with the increasingly infrequent use of an extravesical, rather than a transvesical, ureteroneocystostomy to restore urinary continuity at the time of transplantation (93,295). The diagnosis of a bladder fistula is relatively easy to establish with a cystogram, which generally reveals extravasation of contrast. If a catheter had not been indwelling at the time the extravasation became evident, a cautious trial of standard catheter bladder drainage alone can be instituted, although separate percutaneous drainage of a urinoma may be indicated as described earlier. Failure of this management to result in resolution should prompt open exploration with debridement and repair.

A bladder fistula diagnosed in the presence of an extravesical ureteroneocystostomy is generally diagnostic of leakage at the ureteroneocystostomy itself. In such cases, catheter drainage alone will rarely be successful. However, if the extravasation is limited to the distal ureter as defined by intravenous or antegrade pyelography, a trial of percutaneous management can be instituted as described for ureteral fistulae. A failure of or contraindication to percutaneous management necessitates prompt open operative intervention as for ureteral fistulae.

Ureteral Obstruction

Ureteral obstruction is generally a late complication of renal transplantation. The contemporary incidence has decreased to less than 5% to 10% of renal allograft recipients, but this complication still accounts for up to one-third of all significant urologic complications (139). The diagnosis is usually made during evaluation of azotemia in an otherwise asymptomatic patient, at which time standard radiographic study with ultrasonography will identify hydronephrosis. If renal function is adequate, intravenous urography may allow delineation of the site of obstruction (Fig. 22.42). Retrograde pyelography may be attempted to define the site of obstruction, although difficulty in cannulation of the neoureteral orifice has generally led to abandonment of this study in favor of percutaneous nephrostomy placement with antegrade pyelography. In some cases, the functional significance of a mildly dilated collecting system may be unclear. In these cases, the effect on renal function of prolonged percutaneous drainage can provide a definitive answer. Further evaluation with antegrade pressure/perfusion studies may also be of benefit in select cases. Definitive operative reconstruction of transplant ureter obstruction is dependent on the etiology and site of obstruction. The most common problem is distal obstruction that involves the ureteroneocystostomy. Although technical factors at the time of transplantation may have played a role, ureteral ischemia should be considered. This is especially true when longer segments of the ureter appear to be involved. Less common causes of ureteral obstruction include extrinsic compression by hematoma, lymphocele or abscess, ureteral kinking, or less commonly, previously unrecognized intrinsic ureteropelvic junction obstruction. Rarely, intermittent obstruction can result from placement of the ureteral anastomosis in the mobile anterior dome of the bladder.

FIGURE 22.42. Intravenous pyelogram demonstrates hydronephrosis from distal ureteral obstruction. (From Novick AC, Straffon RA, eds. *Vascular problems in urologic surgery.* Philadelphia: WB Saunders, 1982, with permission.)

If the obstruction is limited to the very distal ureter, a repeat ureteroneocystostomy can be performed (196). In these cases, intraoperative placement of a soft, self-retaining internal stent that is left indwelling for 4 to 6 weeks should be considered. For extensive ureteral involvement, a nearly universally applicable reconstructive technique uses the native ureter for a ureteropyelostomy to the transplant renal pelvis (247). This avoids the need for extensive dissection of the transplant ureter and at the same time obviates the need to use a transplant ureter that may be of marginal quality. When the native ureter is used, the proximal native ureter can generally be ligated and the native kidney left *in situ* (159). However, in the presence of infection, native nephrectomy should be performed. An alternative to nephrectomy is anastomosis of the native ureter in a side-to-side fashion to the transplant renal pelvis (142). This precludes the possibility of a late complication associated with simple ligation of that ureter. Again, an internal stent is left indwelling during the early postoperative period. If a percutaneous nephrostomy had been placed before definitive repair, this also can be left indwelling during the initial postoperative period to provide temporary urinary diversion and access for postreconstructive radiographic studies.

When the native ureter is not available or is otherwise inappropriate for use in reconstruction, a variety of salvage reconstructive procedures may be used. These include vesicopyelostomy during which the bladder is anastomosed directly to the renal pelvis, with or without a bladder flap (229). An alternative to vesicopyelostomy for complicated reconstruction is an ileal interposition. In rare cases in which the transplant renal pelvis cannot be accessed either because of peripelvic fibrosis or an intrarenal anatomy, consideration can be given to native ureterocalicostomy or vesicocalicostomy (123,312).

In recent years, transplant ureteral obstruction has been managed entirely with an endourologic approach by combining percutaneous nephrostomy drainage with

transluminal ureteral dilation or endoscopic incisional ureterotomy. Those patients best suited for an endourologic approach are those with short, discrete strictures limited to the distal ureter or ureterovesical anastomosis itself (276). Midureteral narrowing suggests extrinsic compression, and long areas of stricture suggest extensive fibrosis, in which case endourologic management is unlikely to prove definitive. Similarly, ureteropelvic junction obstruction in transplanted kidneys generally results from unrecognized intrinsic ureteropelvic junction obstruction in the donor organ or from kinking at the time of transplantation. In either case, simple ureteral dilation is again unlikely to be successful. As an endourologic alternative, percutaneous endopyelotomy may have a definitive role. Reports of endourologic management of transplant ureteral stenosis have become available in larger numbers of patients, and these results suggest a 45% to 70% success rate, even after extended periods of follow-up (19,276).

Lymphocele

A *lymphocele* is a collection of lymph around the allograft. Lymphoceles may be unilocular or multilocular or encapsulated, ranging in size from a small, insignificant collection to a large obstructing mass containing more than 1,000 mL of fluid. A lymphocele is caused by lymphatic leakage from the allograft bed or the allograft itself. Care in ligation of perirenal lymphatics during donor nephrectomy and recipient lymphatics during preparation of the iliac fossa is essential in preventing this complication. Normally, severed lymphatics close within 48 hours and regenerate within 7 to 10 days. However, in transplant recipients, several factors can predispose to prolonged lymphatic leakage. These factors include rejection, open transplant biopsy, and the use of various medications such as steroids, diuretics, and anticoagulants. Retransplantation has also been implicated in the development of lymphoceles (273).

The most common initial signs and symptoms of a lymphocele are urinary frequency, suprapubic pressure, a ballottable mass adjacent to the allograft, and edema of the ipsilateral thigh and genitalia. Findings suggestive of rejection, such as hypertension, oliguria, decreased renal function, and proteinuria, may also be present. With a significant lymphocele, intravenous pyelography usually shows hydronephrosis or displacement of the bladder, with no extravasation of contrast material (Fig. 22.43). Cystography will confirm extrinsic bladder compression and the absence of extravasation. Currently, ultrasonography and CT scanning are the diagnostic methods of choice for establishing the presence, location, and extent of perinephric fluid collections. If a urinary fistula is suspected, a CT scan with contrast should be performed. Needle aspiration and determination of the creatinine and urea content of the fluid can also distinguish urinoma from lymphocele.

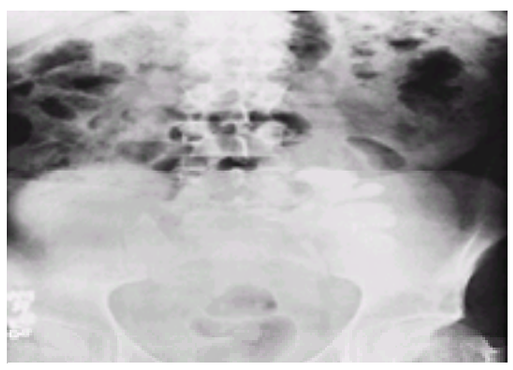

FIGURE 22.43. Intravenous pyelogram demonstrates hydronephrosis and bladder displacement from a large pelvic lymphocele. (From Novick AC, Straffon RA, eds. *Vascular problems in urologic surgery.* Philadelphia: WB Saunders, 1982, with permission.)

Small, loculated, low-density perinephric fluid collections are relatively common following transplantation. If the patient is clinically asymptomatic with no radiographic evidence of obstructive uropathy or urinary extravasation, no treatment is necessary.

When a significant lymphocele is present, a drainage procedure is indicated. Percutaneous aspiration of the lymphocele with injection of a sclerosing agent may be performed but has a variable success rate (288,315). Definitive therapy is provided by internal marsupialization of the lymphocele into the peritoneal cavity (134,320). This was formerly accomplished through a surgical abdominal incision, but laparoscopic internal lymphocele drainage can now be performed with excellent results (69,138,184,311).

Hydrocele

The incidence of ipsilateral hydrocele formation after renal transplantation has been reported to be as high as 68% when the spermatic cord is transacted at the time of transplantation (213). Therefore this practice has largely been abandoned. Transection of the spermatic cord results in interference with lymphatic drainage of the testicle and leads to accumulation of hydrocele fluid. In addition, the testicle is rendered ischemic due to interruption of the main blood supply, making its viability totally dependent on collateral circulation. Hydrocelectomy in these patients is fraught with the potential complications of testicular loss and abscess formation (213). Aspiration of a hydrocele with tetracycline sclerotherapy is an alternative and effective treatment modality (246). Fortunately, the majority of hydroceles after renal transplantation are asymptomatic, and only a few require treatment. Symptoms are usually related to discomfort, pain, interference with sexual activity, or embarrassment related to size. The diagnosis is usually evident on physical examination and by transillumination. Ultrasound may be used to document the size and pattern of the hydrocele, to assess the testicle, and as an adjunct to aspiration and sclerotherapy.

RESULTS OF RENAL TRANSPLANTATION

More sensitive histocompatibility crossmatching techniques, which have virtually eliminated hyperacute rejection episodes; careful patient selection with appropriate preoperative evaluation, reducing immediate postoperative complications; refinements in surgical techniques, minimizing technical losses; development of newer immunosuppressive drugs and strategies, lowering the incidence of early rejection; and enhanced therapy against infections, especially antiviral agents, have all contributed to an improvement in the success of renal transplantation in the past few years. One-year patient survival now exceeds 95% for all transplant groups, and 1-year allograft survival exceeds 85% for cadaveric and 95% for one-haplotype and HLA-identical recipients, respectively (Fig. 22.44). As depicted in Fig. 22.45, this enhanced 1-year survival has resulted in a slowly increasing graft survival half-life for cadaveric as well as living donor recipients (42).

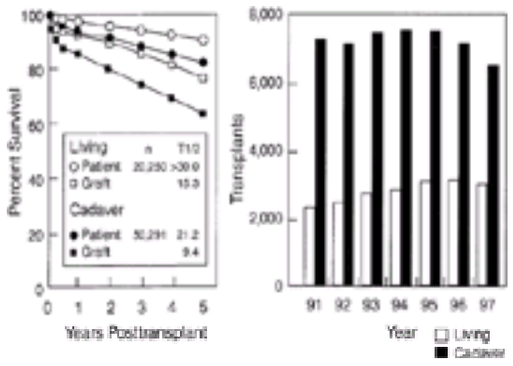

FIGURE 22.44. Patient and allograft survival by year based on donor relationship. (From Cecka JM. The UNOS scientific renal transplant registry. In: Terasaki PI, Cecka JM, eds. *Clinical transplants, 1998.* Los Angeles: UCLA Tissue Typing Laboratory, 1998:2, with permission.)

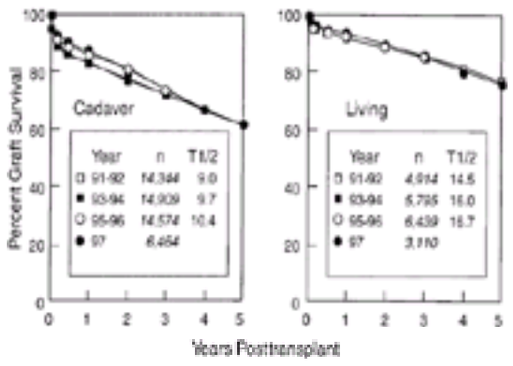

FIGURE 22.45. Allograft survival rates by year for major subgroups. (From Cecka JM. The UNOS scientific renal transplant registry. In: Terasaki PI, Cecka JM, eds. *Clinical transplants, 1998.* Los Angeles: UCLA Tissue Typing Laboratory, 1998:2, with permission.)

During the 1990s, there was a slow but persistent improvement in long-term renal allograft survival. This is best analyzed by comparing the survival half-lives of kidneys. The introduction of cyclosporine in the early 1980s resulted in improved 1-year survivals of up to 80%, but little improvement in cadaveric half-life of more than 7 to 8 years. However, further incremental advances in immunosuppression and patient management have now produced a significant prolongation in survival half-life of 21.6 years for live donor and 13.8 years for cadaveric donor recipients (108). It has been suggested that these findings may be a direct result of the decreased rates of acute rejection during the first posttransplant year, because these early rejection episodes have been shown to be a major cause of chronic rejection and late graft loss (6,70,80,124).

The influence of HLA matching on graft survival is obvious between live donor and cadaveric recipients (42). As illustrated in Fig. 22.46, 5-year survival rates are 87%, 75%, and 60% with corresponding half-lives of 24.8 years, 13.9 years, and 9 years for HLA-identical, one-haplotype, and cadaver recipients, respectively. However, the exact benefit of HLA matching within subgroups, especially cadaveric recipients, is not so obvious. The data demonstrate 5-year graft survival of 70% for six-antigen matched kidneys versus 58% for zero-antigen matched cadaver kidneys (Fig. 22.46). More impressively, six-antigen matched kidneys exhibited a half-life of 12.7 years compared with 8.0 years for kidneys with one or more mismatched antigens. It would appear reasonable to continue policies aimed at ensuring that best matched transplants are maximized (281). Unfortunately, incremental benefits (e.g., three-antigen versus four-antigen) are not as impressive (203). One reason for this latter observation is that prolonged cold ischemia times and shipping of kidneys have a detrimental effect on graft survival. Prolonged cold ischemia times increase the incidence of delayed graft function after transplant (Fig. 22.47). This is especially true for older-age cadaver kidneys. Delayed graft function in turn may negate any small advantage from fewer degrees of HLA matching.

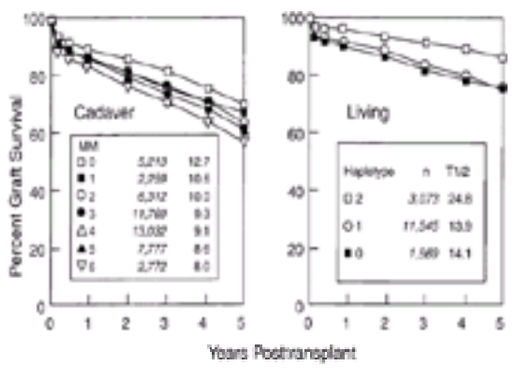

FIGURE 22.46. Rate of cadaveric and live donor graft loss at 5 years based on HLA matching. Data from more than 65,000 transplants, 1991–1997. Cadaveric transplants ranged from zero to six mismatched HLA antigens. (From Cecka JM. The UNOS scientific renal transplant registry. In: Terasaki PI, Cecka JM, eds. *Clinical transplants, 1998.* Los Angeles: UCLA Tissue Typing Laboratory, 1998:10, with permission.)

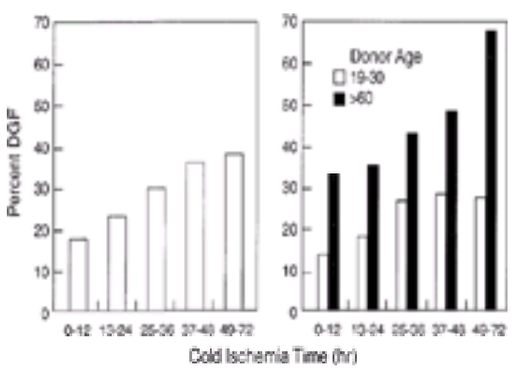

FIGURE 22.47. The effect of cold ischemia time on incidence of delayed graft function. Kidneys older than age 60 were especially susceptible, demonstrating twice the rate of delayed graft function at each 12-hour interval compared with kidneys age 19 to 30. (From Cecka JM. The UNOS scientific renal transplant registry. In: Terasaki PI, Cecka JM, eds. *Clinical transplants, 1998.* Los Angeles: UCLA Tissue Typing Laboratory, 1998:8, with permission.)

The most commonly cited cause of allograft failure after the first year is chronic rejection. Unfortunately, chronic rejection is largely an ill-defined, poorly understood process that results in unrelenting, progressive renal damage (80,118,124,170). The diagnosis of chronic rejection is usually based on histopathology, which includes among other findings interstitial fibrosis, tubular atrophy, arteriolar intimal thickening with narrowing of the lumen, and glomerulosclerosis (261). No specific treatment exists for chronic rejection other than preventing precipitating events and treating potential exacerbating factors (e.g., hypertension). A number of studies have implicated acute rejection as a risk factor for chronic rejection and subsequent allograft loss (6,70,80). Ferguson (70) reported a half-life of 16.9 years in patients experiencing no rejection versus 3.9 years in recipients experiencing more than one rejection episode. However, it is clear that not all patients experiencing acute rejection are destined to develop chronic rejection and allograft loss. In reviewing 53 patients at our institute who had functioning grafts surviving more than 20 years, Braun and colleagues (29) reported that 58% had experienced acute rejection episodes. Nevertheless, the recent increase in survival half-lives appears to be enjoyed by patients who experienced no acute rejection episodes during the first year (Fig. 22.48). Although predicting who develops chronic rejection after an acute rejection episode may not be possible, the data suggest that preventing an acute rejection episode is the most effective way to achieve long-term graft success.

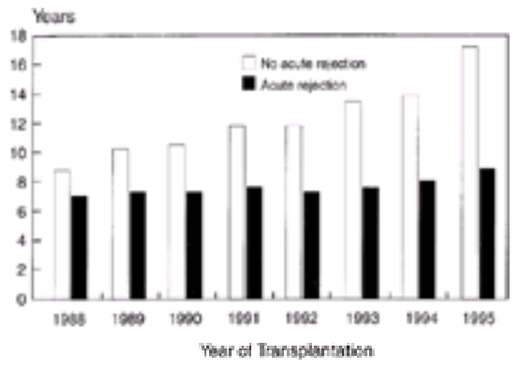

FIGURE 22.48. Projected half-life of grafts from cadaveric donors according to the presence or absence of clinical acute rejection during the first year after transplantation. (From Hariharan S, Johnson CP, Bresnahan BA, et al. Improved graft survival after renal transplantation in the United States 1988–1996. *N Engl J Med* 2000;342:605.)

Death with a functioning allograft has emerged as a major cause of long-term graft loss, especially in older recipients and diabetics. Matas and colleagues (171) have indicated that survival rates calculated counting death with a functioning graft as a cause of allograft loss are dramatically different from those calculated censoring patients who die with a functioning graft, and they have suggested that results should be reported both ways. In their series, nondiabetic living donor non–HLA-identical recipients greater than age 50 had a half-life of 9 years when death with function was considered graft loss, compared with a half-life of 62 years when data with function were censored. Other centers have reported similar results and have even demonstrated better survival in older recipients than young ones (suggesting less immunologic graft loss) when death with a functioning graft was censored (223,290). As more high-risk patients, especially diabetic and older patients, are transplanted and survive the early posttransplant period, death with a functioning graft is likely to become the predominant cause of graft loss in centers where it has not already done so.

Delayed graft function also adversely affects long-term survival, although the primary effect may be earlier (42,186,257). Although donor and organ preservation factors clearly affect the quality of initial function of the kidney following transplantation, evidence exists suggesting that immunologic factors contribute as well. Animal models have demonstrated increased MHC antigen expression related to ischemia (258). In addition, brain death itself may cause an upregulation of cell surface immunoreactive products and release of cytokines that promote both ischemic renal injury and immunologic injury (227). Other nonimmunologic causes may be responsible for long-term graft loss as well. Brenner and colleagues (31), noting diminished results with pediatric donors, female donors, and transplants into larger recipients, suggest that “one size may not fit all” and recommend matching of kidneys based on nephron dosing as well as HLA matching. Terasaki and colleagues (284) observed that elevated serum creatinines at the time of discharge from the hospital following transplantation correlated with decreased graft survival. They suggested that the hyperfiltration hypothesis (32) could explain diminished results seen in transplants using kidneys from infant and older donors, using kidneys from female donors to male recipients, occurring in obese patients, or following early acute rejection episodes.

As stated earlier, the ultimate goal for long-term success in renal transplantation is the induction of donor-specific tolerance in the recipient. Although this is not clinically achievable at present, recent observations have generated hope of its accomplishment in the near future. Using DNA typing and other technologies, Starzl and colleagues (267) have demonstrated the peripheral migration of donor cells (chimerism) in patients with long-term allograft survival who exhibit donor-specific nonreactivity following renal transplantation. Although a direct cause and effect of microchimerism and donor-specific hyporesponsiveness has not been demonstrated, it has allowed for investigation of immunosuppressive strategies. The infusion of donor allogeneic bone marrow into a recipient who has undergone myeloablation can lead to tolerance of allografts from the same donor (278). This involves the creation of a new immune system that becomes “educated” to recognize the alloantigens as “self.” However, because of toxicity, the use of myeloablation has been limited to animals. A clinical trial using donor bone marrow and concomitant T-cell depletion with polyclonal antibodies has been encouraging, but has not resulted in tolerance (17). More recently, tolerance induction has been demonstrated in animals by blocking costimulatory signals to T cells. Costimulation is required for T-cell activation and to prevent T-cell anergy. Tolerance can be induced in animal models using blockade of the CD28–B7 interaction with a soluble recombinant fusion protein called CTLA-4Ig (155). In addition, blockade of CD154 (ligand of CD40) by monoclonal antibodies can tolerize murine skin and cardiac allografts (149). Clinical trials of costimulatory blockade are anticipated. Future improvement in results of renal transplantation will depend on utilization of knowledge of molecular events to develop more highly specific immunosuppressive agents—or, preferably, induce donor-specific tolerance, obviating the need for immunosuppressive agents altogether.

Sixty million Americans have high blood pressure. Hypertension secondary to renovascular disease is a leading cause of secondary hypertension in adults. The incidence of renovascular hypertension (RVH) is not known. It has been estimated that 3% to 5% of all hypertensive patients have RVH (44). An improved understanding of the renin-angiotensin-aldosterone system has permitted researchers to establish more sensitive and specific diagnostic screening tests for RVH. Advances in pharmacology, renal revascularization, and interventional radiology have steadily improved the efficacy and safety of treatment for patients diagnosed to have renovascular hypertension (127). The challenge for the physician is to accurately diagnose RVH and to select a treatment strategy suitable for his or her patient.

The importance of diagnosing RVH is multifold. First, sustained hypertension is a leading risk factor for premature illness and death. Poorly controlled or uncontrolled pressure elevation leads to small-vessel disease and end-organ damage, principally affecting the heart, kidneys, and central nervous system (59). Moreover, renin-dependent hypertension results in more severe vascular damage and hence in a higher incidence of myocardial infarctions and strokes at a younger age than is found in patients with normal or low renin hypertension, who are generally older (10). Second, RVH is difficult to manage medically (49). Even if adequate blood pressure control is maintained by pharmacologic means, progression of arterial disease is not prevented (103,135) and renal ischemia may actually worsen when the pressure is lowered to clinically desirable levels (1). Third, RVH is potentially curable by renal revascularization (21) or angioplasty, and renal function can be stabilized or enhanced by renal revascularization (134). Fourth, renal arterial disease can lead to ischemic nephropathy, renal failure, if not diagnosed and treated (79).

This chapter presents the current understanding of the natural history and pathophysiology of RVH. A strategy for a cost-effective and reliable diagnostic evaluation of RVH is described. Established and new options for treatment are discussed and compared.

DEFINITIONS

Hypertension

It is estimated that 60 million individuals in the United States have hypertension. At what blood pressure is a person said to be hypertensive? It is difficult to define a precise cutoff that marks the upper limit of acceptable blood pressure, but it is generally acknowledged that the higher the blood pressure, the worse the resultant risk of morbidity and mortality (89). As a working definition, the 1984 Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure recommended that a sustained blood pressure of 140/90 mm Hg be considered the cutoff point between normal blood pressure and mild hypertension for all patients older than 18 years of age. Children with a sustained increase in arterial pressure greater than or equal to the 90th percentile for age are considered hypertensive. Whatever the patient's age, an elevation in blood pressure should be documented on at least three separate occasions, when measured with an appropriate-sized blood pressure cuff, to justify the diagnosis of hypertension. It is not unusual to find that a patient who is hypertensive at an initial evaluation remains normotensive at subsequent measurements (12).

Renovascular Disease

Renal disease has been recognized in association with hypertension since the early nineteenth century (8). In 1898, Tigerstedt and Bergmann (121) demonstrated that a water-soluble extract that they called renin, derived from the renal cortex of a healthy rabbit, could produce a marked and sustained hypertension when injected intravenously into a second rabbit. Interest in the relationship between renal disease and hypertension did not flourish, however, until the classic experiments by Goldblatt and associates (37) in the dog demonstrated that reversible elevation in the systemic arterial pressure could be produced by clamping the main renal artery of one of two healthy kidneys. The blood pressure returned to normal on removal of the kidney or the clamp.

The development and widespread use of arteriography in the 1950s focused attention on renal arterial disease in hypertensive patients and led to advances in renovascular surgery (34). It quickly became apparent, however, that lesions of the renal artery could be demonstrated angiographically in normotensive patients. Moreover, the results of the national cooperative study on renovascular surgery for treatment of hypertension revealed a sobering 34% failure rate in hypertensive patients subjected to renal revascularization (33). It became clear that angiographic documentation of renal artery disease in a hypertensive patient was not sufficient to justify surgical correction of the arterial lesion.

Greater insight into the pathophysiology of renal artery disease was gained by experiments in vessel hemodynamics. It was determined that the internal diameter of an artery must be reduced by greater than 70% for a significant decrease in blood flow to occur (66) and that a pressure gradient greater than 40 mm Hg across a stenosis in the renal artery was necessary to produce a significant decrease in the renal plasma flow, glomerular filtration rate (GFR), urinary sodium excretion, and urine flow rate (106).

The discovery of angiotensin (7,85) and the determination of its sequence (108) led to the eventual development of accurate radioimmunoassays to quantify the activity of the renin-angiotensin system. Researchers established that a significant decrease in blood flow to a kidney results in the activation of the renin-angiotensin-aldosterone cascade, establishing a hypertensive state. Correction of the stenosis or removal of the ischemic kidney eliminates the hyperreninemic state, allowing the blood pressure to return to normal levels.

Accordingly, *renovascular hypertension* can be defined as a sustained blood pressure elevation secondary to a physiologically significant renal artery stenosis that is

correctable by repair of the lesion or by removal of the kidney. From a clinical point of view, however, it is imperative to be able to diagnose RVH prospectively. The availability of pharmacologic agents that block different steps in the renin-angiotensin-aldosterone cascade, such as converting enzyme inhibitors (CEIs) and technical advances in interventional radiology, have contributed to our understanding of the pathophysiology of RVH. On the basis of this knowledge, sensitive and specific tests that prospectively identify patients with RVH are in current clinical use.

PATHOLOGY AND NATURAL HISTORY OF RENAL ARTERY DISEASE

Atherosclerosis and fibromuscular disease of the renal artery account for most cases of RVH. Two-thirds of patients with RVH have atheromatous lesions of the renal artery. Atherosclerotic plaques typically are located in the proximal 2 cm of the main renal artery, but they also may involve the distal artery and its branches. The earliest morphologic change is vascular smooth muscle hypertrophy and hyperplasia. Angiotensin II is an important growth factor in vascular smooth muscle cells (101). The chronic administration of angiotensin-converting enzyme inhibitors will reverse many changes of vascular hypertrophy in experimental animal models and will improve vascular compliance in the hypertensive patient. Following the onset of vascular smooth muscle hypertrophy and hyperplasia, lipid deposition occurs, with necrosis, inflammation, and formation of atherosclerotic intimal plaques that protrude into the lumen. Blood pressure elevation appears to aggravate the severity of atheromatous lesions. Calcification, surface erosion with thrombus formation, or dissection of the vessel wall may ensue (96).

Atheromatous renal arterial disease predominantly afflicts men in older age groups. The disease is often diffuse, affecting the aorta and its major branches, as well as the coronary and cerebral arteries. The renal arteries are involved bilaterally in up to 40% of cases. In the national cooperative study on RVH, patients with bilateral disease had the lowest cure rate and the highest morbidity (33). A review by Schreiber and colleagues (103) of 85 patients with atheromatous renovascular disease treated medically and followed up for a mean of 52 months revealed that the disease was progressive in over 44% of patients, with progression to complete occlusion of the renal artery in 16% of renal units. Reducing the blood pressure alone has not been shown to reduce the risk of atherosclerotic complications of hypertension. Bilateral progression has been found in 20% to 30% of patients (100).

Fibromuscular diseases of the renal artery are responsible for one-third of cases of RVH. Four pathologically different types of renal artery dysplasia have been described (114). Intimal fibroplasia accounts for approximately 10% of the fibromuscular diseases. This disorder primarily involves the intima by the circumferential accumulation of collagen, compromising the arterial lumen. The disease is progressive, and dissecting hematomas may form. Children and young male adults are principally afflicted. Vessels other than the renals may be involved. Angiographically, a smooth focal stenosis is typically seen at the midrenal artery or its branches. Dissection may alter the appearance of the stenosis and of the vessel. Because of the progressive nature of this disease, prompt repair of the lesion is advised.

Fibromuscular hyperplasia is the rarest of the fibrous dysplasias. It is characterized by hyperplasia of the smooth muscle and fibrous tissue, producing a concentric thickening of the renal artery wall. This disease afflicts children and young adults and is progressive.

Medial fibroplasia accounts for 75% to 80% of the fibromuscular dysplasias. On angiogram the diseased artery has the appearance of a string of beads. This angiographic pattern is caused by a series of collagenous rings alternating with aneurysmal dilations, involving the media of the main renal artery, often extending into its branches. Women in their thirties or forties are usually afflicted. This lesion does not dissect, and complete occlusion has not been reported. Schreiber and co-workers (103) followed up a group of 75 patients with this disease for a mean of 65 months and noted that progression of the lesions occurred in 33% of patients regardless of their age. Correction of the lesion by angioplasty is the treatment of choice.

In perimedial fibroplasia, a collar of dense collagen envelops the renal artery just beneath the adventitia. The lesions are tightly stenotic, and therefore extensive collateral vessels are commonly identified on angiography. Young women, 15 to 30 years of age, are most commonly afflicted. The lesion may be progressive, and repair is recommended.

PHYSIOLOGY OF THE RENIN-ANGIOTENSIN SYSTEM

The renin-angiotensin-aldosterone system plays an important role in the regulation of blood pressure and sodium-volume homeostasis. The renin-angiotensin system (RAS) is involved in the maintenance of a constant arterial blood pressure despite extremes of sodium intake. A decrease in sodium intake increases the formation and secretion of angiotensin II by mechanisms that are discussed later in this chapter. Angiotensin II enhances aldosterone biosynthesis by the glomerulosa cells of the adrenal cortex and increases sodium reabsorption at the proximal tubule. In states of increased sodium intake, the activity of the RAS is depressed, and excess sodium is excreted to maintain balance.

The RAS also protects the organism from the potential catastrophic effects of rapid-onset hypotension by responding to a sudden pressure decrease with an immediate increase in renin release. As discussed later, renin initiates a cascade of enzymatic reactions, resulting in the formation of angiotensin II. Angiotensin II is a potent vasopressor that helps restore the systemic blood pressure. It is particularly effective in constricting the precapillary and postcapillary resistance vessels. In addition, in the peripheral nerves angiotensin II potentiates the effects of norepinephrine at the noradrenergic neuroeffector junctions by increasing norepinephrine release, decreasing norepinephrine uptake, and increasing vascular sensitivity to norepinephrine. In summary, RAS buffers a decrease in blood pressure by direct constriction of resistant vessels, by interaction with the noradrenergic receptors in the vascular smooth muscles.

Renin is a proteolytic enzyme formed in modified smooth muscle cells known as the *juxtaglomerular cells* of the afferent arteriole. The juxtaglomerular cells are in intimate proximity of the macula densa of the distal tubule. Together, these microstructures are known as the juxtaglomerular apparatus. Renin is primarily released in response to (a) low renal perfusion pressure in the afferent arteriole (baroreceptor mechanism), resulting from either renal artery stenosis or a decrease in the mean systemic arterial pressure (this response is independent of renal innervation or of the GFR); (b) a low chloride (or sodium) concentration in the filtrate reaching the distal convoluted tubule (macula densa mechanism); and (c) adrenergic stimulation of the b_1-adrenergic receptors in the juxtaglomerular cells. In the intact animal, decreases in mean arterial pressure and central blood volume activate baroreceptor and volume reflexes, eliciting adrenergic efferent signals that stimulate renin release (Fig. 23.1).

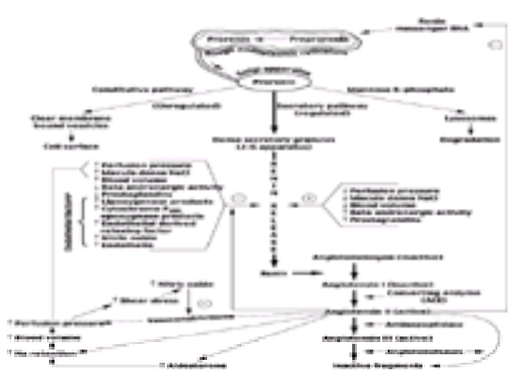

FIGURE 23.1. Renin-angiotensin-aldosterone system. (Modified from Felsen D, Vaughan ED Jr. In: Rajfer J, ed. *Urologic endocrinology.* Philadelphia: Saunders, 1986:112, with permission.)

The enzymatic action of renin splits angiotensin I off the a_2-globulin angiotensinogen. Angiotensin I generally is considered an inactive molecule. Angiotensin-converting enzyme then cleaves a dipeptide off angiotensin I to produce angiotensin II.

Angiotensin II has a wide range of biologic activities. It is the protagonist through which the RAS regulates blood pressure and fluid-volume homeostasis. It is believed that angiotensin II plays an important role in renal autoregulation at low renal perfusion pressures. Normal dogs with an intact RAS subjected to graded decreases in mean renal perfusion pressure are able to maintain normal GFR. However, if the activity of the RAS is blocked by high salt intake or by CEIs, a decrease of mean renal perfusion pressure to the same levels is associated with a decrease in GFR (41). At low renal perfusion pressures, angiotensin II produces a selective efferent arteriolar vasoconstrictor to increase the glomerular capillary hydrostatic pressure and thus maintain GFR. Clinically, it has been shown that use of CEIs in patients with bilateral renal artery stenosis or stenosis of a renal artery to a solitary kidney is associated with azotemia that reverses when the drug is suspended. However,

lowering of the pressure to the same level with antihypertensives that do not interfere with the RAS does not appear to compromise renal function (1,95,97). Use of CEIs in patients with unilateral renal artery stenosis also has been shown to decrease the GFR and renal blood flow of the ipsilateral kidney but not of the contralateral normal kidney (131).

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

Our current understanding of the pathophysiology of RVH has been derived to a large extent from work in experimental models of hypertension. Goldblatt and associates (37) first demonstrated that clamping one renal artery in a normal dog produced hypertension that was correctable by removing the clamp or the ischemic kidney. Currently, two models of RVH have been identified and characterized. The two kidney–one clip model is prepared by clipping the renal artery to one of the two kidneys. The ischemic kidney is designated by the ipsilateral kidney, and the untouched kidney is the contralateral kidney. In the one kidney–one clip model, the renal artery to the one kidney is clipped, and the contralateral kidney is removed. The degree of hypertension is similar for these two hypertensive models, but the mechanisms of hypertension differ in some respects.

The decrease in perfusion pressure and blood flow to the ipsilateral kidney in the two kidney–one clip model is associated with a decrease in the ipsilateral GFR, filtered sodium load, and urine sodium excretion (113). An increase in the reabsorption of water and electrolytes is dictated by glomerular-tubular balance in the ipsilateral kidney, increasing the urinary concentration of nonreabsorbable solutes and hence of urine osmolality. The decrease in mean renal perfusion pressure stimulates the baroreceptor mechanism and the decrease in the filtered load sodium (or chloride) activates the macula densa mechanism to increase renin secretion from the ischemic kidney.

The increase in the plasma renin activity invokes an angiotensin II–induced increase in mean systemic arterial blood pressure. The contralateral GFR does not change significantly, but a pressure-induced natriuresis and diuresis can be observed (112). Contralateral renin secretion is totally suppressed as the baroreceptor and macula densa mechanisms are turned off by the described physiologic changes. Tubular absorption of electrolytes and water is less marked than in the ipsilateral kidney because GFR is maintained. The contralateral urine osmolality is accordingly lower than that of the ipsilateral kidney.

The increase in arterial blood pressure in the one kidney–one clip model of hypertension is initially maintained by the vasoconstrictive properties of angiotensin II. If the renal artery clip is maintained for several weeks in the dog or rat, plasma renin activity is noted to return to normal or below normal levels. In this “chronic phase” of RVH, the degree of pressure elevation is equal to that observed in the acute phase, but salt and volume retention primarily account for the hypertension. The short-term administration of RAS blockers does not have a significant depressor effect. Sodium deprivation at this point increases the plasma renin activity and reestablishes sensitivity to the depressor effects of RAS blockers (35).

There is also evidence that other mechanisms are active. These include decreased nerve traffic (57) and increased production of nitric oxide. Nitric oxide inhibitors exacerbate hypertension in experimental renovascular models (76). In addition, there is evidence for a role of prostaglandin endoperoxides because the T_xA_2/PC-H_2 receptor antagonist (ifetroban) also lowers blood pressure in both the acute and chronic phase of the two kidney–one clip model (132).

PHARMACOLOGIC PROBES FOR THE RENIN-ANGIOTENSIN SYSTEM

Insight into the physiology of the RAS has been gained from the development of pharmacologic compounds that inhibit the release of the renin, block the conversion of angiotensin II, or are specific angiotensin II receptor analogs (Fig. 23.1).

The first drug that specifically blocked the action of angiotensin II was saralasin. Saralasin is an angiotensin II analog with affinity for the angiotensin II receptor, but with partial agonist activity (86). Administration of saralasin to two kidney–one clip hypertensive models or to patients with RVH produces a depressor response. However, saralasin lost favor as a screening agent for RVH because of its agonist activity, which produces an increase in blood pressure and hence an underestimation of the contribution of angiotensin II to the maintenance of hypertension.

CEIs prevent the conversion of angiotensin I to angiotensin II. Naturally occurring CEIs initially were found in snake venom (3). Captopril, an orally active synthetic CEI with a rapid onset of action, currently is used in a screening role for renin-dependent hypertension (see Single-dose Captopril Test) and to treat RVH in select cases.

More recently, a number of oral drugs have been developed that block the action of angiotensin II at the receptor level. Losartan is the prototype. At present, the angiotensin II subtype AT_1 receptor appears to be the primary angiotensin receptor in the kidney and vasculature (38).

CLINICAL EVALUATION OF RENOVASCULAR HYPERTENSION

It is now clear that the angiographic finding of a stenosed renal artery in a hypertensive patient is insufficient evidence on which to diagnose RVH. In this regard, hypertensive patients with a renal artery stenosis may not improve after renal revascularization (33). Moreover, radiologic (28) and autopsy (46) series have shown that normotensive patients can have severely diseased renal arteries. Patients with atherosclerotic disease elsewhere have a 20% to 50% chance of having renal arterial disease (129,136).

Until recently, means by which to reliably identify patients with a physiologically significant renal artery stenosis have eluded the clinician. There are no pathognomonic clinical characteristics that reliably lead to the diagnosis (107), but certain clinical features should arouse suspicion that RVH may be present (Table 23.1).

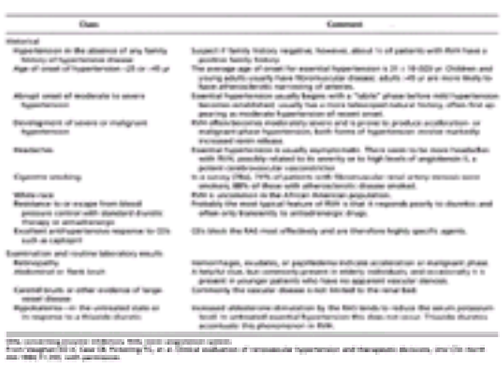

TABLE 23.1. CLINICAL CLUES SUGGESTIVE OF RENOVASCULAR HYPERTENSION (RVH)

Taking these clinical findings altogether, Mann and Pickering (67) have defined patients who are at low, moderate, or high risk for renovascular hypertension (Table 23.2). Patients at moderate or high risk warrant further study (90).

Index of Clinical Suspicion
Low (should not be tested) • Borderline, mild, or moderate hypertension in the absence of clinical clues
Moderate (noninvasive tests recommended) • Severe hypertension (diastolic blood pressure >120 mm Hg) • Hypertension refractory to standard therapy • Abrupt onset of sustained moderate to severe hypertension at age <20 or >50 yr • Hypertension with a suggestive abdominal bruit (long, high-pitched, and localized to the region of the renal artery) • Moderate hypertension (diastolic blood pressure >105 mm Hg) in a smoker, a patient with evidence of occlusive vascular disease (cerebrovascular, coronary, peripheral vascular), or a patient with unexplained but stable elevation of serum creatinine • Normalization of blood pressure by an angiotensin-converting enzyme inhibitor in a patient with moderate or severe hypertension (particularly in a smoker or patient with recent onset of hypertension)

Modified from reference 90.

TABLE 23.2. TESTING FOR RENOVASCULAR HYPERTENSION: CLINICAL INDEX OF SUSPICION AS A GUIDE TO SELECTING PATIENTS FOR WORKUP

The lack of reliable clinical clues stimulated further study in laboratory animals in pursuit of understanding the physiologic profiles that characterize laboratory models of Goldblatt's hypertension. These endeavors have resulted in the delineation of a variety of approaches to screen for patients with RVH.

The emergence of methods to reliably assay the activity of the RAS and the development of pharmacologic probes that block specific steps in the renin-angiotensin cascade have led to the use of renin determinations to diagnose RVH. Goldblatt's initial animal work led to the assumption that the underlying derangement in RVH is excess renin secretion resulting in angiotensin II formation. The hypertensive animal model most analogous to human RVH is the two kidney–one clip Goldblatt preparation. In this model, the hypertension initially is depending on the increased renin secretion from the clipped kidney. The administration of CEIs or competitive angiotensin II analogs (9) can prevent or reverse the hypertension. This early phase of two kidney–one clip hypertension exhibits four characteristics: increased secretion of renin from the clipped kidney, absence of renin secretion from the opposite kidney, decreased renal blood flow to the clipped kidney, and elevated pressure secondary to angiotensin II–induced vasoconstriction. The identification of these characteristics permitted the development of a rational approach to the use of plasma renin activity determinations and angiotensin blockade in the diagnosis of RVH (90,127) (Fig. 23.2).

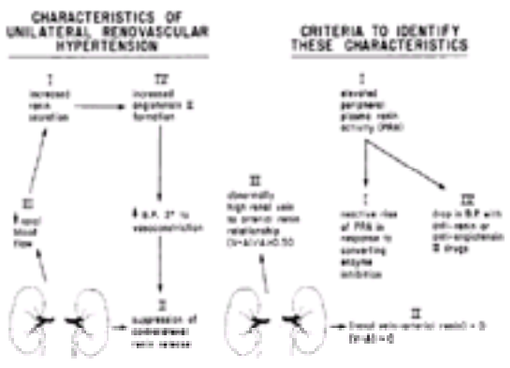

FIGURE 23.2. Characteristics of the early phase of two kidney–one clip Goldblatt's hypertension in the rat *(left)* and the criteria derived from the animal model that identify the patient with correctable renal hypertension. (From Vaughan ED Jr, Case DB, Pickering TG, et al. Clinical evaluation of renovascular hypertension and therapeutic decisions. *Urol Clin North Am* 1984;11:393, with permission.)

Until recently, the combined analysis of the peripheral renin level and determination of differential renal vein renin levels was the standard methodology for identifying potentially curable patients with renovascular hypertension (127). Less invasive tests that give both anatomic and physiologic evidence for curable renovascular hypertension are currently being explored. These tests include captopril renography, color Doppler sonography, spiral computed tomography (CT) angiography, and magnetic resonance angiography (MRA) (52,88).

However, before discussing these tests, it is important to review the use of renin determinations to understand the pathophysiology of renovascular hypertension.

PERIPHERAL PLASMA RENIN ACTIVITY

Peripheral ambulatory plasma renin activity samples are collected in a standardized setting that requires that the patient be salt replete and off all antihypertensive medicines that influence plasma renin activity for at least 2 weeks. In addition, the plasma renin activity is sampled after 4 hours of ambulation and is indexed against a 24-hour urine sodium determination.

The rationale for emphasizing the peripheral plasma renin activity determination is that it is an index of renin secretion (105). In a study of hypertensive patients who had successful angioplasty, the peripheral plasma renin activity was elevated in 80% before angioplasty (93). The plasma renin activity always decreased and usually returned to normal after successful angioplasty (Fig. 23.3).

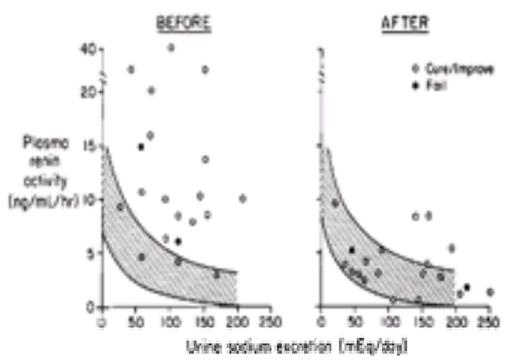

FIGURE 23.3. Effect of angioplasty on peripheral plasma renin activity indexed against 24-hour sodium excretion. *Left panel:* Before angioplasty. *Right panel:* 6 months after angioplasty. *Hatched area* shows normal range. (From Pickering TG, Sos TA, Vaughan ED Jr, et al. Predictive value and changes of renin secretion in hypertensive patients with unilateral renovascular disease undergoing successful renal angioplasty. *Am J Med* 1984;76:394, with permission.)

The 20% false-negative rate places definitive limitations on the use of peripheral plasma renin activity as a screening test for RVH. In addition, many patients with proved RVH have severe, life-threatening hypertension that precludes cessation of antihypertensive medications before blood sampling. Performance of plasma renin activity determinations while the patient is taking medication invalidates the accuracy of the test and eliminates the quantification of peripheral plasma renin activity as a practical screening tool. A third factor is the finding that 16% of patients with essential hypertension also have high plasma renin activity when indexed against a 24-hour urine sodium determination (10). Thus the positive predictive value is poor.

Enhanced Accuracy of Peripheral Plasma Renin Activity by Stimulation with Angiotensin-blocking Agents

The first angiotensin-blocking agent used for testing in human hypertension was saralasin. The initial results demonstrated that the compound, as predicted, lowered blood pressure in high-renin forms of hypertension (9).

A second approach to the use of angiotensin blockade to expose RVH came from experience after the development of CEIs that block angiotensin II formation. One of the peptides, teprotide, was shown to block the vasopressor effect of angiotensin II, and it was possible to demonstrate a close direct correlation between the pretreatment level of plasma renin activity and the magnitude of the depressor response (17).

The success of teprotide was a potent stimulus to the development of the orally active CEI captopril. Captopril has the potential for use as a diagnostic probe, like teprotide, because it has a rapid onset of action (within 10 to 15 minutes), reaching a peak effect by 90 minutes (16) (Fig. 23.4).

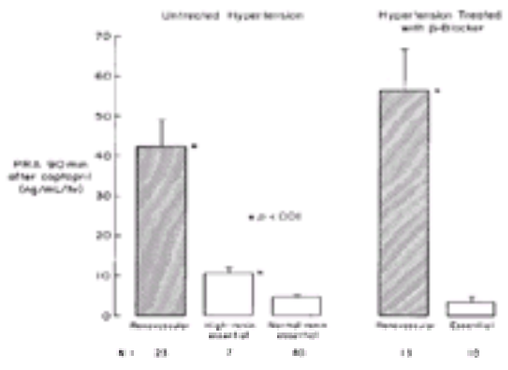

FIGURE 23.4. Levels of plasma renin activity in renovascular hypertension (RVH) and essential hypertension 90 minutes after a single dose of captopril. A marked reactive hyperreninemia was found in the group with RVH whether or not they were already receiving b-blocker therapy. (From Case DB, Atlas SA, Laragh JH. Physiologic effects and blockade. In: Laragh JH, Buhler FR, Seldin DW, eds. *Frontiers in hypertension research. New* York: Springer-Verlag, 1982, with permission.)

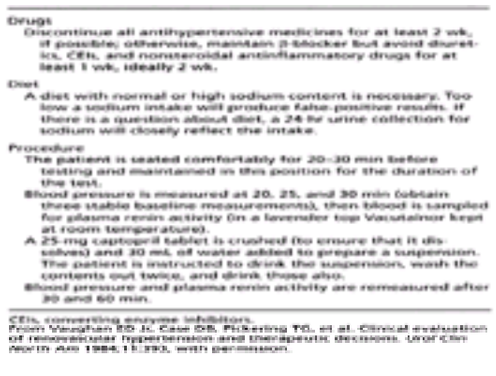
During the early studies of the effect of these agents on blood pressure in hypertensive patients, it was noted that angiotensin blockade resulted in a marked rise in plasma renin activity in selected patients. Accordingly, the induction of marked rises in plasma activity appeared to be a more specific test for RVH than the induction of depressor responses.

Single-dose Captopril Test

The captopril test is a reliable screening test well suited for outpatient use. Diuretics and preferably all other antihypertensive medications are discontinued at least 2 weeks before testing. Patients are advised not to restrict their salt intake. Twenty to thirty minutes before testing, the patient is seated comfortably in a quiet room, during which time an intravenous catheter is placed for blood sampling, and baseline blood pressure is taken for a baseline plasma renin activity determination before the oral administration of 25 mg of captopril. Blood pressure measurements are then taken every 15 minutes for 1 hour. Venous blood sampling is repeated at 30 and 60 minutes after captopril administration. A depressor renin activity level (92) is seen in patients with renin-dependent hypertension (diastolic pressure decrease of 15% or more). However, the change in blood pressure has low specificity, because patients with essential hypertension also may have a depressor response.

Formation of angiotensin II is greatly decreased by captopril. The resulting decrease in systemic blood pressure in patients with renin-dependent hypertension further decreases the blood flow to the ischemic kidney. The lower perfusion pressure produces a decrease in the glomerular capillary hydrostatic pressure, diminishing the GFR. In addition, the efferent arteriole, which undergoes angiotensin II–induced vasoconstriction at low perfusion pressures to maintain glomerular filtration, relaxes as angiotensin II formation is blocked, thus decreasing the ipsilateral GFR further. The macula densa and baroreceptor mechanisms are activated, and more renin is released from the ischemic kidney. In renin-dependent hypertension, but not in essential hypertension, inhibition of the converting enzyme is associated with a rise in plasma renin activity to 12 ng/mL per hour or greater, an increment in plasma renin activity of 10 ng/mL per hour or more above baseline levels, and a percent increase in plasma renin activity of 170% or more (or 400% if the baseline plasma renin activity was less than 3 ng/mL per hour). If these three criteria are present in a patient with normal renal function off diuretics, RVH can be distinguished from essential hypertension with a specificity of 100% and a sensitivity of 95% (75). Prior sodium depletion by diuretics or by dietary restraint increases plasma renin activity and abolishes the specificity of this test. Patients in treatment with b-adrenergic blockers remain responsive to captopril as described previously unless their baseline plasma renin activity is less than 2.5, in which case the test may be unreliable (Table 23.3).



Drugs
Discontinue all antihypertensive medicines for at least 2 wk, if possible; otherwise, maintain β-blocker but avoid diuretics, CEIs, and nonsteroidal antiinflammatory drugs for at least 1 wk, ideally 2 wk.
Diet
A diet with normal or high sodium content is necessary. Too low a sodium intake will produce false-positive results. If there is a question about diet, a 24 hr urine collection for sodium will closely reflect the intake.
Procedure
The patient is seated comfortably for 20–30 min before testing and maintained in this position for the duration of the test.
Blood pressure is measured at 20, 25, and 30 min (obtain three stable baseline measurements), then blood is sampled for plasma renin activity (in a lavender top Vacutainer kept at room temperature).
A 25-mg captopril tablet is crushed (to ensure that it dissolves) and 30 mL of water added to prepare a suspension. The patient is instructed to drink the suspension, wash the contents out twice, and drink those also.
Blood pressure and plasma renin activity are remeasured after 30 and 60 min.

CEIs, converting enzyme inhibitors.

TABLE 23.3. SINGLE-DOSE CAPTOPRIL TEST

In summary, the single-dose captopril test appears to accurately separate patients with RVH from those with essential hypertension. In addition, a 24-hour urine collection is not necessary, and the patient can remain on b-blockade.

Captopril Renogram Insert

The captopril renogram is performed in a similar fashion as the single-dose captopril test. A crushed tablet of 25 mg of captopril is given 1 hour before the procedure. Numerous isotopes have been used (Table 23.3), with ^{99m}Tc mercaptoacetylglycylglycyl-glycine (MAG3) being most commonly used today. Interpretation depends on the isotope chosen and the parameter calculated. Commonly used parameters are (a) split renal function percent uptake left to right; (b) maximum activity (A_{max}); (c) single-kidney GFR or renal blood flow, depending on which isotope is used; (d) time to peak activity (T_{max}); (e) the transit time; and (f) residual cortical activity indicating slow isotopic washout. Often, the renogram curves are graded. If the test is positive, imaging studies are necessary because there can be positive tests in patients with parenchymal disease (78). Table 23.4 lists the recent literature concerning the captopril scan, including predictive value (88). False-negative scans can occur in azotemic patients with segmental branch disease. Taken altogether, along with color Doppler sonography, the captopril renogram is gaining popularity as the initial test to identify RVH.

TABLE 23.4. ANGIOTENSIN-CONVERTING ENZYME INHIBITOR RENOGRAPHY WITH DIFFERENT TRACERS IN DIAGNOSING RENAL ARTERY STENOSIS

Contralateral Suppression of Renin Secretion and an Elevated Renal Vein–to–Arterial Renin Relationship: Use of Differential Renal Vein Renin Determinations

The emergence of the captopril renogram coupled with noninvasive imaging of the renal arteries has relegated renal vein renin determinations to a supportive role in difficult cases. However, the understanding of renal vein renin secretion enhances our understanding of RVH.

In view of limitations of the traditional renal vein ratio analysis, a method for analysis of renal values has been devised and is based on the characteristics of experimental two kidney–one clip Goldblatt's hypertension (Table 23.5) (Fig. 23.2).

Collection of samples (moderate sodium intake: 100 mEq/day)	
Ambulatory peripheral renin and 24-hr urine sodium excretion under steady state conditions (i.e., not on day of arteriography)	
Collection of blood for PRA before and after converting enzyme blockade	
Collection of supine:	
Renal vein renin from suspect kidney (V1) and inferior vena caval renin (A1)	
Renal vein from contralateral kidney (V2) and inferior vena caval renin (A2)	
Enhancement of renin secretion by converting enzyme blockade if initial renin sampling is inconclusive	
Criteria for predicting cure	
High PRA in relation to urinary	Measurement of hypersecretion of renin
Contralateral kidney: $\frac{V2 - A2}{A} = 0$	An indicator of absent renin secretion from the contralateral kidney
Suspect kidney: $\frac{V1 - A1}{A1} = 0.50$	Measurement of reduced renal blood flow
$\frac{V - A}{A}$, $\frac{V - A}{A} = 0.50$ in patients with high PRA means	
Incorrect sampling	
Segmental disease	Repeat with segmental sampling

PRA, plasma renin activity.

From Vaughan ED Jr, Sealy TA, Sniderman KW, et al. Renal vein renin secretory patterns before and after bi-unilateral angioplasty in patients with renovascular hypertension: verification of analytic criteria. In: Laragh JH, ed. Frontiers in hypertension research. New York: Springer-Verlag, 1981, with permission.

TABLE 23.5. RENIN VALUES FOR PREDICTING CURABILITY OF RENOVASCULAR HYPERTENSION

Hypersecretion of renin, as determined by the renin-sodium index or captopril stimulation, serves as the primary criterion for the diagnosis of RVH. A second criterion is the demonstration of the absence of renin secretion from the contralateral (or noninvolved) kidney. Suppression of renin secretion from this kidney can be determined by subtracting the arterial plasma renin activity (A) from the renal venous renin activity (V). Because the inferior vena caval (IVC) renin and aortic renin are the same, the IVC renin value can be substituted for A in this equation (105). Hence, patients with curable RVH exhibit an absence of renin secretion from the opposite kidney; that is, V – A = 0, also called *contralateral suppression of renin* (115,123). Contralateral suppression of renin indicates that the noninvolved kidney is responding in an appropriate, “normal” fashion to the elevated blood pressure, increased circulatory angiotensin II levels, or increased sodium chloride at the macula densa by shutting off renin secretion. This phenomenon is at times present not only in patients with unilateral renal arterial lesions but also in patients with bilateral disease demonstrated by arteriograms who have a dominant lesion on one side (91).

A third criterion is based on studies of renal vein and arterial vein relationships in patients with essential hypertension. The mean renal venous renin level has been determined to be about 25% higher than arterial plasma renin activity (105). Hence, a total renin increment (both kidneys) of approximately 50% is necessary to maintain a given peripheral renin level: (V – A)/A = 50%. However, a reduction in renal blood flow also influences the renal venous renin level. In this setting, the renal venous renin concentration is misleadingly high, shifting the renal vein–to–arterial renin relationships upward. Thus the elevation of the increment above approximately 50% becomes an index of the severity of the reduction in blood flow consequent to the obstructing vascular lesion (Fig. 23.5). The combination of these criteria found in a group of patients managed by renal revascularization is shown in Fig. 23.6 (124).

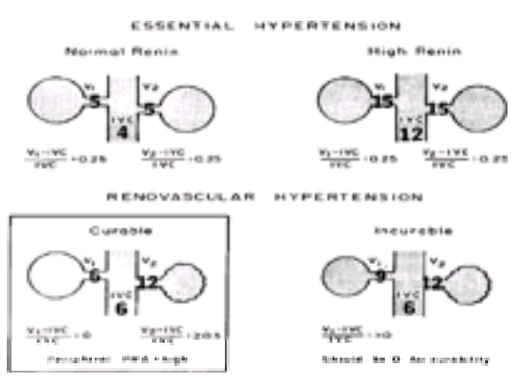

FIGURE 23.5. Renal vein renin diagnostic pattern. In essential hypertension *(top)* at all levels of renin secretion the renin level of each renal vein is approximately 25% greater than either the peripheral arterial or venous levels. In the setting of unilateral renin secretion (curable RVH) the active kidney is solely responsible for maintaining the peripheral renin levels. Hence, the increment is 50% (0.5) and becomes progressively greater as renal blood flow is reduced. Unequal bilateral renin secretion *(bottom right)* indicates bilateral disease and decreases the chance of cure after corrective unilateral surgery. (From Laragh JH, Sealey JE. Renin sodium profiling: why, how and when in clinical practice. *Cardiovasc Med* 1977;2:1503, with permission.)

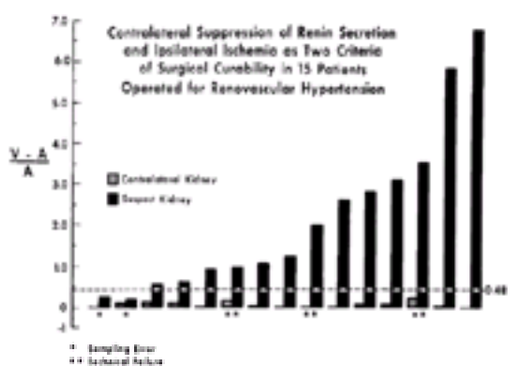

FIGURE 23.6. Of 15 patients with renovascular hypertension, 13 exhibited (V – A)/A in excess of 48% from the suspect kidney and a suppressed value from the

contralateral kidney. V is renal venous plasma renin activity; A is arterial or infrarenal inferior vena cava plasma renin activity. Asterisks (**) denote the three patients who had values suggesting surgical curability yet had residual or recurrent hypertension resulting from technical failure. (From Vaughan ED Jr, Carey RM, Ayers CR, et al. A physiologic definition of blood pressure response to renal revascularization in patients with renovascular hypertension. *Kidney Int* 1979;15:S83, with permission.)

An additional aid to renal vein sampling is the utilization of segmental renal venous sampling (102), especially in cases in which sampling of blood from the major renal vein fails to demonstrate a combined renin increment of 50% from both kidneys, suggesting either a technical error or segmental disease. This approach may be particularly helpful in children with segmental parenchymal disease (87).

The patterns of renal vein renin activity in bilateral RVH are less consistent than in unilateral disease (92).

Validation of the Four Criteria

In addition to a favorable clinical response to renal angioplasty, we also have had the unique opportunity to study the effect of restoration of blood flow on renal vein renin concentration and renin excretion (92,126). To accomplish this goal we have monitored the immediate effect of successful angioplasty on renal renin secretion. Thirty minutes after angioplasty, a marked reduction was noted in the renal vein renin from the previously stenotic side (Fig. 23.7). The residual ipsilateral increment of renal vein renin was approximately 50% above the peripheral level, whereas contralateral renin suppression persisted. This 50% increment has been predicted previously to occur in the setting of unilateral renin secretion and normal renal blood flow (105).

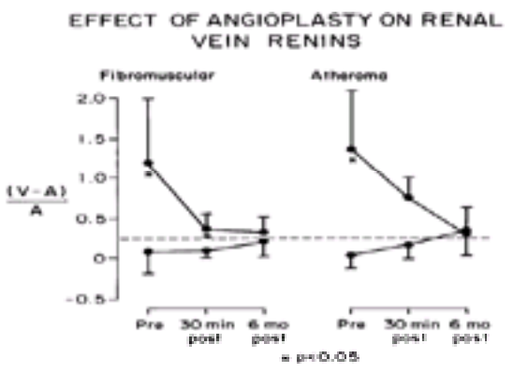

FIGURE 23.7. Effect of angioplasty on renal vein renins. Samples were taken immediately before angioplasty, 30 minutes after, and 6 months later. The higher values were for the ischemic kidney, the lower for the contralateral kidney. Asterisks (*) indicate significant difference between the two kidneys, and the *dotted line* is the normal level of (V – A)/A (0.24). (From Pickering TG, Sos TA, Vaughan ED Jr, et al. Predictive value and changes of renin secretion in hypertensive patients with unilateral renovascular disease undergoing successful renal angioplasty. *Am J Med* 1984;76:398, with permission.)

The finding that the renal renin secretory characteristics of RVH reverse after successful angioplasty with correction of the hypertension is strong support that they truly reflect the abnormal secretory behavior of renin in curable RVH.

Color Doppler Sonography

Renal sonography has rapidly evolved from a technique that gave only anatomic information to a functional test. The advances include the use of a Doppler probe (116), the color technique, the use of contrast (74), and the captopril Doppler sonogram (128). Similar to the captopril renogram, several indexes have been used: peak systolic velocity, renal aortic ratio, end-systolic index, acceleration time, and acceleration index. The overall results as compiled by Pedersen (88) are shown in Table 23.6.

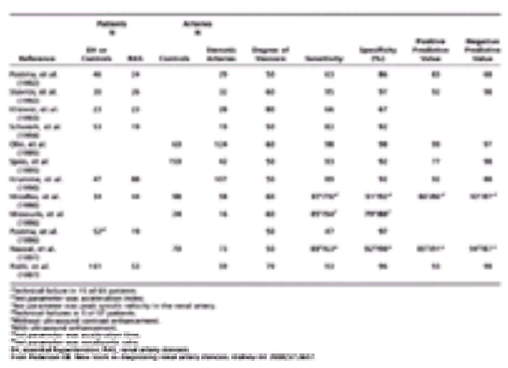

TABLE 23.6. COLOR DOPPLER SONOGRAPHY IN DIAGNOSING RENAL ARTERY STENOSIS

The major difficulties have been in the development of competent personnel with experience. Moreover, obesity and intestinal gas are limitations. Other variables include whether attention is placed on intrarenal vessels, which cannot always be localized (99), or directly on the main renal artery (73). Regardless of differences in technique, the test is gaining wider usage (52). Again, a positive test requires anatomic confirmation.

Imaging Studies

Following a positive screening test, the traditional approach has been renal angiography followed immediately by angioplasty if possible. In a patient in whom there is a high index of clinical suspicion, angiography is still preferred (Fig. 23.8) (90).

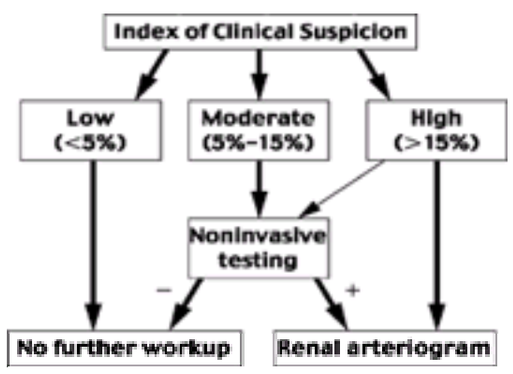

FIGURE 23.8. Suggested workup of a patient suspected of having renovascular disease. (From Pickering TG, Blumenfield JD. Renovascular hypertension and

ischemic nephropathy. In: Brenner BM, ed. *The kidney.* Philadelphia: WB Saunders, 2000:2007.)

Recently, two newer, less invasive techniques are being used to diagnose renal artery stenosis.

Spiral Computed Tomography Angiography

The development of spiral CT has permitted data acquisition during a single breath hold. The scanning time is approximately 35 seconds, the examination time is approximately 20 minutes, and the data analysis takes approximately 30 minutes. The results are impressive (Fig. 23.9). This technique is now being used routinely to evaluate renal donors (94). The reported sensitivity ranges from 88% to 98% and the specificity ranges from 82% to 98%, giving a positive predictive value greater than 85% (88). The one caveat is that a relatively high volume (150 mL) of contrast is given peripherally; thus there is a risk of nephrotoxicity. In addition, the accuracy appears to be decreased in azotemic patients.

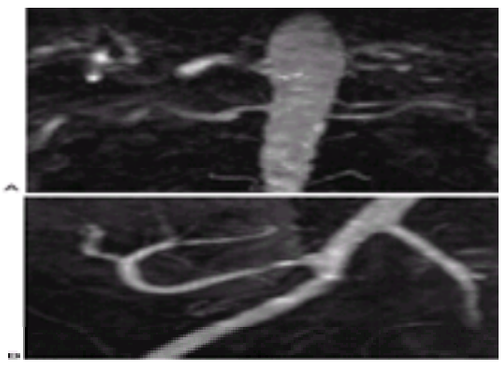

FIGURE 23.9. Spiral computed tomography scans showing bilateral renal artery stenosis **(A)** and stenosis of a transplant renal artery **(B).**

Magnetic Resonance Angiography

The two MRA techniques used are time-of-flight and phase-contrast sequences. MRA avoids the problem of renal toxicity but is limited to visualization of the main renal artery and the larger branches (39) (Fig. 23.10). The use of gadolinium may enhance the sensitivity of the technique (109). The technique is most useful in patients with atherosclerotic disease where the lesion is in the proximal renal artery, particularly if the patient has impaired renal function.

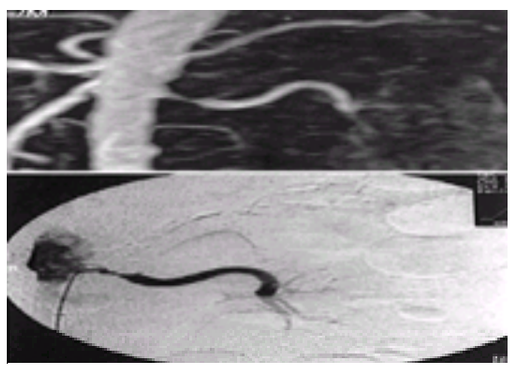

FIGURE 23.10. Three-dimensional, gadolinium-enhanced magnetic resonance angiography showing a thrombosis of the left renal artery and severe stenosis of the left renal artery. [From Grenier N, Trilland M. 2000;86(Suppl):84.]

Identifying the Potentially Curable Patient

The approach of Pickering and Blumenfeld (90) already alluded to (Fig. 23.8) seems rational. Thus the low-risk patient, in whom screening tests have low predictive value, is initially treated without evaluation. In contrast, for high-risk patients (Table 23.2), angiography is the initial study. Patients at moderate risk begin their evaluation with either a captopril renogram or a color duplex Doppler scan. If the test is negative, no additional studies are done. If the initial test is positive, anatomic localizing tests are necessary.

Ischemic Nephropathy

The other entity associated with renal artery stenosis is ischemic nephropathy. Thus renal artery stenosis is an important cause of chronic renal insufficiency due to a reduction in GFR (50,79,100).

Hypertension is now the most common cause of end-stage renal disease (ESRD) in patients older than 65 years of age (56). The subset of these patients with renal artery stenosis is unclear. However, in one study, 83 of 687 dialysis patients (12%) were found to have renal artery disease (65). Novick and colleagues (82) established the following criteria for screening for atherosclerotic renal artery disease: (a) evidence of generalized atherosclerosis, (b) a unilateral small kidney, and (c) mild to moderate azotemia (serum creatinine greater than 1.5 mg/dL). If the patient was found to have a high-grade stenosis (greater than 75%) bilaterally or in a solitary kidney, intervention was recommended (82).

Preservation of renal function has been demonstrated after renal revascularization (4) or angioplasty (13,104). However, randomized trials, now in progress, are necessary to prove that intervention is more successful than medical management in forestalling ESRD.

In addition, the evaluation previously described using peripheral and renal vein renin determinations are often inaccurate in azotemic patients. Thus color Doppler or MRA studies are necessary to exclude ischemic nephropathy as the cause of azotemia.

TREATMENT OF RENOVASCULAR HYPERTENSION

The therapeutic options for the treatment of RVH include percutaneous transluminal angioplasty, renal artery stent placement, surgical revascularization, autotransplantation, pharmacologic interference of the RAS, and removal of the ischemic kidney.

Renal Artery Angioplasty for Renovascular Hypertension

Percutaneous transluminal angioplasty was first introduced by Dotter and Judkins in 1964 for the treatment of peripheral vascular stenoses. The introduction of flexible, double-lumen balloon catheters by Gruntzig and Hopff (40) permitted the development of percutaneous transluminal angioplasty of renal artery stenoses. The fibromuscular dysplasias and unilateral, nonostial, nonoccluded atherosclerotic renal artery stenoses are the most suitable lesions for treatment with percutaneous

transluminal renal angioplasty (PTRA). The ability to avoid a general anesthetic and the relatively low morbidity of this procedure have allowed renal revascularization in patients who might have been deemed unsuitable for surgery secondary to concurrent present diseases. However, PTRA does have inherent limitations and is not suitable for dilation of ostial lesions or arterial occlusions. Therefore careful patient selection is necessary. In addition, percutaneous transluminal angioplasty is not universally available because it can be performed only by well-trained and skilled interventional radiologists with a vascular surgical team backup.

Technical success is defined as complete if the residual stenosis is 50% or less and as partial if the residual stenosis is 50% to 70% (110). The criteria to determine blood pressure are those of the national cooperative study on RVH (33). A decrease in the diastolic blood pressure to less than 90 mm Hg in the absence of antihypertensive medication is considered a cure, and a decrease in diastolic blood pressure of 15% or greater with or without antihypertensive medication is considered an improvement. A decrement in diastolic blood pressure of less than 15% is considered a failure.

Renal artery angioplasty is technically successful in approximately 80% of patients with atherosclerotic renal disease. However, the cure rate is only about 30%, with 50% improved, probably due to generalized disease. Nonostial, nonoccluded unilateral lesions were noted to be most amenable to angioplasty. Ostial lesions, total renal artery occlusions, and bilateral lesions, which often tend to be ostial and occluded, did not respond satisfactorily to angioplasty. The technical success rate in these patients as a group was 12% (110). Ostial lesions result from aortic plaques that impinge on the renal artery orifice. Inflation of the balloon catheter displaces the plaque, with recoil and assumption of the original position, occurring at deflation of the balloon. Martin and colleagues (70) reported a 25% blood pressure benefit with no cures for a group of 20 patients with ostial lesions. The development of renal artery stents now allows ostial lesions to be treated successfully with percutaneous angiographic techniques. In patients with bilateral RVH, the cure rate was a disappointing 5% and the improvement rate 41% in contrast to a 25% cure and a 47% improvement rate for patients with unilateral disease.

Renal artery angioplasty has been more successful in the treatment of the fibromuscular dysplasias. In approximately 90% of patients, the stenosed arteries are dilated successfully. Of this subgroup, 88% enjoyed a blood pressure benefit as a result of the treatment (38% cured and 50% improved). Restenosis after dilation occurred in fewer than 5% of cases in a review of long-term follow-up (117).

Complications of PTRA are reported in 10% of cases and include trauma to the access vessels (femoral or axillary) with hemorrhage. Renal artery damage by dissection, aneurysm formation, perforation, and balloon malfunction or rupture has been reported (19,31,117). Cholesterol embolization of the kidney with resulting loss in renal function or of the lower extremities resulting in distal vascular compromise have been reported. Complications of angioplasty resulting in the loss of renal unit have been infrequent, and associated deaths have been rare.

Renal Artery Stents

Patients whose renal artery strictures cannot be adequately dilated by angioplasty or whose arteries restenose following an initially successful dilation have limited therapeutic alternatives. However, an exciting alternative treatment currently is being used for these patients. A stainless steel balloon-expandable stent may be placed across a stricture to reestablish the renal artery lumen. The stents (Fig. 23.11) are 1 to 3 cm in length and may be expanded to a diameter of 4 to 9 mm (medium stents) or 8 to 12 mm (large stents).

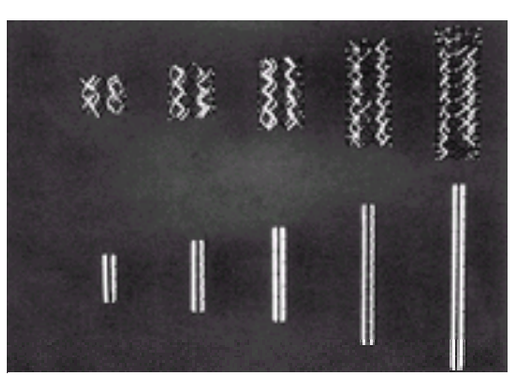

FIGURE 23.11. Palmaz stents for treatment of renal artery stenosis. Stents of various lengths are seen in the *lower row.* The *upper row* shows the stents after balloon expansion.

The renal artery stents are placed by angiographic techniques. Percutaneous transluminal angioplasty precedes introduction of a renal artery stent. If adequate dilation is not established, a stent is positioned across the renal artery stricture and is balloon expanded to reestablish the lumen. The Department of Radiology at the New York Hospital–Cornell Medical Center placed 24 stents to treat 23 renal artery stenoses in 21 patients between May 1989 and December 1993 (122). One patient was treated for a transplant renal artery stenosis. The remaining 20 patients had ostial, atherosclerotic renal artery lesions, which are generally refractory to percutaneous angioplasty. Eight stents (33%) were placed immediately following an inadequate percutaneous renal artery angioplasty. Sixteen stents (66%) were placed following a restenosis.

The percent stenosis for this group of patients was angiographically determined to be 86.3% ± 9.8%. Immediately after stent placement, the percent stenosis decreased to 1.67% ± 8.1%. At a mean angiographic follow-up of 7.6 months (range of 3 to 12 months), the percent stenosis was found to be 44% ± 23% ($p < 0001$ when compared with the prestent angiogram). Restenosis appeared to be due to endothelial ingrowth into the stent and not to stent compression or kinking. In 11 patients, the hypertension was cured (3 patients) or improved (8 patients). Although individual patients enjoyed improvement in renal function (7 of 11 patients with a creatinine greater than 1.5 mg/dL improved), the change in renal function for this small group as a whole was not statistically significant. Of 21 patients, 15 (71%) benefited from this procedure by an improvement in renal function, an improvement in blood pressure control, or both.

In looking at these preliminary results, it must be borne in mind that patients with recurrence of ostial renal artery lesions have a high failure rate when managed by angioplasty alone. Surgical revascularization is associated with much greater morbidity and mortality rates than angioplasty. Medical management can be complicated by progressive loss of renal function despite good blood pressure control. Table 23.7 reviews renal function after angioplasty (90).

TABLE 23.7. RENAL FUNCTION AFTER RENAL ANGIOPLASTY

Case I

A 73-year-old woman, following a right nephrectomy many years before, had a 30-year history of hypertension. She was found to have a significant ostial lesion that

could not be dilated by percutaneous transluminal angioplasty (Fig. 23.12). She underwent renal stent placement (Fig. 23.13). Seven months after stent placement, her renal artery remains patent and her creatinine and blood pressure are improved and stable (Fig. 23.14).

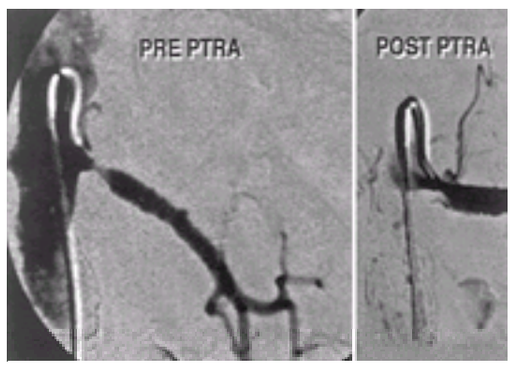

FIGURE 23.12. An ostial, left renal artery lesion is angiographically defined before percutaneous transluminal renal angioplasty **(PTRA).** After dilation, the lumen is larger. The renal artery stent can be positioned on an angioplasty balloon across the stenosis and expanded.

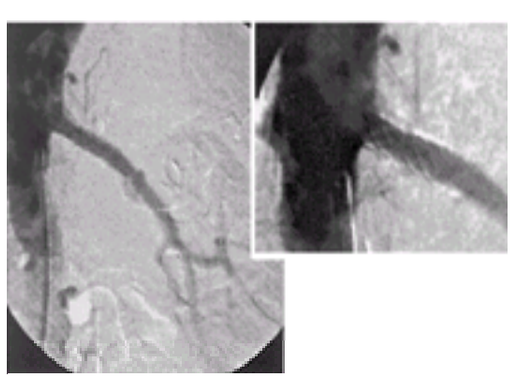

FIGURE 23.13. Poststent. A wide-caliber ostium and renal artery can be seen after the stent is expanded. The cone-down view on the inset allows the expanded stent to be recognized across the ostium and proximal renal artery.

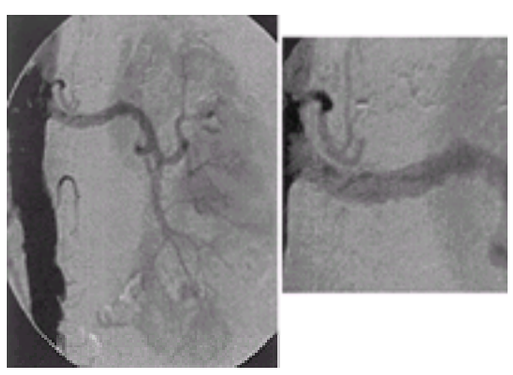

FIGURE 23.14. At a 7-month angiographic follow-up, the left renal artery and ostium remain open.

Case II

A 53-year-old white woman with a long history of hypertension has bilateral atherosclerotic ostial lesions. Percutaneous transluminal angioplasty on two lesions failed to correct her stenoses. The patient had diabetes mellitus, hypertension, and gradients of 100 mm Hg across each stenosis (Fig. 23.15). Renal artery stents were placed bilaterally (Fig. 23.16), with disappearance of the gradients and improvement in her blood pressure control.

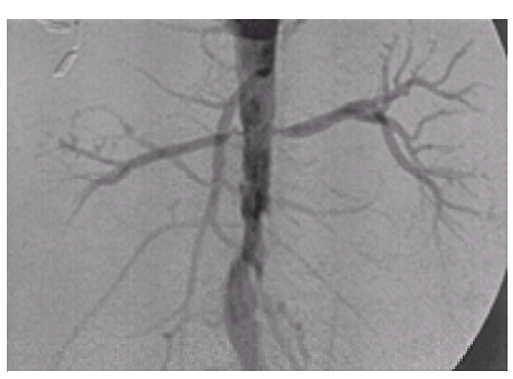

FIGURE 23.15. The angiogram of a 53-year-old white female with IDDM, hypertension, and an abdominal bruit reveals bilateral atherosclerotic ostial lesions. The gradient measured across each stenosis was 100 mm Hg (see Case II).

FIGURE 23.16. An angiogram performed immediately following bilateral renal stent placement reveals wide-open lumina. There was no pressure gradient across the

ostia.

Surgical Treatment for Renovascular Hypertension

The first surgical treatment described for RVH was nephrectomy (61). During the 1940s and 1950s, small kidneys were removed from hypertensive patients with the idea of controlling the blood pressure. In 1956, a careful review of the effects of nephrectomy on the treatment of hypertension revealed a dismal 19% success rate. However, it was appreciated that patients with unilateral renovascular disease fared somewhat better than patients with unilateral renal parenchymal disease (120). This observation plus the development and widespread use of angiography in the 1950s redirected the focus of surgical treatment of renovascular disease to revascularization of ischemic kidneys. Freeman and colleagues (34) pioneered revascularization of ischemic kidneys by performing aortic and bilateral renal artery thromboendarterectomy to treat hypertension. Aortorenal bypass quickly became the preferred method of renal revascularization, and angiography was relied on as the definitive test to predict blood pressure response to surgical correction.

The national cooperative study on RVH (33) reviewed the efficacy of surgically correcting renal artery lesions to cure hypertension. Despite a 51% cure rate, the results revealed a disappointing 34% failure rate and an unacceptable operative mortality rate approaching 10%. The patients at highest risk for operative morbidity and mortality were those with concurrent coronary or cerebrovascular disease or with bilateral renovascular disease often associated with azotemia.

In the past decade, the results of surgical renal vascularization have improved as a result of better patient selection, which can be attributed to a better understanding of the natural history of renal artery disease, to a better understanding of the physiology and pathophysiology of the renin-angiotensin-aldosterone system, and to the development of pharmacologic probes that serve as highly reliable screening tests. There is growing recognition that patients with decreased renal function, even those with total occlusion of a renal artery, may recover renal function and enjoy a blood pressure benefit after renal revascularization (63). In the latter group, angiography demonstrates a delayed nephrogram because of a rich network of collateral vessels that preserve renal morphology and function. In patients with a preoperative serum creatinine level of less than 3 mg/dL, postoperative renal function was stable and improved in 89%. Conversely, renal revascularization in patients with a baseline serum creatinine level of greater than 4 mg/dL was not worthwhile because advanced underlying renal parenchymal disease prevented improvement in renal function. Table 23.8 reviews renal function after surgical revascularization (90).

TABLE 23.8. RENAL FUNCTION AFTER SURGICAL REVASCULARIZATION

The previously unacceptable operative morbidity and mortality rates associated with renal revascularization have improved substantially by careful patient selection and preparation. It has been recognized that concurrent coronary and cerebrovascular disease and bilateral renovascular disease with azotemia greatly increase the risk of operative intervention (81). Accordingly, cardiac and cerebral revascularization are performed, when appropriate, before renal revascularization. Using this protocol, operative morbidity and mortality rates have been greatly reduced. Novick and colleagues (81) achieved a 91% blood pressure benefit in 100 consecutive renal revascularizations for atherosclerotic RVH. Bilateral revascularization is not routinely performed. Instead, the more severely affected kidney is revascularized first. Contralateral repair is reserved for patients with persistent hypertension in whom repeat renal vein renins lateralize to the unoperated side.

Aortorenal bypass with an autogenous vascular graft is the surgical treatment of choice for renal revascularization. The saphenous vein is employed most commonly. Patients with branch renal artery stenosis can be treated with multiple branch grafts employing microsurgical techniques *in vivo* or with *ex vivo* bench surgery (82). Branch intraparenchymal stenoses also may be amenable to intraoperative dilation with rigid dilators (Fig. 23.17) or angiographic-type balloon catheters introduced through the main renal artery. Most patients with bilateral disease require repair of only one side (82,118). If a bilateral repair is planned, it is performed most safely as a staged procedure.

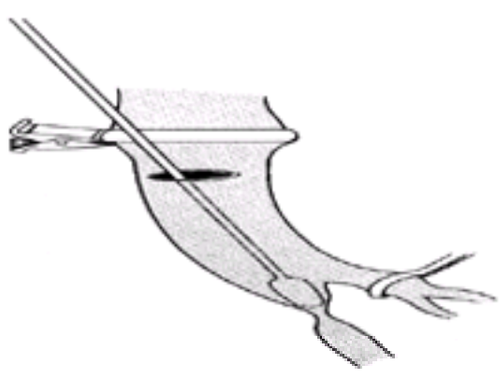

FIGURE 23.17. Intraoperative dilation of a stenosed renal artery branch with a rigid dilator.

In patients with severe aortoiliac disease, it is possible to revascularize the kidneys without performing a complete aortic replacement. Libertino and colleagues (63) developed and described hepatorenal and splenorenal bypass operations to revascularize the right and left kidneys, respectively (18). The splenorenal bypass requires patent celiac and splenic arteries. A single end-to-end vascular anastomosis is fashioned (Fig. 23.18). The spleen is preserved and nourished by collateral short gastric arteries.

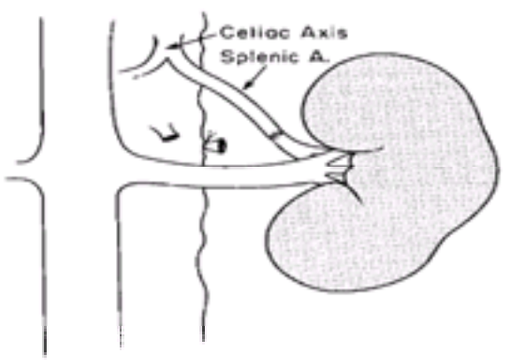

FIGURE 23.18. End-to-end splenorenal bypass to the left kidney.

The hepatic artery is ideal for bypass to the right kidney because this vessel rarely is involved by atherosclerotic disease. The most common method of hepatorenal bypass is interposition of a saphenous vein graft, end-to-side to the common hepatic artery, just beyond the gastroduodenal artery (Fig. 23.19). If the right hepatic artery is used, the gallbladder becomes ischemic, and an adjunctive cholecystectomy is necessary (Fig. 23.20). An end-to-end gastroduodenal-renal anastomosis with saphenous vein interposition also is feasible (Fig. 23.21), although the gastroduodenal artery is difficult to mobilize. Results of follow-up studies of 1 to 8 years (mean of 4 years) after hepatorenal bypass are encouraging (18). The operation was successful in 33 of 36 patients (92%). There was no evidence of permanent hepatic impairment, graft stenosis, or late complications within this period of follow-up.

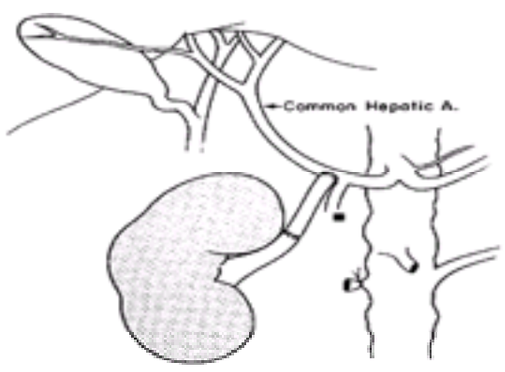

FIGURE 23.19. End-to-side hepatorenal bypass, from the common hepatic artery to the right renal artery with a saphenous vein graft interposition.

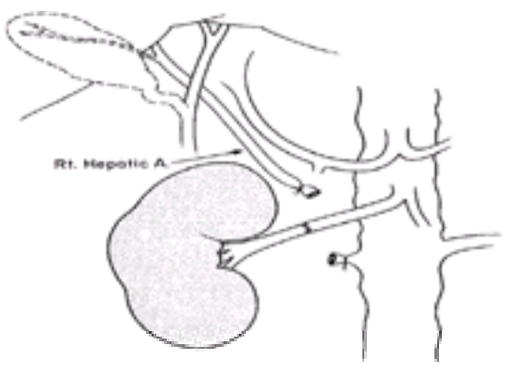

FIGURE 23.20. End-to-end hepatorenal bypass from the right hepatic artery to the right renal artery. An adjunctive cholecystectomy is necessary, because the gallbladder loses its nutrient artery.

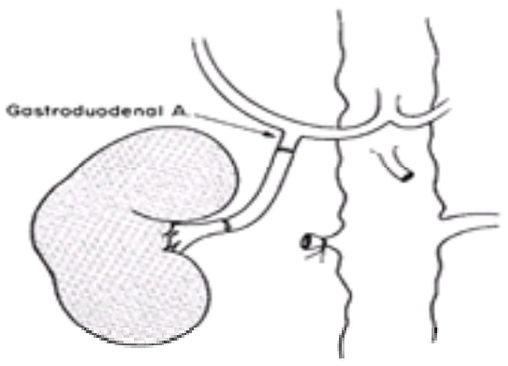

FIGURE 23.21. End-to-end gastroduodenal-renal artery anastomosis with a saphenous vein interposition.

Renal autotransplantation and iliorenal bypass with a long saphenous vein graft are useful alternative techniques for renal revascularization in patients with severe aortic atherosclerosis and absence of severe iliac disease (Fig. 23.22 and Fig. 23.23). However, the atherosclerotic process may progress to involve the iliac vessels and compromise the blood flow of the revascularized kidney. Accordingly, Novick and colleagues (82) recommend that renal autotransplantation be considered only when a splenorenal or hepatorenal bypass cannot be performed. Early results after renal revascularization are favorable. However, data on the durability of vascular anastomoses and the long-term blood pressure benefit are more limited. Dean (22) reviewed the 20-year experience at Vanderbilt University with aortorenal bypass. He found that blood pressure was cured or improved in 95% of patients with fibromuscular renal artery disease and in 78% of patients operated on for atheromatous renal artery disease. The beneficial effect of operative treatment was maintained in this group over a follow-up period of up to 23 years. Dean (22) noted that the fate of a bypass graft is determined by several factors. These include the graft material, its length, and the flow through the conduit, as well as the surgical prevision of the anastomosis. A short graft length and high flow rate are favorable for long-term patency. An autogenous artery would seem the ideal graft to use.

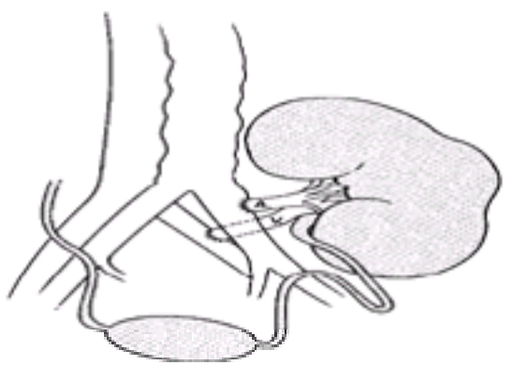

FIGURE 23.22. Renal revascularization by autotransplantation leaving the ureter intact.

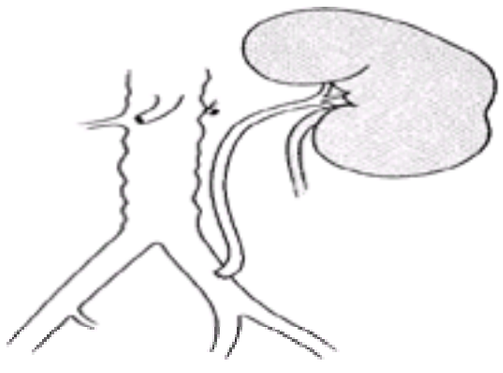

FIGURE 23.23. Renal revascularization by ileorenal bypass by means of a long saphenous vein graft.

Wylie (133) used the hypogastric artery for renal revascularization. He reported 98% patency and no late degenerative changes at a 5-year follow-up. The hypogastric autograft has particular appeal in the pediatric patient, because the graft enlarges with age in proportion to the increased demand for flow. However, the iliac arteries are not immune from the fibromuscular and atherosclerotic diseases involving the renal arteries and may succumb to these same disease processes or may already be involved at the time that renal revascularization is planned.

Venous autografts are structurally weaker than arterial autografts and represent an increased risk for aneurysmal degeneration. The saphenous vein has been used frequently in aortorenal revascularization. There is a 3% to 7% degeneration in follow-up of at least 1 year (22,27). Dacron was previously employed as a synthetic graft, but recently, polytetrafluoroethylene (Gore-Tex) grafts are preferred because of greater ease in suturing. Synthetic grafts also have the advantage of being available in a variety of sizes. However, they are subject to anastomotic aneurysmal degeneration and stenosis.

The results of surgical revascularization from the experience at the Cleveland Clinic are shown in Table 23.9 (80). The surgical techniques used in this series are shown in Table 23.10. The postoperative renal function was improved or stabilized in 89% of the patients with atherosclerotic renovascular disease who underwent renal revascularization.

TABLE 23.10. SURGICAL REVASCULARIZATION TECHNIQUE FOR RENAL ARTERY DISEASE AT THE CLEVELAND CLINIC

Darling and co-workers (21) recently published a large series that emphasizes the success of renal artery reconstruction in a series of 568 complex cases. The cases were selected because of extensive disease in the angioplasty era. For example, 406 patients had a coexisting abdominal aortic aneurysm, 125 had aortoiliac occlusive disease, and in only 156 (23%) was renal revascularization the primary procedure. Remarkably, the death rate was only 5.5% and the occlusion rate was only 2.8% (21). Moreover, the long-term (5 years) patency rate was 95%. In patients who underwent reconstruction for symptomatic lesions, 26% improved, 68% stabilized, and 6% worsened.

Medical Management of Renovascular Hypertension

Medical management of RVH has been unsatisfactory in the past. Hunt and colleagues (49) followed up 214 patients with RVH for 7 to 14 years. One hundred patients were selected for surgical therapy after failing to respond to 3 months of medical therapy. Patients treated medically had a higher mortality rate (40% versus 16%) and overall less effective control of their blood pressure than their surgically treated counterparts. Dean and colleagues (23) medically treated 41 patients with RVH. They found that the arterial stenosis progressed in 41% of patients and that progression to complete occlusion occurred in 12%. In all fairness to the medical management of RVH, it must be pointed out that the drugs used in these studies were far less specific to control a hyperactive RAS than the b-adrenergic blockers and CEIs available today. These newer drugs have been more effective in controlling blood pressure in patients with fibromuscular dysplasia than in those with atherosclerotic renovascular disease. Patients in the latter group tend to be older, have more target organ damage, and require more drugs for blood pressure control than the younger patients with fibromuscular disease.

Despite the greater specificity of these drugs for the RAS, their safety and efficacy in the treatment of RVH remain in doubt. Many reports have documented the onset of reversible decrease in renal function associated with use of CEIs in patients with bilateral renal artery stenosis or stenosis of the renal artery to a solitary kidney (54). The decrement in renal function does not appear to be caused entirely by the depressor effect of these drugs, because lowering the blood pressure to the same degree with a drug that does not interfere with the RAS does not usually lead to a comparable decrease in renal function. Micropuncture studies suggest that at low perfusion pressures the glomerular capillary hydrostatic pressure is increased by an angiotensin II–dependent constriction of the efferent arteriole (41). Inhibition of angiotensin II formation in the setting of a decreased perfusion pressure lowers glomerular filtration. Discontinuation of the CEI restores renal function to baseline.

Unfortunately, the drug-induced decrease in renal function is not limited to patients with bilateral renal artery disease. Experimental administration of CEIs in two kidney–one clip animals reveals that the ischemic kidney has a severe decline in GFR, whereas the contralateral kidney remains unaffected (130). Clinically, Wenting and colleagues (131) demonstrated, with the use of nuclear renal scans, significant impairment of renal function in the ischemic kidney of patients with unilateral renal

artery stenosis treated with captopril.

Textor and colleagues (118) argued against medical management for RVH beyond the use of CEIs, possibly to implicate a wide range of antihypertensive medications. In eight patients with bilateral renal artery disease in which both renal arteries had luminal stenoses of 75% or greater, decreasing the blood pressure from a baseline of approximately 200/100 to 140/85 mm Hg by graded increases in intravenous nitroprusside produced significant decreases in total renal plasma flow and GFR. Nitroprusside is known to increase renin secretion, and therefore interference with the autoregulatory actions of angiotensin II cannot be implicated. It appears that renal units whose blood flow is already compromised cannot tolerate reduction in blood pressure to clinically relevant levels.

Four of those eight patients underwent unilateral renal revascularization of the more ischemic kidney. Although renal function per se was not significantly improved by surgery, repeated challenge with graded nitroprusside infusions, attaining the same lower levels of blood pressure, did not lower renal plasma flow or GFR. This observation strongly suggests that revascularization may protect the kidneys from loss of renal function when the blood pressure is lowered to clinically desirable levels by antihypertensive medicines (118).

Finally, it must be borne in mind that RVH is a vascular disease whose manifestations can include loss of renal function and renin-dependent hypertension. Pharmacologic treatment of the hypertension does not address the cause of the problem. However, despite the superior results generally achieved by the revascularization of a renal artery stenosis, there is a role for medical management in the treatment of RVH. Medical management must be employed in patients who have not benefited from angioplasty or surgical revascularization, in patients who are not candidates for intervention because of the presence of other serious diseases, and in those who have refused intervention. Whatever the case, all patients with RVH who are treated pharmacologically must be evaluated carefully and routinely for changes in renal function and size (25).

The function of the upper urinary tract is to transport urine from the minor calyces toward the bladder and to protect the renal parenchyma and cranial portions of the urinary tract from distally generated backflow and back-pressure. Peristaltic activity begins with the origin of the electrical activity at pacemaker sites situated in the proximal portion of the renal collecting system (20,34,66,106,211,231,242). The electrical activity is transmitted distally from cell to cell and gives rise to the ureteral contraction wave, which propels the bolus of urine distally. Efficient collection and propulsion of urine is dependent on the passive and active properties of the ureter and on the ability of the ureter to coapt its walls completely (240). Urine passes into the bladder via the ureterovesical junction (UVJ), which under normal conditions permits antegrade transport of urine from the ureter into the bladder and prevents retrograde passage of urine from the bladder into the ureter.

ANATOMY

Gross Anatomy

The ureter is a 25- to 30-cm-long tube extending from the renal pelvis to the bladder. The three narrowest areas of the ureter are (a) at the ureteropelvic junction (UPJ), (b) at the site where the ureter crosses the iliac vessels, and (c) at the intramural portion of the distal ureter. It is at these sites that calculi most frequently become impacted.

As the ureter descends in a medial direction from the kidney, it lies on the psoas muscle in close apposition to the peritoneum, to which it is attached. In its abdominal course, both ureters are crossed anteriorly by the gonadal vessels, and they in turn cross anterior to the genitofemoral nerve (Fig 24.1A). On the right side, the descending portion of the duodenum usually lies in front of the ureter, and more distally the right ureter is crossed anteriorly by the right colic and ileocolic vessels in the root of the mesentery (Fig. 24.1B). The appendix may overlie the right ureter. On the left side, the ureter is crossed anteriorly by the left colic vessels, and as it passes over the pelvic brim, it passes behind the sigmoid colon.

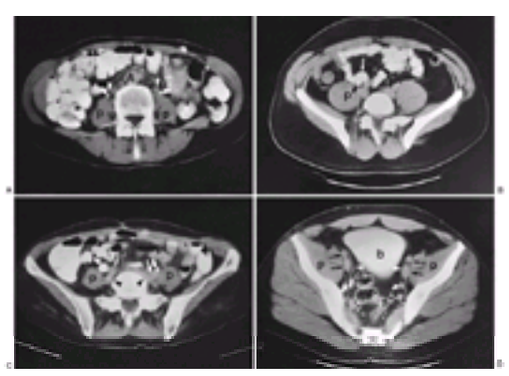

FIGURE 24.1. Computed tomography scans. **A:** Transverse section showing ureters *(curved arrows)* lying on top of psoas muscle *(p).* The gonadal vessels *(arrowheads)* are located anterior and medial to the ureter. A, aorta; C, vena cava. **B:** Close relationship between right ureter *(curved arrow)* and bowel *(straight arrow).* Right ureter is dilated. p, psoas muscle. **C:** Ureters *(curved arrows)* passing over common iliac arteries *(straight arrow)* and veins *(arrowheads).* Ureters are dilated. p, psoas muscle. **D:** Ureters *(curved arrows)* are crossed anteromedially by vasa deferentia *(arrowheads). Straight arrows* show external iliac arteries and veins; *open arrows* show hypogastric vessels. p, iliopsoas muscle; b, bladder.

As the ureters descend into the true pelvis, they pass over the terminal portion of the common or the first portion of the external iliac arteries (Fig. 24.1C). At this point, the two ureters are approximately 5 cm apart. After crossing into the pelvis, the ureters first diverge laterally and then converge medially toward the trigone. In the male, the pelvic ureter passes anterior to the internal iliac (hypogastric) artery and then just before it enters the bladder it is crossed anteriorly by the vas deferens (Fig. 24.1D). In the female, the pelvic ureter passes anterior to the internal iliac (hypogastric) artery, below the root of the broad ligament of the uterus, and then runs along the lateral aspect of the cervix, passing under the uterine artery. The ureter is crossed by the obliterated umbilical vessels in both males and females.

Blood Supply

The ureter is supplied by a variable number of segmental arteries that arise from the aorta and from a variety of its branches or subbranches, including the renal, gonadal, adrenal, common iliac, internal iliac, external iliac, superior vesical, inferior vesical, vesiculodeferential, uterine, obturator, gluteal, vaginal, and middle hemorrhoidal arteries (39). As these segmental vessels reach the ureter, they divide into ascending and descending branches that run in the adventitial layer of the

ureter. The descending branches of proximally located segmental arteries anastomose with the ascending branches of more distally located segmental vessels, thus forming long, longitudinally running vascular channels. These anastomosing arteries may give off secondary branches that form arterial plexuses in the adventitial layer of the ureter. Tributaries from the adventitial plexus pierce the muscular coat and form delicate plexuses in the submucosal layer.

Lymphatic Supply

Ureteral lymph vessels begin in communicating submucosal, intramuscular, and adventitial plexuses (239). Lymphatics from the proximal ureter may join lymphatics of the kidney, which follow the course of the renal vein to end in the lateral aortic nodes, or they may drain directly into the lateral aortic nodes near the origin of the gonadal arteries. Lymphatics from the midureter drain into the lumbar nodes along the aorta and inferior vena cava, and lymphatics from the lower ureter terminate in the common, external, and internal iliac glands.

Nerve Supply

In a syncytial-type smooth muscle such as the ureter, there is a diffuse release of transmitter from nerve bundles, with the subsequent spread of excitation from one muscle cell to another (25). The lack of discrete neuromuscular junctions in such a system accounts for the difficulty in anatomically demonstrating the presence of ureteral innervation.

The nerves to the ureter arise from the celiac, aorticorenal, and mesenteric ganglia and also from the aortic, superior hypogastric, and inferior hypogastric plexuses. The sympathetic fibers arise from T-11 to L-1. The parasympathetic fibers to the upper ureter are derived from the vagus, and those to the lower ureter are from S-2 to S-4. In humans, the lower ureter receives a denser innervation than the upper ureter (49).

The ureter also is supplied by capsaicin-sensitive primary afferent nerve fibers that contain the tachykinins, substance P (SP), neurokinin A (NKA), neuropeptide K (NPK), and calcitonin gene–related peptide (CGRP) (45,88,130,189). The afferent innervation is densest proximally and decreases caudally (136).

Cross-sectional Anatomy

Histologically, the ureter is composed of three layers:

1. An inner mucosal layer, consisting of urothelium and its supporting lamina propria
2. A muscular layer
3. An outer adventitial layer

The inner lining of the ureter, or urothelium, is composed of transitional cell epithelium. In the contracted state, the urothelium assumes a stellate appearance, with the lumen of the ureter being completely occluded. Beneath the urothelium and separating it from the muscular coat is the lamina propria, which contains both elastic and collagenous fibers.

In humans, typical spindle-shaped smooth muscle cells, grouped together in compact bundles and rich in nonspecific cholinesterase, originate in the distal part of each minor calyx (43). These cells, which compose the outer muscle layer of the calyces and renal pelvis, are continuous with the muscular coat of the ureter.

There have been a variety of descriptions of the arrangement of the fibers in the muscular coat of the ureter. A classic description is that the muscular coat consists of an inner and outer longitudinal layer separated by a circular layer (37). Satani (179) noted that the musculature of the upper ureter ran haphazardly in all directions, whereas that of the lower ureter consisted of inner longitudinal and outer circular fibers. Murnaghan (149) described the muscle bundles as a long spiral that begins proximally as longitudinal strands in the outer region of the musculature, forms a middle circular layer as the spiral turn is made, and terminates in a distal longitudinal inner layer. Tanagho (204) emphasized that ureteral muscle bundles assume a helical or spiral configuration. More recently, Gosling and Dixon (67) noted that individual muscle bundles do not spiral around the ureter but rather form a complex meshwork of interweaving and interconnecting smooth muscle bundles without distinct longitudinal and circular layers. A scanning electron microscopic study of the guinea pig ureter showed a primarily circular arrangement in the upper ureter with a few outer longitudinal and obliquely oriented fibers, a highly irregular orientation of interlacing muscle bundles in the midureter, and predominantly longitudinally oriented muscle bundles with an underlying circular muscle coat in the lower ureter (201). The adventitia of the ureter is composed of areolar and fibroelastic connective tissue, which contains the blood vessels, lymphatics, and nerve fibers that subdivide, ramify, and enter the ureter proper.

Cellular Anatomy

The primary functional anatomic unit of the ureter is the smooth muscle cell, whose main function is to contract. The cell is extremely small, approximately 250 to 400 µmm long and 5 to 7 µmm in diameter, which permits a significant proportion of the calcium (Ca^{2+}) involved in the contractile process to enter the cell from extracellular sources at the time of excitation. The nucleus of the cell is ellipsoid and contains a darkly staining body, the nucleolus, and the genetic material of the cell. Surrounding the nucleus is the cytoplasm or sarcoplasm, which contains the structures involved in cell function. In the cytoplasm, frequently in close approximation to the nucleus, are *mitochondria,* which perform many of the nutritive functions of the cell (Fig. 24.2). Also within the cytoplasm are lattice-shaped structures called *endoplasmic* or *sarcoplasmic reticulum.* These structures serve as a site for internal storage of calcium, which plays an important role in the contraction of the smooth muscle cell.

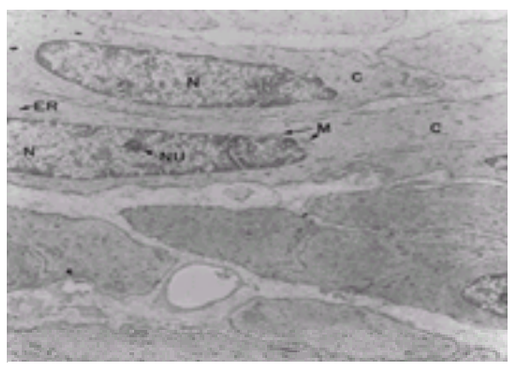

FIGURE 24.2. Electron micrograph of human ureter. C, cytoplasm (sarcoplasm); ER, endoplasmic (sarcoplasmic) reticulum; M, mitochondria; N, nucleus; NU, nucleolus. (Modified from Weiss RM. Ureteral function. *Urology* 1978;12:114, with permission.)

Dispersed in the sarcoplasm are the contractile proteins, actin and myosin, which interact—depending on the local Ca^{2+} concentration—to result in contraction or relaxation. The actin is dispersed through the sarcoplasm in hexagonal clumps and is interspersed with the less numerous clumps of the more deeply staining myosin. Attachment plaques are dark bands along the cell surface that serve as attachment devices for the actin. Any process that leads to an increase in Ca^{2+} concentration in the region of the contractile proteins results in contraction, and, conversely, any process that leads to a decrease in Ca^{2+} concentration in the region of the contractile proteins results in relaxation.

Along the periphery of the cell are numerous cavitary structures, some of which open to the outside of the cell, referred to as *caveolae.* These structures may serve a role in the nutritive functions of the cell or in the transport of ions across the cell membrane. Surrounding the cell is a doubled layer cell membrane. The *inner plasma* membrane surrounds the entire cell, whereas the *outer basement membrane* is absent at areas of close cell-to-cell contact, referred to as *intermediate junctions* (Fig. 24.3).

PHYSIOLOGY

Electrical Activity

The electrical properties of excitable tissues depend on the distribution of ions on the inside and outside of the cell membrane and on the relative permeability of the cell membrane to these ions (81). When a ureteral muscle cell is in a nonexcited or resting state, the electrical potential difference across the cell membrane, or transmembrane potential, is referred to as the resting membrane potential (RMP). The RMP is primarily determined by the distribution of potassium ions (K^+) across the cell membrane and by the preferential permeability of the resting membrane to potassium (76,222). In the resting state, the tendency for the positively charged K^+ ions to diffuse from the inside of the cell, where they are more concentrated, to the outside of the cell, where they are less concentrated, creates an electrical gradient in which the inside of the cell membrane is more negative than the outside. The electrical gradient that is formed tends to oppose the further movement of K^+ ions outward across the cell membrane along its concentration gradient. Thus an equilibrium is reached with a greater concentration of K^+ on the inside of the membrane and with the inside of the cell membrane being negatively charged with respect to the outside of the cell membrane.

The RMP in smooth muscle is lower than that which would be expected if the resting cell membrane were exclusively permeable to potassium. The RMP in the ureter is in the range of -33 to -70 mV (99,222). In the resting state, the sodium concentration on the outside of the cell membrane is greater than that on the inside. If the resting membrane were somewhat permeable to Na^+, both the concentration and electrical gradient would support an inward movement of Na^+ across the cell membrane, with a resultant decrease in the electronegativity of the inner surface of the cell membrane. Such a process could be a factor in the maintenance of a low RMP in smooth muscle. The RMP also may be maintained in part by an active mechanism capable of extruding Na^+ from within the cell against a concentration and an electrochemical gradient, and also by the relative permeability and distribution of chloride (Cl) ions across the cell membrane (105).

The transmembrane potential of an inactive or resting ureteral cell remains stable until it is excited by an external stimulus, whether electrical, mechanical (stretch), or chemical, or by conduction of electrical activity from an already excited adjacent cell. When a ureteral cell is stimulated, depolarization occurs, with the inside of the cell membrane becoming less negative than it was before stimulation. If a sufficient area of the cell membrane is depolarized rapidly enough to reach a critical level of transmembrane potential, referred to as the *threshold potential,* a regenerative depolarization, or action potential, is initiated (Fig. 24.4). The action potential has the capacity to act as the stimulus for excitation of adjacent quiescent cells, and through a complicated chain of events gives rise to the ureteral contraction.

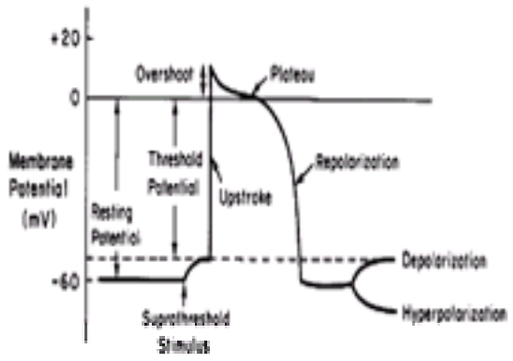

FIGURE 24.4. Schematic diagram of ureteral action potential.

When the ureteral smooth muscle cell is excited, its membrane loses its preferential permeability to K^+ and becomes more permeable to Na^+ and Ca^{2+} ions, which move inward across the cell membrane and give rise to the upstroke of the action potential (21,100,188,218,219). As the positively charged Na^+ and Ca^{2+} ions move inward across the cell membrane, the inside of the membrane becomes less negative with respect to the outside and may even become positive with respect to the outside at the peak of the action potential, a state referred to as *overshoot.* The rate of rise of the upstroke of the ureteral action potential is relatively slow, 1.2 ± 0.06 V per second in the cat (99), and accounts in part for the slow conduction velocity in the ureter.

After reaching the peak of its action potential, the ureter maintains its potential for a period of time (plateau of the action potential) before the transmembrane potential returns to its resting level (repolarization). The plateau phase appears to depend on the persistence of a high inward Na^+ conductance, and the repolarization phase appears at least in part to be due to an outward movement of K^+ across the cell membrane (21,103,104,188). The duration of the action potential in the cat ranges from 259 to 405 milliseconds (98).

In summary, the transmembrane potential of the resting ureteral cell (RMP) is approximately –33 to –70 mV and is primarily determined by the distribution of K^+ ions across the cell membrane and by the relative selective permeability of the resting cell membrane to K^+. When excited by a suprathreshold stimulus, the membrane becomes less permeable to K^+ ions and more permeable to Na^+ and Ca^{2+} ions, which move inward across the cell membrane and provide the ionic mechanism for the development of the upstroke of the action potential. Calcium also plays a prominent role in the contractile mechanism. After reaching the peak of its action potential, the membrane maintains a depolarized state (plateau of the action potential) for a time before the membrane potential of the activated cell returns to its resting level, repolarization. The plateau appears to be related to a persisting inward Na^+ current, and repolarization of the membrane probably is related to a decrease in the membrane permeability to Na^+ and Ca^{2+} and a renewed increase in permeability to K^+.

Pacemaker Potentials and Pacemaker Activity

Cells that develop electrical activity spontaneously are referred to as *pacemaker cells.* Pacemaker cells differ from nonpacemaker cells in that their resting transmembrane potential tends to be lower (less negative) than nonpacemaker cells (108) and does not remain constant but rather undergoes a slow spontaneous depolarization. If the spontaneously changing membrane potential reaches the threshold potential, the upstroke of an action potential occurs.

Dixon and Gosling (42,43,65,66,68) provided morphologic evidence of specialized pacemaker tissues in the proximal portion of the urinary collecting system. In humans, Dixon and Gosling (43) identified atypical smooth muscle cells in the region of attachment of each minor calyx to the renal parenchyma that are devoid of nonspecific cholinesterase. These distinctive cells, loosely arranged and separated from one another by connective tissue, form a thin sheet of muscle that covers each minor calyceal fornix. The atypical cells run across the renal parenchyma that lies between the renal attachments of the minor calcyes and thus serve as a connector between the minor calyces. Atypical cells are arranged longitudinally as an inner layer of the muscle coat of the minor and major calyces and of the renal

pelvis. They appear to be closely applied to and to interconnect with typical muscle cells in these structures, but they do not extend beyond the UPJ into the ureter. The atypical cells may act as pacemaker cells or as a preferential conduction pathway. Lang and colleagues (107) described fibroblast-like cells in the proximal portion of the guinea pig renal pelvis that resemble the interstitial cells of Cajal that act as pacemaker cells in the intestine.

In the multicalyceal kidney, Morita and associates (146,147), using extracellular electrodes, recorded low voltage potentials, which appear to be pacemaker potentials, from the junction of the minor calyces and the major calyx. They noted that the contraction rhythm varied in each calyx. Calyceal contractions, with resultant coaptation of the walls of the calyces, facilitate outflow of urine from the papillae and protect the renal parenchyma from pressure increases transmitted from the renal pelvis. At normal urine flow rates in the multicalyceal kidney, pacemaker contractions of the calyces occur at a rate of approximately six per minute. At normal rates of flow, the contraction waves are frequently blocked in the renal pelvis or at the UPJ (146). With increasing flow, there is a cessation of this block, and a 1:1 relationship is observed between pacemaker and ureteral contractions (33). In other words, at high flows, ureteral contractions occur at the same frequency as that of the calyces, whereas at low flows, calyceal contraction frequencies are greater than those of the ureter.

Under normal conditions, electrical activity arises proximally and is conducted distally from one muscle cell to another across the intermediate junctions (113,212). These close cellular contacts are similar to nexuses, which have been shown in other smooth muscles to be low-resistance pathways for cell-to-cell conduction (8). Although the primary pacemaker for ureteral peristalsis is located in the proximal portion of the collecting system, latent pacemakers are present in all regions of the ureter (90,140). Action potentials arising at these sites can propagate proximally and distally. Under normal conditions, these latent pacemaker regions are dominated by activity arising at the primary pacemaker sites. When the latent pacemaker sites are freed of their domination by the primary pacemaker, they in turn may act as a pacemaker.

Contractile Activity

The contractile event is dependent on the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins actin and myosin. Any process that results in an increase in Ca^{2+} in the region of the contractile proteins favors the development of a contraction; any process that results in a decrease in Ca^{2+} in the region of the contractile proteins favors relaxation.

Contractile Proteins

In smooth muscle, the most widely accepted theory suggests that phosphorylation of myosin is involved in the contractile process. With excitation, there is a transient increase in the sarcoplasmic Ca^{2+} concentration from a steady state concentration of 10^{-8} M to 10^{-7} M to a concentration of 10^{-6} M or higher. At this higher concentration, Ca^{2+} forms an active complex with the calcium-binding protein calmodulin (223) (Fig. 24.5). Calmodulin without Ca^{2+} is inactive. The calcium–calmodulin complex activates a calmodulin-dependent enzyme, myosin light-chain kinase, which in turn catalyzes the phosphorylation of the 20,000-Da light chain of myosin (Fig. 24.6). Phosphorylation of the myosin light chain is a prerequisite for activation by actin of myosin Mg^{2+}-adenosine triphosphatase (ATPase) activity, with resultant hydrolysis or adenosine triphosphate (ATP) and the development of smooth muscle tension or shortening (Fig. 24.7).

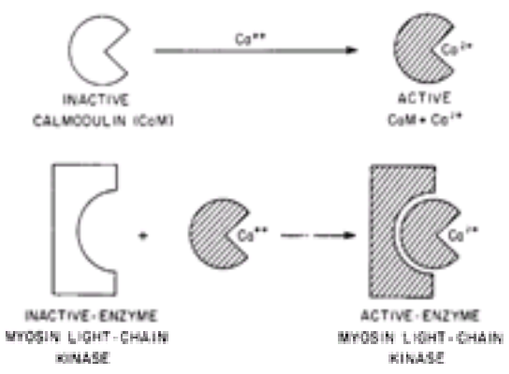

FIGURE 24.5. Schematic representation of contractile process in smooth muscle. Calmodulin is activated by Ca^{2+}. The activated calcium–calmodulin complex activates the enzyme myosin light-chain kinase. (Modified from Weiss RM. Physiology and pharmacology of the renal pelvis and ureter. In: Walsh PC, et al, eds. *Campbell's urology,* ed 5. Philadelphia: Saunders, 1986, with permission.)

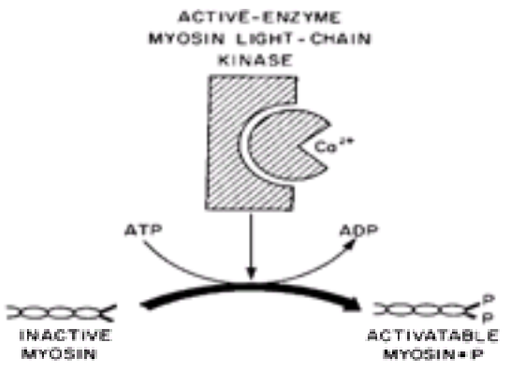

FIGURE 24.6. Schematic representation of contractile process in smooth muscle. The activated enzyme, myosin light-chain kinase, catalyzes the phosphorylation of myosin. Myosin must be phosphorylated for actin to activate myosin ATPase. (Modified from Weiss RM. Physiology and pharmacology of the renal pelvis and ureter. In: Walsh PC, et al, eds. *Campbell's urology,* ed 5. Philadelphia: Saunders, 1986, with permission.)

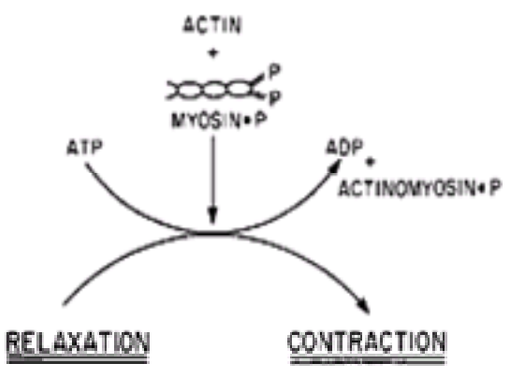

FIGURE 24.7. Schematic representation of contractile process in smooth muscle. Actin activates ATPase activity of phosphorylated myosin with the resultant development of contraction. (Modified from Weiss RM. Physiology and pharmacology of the renal pelvis and ureter. In: Walsh PC, et al, eds. *Campbell's urology,* ed 5. Philadelphia: Saunders, 1986, with permission.)

When the Ca^{2+} concentration in the region of the contractile proteins is low, myosin light-chain kinase is not activated, because calmodulin requires Ca^{2+} to activate the enzyme. This prevents activation of the contractile apparatus, because the myosin light chain cannot be phosphorylated, a process that must precede tension

development. Furthermore, a phosphatase dephosphorylates the myosin light chain, preventing actin activation of myosin ATPase activity, and relaxation results.

The calcium involved in the ureteral contraction is derived from two main sources (Fig. 24.8). Because smooth muscle cells have a small diameter, the inward movement of extracellular Ca^{2+} into the cell through L-type calcium channels during the upstroke of the action potential provides a significant source of sarcoplasmic calcium (79,125). Calcium release from a more tightly bound storage site, that is, the endoplasmic (sarcoplasmic) reticulum, is another possible source of sarcoplasmic calcium (218), although pharmacologic evidence suggests that Ca^{2+} release from the sarcoplasmic reticulum does not play a significant role in ureteral contractions, at least in the guinea pig (122,124,125). Relaxation results from a decrease in the concentration of free sarcoplasmic Ca^{2+} in the region of the contractile proteins. The decrease in sarcoplasmic Ca^{2+} can result from uptake of Ca^{2+} into intracellular storage sites (124,125) or from extrusion of Ca^{2+} from the cell (24).

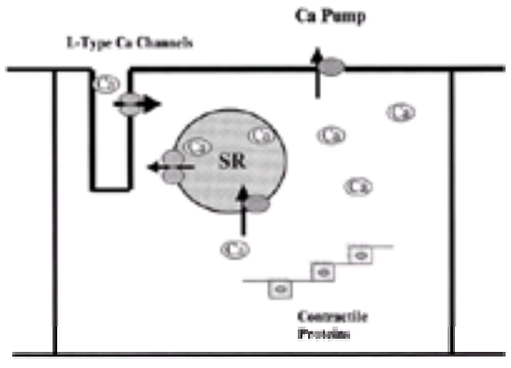

FIGURE 24.8. Schematic representation of calcium *(Ca)* movements involved in ureteral contraction. Ca involved in contractile process may be derived from extracellular sources or from tightly bound intracellular storage sites. SR, sarcoplasmic reticulum.

Role of Nervous System in Ureteral Function

The ureter is a syncytial type of smooth muscle without discrete neuromuscular junctions. Because peristalsis may persist after transplantation (155) or denervation (234), and because normal antegrade peristalsis persists after reversal of a segment of ureter *in situ* (142), it is apparent that ureteral peristalsis can occur without innervation. Further evidence indicating that an intact innervation is not required for ureteral peristalsis is that neither pacemaker activity nor the propagation of ureteral peristalsis is affected by the neural poison tetrodotoxin (61,185). It is, however, also apparent that the nervous system plays at least a modulating role in ureteral peristalsis. Autonomic drugs may affect the rate of urine transport through the ureter by modulating not only peristaltic frequency but also bolus volume (148). There is strong evidence to support the presence of excitatory a-adrenergic and inhibitory b-adrenergic receptors in the ureter (139,171,225). Support for the presence of excitatory a-adrenergic and inhibitory b-adrenergic receptor mechanisms in the ureter includes the demonstration of adenylyl cyclase activity in the ureter (230,236), the demonstration of a- and b-adrenergic receptors in the ureter using receptor binding techniques (110,111), and the finding that the application of a given intraluminal pressure results in a greater degree of ureteral deformation in rabbits depleted of catecholamines by the administration of reserpine than results from the application of the same pressure load to a ureter of a normal non–reserpine-treated animal (226). Furthermore, electrical stimulation with high-intensity, high-frequency, short-duration pulses has been shown to release catecholamines, presumably from neural tissue intrinsic within the wall of the ureter (225) and renal calyx (116), and catecholamine-containing nerve fibers and cells have been demonstrated in the ureter (163).

Available data suggest that cholinergic (parasympathetic) agonists potentiate ureteral and renal pelvic contractility by directly stimulating cholinergic receptors (128,164,220) or by indirectly causing the release of catecholamines (171). The ureter contains acetylcholinesterase-positive nerve fibers and cells, with the intravesical ureter being the most densely innervated (164), and cholinergic (muscarinic) receptors have been demonstrated in the ureter (110,111). DelTacca's demonstration (41) of acetylcholine release from isolated guinea pig, rabbit, and human ureters during field stimulation, and the inhibition of this release by the neural poison tetrodotoxin, provides further evidence for a role of the parasympathetic nervous system in the control of ureteral activity.

Anatomic support for a role of the nervous system in the modulation of peristalsis is provided by the demonstration of adventitial nerves in the human ureter (152,153) and the immunohistochemical demonstration of nerves and nerve cells beneath the muscularis and adventitia in the human and pig ureter (93).

Release of the tachykinins SP, NKA, and NPK from capsaicin-sensitive sensory nerves of the ureter has an excitatory effect on ureteral peristalsis, whereas release of CGRP from these nerves has an inhibitory effect on ureteral peristalsis (87). The excitatory effect of the tachykinins involves excitation of NK2 receptors in guinea pig and human ureters (158). The inhibitory effect of CGRP is associated with an increase in cyclic adenosine monophosphate (cAMP) (177). Maggi and associates (132) noted that the excitatory effects of tachykinins are more prominent in the renal pelvis than in the ureter and that the inhibitory effects of CGRP are more prominent in the ureter than in the renal pelvis. Histochemical studies have shown that the tachykinins and CGRP colocalize in the same nerves in the guinea pig and human ureter (88). Peptidergic neurons containing neuropeptide Y (NPY) and vasoactive intestinal polypeptide (VIP) also are present in the rat, cat, guinea pig, and human ureters (3,5,49,162). NPY potentiates the contractile responses to norepinephrine (162). VIP decreases ureteral peristaltic frequency and amplitude (109).

Nitric oxide (NO) and NO donors cause an increase in cyclic guanosine monophosphate (cGMP), with resultant relaxation of the renal pelvis and ureter (91,92). Nerves displaying immunoreactivity for nitric oxide synthase (NOS) or nicotinamide-adenine-dinucleotide phosphate (NADPH) diaphorase are present in the human ureter (60,91,193). There is some evidence that NO may be a transmitter in the ureter and renal pelvis, but there may be species and anatomic differences. NOS inhibitors have been shown to block nonadrenergic, noncholinergic (NANC) nerve-mediated relaxations of pig intravesical ureter (77), but they do not influence the spontaneous motility of isolated guinea pig renal pelvis or guinea pig and sheep ureter (57,127).

Physiology of the Ureteropelvic Junction

Griffiths and Notschaele (70) described the dynamics of urine transport within the ureter. As the renal pelvis fills, there is a rise in renal pelvic pressure, and urine is ultimately extruded into the upper ureter, which is initially in a collapsed state. After transporting the urine into the upper ureter, renal pelvic pressure declines to its baseline value, and the cycle of pelvic filling, increase in pressure, and launching of urine into the ureter occurs again. The closed UPJ may be protective to the kidney in dissipating back-pressure from the ureter, because ureteral contractile pressures are higher than renal pelvic pressures.

The mechanism for urine launching into the upper ureter is not completely understood, and abnormalities in a rather complicated regulatory mechanism may cause the hydronephrosis associated with functional UPJ obstructions in which urine transport is impaired, even though large-caliber catheters can be passed readily through the UPJ. Whereas in the normal system, peristalsis is controlled by pacemaker cells that generate high-frequency action potentials in the proximal pelvicalyceal region, in the chronically dilated system, the frequency gradient in the renal pelvis is lost. This can be associated with latent pacemakers initiating dystropic orthograde peristaltic activity or retrograde contractions. Obstruction alters the hierarchic organization of the multiple coupled pacemakers that normally coordinate peristaltic activity (31). Such disruption causes uncoordinated pelvic contractions that may result in hypertrophy of the renal pelvic smooth muscle and impaired transport of urine into the ureter. Whether these functional changes are secondary to or the cause of the dilation is not certain.

Murnaghan (150) related the functional abnormality at the UPJ to an alteration in the configuration of the muscle bundles, and Foote and associates (54) observed a decrease in musculature at the UPJ in patients with a UPJ obstruction. Hanna (73) noted in severe UPJ obstruction abnormalities in the musculature of the renal pelvis and disruption of intercellular relationships at the UPJ itself. Gosling and Dixon (64) also observed histologic abnormalities in the dilated renal pelvis. In some instances, there may be areas of actual narrowing or valvelike processes at the UPJ. Furthermore, a vessel or adhesive band crossing the UPJ may potentiate the degree of dilation in any of the forms of UPJ obstruction.

Propulsion of Urinary Bolus

Following extrusion into the ureter, the urine forms a bolus owing to a ureteral contraction ring that completely coapts the ureteral walls (70). The contraction ring at the rear end of the bolus progresses distally at a constant velocity, while the velocity of the leading edge of the bolus varies along the ureter (46). Therefore the width and length of the bolus is not uniform as it moves from the renal pelvis to the bladder. The bolus of urine that is pushed distally in front of the contraction ring lies

almost entirely in a passive, noncontracting part of the ureter (224). Contraction waves normally occur two to six times per minute in the normal human ureter (47) and are conducted at a velocity of approximately 2 to 5 cm per second (26). Baseline (resting) ureteral pressure is approximately 0 to 5 cm H_2O, and contractile pressures may range from 20 to 60 cm H_2O (47). The major component of the recorded pressure is derived from the contraction wave, with only a small component derived from the bolus pressure. The urine bolus is forced into the bladder by the advancing contraction wave, which dissipates at the UVJ (Fig. 24.9). When functioning properly, the UVJ ensures one-way transport of urine.

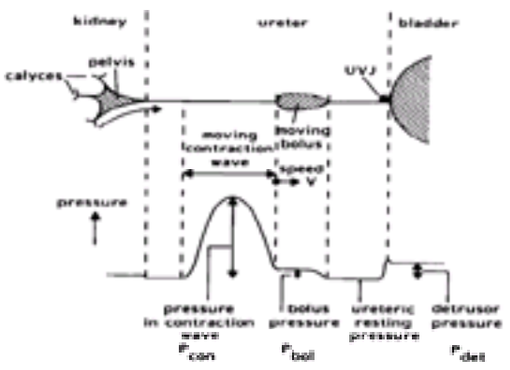

FIGURE 24.9. Schematic representation of a single bolus in the ureter moving from the renal pelvis to the bladder. Corresponding distribution of pressure within the urinary tract is shown *(lower tracing).* UVJ, ureterovesical junction; V, speed of bolus movement. (From Griffiths DJ, Notschaele C. The mechanics of urine transport in the upper urinary tract. I. The dynamics of the isolated bolus. *Neurol Urodynam* 1983;2:155, with permission.)

As with any tubular structure, the ureter can transport a set maximum amount of fluid per unit time. Under normal flows, in which bolus formation occurs, the amount of urine transported per unit time is significantly less than the maximum transport capacity of the ureter. At high flows, the ureteral walls do not coapt, and fluid is transported in a continuous column rather than in a series of boluses.

Changes in the dimensions of the ureter that occur in pathologic states may in themselves account for inefficient urine transport, even if the contractile force of the individual fibers remains unchanged (11,70,227). The Laplace equation expresses the relationship between the variables that affect intraluminal pressure:

$$\text{Pressure} = \frac{\text{Stress} \times \text{Wall Thickness}}{\text{Radius}}$$

An increase in ureteral diameter in itself can cause a decrease in intraluminal pressure and result in inefficient urine transport.

The Laplace relationship also may provide a rationale for ureteral tapering of the dilated ureter. With ureteral tapering, muscle thickness and the ability of the ureter to contract remain unchanged. The decrease in radius occurring with ureteral tapering may in itself account for higher intraluminal pressure, with resultant improved urine transport. The tapered ureter can coapt its walls more readily and generate a higher intraluminal pressure, even though the material itself has not been changed (227). Diagrammatically, with ureteral tapering, force or the number of blocks remains unchanged, but intraluminal pressure increases as the load is supported over a smaller area; thus pressure or the height of the pile of blocks increases (Fig. 24.10).

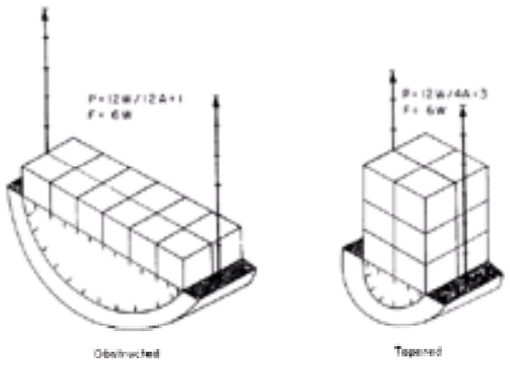

FIGURE 24.10. Diagrammatic representation of changes that occur with tapering of the obstructed ureter. A, area over which force is distributed; F, force developed by each half of ureter; P, pressure; W, blocks or weights representing load proportional to force. (From Weiss RM, Biancani P. A rationale for ureteral tapering. *Urology* 1982;20:482, with permission.)

Effect of Diuresis on Ureteral Function

The upper urinary tract alters its characteristics according to the amount of urine to be transported. Smooth muscle function is affected by the amount of stretch and the rate with which the stretch is applied. The initial response of the ureter to an increase in urine flow is an increase in the frequency of peristalsis. At relatively low flow rates, small increases in flow result in large increases in peristaltic frequency. At higher flow rates, relatively large increases in flow result in only small increases in peristaltic frequency. With increasing urine flow, peristaltic frequency increases to a maximum, and further increases in urine transport occur by means of increases in bolus volume (32). As the volume of the bolus increases, the leading edge of the bolus approximates the contraction ring of the preceding bolus. The pressure in the bolus increases because of increased resistance at the leading edge of the bolus, where it touches the preceding contraction wave. At very high flows, the pressure within the bolus exceeds the contraction pressure in the ring, and the contraction pressure is no longer sufficient to coapt the ureteral wall. The boluses then coalesce, and the ureter becomes filled with a column of fluid and dilates. At high flows, urine is transported through an open tube by columnar flow rather than by a series of boluses.

Physiology of the Ureterovesical Junction

Griffiths (71) analyzed the factors involved in urine transport across the UVJ. Under normal conditions and at normal flow rates, the contraction wave that occludes the ureteral lumen propagates distally with the urine bolus in front of it. When the bolus reaches the UVJ, the pressure within the bolus must exceed intravesical pressure for the bolus of urine to pass across the UVJ into the bladder. For the contraction wave to coapt the ureter walls and move the urine bolus distally, the pressure generated by the contraction wave must exceed the pressure within the urinary bolus. The UVJ does not relax (228).

Blok and co-workers (14) demonstrated fast and slow pressure waves at the UVJ. The fast pressure waves originate from intrinsic ureteral contractions, are related to retraction of the distal ureter within its sheaths, and are accompanied by bolus ejection of fluid into the bladder. This telescoping, dynamic event decreases the UVJ resistance to flow and thus facilitates urine passage into the bladder. The slow pressure waves originate from the surrounding detrusor muscles and represent the influence of detrusor activity on flow through the UVJ. Coolsaet and associates (36) demonstrated that resistance to flow through the UVJ is due to (a) stretch of the bladder base and UVJ, (b) intravesical pressure transmitted to the submucosal ureteral segment, (c) activity of the detrusor muscle surrounding the UVJ, and (d) dynamics of the ureteral segment composing the UVJ.

The relationship between upper urinary tract function and resistance to outflow at the UVJ is of major clinical importance. The pressure within the bladder during the storage phase is of paramount importance in determining the efficacy of urine transport across the UVJ. This is the pressure that the ureter must work against for the

greatest period of time. During filling of the normal bladder, sympathetic impulses and the viscoelastic properties of bladder wall inhibit the magnitude of the intravesical pressure rise. With filling, the normal bladder maintains a relatively low intravesical pressure (138). The low intravesical pressure facilitates urine transport across the UVJ and prevents ureteral dilation.

Renal function and the functional integrity of the upper urinary tract are at risk in individuals with noncompliant or hyperactive bladders. In the noncompliant fibrotic bladder and in some forms of neurogenic vesical dysfunction, the bladder is autonomous, and relatively small increases in bladder volume result in large increases in intravesical pressure with impairment of ureteral emptying. Regular emptying of these bladders may not be sufficient to protect the upper tracts, and intravesical pressure may need to be lowered by reduction in detrusor tonus. Furthermore, outflow resistance at the UVJ may be high in the overdistended bladder even at low intravesical pressures. This results from stretch of the UVJ and decreased retractability of the submucosal ureteral segment. Intravesical volume thus should be kept at reasonable levels, which may require intermittent catheterization. Increased resistance to bolus outflow across the UVJ can occur when there is obstruction at the UVJ, when intravesical pressure or volume is excessive, or when flow rates are so high as to exceed the transport capacity of the UVJ. Under such conditions, in which the bolus of urine cannot freely pass into the bladder, the pressure within the bolus, propelled by the ureteral contraction ring, increases and may exceed the pressure within the contraction ring. Under these conditions, the contraction wave will be unable to coapt the ureteral wall and intraureter reflux will occur. This impaired bolus transport will cause secondary widening of the ureter and weaker ureteral contractions, with only a fraction of the bolus volume passing distally. Griffiths (71) presented theoretic evidence to show that a similar situation of impaired bolus transport across the UVJ would be expected if the ureter was wide or weakly contracting, even if the UVJ was perfectly normal. Under these conditions, a similar breakdown of bolus discharge into the bladder can occur in the wide or weakly contracting ureter at high flow rates, even if the UVJ is normal.

There is some evidence that gravity may assist urine transport and that the erect position, by enhancing hydrostatic loading of the UVJ, may facilitate urine transport across the UVJ, especially in individuals with wide upper tracts (181). From a clinical viewpoint, some workers have suggested that bed rest may be deleterious to renal function in the patient with urinary retention and dilated upper urinary tracts (58).

Relationship Between Vesicoureteral Reflux and Ureteral Function

The intravesical ureter is approximately 1.5 cm long and takes an oblique course through the bladder wall. It is composed of an intramural segment, which is surrounded by detrusor muscle, and a submucosal segment, which lies directly under the bladder urothelium (203). The relationship between the length and diameter of the intravesical segment of ureter appears to be a factor in the prevention of vesicoureteral reflux (156). Trigonal function also may be a factor in the prevention of vesicoureteral reflux (202). Furthermore, the development of vesicoureteral reflux in individuals with bladder outlet obstruction and neurogenic vesical dysfunction provides evidence that increased intravesical pressures also may be a factor in certain instances of reflux.

Although an abnormality of the UVJ is the primary etiologic factor in most cases of reflux, there is evidence to suggest that decreased ureteral peristaltic activity may be a contributory factor (96,141,228). Support for this contention may be derived from the findings that a normal ureter may not reflux, even when reimplanted into a bladder without a submucosal tunnel (40), and that a defunctionalized refluxing ureter may cease to reflux when a proximal diversion is taken down and urine flow through the ureter is reinstated (206,233). Furthermore, the success rate of antireflux procedures is less with poorly functioning dilated ureters, and, although this may be related to technical factors, decreased peristaltic activity may be a reason for failure in many instances.

Studies in normal and mildly refluxing systems have shown that there is a high-pressure zone in the distal ureter with a resultant pressure gradient across the UVJ (228). With bladder filling, the resultant UVJ–bladder pressure gradient increases in nonrefluxing systems, whereas it decreases and may disappear in refluxing systems (228) (Fig. 24.11). This decrease in the pressure gradient in refluxing systems may be related to lateralization of the ureteral orifice and shortening of the intravesical tunnel and may correspond to the time when reflux occurs.

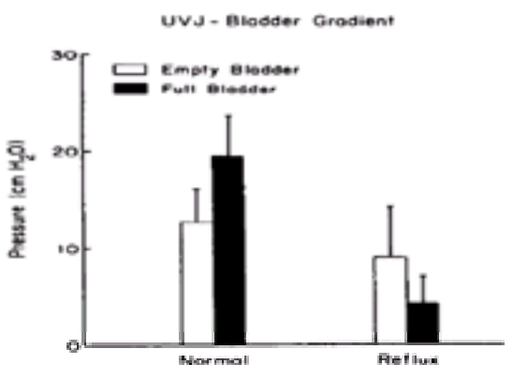

FIGURE 24.11. Pressure gradient across the ureterovesical junction *(UVJ)* in normal and mildly refluxing (grades II and III) systems. (From Weiss RM, Biancani P. Characteristics of normal and refluxing ureterovesical junctions. *J Urol* 1983;129:858, with permission.)

Effect of Infection on Ureteral Function

Infection within the upper urinary tract may impair urine transport. Bacteria and endotoxins have been shown to inhibit ureteral activity (95,165,205), and pyelonephritis in the monkey has been associated with decreased peristaltic activity (168). Furthermore, Rose and Gillenwater (170) have shown that infection can potentiate the deleterious effects of obstruction on ureteral function.

In humans, irregular peristaltic contractions, often with a decreased amplitude, have been recorded with infection. In more severe cases, absence of activity has been noted (173). Furthermore, ureteral dilation may occur with retroperitoneal inflammatory processes secondary to appendicitis, regional enteritis, ulcerative colitis, or peritonitis (134). Infection also may reduce the compliance of the intravesical ureter and permit reflux to occur in situations in which the UVJ is intrinsically of marginal competence (35).

Effect of Calculi on Ureteral Function

Factors that can affect the spontaneous passage of calculi include the size and shape of the stone (213); areas of narrowing within the ureteral lumen; ureteral peristalsis; the hydrostatic pressure of the column of urine proximal to the calculus (190); and edema, inflammation, and spasm of the ureter at the site of the stone (82).

Two factors that appear to be most useful in facilitating stone passage are an increase in hydrostatic pressure proximal to a calculus and relaxation of the ureter in the vicinity of the stone. In support of the theory that increased hydrostatic pressure facilitates stone passage, it has been shown in the rabbit and dog ureter that artificial concentrations with holes move more slowly than those without holes (190). Furthermore, ureteral ligation proximal to a concretion has been shown to decrease hydrostatic pressure, with resultant inhibition of stone passage (190). Theoretically, high fluid intake will increase hydrostatic pressure proximal to a stone and thus may aid in its passage; however, the elevated hydrostatic pressure, if prolonged, is potentially deleterious to the kidney.

With respect to the potential facilitative effect of ureteral relaxation on stone passage, Peters and Eckstein (161) showed that the spasmolytic agents phentolamine, an a-adrenergic antagonist, and orciprenaline, a b-adrenergic agonist, dilated the canine ureter at the level of an artificial concretion and thus permitted increased fluid flow beyond a partially obstructive concretion. It appears that resistance to urine flow in this experimental model was caused in part by the artificial concretion and in part by local spasm and that the resistance could be decreased by spasmolytic drugs, such as phentolamine and orciprenaline. Although it has not been determined whether this spasmolytic effect would aid in stone passage, the same principle has been used to float upper ureteral stones proximally into the renal pelvis as a prelude to percutaneous nephrostolithotomy. Obstruction of the ureter with a balloon catheter leads to dilation of the ureter, with the impacted stone then being able to migrate proximally (9). Furthermore, placement of a nephrostomy tube proximal to a steinstrasse appears to facilitate passage of the stones. This may result from decreasing peristaltic activity that acts as a spasmodic factor in the region of the stone.

Although these data can be interpreted to imply that ureteral relaxation in the region of a concretion would aid in stone passage, a controlled study currently is not available. Such a study with an agent known to have strong relaxant effects on the ureter, such as theophylline (69,230), would be of value, but the interpretation of the data obtained might be difficult because of the marked variability of spontaneous stone passage in the clinical setting.

Ureterolithotomy

With the advent of ureteroscopy, percutaneous nephrostolithotomy, and extracorporeal shock wave lithotripsy (ESWL), open ureterolithotomy has become a less frequently used procedure. However, it may still be the preferred technique for the removal of large midureteral stones that are impacted at the level of the iliac vessels. For upper ureteral calculi, a standard flank incision below or through the bed of the twelfth rib has been the standard approach, although a posterior lumbotomy has a role in the management of larger, well-impacted calculi. During the procedure, avoidance of stone migration, especially proximally, should be ensured by control of the ureter above and below the calculus with vessel loops or Babcock forceps. A longitudinal incision in the ureter is made directly over the stone, and the stone is extracted. A small catheter is passed proximally into the renal pelvis for irrigation and to ensure that the system is unobstructed. Although distal passage of the catheter into the bladder can be used to assess distal obstruction, it can cause edema at the UVJ, with prolongation of flank drainage postoperatively. For this reason, the use of distal catheter passage can be individualized depending on the clinical situation.

Some authors favor a loose closure of the ureter with only one or two fine sutures, and others seek a watertight closure with either interrupted or continuous fine sutures. Both methods work. Our preference is multiple interrupted 5-0 chromic adventitial sutures, which avoid excessive prolonged leakage yet provide a means for urine egress, if necessary. One or two Penrose drains brought to the exterior through a stab wound provide for drainage.

The technical details for removal of midureteral stones are essentially the same as for upper ureteral calculi. The approach can either be via a subcostal flank incision or via an anterior extraperitoneal approach, using a horizontal incision beginning below the tip of the twelfth rib and extending anteriorly, with the patient in the supine position with a roll of towels beneath the shoulder and buttock. This approach, classically employed for sympathectomy, can involve muscle splitting, or the muscle layers can be divided.

Lower ureteral calculi can be approached through a modified Gibson's incision as used for renal transplantation or through a vertical suprapubic incision with retraction of the bladder toward the contralateral side. At times, with a periureteral inflammatory reaction or scarring from previous surgery, the ureter and stone may be difficult to identify. Identification of the ureter proximally, where it crosses the bifurcation of the common iliac artery, may facilitate its localization, and opening the peritoneum with visualization of the ureter through the posterior parietal peritoneum can be helpful. Identification and division of the obliterated umbilical vessels also can aid in localizing the ureter and facilitating removal of the calculus. The technique for stone removal is similar to that employed for higher stones, and early control of the ureter proximal to the calculus with a vessel loop is imperative.

For calculi in the most distal portions of the ureter, such as in the intramural portion of the UVJ, a transvesical approach can be used. If the stone can be palpated with the bladder open, an incision is made in the vesical mucosa directly over the calculus. If the stone is somewhat more proximal, proximal ureteral control with a vessel loop is obtained extravesically, and the incision in the ureter can be extended proximally from within the bladder. If there is concern about distal ureteral damage in cases in which there is significant periureteral inflammation, a ureteroneocystostomy using a short submucosal tunnel may be required and would be preferable to the development of a ureteral obstruction necessitating a secondary procedure. In women, a transvaginal approach can be used for distal ureteral calculi.

Effect of Pregnancy on Ureteral Function

Hydroureteronephrosis of pregnancy begins in the second trimester of gestation and subsides within the first month after parturition. It is more severe on the right than on the left side, and ureteral dilation does not occur below the pelvic brim. Roberts (169) presented a strong argument in favor of obstruction as the primary etiologic factor in the development of hydroureteronephrosis of pregnancy. Others have suggested a hormonal mechanism for the ureteral dilation of pregnancy (216). As emphasized by Roberts (169):

1. Elevated baseline (resting) ureteral pressures consistent with obstruction have been recorded above the pelvic brim in pregnant women, which decrease when positional changes permit the uterus to fall away from the ureters (176).
2. Normal ureteral contractile pressures have been recorded in pregnant women, suggesting that hormonally induced ureteral atony is not the prime factor in ureteral dilation of pregnancy.
3. Women whose ureters do not cross the pelvic brim, that is, those with pelvic kidneys or ileal conduits, do not develop ureteral dilation of pregnancy.
4. Hydronephrosis of pregnancy usually does not occur in quadripeds whose uterus hangs away from the ureters (210).
5. Elevated ureteral pressures in the pregnant monkey return to normal when the uterus is elevated from the ureters at laparotomy or when the fetus and placenta are removed from the uterus.

Studies of the effects of hormones of pregnancy on ureteral function have been conflicting. Although several studies have shown an inhibitory effect of progesterone on ureteral function (89,102) this has not been a universal finding (159,182). Progesterone has been noted to increase the degree of ureteral dilation during pregnancy and to retard the rate of disappearance of hydroureter in postpartum women (119). Furthermore, hydronephrosis has been reported in women taking oral contraceptives (72,137). Others, however, failed to induce changes in ureteral activity in women by the administration of estrogen, progesterone, or a mixture of these drugs (29,135). Thus, although obstruction appears to be the primary factor in the development of hydronephrosis of pregnancy, it is possible that a combination of hormonal and obstructive factors is involved (52).

Effect of Age on Ureteral Function

Aging affects the structure and function of the ureter. In a human autopsy study of subjects ranging in age from 12 weeks of gestation to 12 years of age, Cussen (38) noted a progressive increase in the population of smooth muscle cells and a small increase in the overall size of the individual smooth muscle cells with age. This is accompanied by an irregular increase in the number of elastic fibers. A progressive increase in ureteral cross-sectional muscle area is also observed in the ureter of the guinea pig between 3 weeks and 3 years of age, accompanied by an increase in developed force (85) (Fig. 24.12). The increase in force developed between 3 weeks and 3 months of age seems to be attributable to an increase in contractility, because there is an associated increase in active stress, or force per unit area of muscle. The increase in force developed between 3 months and 3 years of age can be explained by an increase in muscle mass alone, because there is no change in active stress between these two age groups (Fig. 24.13). Although changes in the force–length relationships of guinea pig ureter occur with age, the force–velocity relationships do not change with age (12).

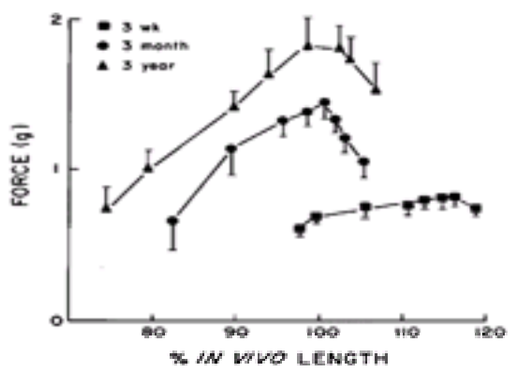

FIGURE 24.12. Active force–length curves of isolated guinea pig ureteral segments as a function of age. Developed force increases with age. Data are shown as mean ± SEM. (Modified from Hong KW, Biancani P, Weiss RM. Effect of age on contractility of guinea pig ureter. *J Urol* 1980;17:459, with permission.)

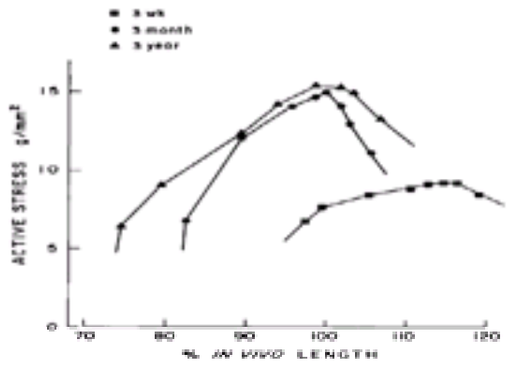

FIGURE 24.13. Active stress (force/unit area) – length curves of isolated guinea pig ureteral segments as a function of age. Stress increases between the 3-week and 3-month age groups and then remains constant with further aging. (Modified from Hong KW, Biancani P, Weiss RM. Effect of age on contractility of guinea pig ureter. *J Urol* 1980;17:459, with permission.)

The response of the ureter to pathologic insults depends not only on the magnitude and duration of the pathologic insult but also on the age of the individual affected. The neonatal rabbit ureter undergoes greater degrees of deformation in response to an applied intraluminal pressure than does the adult rabbit ureter (1). This decrease in compliance with age also is noted clinically, where more marked degrees of ureteral dilation occur in the neonate and young child in response to obstruction than in the adult. Experimental data suggest that aging has effects on the mechanical and biochemical properties of the ureter (1,85,236), and these changes may affect the response of the ureter to pathologic insult.

URETERAL PHARMACOLOGY

The ureter is affected by both the parasympathetic (cholinergic) and sympathetic (adrenergic) branches of the autonomic nervous system.

Parasympathetic (Cholinergic) System

Acetylcholine (ACh), the prototype cholinergic agonist, serves as the neurotransmitter at (a) neuromuscular junctions of somatic motor nerves (nicotinic sites), (b) preganglionic parasympathetic and sympathetic neuroeffector junctions (nicotinic sites), and (c) postganglionic parasympathetic neuroeffector sites, such as smooth muscle cells (muscarinic sites). ACh, synthesized in the nerve terminals from acetyl coenzyme A (CoA) and choline by the enzyme choline acetyltransferase, is released into the synaptic cleft and interacts with postganglionic receptor sites to elicit a functional response. ACh subsequently is hydrolyzed (degraded) by the enzyme acetylcholinesterase (AChE). The muscarinic effects of cholinergic agonists can be blocked by the parasympatholytic agent atropine. The effects of nicotinic agonists can be blocked by nondepolarizing ganglionic blocking agents or by high concentrations of the nicotinic agonist itself, which may cause ganglionic blockade by desensitization of receptor sites after an initial period of ganglionic stimulation.

ACh and other cholinergic agonists, such as methacholine, carbamylcholine (carbachol), and bethanechol (Urecholine), have in general been observed to have an excitatory effect on ureteral function, that is, they increase the frequency and force of contractions (171,220). The excitatory responses to carbachol and ACh appear to be more marked in ureters from younger than from older guinea pigs (232).

Anticholinesterases (anti-ChEs) prevent hydrolysis of ACh by cholinesterases and thus potentiate the actions of ACh. The effects of anti-ChEs, such as physostigmine and neostigmine, parallel the excitatory effects of ACh and other parasympathomimetics on the ureter (121). Although atropine, a competitive antagonist of the muscarinic effects of ACh, has been shown to inhibit the excitatory effects of parasympathomimetic agents (121,220) and physostigmine (121) on a variety of ureteral and calyceal preparations, the majority of studies have shown that atropine itself has little direct effect on ureteral activity in many species, including humans (94,167). Even when atropine has been observed to inhibit ureteral activity, its effects are frequently minimal and inconsistent (172), providing little rationale for its use in the treatment of ureteral colic.

Sympathetic (Adrenergic) System

Most investigators have noted that a-adrenergic agonists, such as norepinephrine and phenylephrine, stimulate ureteral activity (74,139,171,220,225). Norepinephrine, the chemical mediator responsible for adrenergic transmission, is synthesized in the neuron from tyrosine. Once released from the nerve terminal, some of the norepinephrine combines with postsynaptic receptors on the effector organs, such as smooth muscle, leading to a physiologic response. There are both a_1- and a_2-postsynaptic receptors in smooth muscle, and stimulation of either results in a contractile response. Presynaptic a_2-adrenergic receptors in the neuron inhibit the release of norepinephrine from the nerve terminal, and thus excitation of these receptors is inhibitory to smooth muscle function (Fig. 24.14). Reuptake or neuronal uptake of norepinephrine into the neuron limits the amount of time that norepinephrine is in contact with the innervated tissue and thus regulates the magnitude and duration of the catecholamine-induced response. Agents such as cocaine and imipramine (Tofranil), which inhibit neuronal uptake, potentiate the physiologic response to norepinephrine. The enzymes monoamine oxidase (MAO) and catechol- *O*-methyltransferase (COMT) provide degradation pathways for norepinephrine.

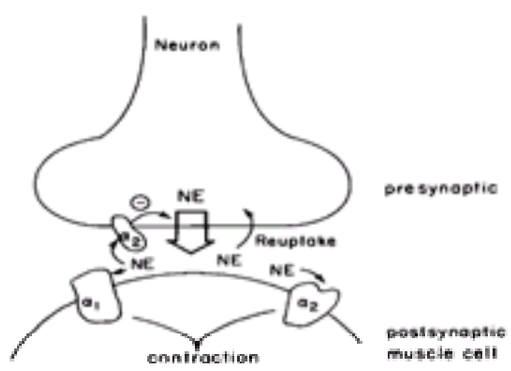

FIGURE 24.14. Diagrammatic representation of the role of presynaptic and postsynaptic a-adrenergic receptors. Norepinephrine *(NE)* released from nerve terminals may combine with postsynaptic a_1- and a_2-adrenergic receptors on smooth muscle to cause contraction. Norepinephrine combining with presynaptic a_2-adrenergic receptors on the nerve terminal prevents further release of NE from the neuron.

b-Adrenergic agonists, such as isoproterenol, inhibit ureteral activity (139,171,220,225). The relaxant effects of isoproterenol are greater in ureters from young than from old guinea pigs (232,235). It appears that the b-adrenoceptor subtype involved in the relaxation response is species specific (209). Tyramine, whose adrenergic agonist effects are primarily due to the release of norepinephrine from adrenergic terminals, has a stimulatory effect on the upper urinary tract (53,115).

The a-adrenergic antagonists phentolamine and phenoxybenzamine (Dibenzyline) have been shown to inhibit the stimulatory effects of norepinephrine and other a-adrenergic agonists in a variety of ureteral preparations (53,74,115,139,171,220,225). The b-adrenergic antagonist propranolol has been shown to block the inhibitory effects of b-adrenergic agonists, such as isoproterenol, in a variety of ureteral preparations. A prototype a_1-adrenergic antagonist is prazosin, and a prototype a_2-adrenergic antagonist is yohimbine.

Second Messengers

Adrenergic and cholinergic agonists regulate physiologic processes via their interaction with a variety of specific membrane-bound receptors (6,56), and the responses to these agonists are mediated via "second messengers," such as cAMP, cGMP, Ca^{2+}, inositol 1,4,5-trisphosphate (IP_3), and diacylglycerol (DG).

cAMP mediates the relaxing effects of b-adrenergic agonists in a variety of smooth muscles including the ureter (230,235,236). The b-adrenergic agonist, such as isoproterenol, combines with a receptor on the outer surface of the cell membrane (Fig. 24.15). The b-adrenergic agonist itself does not enter the cell. The agonist–receptor complex in turn activates the enzyme adenylyl cyclase on the inner surface of the cell membrane with the conversion of ATP to cAMP. A stimulatory guanine nucleotide-regulatory protein (G protein), G_s, acts as a functional communication between the hormone-occupied receptor and the catalytic or active unit of the adenylyl cyclase. Age-dependent changes in the ability of isoproterenol to activate adenylyl cyclase play a role in the effect of age on isoproterenol-induced ureteral relaxation (236). cAMP acts as a second or "internal" messenger for the response elicited by the b-adrenergic agonist. cAMP, through activation of a protein kinase and subsequent phosphorylation of proteins, has been suggested to lead to the uptake of Ca^{2+} into intracellular storage sites, such as the endoplasmic reticulum, with a resultant decrease in free sarcoplasmic Ca^{2+} and the development of relaxation (7).

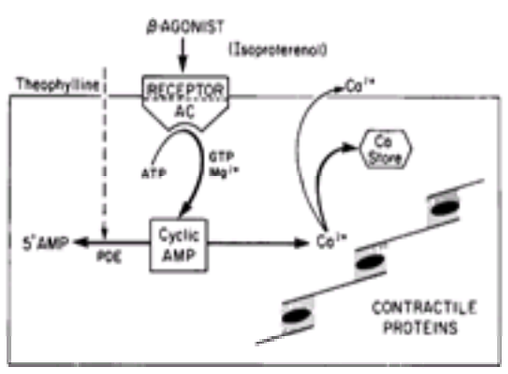

FIGURE 24.15. Diagrammatic representation of the role of cyclic adenosine monophosphate (cAMP) in b-adrenergic agonist–induced relaxation of smooth muscle. Agonist combines with receptor on the outer surface of the cell membrane. The receptor–agonist complex, in turn, activates the enzyme adenylyl cyclase on the inner surface of the cell membrane, which in the presence of Mg^{2+} and guanosine triphosphate (GTP) results in the conversion of adenosine triphosphate (ATP) to cAMP. cAMP is postulated to cause an increased uptake of Ca^{2+} into intracellular storage sites with a resultant decrease in Ca^{2+} in the region of the contractile proteins, resulting in relaxation. cAMP also may act directly on the contractile proteins to inhibit the contractile process. The enzyme phosphodiesterase *(PDE)* degrades cAMP to 5'AMP. Theophylline is a PDE inhibitor and thus also can increase cAMP with resultant smooth muscle relaxation.

cAMP levels may be increased by increasing its synthesis or by decreasing its degradation. Synthesis of cAMP involves activation of the enzyme adenylyl cyclase, and degradation of cAMP involves activation of the enzyme phosphodiesterase. Two agents that relax ureteral smooth muscle increase cAMP levels: isoproterenol, by increasing synthesis, and theophylline, by decreasing degradation (28,196,229,230). Further support for a role of cAMP in relaxation of smooth muscles can be derived from the finding that dibutyryl cAMP, which more readily diffuses into the intact cell and is more resistant to breakdown by phosphodiesterase than cAMP, can relax smooth muscle (235).

Some of the actions of the a_2-adrenergic and muscarinic cholinergic agonists appear to involve the inhibition of adenylyl cyclase via stimulation of an inhibitory G protein, G_i (Fig. 24.16) (114). Other actions of muscarinic cholinergic agonists and some actions of a $_1$-adrenergic agonists and a number of hormones or neurotransmitters, whose actions are associated with an increase in intracellular Ca^{2+}, are related to changes in inositol lipid metabolism. Interaction of these agents with a receptor leads to the hydrolysis of polyphosphatidylinositol 4,5-biphosphate (PIP_2) by a phosphodiesterase (phospholipase C) with the formation of IP_3 and DG (10) (Fig. 24.17). IP_3 is involved in Ca^{2+} mobilization from intracellular stores, such as the endoplasmic reticulum (198). IP_3 initiates the flow of information in the calmodulin branch of the calcium messenger system and is thought to be responsible either for brief contractile responses or for the initial phase of sustained responses (157). DG binds to protein kinase C (PKC), causes its translocation to the cell membrane, and, by reducing the Ca^{2+} requirements for PKC activation, allows the enzyme to become more active. The physiologic response to DG depends on protein phosphorylation (151). The PKC branch of the calcium messenger system is thought to be responsible for the sustained phase of the contractile response (157) and is responsive to hormonally induced changes in intracellular calcium. DG, by activating phospholipase A, serves as a source of arachidonic acid (AA), the substrate for prostaglandin synthesis (133). Arachidonic acid may be involved in the stimulation of guanylyl cyclase with the formation of cGMP (10). This would explain the calcium-dependent increase in cGMP associated with the smooth muscle contractions induced by the cholinergic agonist, carbachol, and the a $_1$-adrenergic agonist, norepinephrine. These increases in cGMP follow the onset of the contractile event. cGMP itself appears to be inhibitory to smooth muscle function. 8-Bromo cGMP relaxes the ureter and other smooth muscles, and sodium nitroprusside–induced smooth muscle relaxation is associated with an increase in cGMP (27,184).

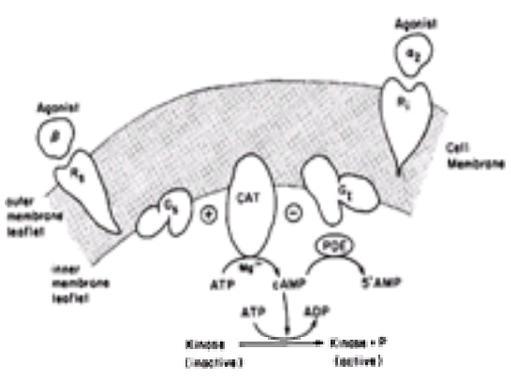

FIGURE 24.16. Diagrammatic representation of the relationship between the functional response to b- and a $_2$-adrenergic agonists and the cyclic nucleotide system. b-Adrenergic agonists activate the enzyme adenylyl cyclase and increase cyclic adenosine monophosphate *(cAMP)* production by working through a stimulatory receptor, R_S, and a stimulatory G protein, G_S. a_2-Adrenergic agonists inhibit adenylyl cyclase activity by working through an inhibitory receptor, R $_i$, and an inhibitory G-protein, G_I. The enzyme phosphodiesterase *(PDE)* degrades cAMP to 5'AMP. CAT, catalytic subunit of adenylyl cyclase.

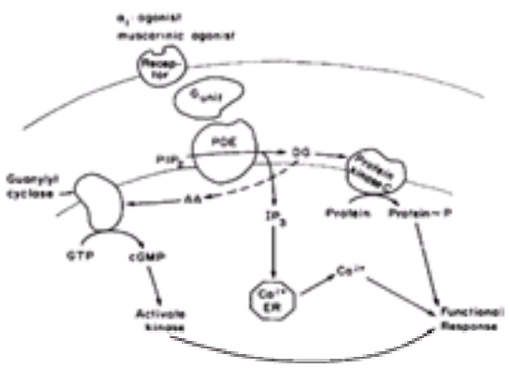

FIGURE 24.17. Diagrammatic representation of the role of inositol lipid metabolism in smooth muscle function. Agonists, such as a $_1$-adrenergic agonists and some muscarinic agonists, interact with a receptor, with the resultant hydrolysis of polyphosphatidylinositol 4,5 biphosphate (PIP $_2$), by a phosphodiesterase (phospholipase C) with the formation of 1,4,5-trisphosphate (IP_3), and diacylglycerol (DG). The functional response resulting from IP $_3$ is related to Ca^{2+} mobilization. DG activates protein kinase C, with the resultant functional response being dependent on protein phosphorylation. There is some evidence that DG may cause an increase in cyclic guanosine monophosphate (cGMP), which may explain the increase in cGMP observed in association with the contractile response to some autonomic agonists. AA, arachidonic acid; ER, endoplasmic reticulum; GTP, guanosine triphosphate.

Studies indicate that NO is a mediator of smooth muscle relaxation (23). NOS converts L-arginine to NO and citrulline (Fig. 24.18). The NO, in turn, activates an enzyme, guanylyl cyclase, that converts guanosine triphosphate (GTP) to cGMP, which results in smooth muscle relaxation. Nitric oxide also may cause smooth muscle relaxation by opening potassium channels (16,78).

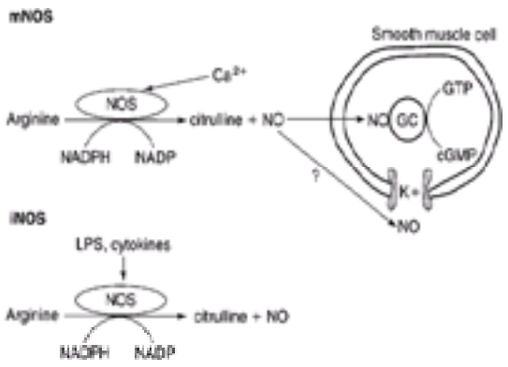

FIGURE 24.18. Schematic representation of nitric oxide synthase (mNOS, iNOS). GC, guanylyl cyclase; K^+, calcium-dependent potassium channel; LPS, lipopolysaccharide.

There are multiple isoforms of NOS. Neuronal NOS (nNOS) is Ca^{2+} and NADPH dependent (22). Neuronal excitation activates this enzyme, and the NO produced may result in smooth muscle relaxation. Endothelial NOS (eNOS) is also Ca^{2+} and NADPH dependent (186). Inducible NOS (iNOS) is NADPH dependent but Ca^{2+} independent and has been identified in ureteral (194) and other smooth muscles, and NOS-immunoreactive nerve fibers have been demonstrated in human ureter (195,197). NOS has been reported to colocalize with VIP, NPY, and tyrosine hydroxylase in nerves supplying the human ureter, including the intravesical segment (48,91,193).

Studies of isolated human ureteral segments suggest that the NO pathway may be involved in human ureteral relaxation (197). The NO donor 3-morpholinosyndonimine (SIN-1) can relax human ureteral segments, an action inhibited by the guanylyl cyclase inhibitor, methylene blue. The L-arginine–NO–cGMP pathway also may play a role in the function of the ureterovesical junction (91). NO donors inhibited agonist-induced contractions of isolated pig and human intravesical ureteral segments, and this inhibition was associated with an increase in cGMP levels.

Other Pharmacologic Agents

There are numerous reports of the excitatory effects of morphine and meperidine (Demerol) on the ureter, although these findings have not been universal (94,172). Both morphine and meperidine may have ureteral spasmogenic effects that theoretically would detract from their value in the management of ureteral colic. The efficacy of these agents in treating ureteral colic depends on their central nervous system actions, which decrease the perception of pain.

The primary prostaglandins (PGs), PGE_1, PGE_2, and PGF_{2a}, are synthesized from the fatty acid, arachidonic acid. Two cyclooxygenase (COX) isoforms, COX-1 and COX-2, are the key regulatory enzymes in the biosynthesis of PGs from arachidonic acid (217). Indomethacin and aspirin can inhibit PG synthesis, and relatively specific COX-1 and COX-2 inhibitors have been developed. The functional response to PGs varies with the specific smooth muscle. In the ureter, PGE $_1$ activates adenylyl cyclase activity (236), increases cAMP levels (221), and inhibits activity. In contrast, PGF_{2a} is excitatory (19,30). Prostacyclin (PGI_2), a prostanoid, is synthesized in the urothelium of the ureter (2).

Indomethacin has been employed in the management of ureteral colic (83). COX inhibitors such as indomethacin inhibit pyeloureteral motility (30,177,208,242). The pain relief resulting from indomethacin, however, probably is due to inhibition of the prostaglandin-mediated vasodilation that occurs subsequent to obstruction (4,191). This prostaglandin-mediated vasodilation aids in preserving renal function, and thus, although indomethacin may provide pain relief, it is potentially deleterious to renal function (160). Endothelins (ETs) are potent vasoconstrictor peptides that exist in three isoforms (i.e., ET-1, ET-2, and ET-3). Endothelins have been shown to initiate contractions in isolated guinea pig and porcine ureters (50,129). There are two major endothelin receptor subtypes, ET_A and ET_B, with the ET_A receptor subtype being the predominant subtype in the ureter (112).

Histamine and the H_1-receptor agonist 2-(2-pyridyl) ethylamine cause contraction of the ureter, an effect that is antagonized by the H $_1$-receptor antagonist dimethindene. The H_2-receptor antagonist cimetidine does not affect the contractile response to histamine. These data show that the excitatory effects of histamine are mediated by the H_1-receptor subtype (44). Histamine and the H_2-receptor agonist impromidine relax precontracted ureteral segments, actions that are antagonized by cimetidine. These data are consistent with H_2-receptors mediating ureteral relaxant effects (44). 5-Hydroxytryptamine induces concentration-dependent contractions of isolated human ureteral segments (59).

Because Ca^{2+} is necessary for the development of the action potential and contraction of the ureter, agents that block the movement of Ca $^{2+}$ into the cell would be expected to depress ureteral function. Calcium channel blockers, such as verapamil, diltiazem, and nifedipine, have been shown to inhibit ureteral activity (62,80,84,125,174,175,218), and calcium antagonist receptors are present in the ureter (241). L-type voltage-dependent calcium channels mediate K^+-induced contractions in the guinea pig ureter (127). This is supported by the finding that the L-type calcium agonist Bay K 8644 potentiates K $^+$-induced contractions.

Potassium channel openers, such as pinacidil, cromakalim, and BRL 38227, hyperpolarize smooth muscle membranes and decrease spontaneous activity of the smooth muscle (55). BRL 38227 and cromakalim have been shown to inhibit ureteral activity (101,126). The effects of cromakalim are inhibited by glibenclamide (126).

In the clinical situation, the ureter's relatively sparse blood supply limits the distribution of drug to the ureter. In addition, many drugs that have theoretic potential use in the management of ureteral pathology have untoward side effects when used in the necessary concentrations. Although many drugs can affect ureteral function, their current clinical usefulness is limited.

URETERAL REPLACEMENT

Many clinical conditions have provided an impetus for the use of ureteral substitutes. Indications for ureteral replacement include recurrent calculi, ureteral trauma, hydronephrosis, ureterovaginal fistulae, ureteral obstruction, inflammatory disease, ureteral tumors, retroperitoneal fibrosis, and a variety of undiversions. Methods for ureteral replacement can be classified as synthetic prostheses, free grafts, and pedicle grafts. The use of free grafts and prosthetics has primarily been experimental,

with most of the success being found with pedicle grafts.

A variety of synthetic materials have been used as ureteral substitutes, including Vitallium (117), tantalum (118), polyvinylchloride (215), silicone (183), Teflon (214), Dacron (13), polyethylene tubing (75), and silicone rubber (15). These materials have not gained general acceptance because of the occurrence of salt deposits and the lack of peristalsis, resulting in a functional obstruction. Studies continue toward finding a suitable biocompatible synthetic material. A tube of collagen sponge has been tried in an effort to capitalize on the regenerative growth potential of the ureter (200). The collagen sponge acts as a biodegradable scaffold for the regenerative activity of the ureter.

Free grafts have included bladder mucosa (86), peritoneum (51), vessels (187), stomach (145), and fetal umbilical vessels (97). Disruption and the lack of peristalsis have interfered with the clinical use of these materials.

In clinical practice, ureteral replacement has in general involved the use of pedicle grafts. Bladder flaps (Boari flaps), with or without hitching the bladder to the psoas muscle, have been a highly effective means of replacing the lower ureter (154). Flaps of the renal capsule have been used to enlarge the UPJ (207). Although pedicle flaps of the fallopian tube and appendix have been tried, they have not provided the required peristaltic function, and hydronephrosis has resulted (143,180).

Ileum has been the most widely used pedicle graft and the most successful (18,63,192). Proponents of the use of the ileum for replacement of the entire ureter have cautioned against its use in individuals with a serum creatinine level of 2 mg/dL or greater because of the ensuant electrolyte abnormalities (17). Middleton (144) suggested that the absorptive surface of the ileal ureter could be minimized by tapering the segment. This procedure also could aid in the construction of an antirefluxing ileovesical anastomosis. When using the ileum to replace the ureter, the ileum should be used in an isoperistaltic manner, and there should be no evidence of distal obstruction. Immediately following the procedure, there may be considerable mucus in the urine, but this tends to clear with time. Normal saline or acetylcysteine (Mucomyst) may aid in preventing mucous clogging of the urinary tract. Colon also has been used as a ureteral substitute, but less widely (199).

Lytton and Schiff (120) used a short, isolated segment of ileum to replace a segment of ureter, with the distal anastomosis of the ileum being to the ureter. This interposition, rather than replacement, gives one the opportunity to take advantage of a normal, nonrefluxing UVJ and diminishes the risk of electrolyte disturbances, especially in the patient with mild renal insufficiency. The ileal segment is tapered on its distal antimesenteric surface and, if possible, placed retroperitoneally by passing it through a window in the mesentery. The long-term results with this procedure have been excellent.

DISEASES OF THE RETROPERITONEUM

BRIAN E. NICHOLSON
DAN THEODORESCU

B.E. Nicholson and D. Theodorescu: Department of Urology, University of Virginia, Charlottesville, VA 22908.

Anatomic Considerations
Tumors of the Retroperitoneum
Clinical Presentation
Diagnostic Approach
Benign Primary Retroperitoneal Tumors
Soft Tissue Sarcomas
Inflammatory Diseases of the Retroperitoneum
Retroperitoneal Fibrosis
Pelvic Lipomatosis
Miscellaneous Diseases of the Retroperitoneum
Retroperitoneal Abscess
Spontaneous Retroperitoneal Hemorrhage
Conclusion
Chapter References

> Many a clinical reputation lie buried behind the peritoneum. In this hinterland of straggling mesenchyme, with its vascular and nervous plexuses, its weird embryonic rests, and its shadowy fascial boundaries, clinicians are often left with only their flair and their diagnostic first principles to guide them (Editorial, Periureteral fibrosis. *Lancet* 1957;2:780).

The retroperitoneum contains some of the major organs that fall under the jurisdiction of urology, most notably the kidneys, ureters, adrenal glands, and the retroperitoneal lymph nodes. Inflammatory processes, benign and malignant primary tumors, as well as regional lymph node metastases are found within this space. Because diseases within the retroperitoneum fall into the realm of urology and urologists often access this space during operative procedures, it seems prudent to provide a global view of the retroperitoneum.

A detailed discussion of renal pathology, adrenal conditions, and metastatic testes tumors is provided in other chapters of this text. The aim of this chapter is to provide information relating to the other diseases that occur within this “hinterland.” The conditions that present in the retroperitoneum are some of the most challenging to manage, in terms of both diagnosis and treatment. It is vital to have a thorough understanding of these disorders to successfully care for patients with disease of the retroperitoneum.

The first section of this chapter addresses retroperitoneal tumors: benign primary retroperitoneal tumors as well as the more common and clinically more significant malignant primary retroperitoneal tumors, primarily retroperitoneal sarcomas. Second, inflammatory diseases of the retroperitoneum, including retroperitoneal fibrosis and pelvic lipomatosis, are discussed. This chapter concludes with consideration of retroperitoneal abscesses and spontaneous retroperitoneal hemorrhage.

ANATOMIC CONSIDERATIONS

The retroperitoneum, or spatium retroperitoneale, is a potential space between the parietal peritoneum and the posterior abdominal wall that is occupied by the retroperitoneal connective tissue (Fig. 25.1). This retroperitoneal connective tissue is comprised of three layers called *strata.* The inner stratum lies immediately behind the peritoneum and covers the gastrointestinal (GI) viscera along with their blood supply. The intermediate stratum envelops the adrenals, kidneys, ureters, and great vessels. The outer stratum forms the fascia of the posterior abdominal wall (255). The boundaries of the retroperitoneum are the muscular diaphragm superiorly, the posterior parietal peritoneum anteriorly, the body wall both posteriorly and laterally, and the pelvic diaphragm inferiorly. Urologic, vascular, GI, lymphatic, and neural structures lie within the retroperitoneum (Table 25.1). A detailed description of the anatomy of the retroperitoneum can be found in Chapter 1.

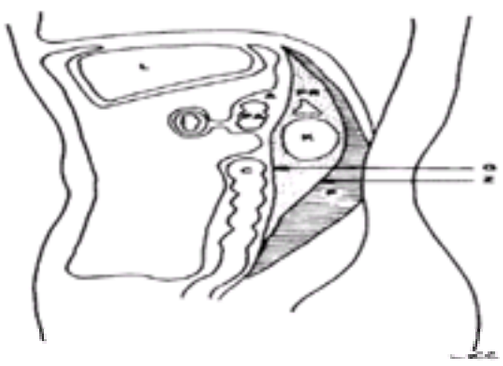

FIGURE 25.1. The retroperitoneal space and its subdivisions (sagittal section). A, anterior renal space; C, colon; G, Gerota's fascia; K, kidney; L, liver; P, posterior renal space; PA, pancreas; PR, perirenal space; Z, Zuckerkandl's fascia.

Urologic	Kidneys Ureters Adrenal glands
Vascular	Great vessels (aorta and inferior vena cava and their branches) Portal veins
Gastrointestinal	Pancreas, portions of duodenum and colon Rectosigmoid
Lymphatic	Parietal and visceral lymph nodes and channels Cisterna chyli Thoracic duct
Neural	
Nerve plexuses	Celiac, superoinferior hypogastric, sacral, sympathetic trunks
Nerves	Ilioinguinal, iliohypogastric, lateral cutaneous, femoral, genitofemoral, obturator, sciatic, pudendal

TABLE 25.1. STRUCTURES WITHIN THE RETROPERITONEUM

TUMORS OF THE RETROPERITONEUM

Retroperitoneal tumors comprise a heterogeneous group, of which metastatic carcinoma is the most common. Primary retroperitoneal tumors are defined as

neoplasms originating from the retroperitoneal connective tissues. Excluded from this category are tumors of the kidney, ureter, adrenal glands, and pancreas. Approximately 85% of primary retroperitoneal tumors are malignant, with soft tissue sarcomas accounting for roughly half of these cases. A classification, as well as approximate frequency, of retroperitoneal tumors is given in Table 25.2. These tumors are of importance to urologic surgeons because, with the exception of the lymphomas, primary treatment is surgical and the outcome is determined by the completeness of resection and the extent of adjacent organ involvement. Although histology does affect the biologic behavior and prognosis following treatment of these tumors, they can be considered together for the purposes of assessment and treatment planning because they tend to present similarly and management is largely independent of their histiogenic origin.

Tumor Type	%
Benign	**15**
Neural	30
Cysts	22
Lipoma	16
Fibroma	6
Hemangioma	6
Leiomyoma	5
Other	15
Malignant	**85**
Soft tissue sarcoma	50
Lymphoma	25
Carcinoma	10
Undifferentiated/unclassified	13
Germ cell	2

Data obtained from references 27, 72, 143, 148, 193, 202, and 233.

TABLE 25.2. CLASSIFICATION OF PRIMARY RETROPERITONEAL TUMORS

Clinical Presentation

Although the retroperitoneum is a distinct anatomic compartment of the abdomen, it does not have rigid boundaries. Instead, it consists of loose, areolar connective tissue that provides little barrier to the growth of tumors. Hence, these retroperitoneal lesions can reach a considerable size before becoming symptomatic, resulting in most patients being diagnosed late in the course of their disease. Presenting symptoms are characteristically vague and nonspecific:Anorexia and weight loss, general malaise, poorly localized abdominal discomfort, and backaches are common. Abdominal distention and GI complaints, such as nausea, vomiting, epigastric discomfort, and change in bowel habits, occur in some patients, and advanced tumors may actually present with intestinal obstruction. Obstruction of the urinary tract is unusual. At times, ascites, lower-extremity edema, or abnormal abdominal venous collaterals occur secondary to obstruction of the vena cava. Fever is typical not only of lymphomas but also of large sarcomas that have substantial necrotic areas. Because of the insidious onset and the nonspecific nature of the symptoms, there is typically a considerable delay, ranging from 5 to 7 months, between the onset of symptoms and clinical presentation. At the time of diagnosis, most patients complain of pain in the abdomen, flank, or back, and most will have a palpable abdominal mass on physical examination (46,52,168,233,280). Because most of these series that have documented the presenting symptoms are more than 10 years old, it is conceivable that current tumors are diagnosed at earlier stages due to the relatively high prevalence of ultrasound examinations of the abdomen in routine clinical practice. Such increased detection of early tumors as a result of increased abdominal ultrasound use has been shown for renal cell carcinoma (156,259).

Diagnostic Approach

By obtaining a careful history and physical examination along with appropriate imaging studies, the diagnosis of most retroperitoneal masses can be made. Because of the nonspecific and vague presenting symptoms, various radiologic studies are often obtained initially. These studies may include abdominal ultrasound, upper and lower GI contrast studies, and excretory urography. In particular, abdominal ultrasonography is often the first study obtained in patients presenting with nonspecific GI symptoms. This technique provides excellent accuracy in recognizing the solid or cystic nature of mass lesions, but it is often limited by the presence of bowel gas (157). When the mass is clearly delineated, ultrasonography provides a means for guidance of percutaneous biopsy techniques but currently is not the most common modality for this because of its dependence on patient body habitus.

The most important imaging technique is abdominal computed tomography (CT) scanning, which has revolutionized the diagnosis and staging of retroperitoneal masses. This study not only demonstrates the retroperitoneal location of the mass but also provides information about the nature of the lesion that is important in the differential diagnosis. Such information includes the composition, whether cystic or solid, the presence or absence of necrosis, the extent of involvement of adjacent structures, and the presence of intraabdominal metastases (143,198). Indeed, the diagnosis of a soft tissue retroperitoneal sarcoma is often strongly suspected on the basis of CT findings demonstrating a heterogeneous, irregular retroperitoneal mass with patchy areas of necrosis (Fig. 25.2).

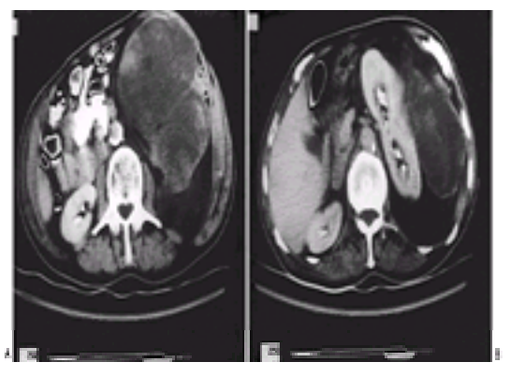

FIGURE 25.2. A: Computed tomography scan through upper abdomen demonstrates the presence of a huge, left-sided retroperitoneal liposarcoma. The mass is composed of tissues of varying densities, including soft tissue and fat. In contrast to benign lipomas, retroperitoneal sarcomas frequently demonstrate only minimal amounts of fat. **B:** Scan from same patient several cuts lower demonstrates relationship of mass to medially deviated left kidney that was resected en bloc with the tumor.

Findings on CT scan are also valuable in differentiating sarcomas from other primary and metastatic retroperitoneal malignancies. For example, the demonstration of the involvement of multiple retroperitoneal lymph nodes in association with a retroperitoneal mass may suggest a lymphoma that may be confirmed by a lymph node biopsy. This is an important distinction to make because treatment for lymphoma is nonsurgical. A high index of suspicion for males at risk for testicular carcinoma is also warranted in patients presenting with large retroperitoneal masses. In this situation, a careful testicular examination with and without scrotal ultrasonography, and evaluation of serum a-fetoprotein and b-human chorionic gonadotropin (b-hCG) should be carried out. Similarly, when symptoms and signs suggest a tumor all of adrenal origin, tests of adrenocortical and medullary function are indicated. In contrast, the CT scan cannot provide conclusive evidence that a lesion is benign or that it is malignant. This is primarily because benign lesions are seen to enhance in 30% to 100 % of cases (104). However, despite these limitations, several groups are exploring the development of scoring systems combining multiple factors such as tumor size, presence of symptoms, absence of calcifications, presence of irregular margins, and the presence of necrosis to predict whether a lesion is benign or malignant (184).

When a soft tissue sarcoma of the retroperitoneum is suspected on the basis of CT scanning, magnetic resonance imaging (MRI) with gadolinium contrast administration provides important staging information (51,75). This technique delivers no ionizing radiation and requires no contrast. It offers the additional advantage of imaging in multiple planes, which can be helpful when planning tumor resection. MRI often provides information superior to that of CT scanning because it more clearly shows the anatomic relationships of the mass to adjacent structures, especially vascular structures, and the extent of tumor involvement of adjacent structures. This applies especially to sarcomatous infiltration along nerve roots with possible involvement of spinal foramina. Further uses of CT, MRI, and other imaging modalities are discussed later in the section on the preoperative evaluation.

Benign Primary Retroperitoneal Tumors

Approximately 15% of primary retroperitoneal tumors are benign. Table 25.2 lists the pathologic findings compiled from 13 series for 158 benign retroperitoneal tumors. As can be seen, most of these lesions are stromal neoplasms and cysts. In contrast to their malignant counterparts, most of these lesions can be completely resected with a low risk of recurrence and an excellent prognosis. At times, complete resection may be difficult because of the considerable size of these masses and their proximity to vital structures. Three of twenty benign tumors in the series of Pinson and colleagues (202) and two of the thirteen tumors in the study of Braasch and Mon (27) were unresectable; one patient in the latter group ultimately died of his disease.

Lahey and Eckerson (140) classified retroperitoneal cysts as urogenital, lymphatic, teratomatous, mesocolic, paracytic, or traumatic in origin. Urogenital cysts arise from persistent wolffian remnants and are therefore more common in females. Urogenital cysts may be differentiated from mesocolic cysts at the time of surgery by the relationship of the cysts to the gonadal vessels: Mesocolic cysts are anterior to the vessels and urogenital cysts are posterior (193).

Teratomas and dermoid cysts are seen most commonly in children and usually originate in the gonads or anterior mediastinum. However, 5% of these tumors have been reported in the retroperitoneum (63). From 10% to 25% of these are malignant, and an aggressive surgical approach is warranted for all such lesions in an effort to prevent local recurrence (72,141). For sacrococcygeal teratomas, the resection must include the coccyx because a 33% recurrence rate has been cited for patients in whom the coccyx was not removed (72,148). This underscores the principle that the most important goals in managing any of these benign tumors are to completely resect them and to rule out malignancy. Liberal use of intraoperative frozen sections to ensure that the lesion is benign may eliminate the need for extended resection involving normal adjacent organs.

Soft Tissue Sarcomas

Soft tissue sarcomas are malignant, nonepithelial tumors that arise from the extraskeletal connective tissues of the body, excluding the supporting structures of the various parenchymal organs. Sarcoma is derived from the Greek word *sarkoma,* meaning “fleshy growth.” With the exception of malignant peripheral nerve tumors, which are derived from embryonic ectoderm, these tumors have a common embryonic origin—the primitive mesoderm. Although these tumors are often grouped together because of similarities in management, there is increasing evidence that biologic behavior depends on the histologic type and molecular characteristics of these various lesions. Such nuances are discussed later. In most cases, these tumors present a formidable challenge to the surgeon, primarily because complete surgical resection provides the only possibility for long-term disease-free survival. Therefore the surgeon must have a clear understanding and appreciation of the biology of these unusual neoplasms and their relationships to adjacent organs.

Although retroperitoneal sarcomas share the same histiogenic origin and biology of soft tissue sarcomas found elsewhere, they are rendered unique by virtue of their anatomic location. In the retroperitoneum, even when the surgeon achieves an apparently complete resection, tumor margins are often positive in most patients (37). In addition, this anatomic location renders the application of adjuvant treatments such as radiation more problematic. Unfortunately, the improved survival and quality of life gained over the last decade in the management of extremity sarcomas have not been paralleled in the retroperitoneum (19,203). In fact, a retroperitoneal location is a poor prognostic indicator for patient survival in soft tissue sarcoma (109,118,158,277).

Epidemiology and Etiology

Soft tissue tumors (including those of the heart) constitute less than 1% of all malignancies in adults, with an estimated 8,700 new cases and 4,400 deaths projected for 2001 (93). Approximately 15% of these new cases will occur in the retroperitoneum. These tumors occur equally in males and females, with a peak incidence occurring in the sixth decade of life.

In 1940, James Ewing wrote, “Of the specific etiology of sarcoma, little is definitely known.” Today, our understanding of epidemiologic or etiologic factors in patients with soft tissue sarcomas continues to remain limited. However, several clinical conditions are associated with these tumors. Sarcomas are reported to occur with increased frequency in patients with a number of genetic diseases, such as tuberous sclerosis, Werner syndrome, and intestinal polyposis (79,210,257). Patients with Gardner's syndrome also have an increased incidence of benign soft tissue tumors and may develop a desmoid fibrosarcoma of the mesentery (209).

Patients with neurofibromatosis or von Recklinghausen's disease have an approximate 10% lifetime incidence of neurofibrosarcoma (101,152). Neurofibromatosis is one of the most common autosomal-dominant disorders, affecting approximately 1 in 3,500 in the general population. It is characterized by abnormalities affecting tissues derived from the embryonic neural crest. These patients are predisposed to a variety of benign growths, including neurofibromas and benign and malignant tumors arising from peripheral nervous structures, including pheochromocytomas, schwannomas, and neurofibrosarcomas. The NF-1 tumor-suppressor gene responsible for this syndrome has been localized to the long arm of chromosome 17 (97).

Patients with Li-Fraumeni syndrome, characterized by germ line mutations in the p53 tumor-suppressor gene, have an increased incidence of soft tissue sarcomas, as well as breast cancer, osteosarcoma, brain tumors, leukemia, and adrenal cortical carcinoma (154). There is also evidence that patients treated for retinoblastoma in childhood are predisposed to the development of sarcoma in later life (225). The protein products of the p53 (17p13) and retinoblastoma (13q14) genes are intimately involved in cell-cycle control, angiogenesis, and various other cellular phenotypes, and mutations in these genes have been implicated in the tumorigenesis and progression of many human malignancies (266).

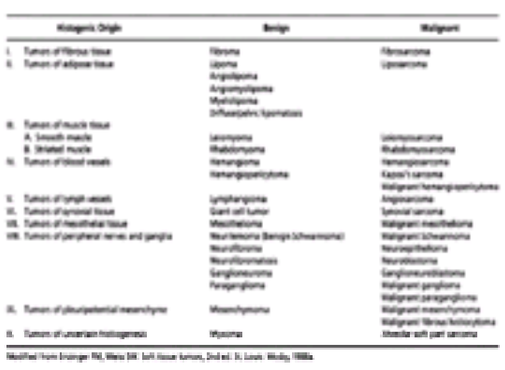
Sarcomas also are known to occur at increased frequency in patients previously exposed to ionizing radiation. At The University of Texas M.D. Anderson Cancer Center, 5% of the 331 chest wall sarcomas that occurred between 1944 and 1984 were radiation induced (244). Halperin and colleagues (99) reported an increased frequency of sarcomas following radiotherapy for Hodgkin's disease. These investigators have calculated a risk of sarcoma of nearly 1% in 5-year survivors of Hodgkin's disease. The latent period for tumorigenesis following radiation therapy is in the range of 10 to 15 years. Although extraskeletal osteosarcomas appear to be the most common, other tumors commonly associated with radiotherapy are fibrosarcomas, malignant fibrous histiocytoma, mixed mesodermal sarcomas, and mesotheliomas (271).

Chemical carcinogens, such as polycyclic hydrocarbons, as well as viruses, can produce sarcomas in experimental animals. There is no convincing link in humans, however, between exposure to chemical carcinogens or viral transformation and sarcoma development.

Pathology

Histologic Classification

Soft tissue tumors are a large and diverse group of histologically distinct but often grossly and biologically similar neoplasms. The pathologic classification of these tumors is based on the presumed cell of origin and is reviewed in abbreviated form in Table 25.3.



Histogenic Origin	Benign	Malignant
I. Tumors of fibrous tissue	Fibroma	Fibrosarcoma
II. Tumors of adipose tissue	Lipoma Angiolipoma Angiomyolipoma Myxolipoma Diffuse(pelvic) lipomatosis	Liposarcoma
III. Tumors of muscle tissue		
A. Smooth muscle	Leiomyoma	Leiomyosarcoma
B. Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
IV. Tumors of blood vessels	Hemangioma Hemangiopericytoma	Hemangiosarcoma Kaposi's sarcoma Malignant hemangiopericytoma
V. Tumors of lymph vessels	Lymphangioma	Angiosarcoma
VI. Tumors of synovial tissue	Giant cell tumor	Synovial sarcoma
VII. Tumors of mesothelial tissue	Mesothelioma	Malignant mesothelioma
VIII. Tumors of peripheral nerves and ganglia	Neurilemoma (Benign Schwannoma) Neurofibroma Neurofibromatosis Ganglioneuroma Paraganglioma	Malignant schwannoma Neuroepithelioma Neuroblastoma Ganglioneuroblastoma Malignant ganglioma Malignant paraganglioma
IX. Tumors of (pluripotential) mesenchyme	Mesenchymoma	Malignant mesenchymoma Malignant fibrous histiocytoma
X. Tumors of uncertain histogenesis	Myxomas	Alveolar soft part sarcoma

Modified from Enzinger FM, Weiss SW: Soft tissue tumors, 2nd ed. St. Louis: Mosby, 1988a.

TABLE 25.3. HISTOLOGIC CLASSIFICATION OF SOFT TISSUE TUMORS

The varied soft tissues can give rise to either benign or malignant tumors. Malignant transformation of benign lesions is rare. The histologic distribution of retroperitoneal sarcomas is given in Table 25.4. Even the abbreviated histologic classification scheme as presented is complex and can be confusing to clinicians unfamiliar with sarcomas. Compounding this confusion are changes in the histologic classification of soft tissue tumors that have occurred over the past 15 years. For example, the recognition of malignant fibrous histiocytoma (MFH) as a separate category has generated wide variations in the reported incidence of specific histologic types in the literature.

	Total	%
Liposarcoma	291	32
Leiomyosarcoma	265	29
Malignant fibrous histiocytoma	89	10
Fibrosarcoma	62	7
Rhabdomyosarcoma	53	6
Malignant peripheral nerve tumor	57	6
Undifferentiated/unclassified	37	4
Hemangiopericytoma	12	1
Other	56	5
	922	100

Compilation of data reported from 1981–1994 from references 7, 46, 52, 124, 168, 224, 233, 260, 273, and 280.

TABLE 25.4. HISTOLOGIC DISTRIBUTION OF RETROPERITONEAL SARCOMAS

Although virtually absent from series reported before 1980, MFH has become one of the most common histologic types, especially in older patients. This category includes tumors previously considered fibrosarcoma or pleomorphic rhabdomyosarcoma and many undifferentiated sarcomas (74). Although originally thought to originate from histiocytes, recent evidence suggests that the cell of origin of MFH is a pluripotential primitive mesenchymal cell. Interestingly, the poorly differentiated component found in dimorphic dedifferentiated sarcomas is often of the MFH type. It has thus been postulated that MFH may represent not only a distinct histologic entity but also a dedifferentiated state. As such, MFH may be viewed as the final common pathway in the transformation of most malignant soft tissue tumors from differentiated to undifferentiated (33).

Tumor Staging

The 1997 TNM/AJCC classification and staging system for soft tissue sarcomas (Table 25.5) is currently used. Although tumor size has been shown to be an important prognostic factor for extremity sarcomas, influencing both outcome and propensity for local recurrence, it is much less important for retroperitoneal sarcomas. Although the AJCC stage grouping takes into account tumor size by assigning B subgroups for tumors larger than 5 cm, at presentation, nearly all retroperitoneal tumors are larger than 5 cm (52). In the Mayo Clinic series of 116 retroperitoneal sarcomas reported by Dalton and associates (52), 92% were larger than 5 cm. The experience from the Royal Marsden Hospital, reported by Alvarenga and associates (7), is similar, with 90% of 120 retroperitoneal sarcomas presenting as larger than 5 cm. In fact, most of these tumors are much larger than 5 cm. McGrath and associates (168) reported median sizes of 114 cm in tumors that were completely resected and 28 cm in those that were incompletely resected.

TABLE 25.5. TNM/AJCC CLASSIFICATION OF SOFT TISSUE TUMORS (ICD-O C38.1, 2, C47-49)

Tumor Grading

Although there is no universally accepted grading system, in general, histologic grading is based on the degree of cellularity, nuclear pleomorphism, frequency of mitoses and pretherapeutic necrosis, and infiltrative qualities (48). Histologic grading defines a wide spectrum of biologic behavior from slow growing, locally recurrent, low-grade tumors that rarely metastasize to anaplastic, high-grade lesions that develop hematogenous metastasis in many cases. Note that these tumors may be heterogeneous, with areas of different histologic grade juxtaposed. Furthermore, recurrent tumors often manifest as progression to a higher grade, which is indicative of the genetic instability of these tumors. To reflect its prognostic significance, grade is an element of the TNM/AJCC and classification system (Table 25.5).

In most series of retroperitoneal sarcomas, approximately 40% of tumors are low grade (grade I), with the remainder equally divided between grades II and III (7,124,168,260,280). Regarding stage at presentation, between one-half and two-thirds of patients present with stage III or IV disease (7,52,124).

Incidence and Patterns of Metastasis

There is a wide range in the reported frequency (4% to 35%) of metastasis at the time of presentation, but most series report an incidence of 15% to 20% (7,52,124,168,233,273,280). Retroperitoneal sarcomas metastasize principally by the hematogenous route to the lung (30% to 60%), liver (20% to 60%), bladder (15%), and bone (10%) (46,168,273). Lymphatic spread, clinically apparent at the time of initial treatment, is uncommon for most histologic types of sarcomas. However, when present, nodal disease portends a poor prognosis and is more commonly associated with certain histologic types (alveolar rhabdomyosarcoma, angiosarcoma, epithelioid sarcoma, clear cell sarcoma) (9,66). As with lymphatic spread, histologic type also influences the frequency of distant hematogenous metastasis. Liposarcomas generally tend to metastasize relatively late, whereas MFH is characterized by early dissemination (66). Finally, tumor grade is an important risk factor for the development of metastatic disease (111).

Diagnosis

Imaging

The diagnostic imaging approach to retroperitoneal masses in general has already been discussed.

Biopsy

Fine-needle Aspiration Biopsy or Core-needle Biopsy. In the past, most authors have recommended formal open biopsy to establish the histologic diagnosis of retroperitoneal masses, contending that fine-needle aspiration biopsy or core-needle biopsy generally does not yield enough tissue to provide the necessary

information for differential diagnosis, regardless of whether the tumor is a sarcoma, lymphoma, or other visceral neoplasm localized in the retroperitoneum (124,249). However, other authors have advocated fine-needle aspiration biopsy, which minimizes the potential for peritoneal seeding during open biopsy (243). This procedure can be guided by either ultrasound or CT imaging and is reliable in differentiating potentially sarcomatous lesions from other neoplasms such as lymphoma and germ cell tumors. A significant caveat of all needle biopsies is its limitation in diagnosing well-differentiated tumors from their benign counterparts (57). In addition, such approaches can mistakenly lead to a benign diagnosis of cellular inflammatory pseudotumor instead of an inflammatory fibrosarcoma (169). Therefore great care and judgment should be exercised in the application of this technique.

Open Biopsy. When an open biopsy is required, extreme care and planning of the biopsy are critical. The technique of biopsy is paramount in preventing peritoneal seeding of the tumor. In one study of patients with retroperitoneal sarcomas, none manifested intraabdominal sarcomatosis without having previously undergone biopsy (249). An incisional biopsy should be carried out by a laparotomy under general anesthesia in most cases. Every effort should be taken to prevent tumor spillage (249). This includes isolating and packing off wound edges and normal structures and performing minimal dissection in the area of the tumor. The tumor capsule should be incised and a small wedge of underlying tumor excised. Closure of the tumor pseudocapsule, with the meticulous attainment of hemostasis, is important to prevent tumor spill or spread by the formation of a hematoma. If a definitive diagnosis cannot be made with frozen sections, the procedure should be terminated, with definitive management awaiting the final diagnosis, which may require the use of immunohistochemical, cytogenetic, or other special studies. It should be emphasized that the tissue planes in the area of the tumor should not be disturbed. Also, a well-defined pseudocapsule characterizes soft tissue sarcomas, such that enucleating the tumor within this plane invariably leaves behind gross or microscopic tumor.

Special Studies. Occasionally, histologic diagnosis may be difficult, and special studies, including the use of special stains, ultrastructural analysis, immunohistochemistry, and cytogenetic analysis, may be required. Combining standard histologic analysis with these techniques, a definitive diagnosis can be made in virtually all soft tissue sarcomas. Immunostaining of a number of antigens, including vimentin, cytokeratin, desmin, factor VIII–related antigen, and S-100 protein, has proven valuable in the characterization and diagnosis of soft tissue sarcomas (48). Furthermore, many of the soft tissue sarcomas have recently been found to contain characteristic chromosomal aberrations that have documented diagnostic relevance (77). However, an in-depth discussion of these techniques and their use is beyond the scope of this chapter, and the reader is referred to two excellent recent reviews (65,76).

Evaluation for Metastatic Disease and Adjacent Organ Involvement

Before definitive management of a retroperitoneal sarcoma is begun, further investigations are necessary to rule out the presence of metastatic disease and to assess other vital structures that may require en bloc resection at the time of definitive surgery. Metastatic evaluation should include abdominal and pelvic CT or MRI imaging and a CT scan of the chest. It is important to note that hepatic metastases may have MRI appearances similar to hemangiomas but harbor subtle distinctions from the latter (245). A bone scan to rule out osseous metastasis is also indicated. Suggestive lesions in any of these locations can usually be accessed by percutaneous biopsy techniques.

Although these tumors are uncommon and no large prospective studies have addressed their management, the collective experience of specialized cancer centers illustrates several important principles for the successful management of these tumors. We cannot overemphasize the importance of preoperatively obtaining the information necessary for making rational treatment decisions. This includes obtaining an idea of the anatomic structures that are likely involved and that will therefore require en bloc resection with the tumor. Since the advent of the routine use of MRI vascular studies and newer CT techniques (e.g., spiral CT with contrast), which provide excellent visualization of vascular structures, the need for routine use of angiography largely has been eliminated (139). When MRI angiography is insufficient in establishing vascular involvement, conventional angiography is useful when further knowledge concerning the anatomy of the tumor blood supply is deemed important for planning the surgical procedure (Fig. 25.3). This is especially important when there is a possibility of aortic or other major vascular resection. MRI venography has virtually eliminated the need for conventional venacavography because MRI provides excellent visualization of the presence and extent of tumor thrombus within the vena cava. Occasionally, if not already obtained in the course of previous evaluation in patients often presenting with nonspecific abdominal complaints, contrast-enhanced upper and lower GI studies and endoscopy may be necessary to define the extent of involvement of the GI tract, which is also often resected en bloc with retroperitoneal sarcomas.

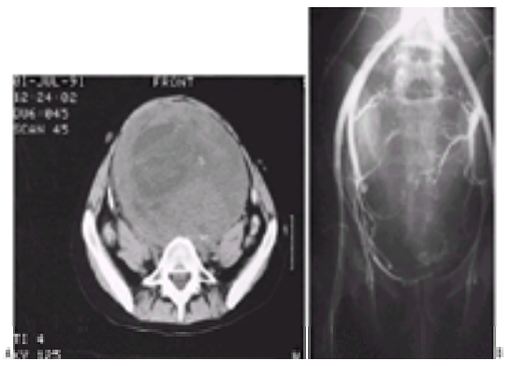


FIGURE 25.3. A: Computed tomography scan of the pelvis demonstrates huge recurrent malignant Schwannoma. **B:** Arteriogram demonstrates vascular anatomy and tumor blood supply. Resection of this tumor required performance of a hemipelvectomy.

Preoperative Assessment and Preparation

Bilateral renal function must be assessed in patients with retroperitoneal sarcomas; the kidney is the most commonly resected adjacent organ in these patients (52,124). In a recent series from Memorial Sloan-Kettering (220), 75 (20%) of the 371 retroperitoneal sarcoma patients who underwent resection needed concomitant nephrectomy. In this series, the most common reasons for renal resection were incasement by sarcoma in 53% of patients and adherence of the tumor to kidney in 28% of patients. Interestingly, on pathologic examination, the kidney was involved in only 27% of cases. Although often accomplished by documenting a normal contralateral kidney on excretory urography or a contrast-enhanced CT scan in a patient with normal renal function, more precise characterization of renal function is often necessary, such as by radionuclide renal imaging with and without the evaluation of glomerular filtration rate. This situation arises when there is a significant size discrepancy between the two kidneys, one kidney has sustained previous damage or undergone surgery, or one kidney has a preexisting lesion such as a stone. Although most cases involving large retroperitoneal sarcomas generally require sacrifice of both right and left sympathetic trunks, if future reproductive potential is an issue, patients should be counseled regarding preoperative sperm banking, as is often recommended before retroperitoneal lymph node dissection for testicular cancer (237).

The preoperative preparation is for the most part routine and not different from that for the typical, often elderly, and at times debilitated, patient undergoing a major intraabdominal oncologic procedure. These patients also are often nutritionally depleted, and optimization of their nutritional status by either the enteral or parenteral route is an important part of their preoperative care. Because of the potential for significant blood loss, the surgeon must also ensure that adequate blood is available. All patients should have a thorough mechanical and antibiotic bowel preparation. Based on the imaging workup of the primary tumor, patients should be asked for consent for the removal of adjacent organs likely to be involved by the tumor and for possible either temporary or permanent urinary and fecal diversion. As dictated preoperatively by the location and extent of the tumor, the placement of retrograde ureteral catheters at the time of surgery may facilitate identification, dissection, and preservation of the ureters.

It is also important to recognize that the successful treatment of complex and extensive retroperitoneal sarcomas necessitates a multidisciplinary surgical approach. Therefore appropriate preoperative consultations should be sought to from general surgical, vascular, orthopedic, microvascular/plastic, neurosurgical, and cardiothoracic surgical specialties as dictated by the preoperative appearance and extent of the tumor. Multiorgan resections have been facilitated greatly over the past decade by the development of techniques for reconstruction.

Surgical Management of Patients with Clinically Resectable Disease

General Principles

Currently, the best chance of survival in patients with retroperitoneal sarcomas is provided by complete surgical resection of the tumor with microscopically tumor-free margins. Invasive monitoring of continuous arterial blood pressure and central venous pressure, and often pulmonary artery occlusion pressure, is required. There has been a trend toward an improvement in the operative mortality over the past 15 to 20 years, with current figures in the range of 2% to 4% (52,124,224,260).

The first principle in the management of these tumors is that of en bloc resection including adjacent involved organs or other structures. Although the optimal extent of visceral resection in the management of these tumors has been debated, most studies suggest that extended resection improves outcome in these patients. In general, attempts at limiting the extent of the en bloc resection result in inadequate margins and subsequent development of locally recurrent disease (22,52,260).

A second important principle in the management of these tumors is that these tumors characteristically have a well-developed pseudocapsule, and invariably, the lesions extend well beyond the confines of this structure. Therefore dissection should be performed well outside this plane because positive margins will be found in virtually all cases in which dissection is carried out at the pseudocapsule. Even when all gross disease is completely resected with an apparent margin of normal tissue, a significant percentage of cases will have microscopically positive margins on subsequent pathologic analysis. In two series that have examined the relationship of positive margins in patients deemed to be macroscopically completely resected, the incidence of positive margins ranged from 12 of 41 (29%) in the Memorial Sloan-Kettering series (124) to 39 of 45 (87%) from the Princess Margaret hospital series (37).

The prevention of possible spillage or tumor rupture is an additional important principle in the management of these tumors. The potential for tumor rupture is greatest when tense lesions, often with extensive cystic or necrotic areas, are encountered. In this situation, resection may be facilitated by decompression of the cystic or necrotic areas, taking care to prevent tumor spillage by using a vacuum trocar secured with a purse-string suture (249).

Incisions

Obtaining adequate exposure is the key to successfully resecting these lesions. Through proper preoperative planning, in most cases, the surgeon can select the incision that will provide optimal exposure. In addition to being large enough to allow delivery of the tumor through the wound, the incision must also provide access to surrounding anatomic landmarks, most importantly, the vascular supply. Regardless of the particular incision, a transperitoneal approach that allows thorough exploration of the abdomen, evaluation of the possible presence of metastasis, and evaluation of the resectability of the lesion is necessary. A vertical midline incision from xiphoid to pubis usually allows adequate exposure for resection of most moderate-sized retroperitoneal sarcomas. However, tumor extension above the crus of the diaphragm or liver, necessitating extension of the incision into the chest for adequate exposure, is not infrequently found at exploration. Because of this, the patient should be prepped preoperatively for possible extension of the incision into the chest.

A thoracoabdominal incision extending from the midaxillary line posteriorly in the eighth, ninth, or tenth interspace and extending inferiorly as a vertical midline incision is well suited for most large retroperitoneal tumors located in the upper abdominal quadrants. In addition to providing excellent intraabdominal exposure, this incision allows palpation of the mediastinum and ipsilateral lung parenchyma, as well as control of the great vessels above the diaphragm. This incision also facilitates exposure by allowing mobilization and cephalad retraction into the chest of the liver or spleen. A Chevron incision that may be extended as a median sternotomy is also an excellent alternative for large, upper retroperitoneal masses.

For tumors localized in the lower abdominal quadrants or pelvis, a midline incision is generally warranted. If necessary, this incision may be extended as an abdominoinguinal incision (129,130). This latter incision, as popularized by Karakousis (128), is especially well suited for exposure and resection of pelvic tumors with lateral fixation. Such exposure has been reported to facilitate the resection of tumors previously considered unresectable and may decrease the need for hemipelvectomy in these difficult cases (74).

Laparotomy and Determination of Resectability

There has been a trend toward improved rates of resectability over the past 15 to 20 years. A compilation of data on 1,031 retroperitoneal sarcomas from 14 major series reported between 1981 and 1994 revealed that in 49% of cases, a complete resection was obtained (Table 25.6). The definitive determination of resectability can be made only at the time of laparotomy. It is important to recognize that tumor fixation is not an indication of unresectability per se. In essence, almost no structure is sacred. However, the determination of the extent of resection must be individualized and based on the patient's general medical condition and ability to withstand the proposed procedure. For example, a sarcoma extensively involving the pancreas may be completely resected by performing an en bloc pancreaticoduodenectomy. Although this procedure may be a viable choice in a relatively young healthy patient, it would be a poor choice for an elderly patient who may not be able to withstand such an extensive resection.

	%
Complete resection	49
Incomplete resection[a]	51
Overall survival	35
Survival after complete resection	56
Overall local recurrence	57

Compilation of data reported from 1981–1994 from references 7, 46, 52, 124, 168, 202, 224, 233, 260 ,273, and 280.

TABLE 25.6. RESECTABILITY, 5-YEAR SURVIVAL, AND LOCAL RECURRENCE RATE FOLLOWING COMPLETE RESECTION OF 1,031 RETROPERITONEAL SOFT TISSUE SARCOMAS

In most cases, the basis for unresectability at the time of laparotomy will be the discovery of unsuspected metastases, in the form of either distant metastases or peritoneal seeding of the tumor. This was the case in approximately 50% of unresectable cases from the Memorial Sloan-Kettering series (124). Another common basis for unresectability is extensive vascular involvement and disease involving irreplaceable structures, such as the root of the mesentery and the spinal cord (124).

In 50% to 80% of patients in whom a complete resection is attained, the removal of adjacent organs is required (46,52,124). Organs most commonly removed are the kidney/adrenal (12% to 46%), pancreas (5% to 15%), spleen (5% to 10%), colon (5% to 24%), and small bowel (5%). Major vascular resections involving the aorta, inferior vena cava, or other major vascular structures (e.g., the iliac vessels) is reported in approximately 5% to 10% of cases (7,46,52,124). However, essentially any intraabdominal organ, as well as the spine, mesentery, and abdominal wall, may require resection to obtain adequate margins.

Overview of Surgical Technique

Wide exposure following the mobilization of pertinent intraabdominal structures is necessary for the safe and adequate resection of these neoplasms. In most cases, when a midline or Chevron transabdominal approach is selected, mobilization is similar to that required for the performance of transabdominal retroperitoneal lymphadenectomy for metastatic testis cancer, as popularized by Donohue and colleagues (59). For right-sided tumors, the mobilization involves incising the posterior peritoneum, mobilizing the hepatic flexure, and extending the incision around the cecum. The incision is then extended up the root of the mesentery to the ligament of Treitz. In the process, the duodenum is kocherized and the superior mesenteric vessels defined. At this point, the ascending colon and entire small bowel, along with the pancreas, are mobilized on the superior mesenteric artery pedicle and wrapped in moist laparotomy pads; they are then placed on the anterior chest wall out of the operative field. Extreme caution must be exercised not to occlude or injure the superior mesenteric artery by excessive traction, and the bowel should be examined periodically during the procedure. Occasionally, when approaching a large, right upper quadrant retroperitoneal lesion, mobilization of the limbs by dividing the coronary and triangular ligaments and short hepatic veins and retracting the liver superiorly into the chest is necessary. Following this mobilization, the surgeon has

access to the entire right retroperitoneum and the great vessels.

Mobilization for left-sided tumors is similar. The peritoneal incision should extend from the splenic flexure around the sigmoid colon to the pelvic brim. Occasionally, it is necessary to combine the mobilization as described for right- and left-sided lesions to achieve adequate exposure. Division of the inferior mesenteric artery facilitates mobilization of the descending colon. If division of the inferior mesenteric artery is necessary, the surgeon must ensure preservation of the marginal artery. In most patients, especially younger patients, division of the inferior mesenteric artery can be done with relative impunity. Occasionally, older patients may develop symptoms such as intermittent abdominal pain and diarrhea, resulting from ischemia following ligation of this vessel. If ischemic damage or significant tumor involvement of the colonic mesentery is noted during the procedure, the colon should be resected en bloc with the tumor. When approaching a large, left upper quadrant retroperitoneal lesion, the surgeon must also mobilize the spleen and tail of the pancreas, a maneuver termed *transabdominal medial visceral rotation* (MVR) (211). Following this mobilization, the surgeon has access to the entire left retroperitoneum.

Following retroperitoneal exposure by mobilization of the intraabdominal contents, the surgeon's attention is then turned to control of the vascular supply, which almost always arises from the midline. This control necessitates the mobilization of the ipsilateral great vessel and, at times, the contralateral great vessel as well. Division of the lumbar vessels below the renal pedicles obtains this mobilization. Because the spinal cord ends at the level of L-1, ischemia to the cord is rare. The blood supply to the cord is from the anterior and posterior spinal arteries that arise from the vertebrals. Additional blood supply comes from the radicular branches that arise from higher lumbar and intercostal arteries.

Tumor invasion of the aorta and vena cava is uncommon. However, to free a retroperitoneal tumor from the vessels, it is sometimes necessary to dissect within a subadventitial plane. Aortic resection also may be required for complete excision, with subsequent reconstruction. When there is extensive tumor involvement of the inferior vena cava, it is usually best to resect the vena cava en bloc with the tumor. In this situation, the tumor has usually resulted in venacaval obstruction with the development of extensive collateral flow. Part of this collateral flow is due to the development of large, very friable retroperitoneal veins that may cause troublesome bleeding if not meticulously controlled during the dissection. In the unusual case in which resection of the vena cava requires ligation above the level of the renal veins, a venous drainage procedure using either the splenic or portal vein to the right renal vein is necessary. When the right kidney is resected en bloc with the tumor and vena cava, it is also prudent to make every reasonable attempt to preserve the connection of the left renal vein with the vena cava. Despite the greater collateral flow through the gonadal, lumbar, adrenal, and capsular veins, the incidence of postoperative acute tubular necrosis requiring temporary dialysis following ligation of the left renal vein has been reported to be as high as 50% (164).

With dissection carried out along the great vessels, a significant number of large lymphatic channels are also encountered. Care should be taken to ligate these vessels, and it is also important to identify and ligate or clip the cisterna chyli, which is medial to the right crus of the diaphragm posterior to the right renal pedicle between the aorta and vena cava. Although most cases involving a large retroperitoneal sarcoma generally require sacrifice of both right and left sympathetic trunks, if future reproductive potential is an issue and it does not compromise the resection, the surgeon should attempt to preserve one side.

Outcomes and Follow-up

Local Recurrence

With a carefully performed preoperative evaluation and a meticulous surgical approach employing a multidisciplinary team experienced in the management of these neoplasms, most retroperitoneal sarcomas can be completely resected. However, a compilation of data on 1,031 retroperitoneal sarcomas from 14 major series reported between 1981 and 1994 revealed that only in 49% of cases was a complete resection obtained (Table 25.6). Unfortunately, the incidence of positive margins even in patients who were completely resected ranges from 29% to 87% (37,124).

Soft tissue sarcomas tend to be locally aggressive neoplasms spreading along anatomic planes created by fascia, blood vessels, nerves, and muscle bundles. As a result, even following apparent complete resection, retroperitoneal sarcomas characteristically have a tremendous propensity for local recurrence. The propensity for local recurrence in this situation is a function of multiple factors, with an overall incidence ranging from 30% to 90% (7,37,110,124). Of the patients who succumb to this disease, only approximately one-third ever develop distant metastasis, most of which occur in patients with high-grade tumors (111,158). The remainder experience progressive recurrent locoregional disease that ultimately leads to death (22,52,84,124,249). Most patients develop progressive, locoregional disease and eventually succumb to late complications, such as GI bleeding and intestinal obstruction. Sepsis and multiple organ failure are common terminal events.

Although the time to local recurrence following complete resection depends on tumor grade, most series report a median interval of 15 months, with 90% of recurrences developing within 5 years (52,124,260). This interval defines a period of intensive follow-up for disease recurrence. Patients should be followed up with physical examination every 3 to 4 months for the first 2 years. Asymptomatic patients should also have a CT scan of the abdomen and pelvis and a chest radiograph every 6 months for 2 years, and yearly thereafter. Low-grade tumors may recur much later, often many years after tumor resection.

Metastatic Recurrence

As mentioned, of the patients who succumb to this disease, only approximately one-third ever develop distant metastasis, most of which occur in patients with high-grade tumors (111,158). Although not as common as local recurrence, nevertheless, appearance of metastatic disease must be monitored during follow-up with regular chest radiographs.

Overall Survival

Overall 5-year survival following surgical resection is reported to be between 29% and 82%, with disease-free survival being significantly less (Table 25.7). The wide range in overall survival is due to the heterogeneity of tumor factors among the various series (see Prognostic Factors section).

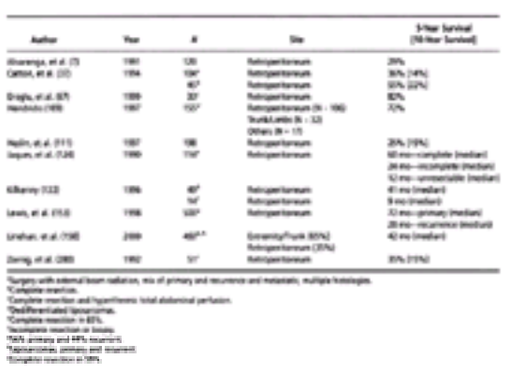

TABLE 25.7. OUTCOME OF SERIES OF RETROPERITONEAL SARCOMAS

Prognostic Factors

Upon analyzing the major series reporting the treatment of retroperitoneal sarcomas, many variables are associated with prognostic importance for recurrence and survival (Table 25.8). However, primarily two variables are reliable independent predictors of ultimate survival in most series: (a) the completeness of tumor resection and (b) tumor grade. The histologic type is far less significant than the histologic grade of the tumor in assessing malignant behavior. The importance of histologic grade in predicting the biologic behavior and subsequent prognosis in retroperitoneal soft tissue sarcomas has been borne out in virtually every series reported on these tumors. Jacques and associates (124) reported a 20-month median survival for 65 patients with high-grade retroperitoneal sarcomas, compared with an 80-month median survival for 49 patients with low-grade retroperitoneal sarcomas. Similarly, Storm and Mahvi (249) reported a 5- and 10-year overall survival of 74% and 42%, respectively, in patients who had completely resected low-grade retroperitoneal sarcomas. This compares with overall survival rates of 24% and 11% at 5 and 10 years, respectively, for grade II or III lesions following complete resection. It is presently unclear whether DNA ploidy analysis adds any additional prognostic

information over that already provided by grade. In general, low-grade tumors tend to be diploid, and high-grade tumors tend to be aneuploid. In some cases, ploidy analysis may be helpful. Similarly, the degree of the differentiation in liposarcomas has also been an important factor in prognosis (102,109).

TABLE 25.8. PROGNOSTIC FACTORS FOR SURVIVAL/RECURRENCE IN RETROPERITONEAL SARCOMAS

In most series, tumor size and either adjuvant radiotherapy or adjuvant chemotherapy are not significant prognostic factors, but the statistical power to evaluate a negative result in these studies is probably low in view of the small number of patients.

Recently, more emphasis has been placed on the evaluation of molecular prognostic markers. Because of these associations of sarcomas with clinical syndromes characterized by altered tumor-suppressor genes (see Etiology section), a number of investigators recently have performed analysis of tumor-suppressor gene loci in sarcomas. These preliminary studies suggest that alterations involving the RB, p53 (69,201), and mdm-2 genes may be important in sarcoma tumorigenesis and progression and may have prognostic significance (34,69,146,201,274). In addition, low levels of the p27 (kip) gene product appear to be a poor prognostic factor in liposarcomas (189).

Adjuvant Therapy

Overview

The alarming incidence of local disease relapse following the surgical resection of retroperitoneal sarcomas underscores the need for effective multimodal therapy. Significant advances in the management of sarcomas at other sites combining surgery, radiotherapy, and chemotherapy have not been duplicated in the retroperitoneum in large part because the opportunity for delivering high-dose intraarterial chemotherapy and radiotherapy to retroperitoneal structures is not as feasible as it is for sarcomas of the extremity. Currently, the role of adjuvant radiotherapy and chemotherapy has not been established for retroperitoneal soft tissue sarcomas. Although these modalities are commonly used, there is no evidence that the results of surgery plus adjuvant radiotherapy and/or chemotherapy are better than those of surgery alone.

Radiotherapy

Most of the data regarding the efficacy of adjuvant radiotherapy for retroperitoneal sarcomas are from uncontrolled, retrospective studies of relatively small numbers of patients. Parameters that vary significantly between series include the histologic composition of the tumors and treatment technique and dose. Because of the lack of prospective, controlled studies, meaningful conclusions are difficult. Some series report a benefit of adjuvant radiotherapy, usually decreased local recurrences (37,46,111,168,260,280). Conversely, others report no benefit using adjuvant radiotherapy (124).

Relatively high doses of radiation are required to effectively treat these tumors. Although well tolerated in other sites (e.g., the extremities), the situation is different in the retroperitoneum because of the presence of radiosensitive adjacent organs, such as the kidney and small bowel. To circumvent this problem, trials using radiation sensitizers and intraoperative radiotherapy (IORT) have been established. Both methods attempt to deliver larger effective doses of radiation to the tumor without compromising radiosensitive adjacent structures. A prospective, randomized trial using IORT was recently completed at The National Cancer Institute (238). Fifteen patients who received IORT plus low-dose (3,540 Gy) postoperative external beam radiotherapy were compared with 20 patients treated with high-dose (5,055 Gy) postoperative radiotherapy alone. There was no difference in survival between the groups after a median follow-up of 8 years. However, there was a significant improvement in local tumor control in patients receiving IORT. The local recurrence rate in these patients was 40%, compared with 80% for patients treated with postoperative radiation alone. There was also a significantly lower incidence of radiation enteritis in IORT-treated patients, although 60% experienced radiation-induced peripheral neuropathy compared with only 5% of patients receiving postoperative radiation alone.

Novel approaches aimed at limiting such toxicity have included the use of inflatable prostheses to displace radiosensitive organs away from the radiation field during treatment, followed by their removal subsequent to treatment completion (13). In addition, abdominal hyperthermia has been used in an attempt to decrease the rate of local recurrence when used in conjunction with complete surgical resection. Very early results on 33 patients reveal promising results (67).

Chemotherapy

The role of adjuvant chemotherapy in the treatment of retroperitoneal sarcomas is also not established. Furthermore, as with adjuvant radiotherapy, meaningful conclusions concerning the efficacy of chemotherapy are made difficult by the relative lack of prospective, controlled trials of adequate size. Several drugs have been shown to have activity against these tumors when used singly or in combination; these include doxorubicin, vincristine, iphosphamide, DTIC, and methotrexate (46,84). The role of multiagent systemic chemotherapy in the treatment of these tumors is the subject of a number of current trials. To date, however, there is no evidence of a significant survival benefit of its use in this setting. At present, the successful management of retroperitoneal sarcomas depends on appropriate preoperative assessment and aggressive complete surgical resection.

Management of Patients with Clinically Unresectable Disease

Surgical Approaches

Currently, the best chance of survival in patients with retroperitoneal sarcomas is provided by complete surgical resection. Unfortunately, as mentioned earlier, up to 50% of patients are unresectable at a laparotomy. Although incomplete tumor resection does not improve eventual outcome, it may in some cases effectively palliate complications of the tumor, such as severe pain and bowel obstruction.

Radiotherapy

Studies in small groups of patients have shown that three-dimensional conformal pion radiation has some beneficial results in patients. However, these studies have included patients with both retroperitoneal and truncal/extremity sarcomas, the latter having better prognosis then the former (94,95).

Treatment of Locally Recurrent Disease

The local recurrence rate 5 years after complete tumor resection ranges from 35% to 79% and at 10 years has been reported to be as high as 90% (249). Only approximately one-third of patients, most with high-grade tumors will develop distant disease, alone or in combination with locally recurrent disease. Therefore the most common pattern of failure following complete tumor resection is recurrent locoregional disease occurring in 75% of patients (206).

Following a thorough evaluation for the presence of disseminated disease, an aggressive surgical approach should be undertaken for locally recurrent disease. With

recurrent disease, however, resectability rates decline and the incidence of another local recurrence increases, with a shorter interval from resection to disease relapse. Jacques and associates (124) reported that 49%, 42%, and 33% of first, second, and third recurrences, respectively, were completely resected. Contributing to the lower resectability rates and the increased aggressiveness of recurrent retroperitoneal tumors is their propensity to undergo grade progression. However, there are reports of patients benefiting with prolonged survival following resections of recurrent retroperitoneal sarcomas (37,133,153). Recently, models based on CT scan imaging have been constructed for the outpatient determination of prognosis following surgery for locally recurrent disease (199). If validated in larger studies, these models help further delineate which patients should undergo reoperation.

Treatment of Recurrent Metastatic Disease

A significant body of evidence also supports an aggressive surgical approach for metastatic disease isolated to the lungs (35,123,181). A thorough evaluation for extrapulmonary disease with special attention to the liver is necessary because patients with extrapulmonary disease are not candidates for lung metastasectomy. In a series of 56 patients who had isolated lung metastasis resected, 40 (71%) were rendered free of disease with an actuarial 3-year survival rate of 40% (206). The median survival of patients with isolated pulmonary metastasis deemed unresectable is dismal and in the range of 7 months (35). Surgical resection of recurrent pulmonary metastasis also may result in long-term survival. A 22% 3-year actuarial survival has been reported from the National Cancer Institute (219) for 29 patients undergoing two or more resections for long metastasis. The M.D. Anderson Cancer Center experience has been similar. In a series of 38 patients with recurrent isolated pulmonary metastasis, 34 were rendered disease free after resection, with a median overall survival of 28 months, compared with 65 months for patients from whom a solitary pulmonary metastasis was completely resected (35).

Most patients treated surgically for pulmonary metastasis also have received systemic chemotherapy. Although complete plus partial response rates approaching 50% have been reported, they have not been durable and the response to chemotherapy does not predict survival following surgical resection (144). It does, however, appear logical to treat these patients before metastasectomy with several courses of systemic chemotherapy. This approach may allow the selection of responders that may benefit from further chemotherapy postoperatively. It also allows aggressive pulmonary disease and initially unsuspected extrapulmonary disease to manifest, thus sparing an unnecessary thoracotomy (243). Despite the occasional need for extended parenchymal resections including the chest wall, diaphragm, and pericardium, these procedures are surprisingly well tolerated. In the M.D. Anderson series (35), mean postoperative hospitalization was 6 days with no operative mortality.

Although resection of pulmonary metastases is the most well-established approach to metastatic lesions, recent data from patients with solitary hepatic lesions have been provided. In a very small study on 11 patients, resection of hepatic lesions from leiomyosarcoma resulted in prolonged survival (41). In addition, surgical debulking of intraabdominal metastases may offer improved survival in select cases (130).

INFLAMMATORY DISEASES OF THE RETROPERITONEUM

Retroperitoneal Fibrosis

Although the eponym assigned to retroperitoneal fibrosis is *Ormond's disease,* it was the French urologist Albarran who first reported the occurrence of hydronephrosis and a fibrous mass discovered in a patient's retroperitoneum at the time of surgery (3). Ormond published the first description of retroperitoneal fibrosis in the English literature in 1948. In his paper (192), he described two patients with generalized malaise, flank pain, anuria, and anemia associated with an inflammatory perivascular retroperitoneal process. In addition to *retroperitoneal fibrosis* and *Ormond's disease,* many terms have been used to describe this malady, including *periureteritis fibrosa, periureteritis plastica, chronic periureteritis, sclerosing retroperitoneal granuloma,* and *fibrous retroperitonitis.* Since the 1960s, the term *retroperitoneal fibrosis* has been favored because it closely reflects the cellular process involved.

The disease is characterized by the presence of an inflammatory proliferation of fibrous tissue within the retroperitoneum, which encases the great vessels, nerves, and ureters. The disease is classified into two varieties: (a) idiopathic retroperitoneal fibrosis, the most common cause, and (b) retroperitoneal fibrosis of a known origin, such as ergot derivative ingestion, retroperitoneal malignancies, previous radiation treatment, and infectious/inflammatory processes.

Pathology

On gross examination, retroperitoneal fibrosis appears as a firm woody mass, tan to white in color, that envelopes the retroperitoneal structures, including the great vessels and often the ureters. Ureteral involvement can occur from the renal pedicle to the pelvic brim, although usually most prominent over the region from the fourth lumbar vertebra to the first sacral vertebra (258). The fibrosis tends to cause medial deviation of the middle third of the ureters in one-half to two-thirds of patients. Encasement of the ureters will lead to hydronephrosis and can cause varying degrees of renal failure. On rare occasions, the process can proceed superiorly and continue as mediastinal fibrosis and has been related to disseminated vasculitis and intrahepatic sclerosing cholangitis (108,178). Great vessel involvement is common, although not often leading to vascular obstruction. Arterial obstruction is rarely significant, whereas venous obstruction does occur and can lead to lower-extremity edema with involvement of the inferior vena cava or the common iliac veins (212). Extrahepatic portal vein involvement has also been reported (80). The size of the mass may vary significantly and may occasionally involve other retroperitoneal as well as intraabdominal organs, including the duodenum, jejunum, ileum, colon, pancreas, spleen, and kidneys; the mass may also extend into the pelvis proper (151).

Histologic examination of biopsy specimens most often reveals fibrous tissue consisting of collagen fibrils and fibroblasts. There is a spectrum of findings, from a predominantly cellular chronic inflammatory tissue to less cellular, more fibrotic collagenous tissue. In the early part of the disease process, the inflammatory cells present consist primarily of B and T lymphocytes, plasma cells, and macrophages, although eosinophils and polymorphonuclear leukocytes are also appreciated (197). Heterogeneity in the amounts of fibrous and cellular composition often occurs from biopsies taken from different areas of a mass. Many authors conclude that contraction of this cellular fibrous tissue with advanced disease may draw the ureters medially, resulting in typical findings found on IVP. Reports have noted the invasion of the psoas muscles and the ureters by the fibrous process (107).

Etiology

No associated etiologic factor is found in two-thirds of cases, and therefore they fall into the category of idiopathic retroperitoneal fibrosis. Some factors that have been associated with retroperitoneal fibrosis include drugs [most notably methysergide (Sansert)], hemorrhage, trauma, urinary extravasation, chronic urinary tract infections, retroperitoneal malignancy, perianeurysmal inflammation or leaky aneurysm, prior radiation therapy, prior surgery, inflammatory bowel disease, ruptured appendix or hollow viscus, Henoch-Schönlein purpura, ascending lymphangitis, biliary tract disease, sarcoidosis, tuberculosis, collagen disease, and fat necrosis (39). Recently, asbestos exposure and intravesical formalin use have been reported as possible etiologic agents for this disease (73,226).

The most notorious etiologic association is ingestion of the ergot derivative methysergide for the treatment of migraine headaches. This association was first reported in 1964 by Graham (91) and has been noted by many authors since. Graham (92,137) later reported a 1% incidence in a large series of patients receiving this drug and a history of methysergide intake in 10% to 12% of patients with retroperitoneal fibrosis. Methysergide has also been linked to fibrosis in other areas, including the chest (myocardium, lungs, and pleura) and the GI tract. Other ergot derivatives, such as lysergic acid diethylamide (LSD), as well as other drugs, including methyldopa, amphetamines, reserpine, phenacetin, adrenergic b-antagonists, and recently pergolide (Permax), have also been implicated as etiologic factors (2,122,176).

The mechanism by which ergot derivatives and other drugs induce retroperitoneal fibrosis is poorly defined, and several theories have been proposed. The ergot derivatives, including methysergide and LSD, are serotonin receptor antagonists and act by competitive inhibition of receptor sites. Increased amounts of endogenous serotonin have been associated with fibrosis in the carcinoid syndrome (232). The most widely held theory as to the mechanism of drug-induced retroperitoneal fibrosis is that the drug may act as a hapten, resulting in a hypersensitivity or autoimmune reaction (267).

Retroperitoneal malignancy is also a well-documented cause of retroperitoneal fibrosis. In their review of 491 patients with retroperitoneal fibrosis, Koep and Zuidema (137) reported a 7.9% incidence of malignancy. Lepor and Walsh (151) described three types of malignant processes that could induce retroperitoneal fibrosis: (a) periureteral metastasis with fibrosis, (b) primary retroperitoneal tumor, and (c) serotonin production by carcinoid tumor. Metastatic breast, stomach, prostate, lung, kidney, and colon cancer are most commonly associated with periureteral metastases (240). Primary retroperitoneal tumors, including lymphomas and sarcomas, may cause an extensive desmoplastic response, resulting in fibrous proliferation. Pathologic analysis in this situation often reveals a predominance of fibrous tissue with small islets of tumor cells interspersed. Authors have stressed biopsy at the time of surgical exploration to differentiate idiopathic from malignant retroperitoneal

fibrosis (151).

Previous radiation therapy is also associated with retroperitoneal fibrosis. Periureteral fibrosis has been noted in approximately 1% of patients treated with irradiation for pelvic tumors (54). In general, the radiation-induced fibrosis becomes clinically apparent several years after radiation therapy. On pathologic analysis, the fibrous tissue has a characteristic appearance, exhibiting large collagen fibers and extensive hyalinization. The blood vessels also show evidence of endarteritis obliterans (117).

Infection has been implicated in the etiology of retroperitoneal fibrosis as well. Urinary tract infection, gonorrhea, syphilis, brucellosis, and tuberculosis may cause a disseminated fibrous inflammatory response (191). Despite their association with fibrosis in general, as well as a report of the association of histoplasmosis with mediastinal fibrosis, active infectious diseases have not been reported concurrently with retroperitoneal fibrosis (151,183).

Retroperitoneal fibrosis is related to and associated with a number of other disease processes characterized by fibrous proliferation. These include mediastinal fibrosis, generalized mesenteric fibrosis, sclerosing colitis, Riedel's thyroiditis, Dupuytren's contracture, Peyronie's disease, keloid formation, pseudotumor of the orbit, systemic lupus erythematosus, and diffuse pleural fibrosis (137,151). On the basis of these associations, some authors have proposed that retroperitoneal fibrosis may be a manifestation of a systemic disease, such as a collagen vascular disease or a generalized autoimmune process (159,279). The frequent favorable response of retroperitoneal fibrosis to steroid therapy and to other immunosuppressive drugs, such as azathioprine, provides circumstantial evidence to support this hypothesis (47,177). Until recently, however, testing for autoantibodies or other markers of autoimmune diseases has rarely been positive. De Luca and associates (53) reported that human leukocyte antigen-B27 (HLA-B27) stained positive in 44% of cases; HLA-B27 is also associated with autoimmune disorders such as Reiter's syndrome and ankylosing spondylitis. A conflicting report by Chevet and associates (42) found no HLA-associated markers and argued against HLA-B27 being linked to the disease. A genetic predisposition has also been reported; two sets of twins with retroperitoneal fibrosis have been described, and a small number of patients have been found to share certain HLA haplotypes (87,263,272).

Finally, it is clear that essentially any process that results in injury or inflammation of the retroperitoneum can elicit the development of a fibrotic process. Postsurgical changes, trauma with subsequent hematoma formation or spontaneous retroperitoneal bleeding, hollow viscus perforation (appendicitis, diverticulitis, or ulcers), and urinary extravasation are all possible etiologic factors for such a process (137,151).

In the two-thirds of patients in whom no etiologic agent can be identified, the diagnosis of idiopathic retroperitoneal fibrosis is made. Evidence has accumulated over the past decade that indicates that “idiopathic” may in fact be a misnomer—the condition may have a defined cause in most cases. CT scanning has shown that the inflammatory process has a striking distribution closely associated with the aorta and often extends along the bifurcation of the common iliac vessels. This distribution, also noted at the time of surgery, led several authors to suggest that it may represent a process of vasculitis. Both Mitchinson (174) and Parums (195) have proposed the unifying concept of “chronic periaortitis” to include not only idiopathic retroperitoneal fibrosis but also the related conditions of perianeurysmal retroperitoneal fibrosis and inflammatory abdominal aortic aneurysm. Also included is subclinical periaortitis associated with atherosclerosis, which can often be demonstrated on postmortem examination (16,58,174,196). Recently, antineutrophil cytoplasmic antibodies (cANCA), which are associated with systemic vasculitis, have been demonstrated in a biopsy of a retroperitoneal fibrosis mass (127).

It appears that idiopathic retroperitoneal fibrosis, inflammatory abdominal aortic aneurysm, perianeurysmal retroperitoneal fibrosis, and subclinical chronic periaortitis merely represent a spectrum of the same disease (Fig. 25.4). These entities share identical histopathologic features, and differences in the clinical and radiologic findings between these conditions relate mainly to whether the aorta is dilated and the extent of the periaortic process (31,195). The pathogenesis of periaortitis and its development into idiopathic retroperitoneal fibrosis or its variants are believed to result from an immunologically mediated inflammatory process directed to a component of the atherosclerotic plaque. Although the exact mechanism of this process awaits further studies, ceroid, an insoluble product of oxidized lipid and protein found in atherosclerotic plaques, has been found to be associated with immunoglobulins in patients with chronic periaortitis. Antibodies directed against ceroid are also detectable in patients with severe chronic periaortitis (195).

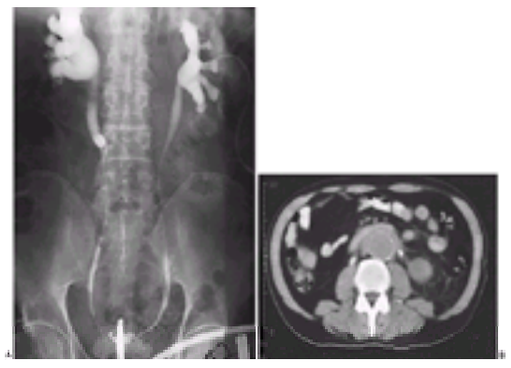

FIGURE 25.4. A: Bilateral retrograde pyelograms of a 61-year-old man presenting with anuria. Note bilateral hydroureteronephrosis and medial deviation and narrowing of both ureters. **B:** Computed tomography scan in same patient following establishment of urinary tract drainage by bilateral double-J stents. Demonstrated is retroperitoneal fibrosis surrounding a calcified inflammatory aortic aneurysm.

Further evidence that idiopathic retroperitoneal fibrosis represents clinical chronic periaortitis in the setting of an undilated aorta is that the inflammatory cells in idiopathic retroperitoneal fibrosis are identical to those seen in inflammatory aneurysms and subclinical periaortitis (195). The aforementioned striking vascular distribution of the disease and the significant frequency of aortic dilation and wall calcification demonstrable by CT also support this concept (31,58). Furthermore, because 2% to 10% of abdominal aortic aneurysms are inflammatory, a significant number of patients with abdominal aortic aneurysms may present with urologic complaints; recognition of this fact is important for the practicing urologist.

Clinical Features

Most patients diagnosed with retroperitoneal fibrosis are in their fourth through seventh decades of life, although the disease has been reported in the elderly and in children as young as 7 years of age (12,40,96,151). There does not appear to be any racial predominance; however, the disease is two to three times more common in men than in women.

Retroperitoneal fibrosis tends to be insidious. There are no specific symptoms or signs suggestive of the diagnosis; rather, a complex of symptoms helps identify patients in the earlier stages of disease. Clinical features commonly seen at the time of presentation are reviewed in Fig. 25.5. Clinical features commonly seen early in the disease process are often vague, nonspecific, and similar to those of other inflammatory disorders. Many patients present with generalized malaise, low-grade fever, anorexia, weight loss, and nonspecific GI complaints. An elevated erythrocyte sedimentation rate (ESR) is present in most patients, as are anemia, hypertension, and varying degrees of renal functional impairment. Most patients present with a complaint of pain localized to the flank, back, or abdomen, perhaps as many as 90% of cases (258). Pain localized to the testis is also reported in up to 10% of patients (151). Interestingly, cases involving the testes and scrotum have been reported (194,230). The pain may vary significantly. Early in the course of the disease, it is often insidious in onset and described as being dull and noncolicky. It also often originates in the lower back and may at times radiate anteriorly to the lower abdominal quadrants and into the groin. The pain is characteristically not influenced by position or activity but has been reported to be relieved in this stage by antiinflammatory agents, such as nonsteroidal antiinflammatory drugs (NSAIDs). Narcotics are usually ineffective in relieving pain in the early stages of disease. Curiously, this noncolicky pain, not otherwise characteristic of obstruction of the urinary tract, is typically relieved following ureterolysis, without any attempt to resect the fibrotic process.

FIGURE 25.5. Algorithm for evaluation and treatment of patients with retroperitoneal fibrosis. BUN/Cr, blood urea nitrogen-to-creatinine ratio; CBC, complete blood count; CS, culture and sensitivity; CT, computed tomography; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; UA, urinalysis; US, ultrasound.

Because of the insidious nature and vague symptoms, there is often a several-month interval from the onset of symptoms to clinical presentation. With disease progression, signs and symptoms reflect the involvement of the retroperitoneal great vessels and ureters because there is often increasing pain, oliguria (which may progress to anuria), lower-extremity edema, and even ischemic pain from arterial compression (151). The disease may mimic other processes such as large bowel obstruction, pancreatic cancer, or an abdominal aortic aneurysm.

Physical examination is usually unrewarding. The most common findings, each occurring in less than 10% of patients, are a palpable mass, uremia, lower-extremity edema, and the presence of a hydrocele. Signs of significant vascular disease, including neck and abdominal bruits, may be appreciated. The insidious onset and progressive nature of this disease are underscored by the fact that at the time of presentation, up to one-third of patients have been reported to have a nonfunctioning kidney and up to 10% have uremia secondary to bilateral ureteral obstruction and anuria (12).

Diagnostic Evaluation

Strictly defined, the diagnosis of retroperitoneal fibrosis requires pathologic confirmation, although it is usually strongly suggested on the basis of history and imaging studies. As mentioned previously, laboratory testing is generally completely nonspecific and reflects only the presence of a chronic disease state with an elevated ESR and some degree of anemia, often correlating with the extent of azotemia that is noted at the time of presentation in most patients (12,137,151). Because retroperitoneal fibrosis is a pathologic diagnosis and retroperitoneal malignancy must be excluded, it is of paramount importance to obtain biopsy specimens. This is usually done at the time of surgical exploration; however, CT-guided fine-needle aspiration biopsy or transcaval Tru-Cut needle biopsy under fluoroscopic guidance has been reported to be possible in patients in whom surgery presents too high a risk (200,246).

The degree of renal function impairment, which ranges from none to chronic renal failure with anuria, guides the strategy for intervention and is a strong prognostic indicator. Intravenous pyelogram (IVP) findings can suggest the diagnosis relatively early in the disease process. Classically, IVP demonstrates medial deviation of the ureter, in contradistinction to retroperitoneal neoplasms and abdominal aortic aneurysms that tend to displace the ureters laterally. Medial deviation usually occurs in the middle third of the ureter at the region of the third to fourth lumbar vertebra. This finding is accompanied by varying degrees of ureteral obstruction and resultant hydronephrosis. Lateral deviation of the ureters has also been reported (228). Ureteral obstruction is generally most prominent at the level of the iliac vessels, usually bilateral, and typically involves several centimeters of the ureter. A completely normal IVP is rare and was found in only 2.5% of the cases reviewed by Koep and Zudima (137). Medial deviation of the ureter on the IVP is, however, not pathognomonic of retroperitoneal fibrosis; there is a significant fraction of patients who have medial deviation of a ureter as the sole abnormal IVP finding. Ureteral deviation in retroperitoneal fibrosis tends to extend higher, and the ureters usually appear more linear than in variant-type medial deviation (223).

Retrograde pyelography can be useful in the diagnosis of retroperitoneal fibrosis and may be performed in patients with impaired renal function that precludes the administration of intravenous contrast or when there is poor visualization following an IVP (Fig. 25.6). It is also often a therapeutic maneuver because placement of retrograde ureteral stents is generally possible. In fact, the ability to pass a 5- or 6-Fr ureteral catheter beyond the area of obstruction is a characteristic feature of retroperitoneal fibrosis.

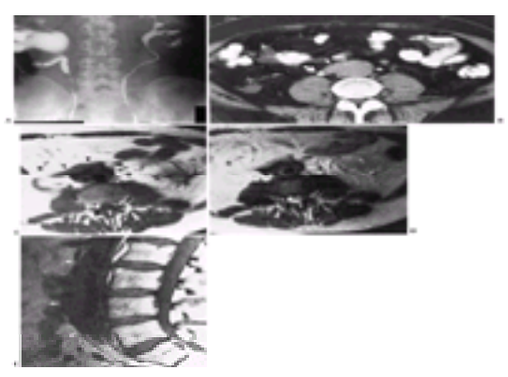

FIGURE 25.6. Benign idiopathic retroperitoneal fibrosis. **A:** Retrograde pyelography demonstrates medial displacement of both ureters at the level of L-5. The right midureter is narrowed, and there is associated right hydroureteronephrosis. **B**: Computed tomography (CT) scan demonstrates plaquelike deposition of fibrous tissue surrounding and obscuring both the aorta and inferior vena cava *(arrowheads).* The right ureter is entrapped by an extension of the fibrous process to the right of the midline *(arrow).* **C:** T_1-weighted magnetic resonance imaging (MRI) scan at 1.5 T demonstrates that the plaque *(arrowheads)* is of low signal intensity consistent with fibrous tissue. Note how the fibrous tissue encompasses both the aorta and inferior vena cava, rendering them almost indistinguishable. Note also the extension of the fibrous plaque to the right as demonstrated in the previous CT scan. **D:** T_2-weighted axial image demonstrates no change in the signal intensity of the retroperitoneal plaque, indicating that it is comprised entirely of fibrous tissue, confirming the diagnosis of benign retroperitoneal fibrosis. The wall of the aorta has increased slightly in intensity, making it now visible. **E:** T_1-weighted sagittal MRI demonstrates the plaque in profile *(arrowheads).* The lesion is extensive and extends from L-1 to L-5.

In the unusual situation in which there is extension of the disease process through the ureteral wall and/or retrograde placement of a catheter is not possible, percutaneous nephrostomy tube placement may be a valuable maneuver. This provides immediate upper tract drainage and allows subsequent anatomic study by antegrade pyelography. This situation should heighten suspicion of a malignant process. Percutaneous nephrostomy is also the procedure of choice in the patient presenting with urosepsis in the setting of retroperitoneal fibrosis and high-grade obstruction.

Ultrasonography is uncommonly used to diagnose retroperitoneal fibrosis, largely because CT is the radiologic examination of choice and can more accurately define the extent of disease. The sonographic findings consist of an extensive retroperitoneal, extrarenal, anechoic, well-marginated, and irregularly contoured mass (68). These findings may be apparent on ultrasound examination for elevated creatinine with flank pain.

CT has become the most useful imaging test for diagnosing retroperitoneal fibrosis. The CT findings consist of a dense mass of variable thickness encompassing the great vessels and ureters, with attenuation values similar to those of muscle. With the administration of an intravenous contrast medium, variable enhancement is present, most prominent in areas of active inflammation and less pronounced in areas where fibrous tissue predominates (71). The extent of the process is variable, but it often extends from the level of the renal pedicles along the great vessels and the bifurcation of the common iliac vessels and laterally to, or beyond, the lateral margin of the psoas muscles. In general, the mass is usually symmetrically distributed and encases the great vessels. The mass in retroperitoneal fibrosis shown by CT scanning also typically lies anterior and lateral to the aorta, sparing the posterior aspect; complete encirclement of the great vessels is rare and should increase

suspicion of malignant nodal disease (31,32,55). However, the typical CT findings, although highly suggestive of retroperitoneal fibrosis, are nonspecific and nondiagnostic because other benign (e.g., amyloidosis) and malignant (e.g., sarcomas, metastatic carcinoma, lymphoma, multiple myeloma) processes may produce similar findings (85,222,247).

The features of CT imaging that may allow the differentiation of retroperitoneal fibrosis from malignant processes have been previously noted and have been reviewed by Brooks (31) and Degesys and co-workers (55). The differentiation between retroperitoneal fibrosis and malignant disease is readily made when there are multiple discrete enlarged periaortic lymph nodes clearly separable from the great vessels; at other times, matting of cancerous lymph nodes obscures the delineation. Factors suggestive of malignancy are the finding of an asymmetric nonconfluent mass with prominent skip areas, lack of enhancement with intravenous contrast, and the finding of discrete periaortic and/or mesenteric nodal enlargement. The mass of retroperitoneal fibrosis is usually confluent, with continuous encasement of the great vessels.

Findings comparable or superior to those obtained with CT imaging have been reported with the use of MRI. MRI has been shown in several reports to provide more information than CT scans, particularly those performed without intravenous contrast, showing the extent of disease better and with greater sensitivity for demonstrating sclerosis as compared with CT (10,31,278). MRI has the advantage of allowing imaging in multiple planes, which may better delineate the relationship of the inflammatory process to adjacent structures. MRI typically identifies a mass with relatively low signal intensity, equal to or less than that of muscle on T_1- and T_2-weighted images (121). This low signal intensity on T_1-weighted and heterogeneous low to medium signal intensity on T_2-weighted images may provide valuable information for differentiating idiopathic retroperitoneal fibrosis from that secondary to malignant disease, which characteristically exhibits a higher signal intensity (177,182,278). Yuh and associates (278) found that all of the patients in their series had relatively low signal intensities on T_2-weighted images, suggesting benign disease. The availability and affordability of CT gives it an advantage over MRI and will suffice in most cases as the treatment is usually based on renal function and not extent of disease.

Evaluation of renal function is important, before extensive use of CT one-third of patients presented with a nonfunctioning kidney due to long-term obstruction. Whitaker (269) demonstrated urodynamic evidence of obstruction due to retroperitoneal fibrosis. The cause of obstruction is hypothesized to be interruption of ureteral peristalsis by periureteral inflammation. The caliber of the ureter is characteristically 5 to 6 Fr except in the rare cases of ureteral invasion. Differential radioisotope renography may be helpful to identify the split function of the kidneys.

Natural History

There are very limited data from which to draw conclusions about the natural history of retroperitoneal fibrosis because most patients undergo surgical treatment, usually consisting of biopsy and ureterolysis. Although uncommon, the long-term resolution of symptoms after surgical exploration and biopsy, as well as spontaneous clinical and radiographic regression, has been reported (70,108). The disease, however, is best characterized as progressive in nature with a propensity for relapse, often many years following initial treatment, therefore necessitating lifelong follow-up. It is interesting to point out as well that several authors have reported instances of rapid progression of the disease with marked growth in the inflammatory mass and the rapid development of complications over a period of several weeks to a few months (11,258).

Management

Overview

The primary goals of management of patients with retroperitoneal fibrosis are making a prompt diagnosis, minimizing the effects of obstructive uropathy, and providing careful long-term follow-up. Treatment of retroperitoneal fibrosis is individualized and depends on the cause, the extent of the disease, and its effect on the urinary tract (Fig. 25.5).

For suspected drug-induced retroperitoneal fibrosis, cessation of the drug has been reported to result in resolution of the disease process; however, this resolution may be uncommon, and progression following the discontinuation of the drug has been reported in several cases (231). Patients should be thoroughly questioned about both medications and illicit drug intake; any known offending agent should be stopped immediately. Although the efficacy of immunosuppressive corticosteroid therapy in this setting has not been well defined, it is commonly used at the time of withdrawal of the offending agent. Smith and cohorts (242) documented a rapid reduction in the size of a retroperitoneal fibrosis mass with corticosteroid therapy.

The type of tumor encountered, the overall prognosis, and the general medical condition of the patient dictates treatment for patients found to have retroperitoneal fibrosis secondary to a malignancy. In most cases, the urologist is called upon to render palliative care and relieve ureteral obstruction by either ureteral stenting or placement of percutaneous nephrostomy tubes.

Classical treatment of idiopathic retroperitoneal fibrosis is surgical exploration with performance of multiple deep biopsies (to rule out a malignant process) and bilateral ureterolysis. Improved imaging modalities, new concepts of the pathogenesis of the disease, and the documented response of the disease to immunosuppressive therapy have made surgical management somewhat controversial. Surgical treatment is still the mainstay for most patients but recently has been combined with immunosuppressive drugs or other medical therapies. Heidenreich and colleagues (105) reported a recent retrospective study on 39 patients in whom combination therapy with oral prednisolone and azathioprine was instituted for 3 months; 3 patients demonstrated complete remission upon reevaluation, whereas 36 had stable or progressive disease and underwent operative correction.

Steroid Therapy

Although many authors continue to recommend formal open biopsy and the surgical relief of obstruction, a significant number of reports now advocate and demonstrate the efficacy of steroid therapy, including its use as primary treatment (4,12,166,177,242). In a study by Higgins and associates (116), most of their 17 patients were managed with primary corticosteroid therapy following initial relief of obstruction by percutaneous nephrostomy. Patients typically received initial dosages of prednisolone between 30 and 60 mg daily and were gradually tapered to 5 to 10 mg daily. Steroid treatment was discontinued at varying intervals, from several months to more than 2 years. These authors reported that, in general, ureteral obstruction resolves rapidly, often within 1 to 2 weeks. These and other authors have concluded that when the diagnosis can be made with near certainty using modern CT and MRI, nonoperative management with primary immunosuppressive therapy is a viable option. It should be emphasized, however, that failure to respond within 2 to 3 weeks following initiation of corticosteroids is an indication for open exploration and biopsy. Several investigators have suggested that the ultimate outcome will be little affected if the diagnosis of an extensive retroperitoneal malignant process is delayed by 2 to 3 weeks (4,32,116).

It should also be pointed out that temporary establishment of urinary tract drainage and corticosteroid therapy may be efficacious in the management of retroperitoneal fibrosis associated with an inflammatory abdominal aortic aneurysm when the aneurysm is to be managed nonoperatively. Furthermore, when the aneurysm is to be approached surgically, surgical correction of the aneurysm may not solve the problem of fibrosis. Persistent fibrosis was associated with ureteral entrapment in 30% of these cases and resulted in renal compromise in 49% as reported by von Fritschen and associates (264). They further demonstrated hydronephrosis, not present at the time of operation, developed in 19% of patients, despite improving or stable inflammatory lesions. This is contrary to the previously held concept that surgery resulted in the resolution of the ureteral obstruction (50,234).

Alternative Medications

Many drugs have been used, with varying success, in the treatment of retroperitoneal fibrosis. Azathioprine, another immunosuppressive drug, has been used both as primary therapy and for recurrence after cessation of steroids with some success (47,100). Harreby and associates (100) also reported using penicillamine in combination with methyl-prednisolone pulse therapy in their article. Tamoxifen, which has some benefit in desmoid tumors, has been used effectively in small numbers of patients either alone or in combination with steroids (44,207). Use of the antimetabolite methotrexate has been reported in one group (229). Cyclophosphamide use has been reported for one patient with retroperitoneal fibrosis and concomitant systemic lupus erythematosus, as well as in one patient also diagnosed with periarteritis nodosa (25,160). Azathioprine or penicillamine as an alternative to corticosteroid therapy and tamoxifen, a nonsteroidal antiestrogen, may have some role in the medical treatment of retroperitoneal fibrosis; however, steroid therapy remains the best choice to date.

Surgery

Despite the documented role for primary nonoperative management, most urologists continue to recommend traditional surgical management consisting of exploratory laparotomy through a midline incision and multiple deep biopsies to establish a pathologic diagnosis. After confirmation of the diagnosis, ureterolysis is carried out. Incising the posterior peritoneum in the midline from the duodenum to the pelvic brim and developing flaps of peritoneum laterally may expose the ureters (112). Alternatively, incising the posterior peritoneum laterally and mobilizing the ascending and descending colon may expose the ureters. In most cases, the dissection is best carried out by localizing and freeing the normal but dilated proximal ureter and following it distally to the point where it is encased in the retroperitoneal mass. Occasionally, when the fibrotic process extends quite superiorly, the normal distal ureter may be identified in the pelvis and traced cephalad.

In most cases, ureterolysis can be accomplished without undo difficulty. The surgeon dissects anterior to the ureter with a right-angle clamp, and the overlying inflammatory tissue is incised sharply. The dissection is facilitated by the preoperative placement of ureteral catheters or double-J stents, which aid palpable identification of the ureters and allow for initial urinary drainage. However, extreme care is important to minimize the risk of ureteral injury. At times, the ureter appears very thin, such that the stent is readily visualized through the ureteral wall. Actual invasion of the ureteral wall by the process is uncommon, but if encountered, segmental resection and primary ureteroureterostomy may be required. Common to all ureteral procedures, the surgeon must be prepared to use any of an extensive armamentarium of reconstructive techniques. These techniques may include the use of a psoas hitch with or without a Boari flap and ureteral reimplantation, dismembered pyeloplasty, ileal replacement of the ureter, or autotransplantation (23,26,136,172).

Following the complete mobilization of the ureters, they may be handled in one of several ways. Care must be taken to prevent ureteral kinking with any operative maneuver; reapproximating the previously incised posterior peritoneum behind the ureters will leave the ureters in an intraperitoneal position. Alternatively, the ureters may be transposed laterally, using an interposition of retroperitoneal fat to buffer the ureter and the fibrotic process. The ureters may also be wrapped using pedicle flaps of omentum (150,254). De Luca and associates (53) reported excellent long-term correction of ureteral obstruction with a mean follow-up of 58 months using omental wraps and ureterolysis. Because of the variable natural history of retroperitoneal fibrosis, with its tendency toward progression and relapse, most authors recommend bilateral ureterolysis, even in the setting of unilateral ureteral obstruction. However, there does not appear to be an indication for ureterolysis for a nonfunctioning renal unit (12). If significant arterial stenosis is present, aortolysis may be required and can be carried past the aortic bifurcation to free the iliac arteries if needed.

Adjuvant Therapy

The optimal role of postoperative steroids has not been established. Numerous reports (mostly anecdotal) tend to suggest an adjuvant role for corticosteroids (12,116,175). In a multiinstitutional, retrospective review of 31 patients with idiopathic retroperitoneal fibrosis, however, Cerfolio and associates (38) concluded that steroids did not influence the restenosis rate following surgical management, including in those patients with “early” idiopathic retroperitoneal fibrosis indicated by a predominance of cellular inflammatory tissue on biopsy.

Outcome and Follow-up

The ultimate outcome of patients with retroperitoneal fibrosis is generally satisfactory, the primary determinant of outcome being the degree of renal functional impairment encountered at the time of diagnosis. Long-term follow-up studies reveal that a number of patients do experience recurrence of ureteral obstruction, often many years after initial treatment. Recurrence of disease also may accompany cessation of corticosteroids or immunosuppressive medications. Ureterolysis with omental wraps, with or without adjuvant immunosuppressive medications, has a 5% recurrence with long-term follow-up (105).

It follows that patients with retroperitoneal fibrosis warrant scrupulous follow-up for the rest of their lives. Monitoring of renal function and imaging of the urinary tract (via ultrasound, radioisotope renal scan, or IVP) should be carried out at regular intervals. Some authors have advocated monitoring the ESR to follow the inflammatory process. The ESR has been noted to return to normal after both surgical and medical therapy. If the ESR increases after treatment or remains elevated, steroid therapy may be considered.

Pelvic Lipomatosis

Pelvic lipomatosis is an obscure and poorly understood entity that was first recognized in 1959 by Engles. In this report, Engles (64) described five patients with marked deformities of the pelvic viscera, who at exploration were found to have multiple fibrous adhesions and an excessive overgrowth of pelvic fat. In 1968, Fogg and Smyth (78) described five similar patients and first used the term *pelvic lipomatosis* to describe the condition. Since the first description in 1959, approximately 130 reports describing more than 200 patients with pelvic lipomatosis have appeared in the literature.

Incidence

The true incidence of this uncommon disease is unknown. The incidence has been estimated to account for approximately 1 in 100,000 hospital admissions in the United States between 1967 and 1975 (187,208). The largest single-center experience is from the Medical College of Virginia, where 18 patients with pelvic lipomatosis were seen over 35 years (135). Few cases of pelvic lipomatosis in females are reported in the literature, and the youngest patient reported is of an 8-year-old girl (15,120). Although pelvic lipomatosis is rare based on the number of reports in the literature, it is probably significantly more common than is generally appreciated because of the lack of physician awareness and likely underreporting of the disease (18,68,163,179).

Pathologic Features

At surgical exploration, dense, often vascular, excessive fatty tissue characteristically is found enveloping the pelvic organs (18,135). Several reports also have documented extension of the disease process cephalad, with involvement of the perirenal space, retroperitoneum, omentum, and small bowel mesentery (98,115). Heyns and colleagues (113) reviewed the pathologic findings from pelvic biopsies reported in the literature in 67 patients with pelvic lipomatosis. In 70% of patients, the only finding was that of mature fat tissue without evidence of atypia or local invasion. Additional findings documented in 30% of patients included chronic inflammatory changes, fibrosis, and increased vascularity. Evidence of cancer is uniformly lacking.

Pelvic lipomatosis may be considered a distinct, although peculiar, type of lipodystrophy. Other conditions characterized by an abnormal proliferation of fibroadipose tissue include adiposis dolorosa (Dercum's disease), nodular nonsuppurative panniculitis (Weber-Christian) disease, sclerosing lipogranulomatosis, benign symmetric lipomatosis, nodular circumscribed lipomatosis, and lipomatosis of the ileocecal region (17,114,187,218). In Heyns and colleagues' (114) review, however, only 5% of the 130 patients reported in the literature had documented extrapelvic lipomatous masses, and the authors emphasize that pelvic lipomatosis should be considered a separate clinicopathologic entity because of the absence of involvement characteristic of the other forms of lipodystrophy.

Etiology

Which etiologic factors are important in the pathogenesis of pelvic lipomatosis are unknown. Initially, a number of investigators hypothesized that the proliferation of fibroadipose tissue within the pelvis is part of an inflammatory response resulting from chronic lower urinary tract infection. In most patients with pelvic lipomatosis, however, there is no documented evidence of concomitant or a prior history of urinary tract infection. Other authors have speculated that pelvic lipomatosis may represent a localized manifestation of obesity. Interestingly, there have been two reports of obese patients with pelvic lipomatosis treated by diet; a decrease in the amount of pelvic fat was demonstrated with weight loss, and an increase in the amount of pelvic fat was associated with weight gain (135,221). However, obesity does not appear to be a primary etiologic factor in that, although many patients have a tendency toward being overweight, few are actually morbidly obese (113).

A number of other factors have been proposed to be potentially important in the etiology of pelvic lipomatosis, including localized abnormalities in lipid metabolism, endocrine dysfunction, venous stasis, and an allergic phenomenon, although there is no firm evidence to implicate any of these in the etiology of this disorder.

Clinical Features

Although pelvic lipomatosis has been reported in children and the elderly, most patients are in their third to sixth decades of life. There is also a marked sex, as well

as racial, predominance with 94% of patients being male and approximately 66% being African American (114). Although occasionally diagnosed incidentally, most patients have presenting symptoms referable to the pelvis or urinary tract. Urinary symptoms and signs are most common and are reported in one-half to three-fourths of patients at the time of presentation. Most commonly, these consist of irritable voiding symptoms and hematuria; obstructive symptoms are occasionally noted. GI symptoms are also common, with patients frequently complaining of nausea, vomiting, and constipation. Other occasional presenting features include suprapubic pain or fullness; low back, flank, or pelvic pain; and lower-extremity edema.

Hypertension also is commonly noted in patients with pelvic lipomatosis. In the Medical College of Virginia experience reported by Klein and associates (135), 5 of 18 patients were discovered during evaluation for hypertension. In Heyns and colleagues' review (114) of 130 patients with pelvic lipomatosis, of the 61 in whom blood pressure was documented, 74% were hypertensive, with moderate to severe hypertension in one-third. As pointed out by Heyns and associates (114) and others, although the true incidence of hypertension in patients with pelvic lipomatosis cannot be accurately determined from case reports, it appears that the incidence is substantially higher than that in the adult United States' population. However, the cause of the hypertension in these patients remains unknown.

In addition to hypertension, pelvic lipomatosis has also been associated with cystitis cystica, cystitis glandularis, and adenocarcinoma of the bladder (114,125). The rectum and colon are often involved in this disease, leading to constipation or bowel obstruction (114,126). Furthermore, patients with pelvic lipomatosis appear to be predisposed to deep venous thrombosis and/or pulmonary embolism, which were documented in 7% of the patients reported in Heyns and colleagues' (114) review. This association has led several authors to advocate prophylactic heparin administration when surgery is performed in these patients (1). In 1992, Goswami and associates (90) described a syndrome linking crossed renal ectopia, pelvic lipomatosis, and translocation of chromosomes 1 and 6. Two groups simultaneously reported an association between achondroplasia and pelvic lipomatosis in 1999 (138,190). Other putative disorders connected with pelvic lipomatosis are the *Proteus* syndrome and nontropical chyluria (49,214).

Natural History

As a result of the displacement and encasement of the pelvic organs by fibroadipose tissue, a number of complications may occur, including obstruction of the urinary tract, rectum, iliac veins, and vena cava. Obstructive uropathy is the most common complication requiring the attention of the urologist. In Heyns and associates' (114) review, nearly half of the patients had some degree of ureterectasis or hydronephrosis, usually bilateral. Of the 18 patients reported by Klein and associates (135), 7 required operative intervention for obstructive uropathy. Interestingly, four of these patients required operative intervention shortly after diagnosis because of moderate to severe azotemia present at the time of diagnosis. The other three patients, however, underwent a diversionary procedure 6, 9, and 12 years following diagnosis for progression of upper tract obstruction and worsening renal functional impairment. One of the patients in this series ultimately died of complications of uremia. In most cases, hydronephrosis can be attributed to encasement of the ureters in the pelvic fibroadipose tissue, although some authors have attributed it to obstruction at the ureteral orifices secondary to proliferative cystitis (276). Vesicoureteral reflux with hydronephrosis has also been reported (5). It should be emphasized that the variable and unpredictable natural history of pelvic lipomatosis dictates prolonged follow-up to prevent progressive upper tract deterioration and demise of renal function.

Association with Proliferative Cystitis

It is well documented that a large percentage of patients with pelvic lipomatosis have bladder epithelial lesions characterized as proliferative cystitis, and a very few with adenocarcinoma of the bladder (114,125,276). Proliferative lesions include bullous edema, von Brunn's nests, cystitis cystica, cystitis glandularis, and cystitis follicularis. In the Medical College of Virginia experience reported by Klein and associates (135), all 12 patients who underwent bladder biopsy had evidence of proliferative cystitis, usually cystitis cystica and/or cystitis glandularis. In Heyns and associates' (114) review of the literature, 78% of patients in whom the bladder mucosa was evaluated demonstrated evidence of proliferative cystitis, usually cystitis cystica and/or cystitis glandularis.

The reason for the high incidence of proliferative epithelial changes in association with pelvic lipomatosis is unknown. Yalla and associates (276) have hypothesized that lymph and venous stasis as a result of encasement of the bladder by the fibroadipose tissue results in mucosal edema, which leads to an altered microenvironment conducive to epithelial proliferation. The true significance of these proliferative lesions in patients with pelvic lipomatosis is likewise unknown. A number of investigators consider cystitis glandularis to be a premalignant lesion, based partly on the frequent association of cystitis glandularis with primary vesical adenocarcinoma (134,180), as well as the documented progression of cystitis glandularis to primary adenocarcinoma of the bladder (62,134,180,235). Furthermore, there have now been three cases reported in the literature of patients with pelvic lipomatosis and adenocarcinoma of the bladder (89,114,125). Two patients with pelvic lipomatosis and adenocarcinoma of the bladder have been seen at The University of Texas M.D. Anderson Cancer Center over a 13-year period. Both patients presented with pelvic lipomatosis and adenocarcinoma (Fig. 25.7). Radical cystoprostatectomy is difficult in this situation because the anatomic cleavage planes are obliterated and the bladder pedicles are greatly thickened, making the dissection extremely difficult. One patient in the M.D. Anderson experience (125) sustained a rectal injury during the procedure, necessitating construction of a temporary diverting colostomy at the time of the operation. Pathologic analysis in both M.D. Anderson cases showed extensive cystitis cystica and cystitis glandularis in addition to invasive adenocarcinoma. In the case of adenocarcinoma and pelvic lipomatosis reported by Heyns and associates (114), the patient initially presented with pelvic lipomatosis associated with cystitis cystica and cystitis glandularis 6 years before the diagnosis of adenocarcinoma.

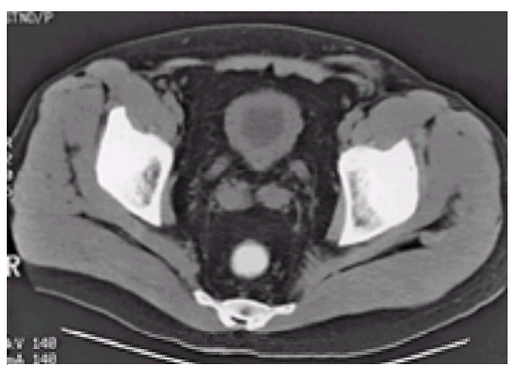

FIGURE 25.7. Computed tomography scan of the pelvis in a patient who presented with pelvic lipomatosis and primary adenocarcinoma of the bladder. Note encasement of bladder and rectum by homogeneous-appearing fat tissue and the increased distance between the seminal vesicles and posterior bladder wall secondary to fat deposition.

Despite the possible premalignant potential for some forms of proliferative cystitis, its true significance remains controversial given its high prevalence in the general population, as revealed in autopsy studies and in urologic patients (8,132,267,270). Regardless, it seems prudent to consider patients with pelvic lipomatosis and proliferative epithelial changes in the bladder to be at an increased risk for adenocarcinoma.

Diagnosis

As mentioned, there is no presenting feature characteristic of pelvic lipomatosis. When symptoms are present, they are usually vague but localized to the pelvis and urinary tract. Complaints include irritative voiding symptoms, hematuria, suprapubic discomfort, perineal pain, low-grade fever, and backache. Despite the deformity of the bladder and posterior urethra, only half of patients describe obstructive voiding complaints (14). Physical examination is only occasionally helpful. A suprapubic mass or fullness representing the displaced bladder is commonly palpable. Rectal examination often reveals a high-riding prostate gland. Owing to venous stasis secondary to iliac vein or venacaval obstruction, lower-extremity edema may be present.

Pelvic lipomatosis is generally first suspected and subsequently diagnosed on the basis of imaging studies. The diagnosis may be suggested on a kidney–ureter bladder (KUB) plain film that demonstrates increased radiolucency in the pelvis (115). Characteristic findings of excretory urography are also generally appreciated. The ureters are usually medially deviated, and often, there is a spectrum of urinary tract obstruction from distal ureterectasis to severe hydroureteronephrosis. Although the ureters typically are deviated medially in their lower third, they also may be laterally deviated. The bladder also has an abnormal appearance. Classically, it is elevated anterosuperiorly and compressed bilaterally, largely in symmetric fashion, with absence of the prostatic indention. This gives a characteristic

appearance to the bladder that has been described as teardrop-shaped or pear-shaped. A voiding cystourethrogram, in addition to demonstrating the bladder abnormalities often appreciated on the IVP, also demonstrates an elongated posterior urethra (187). Barium enema typically demonstrates elongation, straightening, and narrowing of the rectosigmoid, producing the so-called “tower” rectum (Fig. 25.8) (135,219). Before the advent of CT scanning, these findings were considered pathognomonic (103). When the diagnosis was still in question, pelvic arteriography was often obtained; although there is often increased vascularity, no neovascularity or other changes characteristic of malignancy are typically seen with this technique (187). Before CT scanning, exploration and biopsy were required in most cases (114,268).

FIGURE 25.8. A: An intravenous urogram in a patient with pelvic lipomatosis demonstrates marked bilateral extrinsic compression and elongation of the urinary bladder producing the typical pear-shaped deformity. **B**: Double-contrast barium enema in the same patient demonstrates narrowing and elongation of the rectosigmoid portion of the colon attributable to the marked deposition of pelvic fat.

Since the advent of CT, in most cases, the diagnosis can be made noninvasively. CT is the diagnostic modality of choice, demonstrating the displacement and encasement of the pelvic organs by homogeneous-appearing fat tissue with low attenuation identical to that found in the subcutaneous fat. An additional CT finding considered characteristic is an increased distance between the seminal vesicles and posterior bladder wall secondary to fat deposition (135). Other CT findings consistent with the diagnosis of pelvic lipomatosis include nonenhancement of the fibroadipose tissue, the preservation of anatomic planes, and the lack of additional pelvic soft tissue masses (135,227,268). The use of MRI in pelvic lipomatosis has been reported in a limited number of patients. It does, however, allow diagnostic confirmation similar to that provided by CT scanning (56). Ultrasonography use has been reported in a few cases and does not seem to be as advantageous as CT (215).

The differential diagnosis of a pear-shaped bladder is reviewed in Table 25.9. Iliopsoas muscle hypertrophy is particularly important to consider because of its prevalence in young, African American males. Obviously, the most important differential to be made is from that of a malignant process, particularly liposarcoma. In most cases, the CT or MRI findings allow differentiation because liposarcomas typically demonstrate aggressive local invasion and marked asymmetric growth. Areas of localized high density, suggesting a soft tissue mass, are also typical of liposarcoma. However, if the diagnosis remains questionable following the use of the imaging studies available, percutaneous fine-needle or core-needle biopsy or open exploration and biopsy is warranted.

Diagnostic Entity	Comment
Perivesical hematoma, urinoma, abscess, bilateral lymphocoeles	Suggested by history, demonstrated by ultrasound or CT
Iliopsoas hypertrophy	Demonstrated by measured ratio of psoas muscles to pelvis
Pelvic lipomatosis	Barium enema or CT scan confirms diagnosis
Malignant infiltration of pelvic nodes	Usually due to lymphoma
Inferior vena cava obstruction	Due to enlarged venous collaterals and edematous pelvic muscles
Bilateral iliac aneurysm	Usually unilateral; physical examination and ultrasound establish diagnosis
Bladder scarring or edema	History supportive
Pelvic fibrosis, pancreatic pseudocysts, lymphatic lymphadenopathy	Rare
Bilateral hip replacement with extruded cement or severe bladder prolapse	Diagnosis should be clear on cystogram or intravenous urogram alone
Ureteral compression balloons	Can cause artifact on urogram

CT, computed tomography.
Modified from Gutzeit HM, Pelvic lipomatosis. In: Pollack HM, ed. Clinical urography: an atlas and textbook of urological imaging. Philadelphia: WB Saunders, 1990:1450, with permission.

TABLE 25.9. THE DIFFERENTIAL DIAGNOSIS OF A PEAR-SHAPED BLADDER

Because most patients present with urologic symptoms, including irritable voiding complaints, suprapubic pain, or fullness, and sometimes have hematuria, panendoscopy and biopsy are integral diagnostic studies. However, cystoscopy is usually difficult in these patients and at times impossible because of the elongated posterior urethra and bladder displacement. Use of a flexible cystoscope may facilitate the examination.

Management

There is no specific medical therapy that is successful in the management of patients with pelvic lipomatosis. Although antimicrobial therapy, steroids, dietary control, and radiotherapy have been tried, they play no role in the specific management of this condition. Most patients can be managed conservatively, with intervention reserved for the management of complications, primarily ureteral obstruction resulting in obstructive uropathy. Although a few authors have reported that the lipomatous tissue could be excised satisfactorily, most have found this to be extremely difficult or impossible as a result of the absence of cleavage planes between the fat and surrounding pelvic viscera (78,162). Most authors have found excision of the lipomatous tissue and ureterolysis to be difficult without compromising the ureteral blood supply.

The usual treatment for ureteral obstruction associated with pelvic lipomatosis has been supravesical urinary diversion or ureteroneocystostomy performed into the dome of the bladder. As reported by Klein and associates (135), these procedures have been successful in preserving renal function if performed before significant renal parenchymal damage. Use of an ultrasonic assisted lipectomy device was reported to be helpful with ureterolysis in one difficult case (98). Because of the difficulty in performing endoscopic procedures in these patients, transurethral resection, when necessary, may require a perineal urethrostomy for access.

Outcome and Follow-up

Limited information is available concerning the long-term follow-up of patients with pelvic lipomatosis. In the Medical College of Virginia experience reported by Klein and associates (135), after a mean follow-up of 7.5 years, 16 of 18 patients were alive. One patient was lost to follow-up, and one died of uremic complications of the disease. In all, 7 of the 18 patients required diversionary procedures for obstructive uropathy.

From the limited data in the literature concerning the long-term outcome of these patients, it appears that most patients' disease does not progress and can be managed conservatively with a favorable outcome. A significant percentage (approximately 30% to 50%), however, require operative intervention to relieve urinary tract obstruction. Because it is impossible to predict which subset of patients will in fact have disease progression, long-term urologic follow-up is critical. However, specific recommendations and guidelines for follow-up are difficult. It seems reasonable to obtain a renal ultrasound or nuclear renal scan yearly in stable patients and more frequently if there is any evidence of ureteral obstruction. Cystoscopy, as well as bladder biopsy, also may be indicated at the time of presentation because of the association with proliferative cystitis and its possible premalignant potential. Periodic urinary cytology may obviate the need for cystoscopy (135).

MISCELLANEOUS DISEASES OF THE RETROPERITONEUM

Retroperitoneal Abscess

In the past, retroperitoneal abscess was considered an insidious and challenging clinical entity that, if left untreated, would lead to death in virtually 100% of cases (6). With the widespread use of antibiotics, the incidence of retroperitoneal abscess has decreased significantly (0.9 to 4.0 cases per 10,000 hospital admissions) (253). Advances in diagnostic imaging (ultrasonography and CT scanning) and the development of percutaneous drainage techniques have dramatically improved the management of retroperitoneal abscess (81,82,119). Despite these advances, retroperitoneal abscess remains a diagnostic challenge and should be suspected in any patient presenting with pyelonephritis in whom fever persists despite institution of antibiotic therapy (253). Prompt diagnosis and treatment will prevent the high morbidity and mortality once associated with this entity.

Etiology

The etiology of retroperitoneal abscesses is related to either renal or perinephric infection or to inflammatory processes originating in the GI tract, such as appendicitis, Crohn's disease, diverticulitis, pancreatic abscess, or malignancy (161,167,213). Predisposing conditions for perinephric abscess include urolithiasis, diabetes mellitus, a history of urinary tract infections or urinary tract obstruction, and polycystic kidney disease (250,253). Between 36% and 42% of patients have been reported to be diabetics and 20% have calculi (171,253). Several cases of retroperitoneal abscess occurring after normal pregnancy and delivery have been reported (45). Postsurgical abscess formation in the retroperitoneum, generally associated with surgery of the kidney or of the GI tract, is now relatively rare (28). Less common causes of retroperitoneal abscess include tuberculosis, osteomyelitis, and epidural abscess with extension. An incompletely resorbed retroperitoneal hematoma may lead to the formation of an abscess (186,265).

Clinical Presentation

Typically, a patient harboring a retroperitoneal abscess will present with fever, generalized malaise, and occasionally, diffuse abdominal pain. These symptoms will have been present for more than 2 weeks in most patients, and this is useful in distinguishing patients with acute pyelonephritis, who typically present with symptoms present for only a few days (253). Physical examination may reveal fever and a tender abdominal mass. Most often, flank or costovertebral tenderness is noted (236). A positive psoas sign may also be elicited. Further extension of the infective process may cause irritation to the retroperitoneal nerves, and patients will experience tenderness in the groin, lower abdomen, flank, and upper thigh. Irritation of the diaphragm may cause pleuritic chest pain. Clinical evidence of sepsis is present in up to 60% of patients (88).

Failure to diagnose a retroperitoneal abscess or a delay in treatment, in most cases, leads to spread of the infectious process, to sepsis, and ultimately to death. Spontaneous drainage of retroperitoneal abscess by a fistula to the skin or bowel has been reported (60). Finally, extension of the infective process to the psoas muscle is a well-recognized complication of retroperitoneal abscess (188).

Diagnostic Modalities

Laboratory testing is most often nonspecific: Leukocytosis is noted in two-thirds of patients, 42% of patients will have some degree of anemia (hemoglobin less than 10 g/dL), and most patients exhibit an elevated ESR (171,256). Urinalysis will demonstrate pyuria in most patients, and hematuria may be noted, although in only approximately one-third of patients. Radiographic evaluation may include a plain film of the abdomen, ultrasonography, and CT. In the past, urologists depended on the IVP, retrograde pyelography, and renal angiography, but the newer, less invasive radiologic techniques have provided greater accuracy in reaching a diagnosis.

The plain radiograph of the abdomen is abnormal in about 40% of cases (253). When observed, abnormalities are nonspecific and include (a) obliteration of the psoas muscle border on the affected side, (b) displacement of bowel gas or a pattern of ileus, (c) lumbar scoliosis, (d) perinephric gas, and (e) displacement of the kidney. On the IVP, a poor or nonfunctioning renal unit is present in more than half of patients; ureteral dilation, deviation, or both may be noted; and a significant percentage of patients will have coexistent urolithiasis (248). Abdominal ultrasound serves as an excellent screening test and may be performed when a perinephric abscess is suspected. However, it is limited in diagnostic ability in the retroperitoneum by overlying bowel gas, large body habitus, and its relative lack of specificity (119). Although sonography is able to clearly image fluid collections in and around the kidneys, it is unable to detect fascial planes or distinguish the nature of the fluid collection; therefore needle aspiration of the fluid may be necessary to arrive at the correct diagnosis. On the other hand, CT scanning provides more detailed information about the size, content, and extent of the retroperitoneal process, making it the diagnostic procedure of choice in the evaluation of retroperitoneal abscess (82,119,142). Typical findings include the demonstration of air–fluid levels within the mass and the frequent extension of the process along fascial planes that may even reach the pelvis. Its accuracy has been reported to be as high as 96% (170). Angiography and radionuclide imaging in the evaluation of retroperitoneal abscess have not proved to be of great help in enhancing the diagnostic capability and are therefore seldom, if ever, used (170). MRI is useful in detecting and diagnosing retroperitoneal abscesses (252). However, the availability, lower cost, sensitivity, and ability to drain an abscess at the time the diagnosis have made CT the modality of choice.

Management

The most important aspect in the management of retroperitoneal abscesses is to avoid a delay in diagnosis so that prompt and effective drainage may be attained. Relatively large retroperitoneal abscesses may be treated by percutaneous drainage and antibiotic therapy (28,83,88). As stated by Gerzof and co-workers (83), the basic principles of percutaneous drainage of retroperitoneal abscesses are (a) evaluation of the extent of the abscess by cross-sectional imaging (CT scanning being the preferred method); (b) identification of a safe, extraperitoneal, percutaneous window; (c) diagnostic aspiration (because cross-sectional imaging may not be entirely specific); and (d) placement of an indwelling catheter for drainage of the abscess cavity. Multilocular abscesses may also be treated using multiple drainage catheters (261). Adequate drainage of the abscess cavity and resolution of the process can be studied by cross-sectional imaging and injecting contrast material into the cavity (21). CT imaging, aspiration for diagnosis and culture, and drain placement can all be performed without the patient ever leaving the CT suite.

Antibiotic coverage for skin flora is best administered before aspiration and drain placement; Gram stain results will then guide coverage until culture and sensitivity results return. Broad-spectrum antibiotic coverage may be used in patients with clinical sepsis or poor reserves. Antibiotic therapy will be tailored to the culture and sensitivity testing of the aspirate based on identification of the offending organism. In a report on 161 adults, Brook and Frazier (30) highlighted the predominance of polymicrobial aerobic–anaerobic nature of retroperitoneal abscesses. Aerobes were recovered from only 21% abscesses and anaerobes from only 21%, whereas 82% of abscesses were polymicrobial. The most commonly cultured aerobic and facultative organisms included *Escherichia coli* (37%), *Klebsiella pneumonia* (12%), and group D streptococcus (12%), whereas the most predominant anaerobes were *Peptostreptococcus* species (59%), *Bacteroides fragilis* (41%), *Prevotella* species (14%), and *Clostridium* species (14%). Brook (29) also reported the microbial growth from 41 children with retroperitoneal abscesses; 83% of infections were polymicrobial, with 54% containing *Bacteroides* species, 46% containing *E. coli*, 44% having *Peptostreptococcus* species, 15% having *Staphylococcus aureus*, and 12% containing *Prevotella* species. Gram stain of the aspirate is mandatory because a culture will be negative in 5% to 10% of cases (236).

The drainage catheter is removed when signs of clinical improvement, minimal drainage, and little or no fluid remaining in the abscess cavity are noted. Excellent results have been reported, with cure rates between 70% and 85% (21,28,88,262). Abscess recurrence has been observed in 10% of cases (21,262).

Surgical management is still required for large abscesses and for cases in which percutaneous drainage would be hazardous or have little chance of success (e.g., in cases with large, multiloculated abscesses and in those with thick, purulent material), for recurrent abscesses unsuccessfully treated by percutaneous modalities, and for patients with a nonfunctioning kidney in whom nephrectomy is carried out at the time of abscess drainage. In addition, surgical correction of any obstructive process must be considered to alleviate an underlying cause of abscess.

Spontaneous Retroperitoneal Hemorrhage

Spontaneous retroperitoneal hemorrhage is most commonly the result of trauma or rupture of an abdominal aortic aneurysm. If these causes are ruled out, a variety of uncommon causes, often with genitourinary significance and with significant potential for morbidity and mortality, must be considered. Because treatment depends on the specific cause, an awareness of the potential causes and an aggressive diagnostic approach are essential. Pode and Caine (204) published an excellent in-depth review of this subject.

Etiology

The causes of spontaneous retroperitoneal hemorrhage are reviewed in Table 25.10. As can be seen, many of these entities are of urologic significance; in fact, excluding retroperitoneal trauma and ruptured abdominal aortic aneurysms, in most cases, the bleeding is from the kidney or adrenal gland.

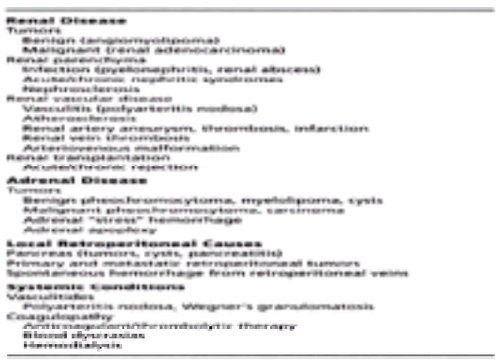

TABLE 25.10. CAUSES OF SPONTANEOUS RETROPERITONEAL HEMORRHAGE

Retroperitoneal hemorrhage secondary to spontaneous rupture of the renal parenchyma was first reported by Bonet in 1700 and described and classified by Wunderlich in 1956; it has been referred to as *Wunderlich's disease* or *syndrome* (205). McDougal and associates (165) reviewed the English literature up to 1974 and reported the findings in 78 cases. A subsequent review of the literature between 1974 and 1984 reported by Cinman and associates (43) documented an additional 27 cases. From these reviews and other subsequent reports, it is clear that most cases of retroperitoneal hemorrhage caused by spontaneous renal parenchyma rupture are associated with tumors of the kidney. Benign and malignant tumors occur with equal frequency in this setting. Although spontaneous renal parenchyma rupture has been associated with a variety of benign tumors, including lipomas, adenomas, and cysts, most cases are associated with angiomyolipoma. This tumor is highly vascular and is prone to hemorrhage. In one review of patients with angiomyolipomas, approximately half of patients with tumors larger than 4 cm presented with retroperitoneal hemorrhage, and a significant number, approaching 10%, presented with symptoms and signs of shock (185). There is an increased tendency for hemorrhage with angiomyolipoma associated with the hemodynamic changes of pregnancy.

As with benign renal tumors, a number of histologic types of malignant renal lesions have been reported in association with spontaneous retroperitoneal hemorrhage; however, most are renal adenocarcinomas. Although fewer than 1% of patients with renal carcinoma present with retroperitoneal bleeding, because of its overall relative incidence, it is the most common cause of spontaneous retroperitoneal hemorrhage (239).

Other renal diseases associated with spontaneous retroperitoneal hemorrhage include pyelonephritis with or without renal or perirenal abscess, other renal inflammatory disorders, and renal vascular disease. A renal vascular cause is present in approximately 20% of patients with spontaneous retroperitoneal hemorrhage. This cause may be renal involvement in a systemic vasculitic syndrome, such as polyarteritis nodosa, or it may take the form of a ruptured renal artery aneurysm, renal vein thrombosis, or arteriovenous malformation. Polyarteritis nodosa is a well-recognized cause of spontaneous retroperitoneal hemorrhage (204,241). This condition, which is an immunologically mediated disease affecting small and medium arteries, is associated with renal involvement in more than 80% of cases. As with renal artery aneurysms in general, there appears to be an increased risk of bleeding in the setting of uncontrolled hypertension and pregnancy.

The adrenal gland is also a well-documented source of spontaneous retroperitoneal hemorrhage. In most cases, clinically significant hemorrhage from an adrenal source is in the setting of severe stress (e.g., pregnancy, trauma, sepsis, burns). Massive bleeding has also been reported in association with adrenal tumors, including pheochromocytoma, myelolipoma, and adrenal carcinoma (86,145,147). Rarely, retroperitoneal bleeding originates from an otherwise normal adrenal gland without recognizable precipitating factors or underlying systemic disease. This condition, referred to as *adrenal apoplexy,* is difficult to diagnose unless it is specifically included in the differential (36,217,251).

Other causes of spontaneous retroperitoneal hemorrhage include diseases of the pancreas, as well as primary and metastatic retroperitoneal tumors. Rarely, spontaneous hemorrhage may arise from retroperitoneal veins. Most of these cases, often involving the common iliac vein or its branches, are associated with proximal venous obstruction secondary to thrombosis (204). Iatrogenic retroperitoneal hemorrhage may occur after groin access is used for percutaneous vascular studies and procedures. Poupart's ligament distinguishes the external iliac vessel from the femoral vessel, and access obtained superior to the inguinal ligament may be difficult to compress; therefore bleeding can occur within the retroperitoneal space. Systemic conditions resulting in spontaneous retroperitoneal hemorrhage include a number of vasculitides, such as polyarteritis nodosa, and coagulopathic states, most notably, iatrogenic anticoagulant and thrombolytic therapy, as well as blood dyscrasias. Also included here are patients receiving long-term dialysis, who, in addition to undergoing frequent systemic anticoagulation, have intrinsic platelet dysfunction because of their uremic state. It should also be emphasized, as pointed out by Pode and Caine (204), that there is a possibility that the coagulopathic state may merely unmask an additional local factor, such as a tumor, that caused the retroperitoneal hemorrhage.

Clinical Features

The clinical signs and symptoms of patients with spontaneous retroperitoneal hemorrhage are protean and nonspecific. As a result, a high index of suspicion and an aggressive diagnostic approach are necessary for a satisfactory outcome. Clinical presentations can range from a patient with vague abdominal or flank pain that gradually developed over several days to a severely ill patient with clinical features suggestive of an intraabdominal catastrophe. In addition to the presence of localized abdominal or flank pain in most patients, other findings may include microscopic or gross hematuria, occurring in most patients with retroperitoneal hemorrhage secondary to a renal cause, and evidence of significant blood loss. Patients also commonly have nonspecific GI complaints, such as nausea and vomiting, and may have a palpable mass and tenderness over the involved area. Peritoneal signs or diaphragmatic irritation also are occasionally present. Variable degrees of renal functional impairment are common. Important historical factors include trauma, anticoagulant use, vasculitis, tuberous sclerosis, hemodialysis, and pregnancy.

The diagnosis of bilateral spontaneous adrenal hemorrhage occurring in the clinical setting of severe stress requires a high index of suspicion. This clinical scenario usually occurs in an already critically ill patient who subsequently exhibits progressive deterioration. Clinical features that may suggest the diagnosis include mental status changes, low-grade fever, hypotension refractory to treatment, fluid and electrolyte abnormalities (most commonly hyponatremia), and variable degrees of renal functional impairment (204,275).

Diagnosis

Currently, based on clinical findings and the use of modern imaging modalities, a diagnosis of spontaneous retroperitoneal hemorrhage and the underlying cause can be determined before surgical exploration in most cases (20,204). In contrast, before the advent of CT scanning, when imaging studies were based largely on excretory urography and angiography, the specific diagnosis was rarely made before surgical exploration (165). CT is currently the most valuable imaging modality for patients with spontaneous retroperitoneal hemorrhage. CT readily demonstrates the presence and extent of the hematoma and also may demonstrate the underlying pathology responsible, such as a solid renal mass suggestive of a renal carcinoma or, if fatty tissue is identified within the tumor, an angiomyolipoma.

In a recent study of 18 patients with spontaneous retroperitoneal hemorrhage, Belville and associates (20) reported a diagnostic accuracy of 92% in 12 patients whose preoperative CT scans revealed a solid mass. In the remaining six patients, no mass was appreciated at the time of the initial study. One of these patients had CT findings characteristic of renal infarction; in two others, follow-up CT scans obtained after the hematoma had been reabsorbed revealed a small renal cell carcinoma, enabling an accurate diagnosis and appropriate subsequent treatment. The other three patients underwent exploratory laparotomy and nephrectomy, which revealed a small renal cell carcinoma in one patient, an angiomyolipoma in another, and no apparent abnormality accounting for the bleeding was discovered in the third patient.

CT scanning may also indicate the presence of polyarteritis nodosa, with multiple wedge-shaped defects present on the contrast-enhanced scan indicative of severe ischemia or infarction (106,204). When a mass is not appreciated on the initial CT scan in the presence of a retroperitoneal hemorrhage, Bosniak (24) has stressed

the importance of technique in CT imaging. Optimally, both precontrast and postcontrast scans should be obtained, with thin cuts (5 mm) taken through the adrenal and renal beds. Furthermore, until the hematoma is completely reabsorbed, follow-up serial CT scans are crucial. Follow-up scans allow detection of a small renal mass previously obscured by the hematoma.

Although angiography was more important before the advent of CT scanning, it is still recommended in patients with spontaneous retroperitoneal hemorrhage, primarily to rule out the presence of a vascular cause. It may also add valuable diagnostic information if the CT findings are equivocal (204). Furthermore, angiography may be therapeutic, allowing selective embolization of active bleeding sites. Other diagnostic maneuvers may be useful depending on the presumed cause of retroperitoneal hemorrhage. For example, tests of adrenocortical and adrenomedullary function are mandatory in the presence of a suprarenal mass associated with retroperitoneal hemorrhage.

Ultrasound is also an important diagnostic imaging modality in the setting of spontaneous retroperitoneal hemorrhage. In addition to allowing one to rapidly rule out the presence of an abdominal aortic aneurysm, in most cases, an ultrasound examination will reveal the presence and the location of a retroperitoneal hematoma. Although less useful than a CT scan, it also may suggest the underlying pathology by demonstrating a renal or suprarenal mass associated with the hematoma. However, in most cases, ultrasound is unable to discriminate a solid mass from a hematoma.

Management

Optimal management of patients with spontaneous retroperitoneal hemorrhage depends on a high index of suspicion, an awareness of potential etiologic factors, an aggressive and systematic diagnostic approach, and treatment tailored to the specific cause. Occasionally, patients with spontaneous retroperitoneal hemorrhage may be critically ill, with symptoms and signs of hypovolemic shock at presentation, perhaps even necessitating an emergency exploratory laparotomy for definitive diagnosis and treatment. In most cases, however, patients can be resuscitated and stabilized such that the necessary diagnostic studies can be performed and a preoperative diagnosis made.

Patients with spontaneous retroperitoneal hemorrhage in a setting of a systemic coagulopathy should be managed conservatively because an obvious bleeding source is almost never found at the time of exploration (173). Furthermore, angiography also generally fails to reveal a specific bleeding site in this situation (204). Therefore management should focus on measures to correct the bleeding diathesis and restore blood volume as indicated.

Spontaneous retroperitoneal hemorrhage in the setting of systemic vasculitis, most commonly secondary to renal involvement by polyarteritis nodosa, is also best approached conservatively. The importance of a renal-sparing approach in this situation is underscored by the nearly always bilateral involvement of the kidneys in this disease and the propensity for progressive renal deterioration. Medical management using immunosuppressive agents may be effective (149). When the clinical situation dictates a more aggressive approach, nephrectomy should still be avoided if possible; selective embolization and partial nephrectomy are viable options (204,241).

If the CT scan reveals a renal tumor, the possibility of angiomyolipoma must be entertained. When a diagnosis of angiomyolipoma is made, especially in the setting of tuberous sclerosis with a high frequency of bilateral involvement, a renal-sparing approach, usually in the form of a partial nephrectomy, may prove optimal. If a solid tumor suggestive of renal malignancy is identified, in most cases, one may then properly evaluate the patient preoperatively, as one would for any patient with a solid renal mass suggestive of malignancy.

In the past, most authors have advocated prompt surgical exploration in the setting of spontaneous renal hemorrhage arising from the kidney with no apparent lesion on imaging analysis (61,131,165). This philosophy was based largely on experience before CT availability; on exploration in this situation, a large number of kidneys were found to harbor renal adenocarcinoma. However, in a number of cases, otherwise normal kidneys were also removed. With the advent of CT scanning, it seems prudent to monitor the regression of the hematoma by serial CT scan examinations with thin cuts through the adrenal and renal beds until the hematoma is completely reabsorbed, thereby avoiding unnecessary exploration with the risk of removal of a normal kidney (20,24).

If the cause of spontaneous retroperitoneal hemorrhage is an adrenal tumor, tests of adrenal medullary and cortical function are mandatory. Because of the extremely high mortality rate associated with the resection of an unsuspected pheochromocytoma, every effort should be made to diagnose this tumor preoperatively and to prepare the patient properly for surgery. Furthermore, a high index of suspicion for the presence of bilateral adrenal hemorrhage in the setting of severe stress should lead to further diagnostic evaluation with functional adrenal studies and the prompt administration of corticosteroids as indicated.

CONCLUSION

This chapter addressed a number of conditions that pose major diagnostic and therapeutic challenges to the urologic surgeon. A high index of suspicion is necessary to provide proper care for patients with disease of the retroperitoneum. In some cases, it is prudent to take a multiteam approach to surgical procedures, at times involving the general surgeon or vascular surgeon.

Chapter References

The past 30 years have seen an exponential rise in the literature characterizing normal and pathologic bladder function. Earlier reviews placed a heavy emphasis on the physiology of micturition (352) and the pharmacology of the urinary bladder (213,340). Basic neurophysiology research with identification of neural pathways controlling micturition began to appear in the literature with increasing frequency and ever greater sophistication (44,87,94). With the development of monoclonal antibodies, it now is possible to look at specific aspects of protein expression to study how physiology and microanatomy are altered by normal development, aging, and obstruction. The last 10 years have seen a remarkable increase in the number of papers using modern molecular techniques such as Western blotting (to probe for protein expression) along with Northern blotting and polymerase chain reaction technology (to probe for mRNA expression). Research studying bladder function in knockout and transgenic mice is just beginning to appear in the urology literature. DNA microarray technology now is readily available, which allows for the simultaneous comparison of thousands of genes between two tissues (i.e., normal versus pathologic). A growing number of basic scientists now are conducting active research in bladder function, and the urologic literature in the basic sciences will expand at an even faster pace. Even the most current research monographs (12,23,26,230,366,366a) will have an effective scientific half-life of 2 or 3 years.

With these ideas in mind, we wish to briefly express our objectives for this chapter. If we attempted to cover every aspect of urinary bladder function in maximal detail, the overwhelming amount of information would result in an unwieldy chapter of limited use to the practicing clinician. This makes it necessary for us to exercise judgment regarding which literature and viewpoints will be emphasized; however, every effort will be made to present divergent viewpoints. In addition to summarizing

current views on the structure and function of the lower urinary tract, we wish to prepare the reader for the challenge of keeping up with this literature over the next 5 years.

The lower urinary tract functions as a group of interrelated structures whose integrated function allows for the normal voiding cycle to occur. In brief, the normal voiding cycle consists of bladder filling and storage at low pressure with perfect continence, and the subsequent voluntary and efficient expulsion of urine also at low pressure. With normal filling, a gradual rise in intravesical pressure occurs despite large increases in volume; the bladder is one of the most compliant structures in the body. Bladder filling is accompanied by an increase in proximal urethral resistance resulting from increased tension in the urethral striated muscle, called the *striated sphincter.* Normal bladder filling is not accompanied by phasic involuntary smooth muscle contractions or a significant tonic increase in intravesical pressure; contractility is suppressed until the proper moment. Under normal conditions, there is no urinary leakage, even with increases in abdominal pressure. At some point, sensory pathways convey to the central nervous system (CNS) the sensation of fullness, and if the situation is appropriate, micturition is initiated. At this point, a complex series of coordinated neural signals initiates the detrusor contraction, which must be accompanied by simultaneous funneling of the bladder neck and relaxation of the bladder outlet. During this voiding phase, the neural excitatory input to the striated musculature of the pelvic floor ceases. Once voiding is completed, the tension returns to the bladder outlet, and the detrusor muscle relaxes to allow a new cycle of filling to begin.

Each aspect of this voiding cycle is described in detail in this chapter. This requires an integration of basic concepts from several major disciplines. For example, the urinary bladder's main distinguishing feature is its remarkable compliance—the ability to store large volumes at low pressures. To explain this one property requires an understanding of biomechanics, neurophysiology, smooth muscle physiology, pharmacology, extracellular matrix (ECM) biochemistry, and basic molecular cell biology.

Because it is impossible to list all the data in an order that is entirely logical on the first reading, we suggest an initial rapid review of the chapter to capture the major features. This can be followed by an in-depth reading with the use of bibliographic references to enhance understanding of some of the more complex topics. Schematic diagrams have been included; they are simplifications of complex biologic systems, but serve to introduce the reader to essential basic concepts. We wish to avoid presenting pure experimental data without correlating them with some aspect of the micturition cycle. In the bibliography, we place an emphasis on current review articles and thus apologize to those authors whose classic references have been omitted.

The reader of this chapter is encouraged to be critical of our views. Over the previous editions of this chapter (354), we have offered the following recommendations (with only minor revisions) when considering this contribution, as well as the current and future literature.

1. A bewildering array of experimental models exist, which must be considered carefully. A small change in one model may make the results impossible to compare with another.
2. Significant differences do exist within species; results in one animal species do not necessarily hold up in another species nor in humans.
3. Results obtained in another organ or tissue (e.g., cardiac or vascular, intestinal, or uterine smooth muscle) may not be equivalent in the smooth muscle of the lower urinary tract, even if the tissues compared are from the same species or are anatomically adjacent.
4. Substantial changes in anatomy, physiology, pharmacology, and molecular properties of the smooth muscle of the lower urinary tract may be secondary to alterations associated with or induced by gender, normal aging, hormonal status (e.g., menopause, pregnancy), denervation, decentralization, stretch, and drug effects (including those used in laboratory and clinical anesthetics).
5. *In vitro* experimental results are not always equivalent to *in vivo* findings, and neither of these is necessarily equivalent to “normal.”
6. The lack of an adequate control group makes experimental work in human tissues far more difficult to interpret. This is not to imply that such studies have no merit, as long as this limitation is acknowledged; if properly performed and presented, these studies can contribute a great deal to the literature.
7. Anatomy or histology do not necessarily imply a specific function or physiologic finding will be present, and vice versa.
8. Any *in vivo* or *in vitro* effect induced by an agonist or antagonist does not necessarily impart a major physiologic significance to this neurotransmitter or its associated component of the nervous system under normal systems.
9. Pressure- or tension-generating ability in the whole organ or a strip does not necessarily correlate with contractility, and neither need correlate with bladder emptying ability.
10. The presence of receptors in a tissue in and of itself does not imply innervation or function.
11. Changes in mRNA expression alone are not necessarily of physiologic significance, unless accompanied by an associated change in protein expression that can be correlated with the physiologic findings.
12. Even a seemingly simple concept such as bladder compliance is a highly complex biologic property that probably involves the expression of multiple proteins in the correct chronologic order as well as proper anatomic domain with the proper spatial orientation. It is unwise to assume that variation in expression of one protein alone is responsible for change in the observed physiology.
13. The physiology of any portion or type of normal and abnormal bladder function usually can be explained by at least a part of one complete theory of micturition. This does not validate the entire theory or invalidate another.
14. Authors (ourselves included, despite our best efforts) must be somewhat selective in their citation of references. References that cite an author's point of view tend to be cited more conspicuously and more favorably than those that do not.

RELEVANT ANATOMY

The Bladder

The urinary bladder is a hollow muscular organ that, from an anatomic viewpoint, may be divided into the detrusor and trigone. From a pharmacologic and physiologic standpoint, the bladder is best divided into a body and base, because these two zones of the bladder differ substantially (123,292). The urinary bladder wall consists of three layers: an outer serosal layer primarily composed of connective tissue, a smooth muscle layer, and an inner mucous membrane completely lining the interior. In the human, the outer serosal layers and the smooth muscle layers are less distinct when viewed histologically.

Mucosal Layer

The mucosa of the bladder is composed of two zones: (a) the urothelium, composed of transitional epithelial cells that rest on (b) the lamina propria, a supporting structure. The lamina propria contains ECM components, fibroblasts, and sparse smooth muscle cells. Evidence suggests that the fibroblasts (334) and smooth muscle cells (127) may become activated during obstruction to increase the secretion of matrix components in this layer. The transitional cells are a specialized epithelial layer whose structure allows the cells to unfold and expand their size as the bladder fills. These cells also are highly active metabolically, with significant enzymatic activity for enzymes involved in the tricarboxylic acid cycle, which are most likely required because of the tremendous osmotic gradients that exist between the cytosol and the bladder lumen (158). The urothelium also is important during normal embryologic development and bladder regeneration in ways that still are not fully understood. Baskin and colleagues (23,24) have shown that urothelial cells must be present if primitive mesenchyme from the fetal rat bladder is to differentiate into smooth muscle. Sutherland and associates (327) also have shown that in an acellular matrix graft inserted into the rat bladder, urothelial ingrowth precedes the appearance of smooth muscle. These studies imply that the urothelium secretes factors that act locally to affect cellular growth and differentiation. Freeman and co-authors (129) have demonstrated that cultured urothelium is capable of secreting heparin-binding epidermal growth factor, which is a potent mitogen for fibroblasts and smooth muscle.

Detrusor

The detrusor smooth muscle layer is heterogeneous, consisting of smooth muscle cells, fibroblasts, collagens, proteoglycans, elastin, and numerous other molecules in various stages of being identified. The actual smooth muscle fraction in a cross-sectional area of detrusor smooth muscle as determined by morphometric analysis may vary from 50% to 60%, and this fraction may diminish in the face of obstruction (287,305,320). Interspersed between these smooth muscle cells and bundles are zones of connective tissue (i.e., fibroblasts embedded within the ECM) that allow for force transmission from cell to cell. Smooth muscle has no skeleton upon which to exert its forces to allow for the propagation of energy. It also is generally agreed upon that, in the resting position, the detrusor smooth muscle bundles lack a particular uniform orientation, unlike striated or cardiac muscle. Histologic evidence also suggests that as the bladder is stretched, these muscle bundles (347) and matrix elements (227) become reoriented.

The bundles of the detrusor smooth muscle merge into the trigone and bladder base. The bladder base is defined as that zone below a circumferential line, determined by the level at which the ureters enter posteriorly. As such, it has an anterior and a posterior zone. The posterior zone includes the urethra and ureteral orifices, and is called the *trigone.* If one views the urethrovesical junction smooth muscle in cross section, these muscle bundles appear to form a structure analogous

to the shutter of a camera (Fig. 26A.1). At baseline when these fibers are at rest and during passive filling, occlusion of the bladder outlet occurs. Realignment and coordinated relaxation of these fibers during micturition is critical if the outlet is to open and allow for low-pressure voiding. The trigone may be divided into a superficial and a deep smooth muscle layer, and continuity has been reported between the deep layer of the detrusor (123,137) and ureter (333).

FIGURE 26A.1. Smooth muscle bundles in the area of the bladder neck. (From Woodburne RT. Anatomy of the bladder. In: Boyarsky S, ed. *The neurogenic bladder.* Baltimore: Williams & Wilkins, 1967, with permission.)

Female Urethra

The adult female urethra is approximately 4 to 6 cm in length and 6 mm in diameter. It extends from the bladder neck behind the pubic symphysis and lies embedded in the anterior wall of the vagina until it reaches the meatus at the perineum. The wall of the female urethra is composed of an outer muscular layer and an inner epithelial layer. This inner epithelial layer generally is thrown into folds that form a mucosal seal (Fig. 26A.2), which is thought to contribute to the continence mechanism (373). The smooth muscle component extends throughout the length of the inner epithelial layer, and most agree on the existence of an inner longitudinal layer (137,332). Tanagho (332) believes that the outer longitudinal layer is substantial and represents a direct continuation of the detrusor layer, but this is disputed by Gosling (137,138) and Dorschner and co-workers (111), who believe that no such continuity exists. Arner and associates (16) have shown that different shortening velocities for fibers exist within the inner and outer smooth muscle layers of the rabbit urethra. The urethral smooth muscle cells are embedded in ECM, which, according to Hickey and co-authors (147), may account for the major structural component in the human female urethra. These distinctions will prove important in future research, considering how much active urethral smooth muscle "tone" is involved in maintaining continence. The striated component of the female urethra is discussed in a subsequent section.

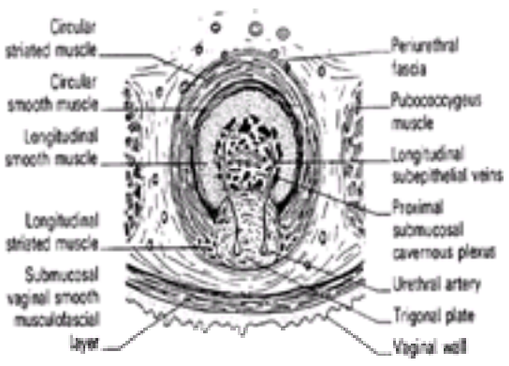

FIGURE 26A.2. Cross-sectional view of the female urethra showing the longitudinal arrangements of the smooth muscle fibers and the circular striated fibers. This diagram emphasizes the richly vascularized submucosal layer, which helps create a seal effect. (From Asmussen M, Miller A, eds. *Clinical gynaecologic urology.* Oxford: Blackwell Scientific, 1983, with permission.)

Male Urethra

The male urethra has been divided into prostatic, membranous, bulbar, and anterior zones, with the latter two zones functioning as conduits with minimal urodynamic significance. The preprostatic urethra has been described as being 1 to 1.5 cm in length and contains smooth muscle bundles embedded in collagen oriented in a distinct circular collar that becomes continuous distally with the prostatic capsule. The prostatic urethra is 3 to 4 cm long. The male posterior and membranous urethra contains an inner longitudinal and outer circular layer of smooth muscle, with poor development in the dorsal midline (331). These smooth muscle fibers are in continuity with the apex of the prostate, and distally with the bulbar urethra.

Anatomic Continuity Between Bladder and Urethra

Many authors support the view that trigonal smooth muscle bundles extend down into the urethra (193,330,360,361). This extension is consistent with the hypothesis that, during micturition, there is an opening and funneling of the bladder neck associated with a readjustment of the urethrovesical junction (angle) that depends on these anatomic relationships. Others disagree with this view and believe that the urethral smooth muscle is in no way connected with the trigone (137,246). A current view is that the unique physiology and pharmacology of the trigone and urethra are more likely to explain the funneling of the bladder neck seen with micturition (111) as opposed to anatomic relationships.

Striated Muscle Component

The once-classic view of the external sphincter—that of striated muscle fibers within the leaves of a "urogenital diaphragm" that, when contracted, will stop the urinary flow (352)—is no longer valid. The current view is that the urethral striated musculature has both an intrinsic component (i.e., within the urethral wall) and extrinsic or extramural components (42). The intrinsic layer, or *rhabdosphincter,* wraps around the urethral lumen in an oblique spiral pattern, and its fibers interdigitate with the outer muscular layer of the urethra. These fibers have a more circular orientation in the male, are thinner posteriorly, and extend from the verumontanum to the striated pelvic floor musculature. The middle third of the female urethra contains the most prominent intrinsic skeletal muscle, and it also is deficient in the posterior midline.

In both sexes, the distal end of the intrinsic striated muscle component is described as lying adjacent to a bulky skeletal muscle group oriented in the horizontal plane of the pelvic floor and encircling the membranous urethra. This is the classic description of the "external urinary sphincter" of standard anatomy texts. This extrinsic skeletal muscle is separate from the urethral wall despite anatomic apposition, and is related to the levator ani muscle group. The older literature implies a clear-cut separation between the intrinsic and extrinsic striated sphincter groups. In truth, this distinction cannot always be made on gross inspection of the sphincter, but relies on a histologic assessment. Oelrich (275) thinks that the skeletal muscle in the male urethra is derived from a single primordium extending from the bladder to the perineal membrane. The prostate, which evolves from glandular differentiation within the urethra, grows predominately into the posterior midline and creates atrophy of these striated muscle fibers (Fig. 26A.3). This also can help explain why striated muscle fibers may be seen in radical prostatectomy specimens at points far removed from the apex.

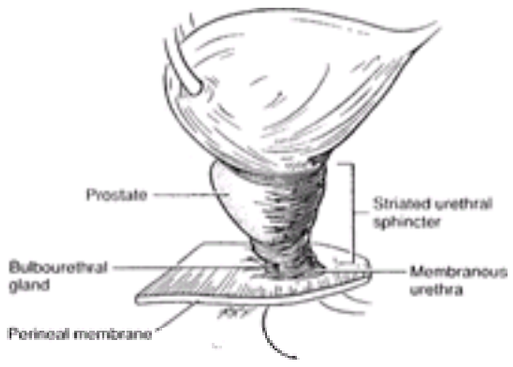

FIGURE 26A.3. This schematic representation conveys Oelrich's concept of the striated urethral sphincter in the male, which varies in its circumferential extent as it extends from the vesicoprostatic junction down to the level of the perineal membrane. (From Angermeir KW, Devine CJ. Anatomy of the penis and male perineum. *AUA Update Series* 1994;XIII:3, with permission.)

Oelrich (274) describes two striated muscle components in the female: one surrounding the urethra alone, and one enveloping the urethral and vaginal introitus. Both of these striated muscle groups become infiltrated with smooth muscle, making these descriptions histologic as opposed to surgical. A separate bundle of striated muscle fibers loop around the ventral aspect of the urethra and has attachments to the ischiopubic rami, serving as a “compressing” muscle. Again, it must be stressed that these muscles are all in continuity with one another and, taken together, form the urogenital hiatus of the pelvic diaphragm. The use of dynamic or functional magnetic resonance imaging (MRI) will help unravel the functional impact that these muscle groups have in maintaining continence. Mikuma and colleagues (250) reported on MRI scanning in young male volunteers and noted that, with pelvic floor contraction, the urethra thinned in the sphincteric area, and the entire urethra and prostate were pulled anteriorly toward the pubic bone, effectively narrowing the retropubic space (Fig. 26A.4).

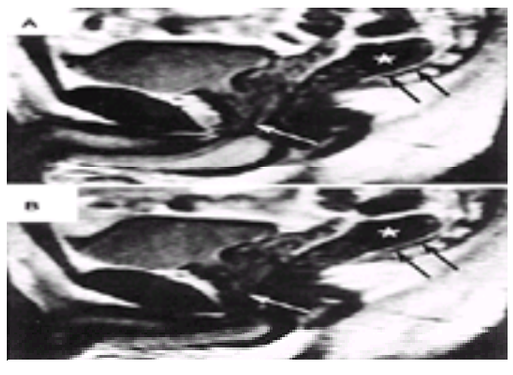

FIGURE 26A.4. Sagittal magnetic resonance images of the male pelvis taken at rest **(A)** and during contraction of the pelvic floor muscles **(B).** These functional magnetic resonance images show that with contraction of the pelvic floor there is an elevation of the prostate and bladder base such that the membranous urethra is elongated (an average of 0.5 cm) and the retropubic space narrows. (From Mikuma N, Tamagawa M, Morita K, et al. Magnetic resonance imaging of the male pelvic floor: the anatomical configuration and dynamic movement in healthy men. *Neurourol Urodyn* 1998;17:591, with permission.)

Sphincter Concept

Smooth Sphincter

No classic anatomic “sphincter” exists at the bladder neck that is analogous to the coils of the anal sphincter. Instead, there is a shutterlike opening (Fig. 26A.1) that consists of swirls of smooth muscle bundles that are rich in collagen and elastin. Thus the tone exerted on the lumen of the bladder neck is dependent on the passive recoil forces caused by the ECM components and the active tone of the smooth muscle. Tone in this region and in the proximal urethra increases as the bladder fills, so that urethral pressure exceeds intravesical pressure. With normal micturition, this smooth muscle (“sphincter”) tone is reduced, then followed by a rise in detrusor contractile force to produce low-pressure voiding. A functional obstruction can occur at this point resulting from incoordination between the bladder neck and the detrusor (smooth sphincter dyssynergia), although this is rare clinically. Dyssynergia is far more likely to result from incoordination between the detrusor and the striated sphincters.

Striated Sphincters

The striated sphincters comprise both intrinsic and extrinsic components surrounding the female urethra and the posterior male urethra. This sphincter is not essential for continence if the bladder neck is competent (146). For example, in a male with a pelvic fracture and urethral avulsion injury, the external sphincter may be rendered incompetent, yet the patient remains continent. However, if this patient were to undergo a transurethral resection of the prostate (TURP) with cuts into the bladder neck, he very well could be rendered incontinent. *Striated detrusor sphincter dyssynergia* refers to the involuntary contraction of the striated external sphincter during a bladder contraction in a patient with neurologic disease, and implies a neurologic disease or lesion is present between the brainstem and sacral cord. The one exception to this is the urodynamic findings of what appear to be detrusor sphincter dyssynergia in the absence of any “overt” neurologic findings on clinical examination or MRI. In its extreme case, this can result in a trabeculated bladder with upper urinary tract decompensation, also known as the *Hinman syndrome,* which is seen almost exclusively in children (149).

SMOOTH MUSCLE STRUCTURE AND FUNCTION

The literature describing the physiology, structure, and molecular basis for bladder smooth muscle function continues to expand. In this section, traditional views of smooth muscle are presented and integrated with newer molecular concepts. Normal function is emphasized, but some examples of how bladder smooth muscle changes in response to outlet obstruction are offered.

Structure

Smooth muscle is composed of long slender cells, whose exact dimensions vary greatly depending on the conditions under which the tissue is studied. The average diameter of the fibers is 2 to 5 µm and the length ranges from 50 to 200 µm (298,347). Cell length, diameter, and volume are some of the most difficult experimental measurements to make, because they depend on the degree of distention that the smooth muscle is subjected to at the time the tissues are fixed. The cell membrane surface is coated with numerous pits or indentations, called *caveolae,* which probably are involved in the uptake and release of humoral substances from the muscle cell (Fig. 26A.5). These caveolae increase during normal development in rat bladder (363), and diminish with aging (125).

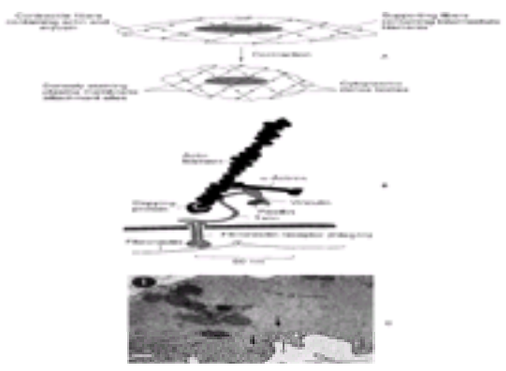

FIGURE 26A.5. A: A schematic representation of how smooth muscle contracts, which features the role of actin and myosin *(dark lines)* and their relationship to the intermediate filaments of the cytoskeleton *(light lines).* As the actin and myosin interact, these fibers shorten to produce a significant change in cell dimensions. Changes in the ratios of actin, myosin, and intermediate filaments will alter the cell's ability to contract. **B:** A schematic representation of the complex cytoskeletal elements involved in anchoring the contractile filaments to the plasma membrane. These complex interactions allow for the force of the contractile elements to be transmitted to the plasma membrane and, via the transmembrane fibronectin receptor (integrin), allow for force transmission to the extracellular matrix. **C:** An electron micrograph of a smooth muscle cell taken from the abdominal aorta fixed *in situ* and cross sectioned. Shown are the thick filaments (myosin) *(large arrows)* and small filaments (actin) *(small arrow).* Dense bodies *(d)* and surface vesicles or caveolae *(v)* also are identified. The bar in the lower right-hand corner is 1 micron. (From Alberts B, Bray D, Lewis J, et al. *Molecular biology of the cell,* 2nd ed. New York: Garland Publishing, 1989; and Chacko S, Blose SH, Adelstein RS. Phosphorylation and calcium regulation of actin activated ATPase activity of myosin isolated from cultured aortic and vas deferens smooth muscle cells. In: Casteels R, ed. *Excitation contraction coupling in smooth muscle.* New York: Elsevier/North Holland Press, 1977, with permission.)

Within the cell membrane, the cytosol contains several major organelles and a growing list of thick and thin filaments that merit discussion. The classic organelles of smooth muscle include the nucleus, mitochondria, ribosomes, and endoplasmic reticulum. Smooth muscle contains myosin and actin similar to striated muscle systems, but the myosin content is far less and actin is the predominant myofilament (Fig. 26A.5). With the increasing availability of monoclonal antibodies, a whole new family of cytoskeletal filament proteins have been described (224). Vimentin, desmin, spectrin, and caldesmon are thought to offer structural support and have been identified in bladder smooth muscle, with changes in their composition noted after outlet obstruction (74,219,371). Ankyrin, vinculin, talin, and tensin serve to anchor these filaments to the cell membrane (Fig. 26A.5). Controversy remains regarding whether these elements act merely as passive supports or, as in the case of caldesmon, actually contribute to the generation of contractile force (68,219).

Less controversy exists regarding the roles of actin and myosin in generating contractile force in bladder smooth muscle. As in striated muscle, these two proteins interact after phosphorylation of the 20-kilodalton (kDa) myosin light chain to allow for advancement of the myosin molecules along the actin filaments. The finer points of this interaction and its molecular basis are discussed in the section on excitation-contraction coupling. It is known that myosin filaments are present at ratios of 1:10 as opposed to the 1:1 ratio seen in striated muscles. Despite this difference, smooth muscle is capable of exerting tremendous contractile force equal to, and in some cases surpassing, striated muscle. However, smooth muscle has a much slower velocity of contraction.

In addition to these intracellular elements that contribute to smooth muscle tone and contractility, a major consideration is the role of the ECM. It is impossible to offer a current review of bladder smooth muscle without discussing the role of the connective tissue. Unlike skeletal muscle, which transmits its force by tendons attached to bone, smooth muscle cells can transmit force only by contracting against one another. The fibroblasts, collagens, elastins, and glycosaminoglycans are the elements of the ECM that serve to bind the smooth muscle cells together. Depending on the way in which the morphometric measurements are made, this matrix component may occupy up to 50% of the cross-sectional area on histologic examination. Molecular aspects of the ECM are discussed in greater detail in a subsequent section.

Fiber Arrangement and Spread of the Contractile Impulse

Two broad categories of smooth muscle have been proposed on the basis of general physiologic characteristics: multiunit and unitary (or syncytial). The multiunit smooth muscle receives a rich 1:1 innervation between the neurons and muscle cells. A thin glycoprotein layer shields these cells from one another so that they act truly independently in response to stimulation. These systems tend to be under direct control of the nervous system, and such an arrangement confers major advantages for fine muscle control. Examples include the ciliary and iris muscles of the eye. In contrast, unitary (or syncytial) smooth muscle differs by receiving a much less extensive innervation, with cells arranged in sheets or bundles. Instead of having insulating glycoproteins between the adjacent cells, gap junctions function as bridging ion channels connecting one cell to another. Motor function in these muscle groups is highly dependent on myogenic conduction from one fiber to another. Classic examples of such muscle groups are the ureter and uterus. Despite the fact that no gap junction proteins have been identified in bladder smooth muscle, it appears to share some characteristics of both multiunit and unitary types (78). Using a guinea pig model, Mostwin and colleagues (255,256) have demonstrated that bladder smooth muscle has some cable properties, implying that some cell-to-cell communication exists.

Innervation

Some current concepts in the structural relationships of the peripheral autonomic nervous system to the bladder smooth muscle cells should be reviewed (153). Neuroeffector junctions are elaborate in smooth muscle, with long neurons sprouting off small varicosities 1 to 2 µm in diameter in a zone that is free of enveloping Schwann cells. As the nerve is depolarized along its axis, these varicosities release their neurotransmitters from stored secretory vesicles. Each varicosity is located adjacent to a cleft 20 to 50 µm wide across which these transmitters diffuse (Fig. 26A.6). Vesicles containing neurotransmitters are a histologic hallmark of the autonomic nerve endings, and are identified via immunohistochemical techniques (169).

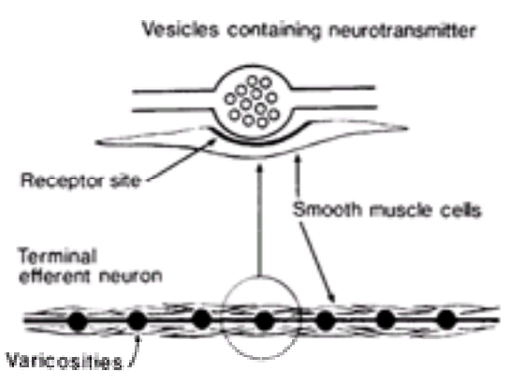

FIGURE 26A.6. Peripheral autonomic neuroeffector junction. (From Mundy AR. Clinical physiology of the bladder, urethra, and pelvic floor. In: Mundy AR, Stephenson TP, Wein AJ, eds. *Urodynamics: principles, practice, and application.* New York: Churchill Livingstone, 1984, with permission.)

Excitation-contraction Coupling

Once a neurotransmitter crosses the postsynaptic cleft, the molecular changes that lead to force generation are complex. The overall process of force generation following ligand binding is called *excitation-contraction coupling.* It is useful to divide this general topic into two distinct headings: (a) the molecular events leading to cell contraction, and (b) those events associated with cell relaxation. A simplified schematic representation of these molecular events is outlined in Fig. 26A.7 (contraction) and Fig. 26A.8 (relaxation), and serve as a useful starting point for this discussion.

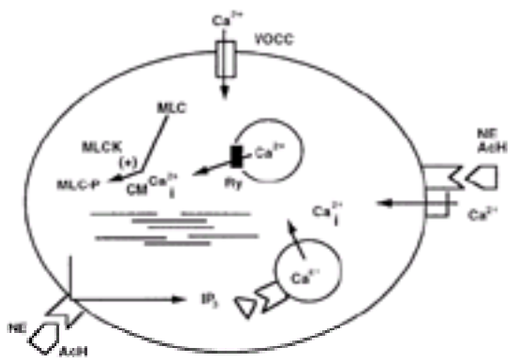

FIGURE 26A.7. A schematic outline of the events underlying excitation-contraction coupling. Excitation is induced by a ligand (NE/AcH) binding to specific cell surface receptors (adrenergic or muscarinic), which produces a rise in cytosolic free calcium. This increased cytosolic calcium may be secondary to extracellular calcium influx across the plasma membrane, or via calcium release from intracellular storage sites triggered by one of several secondary messengers such as IP_3. The release of intracellular calcium takes place via a calcium channel that, in many species, is sensitive to the effects of ryanodine *(Ry).* The rise in free cytosolic calcium triggers the phosphorylation of myosin light chain kinase, which initiates the development of contractile force. CM, cellular matrix; MLC, myosin light chain; MLCK, myosin light-chain kinase; MLC-P, myosin light chain phosphate; VOCC, voltage-operated calcium channel.

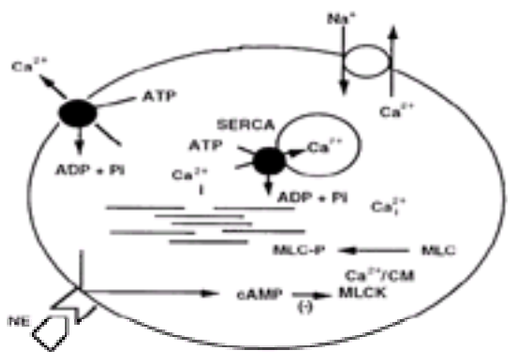

FIGURE 26A.8. A schematic outline of the events associated with relaxation of smooth muscle. The process of relaxation begins as the cytosolic free calcium concentration drops back into the normal range. This is accomplished by several mechanisms, including active pumping into intracellular storage sites by the sarcoplasmic–endoplasmic reticulum calcium ATPase (SERCA); active pumping of calcium out across the plasma membrane; and a passive exchange of sodium and calcium across the plasma membrane driven by the sodium gradient. In addition, the binding of epinephrine to a b-receptor triggers an increase in cyclic adenosine monophosphate (cAMP), which in turn inhibits the effects of myosin light-chain kinase (MLCK). ADP, adenosine diphosphate; ATP, adenosine triphosphate; CM, calmudulin; MLC, myosin light chain.

Resting smooth muscle cells maintain a cytosolic free calcium–ion concentration of less than 0.1 µM. Total intracellular calcium concentrations are higher (most intracellular calcium is protein bound), but only free cytosolic calcium is involved in generating force and maintaining tone. With excitation of the smooth muscle cell by either ligand-specific receptor stimulation or membrane depolarization, the first step in force generation is a rise in cytosolic free calcium levels above a threshold level of 20 to 30 nM, with full activation occurring at levels approaching 300 nM (145,298,362). Given its central role in initiating contraction, the cell is adapted with a number of mechanisms to help maintain calcium homeostasis (167,288). Cytosolic calcium may rise owing to ligand binding to a receptor coupled to an adjacent ion channel, which then opens allowing for calcium influx (Fig. 26A.7). Alternatively, such a receptor might activate a G-protein that couples this binding to the generation of a second messenger. G-proteins are located on the cytoplasmic face of the plasma membrane and serve to couple the binding of a ligand and its receptor with a secondary intracellular event such as the production of cyclic guanosine monophosphate (cGMP) (132,221). This second messenger then serves to activate the release of calcium from intracellular storage sites. The second messenger family may include cyclic adenosine monophosphate (cAMP), guanosine triphosphate (GTP), and inositol triphosphate (IP_3), and is discussed subsequently. In the case of the bladder body, the muscarinic cholinergic receptors are activated by the binding of acetylcholine to initiate the influx of calcium, which triggers contraction. In addition to the receptor-activated calcium channels, voltage-sensitive channels exist within the plasma membrane, which are opened with changes in the cell's membrane potential. Unlike neurons in which sodium influx alters the membrane potential, calcium ion influx accounts for the cell membrane depolarization in bladder smooth muscle.

The smooth muscle cell then must transform this signal, in the form of a rise in free cytosolic calcium, into force mediated by several steps and protein interactions. Calmodulin is a calcium-binding protein with an affinity constant for the free calcium ion of 100 nM. This means that as soon as the free cytosolic-cell calcium exceeds 100 nM, the calmodulin calcium-binding sites begin to fill, altering the three-dimensional conformation of this molecule (247). Once this conformational change has taken place, the calmodulin is able to bind to and activate the enzyme, myosin light-chain kinase (MLCK) (4). This enzyme serves the crucial function of phosphorylation of the 20-kDa myosin light chain (LC_{20}), with adenosine triphosphate (ATP) as the necessary cofactor. The actin-activated adenosine triphosphatase (ATPase) activity is increased with phosphorylation (67,69), and myosin light chain phosphorylation has been correlated with force development (165,259). With the light chain phosphorylation, the actin and myosin filaments interact, changing their three-dimensional conformations to slide past one another (Fig. 26A.9). This cycle may be repeated until the stimulus has been removed or the muscle reaches a new resting length. The events that lead to smooth muscle cell contraction are summarized in Table 26A.1.

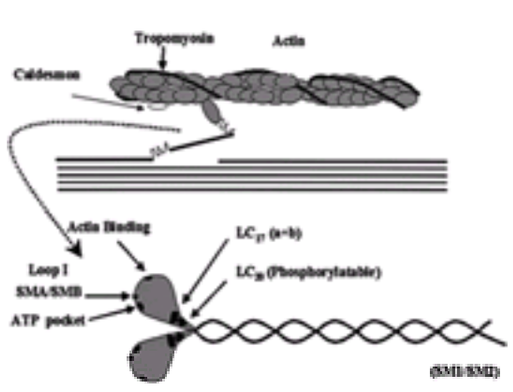

FIGURE 26A.9. This figure demonstrates a schematic representation of the smooth muscle contraction apparatus. The *top portion* of this figure shows a myosin head protruding from the thick filament to interact with the actin of the thin filament. A caldesmon molecule with its N-terminal region binding to actin and its C-terminal region binding to the flexible hinge region of the myosin is also indicated. The *bottom portion* shows a detailed view of the myosin molecule. The regions of the myosin heavy chain where the SM1/SM2 (C-terminus) and SMA/SMB (near the ATP binding site) isoforms differ, as well as the actin-binding region are shown. Also shown are the sites where the pairs of the myosin light chain (LC_{17} and LC_{20}) wrap around the myosin heavy chain. ATP, adenosine triphosphate. [From DiSanto ME, et al. Lower urinary tract physiology and pharmacology. *Curr Urol* 2001 *(in press).*]

1. Binding to cell surface receptors triggers a rise in free cytosolic calcium
2. Extracellular calcium influx and/or release from intracellular storage sites
3. Cytosolic calcium in excess of 0.1 μM binds to calmodulin
4. The Ca^{2+} calmodulin complex binds to myosin light-chain kinase
5. Myosin light chain is phosphorylated
6. Force is developed as myosin and actin interact

TABLE 26A.1. EVENTS LEADING TO SMOOTH MUSCLE–CELL CONTRACTION

The relaxation of smooth muscle begins when the agonist binding to the receptor is degraded, either by uptake of the ligand-receptor complex into a vacuole or by enzymatic degradation within the neuromuscular junction. Stimulation of b-adrenergic receptors or nitric oxide (NO) also may result in smooth muscle relaxation. Regardless of which of the aforementioned mechanisms is used, relaxation of the cell is accomplished by pumping calcium out of the cell or into sequestration sites within the cell (i.e., sarcoplasmic reticulum). These ion pumps translocate the calcium ion against large gradients, allowing for calcium concentrations of 2 mM in the serum, and less than 300 nM in the cytosol. These pumps, called the *Ca^{2+}-Mg^{2+}-ATPases,* consume energy in the form of ATP. Three sarcoplasmic–endoplasmic reticulum calcium ATPase (SERCA) isoforms exist: type I, fast (skeletal and cardiac muscle); type II, slow (slow twitch fibers and smooth muscle); and type III, non-muscle. Both the plasma membrane and SERCA ATPases share in common a site for binding of the calcium-calmodulin complex and cAMP (62). This implies that as soon as the muscle is stimulated, the cell already is activating its system for the restoration of calcium homeostasis.

In addition to the previously mentioned two pumps (located on the plasma membrane and sarcoplasmic reticulum) that consume ATP, a third "pump" exists in most systems that allows for extrusion of cell calcium. The sodium calcium exchanger is a passive system that allows for ion exchanges along an electrochemical gradient (290). Under ordinary circumstances, the pump operates to extrude one calcium ion from the cytosol by exchanging it for one sodium ion on a one-to-one molar ratio. When the cell membrane is depolarized, this pump may become uncoupled and allow for calcium influx. This is an exchange pump that does not use energy directly to affect these ion transfers (energy is still required because the pump depends on the sodium gradient across the membrane that is maintained by a sodium-potassium ATPase). A brief outline of the events contributing to smooth muscle–cell relaxation is presented in Table 26A.2.

1. Cytosolic calcium exceeds 0.1 μM and binds to calmodulin
2. The calcium calmodulin complex activates the Ca^{2+} ATPases of both the plasma membrane and the sarcoplasmic reticulum
3. In response to β-agonists, cAMP increases and binds to the Ca^{2+} ATPases
4. Nitric oxide (NO) also stimulates calcium sequestration via increasing cGMP
5. The Na-Ca exchanger pumps calcium out of the cytosol
6. The receptor ligand complex is inactivated by vacuolization within the cell
7. Degradative enzymes (acetylcholinesterase) break down the excess neurotransmitter within the cleft

cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate.

TABLE 26A.2. EVENTS LEADING TO SMOOTH MUSCLE–CELL RELAXATION

The resting membrane potential of smooth muscle cells is maintained on the order of –50 to –60 mV (i.e., 30 mV less than striated muscle). In unitary (syncytial) smooth muscles such as ureter, the action potentials are similar to those in skeletal muscle. In pure multiunit smooth muscle (such as the iris), action potentials do not seem to occur. In some visceral smooth muscle, the resting potentials change with time until the threshold level of –35 mV is achieved, triggering depolarization and subsequent contraction. In the ureter, pacing cells perform this function, which induces depolarization that then spreads downstream as a result of cell-to-cell coupling (356). In the bladder, there is no evidence of such a pacing system, and some question exists regarding whether the bladder has spontaneous slow-wave fluctuations. From the standpoint of bladder function, which is to store urine for prolonged periods at low pressure, such a system would be counterproductive.

Intracellular calcium stores exist within bladder smooth muscle that may be released upon the arrival of a specific intracellular signal (84,254,366,367). The sarcoplasmic reticulum of striated muscle has a detailed and well-described histologic structure. In smooth muscle, the sarcoplasmic reticulum lacks this classic histologic appearance and consists of small vacuoles of the endoplasmic reticulum that have differentiated into performing this function. Second messengers implicated in the release of such intracellular calcium stores include IP_3, cGMP, and even free Ca^{2+} (calcium-induced calcium release) (314). Calcium release from the sarcoplasmic reticulum into the cytoplasm occurs via the ryanodine-sensitive ion channel. In the rabbit, the ryanodine channel is functionally active, and its expression appears to be developmentally regulated (136,367). However, despite being present in bovine and murine (157) bladder smooth muscle, its physiologic role could not be demonstrated functionally. This distinction is important because it illustrates two major points about this literature:

1. Molecular findings, such as an ion channel being present based on a ligand-binding study or an immunoblot, must always be correlated with a functional (i.e., physiology) study.
2. Variations do exist between species and must be considered when comparing studies.

The molecular events that comprise the process of excitation-contraction coupling and force generation in smooth muscle have been simplified for the sake of this discussion. A large and growing literature exists for each of the points that have been mentioned (37,252). The next section illustrates how two of the components mentioned in this section are altered by partial bladder outlet obstruction.

Molecular Consequences of Bladder Outlet Obstruction

The challenge of understanding bladder function at a molecular level is demonstrated nicely by considering myosin heavy-chain (MHC) expression, a critical element of the molecular motor for contraction. The MHC expressed in smooth muscle is the product of alternative splicing at several sites within the precursor mRNA molecule. As shown in Fig. 26A.9, two major isoforms of MHC exist that are the result of changes at the tail carboxyl terminus. These changes result in the SM1 and SM2 MHC isoforms, which differ slightly in their molecular weights allowing for their resolution by SDS-polyacrylamide gel electrophoresis. SM1 and SM2 MHC isoform expression have been shown to be altered by normal development (219) and obstruction (70,350). However, the shift from SM1 to SM2 has not been correlated consistently with alterations in the ability of smooth muscle to generate tension or velocity of contraction.

Additional MHC isoforms are produced by insertion of a small 21-nucleotide sequence that encodes an additional seven-amino-acid stretch in the N-terminal region near the ATP binding site to produce the SMB MHC isoform (Fig. 26A.9B). The MHC SMB isoform has been associated with a higher rate of ATPase activity (the active site for the ATPase is adjacent to this insert) and a higher shortening velocity (107,170). Comparison of the relative SMB expression between the aorta (minimal) and bladder body (maximal) correlates with the roles that these structures play. Structures that must undergo rapid contraction will express the SMB isoform, as opposed to aorta, in which tone is merely slowly adjusted. In the lower urinary tract, the amount of SMA MHC isoform is increased in the urethra (159,364). Following partial outlet obstruction, MHC expression is altered in the urinary bladder. A shift has been reported in the SM1-to-SM2 ratio after outlet obstruction, which is reversed after the obstruction is relieved (68,70). Similarly, the expression of SMA and SMB isoforms is altered by obstruction, and then shows signs of recovery after the reversal of the outlet obstruction and recovery (71) (Fig. 26A.10).

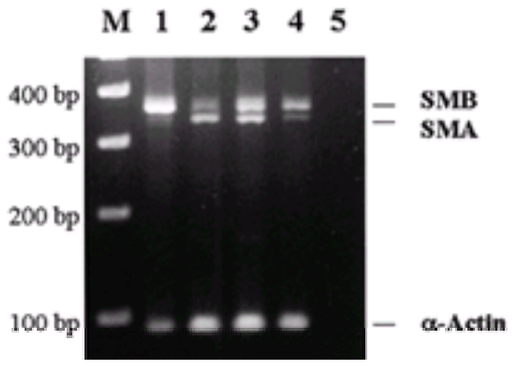

FIGURE 26A.10. Modulation of the SMA/SMB composition by the bladder in response to partial bladder outlet obstruction (PBOO). The expression of bladder mRNA coding for myosin isoforms with (SMB) and without (SMA) the seven-amino-acid insert in response to PBOO was determined using reverse transcriptase-polymerase chain reaction (RT-PCR) with specific upstream and downstream nucleotide probes designed to amplify a region of the myosin heavy chain (MHC) containing this alternative splice site. The normal bladder smooth muscle contains predominantly the SMB isoform *(lane 1),* whereas smooth muscle from 7-day obstructed bladder expresses significant amounts of the noninserted SMA mRNA transcript *(lane 2).* Upon reversal of the obstruction for 7 days *(lane 3),* the expression of SMA declines, reaching near-normal levels by 14 days postreversal *(lane 4). Lane 5* is a negative control in which no RT was added to the PCR reaction. Primers that specifically amplify a-actin were coamplified as an internal standard. A 100-bp DNA ladder as molecular size standard also was run *(lane M).*

The generation of active force by smooth muscle takes place when the 20-kDa myosin light chain is phosphorylated by MLCK. Initial reports suggested that the degree of light chain phosphorylation is unaffected by obstruction. However, Su and Moreland (323) have offered evidence to suggest that although maximal light chain phosphorylation values are not affected by obstruction, the basal level of phosphorylation is increased significantly. They also have shown that although the peak tension developed in bladder smooth muscle strips is unaffected by the obstruction, the velocity of contraction drops tenfold. One possible mechanism for this elevated baseline phosphorylation is raised by the demonstration of alterations in the sarcoplasmic reticulum, which could produce altered basal cytosolic calcium. Other possible mechanisms for such a finding include alterations in the kinase and phosphatase pathways.

The existence of the slow isoform of the Ca^{2+}-Mg^{2+}-ATPase (SERCA2) has been confirmed in bovine and rabbit bladder smooth muscle. Protein and mRNA for SERCA2 expression in rabbit bladder increase with normal development while the bladder is doing increasing volume work in the absence of anatomic obstruction (366,368). Ryanodine increases significantly during normal development (136). Loss of SERCA2 and ryanodine expression also has been reported following partial outlet obstruction in a rabbit model, implying that major perturbations are taking place in the sarcoplasmic reticulum (Fig. 26A.11) (318,319,320 and 321,368,369). These findings are noted in the absence of any major shifts in the expression of the voltage-operated calcium channels, suggesting a strong association between the presence of functional sarcoplasmic reticulum and the bladder's ability to empty. These alterations in the proteins of the sarcoplasmic reticulum return toward normal only in those bladders that experience recovery of function after the obstruction is relieved. Alterations in these calcium-regulatory proteins would suggest that basal cytosolic calcium rises with significant outlet obstruction, which in turn may result in altered contractile performance or serve as a signal to trigger cellular hypertrophy.

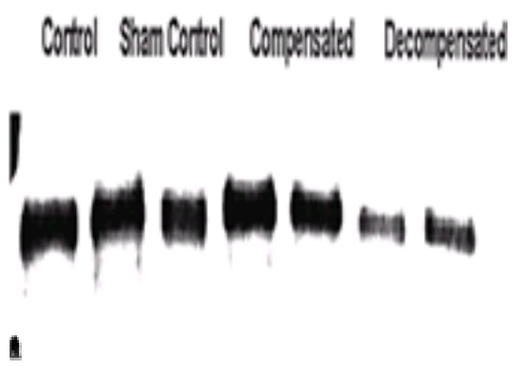

FIGURE 26A.11. A Western blot showing the loss of sarcoplasmic–endoplasmic reticulum calcium ATPase (SERCA)-2 expression following outlet obstruction for the categories of response. Equal amounts of membrane protein were subjected to SDS gel electrophoresis, and bands were visualized with a primary monoclonal antibody to SERCA2 and a chemiluminescence detection system coupled to a secondary antibody. Control and sham control bladders had no change in terms of bladder mass, voiding frequencies, voided volumes, or *in vivo* and unsedated videourodynamic performance. In contrast, bladder mass, voiding frequencies, and voiding pressures were elevated in the compensated group and significantly elevated in the decompensated group. The average voided volumes declined in both groups following outlet obstruction. Bladder decompensation was accompanied by a loss of SERCA2 expression, which was mediated by a downregulation of mRNA expression (Northern blot not shown). (From Stein R, Hutcheson JC, Gong C, et al. The decompensated detrusor III: the impact of bladder outlet obstruction on SERCA protein and gene expression. *J Urol* 2000;164:1026, with permission.)

It is clear that the preceding paragraphs are simply a beginning in terms of our ability to understand the molecular basis for smooth muscle function after bladder outlet obstruction. Other findings noted following outlet obstruction include bladder wall hypoxia (19,40,41,141), alterations in mitochondrial function (206,345), ECM deposition (127,287), and alterations in the nervous system (98), to name a few. Each of these pathways will be investigated fully in the next 10 years, using the ever-more sophisticated tools of molecular biology.

Passive Properties

If a strip of bladder smooth muscle is stretched, a sharp rise in the tension recorded by a force transducer will be seen, followed by a rapid decline to a new equilibrium (Fig. 26A.12). There is an energy cost for increasing the length of the bladder smooth muscle strip, which has several components.

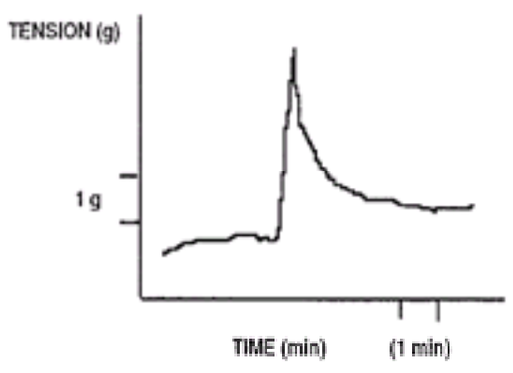

FIGURE 26A.12. The length-tension relationship for bladder smooth muscle as measured on a recording strip. A muscle strip is suspended in an organ bath with one end attached to a force transducer. The muscle strip is stretched rapidly by 25% of its resting or slack length. The recorded tension rises rapidly, then falls quickly to a new equilibrium value. The strip's resistance to deformation has at least four components: (a) baseline actin-myosin cross-bridging; (b) a transient rise in intracellular calcium during the deformation; (c) the cytosol and cytoskeleton of the cells must undergo a realignment; and (d) the extracellular matrix.

1. It is necessary to overcome the actin-myosin interactions that are present while the muscle is resting at equilibrium. Even in a muscle that is not actively contracting, actin-myosin cross-bridges are formed, and their realignment expends energy.
2. As the muscle is stretched, there is a transient rise in intracellular calcium, which triggers new actin-myosin interactions.
3. With all of its intrinsic components, the cell itself offers resistance to deformation because it must undergo a geometric (cytosol and cytoskeleton) reorientation.
4. The ECM components also offer a resistance to this displacement.

A simplistic model might consider each of these components as separate springs arranged in parallel in a system that one is trying to pull apart. Such a model might lead one to consider the application of Hook's law, which states that the force of displacement *(f)* is equal to a constant *(K)* multiplied by the displacement length *(x):* (f = Kx). However, bladder smooth muscle does not follow Hook's law, because an additional feature of the bladder is its elasticity. Once the bladder is mechanically deformed, it will slowly return to its baseline shape even in the absence of an active contraction, whereas the spring retains memory and, upon release, returns to its baseline state in a linear fashion (Fig. 26A.13).

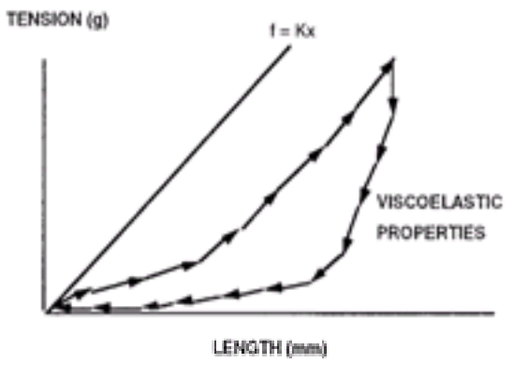

FIGURE 26A.13. The concept of elastic versus nonelastic properties. A spring would follow Hook's law, in which tension is related to displacement in a linear fashion. The normal bladder demonstrates viscoelastic properties. As shown in this diagram, progressive linear displacements produce very gradual increases in tension until a critical length is reached. Furthermore, if this process is reversed and an equal displacement is made in the reverse direction, there is a much greater fall in tension. These viscoelastic properties represent a complex interaction between the smooth muscle cells undergoing geometric rearrangements, and the extracellular matrix rich in collagens types I and III and elastin.

Extracellular Matrix

A full review of ECM physiology, structure, and molecular biology is beyond the scope of this chapter; however, the urologic aspects have been reviewed by Macarak and Howards (225,226 and 227). The ECM is a difficult component of smooth muscle to study, because these high-molecular-weight proteins are extremely insoluble. Selective proteases or cyanogen bromide–cleavage (which cleaves the peptide bond on the N-terminal side of a methionine residue) techniques break down these large macromolecules into peptide fragments that can be studied using more conventional methods of protein chemistry. In addition to the difficult protein chemistry, raising monoclonal antibodies for further research is extremely difficult, and only certain peptide fragments will have a unique enough antigenic configuration to produce a useful reagent. Despite these technical challenges, antibodies are now available that recognize the collagens in several species and these genes have been sequenced. Metabolism of the ECM consists of a biosynthetic and a degradative phase, and each is covered in this chapter, because they will increasingly become targets for future urologic therapy.

Four basic elements compose the ECM: fibrillar proteins (collagen and elastin), microfibrillar proteins, nonfibrillar proteins (the glycosaminoglycans), and fibroblasts. The cross-sectional area occupied by the matrix will vary from 30% to 70% depending on which tissues are sampled. Shapiro and associates (305) have used morphometric analysis to determine the muscle matrix ratio in both normal and pathologic states, and have demonstrated an increase in the matrix component in patients with spina bifida. However in cadaveric studies (163), no difference in smooth muscle cross-sectional areas was found between those bladders with and those without outlet obstruction. These kinds of studies are of great importance because they are performed in human tissues obtained at the time of surgery. However, chemical-based staining procedures will not differentiate the collagen types, a process that requires monoclonal antibodies or the techniques of peptide fragment analysis.

Collagen biosynthesis is a complex process that originates in either the fibroblast or the smooth muscle and involves the expression of complex gene structures. The DNA transcription into mRNA produces a long initial transcript that contains a great deal of additional genetic information (58). The mechanical, hormonal, and other unknown factors that regulate the expression of collagen genes are under active investigation. Following their biosynthesis, the collagen and elastin fibers are extruded from their cells of origin, and deposited in the extracellular space. Here, ionic bonds hold them in alignment until covalent linkages can form to provide long-term stability (Fig. 26A.14). Were these linkages not present, strength would be absent, and the smaller matrix molecules would be more soluble. The importance of proper cross-linking is illustrated by the urologic findings in the Ehlers-Danlos syndrome, in which proper cross-linking is precluded resulting in a more compliant bladder with associated diverticula (105). Once this large mesh of fibrillar proteins is assembled, smaller microfibrillar proteins and glycoproteins are inserted into this matrix, giving it additional physiologic properties. Other complex matrix elements include fibronectin (which anchors the cell membrane to collagen), heparin, and complex glycoproteins (359). The urologic aspects of matrix biosynthesis have been commented on by Ehrlich (115), Macarak and Howards (225,226 and 227), and Rosenbloom and co-workers (297).

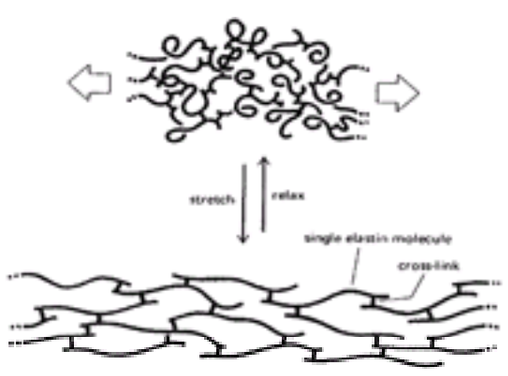

FIGURE 26A.14. Elastin molecules are joined together by covalent bonds to produce an extensive cross-linked network. The properties of the elastin molecule allow it to stretch and recoil over wide distances. The cross-links are essential in determining just how far the network may distend. (From Alberts B, Bray D, Lewis J, et al. *Molecular biology of the cell,* 2nd ed. New York: Garland Publishing, 1989, with permission.)

In response to outlet obstruction, bladder smooth muscle undergoes hypertrophy and expansion of the matrix component (237,346), which is partly reversible if the obstruction is relieved early enough. The cell's ability to synthesize matrix is balanced by its ability to break down the matrix, allowing for remodeling to take place. Fibroblasts and smooth muscle cells have acquired the ability to secrete collagenases capable of local action that remodel the immediate extracellular spaces. The collagenases are a family of metalloenzymes that predominantly use zinc as a cofactor [matrix metalloproteinases (MMP)] and are capable of breaking down collagen fibrils. The collagenases are assisted by other enzymes such as the elastases. In this manner, smooth muscle cells embedded within lattices of collagen are capable of undergoing realignment in response to stress, as has been shown experimentally (115).

The unopposed release of collagenases would result in detrimental tissue destruction; thus tissues have acquired a natural set of collagenase inhibitors. Tissue

inhibitors of the metalloproteinase (TIMP) system are of growing importance in understanding how the remodeling process is kept in check. Obviously the regulation of the ECM depends on achieving a balance between synthesis and degradation (Fig. 26A.15). The urologic aspects of the collagenases and the TIMP system have been reviewed by Corcoran and associates (81). Peters and co-authors (286,287) have demonstrated a decreased production of MMP and an increase in TIMP levels following bladder outlet obstruction in the fetal lamb. These changes would alter the balance in favor of an increased deposition of the ECM.

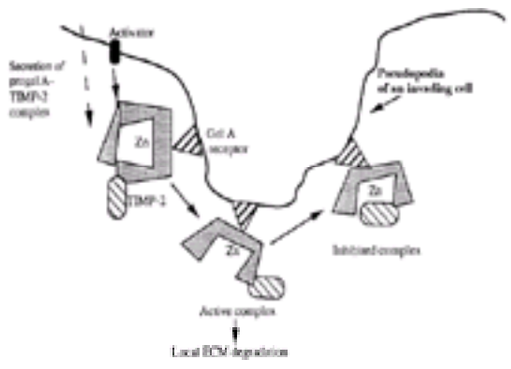

FIGURE 26A.15. The regulation of the extracellular matrix (ECM) is a delicate process balancing new synthesis against degradation. This diagram illustrates the degradation pathway via the cellular secretion of the matrix metalloproteinases, which require a zinc (Zn) cofactor. When activated in the extracellular space, these enzymes will break down the extracellular matrix products. In turn, these proteases will be regulated by inhibitors called *tissue inhibitors of metalloproteinases* (TIMP). If the TIMP concentrations rise in tissue, as has been shown in fetal bladder outlet obstruction, the net effect will be an increase in collagen accumulation. (From Corcoran ML, Kleiner DE, Stetler-Stevenson WG, et al. Regulation of matrix metalloproteinases during extracellular matrix turnover. In: Zderic SA, ed. *Muscle, matrix, and bladder function.* New York: Plenum Press, 1995, with permission.)

Striated Muscle of the Lower Urinary Tract

Skeletal muscle fibers exist in two major forms: fast and slow twitch. Skeletal fast-twitch muscle, like cardiac muscle, must be able to exhibit rapid bursts of contractile force and velocity over a wide range of physiologic demands. Fast-twitch muscles are rich in myosin ATPase that catalyzes the actin-myosin interaction. In addition, expression of SERCA1, the fast isoform, will predominate in fast-twitch muscles. Examples of such muscle groups include the biceps and rectus femoris. Slow-twitch fibers are found in muscles that require more sustained tension, such as the pelvic levators, soleus, and abdominal wall muscles. These muscles show diminished actin-activated myosin ATPase activity and an increased expression of the slow isoform, SERCA2. No muscle group contains a pure population of fast or slow forms, but rather a blend of these fiber types.

Gosling and colleagues (140) suggested that the human external urinary sphincter primarily is composed of slow-twitch fibers. These fibers give rise to the background electromyographic activity seen during a cystometrogram (CMG). Within this sphincter exists a population of fast-twitch muscle cells that are “recruited” to increase this muscle's tone during sudden rises in intraabdominal pressure. This finding is not always correlated with the fiber distribution in other species. In the dog, only 35% of the fibers are slow twitch (27), whereas in the rabbit, fast-twitch fibers and fatigue-resistant, slow-twitch fibers are found (337). The intriguing potential for altering the fast- and slow-twitch content of the striated muscle of the outlet, by pacing or other forms of stimulation, continues to challenge investigators (329).

Summary of Smooth Muscle Properties

This section has been devoted to a discussion of the factors involved in the production of tone, force generation, and the bladder's viscoelastic qualities. These are complex biologic properties and, under normal circumstances alone, the challenge of understanding the underlying physiology and molecular biology is substantial. Out of necessity, this discussion has considered the smooth muscle as consisting of intracellular and extracellular components. In the ensuing sections, attention focuses on an understanding of the nervous system and its ability to interact with the bladder smooth muscle. Once the basic scientific principles underlying the functioning of the nervous system are reviewed, attention is directed to integrating these concepts with the preceding information.

NEURAL CONTROL OF THE LOWER URINARY TRACT

Overview

Micturition is a complex function that involves coordinated interactions between the smooth muscle of the detrusor, bladder neck, and urethra. The central and peripheral nervous systems serve to coordinate these actions. Neural regulation of the lower urinary tract requires the use of both the autonomic (involuntary) and somatic (voluntary) nervous systems. In the infant, voiding is autonomic and involuntary, but with normal maturation, somatic control over lower urinary tract function develops. In the somatic nervous system, one neuron arises in the anterior horn of the spinal column, exits the vertebral column, and courses to the muscle it serves. At the neuromuscular junction, the activated somatic neuron releases its neurotransmitter (acetylcholine). In contrast, the following points demonstrate why the autonomic nervous system is more complex:

1. Autonomic innervation involves a preganglionic fiber that travels from the spinal cord to a collection of synapses (e.g., ganglia or peripheral plexuses) from which a second postganglionic fiber travels to the neuromuscular junction.
2. These ganglia, or peripheral plexuses, give rise to distal autonomic fibers that tend to be nonmyelinated. In contrast, somatic nerves are myelinated in their entirety (myelination increases nerve conduction velocity).
3. Severing a somatic nerve may induce muscular atrophy, whereas ablation of an autonomic nerve has less pronounced changes. This may be interpreted as the autonomic system having a greater plasticity, because the extensive ganglionic connections make it easier to reroute the signals.

Classic Views of the Autonomic Nervous System

The classic sympathetic and parasympathetic categorization refers to an anatomic division of the autonomic nervous system. In the sympathetic system (Fig. 26A.16), the preganglionic neurons exit the thoracic and lumbar spinal segments to reach the first synapse in one of three possible ganglia: (a) adjacent to the vertebral bodies (paraganglia), (b) in between the vertebrae and the organ (preganglia), and (c) located with the end organ (peripheral ganglia). The parasympathetic nervous system (Fig. 26A.17) differs in that the cranial or sacral preganglionic neurons exit the spinal column and travel long distances to peripheral ganglia, which are located either within or adjacent to the target organ. These observations apply to the portion of the autonomic nervous system controlling motor functions. For sensory roles, most of the autonomic nervous system's afferent fibers leave the organ and pass through the ganglia without making any synaptic contacts until the spinal column is reached. For both divisions of the autonomic system, preganglionic fibers are myelinated, whereas postganglionic fibers are not. In the classic view, the preganglionic neurotransmitter was acetylcholine, whereas the neurotransmitters of the postganglionic fibers were either acetylcholine (parasympathetic) or adrenergic (sympathetic). It is now clear that this view is an oversimplification.

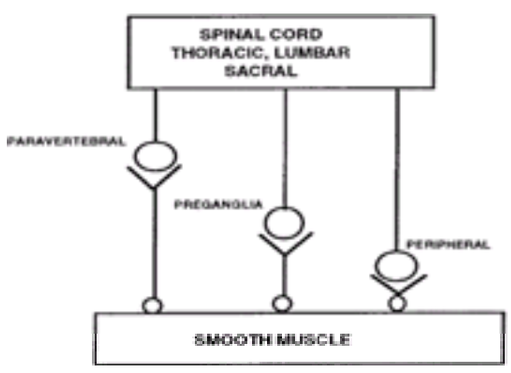

FIGURE 26A.16. A simplified schematic diagram of the sympathetic nervous system demonstrating the origins of pregangliar fibers from three levels of the spinal cord. In addition, the ganglia may be divided into three categories depending on their anatomic location.

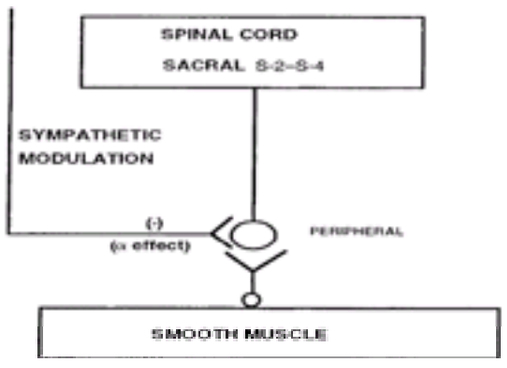

FIGURE 26A.17. A simplified schematic diagram of the parasympathetic nervous system demonstrating the origins of pregangliar fibers in the sacral segments S-2 through S-4. The parasympathetic ganglia are located predominately near their organ of innervation. A major feature in this diagram is the sympathetic input into the ganglia, where adrenergic stimulation via a-receptors can produce an inhibitory effect on parasympathetic transmission.

Contemporary Views of the Autonomic Nervous System

The motor innervation of the lower urinary tract primarily is supplied by postganglionic neurons, also known as the *urogenital short neuron system,* which arise from ganglia within or in extremely close proximity to the bladder wall. A complex intraganglionic network of fibers link one ganglion to another and can modulate the activity of these synapses. Evidence suggests that in some cases urogenital fibers arise from the smooth muscle, travel to the peripheral ganglion, and synapse with an efferent neuron (which triggers a muscle response), all of which takes place independently of the spinal cord (161). It is also now accepted that the sympathetic system via a-receptors may act at the parasympathetic ganglia to modulate motor activity to the bladder (96,97) (Fig. 26A.17).

The traditional autonomic neurotransmitters were acetylcholine and norepinephrine. It now is apparent that many other molecules serve as neurotransmitters within the central and peripheral nervous system. These noncholinergic nonadrenergic neurotransmitters include ATP, serotonin, histamine, prostaglandins, peptides, and nitric oxide, and most likely play a critical role in the modulation of autonomic neurotransmission. In the traditional view, one neuron delivered one neurotransmitter to the effector endplate; it now is known that single neurons contain packages of different transmitters that often are released in groups. A currently accepted concept is of a cotransmitter—a molecule or peptide that alters the response of a postjunctional cell to the primary neurotransmitter.

Neurotransmitters and Receptors

Once the appropriate neuron is stimulated, an action potential travels down the axon to the synapse, and via an increase in calcium ion concentration in the cell, the secretory vesicles empty their transmitters into the postsynaptic cleft. This neurotransmitter crosses the postsynaptic membrane to reach the cell membrane of the smooth muscle. On this membrane, cell surface receptors are present that recognize the neurotransmitter and bind it in a specific manner. This interaction between ligand and receptor triggers the process of excitation-contraction coupling by initiating a rise in the free cytosolic–calcium concentration within the target or effector cell.

Cholinergic Receptors

Cholinergic receptors are membrane proteins to which acetylcholine binds to exert its effects as a neurotransmitter. Neurons whose transmission is cholinergic include somatic fibers, all preganglionic autonomic fibers, and all postganglionic parasympathetic fibers. The two major subdivisions of cholinergic receptors are (a) nicotinic and (b) muscarinic. This classic terminology resulted from an old observation that the alkaloid muscarine inhibits some cholinergic transmission, and low doses of nicotine mimic acetylcholine effects at other sites. The nicotinic receptors are found in skeletal-muscle motor endplates and in the autonomic ganglia. These nicotinic sites are not identical, and their structures, which are composed of six high-molecular-weight subunits, are very complex. Recent evidence suggests they have a role in the autonomic control over bladder function (106,114).

The muscarinic receptor is found in all autonomic effector cells such as sweat glands, large and small bowel, gallbladder, and bladder. There are at least five subtypes of muscarinic receptors, and these differ in terms of their anatomic location and the effects they produce upon being activated. The muscarinic-receptor proteins are classified as M_1 through M_5. The capital “M” designates the protein, whereas the lower-case “m” defines the message RNA coding for these receptors. This distinction is important because the muscarinic-receptor proteins are similar enough in structure that their biochemical differentiation becomes quite difficult. For example, it has been possible to distinguish the M_1 and M_2 receptors based on the high affinity of the M_1 receptor for the agonist pirenzepine (45). However, the molecular distinction between the M_2 and M_3 proteins is more difficult. For some receptors, the mRNA coding for the protein structure has been studied far better than the actual receptor protein itself (228).

These distinctions among muscarinic receptors are clinically relevant when considering pharmacologic therapy of the lower urinary tract (73,162). M_1 muscarinic receptors primarily are confined to the CNS, glands, and sympathetic ganglia. M_3 receptors are seen on the cell surface of the peripheral target organs, whereas M_2 receptors also reside on the neuron's synaptic membrane (Fig. 26A.18). Presynaptic M_2 receptors (with some contribution from M_4 type) bind acetylcholine once its concentration reaches a certain level in the postsynaptic cleft, and inhibit the release of more acetylcholine; this serves as a negative feedback loop. Despite accounting for only 20% of the muscarinic-receptor density in the bladder, it is the activation of the M_3 receptor that triggers a rise in intracellular cytosolic calcium levels and initiates bladder contraction. New studies suggest that M_2 receptors also exist on the smooth muscle cell surface and contribute to force generation by inhibiting adrenergic pathways (which under pure adrenergic conditions would cause the muscle to relax) (46,73,322).

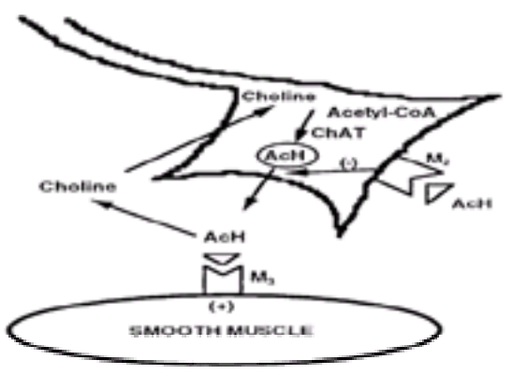

FIGURE 26A.18. A simplification of muscarinic cholinergic neuromuscular transmission. Acetylcholine is synthesized by the acetylation of choline by choline acetyl-transferase in the neuron and packaged into vesicles. The vesicles release their acetylcholine content into the neuromuscular cleft in response to a rise in axonal calcium. The acetylcholine binds to an M_3 receptor to effect a contractile response. It also will bind to a presynaptic M_2 receptor, which will inhibit the release of more acetylcholine (130). The bladder contains both M_2 and M_3 receptors. Acetylcholine is broken down in the neuromuscular cleft by the serine protease, acetylcholinesterase, and the choline moiety is recycled. This sequence of events may be modified by the addition of cotransmitters such as nitric oxide or adenosine

triphosphate (ATP).

The muscarinic cholinergic receptor is composed of a single peptide chain with seven hydrophobic or transmembrane domains (66,152,357). These membrane-spanning segments are quite similar among the five receptor subtypes, and the real diversity comes when looking at the cytoplasmic loops. This allows each of the subtypes to perform a slightly different intracellular function. With some muscarinic receptors, the cytoplasmic domain is attached to a G-protein that serves to produce a second messenger such as IP_3. In other cases, the cytoplasmic portion of the muscarinic receptor is linked to proteins that affect cytosolic levels of cAMP and or cGMP.

Muscarinic cholinergic–receptor density is affected by hormonal factors such as pregnancy (downregulation) (217), estrogen (upregulation) (306), spinal cord injury (46,312), acute obstruction (187,237), and diabetes (339), and by contractile activity itself (204). The molecular basis for contractile activity regulating the receptor density was tested by Levin and colleagues (210), who showed that if the detrusor smooth muscle was stimulated repeatedly, the muscarinic binding sites were decreased. This most likely is explained by a receptor binding its ligand, and the entire complex being subjected to endocytosis by the cell. The mechanisms by which cholinergic-receptor density is altered by hormones or spinal cord injury are not understood. In samples taken from patients with myelodysplasia, Lepor and associates (200) demonstrated a decrease in the expression of the muscarinic cholinergic receptor.

Acetylcholine is synthesized in neurons from acetyl-coenzyme A, and choline is synthesized by the enzyme, choline acetyltransferase. Once acetylcholine is released into the synaptic cleft, it has four possible actions (Fig. 26A.18):

1. It may bind to an M_3 receptor and initiate smooth muscle contraction.
2. It may bind to an M_2 receptor and inhibit further acetylcholine release.
3. It may bind to either receptor and be taken up into the cell by endocytosis.
4. It may be broken down by acetylcholine-esterase, a serine protease that functions to cleave the hormone into inactive fragments.

Although the neuron will not take up unbound acetylcholine, it will reabsorb choline and recycle it for further use.

Adrenergic Receptors

The sites at which catecholamines act as the primary neurotransmitter are classified as adrenergic, and include most of the postganglionic sympathetic fibers. Norepinephrine is the catecholamine released into the postsynaptic cleft, at which point it diffuses across to the effector cell to bind to an adrenergic receptor. Adrenergic receptors classically are defined as a or b depending on the physiologic reaction they elicit. The a-receptors produce vasoconstriction and smooth muscle contraction. Norepinephrine and methoxamine are the primary a-agonists eliciting a maximal response, whereas epinephrine has a weak effect at a-receptors. Stimulation of b-adrenergic receptors will increase myocardial contractility and elicit some smooth muscle relaxation (bronchodilation). Maximal b-effects are seen with isoproterenol, moderate with epinephrine, and minimal with norepinephrine.

Adrenergic receptors are composed of one polypeptide chain of approximately 500 amino acids with seven hydrophobic regions spanning the cell membrane. When a transmitter binds to the active site at the plasma membrane, conformational changes result in realignment of the intracellular receptor components. This in turn activates several pathways (G-proteins and others) and second messengers that produce smooth muscle contraction or relaxation. Distinguishing between a- or b-receptor proteins using classic radioligand methods is limited because the differences in recognition sites are subtle. The major molecular differences are in the intracellular regions, which enable the receptor subtypes to carry out their diverse functions. Some subclassifications of adrenergic receptors cannot be made on the basis of ligand specificity, but by DNA sequence analysis only. Excellent reviews of the molecular aspects of the adrenergic receptors have been compiled by Hoffman and Lefkowitz (150) and Ruffolo and associates (299).

The a-receptors traditionally were divided into types 1 (postsynaptic) and 2 (presynaptic) depending on their location within the synapse (Fig. 26A.19). It now is apparent that type-2 receptors are located in postsynaptic and nonsynaptic sites (such as vascular smooth muscle). The a_1-receptors were then classified further, using ligand-binding studies, into two subtypes (A and B), and molecular cloning studies revealed a third (D), as well as a fourth related receptor, referred to as *a-1-L* (which may be a close variant of a_{1A}) (86). The a_{1A}- and a_{1B}-receptors are located in smooth muscle, where they elicit a contraction by coupling either with a G-protein (to produce IP_3) or to a dihydropyridine-sensitive calcium channel (222). The a_{1d} type has been identified in bovine brain, and its mRNA has been identified in the prostatic stroma (289). Smooth muscle contraction in the lower urinary tract is mediated predominately by the a_{1A}-receptors (109,249,304). The family of human a_1-adrenergic receptors has been localized to chromosome 5q (283). Three human type-2 a-receptors have been classified and their chromosomal locations have been mapped. In contrast to the $a_{1A,B,D}$ class, these receptors have been mapped to three different locations in the genome: a_{2A} to chromosome 10q, a_{2B} to chromosome 2, and a_{2C} to chromosome 4 (283).

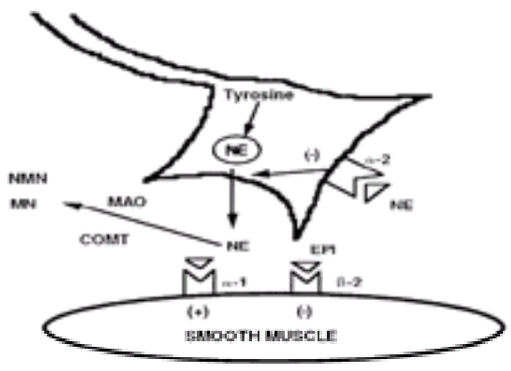

FIGURE 26A.19. A simplification of adrenergic neuromuscular transmission. Tyrosine serves as the ultimate precursor of epinephrine and norepinephrine, which, following their biosynthesis by well-described pathways (150), are packaged in vesicles. The vesicles release their contents into the cleft. Norepinephrine (NE) binds preferentially to a_1-receptors to effect a contraction of smooth muscle, whereas epinephrine (EPI) binds preferentially to a_2-receptors to produce relaxation. Feedback may occur at a_2-receptors to inhibit the release of more adrenergic neurotransmitters. NE and EPI are broken down by monoamine oxidase (MAO) and catecholamine-O-methyltransferase (COMT) into metanephrine (MN) and normetanephrine (NMN). This diagram may be modified by the addition of cotransmitters such as nitric oxide or adenosine triphosphate (ATP).

The b-adrenergic receptors exist in at least three major forms designated as subtypes 1, 2, and 3, with the genes located on chromosome 5q. The b_1-receptors are postsynaptic and produce a positive chronotropic and inotropic effect in the heart. Norepinephrine has a higher affinity for the b_1-receptors, whereas epinephrine has a greater affinity for the b_2-receptors. The b_2-receptors are found in the presynaptic and postsynaptic membranes and in the urinary bladder, uterus, intestinal tract, and bronchi. Stimulation of the b_2-receptors causes relaxation of these smooth muscle groups. A b_3-adrenergic receptor has been defined recently in the digestive tract, skeletal muscle, and adipose tissues (283).

The catecholamines are synthesized from the amino acid, tyrosine, as a precursor by well-defined biochemical pathways (150). Once the catecholamines are released into the synaptic cleft, several events may take place (Fig. 26A.19). The catecholamines may bind to a postsynaptic effector cell to cause either contraction or relaxation. They may be taken back up into the presynaptic membrane and recycled, or bind to a presynaptic receptor and inhibit further neurotransmitter release. They may be metabolized and inactivated by either monoamine oxidase (MAO) inhibitors or by catechol-O-methyltransferase.

Clinical Relevance of Receptor Molecular Biology

These differences among receptor populations are important in selecting drugs for clinical urologic applications. In the past, urologic medical therapy tended to have minimal uroreceptor selectivity. Therapy for benign prostatic hypertrophy (BPH) using a-blockers will benefit from an improved understanding of this pharmacology, because the prostatic capsule and stroma are rich in these receptors. Conventional drugs such as phenoxybenzamine bind to both the a_1- and a_2-receptors; although producing an enhanced urinary flow rate (a_1 prostatic effect), vasodilation and orthostatic hypotension may result (a_2 effect in vascular smooth muscle). Even a drug such as prazosin, with greater a_1 specificity, will have some vasodilating side effects. Although these side effects may be minimal in a young, healthy patient, they may become problematic in the older patient with BPH. The development of long-acting selective a_1-blockers such as terazosin, tamsulosin, and doxazosin has provided a greater urologic benefit in the management of prostatism while minimizing side effects (202). Current pharmacologic therapy with a-blockers has been reviewed well by Langer (191) and Blaivas (35).

The traditional drug for bladder instability, oxybutynin hydrochloride, also binds to ocular, gastrointestinal, or salivary gland sites. Subsequent side effects result, which often make these drugs unacceptable to the patient at doses with a urologic benefit. Radioligand-binding data demonstrate that tolterodine binding is eightfold lower in the parotid gland when compared with bladder (266). In a pooled analysis of four multicenter trials, this translated into better compliance while still minimizing the episodes of incontinence for those patients treated with tolterodine versus oxybutynin (13).

Other Receptors in the Lower Urinary Tract

Contraction and relaxation of smooth muscle of the lower urinary tract can occur *in vitro* in response to a large number of agonists and antagonists in addition to acetylcholine and norepinephrine. Many of these substances may occur as modulators of neurotransmission. The ability of a substance to elicit a contraction *in vitro* does not imply that it is functionally active in the *in vivo* setting under normal physiologic conditions. For a substance to be categorized as a neurotransmitter, it must meet certain specific criteria (57).

1. The presynaptic neuron should have the enzymes needed to synthesize the substance or its precursor.
2. The substance should be imaged in the presynaptic neuron using chemical, immunologic, or fluorescent methods.
3. At the postsynaptic membrane, the substance should reproduce the specific events of transmission.
4. These events should occur at concentrations that are equivalent to those obtained in the synapse at the time of transmitter release, secondary to nerve stimulation.
5. The effect should be blocked by a known antagonist in a dose-dependent manner.
6. A mechanism to terminate the action of the proposed transmitter, such as a degradative enzyme, must be available.

Receptor Distribution Within the Lower Urinary Tract

Levin and Wein (214) were the first to investigate receptor-binding methods to quantitate the expression of adrenergic and cholinergic receptors within the lower urinary tract. The bladder body has abundant muscarinic receptors, and this pattern extends down into the proximal urethra (119,123). The expression of these receptors is hormonally sensitive. Levin and colleagues (217) showed a diminished response to bethanechol stimulation and a 50% reduction in cholinergic-receptor density among pregnant rabbits.

Muscarinic receptors determined by radioligand-binding assays were expressed at higher concentrations in the bladder body and at lower levels in the bladder base, with no change in the dissociation constant. Similar muscarinic-receptor distributions within the bladder have been reported in guinea pigs (268), rabbits (201), and humans (267). The predominate muscarinic receptor in the bladder is the M_2 (80%) variant (3,210,300), but the M_3 variant (20%) actually is responsible for bladder contraction (73). Evidence now suggests that M_2 stimulation also contributes to the development of active force generation via an inhibitory effect on the intracellular cascade downstream from the b-adrenergic receptor (73). By inhibiting the b-adrenergic effects that induce relaxation, M_2 stimulation contributes to active force generation.

Adrenergic binding sites are expressed within the bladder body with a predominance of b subtypes (11). Several groups have offered data to support rich cholinergic innervation of human bladder smooth muscle (85,117,137). Ek and co-authors (117,118) have described a similar but less extensive innervation of the proximal urethra. Numerous studies agree on the general concept that the smooth muscle of the bladder neck and proximal urethra have a rich adrenergic innervation (123,188). The adrenergic and cholinergic innervation of the bladder appears to be hormonally sensitive. Using immunohistochemical methods, atrophy of the bladder-base adrenergic fibers was noted in pregnant rats (291). This was confirmed by physiology studies in the rabbit, where Tong and associates (338) demonstrated less adrenergic response among pregnant rabbits.

Adrenergic fibers in the human lower urinary tract are localized primarily in the trigonal region (59,326), with minimal expression in the bladder body (29,326). Gosling and Dixon (136a) and Kaneko and co-workers (166) reported adrenergic nerve supplies to the male bladder neck; a dissenting view is provided by Kluck (180), who found little evidence of such fibers. Gosling and Dixon (136a) further noted that such adrenergic innervation was distributed predominately right at the junction of the bladder neck and prostate, and they speculated that its functional role was in the prevention of retrograde ejaculation as opposed to the maintenance of continence. Considering the high incidence of retrograde ejaculation and low incidence of urinary incontinence after radical retroperitoneal lymph node dissection for testes cancer, this explanation makes sense. El Badawi and Atta (120) pointed out that before accepting such significant gender differences in innervation, it is wise to consider the actual studies themselves. A heterogeneity of human tissue is available for study, and none of the material studied in his review of the literature could truly meet the criteria of “normal.”

Striated Sphincter Receptors and Innervation

The striated sphincter is thought to be innervated by the pudendal nerve, which emanates from the S-2 to S-4 cord segments (99,122). The major innervation of this striated sphincter is believed to be somatic by most authors. Transection of the pudendal nerve in the rat has been shown to diminish the striated muscle component of the external sphincter and diminish average fiber size (146). In humans, somatic control of the external sphincter is such that there is activation of these neurons during progressive filling and a loss of activity just before and during micturition. Inhibition of this somatic nerve activity during micturition requires supraspinal mechanisms, which accounts for the failure of the external sphincter to relax in paraplegic patients (99).

Some authors have implicated adrenergic control over the striated external sphincter; however in a study of clinical specimens, Wein and Raezer (352) and Lincoln and associates (220) concluded that the only evidence of adrenergic innervation to the striated component of the external sphincter was associated with blood vessels. Whereas the cholinergic receptors associated with smooth muscle are classified as muscarinic, those responsible for striated muscle contraction are nicotinic. Anticholinergic drugs such as oxybutynin are active at muscarinic sites only, and will have no effect on skeletal muscle. The nicotinic receptors of the striated sphincter can be blocked for up to 3 months with endoscopically placed botulinum toxin (Bo-Tox). Such treatment has been utilized successfully in the therapy of dysfunctional voiding refractory to biofeedback therapy (303) or in paraplegic patients as an alternative to sphincterotomy.

Sensory Innervation

Although much is known about the contractility of the urinary bladder, much less is known about its sensory function, reflecting the experimental difficulties in studying sensory phenomena in animal models. Afferent nerve fibers have been demonstrated in the pelvic, pudendal, and hypogastric nerves (99,190). deGroat and Booth (89) showed that afferent receptors serving the sensation of bladder distention originate in the bladder wall and travel in the pelvic nerve, whereas mechanoreceptors are found in the hypogastric nerve. Both of these nerves carry nociceptive afferents. The afferent neurons from the striated sphincter and urethra transmit sensations of temperature, pain, and urinary distention, and these travel in the pudendal nerve.

Tucker and Moss (342) describe an *in vivo* model in which intravesical potassium chloride (KCl) produces irritation, which is detected by monitoring action potentials in the transected pelvic nerve. Afferent neurons were labeled in the bladder by intravesical injections of wheat germ agglutinin (WGA)–horseradish peroxidase or pseudorabies virus, followed by immunostaining of the spinal cord segments (Fig. 26A.20) (87,316), which showed the sensory neurons localized to discrete zones within the dorsal horn. This area also contains dendrites of neurons that supply the lower urinary tract with motor efferents. If the bladder is subjected to chemical irritation, sectioning of these same spinal segments followed by immunostaining for c-fos expression will show reactivity in the same distribution (Fig. 26A.20)

(33,349). Birder and deGroat (34) also correlated these findings with evidence of increased c-fos gene expression. A major discovery in the study of bladder afferent neurons was that capsaicin blocked this population of neurons and diminished *c-fos* protein and gene expression (235,349). Capsaicin is a natural product isolated from hot red peppers, with the unique ability to bind to sensory neurons and to induce rapid membrane depolarization by the opening of an ion channel that is followed by a prolonged (but reversible) blockade. In addition to blocking small-diameter nociceptive fibers, capsaicin acts to inhibit inflammatory neuropeptide release from peripheral nerve ending (31). The potential clinical use for capsaicin and an extensive review of its pharmacology was updated recently by Maggi (236).

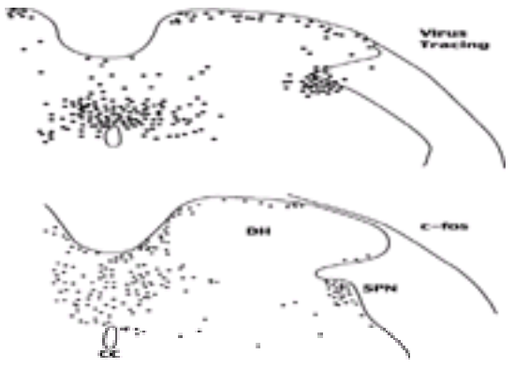

FIGURE 26A.20. Bladder afferent projections at the L-6 level of the rat spinal cord. **A:** The afferents were identified by the retrograde axonal transport of intravesically administered pseudorabies virus followed by immunohistochemical staining. Viral uptake is localized to very discrete regions within the spinal cord. **B:** The spinal cord segment has been stained for the expression of the oncogene c-fos, which is activated following the chemical irritation of the bladder. CC, central canal; DH, dorsal horn; SPN, sacral parasympathetic nucleus. (From deGroat WC, Booth AM, Yoshimura N. Neurophysiology of micturition and its modification in animal models of human disease. In: Maggi CA, ed. *Nervous control of the urogenital system.* London: Harwood Publishers, 1993, with permission.)

Denervation

If the autonomic fibers leading to the bladder are divided, the smooth muscle increases its sensitivity to neurohumoral transmission. Decentralization refers to those injuries in which the *preganglionic* fibers have been divided, whereas denervation refers to those injuries in which the *postganglionic* fibers have been divided. This supersensitivity effect is most pronounced when the postganglionic fibers are transected (352). Westfall (358) suggested several possible mechanisms for this supersensitivity: (a) increased neurotransmitter (possibly caused by diminished reuptake or degradation) with unchanged muscle, (b) altered smooth muscle cells rendered more sensitive to neurotransmitters, and (c) increased muscle-receptor density. No changes in smooth muscle–receptor affinity or density have been documented following experimental peripheral denervations. Saito and colleagues (301) induced denervation in a rabbit model and demonstrated increased force generating capacity with no change in the effective median dose (ED_{50}) for acetylcholine. They also demonstrated significant shifts in the calcium dose-response curves, implying that denervation induces some major, and as yet unknown, alterations in intracellular calcium handling in bladder smooth muscle.

Ample evidence suggests that muscles and nerves communicate with one another to maintain a homeostatic relationship independent of full-fledged contraction. Studies have shown that the peptide hormone, nerve growth factor (NGF) (343) is secreted by bladder smooth muscle cells in response to both obstruction (284) and denervation (343). NGF has been shown to induce the replication of cultured Purkinje cells, and is believed to be responsible for increases in the sizes of pelvic ganglia after experimental obstruction or denervation (316,317). These changes also have been shown to correlate with levels of mRNA coding for NGF. Gabella and Uvelius (131) have shown that, in the obstructed rat bladder, smooth muscle and ganglionic hypertrophy will occur even in the presence of decentralization (i.e., interruption of the preganglionic nerve fibers). The ganglionic hypertrophy was greater if the preganglionic fibers were left intact on one side of the pelvis. They concluded that, in the face of obstruction, smooth muscle can induce changes in the peripheral nervous system independent of the spinal cord. Brading (41) has demonstrated strong evidence in favor of denervation occurring after outlet obstruction, and believes that this destruction of the postganglionic fibers probably is mediated by bladder wall hypoxemia, which arises secondary to increases in intravesical pressure (141). Brading (41) also has noted that regional variations of denervation within the bladder wall after outlet obstruction can be attributed to differences in wall perfusion.

Skehan and co-authors (311) reported on decentralization injuries in a cat model and noted a loss of compliance with significant increases in autonomous wave activity, which could be partly overcome by the use of prazosin or acute sympathectomy. This led them to suspect that, in this decentralization model, the loss of bladder compliance was modulated by a peripheral pathway including a $_1$-receptors.

Most clinical examples of denervation injury are manifested by insults to the preganglionic fibers, such as the injuries incurred during radical hysterectomy or an abdominal perineal resection for rectal carcinoma. These injuries are better classified as decentralization because the postganglionic neurons are still intact leading to the bladder. Denervation in its purest sense implies injuries to the neurons immediately leading up to the smooth muscle.

NEURAL INFLUENCES ON LOWER URINARY TRACT FUNCTION: THE ROLE OF THE PERIPHERAL NERVOUS SYSTEM

In considering neural control over the lower urinary tract, this discussion begins first with a review of how the peripheral nervous system interacts with the lower tract end-organ structures. This is then followed in a subsequent section by a detailed analysis of how the CNS provides ultimate control and integration over lower urinary tract function.

Cholinergic Effects

Muscarinic-receptor sites that can be stimulated with a variety of cholinergic agonists and inhibited by atropine have been demonstrated in the bladder body and base of numerous species including dog (292), rabbit (172,211), fetal lamb (181), and humans (30,212). Stronger muscle strip responses are noted in the bladder body, and weaker responses in the bladder base. Levin and colleagues (211) found that the response to cholinergic stimulation of the bladder was not uniform and was substantially greater in the dome than in the base (Fig. 26A.21), and correlated these physiologic findings with cholinergic receptor–density levels. The bladder responds to cholinergic stimulation with a biphasic contraction (Fig. 26A.22). In bladder smooth muscle strips, application of bethanechol produces a rapid rise in tension to a peak value, followed by a 10% to 30% decline to a plateau value. It is during this plateau phase in a whole organ model, that bladder emptying takes place (207). Although the initial peak pressure is important, it is the sustained plateau pressure that primarily is responsible for the emptying phase. The plateau phase is most sensitive to alterations in extracellular calcium concentrations. If extracellular calcium is depleted and the muscle strips are contracted, the plateau force is lost first, followed by a gradual decline in the peak force (370).

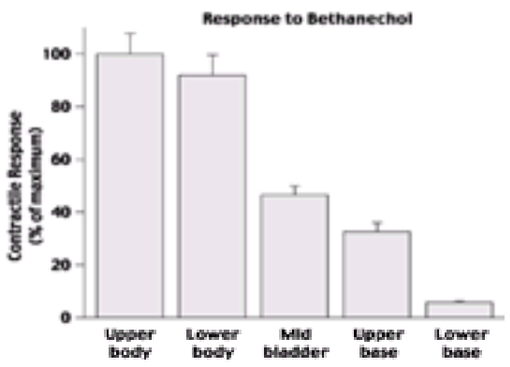

FIGURE 26A.21. Contractile response of sequential strips of isolated rabbit urinary bladder to bethanechol. Bladders were harvested and separated into five sequential longitudinal strips. The response to bethanechol (1 to 500 µM) was determined for each strip. Each bar represents the mean ± standard error of the mean of the maximum response of each strip to bethanechol (*N* = 4 to 6). There were no significant differences in the EC_{50} values (dose required to produce 50% of

maximal response). (From Levin RM, et al. Neuropharmacologic investigations of the lower urinary tract. *World J Urol* 1990;8:180, with permission.)

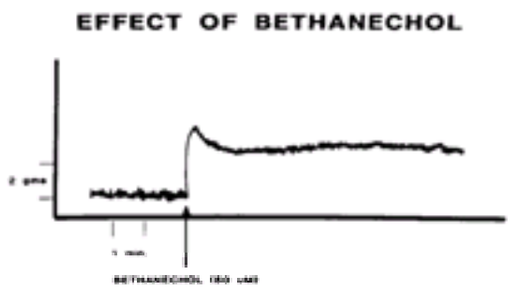

FIGURE 26A.22. Representative response of an isolated longitudinal strip of bladder body to bethanechol. The bladder body was separated into four individual longitudinal strips mounted in individual isolated baths containing 15 mL of oxygenated Tyrode's solution at 37°C. An example of the biphasic response to bethanechol (50 µM) from one strip is presented in this figure.

Muscarinic receptors also are found within the urethra; *in vitro* study of human urethral strips has shown a modest contractile response to acetylcholine that could be blocked by atropine (118). In the rat, Ekstrom and Malmberg (119) reported rapid and forceful contraction of the urethral smooth muscle in response to cholinergic stimulation, which they concluded was secondary to direct action at muscarinic receptors. Minimal responses to cholinergic stimulation were noted in rabbit urethral smooth muscle (172).

Parasympathetic Effects

Sustained increases in intravesical pressures are produced by stimulation of the pelvic nerve (Fig. 26A.23), and most investigators have come to agree that activation of this pathway is responsible for bladder emptying during normal micturition (99,340). However, it is increasingly apparent that acetylcholine is not the sole neurotransmitter released under these circumstances, because atropine blocks the response of the bladder to pelvic nerve stimulation only partially (55). In a fetal lamb model in which voiding was triggered by slow fill cystometry, Kogan (181) demonstrated that voiding pressures diminished (but were not eliminated) with the administration of atropine, implying that other transmitters were still exerting their influence. However with atropine administration, voiding was less efficient, as noted by a major increase in postvoid residual urine. It was Burnstock and associates (55) who first advocated the concept of cotransmitters, and they have identified evidence of direct release of ATP from guinea pig bladder nerves (53,54). Substantial progress has been made in the field of autonomic neurotransmission to the urinary bladder and urethra, and this progress has been reviewed by Hoyle and Burnstock (153).

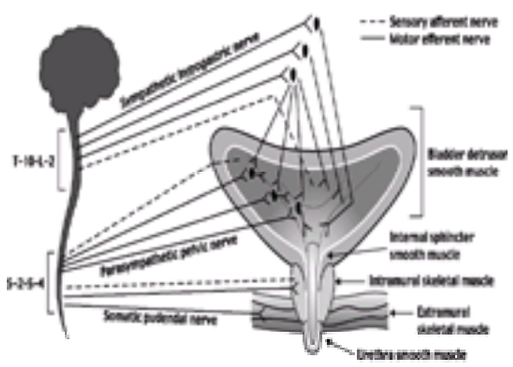

FIGURE 26A.23. A current conceptualization of lower urinary tract innervation. During the storage phase, low-level vesical afferent firing results in (a) increased sympathetic outflow to the bladder base, (b) increased pudendal outflow to the striated urethral sphincter, and (c) suppression of parasympathetic transmission in the ganglia. These neural pathways provide continence in a variety of situations, such as during sudden increases in intraabdominal pressure. It is important to note the coordinated interaction between the somatic efferents to the striated urethral sphincter, the sympathetic efferents via the hypogastric nerve, and the parasympathetic efferents via the pelvic nerve. In particular, there is a sympathetic inhibition of transmission in the parasympathetic ganglia. (From Abrams P, Wein AJ. The overactive bladder—a widespread and treatable condition. Stockholm: Erik Sparre Medical, 1998, with permission.)

Although pelvic nerve stimulation leads to increases in intravesical pressure, there must be associated synergistic effects (under normal circumstances) in the urethra. McGuire and Herlihy (241,245) offered evidence that urethral smooth muscle relaxes in response to pelvic nerve stimulation. The studies were performed with the bladder in a diverted and an undiverted state, and in both instances the urethral smooth muscle was demonstrated to relax. Furthermore, it was observed that urethral relaxation in response to pelvic nerve stimulation could be blocked by propranolol, implying that this is a b-adrenergic response. These data are supplemented by a growing literature that supports a role for NO-mediated relaxation of the urethra and bladder neck during bladder contraction measured *in vivo* (48,248,285). Such a coordinated relaxation of the urethra and bladder neck in conjunction with a detrusor contraction are essential if efficient low pressure voiding is to occur.

The aforementioned studies were *in vivo* demonstrations of parasympathetic function in the lower urinary tract; ample *in vitro* studies have shown that atropine is capable of inhibiting the response to neural stimulation. In human bladder strips, neural stimulation results in contractions that are blocked only partially by atropine (148). This atropine inhibition is variable, is species dependent, and may be affected by pathologic processes. The atropine-resistant contribution to bladder contraction will be influenced by the methodology employed (e.g., neural stimulation by electrical field stimulation at low or high frequencies). This discussion is clinically relevant because it may explain the mechanism by which many of the anticholinergics used to treat the unstable bladder fail to produce an optimal outcome. In some instances, it might make better sense to opt for two drugs with differing modes of action (353).

Some representative *in vitro* data show that, in response to neural stimulation, atropine inhibits active force by 60% in the guinea pig (186), 20% in the cat (263), 50% in the rat (3), and 50% in the human female (82). In rabbit bladder smooth muscle, Sibley (307) demonstrated atropine resistance of 60% at higher frequencies, and 15% at lower frequencies, which may be explained by the fact that higher frequencies of *in vitro* neural stimulation produce greater cholinergic contributions to the contraction.

Brading (39) summarized results showing that, although atropine resistance to field stimulation was prominent in many species, it seemed to have little representation in pigs and none in normal humans. Hutcheson and co-workers (157) demonstrated in a murine *in vitro* whole bladder preparation, that atropine abolished all response to neural stimulation. Kinder and Mundy (175) demonstrated virtually complete atropine inhibition of the response to field stimulation in 13 patients with normal CMGs. In sharp contrast to this, Sjögren and colleagues (310) demonstrated that atropine diminished the response to neural stimulation by 50% in patients with a diagnosis of bladder instability. Using similar techniques, Palea and associates (277) demonstrated an increase in noncholinergic neurotransmission in bladder strips taken at the time of surgery from patients with interstitial cystitis. It appears that noncholinergic nonadrenergic pathways of activation may become more prominent in certain pathologic conditions such as bladder instability or interstitial cystitis. These conflicting data between animal and human studies serve to illustrate again the basic observations that were laid out at the beginning of this chapter. Data from animal species do not necessarily hold up in human studies, and findings in human tissues are often from patients with known or unappreciated urologic conditions, making the definition of “normal” a major challenge.

Atropine Resistance and the Role of Purinergic Neurotransmission

Although many theories have been proposed to explain bladder smooth muscle response to *in vivo* pelvic-nerve or *in vitro* field stimulation in the presence of atropine, the accepted view today is that a substantial fraction of parasympathetic neurotransmission is mediated by noncholinergic and nonadrenergic transmitters (55,153,160,209,239). Burnstock and partners (53,56) suggested that ATP is an excitatory neurotransmitter involved in the detrusor response to pelvic nerve stimulation and used quinacrine fluorescence histochemistry to identify these purinergic neurons. They also demonstrated a bladder contraction in the presence of atropine associated with ATP release from these nerves. Downie and Dean (110,112) also demonstrated a role for ATP in rabbit bladder contraction. ATP acts at purinergic receptors that can be classified as P_2 and P_1 (57,335). The use of arylazido-aminoproprionyl ATP ($ANAPP_3$), a photoaffinity antagonist of the P_2 receptor, inhibits the effects of ATP in the cat bladder (336).

In vivo bladder contraction in response to pelvic nerve stimulation has two distinct phases; an initial peak pressure is followed by a plateau phase. Theobald (336) and Maggi and colleagues (233) demonstrated that atropine had no effect on the initial peak pressure, whereas $ANAPP_3$ produced a loss of pressure. However, although atropine had a minimal effect (10% inhibition) on the first phase of bladder contraction, it did block the second phase of pelvic nerve contraction (60% inhibition). These *in vivo* experimental data suggest that ATP and acetylcholine truly function as cotransmitters.

Results obtained using the *in vitro* whole bladder model give similar results in terms of a two-phase response to electrical field stimulation (Fig. 26A.24). Neural stimulation (via electrical field stimulation) is one of the most realistic means of studying bladder contractility *in vitro,* because it causes neurotransmitter release from peripheral neurons within the bladder wall. In the rabbit, Levin and co-authors (203) demonstrated that atropine is capable of inhibiting 50% of the peak response and completely eliminates the tonic or plateau phase, offering evidence that cholinergic stimulation is an important contributor to these phases of the contraction. With ATP stimulation alone, the pressures generated were equal to those developed in response to field stimulation in the presence of atropine. However, the ejection fraction in the presence of ATP alone was 15%, as opposed to the 95% or more expelled in response to baseline field stimulation. The cholinergic component is decreased and the purinergic component of neurotransmission is increased by pregnancy in the rabbit (217). Long-term incubation (20 minutes) of the bladders with ATP rendered them insensitive to field stimulation with atropine. These data can be explained by the studies of Acevedo and colleagues (2), who demonstrated evidence that intrasynaptic ATP is cleaved to adenosine, which then is taken up by an adenosine receptor located on the presynaptic membrane. This serves as an inhibitory stimulus to the release of further ATP from the neuron. The role of presynaptic and postsynaptic adenosine receptors has been reviewed by Collins and Hourani (77).

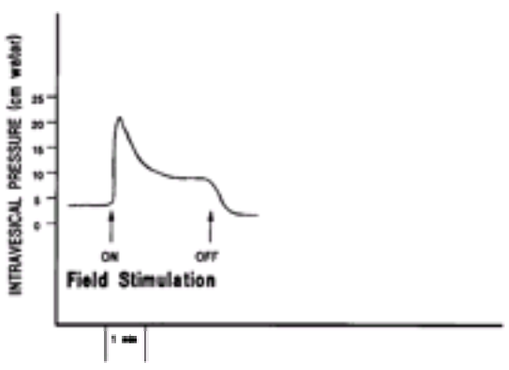

FIGURE 26A.24. Representative response of the whole rabbit bladder preparation to field stimulation. The bladder was harvested, mounted as an intact organ on an electrode-tipped catheter, and placed in an isolated bath containing 300 mL of oxygenated Tyrode's solution at 37°C. The bladder was filled to 20 mL with saline solution, and the intravesical pressure was monitored continually with a pressure transducer and recorded on a polygraph. This figure presents a representative biphasic response of the whole bladder preparation to field stimulation (80 V, 32 Hz, 1 ms). (From Levin RM, et al. Neuropharmacologic investigations of the lower urinary tract. *World J Urol* 1990;8:180, with permission.)

Brading (39) believed that atropine resistance is nonexistent in normal human bladder smooth muscle, and that the purinergic component is not related to contractile events. This does not mean that the purinergic receptors in bladder have no role in bladder function; it merely means that their role may be much more complex than was initially thought. Evidence has accumulated in a mouse with a deletion of the purinergic P2X3 receptor of alterations in sensory neurotransmission (76). These mice show detrusor hyporeflexia with bladder filling and reduced pain-related behavior to noxious stimuli. More work is required to separate the roles for purinergic neurotransmission under both normal and pathologic conditions.

Adrenergic-receptor Distribution, Stimulation, and Blockade

Urologic investigators agree that the smooth muscle of the bladder body, base, and proximal urethra contain both a- and b-adrenergic receptors, and these findings hold true in a variety of species as well as in humans. The a responses predominate in the bladder base and proximal urethra (211), whereas b responses predominate in the body (11). Responses to a- and b-adrenergic stimulation as a function of location within the bladder are presented in Fig. 26A.25 and Fig. 26A.26. Methoxamine, an a-agonist, has its greatest effect in the base of the bladder with only minimal force generated in the upper and lower body (Fig. 26A.25). In notable contrast, isoproterenol, which is a b_2-agonist, exerts its greatest effects in the upper and lower body as well as in the midbladder, with minimal relaxant responses in the base (Fig. 26A.26). Although mild b effects have been reported, the relaxation of the bladder neck and urethra during active bladder contraction more likely appear to be mediated by NO release than by b-agonists (48,50,196,248,285,328).

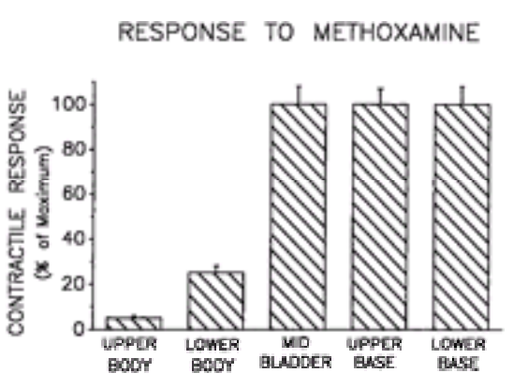

FIGURE 26A.25. Contractile response of sequential strips of isolated rabbit urinary bladder to methoxamine. The bladders were harvested and separated into five sequential longitudinal strips. The response to methoxamine (2 to 1,000 µm) was determined for each strip. Each bar represents the mean ± standard error of the mean of the maximum response of each strip to methoxamine (*N* = 4 to 6). There were no significant differences in the EC_{50} values. (From Levin RM, et al. Neuropharmacologic investigations of the lower urinary tract. *World J Urol* 1990;8:180, with permission.)

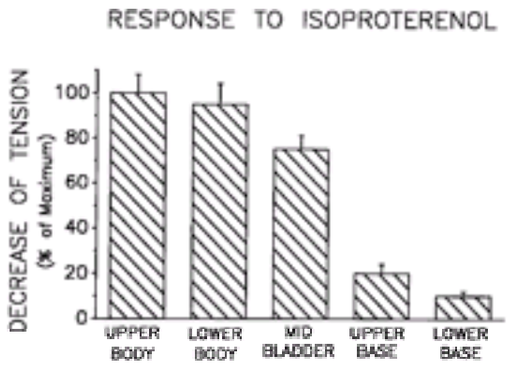

FIGURE 26A.26. Relaxant response of sequential strips of isolated rabbit urinary bladder to isoproterenol. The responses to isoproterenol were determined from 0.1 to 100 µM for each strip. Each bar represents the mean ± standard error of the mean of the maximum response of each strip to isoproterenol (*N* = 4 to 6). There were no differences in the EC_{50} values. (From Levin RM, et al. Neuropharmacologic investigations of the lower urinary tract. *World J Urol* 1990;8:180, with permission.)

The molecular basis for these physiologic findings was made clear by the application of radioligand-binding studies to these same anatomic divisions of the bladder. The a-receptors predominate in the bladder base of humans, dogs, and rabbits, and b-receptors predominate in the bladder body (216). There is some disagreement about whether these are a_1- or a_2-receptors. In the rat, Maggi and Meli (231) found that the sites were of the a_2 class, whereas Anderson and Marks (6) found 80% of rabbit receptors to be of the a_2 class and 20% to be of the a_1 family. Levin and colleagues (210) reported a_2-receptors predominated in both the human and rabbit bladder. Functional studies show that these a_1- and a_2-receptors are active in the production of force. Tong and co-authors (338) have shown that the contractile force produced by the female rabbit bladder base in response to a-agonists is significantly diminished by pregnancy. Given the gestation-induced changes in the muscarinic cholinergic receptor seen in the maternal rabbit bladder, it is not unreasonable to expect that the a-receptor density also will be regulated.

Adrenergic Effects Mediating Bladder Function

The preceding findings regarding the adrenergic contribution the storage phase of the voiding cycle can be summarized (Fig. 26A.23) as follows:

1. Neurons stimulating a-receptors at the bladder base and urethra increase outlet resistance and thereby facilitate storage.
2. Neurons stimulating b-receptors in the bladder body increase bladder compliance and thereby facilitate storage.
3. Adrenergic neurons and associated a-receptors suppress parasympathetic transmission in the pelvic ganglia and therefore inhibit bladder contractility.

These points serve to confirm the major theme established by deGroat and Saum (96); the main role of the adrenergic system is to favor storage at low pressures within the bladder. Over a 30-year span, ample evidence has supported these initial views (87,98). Despite this fairly straightforward view, many authors disagree on the extent to which the sympathetic system affects lower urinary tract function, and some believe its physiologic contribution is of lesser importance (257,272).

Hypogastric nerve stimulation in cats causes a transient rise in intravesical pressure followed by inhibition of spontaneous or evoked bladder contractions (190). According to deGroat and Saum (96), two major mechanisms account for such findings: (a) depression of bladder body contractility by b_2 stimulation and (b) a depression of parasympathetic activity in the pelvic ganglia, mediated by a-receptors (87,91). Also consistent with this view that the adrenergic axis facilitates storage are the facts that surgical or chemical (with a-blockers) sympathectomy produces increased spontaneous activity and a diminished bladder capacity (with a leftward shift of the CMG, that is, a less compliant bladder) in the cat (96) or dog (269,351). Furthermore, deGroat and Theobald (97) thought that this inhibitory pathway is activated only by afferent impulses in the pelvic nerves, which transmit the sensation of intravesical pressure. Considered together, these data suggest a spinal reflex exists in which afferent projections sense bladder distention, and efferents located in the thoracolumbar and sacral sympathetic chains are activated to produce a tightening of the bladder neck. This basic reflex arc and its modulation by the CNS are discussed in greater detail in a subsequent section.

Kleeman (177) first reported that electrical stimulation of presacral nerves and administration of a-adrenergic agonists produced bladder neck closure in dogs, and he is credited with the first observation that a-antagonists could be of use in promoting bladder emptying. The concept of a physiologic internal bladder neck sphincter controlled by adrenergic influences began to evolve (18,184,185). McGuire (242,243 and 244) proposed that with bladder filling there was stimulation of the urethral a-receptors mediated by adrenergic fibers. In his view, the ability of urethral smooth muscle to contract would be independent of any parasympathetic influence, and would be completely lost if the thoracolumbar sympathetic chain were destroyed. Numerous authors agree that under normal conditions of bladder filling, the adrenergic system increases its activity and increases bladder outlet resistance.

Although proponents of the adrenergic system could readily define how increased adrenergic stimulation could enhance bladder outlet resistance, it proved more difficult to understand how this system could be “shut down” to allow for voiding at low pressures. McGuire (243) speculated that this occurred via b-receptor activation mediated by parasympathetic stimulation. This concept is that parasympathetic stimulation leads to contraction of the bladder body and simultaneously leads to diminished outlet resistance at the bladder neck by acting at a b-receptor site. El Badawi (123) also endorsed the concept that “the storage phase of micturition is controlled primarily by the sympathetic system, and the voiding phase by parasympathetic vesicourethral innervation.” He argued that the initial b-mediated relaxation was balanced by tone adjustments in the trigone and posterior urethra was mediated by cholinergic stimulation. Today, much more is understood about which molecular mechanisms may account for the relaxation of the bladder neck and urethra since the discovery of the NO pathway.

Equally strong arguments have been made against such a powerful role for the sympathetic system in controlling the bladder neck during the storage or voiding phases of micturition. Klevmark (178), studying anesthetized cats, noted no difference in slow-fill CMGs before and after sympathectomies, leading him to conclude that the sympathetic system had little effect on bladder activity with filling. Clinically, Wein (353) has observed that patients on a-blockers for hypertension do not experience a clinically significant loss of bladder capacity. Nordling (272) also noted that ample evidence existed to support the notion that the role of the sympathetic system in the normal micturition cycle is minimal. He correctly noted that in the normal individual, “sympathectomy” or retroperitoneal lymphadenectomy almost never produce voiding dysfunction.

Adrenergic Effects on the Striated Sphincter

Today, the striated sphincter is believed to be under somatic control. Some evidence was reported in favor of an adrenergic contribution to the striated external sphincter. Nanninga and associates (261) found that external sphincter electromyelographic (EMG) activity decreased after a-blockade with phentolamine, which they attributed to a direct effect on the striated muscle. Nordling and co-workers (271) demonstrated that clonidine and phenoxybenzamine, which cross the blood-brain barrier, decreased the urethral pressure profile and EMG activity in five normal women. When phentolamine, which does not cross the blood-brain barrier, was used, the urethral pressure decreased with no change in the EMG. The authors concluded that phentolamine's effect was a result of smooth muscle relaxation, whereas clonidine and phenoxybenzamine had a centrally induced change in striated urethral tone.

Lincoln and colleagues (220) carried out a detailed immunohistochemical analysis of the striated external sphincter in normal patients and in patients with spinal cord injuries. They concluded that any adrenergic nerves identified in the sphincter were associated with blood vessels, and that there was no adrenergic component to this group of striated fibers, findings similar to Wein and associates' original study (355). Heidekamp and co-workers (146) demonstrated that transection of the pudendal nerve in the rat leads to significant atrophy of the striated external sphincter both in terms of muscle cross-sectional area and average fiber diameter. However in these animals, voiding frequencies or volumes were not affected.

Nitric Oxide Pathway

To fully understand lower urinary tract physiology, it is important to review the NO pathway. Andersson and associates (9) described the electrically mediated relaxation of the isolated human and rabbit urethra following contraction with noradrenaline. In other words, the ability of neural stimulation to relax the urethra could be “unmasked” only by first precontracting the muscle. At the time of that publication, NO was unheard of, but this report made it clear that other neurotransmitters had to be involved in the physiology of the bladder base and urethra. In the last 18 years, the literature devoted to NO has increased exponentially, and the urologic

implications of this pathway are becoming more apparent.

This field had its inception in the search for an endothelial-relaxing factor, so named because cardiovascular physiologists noted that the endothelium had to be intact if vascular smooth muscle strips were to relax *in vitro.* If this endothelium was removed, the strips lost their ability to relax. Although logic might dictate that in biologic systems, such a relaxing factor would be a peptide or complex molecule, the actual molecule turned out to be NO (278). It is ironic that this simple molecule, which under ordinary circumstances exists as a gas, is an air pollutant, is toxic at high enough concentrations, and also proves to be an important neurotransmitter. Its synthesis takes place from L-arginine, which is enzymatically transformed by the calcium- and calmodulin-dependent nitric oxide synthase (NOS) (Fig. 26A.27). NO biosynthesis requires two nicotinamide adenine dinucleotide phosphate (NADPH) cofactors. This is significant, because the NOS may be imaged histologically by staining for NADPH diaphorase. In addition, this system has a known inhibitor of NOS in the form of *N*-nitro-L-arginine monomethyl ester (L-NAME), which acts to prevent the two oxidation steps. Of the two (D and L) enantiomers, only L-NAME is active in this inhibition. Many physiology studies employ D-NAME as a control, and if L-NAME is applied, any relaxation attributed to NO should disappear. Once NO is produced by the endothelium or neuron, it may diffuse across to the adjacent smooth muscle cell, where it increases cGMP levels, which in turn stimulate the Ca^{2+}-Mg^{2+}-ATPases that pump calcium out of the cytosol and bring about relaxation. Nitroglycerin and nitroprusside, long known to be effective vasodilators, have been shown to exert these effects after their metabolism in the endothelium into NO. At higher concentrations, NO has cytotoxicity and results in degradation of cell nuclei, with breaks in DNA strands (240). It is very important to note that several NOS isoforms exist including endothelial (eNOS), inducible (iNOS), and neuronal (nNOS). Several reviews have presented a larger overview of NO and its role in a number of biologic and urologic systems (47,52,251).

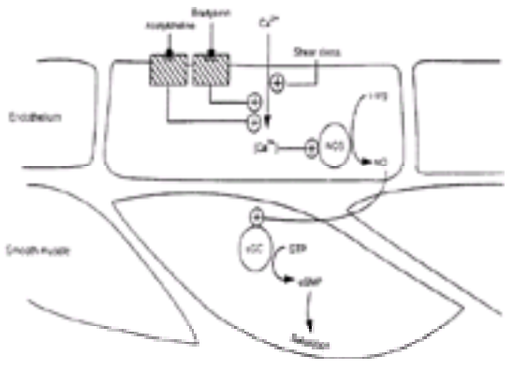

FIGURE 26A.27. A schematic diagram showing the biosynthetic pathway for nitric oxide. In response to cholinergic receptor–mediated stimulation, other ligands (bradykinin), or mechanical stress, intracellular calcium concentrations rise. This results in calcium binding to calmodulin, and this in turn activates the enzyme, nitric oxide synthetase (NOS). NOS allows for L-arginine to be broken down into NO with a required nicotinamide adenine dinucleotide phosphate (NADPH) cofactor (not shown here). NO then diffuses into the adjacent smooth muscle cell to raise cyclic guanosine monophosphate (cGMP) levels by activating soluble guanylate cyclase (sGC). It also is possible for cytokines to bind directly to smooth muscle cells and trigger a calcium-independent synthesis of NO (pathway not shown). GTP, guanosine triphosphate. (From Moncada S, Higgs A. The L-arginine nitric oxide pathway. *N Engl J Med* 1993;329:2004, with permission.)

A growing literature from many research groups suggests a major role for NO in genitourinary smooth muscle. Rajfer and co-workers (293) and Burnett and co-workers (51) have offered strong evidence to suggest that NO is the major final mediator of penile erection. In bladder and urethral smooth muscle, the effects of NO are demonstrated best after muscle strips are precontracted in response to cholinergic or adrenergic stimulation. Once a stable plateau tension is reached, the strips are subjected to field stimulation, and the NO results in a loss of active tension. The effect of NO-induced relaxation may then be expressed as a percentage of the starting baseline tension. The use of D-NAME or L-NAME then establishes that these effects are caused by NO, because only the application of L-NAME should result in a loss of this relaxation. Studies supporting a role for NO in lower tract smooth muscle come from *in vitro* and *in vivo* studies of urethra, fetal models, and detailed phenotypic characterization of the neuronal knockout mouse.

Lee and associates (197) studied the comparative pharmacology of the male and female rabbit bladder neck and urethra. They found that the urethral smooth muscle was significantly more likely to relax than the bladder neck (Fig. 26A.28), and these relaxations were abolished completely by the addition of L-NAME. The degree of NO-mediated relaxations was not different between the sexes. In the pig, Bridgewater and colleagues (48) performed *in vivo* and *in vitro* studies of the urethral smooth muscle. In one series of *in vivo* experiments in anesthetized animals, urethral pressure was monitored simultaneously with intravesical pressure. Urethral pressures were shown to increase with bladder filling. However, just before and even as the intravesical pressure was rising to initiate micturition, the urethral pressures were dropping. *In vitro* urethral smooth muscle strips in the pig also were shown to undergo relaxation in response to field stimulation that was abolished by L-NAME. In the rat, Persson and co-authors (285) demonstrated that intraarterial administration of L-NAME decreased bladder volume and increased spontaneous bladder contractions. Strips from the detrusor had no response to field stimulation, whereas strips from the urethra showed relaxations of 90% to 100% of the baseline tension.

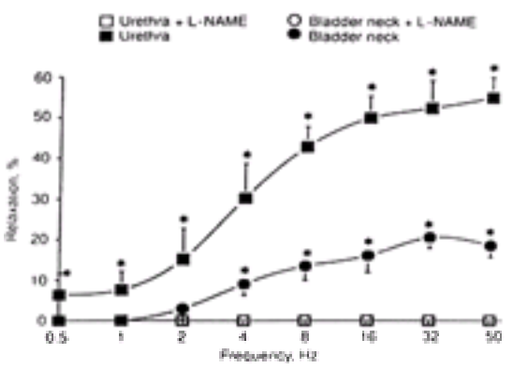

FIGURE 26A.28. The effects of L-NAME, an inhibitor of nitric oxide (NO) synthesis, on the response of the rabbit urethra and bladder neck to field stimulation following precontraction of the strips with phenylephrine. The relaxation of these strips increased with increasing frequency of field stimulation, and was abolished completely by L-NAME. These types of experiments offer evidence in support of the release of NO by neurons within the urethra and bladder neck. [From Lee JG, Wein AJ, Levin RM. Comparative pharmacology of the male and female rabbit bladder neck and urethra: involvement of nitric oxide. *Pharmacology* 1994;48(4):250, with permission.]

Lee (196) and others (183), using bovine fetal bladders, demonstrated that the bladder base showed a greater NO-induced relaxation than the body. They also demonstrated that this relaxation peaked in the last trimester, which coincides with the growing ability of the detrusor to generate tension. Gobet and co-workers (134) demonstrated that urachal ligation alone in the male sheep fetus induced bladder wall hypertrophy, and dilation of the upper tracts suggesting that a patent urachus offers protection from an immature and high-resistance bladder outlet. Kogan and Iwamoto's group (44) developed an *in vivo* fetal lamb model in which the bladder was catheterized to allow for CMGs *in utero* before and after intravenous pharmacologic manipulation. They showed that, after perfusion of L-arginine, it was impossible to fill the bladder to allow a CMG to be performed, and that this effect persisted for several hours. Ligation of the urethra and administration of L-arginine did not enhance bladder capacity on a subsequent CMG. In contrast, the application of L-NAME increased bladder capacity (248,265). In addition, with staining techniques selective for NADPH diaphorase, this group has demonstrated that NOS activity is clustered primarily at the bladder neck. Considered together, these studies suggest that NO is critical in maintaining low muscle tone at the bladder neck and minimizing outlet resistance during fetal development.

In vivo or *in vitro* studies of the NO pathways using L-arginine or L-NAME have made valuable contributions to the understanding of bladder physiology. However, such studies have a major limitation in that the use of L-arginine or L-NAME do not distinguish among the three basic isoforms of NOS. One advantage of knockout technology is that it allows for study of a specifically targeted genetic deletion. Although knockout and transgenic studies will play a great role in urologic science over the next decade, it must be pointed out that, at this time there are no bladder-specific genetic models. This point is illustrated well in the phenotypic study of the

murine model in which the second exon of the neuronal NOS gene underwent a targeted deletion. Burnett and partners (50) studied this murine phenotype, commenting on the prominent bladder wall hypertrophy; nNOS$^-$ bladders weighed a striking 60% more than their wild-type mates (Fig. 26A.29). In addition, this group of investigators measured the responses of bladder and urethral muscle strips, and demonstrated significantly blunted responses to the effects of L-arginine and L-NAME. In contrast, histology studies showed no change in the expression of eNOS, implying the knockout was nNOS specific. With evidence of bladder wall hypertrophy, these investigators also studied the *in vivc* voiding patterns. They noted a significant increase in the number of voids from 2.2 to 4.5 during an 8-hour observation period. However, Mevorach, Bogaert, and Kogan (248) studied this same population of mice, and found that when corrected for water intake, urinary frequency was identical within both groups. That these knockout mice are thirstier than their wild type controls suggests that nNOS deletion probably has other effects that influence water consumption. Mevorach, Bogaert, and Kogan (248) also reported that the nNOS$^-$ mice had a higher leak point pressure and a larger bladder capacity in urodynamic studies performed under anesthesia. Considered together, these two studies provide further support for the theory that bladder neck and urethral tone are very much dependent on NO. The discrepancy in water intake between the wild-type and knockout mouse also serves as a reminder that no technology is available at this time to create a bladder- or urethra-specific gene deletion.

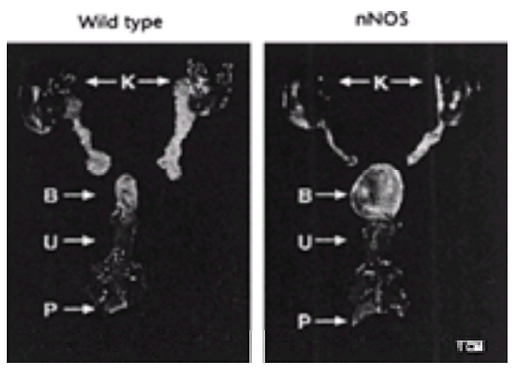

FIGURE 26A.29. A comparison of the urinary tracts from wild-type versus nNOS$^-$ knockout mice. The bladders from the nNOS$^-$ strain weighed 60% more than their wild-type controls (51). The bladders also were shown to have larger capacity and a higher leak point pressure under anesthesia (248). B, bladder; K, kidneys; P, prostate; U, urethra. (Reprinted from Burnett AL et al. Urinary bladder sphincter dysfunction in mice with targeted disruption of neuronal nitric oxide synthase. *Nature Med* 1997;3:571, with permission.)

In summary, a number of independent investigators have shown that NO plays a major role in bladder neck and urethral smooth muscle relaxation, with a lesser role in the bladder body. This has been demonstrated in a number of species, in fetal and adult tissues, and includes *in vivo* and *in vitro* studies, as well as a knockout mouse model. Based on all this evidence, it appears that NO plays a major role in the relaxation of the bladder neck that allows the “shutter mechanism” to open, and in the lowering of urethral pressures. When these events are timed properly, followed by detrusor contraction, voiding proceeds with synergy at low pressures. As molecular methods improve (e.g., antibodies, nucleic acid probes), it will be possible to probe small biopsy specimens to assess patients with clinical voiding dysfunction, by looking for disruptions in NO pathways.

Prostaglandins

It is well established that the bladder is a site of prostaglandin synthesis. This has been shown by the release of prostaglandins following bladder distention (133) or distention and pelvic nerve stimulation (171). The rate-limiting enzyme involved in prostaglandin synthesis is cyclooxygenase (COX), which exists in two isoforms (1 and 2), and the expression of COX-2 has been shown to diminish during fetal gestation in the mouse (280). Although no changes were shown in COX-1, COX-2 protein and gene expression are induced in mature mice via bladder distention (279,280). The deletion of the COX-2 isoform results in a mouse with normal bladder morphology, but these mice later die of renal insufficiency (253). Thus it is clear that, although COX-2 is regulated developmentally and its synthesis is increased with distention, its expression clearly is not mandatory for bladder development and normal function. This does not imply that prostaglandin synthesis in the bladder is unimportant; it does point out that during bladder development, other pathways compensate for the loss of COX-2 expression, and that bladder emptying is not prostaglandin dependent.

The potential roles for prostaglandins in the lower urinary tract might include stimulating smooth muscle contraction, triggering sensory receptors, and altering the microcirculation. Andersson and Sjögren (10) noted that prostaglandin E (PGE) and prostaglandin F (PGF) produce contractions of bladder smooth muscle strips. These contractions were slower to develop and of longer duration than those induced by acetylcholine and were not influenced by tetrodotoxin, atropine, or phenoxybenzamine. This would suggest that prostaglandins are capable of acting directly on the smooth muscle. However, despite such experimental evidence, most authors today believe that prostaglandins do not contribute to normal bladder contraction. Topical application of PGE2 onto the dome of a partially filled rat bladder induced a contraction *in vivo,* and this contraction is abolished if the animal is pretreated with capsaicin (which blocks the C fibers). On review of the collected literature, Andersson and Sjögren (10) concluded that it is unlikely that prostaglandins are involved directly in bladder emptying, but rather serve as modulators of neurotransmission (7). In support of this concept, Downie and Karmazyn (113) observed that mechanical irritation of the epithelium increased the basal tension and active responses to field stimulation. These effects were related to the intensity of the trauma; were mimicked by prostaglandins of the E, F, and I series; and were blocked by prostaglandin-synthesis inhibitors.

Substance P

Substance P, a peptide hormone, originally was detected in extracts from gut and brain and was prepared as a powder (hence the designation P). Its pharmacologic effects are varied, including vasodilation; contraction of bronchial, intestinal, and other smooth muscle; and stimulation of salivary secretion. Small amounts are found in the bladder in a suburothelial position, as well as in the dorsal root ganglion and dorsal horn of the lumbosacral cord (5,258). Substance P also has been shown to be present in cholinergic neurons (108). *In vitro,* substance P produces a bladder contraction that is atropine resistant (258), but does not alter the response to field stimulation. Most authors conclude that substance P is not a mediator of excitatory noncholinergic transmission, but rather serves as a sensory neuromodulator. Mallory and deGroat (238) demonstrated that when injected intrathecally, substance P could inhibit bladder activity, and this effect was reversed by naloxone, indicating that it was mediated by opioid intermediates.

Vasoactive Intestinal Polypeptide

Vasoactive intestinal polypeptide (VIP) contains 28 amino acids and was first isolated from the intestinal tract. It has a wide range of effects, including stimulation of cardiac contractility, glycogenolysis, and potent vasodilation. It serves to relax a variety of smooth muscle systems and stimulates the secretion of pituitary and hypothalamic hormones. VIP is the most common peptide hormone found in all the bladder layers, but its expression is especially prominent submucosally. As with other peptide hormones, *in vitro* studies have demonstrated contraction, relaxation, or no effect directly on bladder smooth muscle; it now appears that VIP may exert its influence at the level of the spinal cord. Igawa and co-workers (161) have shown that VIP given either intraarterially near the bladder or intrathecally leads to diminished bladder capacity and increased spontaneous contractions (intravenous doses had no effect). The use of hexamethonium (a ganglionic-blocking agent) abolished the effects of the intrathecal doses of VIP, but not the intraarterial doses. This led the authors to conclude that VIP may be facilitating the micturition reflex at the spinal cord and ganglionic levels. These views would be supported by studies using immunohistochemical techniques, where VIP has been located in the neurons, ganglia, and spinal segments (169). In addition to serving as a possible modulator of bladder contractility, the presence of VIP in afferent neuron groups has raised the possibility that it is involved in sensory pathways.

Neuropeptide Y

A peptide hormone, neuropeptide Y (NPY), contains 36 amino acids and occurs in numerous locations, including the bladder. Some authors have noted a role in bladder (258) or urethra (374). However, Peekan and associates noted that an NPY agonist had no effects of lower urinary tract smooth muscle. Furthermore, they could not identify specific receptors for NPY in bladder or prostatic smooth muscle. Dixon and colleagues (108) identified strong immunohistochemical evidence of NPY in cholinergic neurons within the bladder. As is the case with substance P and VIP, NPY may play more of a role in modulating sensory signals from the bladder

for processing by the peripheral and central nervous systems.

Enkephalins

The role of opioids in the lower urinary tract has tended to center on their CNS action. However, evidence that opioids bind to specific receptors in the urinary bladder exists, and it has been suggested that the enkephalins may function as inhibitory neuromodulators at the peripheral and ganglionic levels (93). Administration of naloxone to normal patients produces notable changes in their CMGs, with a significant decrease in bladder compliance. This correlates with the studies of Sillen and Rubenson (308), who demonstrated that intravesical instillation of morphine into the bladder produces diminished frequency and amplitude of spontaneous contractions. This work has clinical significance in the postoperative management of patients following intravesical surgery such as open prostatectomy or ureteral reimplantation. Cubina and co-authors (83) used intravesical morphine administered by a catheter placed at the time of open ureteral reimplantation surgery to manage postoperative discomfort and bladder spasms. The analgesic results appeared to be secondary to direct action on local receptors, because no serum morphine levels could be detected.

Other Transmitters

Evidence exists to support a role for histamine and serotonin in bladder smooth muscle contractile function. Contractile H_1 receptors have been documented in rabbit bladder, and the response to histamine is blocked partially by atropine. This has led some to speculate that muscarinic receptors may be partly involved in this pathway. When applied directly to the bladder, serotonin (5-hydroxytryptamine) produces a biphasic contraction. The initial phase is thought to be a result of stimulation of autonomic ganglia, and the prolonged plateau is caused by a direct effect on the smooth muscle (61). It is beginning to appear more likely that serotonin exerts its major effects within the CNS (99). Other transmitters receiving increasing attention include the excitatory amino acids and g-aminobutyric acid (GABA); these are discussed in ensuing sections on the role of CNS modulation of the lower urinary tract. However, Maggi and co-workers (232,233) have shown that GABA may enhance neurotransmission in the bladder body. Furthermore, receptors for GABA have been detected in the bladder.

CENTRAL NERVOUS SYSTEM REGULATION OF THE LOWER URINARY TRACT

Neural Pathways

In the mature individual, the ultimate control of micturition resides in the CNS and is under cortical control (88). With maturity, cortical input then serves to remove any inhibitions over the micturition center, which in turn removes any descending inhibitory influences. It is the removal of this supraspinal influence that allows for micturition to proceed. Upon completion of micturition, the spinal pathways are shifted back into an inhibitory mode. Much has been learned about where these voiding pathways reside within the CNS. Early studies consisted of neural injury models, but the current literature contains neurophysiology studies of increasing sophistication. As a result of the tremendous growth in neuroscience research, an increasing number of inhibitors of CNS neurotransmission are now available to help sort out the role played by various transmitters such as GABA (88). This section begins with a review of basic neuroanatomy, followed by a discussion of some of the newer advances in neurochemistry and neurophysiology.

Tracing Studies

The neural circuits that control lower urinary tract function have been delineated over many years with studies that grow increasingly more sophisticated. It is worth giving a brief overview of how these pathways came to be identified. Intravesical administration of WGA coupled to horseradish-peroxidase resulted in staining of those spinal segments involved with bladder function. Subsequent viral tracing studies have been conducted in animal models in which the pseudorabies virus particles are administered intravesically. This neurotropic virus is then taken up by the afferent nerves within the bladder wall, and transported in a retrograde fashion by axonal transport. Furthermore, the pseudorabies virus crosses synapses, resulting in viral expression in a second-order neuron. The neurons that have been labeled with the pseudorabies virus are then identified by immunohistochemical staining (Fig. 26A.20). In this manner, those segments within the spinal column, brainstem, and cortex that play a role in the micturition process have been identified. These studies give an anatomic picture or circuit diagram, but do not offer insight about how these circuits interact. A second kind of tracing study can not only label the affected spinal column segments, but also begin to assess function. Following chemical or infectious irritation of the rat urinary bladder, it was demonstrated that increased c-fos gene expression over controls was seen in very specific segments of the spinal cord (Fig. 26A.20) (349).

In Vivo and *In Vitro* Physiology Studies

Although the traditional studies (270) to assess neural pathways called upon the use of a controlled surgical injury and assessment of the subsequent change in function, there has been an increasing ability to conduct detailed electrophysiology studies. These are accomplished by stimulating the afferent or efferent nerves and monitoring the resulting changes in bladder pressure or action potentials in the efferent neurons. It also has proven possible in a rat model to remove the bladder, pelvic sidewall, and sacrum, with an intact spinal cord and brainstem and place this preparation in an organ bath (324). This allows for the application of electrical stimulation at various spots along the spinal column, while simultaneously measuring bladder pressures (Fig. 26A.30). This system also allows for the application of receptor agonists or antagonists to sort out which neurotransmitters are active during the voiding cycle. An alternative model that allows for study of the sacral reflex arc is the spinal slice preparation. In this system, the nerves are stained *in vivo* to identify the afferent and efferent limbs, and a thin slice of a sacral level of interest is harvested and maintained in physiologic buffer (Fig. 26A.31). This allows investigators to stimulate the afferent nerves while simultaneously measuring the action potentials in the interneuron and the efferent limb of the circuit (98).

Clinical Findings

In the course of assessing voiding dysfunction in a variety of settings, clinicians have a growing opportunity to understand what role each part of the CNS plays in bladder function. Carefully documenting the voiding history, performing a careful neurologic examination, and tabulating the urodynamic findings now can be correlated with new imaging technologies such as MRI or positron emission tomography (PET) (36) scanning. However as with any clinical study, patients present with a variety of possible explanations for their voiding dysfunction. An elderly patient with lower urinary symptoms and Parkinson's disease may have voiding dysfunction on the basis of structural anatomic findings such as BPH. This heterogeneity in patient population is minimized in animal models where the examiner has more control over the variables. This points out the importance that animal models have had in arriving at the current understanding of how the CNS controls bladder function.

Spinal Cord and Brainstem

Spinal cord segments S-2 to S-4 are responsible for the process of micturition, with the major focus of activity at S-3 (32,90,99,302). These nerve fibers exit the cord at the vertebral T-12 to L-1 level and pass down to the respective vertebral foramen, through which they exit. The interior zones of the spinal cord are composed of gray matter in which groups of neurons that carry out similar functions are bundled together; they are called *nuclei.* The parasympathetic neurons originate from nuclei in the intermediolateral zones of the gray column (Fig. 26A.32). As these tracts descend through the sacral segments, the nuclei controlling the rectal and bladder function become separated, with bladder neurons remaining at the lateral aspect of the gray matter. Some interneurons are thought to connect the nuclei serving the rectum and bladder. Onuf's nucleus is a series of neurons clustered in the midventral spinal gray matter at human levels of S-2 and S-3. It supplies the innervation to the external striated urethral sphincter, the anal sphincter, and most pelvic floor muscles with classic somatic fibers.

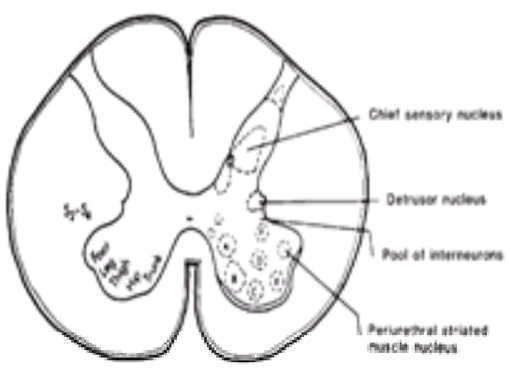

FIGURE 26A.32. Spinal cord at level S-2–S-4. Location of detrusor and pudendal motor nuclei. Bilateral representation, though not pictured, exists. (From Hald T, Bradley W. *The urinary bladder: neurology and dynamics.* Baltimore: Williams & Wilkins, 1982:5, with permission.)

Within the brainstem's anterior pontine region lies a group of neurons called *Barrington's nucleus,* which are still believed today to be the origin of impulses for bladder control (20,87,98). Destruction of this center or any areas below it will introduce permanent voiding dysfunction (43,99). Transection above this pontine center results in detrusor hyperactivity, a phenomenon well known to clinicians evaluating incontinence after strokes. Neurons modulating the pontine micturition center come from the cerebellum, basal ganglia, thalamus, hypothalamus, and cerebral cortex (Fig. 26A.33). Experimental electrical stimulation of Barrington's center caused detrusor contraction and a simultaneous decrease in EMG activity in the external striated sphincter (63,324).

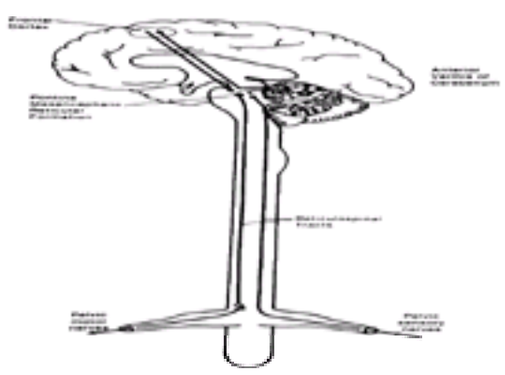

FIGURE 26A.33. The pontine voiding center and its connections with the cerebral cortex, cerebellum, and spinal cord. Sensory stimuli are also integrated in the pontine region before being conveyed to the cortex by the spinothalamic tracts. (From Bhatia NN, Bradley WE. Neuroanatomy and physiology: innervation of the urinary tract. In: Raz S, ed. *Female urology.* Philadelphia: WB Saunders, 1983:12, with permission.)

Sensory stimuli from the lower genitourinary tract must allow the distinction between pain, temperature, touch, stretch, and fullness. These differing sensory functions are handled in different segments of the spinal cord. Sensations of stretch or fullness are carried to the posterior columns of the cord and conveyed to the pons (i.e., the nucleus tegmentalis dorsalis) (32). From there, spinothalamic tracts carry these signals to the cortex (Fig. 26A.33).

Cerebellum

The cerebellum serves to modulate motor activity initiated in other parts of the CNS. It receives sensory input from the bladder and pelvic floor muscles. Its efferent role is to maintain tone and coordination in the pelvic floor striated muscles, and it also has an influence in coordinating relaxation of the pelvic floor with detrusor contraction. Electrical stimulation of the cerebellar fastigial nucleus suppresses the detrusor reflex by inhibiting the pontine micturition center. In a clinical correlate, Leach and colleagues (195) reported on urodynamic findings in 15 patients with cerebellar ataxia. Detrusor hyperreflexia was seen in 60%, and an acontractile bladder was noted in 30% of the patients in this series.

Basal Ganglia, Thalamic Nuclei, and Limbic System

The nuclei of the basal ganglia, located below the cortex and adjacent to the thalamus, consist of the caudate and red nuclei putamen, globus pallidus, and cells of the substantia nigra. Evidence supports the theory that these structures have an inhibitory role on the pontine micturition center (32). The clinical correlate is in patients with Parkinson's disease who have lost their dopaminergic neurons within the substantia nigra, and who have hyperactive detrusors. The thalamic nuclei relay sensory information upward to the cerebral cortex (44,144). It has been shown that bladder distention does cause neuronal activity to increase in these regions. The limbic system comprises areas located primarily in the temporal lobe, and is thought to include the amygdala, hippocampal formation, and cingulate gyrus. Electrical stimulation of these areas produces variable results. Depending on the zones chosen, bladder activity may be facilitated or depressed. There is no obvious clinical pattern for voiding dysfunction following damage to these zones.

Cerebral Cortex

The supermedial portion of the frontal lobes and the genu of the corpus callosum (Fig. 26A.34) are responsible for lower urinary tract control (32,144). Depending on where electrodes are placed, cortical stimulation may either facilitate or inhibit detrusor contractility. However, transection data all suggest that the result is an inhibition of the pontine micturition center (190,262). Following stroke, the most common urodynamic finding is uninhibited detrusor contractions. When voiding occurs, it is with synergistic relaxation of the external sphincter. The areas of the cortex concerned with innervation of the striated sphincter are located on the medial aspect of the cortex within the central sulcus. Axons originating in this region pass caudally through the internal capsule into the lateral columns of the spinal cord. The axons serving the detrusor arise in the frontal lobe and traverse the basal ganglia to synapse with the pontine micturition center. The use of sophisticated imaging modalities such as PET (36) or single-photon emission computed tomography (SPECT) scanning (143) will help to further localize those portions of the cerebral cortex that influence lower urinary tract function (128).

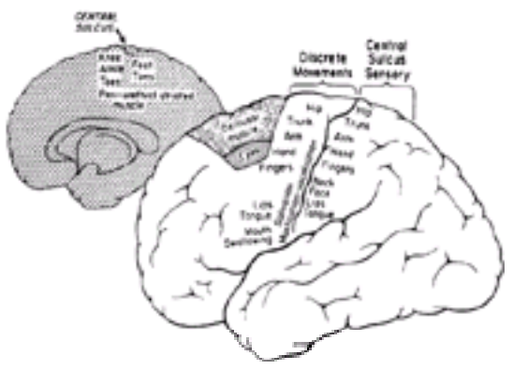

FIGURE 26A.34. Areas in the cerebral hemispheres concerned with innervation of the bladder (lateral surface) and periurethral striated muscle (medial surface). (From Bhatia NN, Bradley WE. Neuroanatomy and physiology: innervation of the urinary tract. In: Raz S, ed. *Female urology.* Philadelphia: WB Saunders, 1983:12, with permission.)

Central Transmitters

The potential transmitters of the CNS governing micturition have been reviewed by deGroat and associates (87,98,99). Both GABA and glycine have been shown to function as inhibitory neurotransmitters within the cord. In addition, there is modulation by the enkephalins, and evidence of facilitation by dopamine. A current view of the factors influencing the pontine micturition center is shown in Fig. 26A.35. Acetylcholine also is a CNS neurotransmitter; muscarinic receptors predominate in the brain, whereas nicotinic receptors populate the spinal cord. Acetylcholine effects at the pontine center may to be facilitative (325) or inhibitory (296).

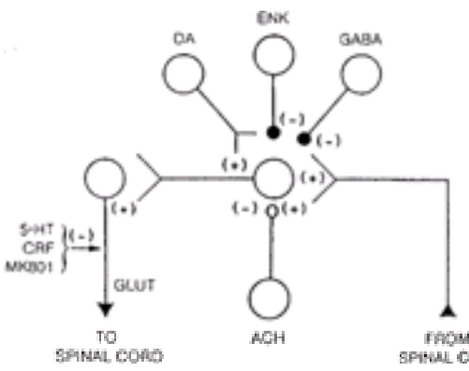

FIGURE 26A.35. A diagram showing the multiple influences demonstrated thus far on neurotransmission in the pontine micturition center, and in the descending tracts of the micturition reflex pathways. ACH, acetylcholine; CRF, corticotropin-releasing factor; DA, dopamine; ENK, enkephalins; GABA, g-aminobutyric acid; GLUT, glutamic acid; 5-HT, 5-hydroxytryptamine; MK801, a noncompetitive *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonist; (+), excitatory synapse *(open circle);* (-), inhibitory synapse *(closed circle).* The pontine voiding center may be activated or depressed by acetylcholine. The descending tracts may be inhibited by 5-HT agonists, CRF, and MK801. (From deGroat WC, Booth AM, Yoshimura N. Neurophysiology of micturition and its modification in animal models of human disease. In: Maggi CA, ed. *The autonomic nervous system, nervous control of the urogenital system,* vol. 3. London: Harwood Academic Publishers, 1993, with permission.)

Ample evidence confirms that GABA functions within the spinal cord as a tonic inhibitor of the parasympathetic nuclei in the sacral cord. Using the isolated brainstem–spinal cord–bladder preparation (Fig. 26A.30), Sugaya and deGroat (324) demonstrated that the amplitude of bladder contractions elicited by electrical stimulation of the medullary voiding center was increased when the GABA-receptor antagonist, BCMI, was added to the bath. They also demonstrated that the increases in amplitude and frequency of spontaneous contractions were more prominent in the 1- to 3-day-old rats than in the 7-day-old group. These data suggest that the GABA-mediated inhibitory actions of the pontine micturition center played a more central role in the neonatal group of rats.

Strong evidence also supports a role for the enkephalins in the central nervous component of the micturition pathways (38,92,99). In cats, the systemic addition of naloxone, an opiate antagonist, increased the frequency and amplitude of spontaneous contractions, diminished bladder capacity, and improved bladder emptying capability. The actions of opiates may occur at central sites such as the pontine micturition center, the sacral cord, or the peripheral bladder ganglia. Staining has identified enkephalin-containing nerve terminals in each of these sites, and at each site the local administration of opioids has produced inhibition of the micturition reflex (38).

These inhibitory actions are mediated by three types of opiate receptors: μ, d, and k. In the cat spinal cord, the k receptors primarily are responsible for the inhibitory effects, whereas in the brain, the μ and d receptors predominate. deGroat and associates (92) proposed that the enkephalins act at d receptors to depress acetylcholine release from the bladder's preganglionic neurons. They felt that the μ receptors in the brainstem are concerned primarily with modulating bladder capacity, and the d receptors in the cord are concerned primarily with modulating the magnitude and duration of the bladder contraction. Motor neurons in the nucleus of Onuf (which supplies the striated external sphincter) have been shown to have a strong enkephalinergic innervation, suggesting a possible role for the enkephalins in relaxing the sphincter in conjunction with micturition. The role of enkephalins has been reviewed by deGroat (99), and it is apparent that these mechanisms may influence bladder tone and capacity. The regulatory mechanisms are complex, and the wide range of receptors involved in these responses opens up the possibility for future pharmacologic manipulation of the lower urinary tract using these pathways.

Central Pathways

In an initial formulation, deGroat and Ryall (95) proposed a straightforward system in which sensory data entered the dorsal columns with a synapse impinging on the motor nucleus of the pelvic nerve. A descending neuron acted to modify this simple reflex arc. The reflex neurogenic bladder that develops after spinal cord transection would be explained by the loss of these inhibitory influences. Over the past 30 years, deGroat and co-workers have continued to provide growing evidence for the concept of a supraspinal regulatory pathway of micturition. The experimental evidence in support of this concept is reviewed in the final paragraphs of this section.

The concept that bladder control is mediated by the spinal cord is shown by classic spinal cord transection experiments. In such studies, cord injury results in an initial

phase in which the bladder is rendered acontractile. This is followed by the emergence of bladder overactivity. Bladder overactivity also is noted in the presence of hexamethonium (a ganglionic blocker) and tetrodotoxin (which abolishes all neural activity). A model of bladder instability has been developed by Sethia in which bladder transection was used to disrupt the neural fibers within the bladder wall. In this setting, the bladder developed uninhibited contractions that could not be ablated by hexamethonium nor tetrodotoxin. This would imply that there is also a myogenic component to the uninhibited bladder contractions seen after spinal cord injury. These studies all suggest that bladder compliance is very dependent on modulation of the bladder smooth muscle tone by descending influences transmitted by the central and peripheral nervous systems.

A number of important functional studies have accumulated to support the notion of a pontine micturition center. Using the *in vitro* brainstem–spinal cord–bladder preparation, Sugaya and deGroat (324) demonstrated that electrical stimulation of a collection of neurons within the pons produced a rise in bladder pressure. In these experiments, they also demonstrated that this rise in bladder pressure was blocked by the addition of either (a) hexamethonium or (b) glutamatergic-receptor antagonists. In these preparations, tactile stimulation of the perineum also produced a rise in bladder pressure that could be inhibited by these same blocking agents as well. Furthermore, transection of the spinal cord above the lumbar segments enhanced the reflex contractions in response to tactile stimulation of the perineum. These data again would imply that the spinal reflex arc mediated within the sacral segments is modulated by influences descending from the brainstem.

Growing evidence also suggests that the function of the sacral reflex arc is age dependent, and that with maturation there is greater influence from the pontine micturition center over the voiding cycle. Evidence comes from experiments performed using the spinal slice preparation. In these experiments, fluorescence labeling allowed for identification of the parasympathetic preganglionic neurons, which were studied with whole-cell recording methods to determine the nerve conductance (14,15,87). Electrical stimulation of interneurons (located within a 100-µm radius of the labeled neurons) produced a postsynaptic current in the parasympathetic neurons that could be measured (Fig. 26A.31). High-efficiency transmission was noted in neonates with a gradual loss taking place in excitatory transmission at 3 weeks of age (Fig. 26A.36). This loss of transmission efficiency was blocked when the animal was spinalized.

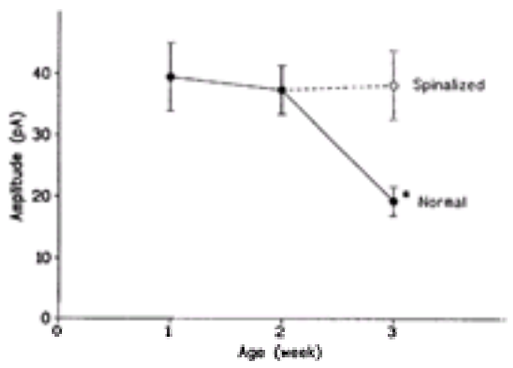

FIGURE 26A.36. There is a developmental shift in excitatory transmission as measured by current amplitude at interneuronal synapses giving rise to parasympathetic preganglionic (motor efferent) fibers. This diagram shows the currents measured in the motor fibers following stimulation of afferent neurons (see experimental design in Fig. 26A.31). With normal development there is a decline in synaptic efficiency and a drop in current amplitude produced by standard presynaptic stimulation. This drop in synaptic efficiency seen with normal development is blocked by spinal cord injury. These data imply that the developmental shift in synaptic transmission at the sacral level is modulated by supraspinal influences. (From deGroat WC, Araki I. Maturation of bladder reflex pathways during postnatal development. In: Baskin LS, Hayward SW, eds. *Advances in bladder research. Advances in experimental medicine and biology,* vol. 462. 1999:253, with permission.)

Summary of Central Nervous System Control Over Micturition

deGroat's current (87,98) concept of this neural axis reflects that two forms of bladder-to-bladder reflexes exist. One is mediated at the sacral level of the cord and is activated by nonmyelinated afferent C fibers; these neurons are blocked by capsaicin. The second reflex arc is called *supraspinal;* it is mediated by myelinated afferent A fibers that enter the dorsal columns and travel upward to the pontine micturition center. At this point, the signals are made available for the cortex to assess the sensory input. If the situation is deemed appropriate, influences descend from the cortex to the pontine micturition center that will either facilitate or inhibit this cluster of neurons (Fig. 26A.37). One point that deGroat has emphasized strongly is the role of the sympathetic system in facilitating the storage of urine (Fig. 26A.37). This diagram emphasizes the detrusor sphincter reflexes and the role of the sympathetic fibers in maintaining tone at the bladder neck in response to filling, as well as an inhibition of the detrusor. However, once micturition is initiated, the adrenergic system plays some role in relaxing the bladder outlet and releasing its inhibition of detrusor function to allow for the parasympathetic system to generate effective voiding pressures. deGroat (99) also believes that the NO pathway plays a critical role in relaxation of the bladder neck in response to the appropriate neuronal signal. The pudendal nerve, which is activated during filling to enhance storage of urine, is inhibited by supraspinal influences during micturition, thereby causing the striated external sphincter to relax.

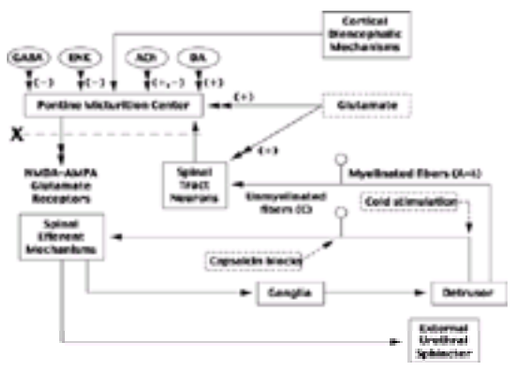

FIGURE 26A.37. Central micturition reflex pathways in the cat. With an intact neural axis, micturition is initiated by a supraspinal reflex pathway centered in the pontine-mesencephalic reticular formation. The reflex is triggered by myelinated afferents (A-d) subserving tension receptors in the bladder wall. In animals with chronic spinal injury, micturition is blocked initially as connections between the brainstem and sacral cord are interrupted. A spinal reflex emerges that is triggered by unmyelinated C-fiber vesical afferents. This reflex is usually weak or undetectable in animals with an intact neural axis. [From deGroat WC. A neurologic basis for the overactive bladder. *Urology* 1997;50(6A):36, with permission.]

The aforementioned distinction between A and C fibers is not merely of academic interest. Under normal circumstances, sensory signals from the bladder wall are transmitted by the myelinated A fibers only. However, in response to spinal cord injury, C-fiber afferents become active, and the clinical relevance of this is the potential role for the use of capsaicin as a therapeutic modality under these circumstances (236,349). These fibers also are mediators of the cold water reflex–stimulation test, which is seen in infants and following spinal cord injury. Sorting out which pathways are activated in various types of bladder injuries will be critical to applying capsaicin or newer analogs thereof in the medical management of patients. Resiniferatoxin, a vanilloid capsaicin analog, is 1,000 times more potent but has less initial neural depolarization, which should minimize the pain experienced with intravesical administration. These recent advances in C-fiber inhibitors and their potential application have been well reviewed (72,104).

IMPORTANT QUESTIONS ABOUT BLADDER FUNCTION

In the final pages of this chapter, the goal is to present some of the key features of bladder function and to use the preceding information to explain the observations made during the storage and emptying phases of the micturition cycle. The goal is to put the science that has been reviewed to work by tying together some of the major concepts about bladder function in a normal setting. This will serve as a stepping stone to the next chapter, in which the clinical aspects of voiding function will be discussed. Every effort has been made to present a balanced viewpoint, and the literature cited, for the most part, has already been presented. Some of the

viewpoints expressed represent the authors' thoughts about bladder function; these are based on their own collective experimental and clinical work.

What Bladder Wall Properties Determine Normal Compliance?

All investigators agree that a unique feature of the urinary bladder is its remarkable compliance, whereby large volumes of urine produce exceptionally low intravesical pressures. All agree that the bladder has notable viscoelastic “passive” properties (79,142,373). The methods may vary, but these clinical and experimental observations demonstrate that the bladder may be filled to a substantial degree before a significant rise in pressure occurs. In assessing the early phases of the CMG curve, one might argue that the bladder merely is “unfolding,” and the smooth muscle simply is undergoing an anatomic realignment from an empty tubular structure to a more spheric configuration. Once this has occurred, the next phase of compliance is a relaxation of the smooth muscle elements to allow the cells to elongate at the expense of becoming thinner. The role of the extracellular matrix is crucial in this phase, because without it, the smooth muscle cells would not be capable of acting in unison. However, this phase of the CMG is going to be more sensitive to pharmacologic manipulation.

What really determines the compliance of the urinary bladder? As shown in Fig. 26A.38, the middle portion of the fetal bovine CMG curve is exquisitely sensitive to the effects of calcium depletion in the buffer and exhibits a significant shift to the right (increased compliance). This also was demonstrated in the rabbit whole bladder model (205), fetal bovine muscle strips (368), and the murine whole bladder (157). Pharmacologic manipulations to affect smooth muscle tone produce a marked increase in bladder capacity in the midportion of the CMG curve. Coplen and associates (80) used the larger size of the bovine bladder to their advantage by repeating sequential CMGs after calcium depletion and after peeling away the muscle layer, leaving only the lamina propria and mucosa. In Fig. 26A.38, these two CMGs are presented and compared with the baseline study. A significant increase in compliance is seen following calcium depletion, and an even greater increase following the myomectomy. Clinically, this compliance of the mucosa and lamina propria was used by Cartwright and Snow (64) as they developed the concept of autoaugmentation for the neurogenic bladder. By peeling away the constricting and fibrotic smooth muscle, a template was left that ballooned out to create a large diverticulum. Smooth muscle and urothelium reappeared onto this “scaffold,” demonstrated on histologic examination in a canine model (65).

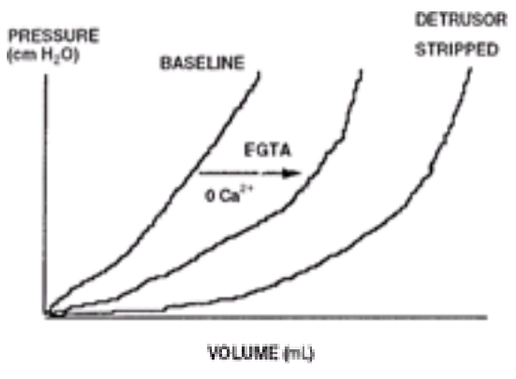

FIGURE 26A.38. The *in vitro* whole bladder model was applied to the fetal bovine bladder in this series of experiments. Each bladder was mounted as an intact organ in an isolated bath containing 300 mL of oxygenated Tyrode's solution at 37°C. The bladder was filled at 1 mL/minute with a pump, and the intravesical pressure was monitored continually with a pressure transducer and recorded on a polygraph. After a baseline cystometrogram (CMG) was obtained, the bladder was emptied and rested for 1 hour. Then the buffer was changed over to a system with 0 calcium and 2 mM EGTA (a powerful calcium-chelating agent), and field-stimulated to deplete intracellular calcium reserves. After 1 hour, the CMG was repeated; as shown there was a significant shift to the right, with some increase in total capacity. The bladder was again emptied and rested for 1 hour. Then the muscle layer was peeled away, and the CMG was repeated. Following detrusor stripping, a remarkable increase in bladder capacity and compliance was noted. (From Coplen D, Macarak E, Levin RM. Developmental changes in normal fetal bovine whole bladder physiology. *J Uro*l 1994;151:1391, with permission.)

Ewalt and co-workers (127) proposed that the lamina propria layer might be responsible for bladder compliance. The experimental evidence in normal fetal and adult bovine bladders (80) supports that the lamina propria and mucosal layers are the most compliant layers of the bladder wall. Ewalt's findings require further explanation—this was an immunohistochemical study in which noncompliant bladders from myelomeningocele patients were compared with control bladders obtained at the time of reimplant surgery. Frozen sections were cut and stained for collagen types 1 and 3 and fibronectin. The results were striking, with a dramatic increase in the deposition of collagen, especially within the lamina propria layer. Furthermore, the collagens that were deposited appeared to have an increased quantity of type 3 (although both types were increased) and of fibronectin. An interesting histologic observation was the deposition of collagen fibers in between the muscle bundles, which possibly could act to restrict the cells. Although Coplen and colleagues' data suggested that the lamina propria layer was the most compliant of the bladder wall components, these data were obtained in normal tissue (80). In the presence of obstructive pathology, it is entirely possible that the dense deposition of matrix elements in the lamina propria will serve to diminish bladder compliance. These observations also might help explain why, despite the logic underlying its development, autoaugmentation has failed to work in every case.

The association of increases in type 3 collagen with noncompliant bladders was strengthened by the work of Baskin and colleagues (21,22,25) in a fetal bovine system. They demonstrated that bladders from the first trimester were the least compliant, with a gradual gain in compliance in the second trimester. The third-trimester bladders were the most compliant. Similar findings were seen in a fetal bovine model using an entirely different experimental methodology (196). Baskin and co-workers (21,22,25) demonstrated that the type 3 collagen fraction was highest in the first-trimester bladders, and then diminished with each trimester in parallel with the increases in compliance. Coplen and co-authors' data (80) pointed out the major contributing role of tone in these measurements of compliance, because these bladders all became more compliant in the absence of calcium. Upon depleting the intracellular calcium reservoirs, Dean and Cargill (101) found that fetal bovine compliance diminished with normal aging, which is contrary to Baskin's original report. Considered together, these data would suggest that compliance is a complex property that is the sum interaction of many variables and is unlikely to be attributable to any one bladder wall component alone.

Experimentally, *in vitro* evidence exists for a loss of bladder compliance following obstruction or ischemia (168,218). Given the collagen deposition in these obstructed bladders, one might make the logical assumption that the deposition of extracellular matrix is responsible for this shift to a less compliant state. However, in a rat model (273) and a murine model (199) of bladder outlet obstruction with *in situ* cystometry performed in a sedated animal, no loss of bladder compliance could be demonstrated. In a detailed videourodynamic analysis of bladder outlet obstruction in the awake rabbit free of sedation, Stein and colleagues (320) demonstrated that bladder compliance remained unchanged. This lack of change in bladder compliance was seen despite the impressive accumulation of extracellular matrix. These findings in the *in vivo* animals free of sedation or anesthesia contrast sharply with observations made in the *in vitro* whole bladder system.

Clinically, many bladders such as those seen in patients with outlet obstruction or spina bifida end up as tiny, fibrotic, and noncompliant. How can these clinical observations be reconciled with the experimental findings of unchanged compliance? In the clinical setting, infection may be superimposed, or additional inflammation secondary to a chronic indwelling catheter may be present. Furthermore, the patient with an outlet obstruction usually is decompressed before any surgical intervention. Regardless of its pathogenesis, all would agree that the end-stage bladder characterized by poor compliance and associated with massive deposition of extracellular matrix responds poorly to medical management. In the future, major emphasis must be placed on interrupting the sequence of molecular events that lead to the end-stage bladder. Intervening to enhance bladder performance will require a multidisciplinary team approach to gain a better understanding of how the muscle, matrix, and nervous system interact during normal development and in response to outlet obstruction.

The response of the bladder to pressure work in terms of collagen expression has been well established; what remains is a more detailed assessment of how the stimulus of mechanical stretch or distention is converted into a signal that triggers collagen synthesis (225,227). Whereas one approach might be to inhibit collagen production, another might be to accelerate its degradation, hence the importance of the work of Peters and co-workers (286) in assessing the role of the collagenases and the TIMP system following outlet obstruction in the fetal lamb. Such observations are important in terms of defining potential pathways to be targeted with pharmacologic intervention.

It also appears that the bladder will respond differently to pressure work than to volume work. Longhurst and associates (223) have shown that, although the collagen content of a bladder doing volume work rises in a diabetic rat model (116) or a tight-skin mouse model (223), the cystometric curves are shifted to the right. That is to say, despite evidence of increased collagen deposition based on hydroxyproline assays, the bladders doing volume work are more compliant. This work must be put in perspective by noting that the collagen determinations were by hydroxyproline assay (hence the types of collagen are not known), and there is controversy over how to express such findings relative to other cell contents. With the advent of transgenic technology, the impact that single gene overexpression may have on the

phenotype may be better understood. Lemack and associates (198) demonstrated that transgenic overexpression of the rat elastin gene produced a more compliant murine bladder.

It is interesting to consider the effects of urinary diversion on bladder function. Chun and colleagues (75) reported on dogs who underwent urinary diversion by intestinal conduits. The bladders experienced a loss of compliance when studied in a whole bladder model using a low–filling-rate CMG technique. In addition, the responses to cholinergic agonists were diminished, and this correlated with a drop in muscarinic-receptor density. These changes proved reversible once the ureters were reimplanted. Therefore it would appear that the bladder, like any other muscle system, must perform a certain amount of work to maintain optimal performance.

How Does the Nervous System Contribute to Bladder Capacity?

It is clear, at least in animals, that a spinal sympathetic reflex that has two components exists, which is evoked during bladder filling. One series of neurons delivers adrenergic stimuli to b-receptors located in the bladder body, which serve to diminish muscle tone. In humans, evidence that this component is significant is sparse. A second set of neurons delivers a-adrenergic influence to the bladder neck and proximal urethra, resulting in an increased resistance that improves storage capacity. In addition, evidence shows that adrenergic stimuli are transmitted to parasympathetic ganglia, where they provide an inhibitory influence over these cholinergic neurons. The pudendal nerve also is activated to provide somatic excitatory stimuli to the striated sphincter during filling. This innervation contributes to compliance, as noted by experimental work in which the administration of a-blockers produces a bladder with reduced compliance. Administration of naloxone has been shown to diminish bladder capacity and increase the pressures generated by spontaneous contractions. Either systemic or direct injections of morphine into the CNS produce enhanced bladder capacity and a decrease in the magnitude of spontaneous contractions (308). These observations argue for a role of the enkephalins in regulating bladder tone.

The presence of spontaneous activity during filling has been studied experimentally. Most smooth muscle strip preparations exhibit a certain degree of rhythmic contractions *in vitro* independent of any stimulation, but a correlation of this with *in vivo* activity is difficult. It also depends on the type of *in vitro* model used. Levin and colleagues (203) observed that, although spontaneous activity is seen in isolated strips, it is not observed in the whole bladder preparation. This implied that the contractions seen in strips are a myogenic response to stretch that is applied incrementally. This has been studied *in vivo* as well. For example, in the anesthetized cat, Klevmark (179) reported that slow-fill cystometry produced rhythmic contractions that were not seen in the awake animal. Furthermore, these contractions were unchanged by cord transection above T-10, and their pattern changed or they were abolished by partial or complete peripheral denervation. These experiments support the notion that bladder contractions are inhibited during filling by neural input from the sacral cord. In a rat model, Sugaya and deGroat (324) have shown that supraspinal neural input helps maintain this state of minimal bladder activity via a pathway with GABA as the main transmitter. Some authors (41,324) have summarized three major experimental findings in support of the notion that neural output from the cord tonically inhibits the bladder. Spontaneous bladder activity was increased by (a) removing the lumbosacral cord, (b) blocking ganglionic function, and (c) abolishing all neural activity with tetrodotoxin.

How do these experimental findings relate to humans? Most contemporary descriptions of urodynamics maintain that any phasic increases in bladder pressure that occur in response to filling are abnormal (1,348). However, it is important to keep in mind that artifact may be introduced into a urodynamic study if the filling rate is not set correctly. It certainly is possible to induce apparent uninhibited contractions at a fast nonphysiologic filling rate, and such contractions will not be reproduced when the filling is accomplished at slower rates. This explains the interest in Holter-type monitoring systems for assessing bladder function in the ambulatory patient.

What Determines Outlet Response During Filling?

Most investigators agree that urethral resistance is increased during filling. This measurement is made using a pressure transducer that is withdrawn across the urethra to produce the urethral pressure profile, a graph of pressure versus urethral distance. This is a difficult measurement to standardize both in clinical practice and experimentally. At least three components contribute to urethral pressure: (a) a thick and soft mucosa that coapts, (b) a smooth muscle layer invested in matrix, and (c) an outer striated muscle layer. Some believe that it is virtually impossible to separate these various components from one another, nor is it possible to separate the striated and smooth muscle components on a pharmacologic basis.

The neurophysiology data suggest increased activity in the pudendal and hypogastric nerves during bladder filling (89,99). This correlates with the clinical urodynamic picture of increasing pelvic floor EMG activity as the bladder progressively fills. This pelvic floor activity is transmitted by the pudendal nerve, which also innervates the striated sphincter. It still is not certain what role pelvic-nerve activity may have in modulating the striated sphincter. How to separate these two muscle components is experimentally difficult. However, it seems logical to assume—based on physiology, morphology, and pharmacology—that the urethral smooth muscle does play a role in increasing urethral resistance. To rigorously prove this either clinically or experimentally is difficult, and much of the evidence is indirect. Not all experimenters report equivalent findings regarding urethral pressures in response to bladder filling. Abdel-Rahman reported no change in urethral pressures while filling a cat bladder. Yet, Bridgewater and co-authors (48) reported an increase in urethral pressure in a pig bladder during filling, and a drop in pressure during micturition. This drop in pressure was inhibited by blockers of NO synthesis, leading these authors to attribute urethral relaxation to neuronal-mediated NO release. This concept is receiving growing support from multiple research groups.

Perhaps the current view of the urethra and bladder neck is best summarized as follows: evidence of a rich sympathetic innervation of the bladder neck and urethra exists, and strong evidence suggests that as bladder filling occurs, the neuronal output to these muscle groups is increased. Given the anatomic arrangement of the base and urethra, this tension results in a closing of the shutter mechanism. Furthermore, evidence shows that some of the bladder base musculature extends into the urethra. With micturition, there is a tightening of some of these muscle fibers so that the angle of the vesicourethral junction changes into a more funneled configuration, in conjunction with a NO-mediated relaxation of parts of the bladder neck and urethra, all of which allow for egress of urine at low pressure.

The passive properties of the urethral wall also contribute to resistance and hence to continence, albeit the extent to which this is feasible may be debated. Some authors have claimed it may contribute 20% to 40% of the resistance accounting for continence. It is important to be aware of the original observations that this mucosa is resting on a rich vascular bed that also is rich in collagen and elastin (372,373). This “mucosal seal mechanism” (60) is important to keep in mind for several reasons when considering the therapy of urinary incontinence (Fig. 26A.2). First, in postmenopausal females, it is a layer that is amenable to hormonal replacement, and this can explain the small number of women whose mild incontinence may be managed by estrogen replacement. Second, it is important in knowing where to place endoscopically injected collagen or autologous fat.

Why Is Continence Preserved During Increases in Intraabdominal Pressure?

Clearly, the forces that maintain outlet resistance are complex. The dynamics of opening the bladder neck and urethra are even more complex, given that the baseline state of affairs is a closed bladder outlet. This is important because egress of urine requires two key features: a sustained detrusor contraction of appropriate magnitude, and an open and funneled bladder neck. Only if these two conditions are met will micturition occur at low pressures. A cough or Valsalva maneuver will result in increased intravesical pressure, as will the administration of subcutaneous bethanechol. However, these maneuvers will not result in urinary leakage in the normal individual because, although these two maneuvers increase intravesical pressure, that is all they accomplish. They do not cause or contribute to a “coordinated” bladder contraction. Because the bladder neck is closed, the pressure is distributed evenly within the bladder.

In addition, some anatomic factors should be taken into account. It is agreed that increases in intraabdominal pressure are transmitted to that portion of the urethra (proximal) that is located within the abdominal cavity, a mechanism first proposed by Enhorning (126). Enhorning speculated that with stress urinary incontinence, the urethra descended out of the abdominal cavity and into the pelvis, where increases in intraperitoneal pressure could not provide additional urethral compression. This view was countered by Tanagho (332), who demonstrated that the urethra was gaining inherent tone from the constriction of sphincteric muscle groups (striated, smooth, or both).

As simple and appealing as these views might be, those who operate frequently in the female pelvis point out that the boundary separating the urethra into “abdominal” and “extraabdominal” zones is not so distinct (102). Based on studies in human cadavers, DeLancey (103) has proposed the hammock hypothesis, in which the urethra lies on a supportive layer composed of the endopelvic fascia and the anterior vaginal wall. If this layer is anchored properly to the arcus tendineus fascia and the levator ani muscles, the result is a urethra that is suspended in a hammock and compressed against the pubis. As long as this hammock is intact, even a cystocele will not affect the urethral pressure profile. But if the hammock is loosened, the urethra falls away from the pubis, and the compressive effect is lost, allowing for egress of urine into the urethra (Fig. 26A.39). An example of just how this hammock may be interrupted is offered by ectopic ureteroceles that, if large enough, can distort the bladder neck and extend down the posterior aspect of the urethra. In doing so, a large ureterocele may create a large cystic cavity posterior to the urethra, and when the ureterocele is deflated by either endoscopic incision or upper-pole partial heminephrectomy, the result is a bladder neck and urethra that

may not function normally. It is noteworthy that following upper pole heminephrectomy only, 10% of the patients developed stress urinary incontinence (154).

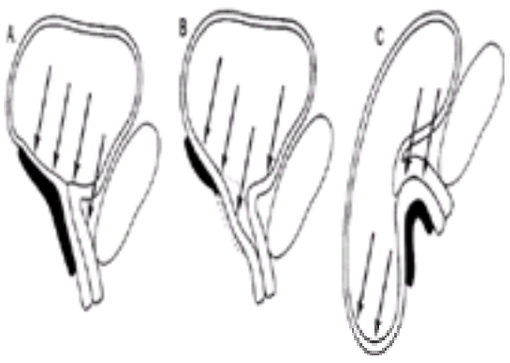

FIGURE 26A.39. The hammock hypothesis is illustrated in these diagrams. **A:** The investing layer of pelvic fascia and anterior vaginal wall, which compose the hammock *(shown in black),* serve to compress the urethra, which feels the effects of the abdominal pressure; this results in elevated urethral resistance. Loss of this sling effect *(dotted line)* produces a zone of low resistance in which increases in abdominal pressure produce egress of urine into the posterior urethra, **(B)** thereby initiating stress incontinence. The presence of a cystourethrocele alone may not produce stress incontinence if there is an adequate sling to counteract the effects of increased abdominal pressure by increasing urethral resistance **(C).** (From DeLancey JOL. Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1713, with permission.)

Although controversy about the exact details may exist, most authors agree that the evidence favors some kind of compressive force that augments the urethral resistance during periods of elevated abdominal pressure. It still is uncertain why a suspension procedure corrects genuine stress incontinence. Whether this is by increasing direct pressure transmission to the urethra, or by locating the urethra closer to the pubis, which can act as a “backboard,” remains controversial. To summarize this section, the following three reasons why normal rises in intraabdominal pressure do not result in urinary incontinence are presented.

1. An increase in total bladder pressure is not the same as a coordinated bladder contraction (with a coordinated contraction there also must be an opening of the bladder neck).
2. A striated sphincter reflex increases tone in the striated external sphincter with cough, strain, or any other rises in abdominal pressure.
3. Anatomic factors such as the cradling of the urethra against the pubic bone by the hammock increase resistance to egress of urine into the urethra. These concepts will be better understood by functional MRI studies of continent and incontinent patients.

Normal Lower Urinary Tract Function: Unifying Concepts

In any scientific review of a process as complex as micturition, there is bound to be ample controversy. Differences in species, methods, models, and investigators combine to create a diversity of opinions in the literature. When searching for ever finer details, these differences become more apparent. Although this is a source of great challenge to the scientist, it is a source of confusion for the clinician struggling to develop a rational strategy for management of voiding dysfunction. In these final paragraphs, the core concepts with which most (99%) scientists and clinicians would agree are summarized.

The bladder must be capable of performing two separate functions—storing and emptying. The bladder is one of the most compliant organs in the body, enabling its volume to expand dramatically without any significant increases in pressure until a critical point is reached. The bladder is composed of mucosa, lamina propria, smooth muscle cells, nerve endings, fibroblasts, and extracellular matrix (perhaps up to 50% of the total cross-sectional area). It is this dynamic combination of elements interacting together that allows low-pressure filling. Once a critical pressure is reached, the autonomic and somatic nervous systems are put into action. Through the pudendal nerve, somatic fibers activate the striated sphincter. An additional spinal sympathetic reflex is evoked, and its efferent fibers are carried via the hypogastric nerve. The activation of this circuit produces three primary effects: inhibition of detrusor contractility (b effect), activation of the bladder base and urethra (a effect), and inhibition of parasympathetic transmission through the ganglia. There appears to be strong support for a role for endogenous opioids and GABA in suppressing spontaneous contractions and enhancing bladder volume on the basis of CNS mechanisms.

Storage is further aided by the anatomic location of the urethra, with intraabdominal pressures being transmitted to it to enhance its resistance. This helps maintain the necessary relationship for continence: urethral pressure must always exceed intravesical pressure. When intravesical pressure exceeds urethral pressure, leakage will result regardless of the anatomy.

Once maturation has occurred, the process of micturition involves a sensation of fullness perceived by the frontal lobes of the cerebral cortex. These sensory signals are conveyed from stretch sensors by myelinated afferents, which pass superiorly to the cortex via the dorsal columns of the spinal cord. If the social setting is deemed appropriate, signals travel from the frontal cortex back down to the pons, where the micturition or voiding center is located. These circuits may offer a stimulatory or inhibitory signal to the pontine voiding center. Endogenous opioids and GABA act as inhibitors of this nucleus, whereas dopamine stimulates these neurons. Once the pontine micturition center has been stimulated, signals are sent down the cord to the intermediolateral zones of the gray matter at the S-2 to S-3 segments, which is where Onuf's nucleus exists. This nucleus contains the motor neurons of the parasympathetic system that, when activated, initiate detrusor contraction.

The supraspinal stimulation of the parasympathetic neurons initiates detrusor contraction and also triggers the inhibition of the sympathetic system and the pudendal nerve reflex. The stimulation of the parasympathetic system via the pelvic nerve results in a sustained bladder contraction of adequate magnitude. This is timed to occur synergistically with a relaxation of the bladder outlet combined with a dilation of the urethra to produce a funneled configuration with low resistance to flow. It is now known from *in vitro* and *in vivo* experiments that NO is a major neurotransmitter involved in the relaxation of the bladder neck and urethra. In addition, the sympathetic and pudendal reflexes are inhibited, resulting in diminished stimulation of the a-receptors of the base and urethra, and producing diminished tone and EMG activity of the striated sphincter. In addition to these “simple” circuits are superimposed influences from the cerebellum, thalamus, basal ganglia, and other supraspinal influences yet to be fully elucidated.

No matter what controversies exist, the experts agree on several major points. The micturition cycle involves two relatively discrete phases: bladder filling and urine storage, and bladder emptying. For these two components of bladder function to occur normally, the following concepts must apply.

Bladder Filling and Urine Storage

1. Increasing urinary volumes at low pressures must be accommodated with appropriate sensation.
2. The bladder outlet must be closed at rest and remain so during increases in intraabdominal pressure.
3. Involuntary bladder contractions must not be present.

Bladder Emptying

1. There must be a coordinated contraction of the detrusor smooth muscle that is sustained and of adequate magnitude.
2. There must be a concomitant relaxation of the bladder neck and lowering of urethral resistance at the level of the smooth and striated sphincter.
3. There must be no anatomic obstruction.

With this background review of the basic science of micturition, and the preceding summary, the authors hope that the reader is now prepared for a discussion of the clinical aspects of voiding dysfunction. In our view, it is extremely important for the clinician to appreciate that no matter how sophisticated the science, two basic phases are involved in maintaining continence: storage and emptying. This provides an excellent means of categorizing voiding dysfunction, because most causes will fall into either of these two main categories. There are, of course, subdivisions within each main category, and some disorders represent combinations of failure to store and empty. Creating these categories also facilitates the conceptualization, choice, and interpretation of urodynamic studies. Most important of all, abnormalities

of these categories and subdivisions have differing treatment options, and by classifying the clinical problem in this way, one can choose the most optimal therapy from treatment menus. These clinical considerations will be expanded upon fully in Chapter 26B.

OVERVIEW

Voiding dysfunction results from an abnormality affecting urine storage or release. A division into causes related to the bladder and etiologies involving its outlet allows all voiding dysfunction to be categorized as disorders related primarily to (a) bladder filling or urine storage, (b) emptying, or (c) a combination of filling or storage and emptying disorders. Within this scheme, combined disorders become understandable, and a therapeutic rationale is evident. Throughout this review of various types of lower urinary tract dysfunction, this classification of the clinical pathophysiology is maintained to provide a coherent description for the explanation of symptoms, urodynamic findings, and therapy. Although urodynamic and other classification schemes are useful, it is simplest to relate each diagnostic term to urine storage or release.

This chapter begins with a brief consideration of the pathophysiology and symptomatology and ends with a general outline of treatment for disorders that are categorized as “failure to empty” or “failure of filling or storage.” All aspects of neurourologic evaluation and integration of data are related within various classification systems for both neurogenic and nonneurogenic voiding dysfunction. This discussion is followed by a review of treatments for all types of voiding dysfunction. Specific voiding dysfunctions associated with neurologic disease are considered along with other disturbances in micturition.

Failure to Empty

Under normal circumstances, the urinary bladder empties completely. Failure to evacuate urine results from reduced smooth muscle content, decreased smooth muscle contractility, loss of proper neural input, excessive bladder outlet resistance, or any combination of the these conditions. Absolute or relative failure of the detrusor to contract may derive from a temporary or permanent alteration in the neuromuscular mechanisms necessary for initiating and maintaining a detrusor contraction. This includes not only loss of communication between a nerve terminal and muscle cell but also communication between muscle cells. Inhibition of the micturition reflex in a neurologically intact individual may occur by means of a reflex mechanism—for example, due to a painful stimulus, generated in the pelvis and perineum. Nonneurogenic causes include impairment of bladder smooth muscle contractility such as may occur following ischemia and metabolic disturbance, severe infection, or fibrosis. Increased outlet resistance can result from anatomic obstruction or failure of coordination of the smooth or striated sphincters during a bladder contraction. Treatments for failure to empty incorporate attempts to increase intravesical pressure, facilitate the micturition reflex, or decrease outlet resistance.

Failure to Store

Within the appropriate social constraints and normal fluid intake and renal function, adult humans urinate up to nine times a day and once or never during 8 hours of sleep. However, as with most human behaviors there is a distribution of these values, and the definition of *normal* is difficult. The function of the bladder for greater than 99% of a 24-hour period is urine storage under low pressure (less than 10 cm H_2O). Because failure to evacuate urine can cause hydronephrosis, renal failure, and eventually death, it is teleologically logical that the default for micturition mechanisms is to empty the bladder in response to stress, disease, injury, and so on.

Thus it is not surprising that one of the most common bladder disorders is urinary incontinence.

Failure of the bladder to fill at low pressure and store urine may be related to the bladder, the outlet (bladder neck, urethra, and external urethral sphincter), or both. The terminology to describe problems with urine storage is confusing. *Overactivity of the bladder* has been recently defined as an inappropriate increase in urinary frequency with or without urgency or urge urinary incontinence (66). It is a useful term that is recognized by patients. Some experts prefer terms such as *lower urinary tract symptoms* (LUTS), the *unstable detrusor,* or *irritative voiding* to describe this problem with urine storage not associated with urine leakage with provocative maneuvers and an abnormality of the bladder outlet. At the extreme end of what may be a spectrum, if pain or discomfort is also present patients are often diagnosed with interstitial cystitis, abacterial prostatitis or prostatodynia, male pelvic floor disorder, or nonbacterial urethritis in the absence of an identifiable cause.

Bladder overactivity can result from increased sensory or motor mechanisms. Moreover, increased excitability of detrusor smooth muscle enhanced excitatory neural mechanisms or reduced inhibitory mechanisms can underlie sensory and motor overactivity. Motor overactivity of the bladder during filling can be associated with identifiable involuntary contractions, or as low compliance (change in pressure divided by change in volume) without a discrete detrusor contraction. Sensory overactivity is characterized by a reduced threshold for first sensation during filling with or without discomfort. Involuntary contractions can occur with aging, neurologic disease, injury, inflammatory or irritative processes in the bladder, and outlet obstruction. Most involuntary contractions are idiopathic. In dementias and aging, changes in blood flow within white matter of the prefrontal cortex, demonstrated by positron emission tomography and single-photon emission computed tomography scanning, correlate with involuntary contractions (224). Ultrastructural changes in the bladder in elderly patients with detrusor hyperreflexia and impaired contractility (DHIC) imply significant changes in the bladder itself during aging (152). Thus both myogenic and neurogenic abnormalities contribute to the increasing complaint of bladder overactivity often with involuntary bladder contractions. The ability to inhibit these contractions in a laboratory or clinical environment yet not during normal routines has been demonstrated using ambulatory urodynamics (23). Thus the absence of involuntary detrusor contractions during urodynamic evaluation fails to exclude motor overactivity as a cause of symptoms. Reduced compliance during filling may be secondary to injury or disease, but it may also result from any process that alters the viscoelastic properties of the bladder wall. Decreased outlet resistance may also develop from structural or biochemical abnormalities of urethral smooth muscle or th e striated urethral sphincter, as well as from changes in innervation due to neurologic, autoimmune, and metabolic diseases or injury.

Disorders of the bladder outlet are often responsible for urine loss. It has been thought that stress urinary incontinence in women is caused by a failure of the transmission of intraabdominal pressures to the bladder neck and proximal urethra with straining. This concept has been challenged by microtip transducer measurements within and outside the urethra during provocative maneuvers (446). Intraurethral pressures rise before extraurethral pressures, suggesting an active neural component to continence. A change in the anatomic position of the vesicourethral junction and proximal urethra during elevated intraabdominal pressure may prevent the roof of the vagina from acting as a support for the bladder neck and urethra (129). Magnetic resonance imaging (MRI) during straining demonstrates abnormalities in the pelvic anatomy in women with stress incontinence (394). In men, stress urinary incontinence is rare. When it does occur, it arises from changes in neural function or is the result of trauma following transurethral or pelvic surgery, such as radical prostatectomy. In the latter condition, stress incontinence has been associated with a loss of urethral compliance, possibly as a result of ischemia. Loss of urethral compliance is also caused by radiation or fibrosis from an indwelling catheter. The treatment of abnormalities related to the filling or storage phase of micturition can be directed toward inhibiting bladder contractility, decreasing sensory input during filling, or increasing outlet resistance, either continuously or during abdominal straining.

EVALUATION OF VOIDING COMPLAINTS

A concise, thorough, yet cost-effective approach to the workup of a patient with voiding dysfunction is outlined in Table 26B.1. In most instances, one should initially proceed with the simplest, least invasive, most inexpensive methods, because these will often yield adequate data to support a reasonable therapeutic trial, especially of reversible therapy. The evaluation should provide insight into etiology or guide therapeutic strategy.

History	Intravenous urogram/ renal sonography
Voiding log	Voiding cystourethrogram
Physical examination including neurologic	Endoscopy
Urinallysis/culture	Urodynamics
Renal function assessment (radionuclide, creatinine)	

TABLE 26B.1. NEUROUROLOGIC EVALUATION

History

A detailed history is the most important element of the evaluation. The lack of specificity and sensitivity for many urodynamic tests heightens the reliance on history to differentiate disorders, determine etiology, and plan therapy. The clinical history of individuals with voiding dysfunction should query for neurologic disease, trauma, surgery, and medications. Drugs can be the sole reason for a change in voiding habits. Symptoms related to other organs that receive similar somatic and autonomic innervation are especially important. A temporal correlation between the triad of bladder, bowel, and sexual dysfunction should alert the clinician to the possibility of a neurogenic etiology. Simultaneous fecal incontinence, constipation, lower abdominal distention, or cramping suggests a neurologic disorder affecting intestinal or rectal sphincteric function. Changes in sexual function, such as reduced frequency, duration, and ability to obtain or maintain erections or a decrease in the volume of semen and force of ejaculation in men, could indicate a neural pathology. Likewise, a history of difficulty with vaginal relaxation or lubrication in women may indicate a neural problem. Questions relating to global neurologic status, such as orthostasis, double vision, loss of coordination, paresis, or paresthesias, should be asked.

The clinician should ascertain two things when obtaining a history. First, what is bothering the patient or most affecting quality of life? Second, what is the basis for the symptom, and does this influence therapy or prognosis? The first issue is important because many mixed symptoms require therapy that may be effective for one symptom yet worsens another. The functional classification of voiding dysfunction, as failure to empty or failure to store, can provide a basis for collecting historical data from the patient. A “wet” patient with an empty bladder is most characteristic of a storage failure, whereas a “dry” patient with a bladder that cannot be emptied is typical of evacuation failure. Primary symptoms such as these are a useful guide to a diagnosis. However, development of secondary symptoms or a combination of complaints confuses the picture. Implementation of therapeutic measures based on historical factors alone can be ineffective due to the lack of specificity of complaints. This is not to say that empiric therapy based solely on symptoms is not a pragmatic or cost-effective approach. Failure of conservative treatments or contemplation of invasive procedures warrants evaluation beyond mere history and physical examination.

Urinary incontinence (failure to store) is the involuntary, socially unacceptable, loss of urine. Incontinence arises from ureteral ectopy, congenital or acquired fistula, neuromuscular dysfunction of the detrusor or urethral sphincter, or abnormalities of the pelvic floor.

Patients with wetness from ureteral ectopy or congenital fistula are almost always females who are seen after failed toilet training. The classic presentation of a female with continuous daytime and nighttime incontinence can sometimes be difficult to obtain. Ureteral ectopy is often associated with other abnormalities of the ureteral bud or urogenital sinus, and urologic imaging should be undertaken. Formerly, an intravenous pyelogram was recommended, but recent evidence suggests that MRI with gadolinium is the most sensitive imaging modality. Administration of indigo carmine with cystoscopy and vaginoscopy is often useful.

Deficiencies in the smooth or striated muscle or fibroelastic tissue that makes up the bladder neck and proximal urethra and surrounding tissues give rise to varying degrees of urinary incontinence. Differing in severity, leakage may occur only with associated increases in intraabdominal pressure, and thus is classified as stress or exertional urinary incontinence. Yet urinary incontinence associated with provocative maneuvers is not always due to an anatomic or functional defect of the outlet. Involuntary contractions can be triggered by rises in intraabdominal pressure. A careful history may uncover a pattern of massive urine loss with minor straining or leakage beyond the straining, or the feeling that the entire bladder is emptying—all suggestive of an involuntary contraction. A scarred, fibrotic, or noncompliant urethra and bladder neck, following trauma, multiple surgical procedures, instrumentation, or radiation therapy, may lead to incontinence. In this latter case, a

constant dribbling or urine loss with minimal exertion occurs. Incontinence may also result from involuntary (unstable) detrusor contractions. This type of incontinence is associated with neurologic disease and is characterized by precipitous and episodic leakage with or without urgency. Involuntary contractions in the absence of sensation can occur. Loss of urine at night should prompt a different line of questioning. Involuntary contractions are often the cause. However, severe stress incontinence could contribute to leakage with movement or on getting out of bed. Enuresis can be classified by etiology. Total incontinence implies that voluntary voiding is prevented by continuous urine loss through an incompetent bladder outlet or decompensation from urinary retention.

Urine loss is not universally a symptom of storage failure. Overflow incontinence may manifest in a patient with detrusor decompensation or dysfunction with failure to empty. The leakage can be continuous if associated with minimal increases in intraabdominal pressure, thereby masquerading as an intrinsic sphincter deficiency or ureteral ectopy if in a child. Alternatively, incontinence may result from involuntary contractions caused by outlet obstruction and failure to empty. In this case, the precise cause of altered detrusor contractility remains unclear, but incontinence is often the resultant symptom.

Urgency is the extreme desire to void either because of discomfort or a fear of leaking. The urgency that is associated with discomfort can be due to inflammatory disease of the lower urinary tract. Urodynamic studies may be normal except for lowered threshold for first sensation and pain (idiopathic). The urgency that is associated with a fear of leaking, or a history of doing so, is usually associated with an involuntary bladder contraction, categorized as detrusor instability (nonneurogenic) or hyperreflexia (neurogenic). Thus urgency may be either a symptom of a primary failure to fill or store, or a manifestation of the detrusor hyperreflexia that develops secondary to bladder outlet obstruction. If associated with urinary frequency greater than eight times in 24 hours, the term *overactive bladder* has been used.

Daytime urinary frequency may be psychogenic. This is easily explained on the basis of multiple interactions between those central nervous system (CNS) centers (limbic, hypothalamic) associated with emotions and autonomic function. However, such an increase may represent a genuine need to void and may indicate inflammation or pain on low-volume bladder distention or detrusor overactivity. Increased frequency of urination may arise from a failure to empty completely, either because of a decreased functional bladder capacity (e.g., residual urine volume), or in association with outlet obstruction–induced detrusor overactivity.

Nocturia can accompany nonpsychogenic urinary frequency and indicate a failure of adequate urine storage or incomplete emptying of the bladder. Patients with nocturnal enuresis may have detrusor hyperreflexia (22). Enuresis may be seen in patients who exhibit a primary failure of storage or in patients who have developed detrusor overactivity because of a failure to empty secondary to outlet obstruction.

The symptom of “pressure” does not equate with the urge to void characterized by a feeling that the bladder is full or that the urge to void will soon occur. Often, no discernible voiding dysfunction is discovered in patients with a pressure symptom. This symptom could represent a resetting of the threshold for visceral afferents supplying the bladder, or it may reflect an intravesical pressure during filling that is pathologically elevated, yet below the level necessary to elicit the sensation of distention or urgency. Pressure also may be representative of the patient's accurate perception of the fact that the bladder does not empty completely and that residual urine exists. Sensation of suprapubic pressure or discomfort is mediated by afferents in the hypogastric nerve. Perineal or penile discomfort suggests mediation by afferents in the pelvic nerve.

Hesitancy and straining to void, when associated with true voiding dysfunction, often reflect a failure to empty. Hesitancy and difficulty initiating a urinary stream is not diagnostic of obstruction. Rather, increased outlet resistance or detrusor hypocontractility can give rise to these complaints.

The lack of specificity of these symptoms, especially in males, has led to an attempt to standardize terminology. The International Continence Society (ICS) and World Health Organization (WHO) have proposed the nomenclature outlined in Table 26B.2. The terms *prostatism, irritative voiding symptoms,* and *obstructive voiding symptoms* should be abandoned because of lack of clarity. The term *lower urinary tract symptoms* collectively encompasses all symptoms. *Storage symptoms* refer to frequency, nocturia, urgency, incontinence, and pain. *Voiding symptoms* refer to slow stream, hesitancy, intermittency, straining, dysuria, hematuria, and terminal dribble. *Postvoid symptoms* include postvoid dribble and the feeling of incomplete emptying. *Prostatic enlargement* describes the increase in prostate size on physical examination or imaging. *Bladder outlet obstruction* is a urodynamic diagnosis defined only by an increase in voiding pressure and simultaneous decrease in flow rate measured during urodynamics. *Benign prostatic hyperplasia* (BPH; not hypertrophy) is reserved exclusively as a histologic diagnosis.

Lower urinary tract symptoms (LUTS)	A collective term to encompass all LUTS
Storage symptoms	Frequency, nocturia, urgency, incontinence (all types), pain
Voiding symptoms	Slow stream, hesitancy, intermittency, straining, dysuria (urethral pain during voiding), hematuria, terminal dribble
Postvoid symptoms	Postmicturition dribble, feeling of incomplete emptying
Prostatic enlargement	Increase in prostate size felt digitally or detected by imaging
Bladder outlet obstruction	Characterized by an increase in voiding pressure (p_{ves} Q_{max}) and a decrease in urine flow rate (Q_{max}) measured during urodynamic studies
Benign prostatic hyperplasia	As a term, would be reserved exclusively as a descriptive histologic term

TABLE 26B.2. INTERNATIONAL CONTINENCE SOCIETY (ICS) AND WORLD HEALTH ORGANIZATION (WHO) PROPOSED NOMENCLATURE

Any combination of symptoms and abnormalities can occur, such as coexistent failure to store and failure to empty. Outlet obstruction may exist in combination with detrusor overactivity. This combination of pathology may give rise to hesitancy, straining to void, frequency, nocturia, and urgency with urge incontinence. Likewise, elements of both sphincteric and detrusor incontinence can exist in a woman who complains of stress incontinence that is accompanied by frequency, nocturia, and urge incontinence. A thorough review of the temporal aspects of these symptoms enhances the clinician's ability to tailor subsequent tests to confirm any diagnoses.

A voiding log or diary provides objective documentation of symptoms. A diary can assess daytime urinary frequency, incontinence, and voided volumes. A voiding log is especially valuable to monitor therapy. Often, patients report that urinary frequency or incontinent episodes have decreased, but inspection of the written record reveals otherwise. Pad weighing and administration of oral dyes excreted in the urine are useful adjuncts to monitor failure to store. Whether a 2-hour log is as representative as a 24-hour log or a 48-hour record is as accurate as a 5-day record is debatable (564). Practically, few patients can record diaries at their place of employment or school.

Physical Examination

In addition to symptoms, physical examination provides visual confirmation of the presence and degree of urinary incontinence and may suggest an etiology. For example, a distended bladder suggests a failure to empty. Cutaneous scars provide evidence of relevant neurosurgical, orthopedic, or pelvic surgical procedures.

A careful neurologic examination is mandatory because it may uncover evidence of a neurologic lesion or disease along with symptoms of voiding dysfunction. The examination should encompass inspection of the skull and vertebral column, assessment of mentation, and evaluation of sensory and motor function. Concentrating on the pelvis, evaluation of rectal sphincter tone and the bulbocavernosus reflex is essential to assess the integrity of sacral reflex arcs. Global assessment of autonomic function can be accomplished in the office with an upright and supine blood pressure. Acknowledgment of the presence of one or another type of neurologic disease may considerably alter further testing and treatment.

Pelvic Floor Abnormalities

A variety of methods have been used to assess the degree of pelvic floor dysfunction in women. A Q-Tip test has been used to determine the degree of urethral hypermobility (Fig. 26B.1). With a moistened Q-Tip in the urethral meatus, the patient is asked to strain. Angulation of the Q-Tip greater than 35 degrees is thought to indicate urethral hypermobility. Unfortunately, variability and lack of correlation with stress incontinence has limited the usefulness of this test. Its diagnostic and prognostic significance is debatable. Nevertheless, this simple test provides comparative data for outcome analysis.

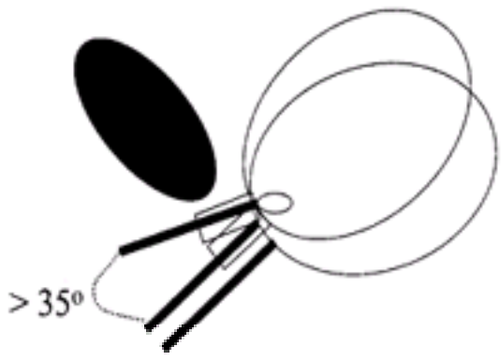

FIGURE 26B.1. Assessment of urethral hypermobility with Q-Tip test. The Q-Tip is placed into the urethra. The patient coughs and strains. A goniometer is used to measure the angle of descent from a horizontal axis. A greater than 35-degree change is considered significant.

Complaints of low back or sacral pain with or without vaginal pressure or overt bulging of a mass from the urethra should raise suspicion for pelvic floor prolapse. Assessing the degree of prolapse is problematic and lacks standardization. One scheme for classifying prolapse is based on physical examination. Physical examination should be initially performed with the patient relaxed in the lithotomy position. Failure to duplicate the symptom of prolapse or stress urinary incontinence warrants instructing the patient tostand and place one foot on a stepping stool. One blade of the speculum or a Sims' speculum is used to inspect the vagina. A clear plastic speculum, especially if transilluminated with a fiberoptic light, is very useful, especially if a fistula is suspected. Prior filling of the bladder with water or methylene blue aids in identification of a vesicovaginal fistula. The patient is asked to gently bear down several times and cough. Some women fail to adequately strain and must be prompted. If a very distal anterior vaginal wall bulge is observed, the differential includes vaginal inclusion cyst, urethral diverticulum, ureterocele, Gartner's duct cyst (off midline), tumor, or urethrocele. Beyond the urethral meatus and distal urethra, a bulge most likely represents the bladder. Determining whether the bladder herniates in the midline or laterally (paravaginal defect) can be difficult. Pelvic MRI in women has clarified many of the potential defects leading to these deformities. One of the most popular and easiest staging schemes to learn for pelvic prolapse is the Baden system. The Baden system is easy to apply based on the hymen as a reference point, but it is difficult to reproduce. In general, no prolapse is grade 0. A prolapse of the bladder on straining in the supine and upright positions is a grade I cystocele. A cystocele at the introitus is categorized as grade II. One that protrudes halfway beyond the introitus is a grade III cystocele. Complete eversion represents a grade IV cystocele. If this degree of cystocele is associated with an everted vaginal cuff or cervix, this has been termed *procidentia* or *complete pelvic floor prolapse.* Grade IV prolapse can cause ureteral obstruction, and upper tract imaging may be useful to determine if hydronephrosis exits. A pelvic floor prolapse staging system has also been developed by the ICS pelvic organ prolapse quantification (POPQ). This system measures, in centimeters, nine sites of the vagina and perineal body in relation to the hymen. It has fairly good intraobserver and interobserver reliabilities (67) (Fig. 26B.2). The nine sites are as follows:

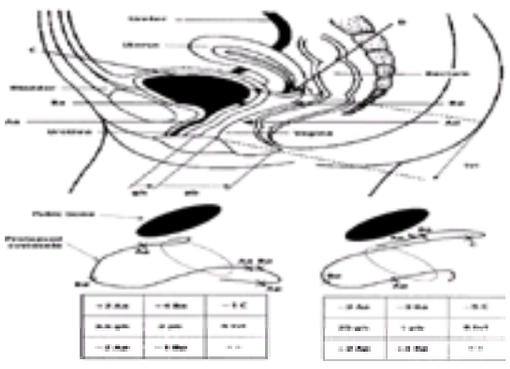

FIGURE 26B.2. Diagrams of anterior and posterior support defects based on POPQ evaluation. Leading point of prolapse is Ba (anterior) on left and Bp (posterior) on right. Numbers are measurements in centimeters for precise quantification. Severity is normalized to total vaginal length (tvl). Pb, perineal body.

1. Aa, located 3 cm proximal to the urethral meatus on the anterior vaginal wall
2. Ba, the most distal portion of the upper anterior wall
3. C, the most distal edge of the cervix or vaginal cuff
4. D, the posterior vaginal fornix
5. Ap, located 3 cm proximal to the hymen on the posterior vaginal wall
6. Bp, the most distal portion of the upper portion of the posterior vaginal wall
7. gh, the diameter of the genital hiatus
8. TVL, the total vaginal length
9. Pb, thickness of the perineal body

What this system gains in accuracy is lost in its cumbersome nature to learn and its complexity to communicate until it becomes second nature to remember during the examination.

If a bulging mass seems to originate more proximally in the vagina, one should suspect an enterocele, especially if a previous hysterectomy has been performed. Rectoceles are identified by digital rectal examination and subjectively graded small, medium, and large. Patients often complain of difficulty evacuating stool, requiring vaginal manipulation. The degree of anal tone is assessed as well. Only with a complete rectovaginal examination can appropriate therapy be formulated.

Urinalysis

Studies of abnormal renal function may uncover an unsuspected failure of emptying, or reflex intrinsic renal disease. Urinalysis and bacteriologic studies are needed because a urinary tract infection can evoke or worsen all of the symptoms of a failure to store and may result from causes of storage failure. Pyuria or persistent or recurrent infection may indicate inadequate emptying with persistent residual urine. Hematuria may be due to a malignant, traumatic, or inflammatory process. An unexplained abnormal urinalysis prompts further diagnostic tests. Recurrent unexplained dysuria, especially in older individuals with a history of smoking, warrants urine cytology to exclude carcinoma *in situ* even if a urinalysis is normal.

Imaging

Routine upper tract imaging is unnecessary in many patients with lower tract dysfunction. Retrospective data suggest that a significant abnormality is detected in only a small percentage of patients studied. However, selective imaging is warranted. Results of a urodynamic evaluation, such as reduced bladder compliance, may serve as useful indicators to select patients who warrant upper tract imaging. Upper tract deterioration can suggest emptying failure that has occurred on the basis of bladder distention, pathologically elevated voiding pressures, or both. In addition, urography is useful in assessing the upper urinary tracts before the institution of any urinary diversion to assess ureteral anatomy. In the absence of hematuria, renal sonography is themost cost-effective tool to screen for hydronephrosis, assess renal parenchyma, and measure bladder wall thickness, as well as measure residual urine. Patients with known neurogenic bladders probably require annual ultrasounds because silent deterioration of the upper tracts can develop with stable neurologic disease or after surgical or pharmacologic therapy designed to decrease bladder contractility (augmentation) or increase outlet resistance (fascial sling, artificial urinary sphincter). It is often useful to have a baseline imaging test for later comparison.

Cystography and voiding cystourethrography provide direct confirmation of leakage with stress, relevant details of bladder and urethral configuration, and

documentation of ureterovesical reflex. A straining cystogram has been used to classify the type of anatomic stress incontinence. Type 0 stress incontinence occurs when the bladder neck and proximal urethra are closed at rest and no urine loss is detected. Voluntary contraction of the outlet may explain this finding, although a phenazopyridine (Pyridium) pad test is needed to document that urinary incontinence really exists. In young women, excess vaginal secretions can occasionally be interpreted as incontinence. Type I stress incontinence is characterized by urine loss with the bladder and proximal urethra positioned above the inferior margin of the symphysis. Type IIA occurs when the bladder neck and proximal urethra descend below the symphysis, as opposed to Type IIB, in which these structures reside below the symphysis at rest. Type III stress incontinence is characterized by an open bladder neck at rest and correlates with intrinsic sphincter insufficiency. An open bladder neck at rest should prompt further evaluation to exclude neurologic disease, although in women this is not the rule. Urethral hypermobility (type II) in the absence of a low abdominal (Valsalva) leak-point pressure indicates that vaginal suspension can be considered.

Real-time voiding cystourethrography can be used to diagnose loss of coordination of the bladder with its outlet (failure to empty). Rarely, unsuspected lesions, such as a urethral diverticulum, can be diagnosed as a cause of postvoid dribbling or prolapsed ureterocele as a cause of intermittent obstruction. Even leakage secondary to an involuntary detrusor contraction can be detected by an astute examiner without the aid of differential bladder and abdominal pressures. An abnormality of emptying might be suggested by secondary signs of outlet obstruction, such as trabeculation, cellules, diverticula, or vesicoureteral reflux. If obstruction has been documented, voiding cystourethrography carefully done during bladder contraction can generally localize the site. For example, it is often useful to have radiographic confirmation of detrusor-sphincter dyssynergia. An open bladder neck can be seen on a cystogram in normal women. However, in individuals with signs or symptoms of neurologic disease, an open bladder neck may signify dysfunction of the thoracolumbar cord or its neural output.

Endoscopic evaluation may be helpful in detecting or suggesting previously unknown inflammatory or neoplastic disease or outlet obstruction. Patients with neurogenic bladders, chronic infections, bowel augmentation, or indwelling foreign bodies (i.e., catheters) for more than 7 to 10 years should be periodically assessed with cystoscopy because of the 0.4% risk of malignancy (402,611). A bloody urethral discharge should prompt immediate evaluation. Cystourethroscopy can also help guide which type of intervention is feasible, such as transurethral prostatectomy versus prostatic incision or thermotherapies for obstruction from BPH. Although conservative management of obstructive symptoms without cystoscopy is the standard of care, missed pathology such as a urethral stricture is possible. Therefore refractory symptoms warrant videourodynamics, retrograde urethrography, or cystoscopy to exclude anatomic defects.

URODYNAMICS

Urodynamics denotes a variety of diagnostic tools for the identification and measurement of physiologic and pathologic parameters involved in the storage, transportation, and evacuation of urine. The goal of urodynamic testing is to identify and quantitate the causative factors that contribute to voiding dysfunction. Because symptoms are nonspecific, the need for urodynamic testing arises when conservative measures fail or symptoms worsen. This is particularly important before advocating invasive therapy. A number of studies have documented the poor correlation between a patient's symptoms and the findings of urodynamic testing. This is true both for patients without neurologic disorders (132,170,450) and those with neurourologic disorders (56). In a study done in patients with multiple sclerosis, it was found that when treatment was instituted on the basis of symptoms and signs, it was effective in only 27% of patients. When treatment was based on urodynamic testing, efficacy rose to 83% (56). However, it is not known under what circumstances empirical treatment based solely on symptoms and examination represents a more cost-effective approach than proceeding with formal urodynamic evaluation. For example, for symptoms of precipitous involuntary loss of urine associated with urgency, does documentation of involuntary contraction on a cystometrogram really influence a trial of anticholinergic medication? How often does urodynamics per se reflect neurologic disease or poor bladder compliance and accurately indicate prognosis?

Urodynamic tests have limitations and present the potential for misinterpretation. Ideally, the symptoms should be reproduced during the urodynamic testing. Failure to elicit the symptom during routine testing suggests that the study must be repeated in as close an approximation as possible to the situation in which the patient's symptoms actually occur, be it rising, standing, coughing, laughing, orjogging. Ambulatory urodynamics has been very useful in this regard. However, evidence for whether ambulatory urodynamics makes any difference in outcome is lacking. Moreover, ambulatory urodynamics is plagued with artifacts. Patients should be asked to assess the similarity of their usual voiding to the voiding sequence evaluated urodynamically. This helps validate urodynamic data. However, the number of indeterminate tests may be high. In one study, reliable pressure/flow data used to diagnose obstruction was obtained in only one-third of patients (133). Details on how the test is performed and how data are generated is critical for accurate interpretation. Even when performed correctly, experts may disagree on interpretation as evidenced by a recent report of pressure/flow studies (290). The intraobserver differences on calculation of an Abrams Griffiths number were substantial. Conversely, there may be certain symptoms elicited during evaluation that have urodynamic correlates, yet do not correspond to the patient's original complaints. These findings may represent artifact or may be early subclinical abnormalities not manifested during normal voiding but revealed by the provocative nature of urodynamic testing. For example, involuntary contractions can be elicited in up to 20% of normal, asymptomatic subjects in the urodynamic laboratory.

Interpreting sensory data during urodynamic testing is obviously subjective. This is unfortunate because many patients with voiding dysfunction have only sensory abnormalities. It is relatively easy to assess whether the sensation of bladder filling is normal, decreased, or absent. However, a number of sensations that may arise during filling are difficult to classify. The most troublesome of these is the symptom of urgency. Although this can correlate with involuntary bladder contractions or detrusor hyperreflexia, it is not uncommon to reproduce this symptom during testing without urodynamic abnormality. The explanation is the lack of sensitivity to record the subtle changes that develop in the bladder or outlet, or the central inhibition that occurs during urodynamic testing. Methods have been developed to more objectively quantify sensory thresholds in the bladder (622,628).

Urodynamics is an operator-dependent and interactive study best performed with physician participation. Basic urodynamic modalities include cystometry with residual volume determination, uroflowmetry (voiding flow rate), leak-pressure evaluation (abdominal and detrusor), urethral pressure profilometry (static and dynamic), and combined studies (with or without fluoroscopy). The type of these tests and sequence in which they are administered is dependent on the presenting symptoms, associated findings, and presumptive diagnosis based on other neurourologic tests. Table 26B.3 lists the urodynamic modalities as they relate to evaluation of the bladder or bladder outlet. In general, the simplest and least invasive modality should be performed first. A detailed outline of the neurourologic assessment has been standardized by the ICS (548).

	Bladder	Outlet	Bld + Out
Fill/store	$P_{det(fill\ CMG)}$ $\Delta P/\Delta V$	$P_{urethra}$ ALPP	DLPP
Empty	$P_{det(void)}$	$P_{urethra}$ EMG	VfR res vol

ALPP, abdominal leak point P; DLPP, detrusor leak point P; EMG, electromyography; res vol, residual urine volume; VFR, voiding flow rate.

TABLE 26B.3. URODYNAMIC ASSESSMENT

Cystometry

Cystometry measures changes in intravesical pressure with progressive increases in bladder volume. A cystometrogram (CMG) evaluates the filling or storage phases of detrusor function. The presence or absence of a detrusor contraction, although an important observation, is not the only important information from this test.

Schematically, a normal CMG may be divided into four phases (Fig. 26B.3). There is an initial rise in pressure to achieve resting bladder pressure (phase I). The second phase—the tonus limb—is thought to reflect the viscoelastic properties of the smooth muscle, collagen, elastin, and mucopolysaccharides of the bladder wall. Distention may also release autocrinelike factors that influence contractility [e.g., parathyroid hormone–related protein, prostaglandin, peptides, and nitric oxide (NO)]. During the filling or storage phase, bladder pressure should rise very little because the normal bladder is designed to accommodate increasing urine volumes at low pressure. Normal adult bladder capacity averages 400 to 750 mL. Within this capacity, bladder pressure should not exceed 15 cm H_2O; the mean rise in normal bladders is 6 cm H_2O. Rapid filling may generate a steeper tonus limb (phase II). Bladder wall fibrosis due to infection, radiation, and detrusor hypertrophy may also

reduce accommodation and produce a steeper tonus limb. At peak capacity, the detrusor muscle and other elastic tissues achieve maximal elongation, and any additional increase in volume will be accompanied by a rise in intravesicalpressure. During this third stage (phase III), the patient should still be able to suppress involuntary voiding contractions. Ruch and Tang (481) believed that the characteristic shape of the cystometry curve is independent of neural control and is an inherent property of the structural elements of the bladder wall. More recent data with lesioning in animals or after intrathecal drugs in humans contradicts this notion, because acute changes in the tonus limb can occur with alterations in neural input (539).

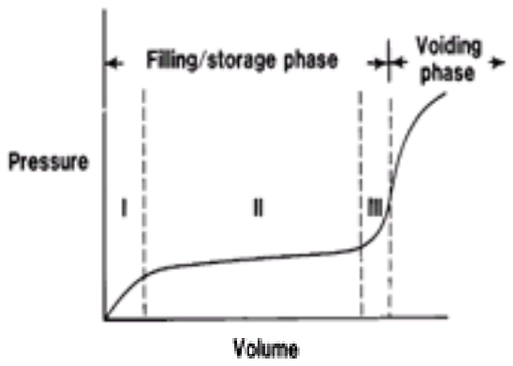

FIGURE 26B.3. Characteristics of normal cystometrogram.

The fourth phase of the normal CMG is the generation of a voluntary voiding that is dependent on smooth muscle and intact neural pathways to the micturition center located in the brainstem. A normal patient should be able to suppress voiding even at capacity. In at least 20% of CMG studies, the patient is unable to generate a micturition reflex on command. This has been attributed to psychologic supraspinal inhibition resulting from the unnatural circumstances of the study. Performance of this phase of the cystometrogram with the male patient in an erect posture and the female patient seated on a commode may facilitate a micturition reflex. Some patients with spinal cord injuries report that reflex voiding occurs only in certain positions. Formerly, urologists thought that compression of the urethra caused such difficulty. It is more likely that stimulation of sacral dermatomes reflexly inhibits micturition. Thus patients can void in the decubitus position but not in the seated position.

In the absence of detrusor contraction, diagnoses such as obstruction cannot be made urodynamically. This accounts for the observation that patients in retention, who are not shown to be obstructed because of the lack of a possible detrusor contraction, may still benefit from surgical intervention. Telemetry has been a valuable addition to urodynamic testing in which documentation of a detrusor contraction is warranted. Ambulatory urodynamics allows as close to normal an environment as possible to avoid profound supraspinal inhibition of micturition.

Both liquid (H_2O, saline) and gas (CO_2) have been used for cystometry. Although CO_2 avoids an air embolus, is clean and portable, allows a rapid rate of bladder filling, and is quick to perform, it introduces sufficient artifact as to be totally unreliable and its use should be abandoned (548). Rapid filling required for CO_2 cystometry causes a nonphysiologic appearance of the tonus limb that can be misinterpreted as reduced compliance, accommodation, and low values for total capacity. CO_2 is irritating to the urothelium, and some patients complain of discomfort and dysuria. Because gas is compressible, phasic bladder contractions of small amplitude may not be detected, and high-pressure contractions may appear to be of low amplitude. Gas may also escape around the catheter unnoticed, particularly if outflow resistance is low. CO_2 cannot be used for pressure/flow studies. Thus CO_2 cystometry cannot assess compliance, obstruction, or incontinence.

The cystometric variables that may be observed during a study are those of compliance, contractility, sensation, and capacity. A stable bladder should remain so even at an unphysiologic rate of filling of 100 mL per minute or with changes in temperatures of filling. Certain patients require a slower rate of bladder filling, including patients with a known neurologic condition, those suspected of having a hyperreflexic bladder, those with bladders with decreased compliance, and children. In adults, slow filling (physiologic filling) is up to 10 mL per minute. Medium filling is defined as 10 to 100 mL per minute. Rapid filling is any value exceeding 100 mL per minute (548). In small-capacity or poorly compliant bladders, rates of 25 to 50 mL per minute are used. During filling, the bladder volumes are recorded at (a) first sensation of filling, (b) sensation of urgency to void, and (c) sensation of maximum capacity. During the filling, provocative measures such as coughing and the Valsalva maneuver should be used to uncover involuntary contractions. The total pressure (P_{ves}) measured within the bladder is intravesical pressure, which is the sum of the pressure induced by the detrusor (P_{det}) and by intraabdominal pressure (P_{abd}). Therefore a rise in intravesical pressure recorded on a simple cystometrogram may at least partially reflect intraabdominal pressure. To eliminate such artifacts, it may be necessary to measure intraabdominal pressure simultaneously by means of a rectal catheter. Cystometers are readily available that electronically subtract the rectal pressure from the total bladder pressure, thus giving the subtracted bladder pressure, which is detrusor pressure. This measurement is crucial for provocative cystometry and for voiding studies to determine the efficiency of the voiding contraction. Subtracted pressures are the standard for measuring intravesical pressures. In this regard, care must be taken to accurately zero the pressures at the beginning of a study. The use of microtip transducers has led to misinterpretation because these devices are difficult to accurately zero. If not properly calibrated and zeroed, cystometry combined with flow rates will provide inaccurate information concerning obstruction, detrusor compliance, and detrusor leak pressures. In essence, the test results are only as valuable as the operator.

Ambulatory Cystometry

Recognition that laboratory urodynamics produces significant artifacts and may fail to evoke symptoms has led to the development of ambulatory urodynamics. Advances in telemetry, microtip pressure transducers, and computer technology allow recording of urodynamic data for delayed playback. The most common finding from ambulatory studies is the detection of involuntary contractions associated with symptoms that have not been seen in the office. However, care must be taken to avoid overdiagnosis of abnormal detrusor activity. Combining ambulatory studieswith voiding and symptom diaries and a rectal pressure probe reduces the number of abnormal contractions by 5% and 19%, respectively. This improved sensitivity rarely changes clinical decision making or therapy but can be extraordinarily useful for clinical trials. Gorton and Stanton (219) demonstrated that ambulatory urodynamics did detect detrusor instability in a greater number of patients but failed to improve outcomes. Vereecken and Vannuland (582) found that filling pressures and volumes are lower, whereas voiding pressures are higher during ambulatory urodynamics compared with standard studies. Finally, the ability to diagnosis obstruction is relatively equivalent whether one uses ambulatory urodynamics or conventional studies (474).

Abnormal Cystometric Patterns

Abnormalities of bladder function that may be detected by cystometry include altered sensation, changes in detrusor compliance, disorders of detrusor contractility, and presence of involuntary detrusor contraction or detrusor areflexia.

Bladder compliance refers to the ratio of the change in bladder volume to pressure that occurs during filling. Normally, filling pressures average 6 cm H_2O and should not exceed 15 cm H_2O. A bladder with decreased compliance is one in which the pressure rises steeply with filling (Fig. 26B.4). Technical variables affecting the absolute value for compliance include method of calculation (Fig. 26B.5) and rate of filling. Some authors refer to initial and terminal compliance, based on the portion of the filling urine from which the measurements are calculated (202). Reduced compliance may result from detrusor hypertrophy, fibrotic changes in the bladder wall, bladder wall inflammation, and possibly neurologic lesions.

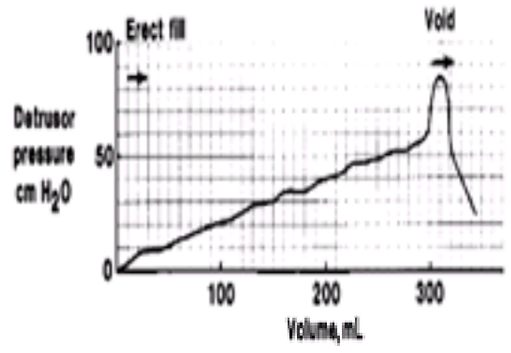

FIGURE 26B.4. Cystometrogram showing decreased detrusor compliance.

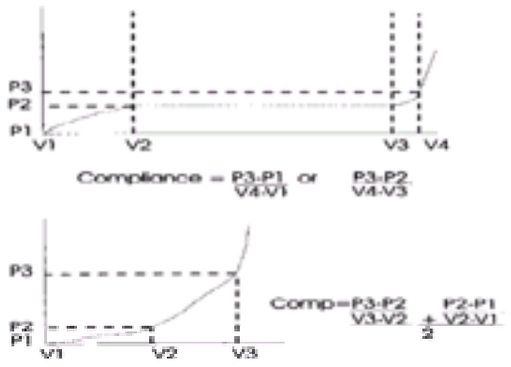

FIGURE 26B.5. Calculated bladder compliance by two different methods.

Involuntary detrusor contraction refers to a phasic rise in bladder pressure. This may occur in response to provocation such as a cough, stress, or postural change, or it may occur spontaneously (Fig. 26B.6). States of increased detrusor contractility have been referred to as *detrusor instability* or *detrusor hyperreflexia.* In general, *detrusor hyperreflexia* refers to an involuntary bladder contraction that is a direct result of associated neurologic disease, whereas *detrusor instability* is seen in the absence of neurologic disease (234). Detrusor hyperreflexia commonly occurs as a result of suprapontine cerebral disorders, such as cerebrovascular accidents or parkinsonism. This may also occur in patients with suprasacral spinal cord disease processes, such as multiple sclerosis, or trauma with or without concomitant detrusor-sphincter dyssynergia.

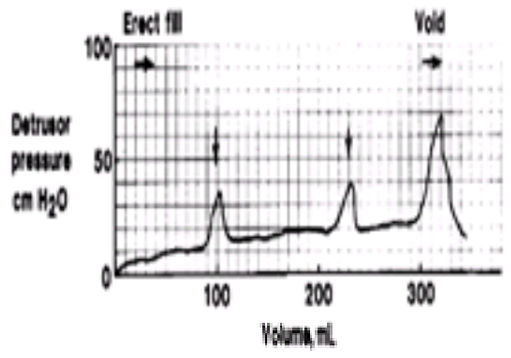

FIGURE 26B.6. Cystometrogram showing increased detrusor contractility.

With marked detrusor instability (or hyperreflexia), the compliance may also be reduced, probably secondary to detrusor muscle hypertrophy, and alterations in extracellular matrix such as collagen subtype (164) (Fig. 26B.7).At the most severe end of the spectrum is the noncompliant bladder with reduced capacity (Fig. 26B.8). Steepness of the curve can be the result of muscle contraction and reduced compliance or severe fibrosis. This may be from a neurogenic cause, although it may be seen in patients with severe outlet obstruction or inflammation. An involuntary contraction can also be masked within the rising slope of the filling curve.

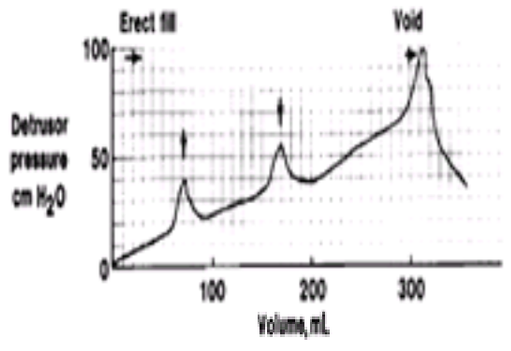

FIGURE 26B.7. Cystometrogram showing decreased compliance and increased detrusor contractility.

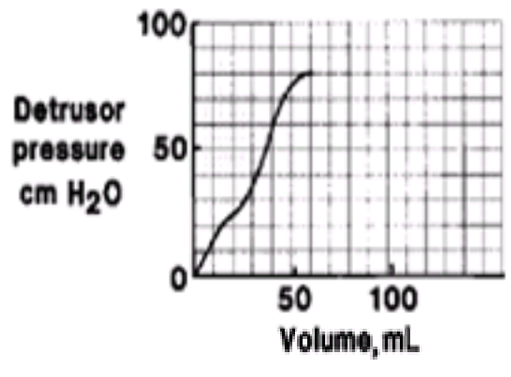

FIGURE 26B.8. A cystometrogram showing noncompliant bladder.

A capacious bladder of normal or increased compliance (Fig. 26B.9) may result from chronic overdistention caused by decreased sensation. This sensory abnormality can occur in the diabetic patient or from chronic outlet obstruction. It may also be a behavioral phenomenon in patients who voluntarily inhibit micturition for long periods. Weir and Jaques (609) found that 30% of patients with bladder capacities in excess of 800 mL were urodynamically normal. Therefore increased bladder capacity alone is not necessarily an indication of disease, especially in patients who can generate a normal detrusor contraction and empty completely.

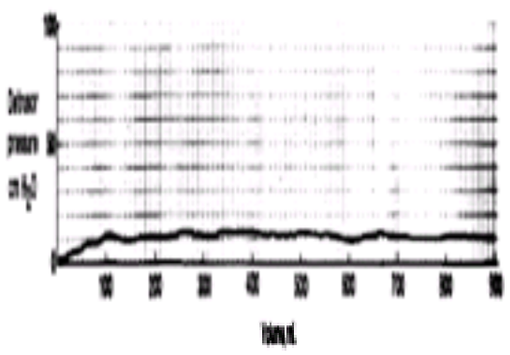

FIGURE 26B.9. Cystometrogram showing increased detrusor compliance.

Decreased bladder capacity may be purely sensory in origin (normal compliance and stability), and it is commonly seen with an idiopathic frequency syndrome and in those with an inflamed bladder. These patients are usually able to produce a voluntary detrusor contraction on ambulatory urodynamics (Fig. 26B.10).

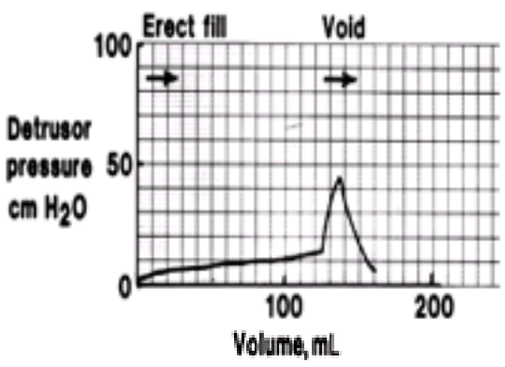

FIGURE 26B.10. Cystometrogram showing normal compliance and contractility, but small capacity.

Reduced or low bladder compliance (DV/DP) is 20 mL/cm H_2O (548). Compliance is determined from the reference value of pressure when the bladder is empty until maximum cystometric capacity or the initiation of a detrusor contraction. A minimal DP of 1 cm H_2O is used. Therefore the maximal potential value for compliance equals the volume range over which it is calculated.

Ice Water Test

The ice water test was introduced in the 1950s to assess micturition reflexes in patients with spinal cord injury and neurogenic bladders (71). The basis for this test is a cold thermoreceptive (cooling) reflex generated by unmyelinated C-fiber bladder afferents. In neurologically intact adults, voiding results from activation of myelinated Ad afferents. In neonates, spinal cord–injured patients, and those with suprasacral injuries, a spinal C-fiber reflex can often be elicited (197). Intravesical administration of C-fiber neurotoxins such as capsaicin and resiniferatoxin can eliminate this reflex (98). Some authors believe the temperature (0°C), rate of filling (300 mL per minute), volume (100 mL), and pressures of the abnormal detrusor activity (greater than 15 cm H_2O) are critical to the definition of a positive test (197). However, these parameters lack a scientific basis and merely reflect thresholds at which abnormal activity appeared during some studies. Slightly slower rates, contractions of lower amplitude, and higher volumes may lead to higher false-positive results (specificity) but increased sensitivity. Therefore using more rigid criteria seems to increase specificity for neurologic disease, but provoking activity with slower rates and including lower pressure contractions increases the likelihood of detecting this C-fiber reflex. It would be interesting to correlate methodology with response to vanilloid neurotoxins (capsaicin, resiniferatoxin) to ascertain the degree specificity with different methods. If patients demonstrate detrusor instability, performing the test as initially defined is problematic.

Initially, the ice water test was thought to be specific only for a “neurogenic” bladder. Subsequently, animal datasuggested that spinal cord injury, inflammation, or obstruction of the bladder may also lead to neuroplasticity with the development of a C-fiber–mediated spinal reflex (121,535,566). From 47% to 71% of patients with obstruction but not idiopathic instability exhibit this reflex (89,220). In one study, 15% of patients without neurologic disease and detrusor instability had a positive ice water test (445). Proponents of using this test to diagnose neurologic disease claim that all clinically active patients will eventually manifest neurologic disease.

Bethanechol Supersensitivity Test

Similar to the ice water test, the bethanechol supersensitivity test was thought to be diagnostic of neuropathology—namely, denervation of the bladder. The basis for this assumption is the pharmacologic principal of denervation supersensitivity known as Cannon's law. Cannon's law of denervation states that when a tissue is deprived of its nerve supply, it will develop hypersensitivity to its own neurotransmitter(s). Bethanechol chloride is a cholinergic agonist that exhibits a relatively selective action on the urinary bladder and gut, with little or no effect at therapeutic dosages on ganglia or the cardiovascular system (287,573). It is cholinesterase resistant and causes a contraction *in vitro* of detrusor smooth muscle from both body and base of the bladder (455). Bethanechol has a minimal effect on the normal bladder, decreasing the capacity slightly, increasing detrusor tone, and increasing the maximum voluntary micturition pressure. It will not cause the normal bladder to become unstable.

Lapides and colleagues (306) argued that this test is accurate in patients with a “denervated” bladder. One major limitation is reports of false-positive bethanechol supersensitivity tests in patients with only detrusor hypertrophy and instability. Furthermore, obstruction of the bladder causes patchy denervation. Thus this test has limited value in diagnosing “neurogenic” pathology. Others have found significant rates of false-negative and false-positive responses (64).

To perform a bethanechol supersensitivity test, subcutaneous injection of 0.035 mg/kg of bethanechol chloride is followed in 15 to 30 minutes by repeated cystometric examination (Fig. 26B.11). Oral bethanechol does not have a significant effect on the bladder. In patients with an areflexic bladder, a neurogenic cause may produce a rise in pressures of at least 15 cm H_2O at 100 mL filling, in excess of the pretreated cystometric pressure. If detrusor hypocontractility exists, a false negative may result.

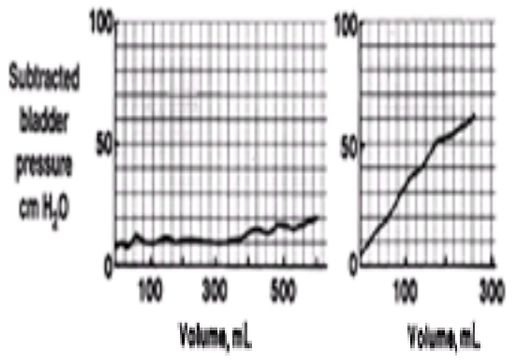

FIGURE 26B.11. Cystometrogram with positive bethanechol stimulation test.

The use of bethanechol is contraindicated in patients with bronchial asthma, peptic ulcer, hyperthyroidism, enteritis, bowel obstruction, bladder outlet obstruction, cardiac disease, or a history of recent gastrointestinal surgery (597,598).

Uroflowmetry

The use of urine flow rates alone has diminished in recent years. Problems with reproducibility and specificity have caused this test to fall out of favor, especially in the evaluation of BPH. However, for following patients sequentially after therapy (e.g., urethroplasty) this test remains valuable. *Flow rate* is the volume of fluid expelled from the urethra per unit time. It is expressed in milliliters per second. Flowmeters record overall rate and flow pattern (Fig. 26B.12). Both parameters provide useful information regarding lower urinary tract function. Urine flow rate is an expression of the combined activity of the detrusor and urethra. A normal flow rate will usually indicate a good function of both organs. Conversely, a low flow rate can result from poor detrusor contractility or outlet obstruction. Thus specificity is limited. Moreover, straining can result in artificial elevations in flow rates.

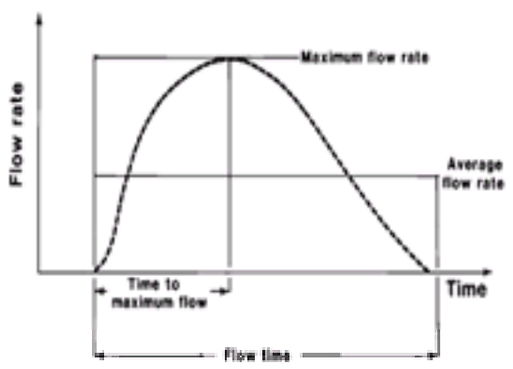

FIGURE 26B.12. Characteristics of normal uroflow.

Obstruction of the urethra (due to benign prostatic hyperplasia or urethral stricture) may be overcome by a more forceful detrusor contraction. Higher bladder pressures during micturition may result in a normal peak flow rate during the early stages of the obstruction, but a reduced average flow (high pressure, normal flow obstruction). Initially, the detrusor may be able to overcome increased outlet resistance, resulting in a normal flow rate. This scenario may be particularly operative in young women and men. This situation demonstrates that a normal flow rate fails to rule out obstruction. For a full definition of lower tract function, simultaneous pressure (cystometry) and flow studies duringvoiding are usually indicated. However, a urine flow study even by itself has some value as a screening test for other types of lower urinary tract dysfunction, such as dyssynergia; for preoperative and postoperative assessment of lower urinary tract surgery; and to study the effects of pharmacologic agents on urethral resistance and voiding efficiency.

To a clinician, urine flow rate variables (Table 26B.4) of most importance are the maximum flow rate, voided volume, and flow pattern. The patient should be asked whether the flow rate obtained represents the usual force. Ideally, urine flow interpretation should be for volumes of at least 10 mL. Interpretation of flow rates with smaller voided volumes can be misleading. Volumes of more than 500 mL are also accompanied by reduced flow rates, perhaps because of overstretching the detrusor fibers. Flow rates, however, are also related to the sex and age of the patient. Most data in the literature relate to measurements of flow in men younger than 55 years of age and cite norms of 15 and 25 mL per second for mean and maximum rates. Flow rates in women may also be influenced by hormones. A recent study showed that instrumentation lowered flow rates and progesterone levels influenced micturition times (583).

1. *Flow time:* time over which measurable flow occurs
2. *Time to maximum flow:* time elapsed from the onset of flow to maximum rate
3. *Maximum flow rate:* maximum rate of flow
4. *Voided volume:* total volume expelled by way of the urethra
5. *Average flow rate:* voided volume divided by flow time
6. *Voiding time:* total duration of micturition, including interruptions
7. *Flow pattern:* may be continuous, interrupted, or specifically described

TABLE 26B.4. URINE FLOW RATE MEASUREMENTS

In one of the largest community-based studies of urinary flow rates, Girman and co-workers (209) analyzed data from 2,000 men 40 to 70 years old. Based on this large number of older men, data showed that peak flow rate and voided volume decrease with each decade after age 40. Peak flow decreased from 20.3 mL per second for ages 40 to 44 to 11.5 mL per second for men 75 to 79 years old. Whereas only 6% of men in the former age group had peak flow rates less than 10 mL per second, 35% of the older group had markedly diminished flow. This difference may be attributed to altered contractility or obstruction. Because of a learning effect and patient variability, several flow rate measurements are more useful than a single test. Females have significantly higher flow rates than males matched for age and voided volumes. The values presented in Table 26B.5 are quoted from Abrams (2) and represent the minimum flow rate for a given sex, age, and voided volume. In children, sex differences exist. However, in one study of 180 children ages 7 to 10 years, no age difference was found for maximum and mean flow rates (360).

Age (yr)	Minimum Voided Volume (mL)	Flow Rates (mL/sec)	
		Males	Females
4–7	100	10	10
8–13	100	12	15
14–45	200	21	18
46–55	200	22	15
56–80	100	9	10

TABLE 26B.5. MINIMUM ACCEPTABLE URINE FLOW RATES

If abdominal straining is used to augment voiding, the stream appears interrupted (Fig. 26B.13). Other causes of an interrupted stream may be striated sphincter contraction during voiding by a patient with detrusor-sphincter dyssynergia, or more commonly, by an anxious child; and artifactual recording, most commonly seen when a male patient directs the urinary stream across the collecting funnel (Fig. 26B.14).

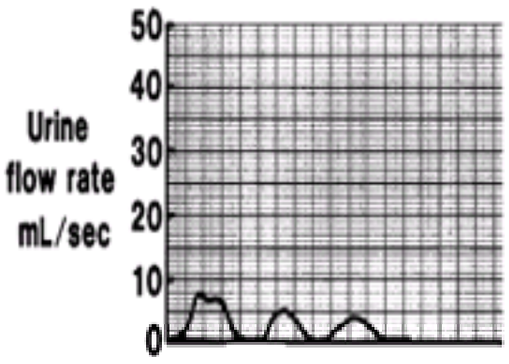

FIGURE 26B.13. Uroflow with interrupted stream during straining to void.

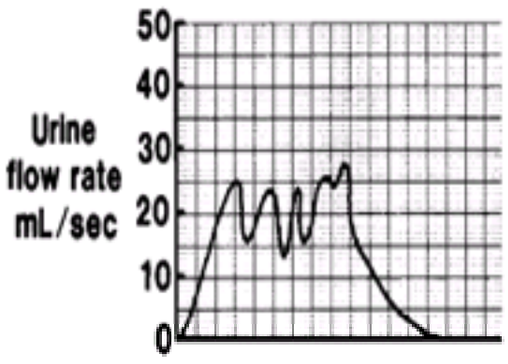

FIGURE 26B.14. Uroflow with interrupted pattern resulting from intermittent sphincter activity.

In outlet obstruction, a flat, elongated curve with a low maximum flow rate is reached in the initial part of the record (Fig. 26B.15). In patients with detrusor hypocontractility, the flow pattern can be persistent, flat, or intermittent if abdominal muscles are recruited to augment voiding. The urine flow rate is reduced, and the maximum flow rate corresponds to the middle portion of the tracing. Despite the suggestion of obstruction that can be basedon uroflow, Chancellor and colleagues (94) and others have established that uroflowmetry alone cannot distinguish between outlet obstruction and impaired detrusor contractility.

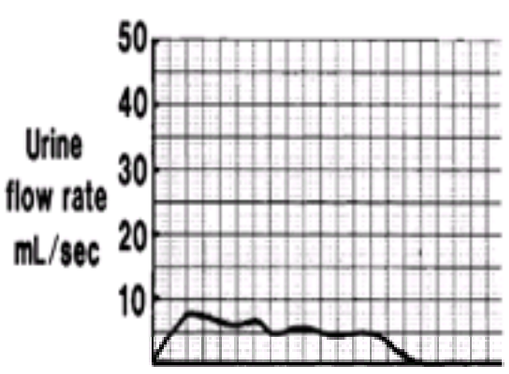

FIGURE 26B.15. Uroflow with abnormal flow rate characteristic of detrusor outlet obstruction.

Residual Urine Volume

Residual urine volume also reflects the activity of the bladder and outlet during the emptying phase of micturition. A consistently increased residual urine volume indicates increased outlet resistance, decreased bladder contractility, or both.

Although the bladder should empty completely, residual urine consistently greater than 150 mL is often deemed clinically significant. Residual urine can be measured in a variety of ways. A postvoid residual is usually measured using ultrasonography or catheterization. Detection following intravenous urography fails to provide volumetric data. More recently, portable bladder scans have been used by health care professionals and patients to detect bladder capacity and retained urine after voiding or instrumentation.

The greater the residual urine, the more likely that detrusor hypocontractility exists (201). Absent residual urine is compatible with normal lower urinary tract function during emptying, but it does not exclude significant disorders of filling or storage (incontinence) and problems with emptying in which the intravesical pressure is still sufficient to overcome increases in outlet resistance. Typical of this latter situation is the patient with outlet obstruction as a result of benign prostatic obstruction. Initially, despite significant obstruction, the detrusor empties the bladder by contracting with a greater force, manifested as hypertrophy and increased intravesical pressure. Yet with time, the detrusor will decompensate, leading to elevated residual volumes and reduced intravesical pressures produced during voiding. Ghoniem (201) and others have suggested that as residual urine volume becomes a greater percentage (greater than 30%) of bladder capacity, the likelihood of impaired

contractility, rather than obstruction, increases. This exemplifies the fact that it is rare to reach a diagnosis on the basis of any single urodynamic study. Results of all studies must be coherent, and ultimately they must be compatible with the symptoms and with the results of the remaining neurourologic evaluation.

Electromyography

Electromyography (EMG) is the measurement of bioelectric potentials generated by depolarization of muscle. Smooth muscle potentials are notoriously difficult to measure. Results of bladder or urethral smooth muscle potential determinations using catheter electrodes are still experimental and often not validated. Even with somatic muscle EMG, most of the activity detected using patch electrodes is noise rather than true neurogenic activity.

Striated muscle is innervated by motoneurons whose cell bodies lie in the anterior horn of the spinal cord. The anterior horn cell in the gray matter of the spinal cord, its axon, and all of the muscle fibers that it innervates is called a *motor unit.* An excitatory impulse from an anterior horn cell causes contraction of all the muscle fibers in that motor unit. The electrical discharge produced by contraction of the muscle fibers of the motor unit by their depolarization is called *motor unit action potential.* This may be detected by electrodes and displayed on an oscilloscope screen, computer monitor, or strip chart. Even more helpful, it may be converted to an audible sound. Individually recorded on an oscilloscope, the motor unit action potentials may exhibit biphasic, triphasic, or rarely, polyphasic configurations. In the relaxed state, the normal striated muscle is almost electrically quiescent, and only infrequent action potentials are recorded. However, with progressive muscle contraction, increasing numbers of motor units are recruited, and each motor unit fires at a more rapid rate. These firings can be individually recorded electromyographically, and the configuration of the action potentials aids diagnosis. At the point of maximum contraction, motor unit action potentials are so frequent that total overlap occurs and EMG separation cannot be achieved, resulting in an interference pattern. It takes considerable experience to interpret the various parameters recorded on an oscilloscope during sphincter EMG. Movement artifacts can often be confused with action potentials. Identification of variations is important in making an accurate neurologic diagnosis. Individual motor unit action potentials may be detected by needle electrodes placed directly into or near the muscle to be studied. When surface electrodes are used, individual motor unit action potentials are not visualized; rather, an overall global recording of the activity of the muscle is detected (field potentials) (32). If one is not interested in individual motor unit action potentials—for example, if one wishes only to document dyssynergia—surface electrodes are adequate. They detect whether the pelvic floor muscles are contracting or relaxing at any given instant. However, because they are unable to detect individual motor unit action potentials, surface electrodes cannot help in assessing the integrity of these muscles and their nerve supply.

During cystometric bladder filling, there should be incremental increase in EMG activity as more motor units are recruited. This has been referred to as the guarding reflex. This activity will reach a maximum near peak bladder capacity, and at the command to void, there should be sudden and persistent cessation of sphincter activity throughout voiding (59). On completion of bladder emptying, resumption of baseline sphincter activity occurs. To assess external sphincter activity, the examiner should ask the patient to interrupt voiding in the middle of the stream, at which point there should be an abrupt increase in sphincter activity that should be sufficient to stop the flow. Resumption of voiding should subsequently occur. If the holding pattern is maintained, the detrusor reflex should ideally be lost in approximately 10 seconds (595). This inhibition of detrusor activity with external sphincter contraction is due to somatic afferent input to the spinal cord, which can inhibit autonomic outflow to the bladder.

Abnormal EMG patterns may be detected in a number of situations. Detrusor-sphincter dyssynergia describes sphincter activity that is inappropriate to the activity of the detrusor. Three varieties of such incoordination (Fig. 26B.16) have been described (365). One pattern involves an appropriate increase in EMG activity with bladder filling, which is followed by inappropriate involuntary increase in activity at the onset of detrusor contraction. Thus the detrusor contracts against a closed sphincter.

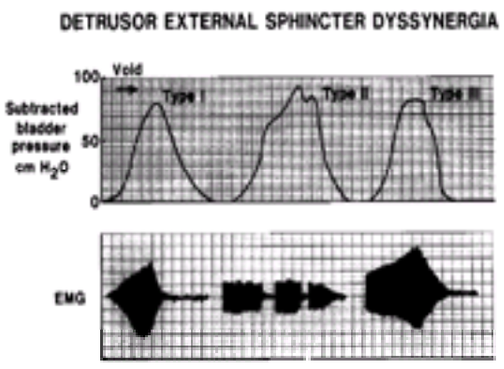

FIGURE 26B.16. Varieties of external sphincter discoordination. EMG, electromyograph. (Adapted from McGuire EJ. Electromyographic evaluation of sphincter function and dysfunction. *Urol Clin North Am* 1979;6:121, with permission.)

A second type of incoordination involves failure to develop an adequate reflex detrusor contraction because of increased EMG activity during voiding, which inhibits the detrusor motor nucleus in the sacral spinal cord, with resultant loss of detrusor contraction. This type of incoordination may be seen in patients with suprasacral spinal cord injury.

The third type involves contraction and relaxation of the sphincter during bladder filling. This amounts to periods of uninhibited sphincter relaxation, which is associated with reflex detrusor contraction leading to urgency and urge incontinence.

Simultaneous EMG activity with an increase in intravesical pressure does not uniformly indicate sphincter dyssynergia. Detrusor striated-sphincter dyssynergia is the most difficult and overdiagnosed entity in the field of voiding dysfunction. Patients suspected of having this diagnosis should always be further investigated with urodynamic or radiologic evaluation to study activity of the bladder and the outlet during the emptying phase of micturition and the spinal cord to exclude neurologic disease. True detrusor striated-sphincter dyssynergia should exist only in patients who have an abnormality in pathways between the sacral spinal cord and brain, usually due to neurologic disease or injury. Such a diagnosis in a patient without such pathology deserves exhaustive study to exclude a neural diagnosis. The exception to this rule appears to be in infants, who occasionally demonstrate apparent detrusor-sphincter dyssynergia without clinical or radiographic evidence of neurologic pathology (37), known as *nonneurogenic dysfunctional voiding* (345). In general, dyssynergia cannot occur unless a lesion resides between the pons and sacral spinal cord.

Interpretation is clouded by a voluntary contraction of the pelvic floor that occurs with a Valsalva maneuver and by voluntary contraction of the striated urethral sphincter as a method to abort urgency, both examples of so-called pseudodyssynergia. Rudy and Woodside (484) have suggested that inspection of the early segment of the CMG-EMG will help distinguish pseudodyssynergia from true dyssynergia (Fig. 26B.17). If EMG activity is recorded after a rise in detrusor pressure, true detrusor-sphincter dyssynergia exists.

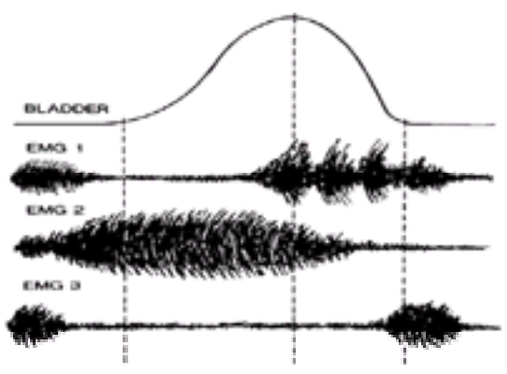

FIGURE 26B.17. Schematic diagram of cystometrogram-EMG. Bladder-intravesical pressure trace. *EMG 1:* Pattern seen in nonneurogenic neurogenic bladder. EMG activity quiets before and with positive *dP/dt,* and augments with negative *dP/dt. EMG 2:* Pattern seen in true external sphincter. Dyssynergia EMG activity augments

before and with positive *dP/dt,* and quiets with negative *dP/dt. EMG 3:* Pattern seen in normal voiding. EMG quiets before and during detrusor contraction. (From Rudy D, Woodside J. Non-neurogenic neurogenic bladder: the relationship between intravesical pressure and the external sphincter electromyogram. *Neurourol Urodyn* 1991;10:169, with permission.)

Learned dysfunctional sphincter habits may be responsible for voiding abnormalities, with resultant recurrent urinary infections, influx, and upper tract deterioration. An attempt has been made to retrain these patients by the application of biofeedback techniques using sphincter EMG during voiding (346). The patient can discern from an EMG audio monitor whether sphincter relaxation is being accomplished; hence positive reinforcement may correct the problem.

Evoked Responses

The value of evoked responses is extremely limited, and these tests are rarely performed. Problems with specificity, sensitivity, and noise, as well as poorly controlled variables, influence evoked potentials and hamper the utility of this method of investigation. Thresholds and latencies tend to be highly laboratory dependent. Evoked responses are potential changes in neural tissue, recorded with averaging techniques, resulting from distant stimulation, usually electrical (257). Evoked responses may be used to test the integrity of peripheral, spinal, and CNS pathways. As with nerve conduction studies, the conduction time (latency)may be measured. In addition, information may be gained from the amplitude and configuration of these responses.

An example of such procedures is the sacral evoked response, which is measured by the latency of the bulbocavernosus reflex (53,63,410). The bulbocavernosus reflex arc is mediated by afferent and efferent pudendal nerve fibers. The reflex is polysynaptic, traversing at least several spinal cord segments. Clinically, the bulbocavernosus reflex is elicited by briskly squeezing the glans penis and observing or feeling a reflex contractility response of the external anal sphincter or bulbocavernosus muscle. Alternatively, the reflex may be stimulated by pulling the balloon of a Foley catheter against the bladder neck. The bulbocavernosus reflex is present in almost all normal men and in approximately 70% of normal women. This reflex is often preserved after complete spinal cord transection. If lost, it is one of the first reflexes to return after recovery from spinal shock. Following spinal cord injury, reflexes return in a caudal to rostral progression. Absence of this reflex in a man is strongly suggestive of a sacral neurologic lesion, but it is preserved in approximately 5% to 10% of patients with an incomplete lower motor neuron lesion.

Probably the best use of this reflex is not as a quantitative assessment, but as an all-or-none test in sequentially following a patient. An absent reflex clinically can occur in a normal subject. However, the loss of the bulbocavernosus reflex after spinal surgery is an ominous sign and could indicate a cauda equina syndrome. The urologist is often the one to alert the orthopedic surgeon or neurosurgeon of this finding in a patient with persistent urinary retention after laminectomy. Because it is difficult to grade the reflex clinically, measurement of the bulbocavernosus reflex latency offers a more sensitive quantitative means of evaluating the sacral reflex arcs. When one side of the penis is stimulated electrically, as by a surface-stimulating electrode, there is a bilateral contractile response in the bulbocavernosus muscle that may be detected by electrodes placed bilaterally into this muscle (63,296). Considerable EMG expertise is required to determine the onset of the evoked response because of the possibility of interference from units that are firing randomly or as a result of the patient's anxiety. Although some authors have recommended that evoked responses of 20 to 30 stimulations be electronically averaged to determine the latency, Blaivas (53) claims that the shortest latency rather than the average is a more reliable means of evaluating the sacral segments, because the bulbocavernosus reflex is polysynaptic.

The bulbocavernosus reflex is a crossed response, and it is therefore possible to stimulate on one side and record from both sides the ipsilateral and contralateral bulbocavernosus muscles. This is useful in detecting subtle abnormalities that affect only a single afferent or efferent pathway. It is possible to evaluate the right and left afferent and efferent pathways individually. The normal bulbocavernosus reflex latency varies from approximately 30 to 40 ms, but the exact values vary slightly from one laboratory to another and with age, sex, and bodily habitus. Any neurologic process that interferes with the integrity of the reflex arc will result in a prolonged latency. Common disorders that result in prolonged latencies include diabetes mellitus, alcoholic neuropathy, and prolapsed discs. Less commonly, a prolonged latency may be an early manifestation of a spinal cord tumor or multiple sclerosis. The indications for such evoked testing are unclear.

Many believe that the clinical neurologic examination is just as sensitive as evoked potential testing as a means of detecting neurologic disease. Conversely, if the clinical assessment is completely normal, an evoked potential study never yields valuable insight. In a consensus statement from the World Health Organization (584), experts concluded that “opinion at this point cannot recommend them [concentric needle electromyography with dorsal nerve of the penis/clitoris stimulation] for clinical practice and classifies them as investigational.” Moreover, a word of caution is warranted in interpretation of the results of sacral evoked responses. This test merely quantitates the integrity of innervation of the striated pelvic floor and perineal musclesand the supraspinal neurologic pathways involved in lower urinary tract function. It does not give information concerning the status of the smooth muscle of the detrusor, bladder neck, and proximal urethra. Although, in general, it is reasonable to assume that when a neurologic lesion affects the striated perineal floor muscles, it is likely that the same process also involves the detrusor, because the pudendal and parasympathetic nuclei in the sacral spinal cord are practically adjacent to one another. Nevertheless, certain neurologic disorders (e.g., amyotrophic lateral sclerosis, Shy-Drager syndrome) may involve one portion of the nervous system and spare another. The value of sphincter electromyography is most appreciated in the differentiation of Parkinson's disease from olivopontocerebellar degeneration (multisystem atrophy). In this case, the detection of denervation potentials in the sphincter EMG will occur only in multisystem atrophy (428).

Leak-point Pressure

Abdominal Leak-point Pressures

Leak pressure terminology is confusing. Detrusor leak pressures are not equivalent to Valsalva leak pressures. Valsalva leak pressures measure the same function as abdominal leak pressures. However, the absolute values may vary depending on whether a slow strain, rapid Valsalva, or cough is used to test the integrating of the continence mechanisms of the bladder outlet. The most commonly performed leak pressure is the abdominal or Valsalva leak-point pressure (ALPP). This is a direct measurement of the abdominal pressure required to overcome urethral resistance. This urethral resistance is known as the urethral opening pressure. The abdominal leak pressure indirectly measures closure forces on the urethra or bladder outlet during straining and represents a simple test to classify urinary incontinence. The abdominal leak-point pressure is used in women to estimate to what degree stress urinary incontinence is due to anatomic displacement of the pelvic floor and bladder or intrinsic sphincter dysfunction. The lower the abdominal leak pressure, the greater the degree of intrinsic sphincter deficiency.

The test is performed with the patient supine or seated. Straining is done at 100, 200, and 250 mL bladder volumes using a 6- or 7-Fr urethral catheter. A smaller catheter is best to avoid artifact or lessen obstruction if a narrow noncoagulant urethra is evaluated. If urethral narrowing is present, a false-negative test can occur. Leakage is documented fluoroscopically or visually. McGuire and associates (371) studied women with urinary incontinence using fluoroscopy and monitoring detrusor and intraabdominal pressures. At a bladder volume of 200 mL, patients increased abdominal pressures by incremental straining. The pressure at which leakage occurred was then recorded. The pressure when fluoroscopic or actual leakage occurred defined the ALPP. Patients with an ALPP of less than 60 cm H_2O were defined as having intrinsic sphincter deficiency (type 3 urinary incontinence) (Fig. 26B.18). Urethral hypermobility (type 2 incontinence) as a cause of stress urinary incontinence was associated with pressure greater than 90 cm H_2O. A gray zone between 60 and 90 cm H_2O exists. In reality, a spectrum of insufficiency probably exists. As with all urodynamic tests, the pressure methodology used to perform the test should be presented in all reports.

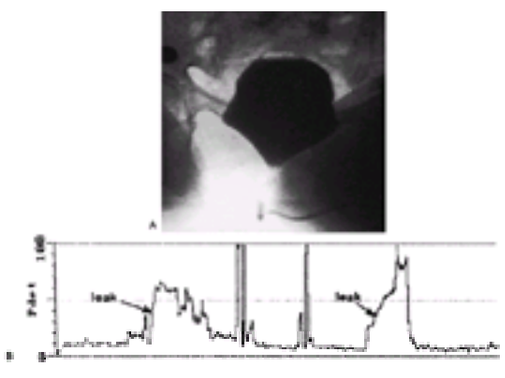

FIGURE 26B.18. Video image **(A)** and pressure recording **(B)** from bladder during straining as part of an abdominal leak-point pressure study in 40-year-old woman

with stress incontinence leakage at 37 cm H_2O, indicating intrinsic sphincter deficiency.

Patients with cystoceles may have elevated ALPPs as a result of pressure transmission to the prolapsed bladder. Therefore an abdominal leak-point pressure should be obtained in all women before repair of prolapse even in the absence of complaints of incontinence. Historically, 60% of women develop stress incontinence after repair of vaginal prolapse. The leak pressure test may help preselect those women needing an additional incontinence procedure. Performing the test after reduction of a significant cystocele with a pessary or similar device is necessary to obtain an accurate ALPP. If an involuntary detrusor contraction occurs, neural relaxation of the outlet will cause a falsely low ALPP. Many reports uncover intrinsic deficiency after reduction of prolapse and use sling surgery to prevent stress incontinence. However, no prospective study exists in which patients discovered to develop intrinsic sphincter deficiency (ISD) after reduction of a cystocele do not receive antiincontinence surgery. ALPP provides valuable information regarding function of the bladder neck and proximal urethra. Although valuable, fluoroscopy is not essential to differentiate anatomic incontinence from urethral dysfunction. An ALPP can also be estimated by measuring the rectal pressure with straining and observing urine leakage. The optimal bladder volume at which to perform this test is debated. One report has suggested that a volume of 1,000 mL identifies more patients with intrinsic sphincter deficiency, probably because of alteration in urethral angle if a large cystocele is present.

Detrusor Leak-point Pressures

Detrusor leak-point pressure (DLPP) is very different from ALPP. It is especially useful in the evaluation of patients with decreased compliance and incontinence. DLPP represents the pressure in the bladder at rest when urine leaks from the urethra. Whereas urine loss should never occur during abdominal straining even at high pressures, urine exits the urethra at relatively low bladder pressures during voiding. This measurement can be difficult to accurately assess if an intrinsic sphincter deficiency or vesicoureteral reflux exists.

A DLPP greater than 40 cm H_2O is predictive of upper tract deterioration, especially in patients with spinal cord injury and in children with myelodysplasia. The results of this test are not 100% predictive. Slower physiologic filling probably accounts for some differences. Yet, in general, the DLPP provides prognostic information regarding future upper tract changes. DLPP is measured by recording detrusorpressure with a 7-Fr urethral catheter or a suprapubic tube. Catheter size can influence the accuracy of the test (117). The pressure at which urine exits the urethra without straining represents the DLPP. The DLLP plus an estimate of bladder compliance provides the best prognostic information as to the risk of upper tract deterioration. The ALPP is a provocative dynamic test that mimics circumstances that may cause leakage. In contrast, the DLPP, along with compliance, assesses pressures detrimental to renal function. Each procedure tests a different aspect of lower urinary tract storage.

Urethral Pressure Profile

Urethral pressure profiles are less commonly performed by urologists. Noteworthy exceptions include research studies on urethral function or assessment of functional urethral length before sphincterotomy, and determination of functional integrity of an artificial urinary sphincter. A urethral pressure profile (UPP) is a recording of the pressure within the urethra at each point along its length. In 1969, Brown and Wickham (77) described a technique that is the basis for perfusion urethral profilometry. They used a specially designed catheter with multiple side holes and an occluded tip. Fluid infused along the catheter escaped through the side holes, and the UPP measured the resistance of the urethral walls to distention by this escaping fluid. This resistance is expressed in terms of the pressure necessary to maintain a steady flow of fluid through the catheter system. The UPP recording commences in the bladder, and constant withdrawal of the catheter is accomplished through the entire length of the urethra.

Being a measure of the urethra's response to distention, various factors affecting urethral compliance will alter the appearance of the profile curve. Contributing to normal urethral compliance are smooth muscle activity, striated muscle activity, fibroelastic component of the urethral wall, vascular tension resulting from the rich spongy network around the urethra, and an extrinsic compression component of varying degrees. Obviously, alteration of any of these variables may significantly alter the appearance of the curve. A high pressure point may be caused by poor compliance or obstruction. For these reasons, perfusion profilometry is often replaced by the use of catheter microtip transducers that record pressure directly. Despite methodology, the diagnostic value of the static UPP is limited because it is astudy that is performed neither during filling or storage nor during emptying. A narrow, poorly compliant yet incompetent urethra may result in a falsely elevated urethral pressure.

Static infusion profilometry does have value in evaluating artificial sphincter function or a potential site of obstruction. Alterations in the static profile correlate in a general way with some disease entities, such as stress incontinence, an enlarged prostate, and striated-sphincter dyssynergia. When obstruction (e.g., detrusor-sphincter dyssynergia) has been diagnosed by other methods (pressure/flow), the UPP may be used to direct the site and length of transurethral incision or laser vaporization. Overlap between normal and abnormal values is large. Thus the utility of infusion profilometry as a specific diagnostic study is limited. Some urodynamic experts question whether this test has a role in evaluating any voiding disorder. More recently, other methods of UPP measurement have been developed.

Static Urethral Pressure Profile

Although the static UPP technique may be modified by altering the position of the patient and the degree of bladder filling, the static UPP measures urethral pressure with the patient lying down, the bladder empty or at half capacity, and the urethra closed. Although perfusion profilometry has historically been the method most commonly used, two techniques have gained popularity to measure static UPP: the balloon catheter technique and the catheter tip transducer.

Perfusion Urethral Pressure Profile

The perfusion UPP technique uses a catheter with side holes through which saline solution or gas is perfused (1 mL per minute) with a motorized syringe pump. The pressure is measured by means of a side arm from the catheter. The pressure registered by the transducer represents the resistance to flow from the catheter side hole, as previously mentioned. Consequently, when the catheter is in the bladder, only bladder pressure opposes the outflow of saline solution, and the measured pressure is low. The catheter is then withdrawn at a constant rate (0.5 to 1.0 mm per second) through the entire length of the urethra. The initial pressure recorded on the chart strip recording is the intravesical pressure, followed by a positive deflection at the bladder neck and progressive increase in urethral pressure to the middle portion of the urethra in the female (Fig. 26B.19) and to the membranous urethra in the male (Fig. 26B.20). Beyond this point, pressure progressively decreases again until the external meatus is reached. Recommended nomenclature for UPP has been proposed by the International Continence Society. The most frequently measured parameters are as follows:

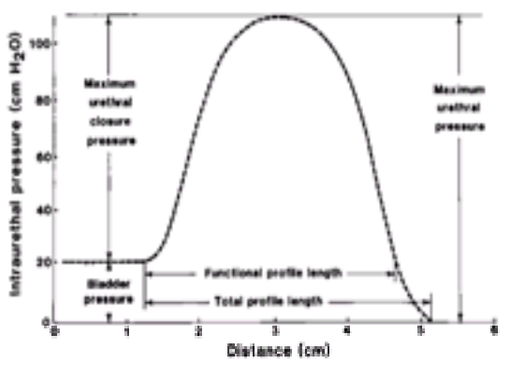

FIGURE 26B.19. Normal perfusion urethral pressure profile in a woman.

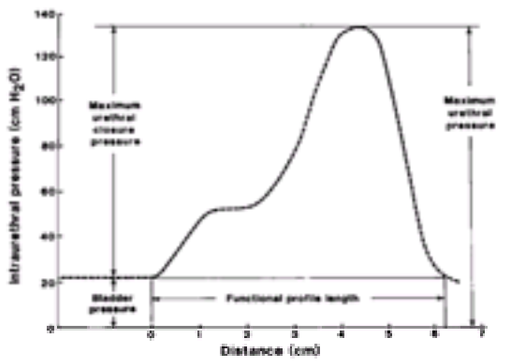

FIGURE 26B.20. Normal perfusion urethral pressure profile in a man.

1. Maximum urethral pressure, which is the maximum pressure of the profile
2. Maximum urethral closing pressure, which is the difference between the maximum urethral pressure and bladder pressure
3. Functional profile length, which is the length of the urethra along which the pressure exceeds bladder pressure

It is probably essential to simultaneously record external sphincter activity during the UPP. This will ensure that unintentional external sphincter contraction does not cause artifactual increase in maximum closing pressure. Many patients find it impossible to inhibit the external sphincter during the perfusion withdrawal process, and this is even more true of those with hypersensitive urethras and neurogenic bladder dysfunction. Simultaneous measurement of rectal pressure is advocated as a means to identify unintentional abdominal straining, which might also alter the normal profile curve.

In normal female patients, there is a gradual tendency for the maximum urethral pressure to decrease with age. This occurs mainly after menopause. The shape of the UPP curve is symmetric. In male patients, there is nodecrease in maximum urethral pressure with age. In defunctionalized bladder or prolonged anuria, an extraordinarily high (greater than 100 cm) maximum urethral pressure is seen (537). However, there is a tendency for the length of the prostatic urethra to increase, particularly after age 45. The shape of the UPP curve in the male is asymmetric. In the proximal part of the profile, there is a variable plateau corresponding to the bladder neck and prostatic tissues. A high pressure with significant plateau depending on withdrawal rate may signify bladder neck obstruction. In the distal part of the profile, there is a variable plateau because of the bladder neck and prostatic tissues. In the distal part of the profile, the pressure recorded is higher than from the distal female urethra because of the length and configuration of the male urethra. The highest pressure is generally recorded at the site of maximal concentration of periurethral striated musculature. Maximum urethral pressures of 20 cm H_2O or less generally correlate with intrinsic sphincter deficiency. The distal urethra is rarely of clinical significance, except on the rare occasion when the profile is recorded in a patient with a urethral stricture.

Balloon Catheter System

With the balloon catheter system, the eyeholes of the catheter are covered by a fine plastic balloon. This technique relies on a closed system that must be free of all bubbles or leaks. Although accurate, frequent calibration and replacement of balloon catheters is required as a result of a gradual change in compliance of the thin-walled balloons. This system is relegated to rectal pressure measurements. Care must be taken to barely distend this balloon to obtain a pressure reading without distending the rectum. Rectal distention similar to fecal impaction inhibits the micturition reflex.

Catheter Tip Transducer

The catheter tip transducer technique uses a catheter on which one or two transducers are mounted. The transducer is at the site of recording and obviates the problems inherent in recording at a distance from the organ being monitored. It allows for urethral pressure measurement during voiding. Double–transducer tip catheters allow for the simultaneous measurement of intravesical and urethral pressure. Small catheters are available that allow CMG and UPP testing during cystoscopy (38). The disadvantages of transducer catheters are their fragility, expense, and limited life span. The most problematic aspect of microtip transducers is the difficulty in zeroing and calibration. Many experts avoid these catheters.

Stress Urethral Pressure Profile

Stress urinary incontinence in women is the main indication for stress UPP, a test usually performed by urogynecologists. The stress UPP is best performed with a dual-sensor catheter tip transducer. The sensors should be separated by a 5- to 10-cm interval. The catheter is introduced into the bladder and then slowly withdrawn through the urethra while the patient is asked to cough at regular intervals. For coughs to be recorded for each 0.2 cm of urethral length, a slow withdrawal speed of 0.1 cm per second is used (2).

In normal patients, the increased pressure seen during coughing on the intravesical pressure trace is also seen superimposed on the urethral pressure trace. In normal patients, the raised intraabdominal pressure is transmitted to the proximal two-thirds of the female urethra. In patients with genuine stress incontinence, there is a failure of pressure transmission. However, the ease, lower cost, and ability of the ALPP to distinguish types of stress urinary incontinence (intrinsic sphincter deficiency) has supplanted urethral pressure profilometry at many institutions.

Static and *dynamic* refer to whether the test is performed with the patient at rest or voiding, respectively. The dynamic pressure profile is intended to show variation in sphincteric closure pressure under various physiologic events, as well as under different maneuvers. Unlike the static UPP, this method supplies information on the outlet during voiding. This dynamic pressure profile is obtained easily by the membrane catheter or microtransducer technique, but it is practically impossible to obtain by perfusion techniques (558). Normally, the pressure profile rises when the bladder is filled. In addition, postural change affects the urethral pressure. The lowest pressure is recorded when the patient is in the supine position. Sitting up increases urethral pressure, functional length, and magnitude of closing pressure. A precipitous rise in intraabdominal pressure, as caused by coughing, or a low sustained increase in intraabdominal pressure, as caused from bearing down, should simultaneously raise urethral pressure, which is normally much higher than the increase in intraabdominal pressure. An elevated pressure that falls off abruptly at some point between the bladder neck and the bulbomembranous urethral junction is sufficient to diagnose proximal sphincter dyssynergia (368). A key observation is a discrete fall in pressure distal to the site of obstruction.

A drop in total urethral pressure occurs just before voiding (556). When fluoroscopic evaluation is unavailable, dynamic profilometry may be applied to diagnose such uncommon causes of obstruction as proximal sphincter dyssynergia. A pressure gradient in an area of the urethra that is normally wide open with a detrusor contraction establishes the diagnosis of obstruction.

Multifunction Studies

In most clinical settings, it is usually practical and more cost-effective to screen patients by performing stopwatch uroflowmetry, ultrasonographic measurement of postvoid residual volume, and eyeball cystometry using a catheter-tip syringe (54). Although some experienced urodynamicistsdisagree, one or more of these simple tests will help the clinician understand the patient's symptoms in most cases. Limited resources, a capitated health care system, generalist medicine, and the trend toward cost-effectiveness will demand justification for all clinical tests. However, in some instances of voiding dysfunction, a more sophisticated study is indicated. Criteria for such a study include the following (62):

1. When simple diagnostic procedures are inconclusive
2. When the patient has persistent symptoms despite what appears to be appropriate treatment
3. When the patient has a preexisting condition known to be associated with complex urodynamic abnormalities
4. When history and physical examination suggest neurologic disease
5. When morbidity of an invasive procedure is deemed excessive
6. When therapy relies on precise diagnosing to determine whether bladder suspension versus periurethral injections is needed

Ideally, abdominal pressure should be measured so that subtracted bladder pressure can be monitored during voiding studies. This is particularly important when the detrusor contractions are of small magnitude and when voiding is accompanied by abdominal straining.

Simultaneous Pressure/Flow Study

Although pressure/flow studies are considered the most accurate tool to define obstruction, their use has been hindered by a lack of consensus on the absolute values diagnostic for obstruction, the invasiveness of the procedure, and the inability to obtain reliable data in patients without a detrusor contraction or with impaired contractility. Outlet obstruction (Fig. 26B.21) can be diagnosed only by simultaneous pressure/flow determination or voiding urethral pressures. Detrusor pressure is measured with a catheter in the bladder while the flow rate is recorded (Fig. 26B.22). Obstruction is a voiding pressure of greater than 100 cm H_2O. A urethral resistance factor $R = P/Q_{max}^2$ with a value greater than 0.6 reflects obstruction. Because the urethra is not a rigid tube, as assumed in Griffith's equation, in 1988 the ICS recommended pressure/flow diagrams to determine obstruction. A 1994 report revealed that only one-third of pressure/flow studies yielded an uninterpretable result (133). Unfortunately, although pressure/flow studies document obstruction better than other methods, they may still fail to predict symptomatic outcomes of therapy. Furthermore, their invasiveness, cost, and time-consuming nature appear to limit their routine use.

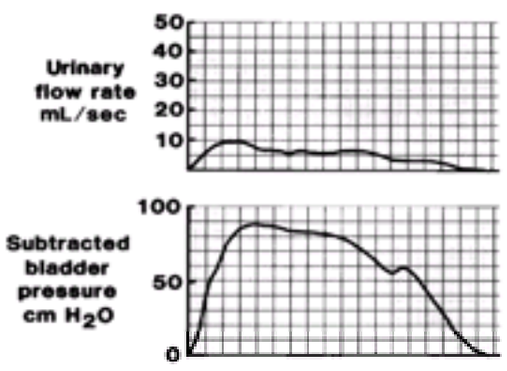

FIGURE 26B.21. Abnormal uroflow consistent with outlet obstruction.

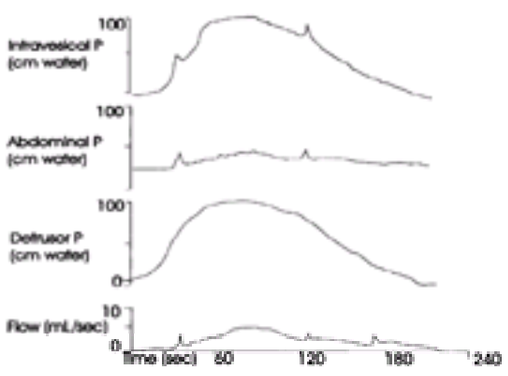

FIGURE 26B.22. Simultaneous combined pressure/flow urodynamic study in 55-year-old man with irritative and obstructive voiding symptoms. Detrusor pressure represents total intravesical pressure minus abdominal pressure. Note elevated detrusor pressure over 90 cm H_2O with low maximum (less than 5 cm H_2O) flow rate consistent with bladder outlet obstruction.

In general, patients identified by pressure/flow studies as being obstructed have better results after surgery. Abrams (2) used pressure/flow studies to select prostatism patients for surgery and achieved an 80% success rate of relieving obstruction in obstructed patients with high voiding pressures. Schaefer and associates (496) developed a computer program analysis of pressure/flow to determine obstruction. They found that 25% of those undergoing transurethral resection of the prostate (TURP) were not obstructed. In addition, patients classified by their program to be severely obstructed did best. Similarly, Rollema and Van Mastrigt (476) created a computer program referred to as CLIM, which uses two parameters to assess obstruction: the maximum extrapolated rate of increase of isometric pressure and the intersection of the quadratic urethral resistance relation. Similar to other reports, 25% of those undergoing TURPwere not obstructed using the CLIM program, and men with obstruction had better outcomes. The continuing debate on testing for BPH has highlighted the shortcomings of any single portion of the neurourologic examination for providing useful prognostic information.

Synchronous cystometry and sphincter EMG is a useful urodynamic combination for assessing spinal cord function (54,59). This test examines the relationship between the striated external urethral sphincter and the detrusor during the storage and voiding phases of micturition.

The disorder diagnosed by simultaneous cystometry and EMG is detrusor external-sphincter dyssynergia (DSD). In normal patients, or in those with detrusor instability or detrusor hyperreflexia resulting from neurologic lesions above the pons, the external urethral sphincter relaxes completely immediately before onset of the rise in detrusor pressure. Detrusor-sphincter dyssynergia is an abnormal reflex that occurs only when the neural pathways between the pons and sacral spinal cord are interrupted. In the absence of such a neurologic lesion, extreme caution should be exercised in diagnosing DSD. Conversely, if DSD is diagnosed, the clinician is obligated to search for such a lesion. The relaxation continues throughout the detrusor contraction unless the patient voluntarily attempts to interrupt micturition.

Detrusor external-sphincter dyssynergia is characterized by an involuntary contraction of the external sphincter coincident with or immediately preceding the rise in detrusor pressure. Blaivas and colleagues (62) have noted three patterns of DSD (Fig. 26B.16). Type 1 is characterized by an abrupt increase in EMG activity whose onset coincides with the beginning of the detrusor contraction. At the peak of the detrusor contraction, there is a sudden complete decrease in EMG activity as detrusor pressures fall. In type 2, there is intermittent EMG activity throughout the detrusor contraction. Type 3 is characterized by a crescendo-decrescendo pattern of external sphincter activity that parallels the detrusor contraction.

Pseudodyssynergia is a behavioral abnormality in which the patient subconsciously or consciously attempts to inhibit micturition (601). This results in “voluntary” contraction of the external sphincter during the detrusor contraction. These pseudodyssynergic syndromes are commonly encountered in children with persistent voiding symptoms, in men with prostatitis, and in women with the urethral syndrome.

It is impossible to distinguish between true dyssynergia and pseudodyssynergia by simultaneous cystometry and EMG unless intraabdominal pressure is measured concurrently. In pseudodyssynergia, there is usually some elevation of intraabdominal pressure as the patient tightens the abdominal and pelvic floor musculature.

Another and possibly simpler way to screen for DSD is by performing the combined uroflow and EMG (33). When uroflow is accompanied by absent external sphincter activity, dyssynergia may be excluded.

Videourodynamics

Videourodynamics is a technique using synchronously recorded urodynamic studies and cystourethrography for the evaluation of complex lower urinary tract problems. It encompasses pressure/flow external-sphincter EMG studies during filling, storage, and voiding phases of the micturition cycle, together with periodic

screening of the synchronous cystourethrographic appearances of the bladder and its outlet.

Radiographic contrast material is infused for cystometry, permitting fluoroscopic visualization of the lower urinary tract. Urodynamic parameters are recorded and displayed on a storage oscilloscope or computer monitor. The fluoroscopic image of the bladder and urethra is electronically mixed with that of the urodynamic data and displayed on the same monitor. The advantage of these studies is that they combine the objectivity of urodynamics with the visual radiographic image of the part being studied, resulting in far more logical interpretation of results. The test also provides a permanent record and excellent tool for teaching. Alternatively, transrectal or transvaginal sonography can be used to image the bladder neck or urethra (50).

Videourodynamics has proved particularly valuable in the identification of complex bladder outlet obstruction problems and in the identification of the precise etiologies of incontinence. If bladder outlet obstruction has been diagnosed or is suspected, but the site of obstruction is not clear, a micturitional static urethral pressure profile determination can provide useful diagnostic criteria (62). Demonstration of a drop in pressure during voiding beyond the suspected site of obstruction, at which time the bladder and proximal urethra are normally isobaric, establishes the diagnosis of an obstruction between the bladder and the site of the decreased pressure. Fluoroscopy also allows visualization of the dilation proximal to site of obstruction (626).

Detrusor external-sphincter dyssynergia is characterized by involuntary contraction of the external sphincter during detrusor contractions (Fig. 26B.23). This is verified by fluoroscopy during voiding. If a patient was treated by external sphincterotomy and a question arises as to the efficacy of surgery, this may be best evaluated by images and urethral pressures during a videourodynamic study.

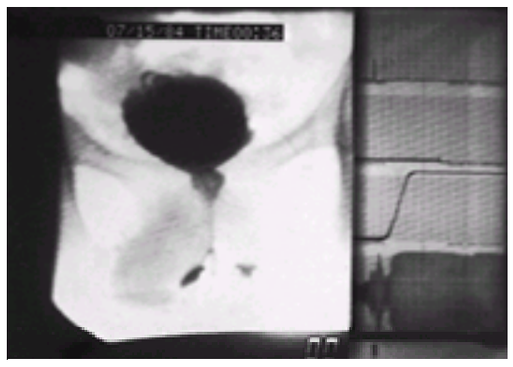

FIGURE 26B.23. Videourodynamic study in a 15-year-old paraplegic (T-5) boy who had high residual urine volumes and recurrent urinary infection. Intravesical pressure exceeded 100 cm H_2O (scale, 0 to 100 cm H_2O), and electromyographic activity was excessive during the detrusor contraction. Although the bladder neck opened, the prostatic urethra was dilated to the level of the external sphincter. There was no urinary flow *(top strip recording)* or increase in abdominal pressure *(second strip recording from the top).* This is classic detrusor external-sphincter dyssynergia.

CLASSIFICATION OF VOIDING DYSFUNCTION

A clinical classification system should clarify principals and management. A good classification system can distill the essence of a clinical situation into a few key words or phrases. An ideal classification system for voiding dysfunction is challenging in that it must integrate data from many sources regarding diurese pathologies. Voiding symptoms should be linked with urodynamic data to provide a pathology and suggest management based on the category ofdysfunction. Although many systems of classification for voiding dysfunction were formulated primarily to describe dysfunction secondary to neurologic disease or injury, contemporary tests often cannot distinguish among myogenic, neurogenic, or psychiatric pathologies. The ideal classification system should be applicable to all types and causes of voiding dysfunction. Thus, in addition to the primarily neurologic systems, urodynamic and functional classification schemes also exist.

Lapides Classification

Lapides (302,303) contributed substantially to the classification and care of patients with neuropathic voiding dysfunction and popularized a modification of a scheme originally proposed by McLellan in 1939 (377). The systems are virtually identical except that Lapides further divided McLellan's category of autonomic bladder into motor neurogenic and sensory neurogenic bladder. The Lapides classification is the scheme most familiar to urologists and describes the clinical and cystometric conditions in most types of neurogenic voiding dysfunction. In the uninhibited neurogenic bladder and reflex neurogenic bladder groups, the exact categorization further implies whether the striated sphincter is dyssynergic (reflex neurogenic bladder) or synergic (uninhibited neurogenic bladder) during bladder contraction. This scheme is attractive for didactic purposes but is of little prognostic or therapeutic value.

A *sensory neurogenic bladder* results from any disease that selectively interrupts the afferents between the bladder and spinal cord or the afferent tracts to the brain. Whether lightly myelinated (Ad) or unmyelinated fibers transmit sensation and pressure in humans is unclear. The distinction may become important as therapies are developed. Ice water tests and electrosensory threshold data indicate that more than one functional type of bladder afferent probably exists in humans. Classically, a sensory bladder is seen with long-standing diabetes mellitus, tabes dorsalis, and pernicious anemia. The first clinical changes consist only of impaired sensation of bladder distention. Unless voiding is initiated out of habit or on a timed basis, varying degrees of bladder overdistention are thought to lead to hypocontractility. With bladder decompensation, significant amounts of residual urine usually are found, and the cystometric curve many times demonstrates a large bladder capacity with a flat, low-pressure filling curve (high compliance). It was thought that the bethanechol supersensitivity test was positive in the early stages, but later negative as decompensation of the bladder smooth muscle occurred. The neurobiologic basis for this scheme has been shown to be conceptually flawed. Sensory nerves—or, more appropriately, afferents—from the bladder contain neuropeptides, including substance P, calcitonin gene-related peptide (CGRP), and vasoactive intestinal polypeptide (VIP). If Canon's laws of denervation hold, loss of these peptides should not cause hypersensitivity to the cholinergic agent bethanechol.

A *motor paralytic bladder* results from disease processes that destroy the parasympathetic motor innervation of the bladder. Extensive pelvic surgery or trauma can produce a motor paralytic bladder. Interestingly, herpes viruses affect dorsal root ganglia (afferents), and their destruction may abolish afferent input necessary for reflex micturition. Theoretically, if myelinated (Ad) afferents mediating reflex micturition are destroyed, unmyelinated axons may still mediate sensation, but a distention-evoked reflex is abolished. This condition would appear to be a paralytic bladder; thus older schemes may list herpetic bladder disorders as motor paralytic. Consistent with this notion, early symptoms may vary from painful urinary retention to a relative inability to initiate and maintain normal micturition. In early stages, the filling limb of the cystometrogram is normal with normal sensation, but without a voluntary bladder contraction at bladder capacity. Later, chronic overdistention and bladder decompensation may occur, and a large-capacity bladder with a flat low-pressure filling limb and generally large residual urine volume will result. Again, the bethanechol test is reported to be positive despite, in some instances, a lack of anatomic and pharmacologic evidence for true afferent denervation.

The *uninhibited neurogenic bladder* is the most common manifestation of neurogenic pathology. A destructive lesion in many regions of the neuraxis can result in facilitation of the micturition reflex. Cerebrovascular accident, brain or spinal cord tumor, Parkinson's disease, and demyelinatingdisease are the most common causes of this type of lesion. These diseases generally result in a voiding dysfunction characterized clinically by frequency, urgency, and incontinence, and cystometrically by normal sensation with an involuntary detrusor contraction at low filling volumes. Nerve irritation or early degeneration, such as with neuropathies and herniated discs, can also elicit involuntary detrusor contraction. Residual urine is characteristically small or absent unless anatomic outlet obstruction or true involuntary smooth or striated sphincter dyssynergia occurs. The patient can initiate a bladder contraction voluntarily but is often unable to do so during cystometry because of insufficient urine storage before onset of detrusor hyperreflexia.

The term *reflex neurogenic bladder* describes the post–spinal shock condition after complete interruption of the sensory and motor pathways between the sacral spinal cord and the pontine micturition center. This develops in traumatic spinal cord injury and transverse myelitis and may occur with extensive demyelinating disease, tumor, or ischemia injury. Typically, the patient has absent bladder sensation and is unable to voluntarily initiate micturition. Incontinence ensues because of low-volume detrusor hyperreflexia, which coincides with striated-sphincter dyssynergia. This type of lesion is equivalent to a complete upper motor neuron lesion in the Bors-Comarr system.

An *autonomous neurogenic bladder* denotes a complete motor and sensory separation of the bladder from the sacral spinal cord. Any disease process that destroys

the sacral spinal cord or causes extensive damage to the sacral roots or pelvic nerves may result in this condition. The patient is unable to void voluntarily. Cystometry reveals detrusor areflexia and absent bladder sensation. This type of bladder is equivalent to the complete lower motor neuron lesion in the Bors-Comarr system and represents parasympathetic decentralization. This is also the type of dysfunction seen in patients with spinal shock until a spinal reflex develops to initiate micturition weeks to months later. The characteristic cystometric pattern is initially similar to the late stages of the motor or sensory paralytic bladder, with a marked shift to the right of the filling curve and a large bladder capacity at low intravesical pressure. However, secondary changes in the filling limb may occur that cause an increase in slope (decreased compliance). This may be secondary to chronic inflammatory change or to the effects of the denervation, with secondary neuromorphologic and neuropharmacologic changes, especially in regulation of a-adrenergic receptors or reorganization of sympathetic pathways. Emptying in an autonomous neurogenic bladder may vary from none to a large percentage of bladder capacity, depending on the resistance offered by the bladder outlet.

Urodynamic Classification

Evolution of this type of classification system has paralleled urodynamic expertise and, in the United States, has been pioneered by Krane and Siroky (294,297). When exact urodynamic classification is possible, this system provides a precise description of the particular voiding dysfunction. If a normal or hyperreflexic detrusor exists with coordinated smooth and striated sphincters and without anatomic obstruction, the bladder should empty completely. Striated-sphincter dyssynergia is most commonly seen in patients with a complete suprasacral spinal cord injury after the period of spinal shock has passed. Smooth-sphincter dyssynergia is seen most in autonomic dysreflexia when it is characteristically associated with detrusor hyperreflexia and striated-sphincter dyssynergia. Detrusor hyperreflexia can occur in nearly all neurologic lesions above the sacral spinal cord, may be associated with inflammatory or infectious disease, or may be idiopathic. Detrusor areflexia may be secondary to bladder muscle decompensation or to various other conditions that produce inhibition at either the level of the brainstem micturition center, sacral spinal cord, bladder ganglia, or bladder smooth muscle. Areflexia also ensues if the sacral autonomic nucleus is destroyed. Patients with a voiding dysfunction that falls into this category often attempt bladder emptying by abdominal straining or a Credé maneuver. Their continence status and the efficiency of their emptying efforts are determined by the status of the smooth and striated sphincters of the outlet.

This classification system is best applied when detrusor hyperreflexia or normoreflexia exists, because urodynamic techniques exist to describe the activity of the smooth and striated sphincters during bladder contraction. Thus a typical T-10 paraplegic patient exhibits detrusor hyperreflexia, smooth-sphincter synergia, and striated-sphincter dyssynergia. When a voluntary or hyperreflexic bladder contraction cannot be elicited, this system is inadequate because it is not appropriate to speak of true dyssynergia in the absence of an opposing bladder contraction.

Rare and difficult to diagnose is smooth muscle or internal-sphincter dyssynergia. Although it often occurs with thoracic spinal cord lesions associated with detrusor hyperreflexia and external-sphincter dyssynergia, isolated pathology may exist. A young, anxious male with functional obstruction isolated to the bladder neck and proximal urethra may represent a spectrum of this disorder. A high urethral pressure at the bladder neck, and a fall in pressure over this region during voiding or fluoroscopic lack of opening during bladder contraction, help diagnose the pathology. Smooth muscle dyssynergia or nonrelaxation of the bladder neck probably results from overactivity of adrenergic nerves. Therefore lesions of the thoracolumbar spinal cord, where sympathetic outflow originates, have also been reported to cause this disorder.

Functional System

Classification of voiding dysfunction can also be formulated on a functional basis, describing the dysfunction simply interms of whether the deficit produced is primarily one of the filling or storage phase of micturition or of the emptying phase (599,604) (Table 26B.6). This type of classification system is an excellent alternative when a particular dysfunction does not lend itself to an agreed-on classification in one of the other systems. This sytem has been promoted primarily because of dissatisfaction with attempts to exactly classify voiding dysfunction based solely on urodynamics or neurologic lesion.

Failure to store	Failure to empty
Because of the bladder	Because of the bladder
Because of the outlet	Because of the outlet

TABLE 26B.6. FUNCTION CLASSIFICATION

This simple scheme is based on agreement on principles governing micturition. Bladder filling and urine storage require accommodation of increasing volumes of urine at a low intravesical pressure and with normal and appropriate sensation; absence of involuntary bladder contractions; and a bladder outlet that is closed at rest and remains so with stress. Storage failure can then result because of problems related to bladder hyperreflexia or low compliance and because of a permanent or intermittent decrease in outlet resistance. Bladder emptying requires a coordinated bladder contraction of adequate magnitude and lack of anatomic obstruction and concomitant lowering of resistance at the level of the smooth and striated sphincter. Failure to empty can then result from inadequate bladder contractility or increased outlet resistance. Failure in either category generally is not absolute but is more often relative.

Such a system can easily accommodate causative or urodynamic connotations (Table 26B.7). However, it avoids argument in those complex situations where the exact cause or urodynamic mechanism of a voiding dysfunction is unclear. A logical extension of this system functions especially well as a “menu” for the treatment of voiding dysfunction (Table 26B.8, Table 26B.9, Table 26B.10, Table 26B.11 and Table 26B.12).

Failure to store
Because of the bladder
Detrusor hyperactivity
Involuntary contractions
Suprasacral neurologic disease
Bladder outlet obstruction
Idiopathic
Decreased compliance

Recurrent sepsis or fever of urinary tract origin	Unacceptable side effects Skin changes secondary to incontinence of collecting device
Lower urinary tract deterioration	
Inadequate storage	

TABLE 26B.12. REASONS TO CHANGE OR AUGMENT A GIVEN REGIMEN

Use of this system for a given voiding dysfunction requires a reasonably accurate notion of urodynamic findings. However, an exact diagnosis is not required for treatment. Some patients just do not have a discrete storage or emptying failure, and the existence of combination deficits must be recognized to properly use this system of classification. For example, T-10 paraplegic patients generally exhibit a relative failure to empty because of striated-sphincter dyssynergia. In such a combination deficit, to use this classification system, one must assume that either one deficit is primary and that significant improvement will result from its treatment alone, or that the voiding dysfunction can be converted primarily to a disorder of storage or emptying by surgical or pharmacologic therapy. The resulting deficit can then either be treated or circumvented. With the same example, the combined deficit in a T-10 paraplegic patient can be converted primarily to a failure to store using surgical procedures (e.g., external sphincterotomy) directed at the dyssynergic striated sphincter, and the resultant incontinence (secondary to detrusor hyperreflexia) can be circumvented (in a male) with an external collecting device. Alternatively, the deficit could be converted primarily to a failure to empty using surgical or pharmacologic measures designed to abolish or reduce the detrusor hyperreflexia, and the resultant failure to empty can be circumvented with clean intermittent catheterization. Other examples of combination deficits include impaired bladder contractility with sphincter dysfunction, bladder outlet obstruction with detrusor

hyperactivity, and bladder outlet obstruction with sphincter malfunction.

The major limitation of this functional classification is that not every voiding dysfunction can be reduced or converted primarily to a failure of storage or emptying. In addition, although the functional classification of therapy that is a correlate of this scheme seems logical, there is a danger of pursuing therapy and overlooking a correctable or serious abnormality. Nonneurogenic voiding dysfunctioncan also be classified within this system, with the possible exception of sensory disorders. Unfortunately, these disorders are virtually ignored by all classification systems.

International Continence Society Classification

The ICS has proposed a classification based on the functional state of the bladder and urethra (256). It has been revised over the years and updated to include incontinence, pressure/flow studies, patients with neurogenic bladders, and ambulatory urodynamics (548,579). An active detrusor function is indicated when, during the filling phase, there are involuntary detrusor contractions that the patient cannot suppress. Involuntary bladder contractions associated with known neurologic disease fall under the category of detrusor hyperreflexia, whereas the term *unstable detrusor* or *bladder instability* is applied to such activities that occur in a patient without known neurologic disease. *Compliance* refers to the volume–pressure relationship in a bladder, and *low compliance* represents another form of detrusor overactivity. The underactive detrusor may be described as *noncontractile* (no contraction under any circumstances), *hypocontractile* (impaired contractility), or *areflexic.* A patient with an underactive detrusor may be described as having a *high-compliance bladder* (a capacious bladder that shows little change in pressure in response to a given volume increment). An overactive urethral closure mechanism contracts involuntarily against the detrusor contraction (dyssynergia) or fails to relax during attempted micturition. An incompetent urethral closure mechanism allows urinary incontinence. This may occur only during a rise in intraabdominal pressure (stress incontinence), or it may be persistent, in which case continuous leakage will occur. It may also be caused by an involuntary decrease in urethral pressure in the absence of detrusor activity (the unstable urethra, or urethral instability).

Urethral instability probably represents the normal neurogenic relaxation of the bladder outlet during voiding. In the absence of the detrusor contraction due to neurogenic or myogenic areflexia, the fall in urethral pressure can be easily observed (364). The patient typically complains of stress urinary incontinence (failure to store) and obstructed symptoms (failure to empty) with residual urine and normal sensation.

Within the ICS system, a T-10 paraplegic patient would be classified as follows: overactive detrusor, overactive urethra, hyposensitive. The condition of a stroke patient with urgency incontinence would most likely be classified as follows: overactive detrusor, normal urethra, normal sensation. The condition of a patient with stress incontinence would be classified as follows: normal detrusor, incompetent urethra, and normal sensation.

TREATMENT OF VOIDING DYSFUNCTION

Therapies available for managing voiding dysfunction are easily categorized on a functional basis according to their effects on the bladder or on the outlet (Table 26B.8 and Table 26B.9). This functional outline is followed in discussing each therapy. Some of the surgical therapies are discussed elsewhere in this text. Surgery for incontinence and neurogenic voiding dysfunction are primarily discussed.

The choice of a surgical versus a nonsurgical mode of management is based on many factors (Table 26B.10). One of the most important concepts to be put forth in recent years is a urodynamic clarification of “adequate storage at low intravesical pressure.” McGuire (367) and McGuire and co-workers (374,376) have clearly shown that upper tract deterioration is apt to occur when storage, even though adequate in terms of continence, occurs at sustained intravesical pressures of greater than 40 cm H_2O. This value corresponds to that obtained in experimental studies in which intravesical pressure was raised until urine did not fully flow in the bladder. Application of this approach to patients with storage problems because of decreased bladder compliance has resulted in the concept of the “detrusor leak-point.” Patients with leakage pressures less than 40 cm H_2O will not experience upper tract deterioration in the absence of other complicating factors, such as significant vesicoureteral reflux with urinary tract infection. Poor bladder compliance (less than 20 cm H_2O) plus an elevated detrusor leak-point pressure places the patient at very high risk for upper tract deterioration.

When treating patients with voiding dysfunction, a perfect result is rarely achieved, and a flexible approach to therapy must be adopted. Any decision must take into account the wishes of an informed patient and the practicality of each proposed solution, especially in those patients with neurologic disease (Table 26B.11). Whether initial therapy is to be surgical or nonsurgical is a decision best made with the patient and family. In every case, the patient and family must be informed of all methods of management, reversibility, side effects, results, and frequency and extent of follow-up and costs. The simplest, least destructive, and most reversible form of therapy that can satisfy the goals of treatment usually should be tried first. A combinationof therapeutic maneuvers, drugs, and surgery can sometimes be used, especially if they act through different mechanisms and their side effects are not synergistic.

Absolute or relative indications for changing or augmenting a particular regimen exist. These are generally agreed on, although the relative importance of an indication for change might be disputed (Table 26B.12).

Therapy to Facilitate Bladder Emptying

Increasing Intravesical Pressure or Bladder Contractility

Credé Maneuver

External compression and Valsalva manual compression of the bladder (Credé maneuver) can be effective in patients with decreased bladder tonicity who can generate a pressure greater than 50 cm H_2O with this maneuver, and whose outlet resistance is low (211,604). The technique of voiding by the open-hand Credé method involves placement of the thumb of each hand over the area of the left and right anterior superior iliac spine and of the digits over the suprapubic area, with slight overlap at the fingertips. The slightly overlapped digits are then pressed into the abdomen, and when they have gotten behind the symphysis, pressed downward to compress the fundus of the bladder. Both hands are then pressed as deeply as possible downward into the real pelvic cavity. At times, compression of the bladder can be accomplished more efficiently by using the fist of one hand (closed-hand method) or a rolled-up towel.

A similar increase in intravesical pressure may be achieved by abdominal straining. This method of voiding is particularly useful in patients with orthotopic neobladders. In both men and women, the technique of straining (Valsalva) involves sitting and resting the abdomen forward on the thighs. During straining in this position, hugging of the knees and legs may be advantageous to prevent bulging of the abdomen. To increase intravesical pressure in this manner requires voluntary control of the abdominal wall and diaphragmatic muscles, or in the case of the Credé maneuver, adequate hand control. Straining at the time the Credé maneuver is applied should be avoided, because this increases intraabdominal pressure and causes bulging of the abdominal wall, which then tends to lift the compressing hands off the fundus of the bladder. The Credé maneuver is much easier in a patient with a lax, lean abdominal wall than with a taut or obese one, and it is more readily performed on the abdominal bladder of a child than on the pelvic bladder of an adult. This straining maneuver is not without complications. Pelvic prolapse in women and hemorrhoids in both sexes can occur. Credé maneuver is not to be recommended after augmentation because of the risk of rupture.

Voiding by these maneuvers is unphysiologic and is resisted by the same forces that prevent stress urinary incontinence. Reflex funneling of the bladder neck and proximal urethra does not generally occur with external compression maneuvers. In contrast, in patients with intact pelvic floor striated muscle reflexes, outlet resistance may increase. If adequate emptying is not achieved, other therapies to decrease outlet resistance may be considered, but these may adversely affect continence. Vesicoureteral reflux is another relative contraindication to Credé or Valsalva maneuvers, especially in patients who are capable of generating a high intravesical pressure. The greatest likelihood of success with this therapy is in patients with an areflexic and hypotonic or atonic bladder and some outlet denervation (striated or smooth sphincter or both). Not uncommonly, the patient also exhibits stress incontinence. The continued use of external compression or the Valsalva maneuver implies that the intravesical pressure between attempted voidings is consistently below that necessary to cause upper tract deterioration. This may be an erroneous assumption, and close follow-up is necessary to avoid this complication in patients with normal outlet resistance. The most flagrant misuse of this form of management is in patients with a decentralized or denervated bladder in whom decreased compliance during filling has developed. Such patients may silently develop upper tract deterioration with minimum filling.

Bladder Latissimus Myoplasty with Electrical Stimulation

For patients with detrusor areflexia or hypocontractility who exhibit low outlet resistance, a technique similar to cardiac assist myoplasty has been pioneered by Stenzl

and colleagues to facilitate emptying (543). Latissimus free flap transfer with microsurgical neural and vascular anastomoses is a complex surgery requiring a team of urologists and plastic surgeons. Operating times exceed 12 hours. Care must be taken to appropriately position the latissimus muscle around the bladder and secure it to pelvic structures so it can generate appropriate force to expel urine. An implantable neurostimulator is controlled using an external wand to activate the nerves supplying this flap. Patient selection is key. Women with sacral lesions causing detrusor areflexia and low outlet resistance are able to empty the bladder completely at low pressures. Although the number of patients eligible for this technique may be limited, early results are encouraging.

Promotion or Initiation of Reflex Contraction

In spinal cord injury or disease characterized by detrusor hyperreflexia, manual stimulation of areas within the sacral and lumbar dermatomes may sometimes provoke a reflex bladder contraction (71,204). Pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; and digital rectal stimulation are examples of the type of activity that sometimes induces “trigger voiding” in these patients. According to Glahn (211), the most effective method ofinducing such a contraction is rhythmic suprapubic manual pressure (seven or eight pushes every 3 seconds). This is thought to produce a summation effect on the tension receptors in the bladder wall, resulting in an afferent neural discharge, which activates the bladder reflex arc. Recent experimental data show that following complete spinal cord transection, somatic (cutaneous and visceral; i.e., vaginal, rectal) afferents can activate a transient spinal micturition reflex. In neurologically intact individuals, these somatic afferents inhibit micturition through spinal mechanism. The same mechanisms are exploited for use with cutaneous electrical stimulation in the treatment of detrusor hyperactivity. Patients who are potentially able to induce bladder contractions by such a maneuver should be encouraged to find their own optimal “trigger points” and position for urination. Manual dexterity, and the ability to transfer to a commode or use of an external collecting device, is required. Unfortunately, this type of patient often suffers from sphincter dyssynergia, and such maneuvers may have to be combined with measures to decrease outlet resistance at the level of the striated or smooth sphincter.

No objective data support the notion that a rhythmic pattern of bladder filling and emptying by maintaining a copious fluid intake, and by periodically clamping and unclamping an indwelling catheter or with intermittent catheterization, can “condition” or “train” the micturition reflex.

Pharmacologic Manipulation

Parasympathomimetic Agents

The final common pathway for a physiologic bladder contraction is stimulation of the muscarinic cholinergic receptors on bladder smooth muscle. Cholinergic nerves supplying the bladder release acetylcholine, which acts primarily on muscarinic receptors of the M_3 subtype to evoke a detrusor contraction and voiding (18). In addition, activation of M_2 receptors on smooth muscle inhibits bladder relaxation by blocking signal transduction pathways that raise cyclic adenosine monophosphate (cAMP) (242). Following injury or denervation, an upregulation of M_2 receptors occurs. Hence, direct activation of muscarinic receptors should enhance detrusor contractility. Agents that imitate the actions of acetylcholine might be expected to be useful in the management of patients who cannot empty because of inadequate bladder contractility. Many acetylcholine-like drugs exist. However, only bethanechol chloride exhibits a relatively selective action on the urinary bladder and gut, with minimal action at ganglia or on the cardiovascular system (573). It is cholinesterase resistant and causes a contraction *in vitro* of smooth muscle from all areas of the bladder (455).

Bethanechol has been recommended for the treatment of postoperative or postpartum urinary retention in a subcutaneous dose of 5 to 10 mg. For more than 40 years, it has been used in the treatment of the atonic or hypotonic bladder (315), and it has been reported to be effective in achieving “rehabilitation” of the chronically atonic or hypotonic detrusor (135,301,522). However, few clinicians would consider this regimen to make a major difference in emptying the bladder. In uncontrolled reports where this drug is effective, it cannot be excluded that retention was psychogenic or that reflex micturition would have returned spontaneously.

Bethanechol has also been used to stimulate or facilitate the development of reflex bladder contractions in patients with suprasacral spinal cord injury (437). Twiddy and associates (572) have concluded that, at least in spinal cats, intact pelvic reflex pathways are required for bethanechol to produce what they described as a brisk and sustained increase in intravesical pressure during bladder filling. However, in hyperreflexic patients with poor bladder compliance, bethanechol may cause upper tract deterioration by raising intravesical pressure.

Although anecdotal success in selected patients has been described, attempts to facilitate bladder emptying in series in which bethanechol was the only variable have been dismal. A pharmacologically active subcutaneous dose (5 mg) did not demonstrate significant changes in flow parameters or residual urine volume in women with a residual urine volume equal to or greater than 20% of bladder capacity and no evidence of neurologic disease or outlet obstruction, or in a group of 27 “normal” women of approximately the same age (603). A similar dose likewise failed to produce urodynamic evidence of improved emptying in patients with a positive bethanechol supersensitivity test (605). Yet this dosage elevates intravesical pressure throughout the filling limb of the cystometrogram while reducing bladder capacity (307,522). Bethanechol is capable of eliciting an increase in tension in bladder smooth muscle such as would be expected from *in vitro* studies, but its ability to stimulate or facilitate a physiologic-like bladder contraction in patients with voiding dysfunction has been unimpressive. Similar sentiments with respect to its use in neuropathic dysfunction, have been expressed by Gibbon (205), Light and Scott (328), Merrill and Rotta (379), and Yalla and colleagues (623). In fact, it is difficult to find reproducible urodynamic data that support recommendations for the usage of bethanechol in any patients. Its use should be abandoned.

No agreement exists as to whether cholinergic stimulation produces an increase in urethral resistance (605). It appears that pharmacologically active doses increase urethral closure pressure in patients with neurogenic bladder dysfunction with detrusor hyperreflexia (526). If so, a reasonable question is whether cholinergic agonists could be combined with agents that decrease outlet resistance to facilitate emptying. Khanna (276) reported that a combination of a total daily oral dose of bethanechol of 50 to 100 mg with 20 to 30 mg of oral phenoxybenzamine producedsatisfactory results in a group of patients with an atonic bladder and functional outlet obstruction. Personal experience with such therapy, using even 200 mg of oral bethanechol daily, has been extremely disappointing. Most clinicians would agree that a daily dose of 50 to 100 mg rarely affects any urodynamic parameter. Moreover, some spinal cord–injured patients develop hydronephrosis on this drug, possibly due to elevated intravesical pressures (personal observation). This is further evidence that bethanechol's use should be abandoned.

Acetylcholinesterase drugs such as physostigmine and neostigmine have been administered to humans. Because these agents prevent the breakdown of acetylcholine, they may facilitate emptying. Neostigmine increases intravesical pressures and elicits detrusor contractions; however, its utility in emptying the bladder is unproven, and its side effects are prohibitive.

Activation of certain receptors enhances release of acetylcholine from nerve terminals in the bladder. In this regard, activation of serotonergic (5-HT_3) receptors has been proposed, but trials demonstrating the clinical usefulness of this approach are lacking.

Prostaglandins

It has been hypothesized that prostaglandins influence bladder contractile activity. With this rationale, Bultitude and associates (78) reported that instillation of 0.5 mg of prostaglandin E_2 (PGE_2) into the bladders of females with varying degrees of urinary retention resulted in short-term emptying and improvement of long-term emptying in two-thirds of the patients studied. Desmond and colleagues (130) also reported results with intravesical use of this agent in patients whose bladders had absent or impaired contractile activity. A total of 20 of 36 patients showed a strongly positive and 6 showed a weakly positive immediate response. Fourteen patients were reported to show prolonged beneficial effects, all but one of whom had shown a strongly positive immediate response. Further analysis revealed that an intact sacral reflex arc was a prerequisite for any positive response. The authors also noted that the effects of PGE_2 appeared to be additive or synergistic with cholinergic stimulation in some patients. Vaidyanathan and colleagues (577) reported that intravesical instillation of 7.5 mg of 15(S)-15-methyl PGF_2 produced reflex voiding in some patients with incomplete suprasacral spinal cord lesions. The favorable response to a single dose of drug when present lasted from 1.0 to 2.5 months. Other investigators, including Delaere and colleagues (126), have failed to show success with this type of treatment. Prostaglandins have a relatively short half-life, and it is difficult to envision a durable response. Hypotension, tachycardia, cardiac arrhythmia, convulsions, hypocalcemia, and diarrhea can occur. The absence of any recent reports on efficacy seems to indicate lack of support for or interest in this approach.

Blockers of Inhibition

Sympathetic reflexes promote urine storage by exerting an inhibitory effect on pelvic parasympathetic ganglionic transmission, increasing outlet resistance, and possibly relaxing the bladder body. Activation of a-adrenergic receptors inhibits ganglion transmission. Some have suggested on this basis that a-adrenergic blockade, in addition to decreasing outlet resistance, may facilitate transmission through these ganglia and thereby enhance bladder contractility. Methyldopa had

been tried with this rationale with at least some good initial results (458). More reports advocate a trial of an a-adrenergic blocking agent for the initial treatment of postoperative or psychogenic urinary retention that is due to BPH.

Recent understanding of the roles of neuropeptides has also provided new insights into lower urinary tract function and its pharmacologic alteration. Endogenous enkephalins, serotonin, and gamma-aminobutyric acid (GABA) are thought to exert a tonic inhibitory effect on the micturition reflex, and agents such as narcotic antagonists and serotonin or GABA antagonists offer new possibilities for enhancing reflex bladder activity (348,533,576). In spinal cord–injured animals and one human trial, the opiate antagonist naloxone facilitated bladder emptying (612).

Electrical Stimulation

Clinical trials of direct electrical stimulation to completely empty the bladder have met with partial success and periodic enthusiasm. Direct electrical stimulation has been attempted in patients with hypotonic and areflexic bladders. Initial success, defined as a low postvoid residual with sterile urine, was achieved in only 50% to 60% of patients, and secondary failure, usually related to equipment malfunction, often supervened. The spread of current to other pelvic structures whose stimulus thresholds were lower than that of the bladder often resulted in abdominal, pelvic, and perineal pain; a desire to defecate; contraction of the pelvic and leg muscles; and erection and ejaculation in males. It was also noted that the increase in intravesical pressure generally was not coordinated with bladder neck opening or pelvic floor relaxation and that other measures to accomplish these ends might be necessary. Grimes and colleagues (225,226) applied electrical stimulation directly to the sacral spinal cord, attempting to take advantage of the remaining intact motor pathways to initiate micturition. Although some short-term success was noted, many of the side effects seen with direct bladder stimulation occurred because the stimulus, so applied, was also unphysiologic.

To overcome stimulation-induced detrusor-sphincter dyssynergia, a variety of methods have been used. Tanagho and colleagues (559) and Schmidt (499), among others, have pursued neurostimulation for both emptying and storage problems. They found that it was not possible at the spinal cord level to separate a bladder center from a striated-sphincter center. However, they have pursued withsome success stimulation of individual sacral nerve roots. The commercially available Finetech-Brindley implantable stimulator uses poststimulus voiding. Poststimulus voiding relies on differences in relaxation times between the detrusor and external urethral sphincter. It evokes voiding in spurts at supraphysiologic pressures. Lower limb movement is not uncommon. Other techniques rely on surgical interruption of pudendal fibers, blockade of somatic transmission, fatiguing of the external urethral sphincter, and activation of small fibers. The latter methodology has been exploited by Rijkhoff and colleagues (470). Small fiber activation requires a tripolar electrode that activates both large-diameter (somatic to external sphincter) and small-diameter (autonomic to bladder and urethra) fibers. The lower current needed to activate large fibers allows a differential activation. Blockade distal to the stimulating cathode using an anode will selectively cancel out the action potential in the large but not small fibers. This is termed *anode blockade.* Although acute experiments in humans are encouraging, problems remain with chronic stimulation because small changes in current alter parameters. Too small a current is insufficient to activate the bladder, and too large a current blocks small-diameter fibers to the bladder. Moreover, charge-balanced biphasic currents are needed to prevent nerve damage. Alternatively, some investigators have explored the use of “cold block” of pudendal nerves (501). These techniques assume that detrusor contractility is preserved. This is rarely the case. Loss of neural input, at least experimentally, alters detrusor contractility and may even lead to apoptosis and fibrosis in the long term. For the outcomes of electrostimulation to surpass those of intermittent self-catheterization, minimal morbidity and nearly complete emptying must be achieved.

Reduction Cystoplasty

On the surface, a reduction cystoplasty seems to be an attractive alternative for patients with chronic urinary retention who have large decompensated bladders. Reduction cystoplasty has been advocated for patients with megacystis due to prune-belly syndrome. In 11 boys with prune-belly syndrome followed for an average of 8 years, reduction cystoplasty allowed only a 50-mL residual urine after double or triple voiding. With techniques of reduction cystoplasty involving either fundus invagination or detrusor duplication (but not simple excision of bladder tissue only), symptomatic successes with lower bladder capacity and lower residual urine volumes have been achieved (237,283,473). However, it is puzzling that despite such improvement, Roberts and colleagues (473) and Kinn (283) reported absolutely no change in bladder or sphincter activity. In patients with contractile bladders, flow rates seem to change only when outlet reduction is also performed.

Decreasing Outlet Resistance at a Site of Anatomic Obstruction

Prostatic enlargement and urethral stricture are two of the more common causes of bladder outlet obstruction in males. The pathophysiology of their development and their surgical and nonsurgical correction are dealt with elsewhere in this volume.

Decreasing Outlet Resistance at the Level of the Smooth Sphincter

Transurethral Resection of Incision of the Bladder Neck

Emmett (156) performed the first transurethral bladder neck resection in a patient with neurogenic bladder dysfunction in 1937, and for years this procedure represented the initial approach in cases of poorly balanced bladder function. Originally, the operation was performed primarily in two groups of patients: those with weak or absent detrusor contractions and those with anatomic or functional obstruction at the level of the bladder neck and proximal urethra, which prevents emptying even with a sustained detrusor contraction (79,206,604). Some urologists still prefer to resect the bladder neck whenever there is significant residual urine or signs of outlet obstruction associated with a neuropathic bladder, and treat other areas of outlet resistance later (203,204,211). However, obstruction is rarely documented. Instead, symptoms and flow rates alone have been used.

More refined urodynamic techniques have resulted in the realization that dyssynergia at the level of the bladder neck or proximal urethra is relatively common in cases of complete paraplegia above T-12 and quadriplegia (502), but uncommon in other neurologic disorders, or in patients with obstruction but without neurologic disease. Kaplan and associates (270) have proven urodynamically that some men diagnosed as having chronic prostatitis actually are obstructed and benefit from bladder neck incision. The prime indication for bladder neck incision is failure of medical therapy (e.g., a-blocker) in a patient with obstruction at the bladder neck or proximal urethra level, diagnosed by combined detrusor pressure/flow studies with either fluoroscopic demonstration of a failure of opening of the smooth-sphincter area, or a micturitional urethral profile showing that the bladder pressure falls off sharply at some point between the bladder neck and the area of the striated sphincter. In the past, it was believed that another category of patient for whom this procedure would be useful was one with a sacral spinal cord lesion and an areflexic bladder who could achieve a measurable increase in intravesical pressure by straining or use of the Credé maneuver, but who could not empty the bladder adequately by these methods (604). The procedure simply creates a form of “graded” stress incontinence in these patients and demonstrates that otheralternatives for adequate emptying should be sought first. Although documented instances of bladder neck obstruction in women have been reported (134), extreme caution must be exercised in surgically treating this entity in females because of the risk of incontinence.

Techniques of resection include the following:

1. A thorough circumferential resection of all tissue between the internal orifice and the verumontanum (in males)
2. A limited resection of dorsal tissue from the 3 o'clock through the 9 o'clock position
3. A resection further limited to the posterior lip
4. Transurethral incision of the bladder neck at the 5 o'clock and/or 7 o'clock position, or both

A 12 o'clock incision is used extending from the bladder base down to the level of the verumontanum because most of the striated muscle is located anteriorly and the vessels are lateral. The issue of preservation of fertility and use of electroejaculation has influenced the technique somewhat in that some urologists no longer routinely incise the bladder neck. Hemostasis is achieved by electrocoagulation with the flat surface of the knife electrode. Ability to empty the bladder varies from the 16% of Moisey and colleagues (389) to 50% by Blaivas and Norlen (61). Whether laser incision produces similar results with less morbidity is unknown (439). Complications of sphincterotomies include hemorrhage, incontinence, urethral stricture, and erectile dysfunction. Whether urethral stents are effective in nondyssynergic patients with primary bladder neck obstruction or reduced bladder contractility has not been assessed.

Y-V Plasty of the Bladder Neck

A simple Y-V plasty of the bladder neck can accomplish the same effect as a transurethral resection or incision. However, urinary incontinence can result in females. This procedure is recommended only when an open surgical procedure is already required to correct a concomitant disorder. When outlet reduction is required to render a refractory, poorly emptying bladder totally incontinent before inserting an artificial sphincter, an open Y-V plasty—although originally mentioned as a

possibility (505)—makes subsequent placement of a bladder neck cuff extremely difficult. The artificial urethral sphincter in women has been abandoned with newer therapies such as periurethral bulking agents that will probably eliminate the need for this procedure. Faced with a frustrated patient with an acontractile or hypocontractile bladder who refuses intermittent self-catheterization, some urologists may resort to incision and Y-V plasties of the bladder neck, with anecdotal success.

Pharmacologic Therapy

Krane and Olsson (292,293) endorsed the concept of a physiologic internal sphincter partially controlled by tonic sympathetic stimulation of contractile a-adrenergic receptors in the smooth musculature of the bladder neck and proximal urethra. Neurally evoked contraction of the proximal urethra is the result of activation of a-adrenergic receptors (298,615). Some obstructions that occur at this level are a result of inadequate opening of the bladder neck or inadequate decrease in resistance in the area of the proximal urethra. Krane and Olsson presented evidence that a-adrenergic blockade could be useful in promoting bladder emptying in patients with an adequate detrusor contraction but without anatomic obstruction or detrusor striated-sphincter dyssynergia. Abel and colleagues (1) called attention to the fact that functional obstruction mediated by the sympathetic nervous system could occur solely in the urethra rather than at the bladder neck, and they coined the term *neuropathic urethra.*

The implication that a-adrenergic blockade could be useful in certain patients with a failure to empty despite adequate intravesical pressure has been confirmed by many reports (265,547,614). Successful results—usually defined as an increase in flow rate, a decrease in residual urine, and improvement in a dilated upper tract—could often be correlated with an objective decrease in urethral profile closure pressures. One would expect success with such therapy to be most evident in patients without DSD, as reported by Hachen (230); however, Mobley (386) reported a startling 86% success rate in 21 patients with a reflex neurogenic bladder, with a corresponding success rate of 66% in what was called flaccid and 57% in what was called autonomous neurogenic bladder dysfunction. Success in those cases was defined as postvoid residual urine volume consistently less than 100 mL. Such effects could be explained by a decrease in perineal striated muscle activity induced by a-adrenergic blockade (193). This effect is probably mediated by a central mechanism. Evidence of adrenergic innervation of the human striated sphincter is controversial (479,602). Scott and Morrow (506) noted excellent results with phenoxybenzamine therapy in 9 of 10 patients with a hypocontractile bladder and a flaccid external sphincter, in a single patient with an upper motor neuron bladder with intact sympathetic innervation, but in only 8 of 21 patients with hyperreflexia and autonomic dysreflexia and 0 of 6 patients with an upper motor neuron bladder and sympathetic denervation (lesion between T-10 and L-2). Terazosin has been shown to facilitate emptying in patients with detrusor-sphincter dyssynergia. However, in the group of 28 men, blood pressure fell and only 42% of patients had a significant drop in voiding pressures (440). In contrast, Swierzewski and co-workers (552) noted improvement in bladder compliance in all 12 patients provided.

There is also a rationale for the addition of a-adrenolytic therapy in patients with inadequate emptying secondary to neuropathic voiding dysfunction after conventional pharmacologic treatment has failed. Parasympathetic decentralizationhas been reported to increase the adrenergic innervation of the bladder, with a resultant conversion of the usual b (relaxant) effect of the bladder body in response to sympathetic stimulation to an a (contractile) effect (120,413,551). Although the alterations in innervation have been disputed (409), the alteration in receptor function has not. Koyanagi (291) showed supersensitivity of the urethra to a-adrenergic stimulation in a group of patients with autonomous neurogenic bladders. Experimental work by de Groat and Kawatani (120) suggests that sympathetic preganglionics sprout and innervate parasympathetic neurons in the pelvic ganglia after decentralization. This implies that a similar change in adrenergic receptor function may develop in the urethra after parasympathetic decentralization. Nordling and colleagues (411) described a similar phenomenon in females after radical hysterectomy and attributed this change to damage to the sympathetic innervation of the lower urinary tract. Despite these observations, Mattiasson and co-workers (356) found that maximal urethral pressure at rest was lower, not greater as would be predicted, in patients with parasympathetic decentralization, as compared with normals.

Prazosin hydrochloride, doxazosin, terazosin, and alfuzosin are antihypertensive agents with an affinity for postsynaptic a_1-adrenergic receptors, in contrast to other a-adrenergic blockers such as phentolamine and phenoxybenzamine, which agonize both a_1- and a_2-receptor sites. These a_1-receptor antagonists relax the smooth muscle of human urethra and lower outlet resistance (17).

The potential side effects of nonselective a_1-adrenergic blockers include dizziness, asthenia, and orthostatic hypotension. The incidence of these phenomena was thought to be minimized by administering them at bedtime. However, subsequent studies have shown that dizziness is unrelated to postural hypotension and occurs regardless of time of dosing (321). Patient compliance has been enhanced and side effects reduced with the development of a-adrenergic blockers with long half-lives (12 hours). Terazosin and doxazosin are currently used to facilitate urine release by reducing bladder outlet resistance. Both drugs are administered at bedtime. Terazosin is initiated at a 1-mg dose and usually achieves optimal effects at 5 mg. However, doses up to 10 mg have been used with only a slightly increased incidence of side effects (319).

Clonidine is another antihypertensive agent that can reduce sympathetic tone, reflected in the urinary tract by a decrease in the urethral closure pressure profile (410). As an a_2-adrenergic agonist, the drug inhibits noradrenergic release and thus indirectly behaves as an a_1-adrenergic blocker. Other commonly used pharmacologic agents with significant a-adrenergic blocking properties include chlorpromazine and haloperidol (607).

These and other agents with a-adrenergic blocking properties that act at various urinary and neuraxis levels have been used for voiding disorders. A trial of such agents to treat failure to empty may be worthwhile, because their efficacy will become obvious within days and the side effects are reversible. Unfortunately, such therapy in some groups has been considerably less spectacular than reported.

b-Adrenergic stimulation has been shown experimentally to decrease the UPP and urethral resistance (565). Similarly, Vaidyanathan and colleagues (575) reported a decrease in urethral closure pressure after administration of terbutaline, a relatively specific b_2-adrenergic agonist. However, acute b-blockade has no effect on resting urethral pressure (565). Thus b-adrenergic agonists and antagonists have not proven useful to facilitate bladder emptying by decreasing outlet resistance.

During voiding, active urethral relaxation occurs through the release of NO from parasympathetic nerves supplying the urethra (16). NO activates guanylate cyclase in urethral smooth muscle, causing a rise in cyclic guanosine monophosphate (cGMP) and a fall in urethral pressure (195). Therefore NO donors or agents that prevent its degradation may be of benefit in functional obstruction of the urethra. Type 5 phosphodiesterase (PDE-5) is responsible for the breakdown of cGMP. Thus agents that prevent the breakdown of cGMP can lower outlet resistance. The PDE-5 inhibitor sildenafil relaxes human urethral smooth muscle (99a). Anecdotally, men report improved voiding symptoms the morning after an evening ingestion of sildenafil. Trials are currently underway examining PDE-5 inhibitors for obstructive disorders. Combination pharmacotherapy, or fusion drugs that contract the bladder yet reduce outlet resistance, merits scrutiny.

Central Activation of Micturition Reflex

Neuropharmacologic experiments suggest that several excitatory central transmitters participate in micturition. Most notably, glutamate (NMDA and AMPA receptors) and dopamine (D_1 and D_2 receptor) agonists, when administered in the pontine micturition center or intrathecally, trigger micturition (348). In parkinsonian patients, subcutaneous apomorphine, a dopamine D_1 and D_2 agonist, can elicit voiding (104). Similarly, the dopamine agonist pergolide (Permax) has been shown to facilitate voiding in Parkinson's patients (627). Recently, it has been shown that sublingual apomorphine triggers a voiding reflex in spinal cord–injured patients (536). With advances in localized drug administration, such as with intrathecal pumps, it is theoretically possibly to devise a pharmacologic cocktail that activates micturition pathways and inhibits storage pathways. Potential side effects of these intrathecal drugs include orthostatic hypotension, reflex tachycardia, nasal congestion, diarrhea, miosis, sedation, and edema. Ejaculatory failure occurs, caused by lack of seminal emission and not byretrograde ejaculation, but without any adverse effect on erection.

Decreasing Outlet Resistance at the Level of the Striated Sphincter

External Sphincterotomy

Therapeutic destruction of the external urethral sphincter was first performed by Watkins (592) in a patient with nonspastic obstruction. The first large clinical series was reported in 1958 by Ross and colleagues (477). The primary indication for this procedure is failure of the bladder to empty in a male patient with a suprasacral lesion when other types of management have been unsuccessful or impossible. An adequate involuntary detrusor contraction is necessary.

A substantial improvement in bladder emptying occurs in 70% to 90% of cases (604). Upper tract deterioration is rare after successful sphincterotomy, and any vesicoureteral reflux often disappears because of lower bladder pressures and the maintenance of sterile urine in a patient with a low residual urine volume and

without an indwelling catheter. An external collecting device is generally worn postoperatively.

External spincterotomy can be performed using incisions at the 5 and 7 o'clock positions; at the 3 and 9 o'clock positions; at the 2, 4, 8, and 10 o'clock positions; and at the 11 and 1 o'clock positions (604). However, the 12 o'clock position, originally proposed by Madersbacher and Scott, is preferred (229,342,343,624). The anatomy of the striated sphincter is such that its main bulk is anterior and lateral. Postoperative erectile dysfunction in those individuals who have erections varies from 5% to 30%, but it is less common (approximately 5%) with incision in the anteromedial position (342). Complications of external sphincterotomy include hemorrhage, erectile dysfunction, and urinary extravasation. Urethral stricture rarely occurs at the site of sphincterotomy.

External sphincterotomy can be performed with a knife electrode, and resection can be performed with a loop electrode or laser vaporization. The incision must extend from the level of the verumontanum at least to the bulbomembranous junction. A gradually deepening incision allows good visual control and minimizes the chances of significant hemorrhage and extravasation. In an effort to reduce hemorrhage after sphincterotomy, a contact sapphire laser has been used (438). The incidence of hemorrhage after laser sphincterotomy has been reported to be significantly lower than with electrocautery (438).

Acute sphincterotomy failure generally indicates an inadequate incision or resection of tissue. Failure may also be caused by the presence of another unsuspected obstruction (e.g., at the bladder neck) or by inadequate bladder contractions, either those of insufficient magnitude or those that are poorly sustained. In fact, sphincterotomy may contribute to the development of poorly sustained detrusor contractions. Residual urine does not always indicate failure, because low pressure but incomplete emptying in an individual may be acceptable.

Regardless of the method chosen, why do sphincterotomies fail to provide complete emptying of the bladder? Theoretically, dyssynergia may help increase the duration of a spinal micturition reflex by boosting afferent firing from the bladder. Eliminating the outlet resistance may decrease intravesical pressure, resulting in poorly sustained reflex-evoked contractions. Alternatively, Light and colleagues (326,327) provide electrophysiologic evidence for subtle sacral cord pathology in spinal cord– injured patients with increased residual urine after sphincterotomy.

The use of sphincterotomy to manage spinal cord–injured patients has waned with realization that long-term management is plagued with problems and with the advent of new, less invasive therapies, such as a_1-adrenoceptor antagonists. Vapnek and associates (580) followed spinal cord–injured patients up to 18 years after sphincterotomy and found that less than 50% were still managed with a condom catheter. The remaining patients required conversion to suprapubic cystotomy tubes because of condom catheter problems, decreased bladder compliance, persistent postvoid residual urine, and renal deterioration. The use of sphincterotomy has greatly diminished because of side effects and questionable long-term efficacy. Urinary diversion is an alternative.

Indwelling Urethral Stents

Because of long-term dissatisfaction with sphincterotomy to completely empty the bladder, and to prevent renal deterioration or infections, new therapies are being investigated. In a multicenter trial of urethral stents for the management of detrusor-sphincter dyssynergia, stents decreased voiding pressures and residual urine (96). However, nearly 30% of patients required two stents to bridge the region of high urethral pressure. Furthermore, 8% of patients needed another procedure for secondary bladder neck obstruction. Long-term follow-up is necessary to determine whether stents are more effective and less morbid than laser or electrocautery sphincterotomy. Side effects of stents include recurrent infection, stenosis, migration, discomfort, and erosion. Removal, if necessary, is often difficult.

Pudendal Nerve Block or Interruption

Relief of obstruction at the level of the striated sphincter has been attained by a pudendal neurectomy, which was first described in 1899 by Rocket (528). Historically, this method enjoyed the same popularity in patients with fixedneurologic lesions and striated-sphincter dyssynergia, but it is seldom used today (604). Assessment of the results using a pudendal block should precede the formal procedure. Neurectomy should be performed only unilaterally because bilateral sectioning results in a high rate of erectile dysfunction and may result in fecal and severe stress urinary incontinence.

Pharmacologic Therapy

There is no class of oral pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. Chlordiazepoxide, methocarbamol, orphenadrine, and diazepam belong to a group of agents classified as centrally acting muscle relaxants (49). The primary side effect of all members of this group is sedation. The recommended oral doses are not effective in controlling striated-sphincter dyssynergia seen secondary to neurologic disease. Centrally acting GABA agonists inhibit motor outflow, but usually at oral doses are associated with profound sedation. The theoretic rationale with GABA agonists is either relaxation of the pelvic floor striated musculature during bladder contraction or such relaxation removing a stimulus that is inhibitory to bladder activity.

Dantrolene sodium is a skeletal muscle relaxant that dissociates excitation–contraction coupling at a site distal to the neuromuscular endplate in the sarcoplasmic reticulum (49). The drug has been used in patients with classical detrusor striated-sphincter dyssynergia and was initially reported as being successful in improving voiding (400). Therapy in adults is begun at a dose of 25 mg twice daily, increasing the dose weekly in 50- to 100-mg increments up to a recommended daily maximum of 400 mg given in divided dosages. Hackler and associates (231) achieved improvement in voiding function in approximately half of their patients treated with dantrolene but found that such improvement required doses of 600 mg per day. Although the drug has no autonomic side effects, like all CNS depressants, it may induce a generalized weakness severe enough to compromise its therapeutic benefits, especially in doses associated with sphincter relaxation. Other potential side effects include euphoria, dizziness, diarrhea, and hepatotoxicity. Toxicity to the liver is thought to be related to high-dose, long-term use and has resulted in some fatalities.

Another approach may be to inhibit neural input to the external urethral sphincter, thereby diminishing bladder outlet resistance. a_2-Adrenergic agonists such as clonidine prevent urethral smooth muscle contraction by inhibiting release of norepinephrine from noradrenergic nerves (17). In addition, clonidine and other a_2-adrenergic agonists are postulated to modulate afferent input from striated muscles. The a_2-adrenergic agonist tizanidine (Zanaflex) is a centrally acting skeletal muscle relaxant (587). Tizanidine is undergoing clinical evaluation in multiple sclerosis patients to determine whether this drug can facilitate bladder emptying by reducing loss of coordination between the bladder and its outlet and detrusor-sphincter dyssynergia due to suppressed neural pathology. Another muscle relaxant that can inhibit the external urethral sphincter is inaperisone, which, in addition to possessing central muscle relaxant properties, is a nicotinic receptor antagonist. Inaperisone is undergoing clinical trials to reduce pelvic floor spasticity and thereby facilitate bladder emptying.

A more commonly used centrally acting agent that relaxes the external urethral sphincter is the GABA agonist baclofen. Baclofen is thought to inhibit primary afferent fiber terminals in the spinal cord, thereby abolishing monosynaptic or polysynaptic spinal reflex activity. It has been found to be useful in the treatment of mild skeletal spasticity resulting from a variety of causes. Treatment is started at an initial dosage of 5 mg three times daily, and the dosage is doubled every 3 days until a daily total dosage level of 60 mg is reached. The manufacturer recommends that the total daily dosage not exceed 20 mg four times daily. Furthermore, a patient should be gradually weaned off baclofen to prevent seizures. Florante and colleagues (175) reported that 73% of their patients with voiding dysfunction secondary to acute and chronic spinal cord injury showed lower striated-sphincter responses and decreased residual urine volume after treatment, but only with an average daily oral dose of 120 mg. Nanninga (401) and Steers and associates (539) have found that intrathecal baclofen is often effective at inhibiting the striated urethral sphincter while circumventing the problems with sedation. Similarly, it can completely abolish hyperreflexia and nocturia and increase compliance, first sensation, and bladder capacity. However, in quadriplegics, care must be taken not to eliminate the micturition reflex necessary for trigger voiding. Side effects include lower-extremity flaccidity at doses necessary to affect the bladder, as well as respiration depression, erectile dysfunction, and constipation. Other potential side effects of baclofen include drowsiness, insomnia, rash, pruritus, dizziness, and weakness. Hallucinations or seizures may sometimes occur after abrupt withdrawal. The use of an intrathecal delivery system offers many potential advantages, and in the future it may be used for other drugs to elicit or inhibit micturition or pain. The latest development relies on the use of injections of botulinum toxin A (Botox) into the external urethral sphincter. This compound blocks the nicotinic neuromuscular function. Clinical trials indicate reduction in residual urine (average 125 mL), urethral pressures, and voiding pressures (148,503).

Biofeedback and Psychotherapy

Biofeedback is a useful adjunct to improve voluntary control of neural, visceral, and skeletal responses (383,384). Biofeedback, behavioral training. and psychotherapy are used to treat disorders of both urine release and storage. These regimens encompass a wide range of maneuvers and are discussed in more detail under therapies for urine storage. In children with difficulty evacuating urine due to nonneurogeniccauses, biofeedback has been very successful for problems with urination and defecation. The data used in biofeedback may be as sophisticated as visual or auditory information produced by modern electronic equipment that is monitoring a physiologic process, or as simple as a self-kept record of symptoms and biologic events (such as a chart for recording the time and volume of voiding

and the presence of urgency and incontinence). The list of physiologic processes subject to some self-control includes blood pressure, heart rate, blood flow, sweat gland activity, skin temperature, body temperature, respiratory function, genital responses, bowel and bladder motility, and skeletal muscle control.

Hinman (248) and Allen (6) were perhaps the first to recognize that nonneurogenic striated-sphincter dyssynergia (or a disorder qualitatively similar to it) can occur on a psychogenic basis and cause gross upper tract damage. Each used a combination of psychologic retraining, suggestion, medication, and parental cooperation in a treatment program. Wear and colleagues (593) described the use of a urodynamic display of external-sphincter EMG activity to facilitate this type of treatment. They reported significant clinical improvement in four of eight patients so treated. Maizels and co-workers (346) further simplified this technique by using anal skin electrodes for the repeated display of striated-sphincter activity without pain or significant inconvenience to the patient. In one of the largest series reported, Rapariz Gonzales (456) described outcomes in 50 consecutive patients (82% female, 18% male) with uncoordinated voiding syndrome (Hinman's syndrome, nonneurogenic neurogenic bladder). The mean age was 12 years. Using flow rates and sphincter EMG for follow-up at 12 months, a reeducation program was curative in 42% of children; 22% were improved, 2% relapsed, and 14% had no response. Successful therapy in this type of situation requires a strongly motivated patient who is capable of understanding the instructions for biofeedback training.

Circumventing Problems

Intermittent Catheterization

Intermittent catheterization is the most effective means of attaining a catheter-free state in patients with acute spinal cord lesions (187). It is also an extremely effective method of treating an adult or child whose bladder fails to empty, especially when efforts to increase intravesical pressure or decrease outlet resistance have been unsuccessful. In patients with inadequate urine storage because of involuntary bladder contractions, decreased compliance, or stress incontinence with adequate or inadequate emptying, it may also be used if the dysfunction can be converted solely or primarily to one of emptying by pharmacologic or surgical means (604). Lapides and associates (305) deserve enormous credit for first applying the concept of intermittent self-catheterization to large groups of outpatients with voiding dysfunction. Subsequently, Lapides and co-workers and many others have demonstrated the long-term efficacy and safety of such a regimen. Requirements for intermittent catheterization include a cooperative, well-motivated patient or family, adequate hand control (or a family member willing to catheterize), and sufficient urethral exposure. Teaching intermittent self-catheterization requires an approach that communicates acceptance of the procedure by the instructor. It is advantageous to have a special urologic nurse who instructs the patients or families in the regimen; provides them with understandable written instructions to refresh their memories regarding technique, precautions, and danger signals; and provides continuing support for patients who call with questions or problems about their regimen.

For adult male patients, 14- or 16-Fr stiff or flexible catheters are generally used. In some cases (e.g., in patients with impaired fine motor skills), stiffer plastic catheters may be easier for the patient to insert. These are also commercially available in a disposable form. A notable advantage to red rubber catheters is their longevity and overall low cost. However, for catheterizing Mitrofanoff stomas, they lack sufficient stiffness. They can be reused indefinitely and boiled for sterilization if desired. Shorter, disposable plastic female catheters, now manufactured by several companies, are recommended for female patients. They are inexpensive and convenient. These 14-Fr, 6-inch catheters are easy to handle. Female patients may catheterize themselves on the toilet without a mirror, making intermittent catheterization less confusing, cleaner, and quicker. Red rubber or Robinson catheters may also be used for female patients if desired. For the patient's convenience, liquid cleansing agents are usually easier to handle in the form of cotton balls soaked in the agent. These can be easily carried in a small jar. Any water-soluble lubricant is suitable for lubricating the catheter before insertion.

Several studies examining urinary tract infections and upper tracts with management by clean intermittent catheterization deserve mention. McGuire and associates (375) advocated intermittent self-catheterization in spinal cord–injured patients as a method to preserve good bladder compliance. They found that urine cultures in roughly one-third of patients remain sterile, one-third have bacteriemia, and one-third suffer recurrent urinary tract infections. Perkash and Giroux (439) followed the upper tracts and urine cultures in 50 spinal cord–injured patients on intermittent catheterization and found that 86% of patients developed positive urine cultures (greater than 10^4 cfu/mL) and 42% had genitourinary complications. However, upper tract deterioration did not occur if adequate bladder compliance and low intravesical pressures were maintained. These latter two goals, rather than self-catheterization per se, may be more important determinants in the preservation of renal function.

Continuous Catheterization

Indwelling urethral catheters are best for short-term bladder drainage, and careful use of a small-bore catheter fails to adversely affect the ultimate outcome. Occasionally, an indwelling catheter is a last resort for long-term bladder drainage. After 72 hours, virtually all patients with an indwelling urethral catheter have bacteriuria. A contracted, fibrotic bladder can result from chronic inflammation. Encrustations may form on the catheter or on the retention balloon. Urethral complications are relatively uncommon in females, but bladder spasm may occur, producing urinary incontinence. The temptation to use a large retention balloon should be resisted, because the continuous use of such a balloon combined with some pressure on the catheter may cause erosion of the bladder neck. A suprapubic trochar catheter may be initially more comfortable than a urethral catheter, and it obviates urethral fistulae and strictures in the male over longer periods. Bladder spasm with incontinence may, however, be more of a problem, and when blockage occurs, nursing personnel are more reluctant to change this type of catheter without physician assistance.

Dolin and associates (139), in examining women who died of bladder cancer, found that the incidence of squamous cell carcinoma was especially high in paraplegic women. Jacobs and Kaufman (259a) reported development of squamous cell carcinoma of the bladder in 6 of 59 patients with spinal cord injuries who had long-term indwelling catheters. Four of these patients had no obvious tumor visible on endoscopy, and the diagnosis was made by bladder biopsy. Five of these patients also had transitional cell elements in their tumor. Broecker and associates (76) surveyed 81 consecutive spinal cord–injured patients with indwelling urinary catheters for more than 10 years, and although they did not find carcinoma, they discovered squamous metaplasia of the bladder in 11 patients and leukoplakia in one patient.

The long-term morbidity of chronic indwelling catheters is recognized, but often other reasonable alternatives are nonexistent. Bennett (40) has suggested that in quadriplegic women, urinary diversion is preferable to indwelling catheters, based on follow-up over 20 years. However, a cohort group of diverted patients was not used to reach this conclusion.

Alternatively, Dewire and co-workers (131) suggest that use of chronic indwelling catheters is not associated with any greater incidence of calculi, pyelonephritis, hematuria, urosepsis, or erosion compared with a retrospective cohort of patients managed with either condom catheters or urinary diversion. Chai and colleagues (88) also reported no significant differences in cord-injured patients managed with indwelling catheters versus those with reflex voiding. However, Chai's group uncovered a greater incidence of renal scarring and caliectasis in the catheterized patients. Age of injury and level of injury help predict upper tract deterioration in spinal cord–injured patients. Management with an indwelling catheter is a risk factor for renal deterioration. Overall, indwelling catheters are to be avoided for long-term usage. In males, suprapubic tubes are preferred. In females, eventual dilation of the urethra limits their use. However, for short-term use proper positioning of a urethral catheter can reduce the likelihood of bulbar urethral erosion (Fig. 26B.24).

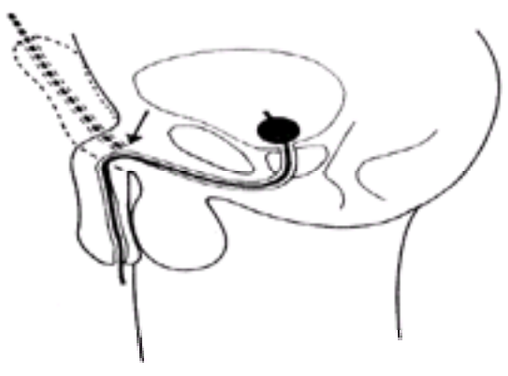

FIGURE 26B.24. In neuropathic patients an indwelling catheter may cause a urethral decubitus at the penoscrotal angle with possible fistula formation *(arrow).* Therefore the penis must be placed to the lower abdomen *(dotted line).*

Ileocystostomy

In patients with competent outlets, adequate bladder capacity, good bladder compliance, and optimal body habitus, the feasibility of ileocystostomy has been suggested (96). Likened to a chimney, this method of bladder drainage avoids ureteral reimplantation and relies on the intrinsic vesicoureteral mechanism to prevent reflux. However, if the patient is not properly selected, residual urine or incontinence can occur, necessitating what would be a more difficult urinary diversion (Fig. 26B.25). Key selection criteria include a small contracted bladder and a thin body habitus. Otherwise, incomplete drainage occurs.

Urinary Diversion

Supravesical Diversion

Supravesical diversion is undergoing a resurgence due to improved techniques, especially continent diversion andpopularity of bladder reconstructive techniques. Indications for performing supravesical diversion may include the following:

1. Progressive hydronephrosis and intractable upper urinary tract dilation (which may be caused by blockage of the ureterovesical junction resulting from a trabeculated, thick bladder or from vesicoureteral reflux that does not respond to conservative measures)
2. Recurrent upper urinary tract infections
3. Difficulty performing or inability to perform urethral catheterization, especially in children

Although the various techniques of supravesical urinary diversion are covered in other chapters of this book, it is important to note that urinary diversion cannot always prevent upper urinary tract deterioration. The initial results of the ileal conduit seemed encouraging in terms of upper tract preservation (73). Unfortunately, long-term results have been disappointing (147,424,447,504). The colonic conduit, which allows a reflux-preventing implantation of the ureters, was expected to produce better long-term results. Although earlier reports seemed to support this supposition (8,9,387), long-term results seem to be equally disappointing (153).

Continent forms of diversion that may be applicable to patients with voiding dysfunction involve the application of a continent abdominal wall stoma (Indiana pouch, ileocecal reservoir, or gastroileal pouch) (215). Obesity, severe scoliosis, and kyphosis are relative contraindications to conduit stomal diversion because of difficulty in fitting a stomal bag. A novel approach in obese patients is to perform liposuction around the stoma to ensure a better fit. Obviously, such a problem does not exist with continent stomal diversion (24). On the other hand, continent stomal diversion requires that the patient be able to perform intermittent catheterization or that dependable assistance be available for catheterizing the stoma. Angulation of the intestinal segment in the abdominal wall can create problems with catheterization. Even preferable to continent diversions is orthotopic bladder replacement, especially in men. Preservation of the distal sphincter mechanism helps preserve continence. Nocturia enuresis is common. The Studer ileal neobladder is becoming a popular method of replacement (430). Voiding dysfunction in orthotopic neobladders includes retention and incontinence, especially enuresis. Risk factors for failure to empty neobladders include increasing age and excessive length of intestine required to fashion the neobladder. A conscious reduction in length and anterior fixation of the neobladder to prevent posterior prolapse have been used to reduce retention rates. A review of voiding dysfunction with neobladders has recently been published (531). Long-term results in patients with these forms of continent diversion may be no better than the traditional ileal conduit, although early operative complications are probably greater (19,618). Bladder reconstruction and substitution are covered more completely elsewhere in this book.

Therapy to Facilitate Urine Storage

Treatments to facilitate urine storage can be applied to patients with urinary incontinence and overactive bladder. The overactive bladder is characterized by urinary frequency, urgency, and nocturia with or without urge incontinence.

Inhibiting Bladder Contractility, Decreasing Sensory Input, and Increasing Bladder Capacity

Timed Bladder Emptying

Timed bladder emptying is actually a form of behavioral therapy (166), although it is not a sophisticated concept. The idea is to completely or partially empty the bladder on a frequent enough schedule to keep the intravesical volume below that at which storage failure results. This may involve nothing more than frequent voiding with a limited fluid intake in patients with detrusor hyperactivity. It may involve a more complicated coordination of an intermittent catheterization schedule with bladder volume in patients with detrusor hyperreflexia and sphincter dyssynergia whose status has been converted to that of relative emptying failure, but only if the bladder is emptied periodically (before the threshold is reached for hyperreflexia or decreasedcompliance causing storage failure or upper tract damage). Formal behavioral programs have gained acceptance in first-line management of failure to store (80,81,84,166). Timed voiding should be a key component of any pharmacologic regimen.

Pharmacologic Therapy

Anticholinergic Agents

Because acetylcholine is the principal neurotransmitter responsible for contraction of the detrusor, anticholinergics are the first-line therapy for the overactive bladder (18). Clinically available anticholinergics are mixed muscarinic antagonists that bind to the M_2 and M_3 muscarinic receptor subtypes (18). The nonselective muscarinic antagonist oxybutynin and its major metabolite directly relax smooth muscle *in vitro* as well (17). It is doubtful whether this is clinically relevant. Several M_3-selective muscarinic antagonists are currently under investigation for the treatment of the overactive bladder and urge incontinence. These M_3-selective antagonists include Darifenacin and YM905 (588). A clever strategy might be to use M_2- or M_3-selective antagonists that possess agonist properties at M_1 or M_4 receptors. Drugs exhibiting this profile may be particularly useful in the elderly, in whom blockade of M_1 receptors may promote confusion or exacerbate various dementias, including Alzheimer's disease. One mixed M_2-M_3 antagonist/M_1 agonist undergoing clinical trials for overactive bladder is LU25109. Experimentally, mixed M_3 antagonist/M_1 agonists exhibit both anticholinergic and antinociceptive properties (509). Therefore an M_3 antagonist/M_1 agonist such as LY297802 could be promising for the treatment of overactive bladders with associated discomfort, such as interstitial cystitis. This drug could provide the added benefit of reduced CNS side effects mediated by M_1 receptors.

Anticholinergic drugs are a logical choice for problems with failure to store urine (35). In the human detrusor, all currently available antagonists bind to virtually all

muscarinic subtypes with equal effectiveness (406). Atropine and atropine-like agents are often effective against detrusor hyperactivity (60,263). In such patients, the volume of the first involuntary contraction is generally increased, the amplitude of the contractions is decreased, and the total bladder capacity is increased, with a proportionate reduction in symptoms. Thus, to be most effective, these agents are best given with advice for timed voiding. Interestingly, bladder compliance in normal individuals and in those with detrusor hyperreflexia, where the initial slope of the filling curve on cystometry is normal before the involuntary contraction, may not be significantly altered (263). The effect of these agents on intravesical pressure during filling in those patients who exhibit only decreased compliance has not been well studied. Despite this lack of data, anticholinergics continue to be recommended in combination with intermittent catheterization for decreased compliance (370). These agents may help prevent loss of compliance (more than they reduce filling pressures) due to changes in extracellular matrix. Although significant clinical improvement may be achieved in patients with detrusor hyperreflexia, only partial inhibition generally results, postulated to be due to afferent hyperactivity, noncholinergic contractile activity, or altered extracellular matrix, among other reasons. Most of the drugs discussed under the heading of inhibiting bladder contractility are agents that inhibit muscarinic cholinergic receptors. These agents, although helpful, leave much to be desired in terms of efficacy. For example, controlled studies on the use of anticholinergics for urinary incontinence report only a 5% to 44% cure rate (361). In one report, the cure rate for oxybutynin was only 5%, and nearly 80% of patients discontinued medication use because of side effects (273).

In a randomized, prospective study comparing propantheline to the anticholinergic and antispasmodic drug oxybutynin (Ditropan), the latter drug was significantly more effective in relieving urgency and increasing bladder capacity (567). Hyoscyamine (Levsinex) is popular as an anticholinergic because it can be administered on a twice-daily regimen (Table 26B.13). Efforts to reduce side effects have been disappointing because of inability to identify either a muscarinic receptor subtype unique to the bladder or drugs selective only for the detrusor smooth muscle. In an effort to minimize the side effects of dry mouth, tolterodine has been developed. This agent, given at 2 mg twice daily, causes less dry mouth than oxybutynin given at 5 mg three times daily. Statistically, tolterodine reduces the number of incontinent episodes and urinary frequency (99). In an analysis of more than 1,200 subjects randomized to oxybutynin 5 mg three times daily or tolterodine 1 or 2 mg twice daily, reduction in micturitions by 20% over 24 hours was reported. A 40% to 60% reduction in incontinence episodes was observed. Dry mouth was seen in 78% of the oxybutynin group but only 24% to 40% of the tolterodine group. It is unclear whether administering oxybutynin at 2.5 mg twice daily would have a similar profile.

Tolterodine 2–4 mg b.i.d.
Oxybutynin 2.5–5 mg t.i.d.
Oxybutynin 5, 10, or 15 mg q.d. × 2
Propantheline 15–45 mg q.i.d.
Hyoscyamine 1 mg b.i.d.

TABLE 26B.13. COMMON ANTICHOLINERGICS FOR STORAGE FAILURE

Despite new formulations, the potential side effects of all antimuscarinic agents remain and include inhibition of salivary secretion (dry mouth), blockade of the iris sphincter muscle (papillary dilation), blockade of the ciliary muscle of the lens to cholinergic stimulation (blurred vision for near objects), tachycardia, drowsiness, and inhibition of gut motility (606). Greater appreciation of central effects of some anticholinergics has been gained from reports ofconfusion in the elderly and restlessness in children on these drugs. Moreover, severe problems with dental disease, especially in the elderly, have been attributed to drugs causing dry mouth. Antimuscarinic agents are generally contraindicated in patients with narrow-angle glaucoma and should be used with caution in patients with significant bladder outlet obstruction, because complete urinary retention may be precipitated.

Purinergic and Indirect Anticholinergic Agents

Atropine only partially antagonizes the bladder response in animals to either pelvic nerve stimulation or direct electrical stimulation. However, atropine completely inhibits the response of the human bladder smooth muscle to exogenously administered acetylcholine and electrical stimulation of the pelvic nerve. At present, there is no completely accepted explanation for this relative atropine resistance, but the most attractive theory is that a major portion of the neurotransmission after injury or with disease, mediated by parasympathetic (pelvic) nerve stimulation, is secondary to release of a transmitter other than acetylcholine or norepinephrine. Candidates include substance P or neurokinin A, released from afferents, and adenosine triphosphate (ATP), found in efferents, In certain disease states, noncholinergic and nonadrenergic neurotransmission may provide excitatory input to the bladder and contribute to involuntary bladder contractions. This finding could explain the inability of anticholinergics to control symptoms in many patients. Experimental evidence in animals and some human data suggest that purinergic transmission provides excitatory input to the diseased bladder in patients with denervation, obstruction, or idiopathic urge incontinence (517). The predominant purinergic receptor expressed by human bladder smooth muscle is of the P_{2X1} subtype, whereas P_{2X3} receptors are expressed by afferent terminals in the human bladder (423). Thus P_{2X} antagonists could offer a combined afferent/efferent approach for the management of the overactive bladder. Unfortunately, agents that block purines (ATP) are not yet clinically available. Suramin, an antipurinergic drug, is an antihelminthic used to treat nematode diseases. It antagonizes the P_2 receptor, but it has not been clinically evaluated for bladder dysfunction. Moreover, this agent blocks the enzyme that degrades ATP, known as ATPase, thus negating some of its effect. Suramin is also highly toxic.

An unexplored approach to combat the overactive bladder may be to inhibit acetylcholine release from cholinergic nerves in the bladder. M_4 agonists inhibit acetylcholine release (112). Galanin and protein kinase C inhibitors also prevent acetylcholine release (17). No trials are underway using these agents for the overactive bladder.

Musculotropic Relaxants (Antispasmodics)

Musculotropic relaxants are direct-acting smooth muscle depressants whose antispasmodic-activity effect on smooth muscle contractility is separate from the cholinergic receptor mechanism (171). Although all agents that relax detrusor smooth muscle *in vitro* also reduce intracellular calcium, many possess variable antimuscarinic and local anesthetic properties. There is still a question as to how much of their clinical efficacy is caused simply by their atropine-like effect. If any of these agents do exert a clinically significant inhibitory effect that is independent of an antimuscarinic action, there exists a therapeutic rationale for combining their use with that of a relatively pure antimuscarinic agent.

Oxybutynin chloride is a moderately potent anticholinergic agent with a strong independent musculotropic relaxant activity and local anesthetic activity (171,567). This agent has been used successfully to depress detrusor hyperreflexia in patients with neurogenic bladder dysfunction. A randomized, double-blind control study in 30 patients with detrusor instability that compared oxybutynin at 5 mg three times daily with a placebo was performed by Moisey and colleagues (388). More recently, a 3-mg dose given three times a day was shown to be as effective in treatment of women (n = 53) with detrusor instability (392). Of 23 patients who completed the study with oxybutynin, 17 had symptomatic improvement and 9 had evidence of urodynamic improvement, mainly an increase in bladder volume at first contraction and an increase in total bladder capacity. In elderly subjects, oxybutynin is tolerated and effective for treatment of detrusor hyperactivity (634). The recommended adult dosage of oxybutynin is 5 mg three or four times daily, although single doses as larger as 10 mg or as small as 3 mg are also used.

The use of osmotic mini-pumps has allowed many formulations to be given once daily. Ditropan XL (oxybutynin) exploits this principal to allow once-daily administration of this anticholinergic. By reducing the peak levels of this drug, fewer side effects are reported (18,213). There is no difference in therapeutic efficacy between controlled-release and immediate-release Ditropan. Dry mouth was reported in 67% and 87% of subjects, respectively, at the dosages necessary to achieve maximal therapeutic effects.

In an effort to improve efficacy and reduce or eliminate side effects, oxybutynin has been administered intravesically (72,222,271). In adults and children, the regimen (5 mg in 20 to 30 mL of saline two or three times daily) has been shown to increase capacity and compliance and reduce urge incontinence of involuntary detrusor

contractions. Side effects, although somewhat reduced, are still common because of systemic absorption from the bladder.

Dicyclomine hydrochloride is also reported to possess a direct relaxant effect on smooth muscle, in addition to an antimuscarinic action (143,278). An oral dose of 20 mg three times daily in adults has been reported to increase bladder capacity in patients with detrusor hyperreflexia (173), and the dose can be raised to at least 30 mg to achieve a clinical effect. The potential side effects are antimuscarinic ones.

Flavoxate hydrochloride is another compound that has been reported to have a direct inhibitory action on smooth muscle, in addition to anticholinergic and local analgesic properties (288). Briggs and associates (74) reported essentially no effect of this agent on detrusor hyperreflexia in an elderly population. Similarly, in a placebo-controlled trial, Chapple and co-workers (101) found flavoxate not to be beneficial in management of detrusor instability. This experience coincides with the subjective impression of limited clinical efficacy in situations in which other anticholinergics have failed (43). The recommended adult dosage is 100 to 200 mg three to four times daily. Reported side effects are rare and are primarily antimuscarinic in nature.

Polysynaptic Inhibitors

Baclofen has been discussed previously in the section on agents that decrease outlet resistance secondary to striated-sphincter dyssynergia. It has also been shown to depress detrusor hyperreflexia secondary to a spinal cord lesion (280,480). In a double-blind crossover study, Taylor and Bates (562) reported baclofen to be effective also in decreasing daytime and nighttime urinary frequency and incontinence in patients with idiopathic detrusor hyperreflexia. By blocking afferent transmission in the sacral spinal cord, or through a GABA-like effect in the pons, this agent may inhibit reflex micturition. However, the systemic doses required to consistently achieve a desired effect on micturition globally depress CNS function. Intrathecal administration can bypass some of the dose-limiting side effects.

Calcium Antagonists

The rationale underlying the potential use of calcium antagonists for the inhibition of bladder contractility relies on the pivotal nature of cytosolic calcium in smooth muscle contraction (532). The calcium antagonist nifedipine has been shown to inhibit contraction induced by several mechanisms in human and guinea pig bladder muscle (179,516). It is also capable of completely blocking the noncholinergic portion of the contraction produced by electrical field stimulation in rabbit bladder (255). Nifedipine more effectively inhibited potassium-induced than carbachol-induced contractions in bladder strips, whereas terodiline, an agent with both calcium-antagonistic and anticholinergic properties, had the opposite effect (255). This agent in low concentrations seemed to have mainly an antimuscarinic action, whereas at higher concentrations it was a calcium antagonist. *In vitro* experiments appeared to show that these two effects are at least additive with regard to bladder contractility. Whether the calcium antagonistic properties of terodiline contributed to its clinical effectiveness *in vivc* is unclear. Rud and colleagues (483) reported that in oral dosages of 12.5 mg two or three times daily, terodiline produced a marked decrease in the number of hyperreflexic contractions in a group of seven women with urgency incontinence and two with nocturnal enuresis. Bladder capacity was approximately doubled, and the amplitude of the contractions was decreased. In a double-blind crossover study in 12 women with motor urge incontinence, Ekman and colleagues (150) reported an increase in bladder capacity, and in the volume at which the sensation of urgency was experienced, in all but one of the patients treated with terodiline, whereas placebo treatment had no effect on either objective or subjective parameters. Unfortunately, deaths occurred on this drug due to cardiac arrhythmias, and it was removed from the market. Clinical trials for the overactive bladder are under way investigating temiverine and its active metabolite RCC36, which inhibit L-type voltage-gated Ca^{2+} channels and muscarinic receptors (106). Like terodiline, temiverine has a dual site of action, and it may have greater efficacy than a pure anticholinergic agent. Cardiac arrhythmias similar to the mixed Ca^{2+} channel blocker–anticholinergic terodiline are unlikely because temiverine does not influence the delayed or inward rectifier K^{+} currents.

Palmer and associates (429) reported a double-blind placebo trial with a single 20-mg daily dose of flunarizine in 14 females with urinary frequency, incontinence, and urodynamically proven detrusor instability. A statistically significant decrease in urgency was produced in the flunarizine-treated group, but there was no change in the frequency of micturition. Although there was a trend toward improvement of cystometric parameters, this was not statistically significant (p =.05). Similarly, Mattiasson and associates (357) demonstrated that intravesical verapamil increases compliance and capacity, as well as decreasing bladder hyperactivity, in patients with nonneurogenic rather than neurogenic causes of involuntary contractions. However, verapamil's clinical usefulness appears to be limited.

The reported side effects produced in patients treated with calcium antagonists for voiding dysfunction are few. Potential adverse effects include hypotension, facial flushing, headache, dizziness, abdominal discomfort, constipation, nausea, rash, weakness, and palpitations. With intravesical administration, hypotension can be profound. Urine must be acidic to prevent precipitation of the drug after intravesical instillation.

Potassium Channel Openers

The use of K^{+} channel openers has been championed for the treatment of overactive bladder. Opening K^{+} channels hyperpolarizes smooth muscle cells, thereby preventing the influx of Ca^{2+} and subsequent refilling of intracellular stores (17). A variety of potassium channel openers relax the detrusor *in vitro,* including minoxidil, glipizide, and pinacidil. The heterogeneity of potassium receptors that can relax smooth muscle raises the possibility of selectivity for the bladder and efficacy in disorders of urine storage. Orally, these agents can trigger profound hypotension, hyperglycemia, and increased hair growth. It has been postulated that intravesical administration of potassium channel openerscan increase bladder compliance and capacity, yet reduce side effects. Experimentally, the K^{+}-ATP channel opener ZD6169 relaxes bladder smooth muscle *in vivo* and *in vitro* (106). Preclinical trials are underway with oral ZD0947, another K^{+}-ATP channel opener. If hypotension is avoided, the use of K^{+}-ATP channel blockers may offer a useful strategy.

b-Adrenergic Agonists

Direct relaxation of the bladder occurs in response to norepinephrine released by sympathetic noradrenergic nerves through the activation of b-adrenergic receptors (17). Based on data showing insensitivity of the detrusor to b_1- and b_2-adrenoceptor antagonists, the predominant b-adrenoceptor subtype expressed by the human bladder is probably b_3 (333). The presence of b-adrenergic receptors in human bladder muscle has prompted attempts to expand bladder capacity with b-adrenergic stimulation. Such stimulation can create significant increases in the capacity of animal bladders, which contain a moderate density of b-adrenergic receptors (308). *In vitro* studies show a strong dose-related relaxant effect of b_2-adrenergic agonists on the bladder body of rabbits, but little effect on the bladder base or proximal urethra (277). In men, b-adrenergic agonists appear to slightly increase bladder capacity, but effects on involuntary contractions and urge incontinence are variable. The b_2-adrenergic agonist terbutaline (Bricanyl) at oral dosages of 5 mg three times daily has been reported to have a “good clinical effect” in some patients with urgency and urge incontinence, but no significant effect on the bladders of neurologically normal humans without voiding difficulty (414). Lindholm and Lose (331), in an uncontrolled trial, found terbutaline useful in 80% of women. Castleden and Morgan (87), in the elderly, and others in children, found that the b-adrenergic agonists did not affect urodynamic parameters or improve urge incontinence. The inability of b-adrenergic agonists to consistently abolish hyperreflexia, increase compliance, or relax the bladder outlet has prevented their widespread use. This lack of efficacy could be due to lack of action at the b_3-adrenergic receptor. There are now several b_3-adrenoceptor agonists in various stages of investigation for nonurologic disorders. These include SK37344, SR59230A, and BRL35135, which is slightly less potent in human bladder tissue than SK37344. *In vitro* SR59230 is less potent than BRL35135 in relaxing human bladder smooth muscle.

a-Adrenergic Antagonists (Table 26B.14)

Phenoxybenzamine 10-20 mg b.i.d. to t.i.d.
Terazosin 3-10 mg q.d.
Doxazosin 4-18 mg q.d.
Tamsulosin 0.4-0.8 mg q.d.
Clonidine 0.1 mg q.d. to b.i.d.

TABLE 26B.14. COMMON a-ADRENERGIC DRUGS FOR FAILURE TO EMPTY OR AUTONOMIC DYSREFLEXIA

There are a variety of reasons to suspect that a_1-adrenergic blockers could be useful in the management of overactive bladder. Jensen (262) reported an increased a-adrenergic tone in patients with “uninhibited” bladders. Short- and long-term administration of prazosin was reported by him to increase bladder capacity and decrease the amplitude of contractions in this category of patients (262,264). Rohner and colleagues (475) reported conversion of the normal b-adrenergic response of canine bladder body to an a-adrenergic response after bladder outlet obstruction. Perlberg and Caine (441) studied the *in vitro* response of bladder dome muscle from patients with obstructive prostatic hypertrophy and found an a-adrenergic response to noradrenaline (instead of the usual b-adrenergic response) in 23% of 47 patients. They speculated as to a potential relationship between irritative symptoms in these patients that altered adrenergic response. Lepor and associates (319) have reported on the long-acting a-adrenergic blocker terazosin in placebo-controlled multicenter trials for obstruction from BPH. Randomized to placebo or 2.5 or 10 mg of terazosin, patients demonstrated significant increases in maximum urine flow and reduction of irritative and obstructive symptoms. Similar results have been reported for doxazosin (396). Shapiro and colleagues (510) have shown that symptomatic (obstructive) and flow rate responses in BPH patients correlate with the percent density of smooth muscle in the adenoma.

The predominant a_1-adrenoceptor subtype mRNA in the prostatic stroma and urethra is a_{1A}, comprising 70% of the total a_1-mRNA (453). The vasculature expresses all three a_1-receptor subtypes. Regardless of effects on obstruction, a_{1A}-receptor antagonists have been developed for BPH to enhance efficacy while ameliorating side effects. The a_1-adrenoceptor blocker tamsulosin is somewhat more selective for a_{1A} than a_{1B} and a_{1D} receptors (468). This is not the same as “uroselectivity.” Not surprisingly, a variety of highly selective a_{1A}-adrenoceptor antagonists are undergoing preclinical or clinical trials for the treatment of symptoms due to BPH. These a_{1A}-adrenoceptor antagonists include RS17053, SB216469, REC 15-2739, KMD 3213, and L-771,688,SNAP6383 (353). Although these agents reduce outlet resistance and raise maximal flow rates, there is concern that the relief of symptoms of urinary urgency, frequency, and nocturia may be less than anticipated. Following obstruction, the mRNA for the a_{1D} receptor is upregulated in the bladder (349). Therefore whether a_{1A} and a_{1D} are nonselective, a_1-adrenoceptor antagonists for BPH symptoms requires further study.

The less-than-anticipated efficacy of highly selective a_1-adrenoceptor antagonists in reducing urgency, frequency, and nocturia may be due to the action of a_1-adrenergic antagonists on sites other than the prostate or urethra (123).For example, intrathecal doxazosin, a nonselective a_1-adrenoceptor antagonist, reduces bladder hyperactivity in obstructed animals (259). It is interesting to note that in animals, a-adrenergic blockers given at the time of fixed urethral obstruction also prevent bladder hyperactivity, raising the possibility of another site of action, possibly the spinal cord (540). Others theorize that at least some of the symptomatic improvement in irritative symptoms seen in patients with BPH who are treated with a-adrenergic blocking agents may be caused by a direct effect of these agents on bladder muscle, rather than their effect on overflow resistance. Likewise, in spinal cord–injured patients, terazosin facilitates bladder emptying and may increase compliance (552).

A dual site of action (prostate and CNS) may also explain the lack of correlation between increased flow rates after a_1-adrenoceptor blockade and relief of irritative symptoms (320,321). The nonselective a_1-adrenergic antagonist alfuzosin has been approved for use in BPH in Europe. Alfuzosin, although a nonselective a_1-adrenergic antagonist, fails to penetrate the CNS. Nevertheless, it is unclear whether this agent is less effective for urgency, frequency, and nocturia than other a_1-adrenoceptor blockers that reach high levels in the cerebrospinal fluid. On the other hand, alfuzosin may have fewer side effects such as asthenia or dizziness.

Phosphodiesterase Inhibitors

Exploitation of signal-transduction pathways in bladder smooth muscle also has potential benefit for the management of failure to store urine or the overactive bladder. A rise in cAMP due to activation of adenylate cyclase causes smooth muscle relaxation. Forskolin, which activates adenylate cyclase, could be clinically useful to treat increased bladder contractility and detrusor overactivity. Endogenous smooth muscle relaxants are also found in the bladder. For example, bladder smooth muscle synthesizes parathyroid hormone–related peptide (PTHrP), which relaxes bladder smooth muscle through the activation of adenylate cyclase (541). Potentially, PTHrP and its analogs could be useful in treating detrusor instability or poor bladder compliance.

Similarly, phosphodiesterase (PDE) inhibitors could have a role in the treatment of urge incontinence. Most notably, PDE $_1$ inhibitors elicit greater relaxation of the human bladder smooth muscle than PDE_3 or PDE_5 inhibitors in response to activation of adenylate or guanylate cyclase (546). Unfortunately, PDE inhibitors are much less potent at relaxing the human bladder than even oxybutynin. Therefore therapeutic efficacy greater than current anticholinergics is unlikely unless other mechanisms of actions are operative. The use of combination therapy using PDE inhibitors and anticholinergics merits investigation.

Prostaglandin Inhibitors

Prostaglandins could have an important role in modulating contractility of lower urinary tract tissues either through a direct action of smooth muscle or by an influence on afferent or efferent neurotransmitter release. Thus there exist multiple mechanisms whereby inhibitors of prostaglandin synthesis might decrease bladder contractility.

Cardozo and colleagues (84) reported such effects in a double-blind placebo study of 30 women with detrusor instability, in whom they used the prostaglandin-synthesis inhibitor flurbiprofen at a dosage of 50 mg three times daily. Abnormal bladder activity was not abolished in significantly more drug-treated than placebo-treated patients, and bladder capacity did not change. It was concluded that the drug failed to abolish detrusor hyperreflexia, but it delayed the intravesical pressure rise to a greater level of distention. Forty-three percent of the patients experienced side effects from the drug, primarily nausea, vomiting, headache, indigestion, gastric distress, constipation, and rash. Cardozo and Stanton (83) reported symptomatic improvement in patients with detrusor instability who were given indomethacin, another prostaglandin-synthesis inhibitor, at dosages of 50 to 200 mg per day. This was a short-term study with no cystometric data, and the drug was compared only with bromocriptine. The incidence of side effects was high, although no patient had to abandon treatment because of them.

Tricyclic Antidepressants (Table 26B.15)

Imipramine	25 mg q.h.s. to 50 mg t.i.d.
	10 mg q.d. elderly
Doxepin	25–50 mg q.h.s.
Amitriptyline	50 mg q.h.s. to 75 mg t.i.d.
Comipramine	25 g q.h.s. to t.i.d.

TABLE 26B.15. TRICYCLICS FOR TREATMENT OF FAILURE TO STORE

Tricyclic antidepressants, particularly imipramine hydrochloride, are useful for facilitating urinary storage (86,385,444). All of these agents possess varying degrees of at least three major pharmacologic actions. First, they have central and peripheral anticholinergic actions at some, but not all, sites. Second, they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters serotonin and noradrenaline. Third, drugs such as imipramine bind to glutamate receptors in the CNS (NMDA) and could influence excitatory neurotransmission in micturition reflex pathways. Serotonin is released from terminals in the spinal cord, and some serotonin agonists inhibit bladder activity. Therefore blocking serotonin uptake would potentially inhibit micturition (533). This would be especially true during rapid eye movement (REM) sleep, during which serotonergic transmission, and thus inhibition of autonomic

outflow, are low. Paradoxically, tricyclics also block both adrenergic and serotonin receptors.

Tricyclics are useful in treating chronic pain. This action has been attributed to the ability of these agents to modulate nonadrenergic and serotonergic influences on afferent input to the spinal cord. The efficacy of tricyclics in bladder hyperactivity in patients in whom anticholinergic drugs have failed argues for a noncholinergic mechanism of action on micturition.

Imipramine has prominent systemic anticholinergic effects. However, it appears to have only a weak antimuscarinic effect on bladder smooth muscle (325,421). A direct inhibitory effect on bladder smooth muscle is neither anticholinergic nor adrenergic (43,421). Effects include a local anesthetic–like action at the nerve terminals in the adjacent effector membrane, an effect that occurs in cardiac muscle (51), or an inhibition of the participation of calcium in the excitation–contraction coupling process (421). Clinically, the drug decreases bladder contractility and increases outlet resistance (86,344). In trying to correlate the mechanism of action with the clinical effect, one might postulate that the increase in outlet resistance is caused by a peripheral blockade of noradrenaline reuptake, which would tend to produce or enhance an a-adrenergic tone in the smooth muscle of the bladder base and proximal urethra. Such combined pharmacologic actions would make tricyclics useful in treating hypersensitivity disorders, urge incontinence, and mixed stress-urge incontinence. However, dose-limiting side effects, especially in the elderly, are often prohibitive, although the drug can be effective. All patients should be warned of drowsiness, confusion, palpitations, and feeding disturbances.

Castleden and associates (86) began therapy in elderly patients who had detrusor instability with a single 25-mg nighttime dose of imipramine, which was increased every third day by 25 mg until the patient was continent or had side effects, or a dose of 150 mg was reached. Of 10 patients, 6 became continent, and in those who underwent repeated cystometry, bladder capacity increased by a mean of 105 mL, and bladder pressure at capacity decreased by a mean of 18 cm H_2O. Maximum urethral pressure increased by a mean of 30 cm H_2O. Although our subjective impression was that such effects became evident only after many days of treatment, some patients in this series became continent after only 3 to 5 days of treatment. This implies that the mechanism for treatment of depression differs from that for the overactive bladder.

Afferent-based Drug Therapy

A variety of disease states are associated with upregulation and activation of unmyelinated C-fiber afferent reflex pathways supplying the lower urinary tract (122). These conditions include spinal cord injury, bladder inflammation, and urethral obstruction. Thus mechanisms associated with the development of C-fiber reflexes could be fruitful targets for drugs to treat the overactive bladder or pain. In this regard, the vanilloid agonists capsaicin and resiniferatoxin have shown promise. Because capsaicin activates afferents, causing dumping of vasoactive calcitonin gene-related peptide (CGRP) and nociceptive peptides (substance P, neurokinins), its use has been abandoned in favor of resiniferatoxin. This agent is several orders of magnitude more potent than capsaicin. In early trials, resiniferatoxin improved or eradicated the overactive bladder and urge incontinence in up to 50% of patients (99).

In neuropathic or inflammatory pain models, expression of tetrodotoxin-resistant sodium channels (TTX-R) occurs in C-fibers (418). Expression of TTX-R receptors is associated with continuous or spontaneous burst firing of C-fiber afferents. It is tempting to postulate that upregulation of TTX-R receptors may contribute to the overactive bladder. By inference, TTX-R antagonists may be useful in the treatment of bladder overactivity or urge incontinence. The experimental drug 403W02 ameliorates neuropathic pain in experimental models (569). It would be of interest to investigate whether this agent also inhibits bladder activity.

Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) is a naturally occurring organic compound that has been used as an industrial solvent. Among its properties is its ability to penetrate the intact skin, transporting chemicals along with it for absorption into the bloodstream. It has multiple pharmacologic actions (membrane penetrant, antiinflammatory, local analgesic, bacteriostatic, diuretic, cholinesterase inhibitor, collagen solvent, vasodilatory) and is used for the treatment of arthritis and other musculoskeletal disorders (110). The only formulation approved for use on the human bladder is a 50% solution; a 70% solution is generally used topically for musculoskeletal disorders.

Stewart and Shirley (545) reported symptomatic improvement in 75% of patients with interstitial cystitis after a course of treatment with this agent and an improvement in bladder capacity in 80% of these patients. Generally, one 50-mL intravesical instillation is performed every other week for a total of six treatments. The solution is allowed to remain in the bladder for 15 minutes, after which it is expelled by spontaneous voiding. Fowler (186) reported results with DMSO in 20 patients with early interstitial cystitis; 3 complete and 16 partial symptomatic remissions were achieved. However, functional bladder capacity measured at the termination of therapy in 18 cases was observed to increase by more than 25% in only 4 patients. In 10 patients with severe detrusor hyperreflexia, Andersen and colleagues (14) were not able to demonstrate any subjective or objective effects of the drug. The unpleasant garliclike odor after systemic DMSO is its primary side effect and makes double-blind placebo studies impossible. Cataracts have been reported in experimental animals; thus ophthalmologic evaluation is recommended with long-term therapy. As a last resort, this drug has been used by some clinicians in the frustrating patient with the urgency-frequency syndrome but without objective evidence of true interstitial cystitis or detrusor hyperreflexia. Although anecdotal improvement is sometimes reported, few if any formalreports of the results of such therapy exist. Currently, DMSO is approved for the treatment of interstitial cystitis.

Behavioral Therapy, Biofeedback, Pelvic Floor Exercises, and Pelvic Floor Muscle Training

This group of nonpharmacologic modalities to treat disorders of urine storage and overactive bladder has long been used in nursing and urogynecology and is now gaining popularity in urologic practices (81,84,166). Bladder training programs generally consist of three components: education, scheduled voiding, and positive reinforcement. Biofeedback uses electronic or mechanical instruments to provide information to patients about the status of the pelvic floor. Studies on the application of behavioral and biofeedback methods report a 54% to 95% improvement in incontinence across diverse populations with varying degrees and causes of failure to store urine. Cardozo and associates (84) reported that 27 of 32 female patients completed the study. According to subjective data, 11 were cured, 11 improved, and 5 were considered failures of therapy. Objectively, the corresponding numbers were 12, 4, and 11. In this series, treatment was most effective in patients with mild to moderate detrusor instability and was not helpful in severe cases, defined as a large detrusor contraction simultaneous with the first sensation of the desire to void.

Frewen (189) used “bladder drill retraining” in patients with cystometrically documented idiopathic detrusor instability and urge incontinence. Each patient was given a detailed explanation of the presumed causation of the symptoms along with a written description. A micturition chart, on which patients recorded the times of and intervals between urination, the volume produced, and the degree of incontinence, served as the biofeedback data. In this study, 75% of the patients were hospitalized for an average stay of 10 days. Supportive therapy with sedatives and anticholinergics was used in all patients. The objective cure rate was 82.5%. In a later study, 30 consecutive patients with urgency, frequency, or both, 10 of whom had urge incontinence, were treated on an outpatient basis. Provocative cystometry was performed in 22 of these patients, only 8 of whom showed detrusor instability. At the conclusion of 12 weeks of treatment, 24 of the 30 patients were subjectively free of urinary symptoms. However, of the 8 patients with bladder instability, only 3 showed objective disappearance of detrusor hyperreflexia. The lack of validated outcome instruments, nontherapeutic controls, and long-term data is a serious shortcoming of behavioral trials.

Elder and Stephenson (154) reported the results of a Frewen-type regimen in the treatment of 21 of 27 patients who completed their study. All patients initially had symptoms of increased frequency, urgency, and urge incontinence. Cystometric studies showed that 7 had detrusor instability, 11 had “reduced compliance,” and 3 had normal filling curves. In addition to the bladder training program, 18 of 21 patients were admitted to the hospital for their initial therapy, which in all cases included an anticholinergic (emperonium bromide) and a tricyclic antidepressant (a combination of nortriptyline and fluphenazine). Of the 3 patients with normal cystometric filling curves, 2 were symptomatically cured and 1 was improved. In 5 of the 11 patients with reduced compliance, there was a reversion of the cystometrogram to normal; all 5 of these women were symptomatically cured. In 6 patients, the filling curve was unchanged; symptomatically, 2 of these were cured, 3 were improved, and 1 was unchanged. None of the 7 patients with detrusor instability showed any change in the bladder filling curves. However, symptomatically, 3 were cured, and 2 were improved. In a group of older women (older than age 55) with either urodynamically proven urethral sphincter incompetence (n = 88) or detrusor instability (n = 35), bladder training reduced incontinent episodes by 57% with patients having detrusor instability (166). Not surprisingly, nocturnal enuresis was not improved.

Recently, the American Urological Association in communication with the American Urogynecologic Society convened a consensus committee to review the world literature on this topic and peripheral nerve stimulation. The consensus was that biofeedback, behavioral therapies, and exercises were useful to treat bladder dysfunction. There is much confusion regarding the term *biofeedback.* Nevertheless, these regimens appear to be useful for both stress and urge urinary incontinence using weekly sessions and no more than ten per year. Hospitalization is no longer done. Biofeedback-assisted pelvic floor muscle training therapy is especially useful in homebound older adults. A recent study by McDowell and colleagues (362) demonstrated a 75% reduction in urinary accidents in 85 of 105 subjects enrolled. A meta-analysis of biofeedback and pelvic muscle exercises revealed a trend toward improvement (594). Although it is difficult to isolate the various factors in each of these studies, the value of some type of behavioral training and biofeedback as noninvasive therapy for disorders of urine storage is evident. Wyman and co-workers

(621) conclude that the specific regimen may not be as important as the structured intervention with education, counseling, and frequent patient contact. This therapy, alone or in combination with pharmacologic therapy, seems justified.

Bladder Overdistention

Cystodistention involves prolonged stretching of the bladder wall with a hydrostatic pressure equal to systolic blood pressure. Smith (520) summarized the experience at his center and detailed the technique used. The procedure is a modification of the original cystodistention procedure described by Helmstein. The bladder is distended to systolic blood pressure for four successive periods of 30 minutes. After each distention, the bladder is emptied and its capacity measured. An indwelling catheter is left overnight. For repeat distentions, longer periods are used. Few, if anyone,still perform such vigorous distention with its inherent risks of bladder ischemia. Distention is usually performed under continuous regional (epidural) anesthesia. Wolk and Bishop (619) also report success with hydrodistention for irritative symptoms. Improvement, when it occurs, is generally attributable to ischemic changes in the nerve endings or terminals in the bladder wall (508). Thus the procedure can be grouped under the general heading of those procedures designed to produce bladder denervation. Interestingly, recent experiments evidenced implications of ischemia in the pathogenesis of detrusor instability with obstruction and aging. Potential complications include bladder rupture (5% to 10%), hematuria, and retention. We have been unimpressed with the results of this procedure in patients with storage failure secondary to neuropathic detrusor hyperactivity. Pengelly and associates (435) studied patients with urinary symptoms associated with detrusor hyperreflexia and came to similar conclusions. A retrospective review based on patient recall of therapies for interstitial cystitis performed by the Interstitial Cystitis Database group sponsored by the National Institutes of Health revealed that hydrodistention of the bladder was the only therapy reported to consistently work, but only for weeks (454). No long-term success was achieved.

Electrical Stimulation

Peripheral Stimulation. Electrical stimulation of somatic (skin, striated muscles), visceral (cervix, vagina), and mixed (spinal roots) nerves can inhibit the micturition reflex and forms the basis of therapy for detrusor hyperreflexia (165,499). The neurophysiologic mechanisms for this inhibition are poorly defined, but retrograde axonal tracing and electrophysiologic studies on animals demonstrate a convergence of somatic and visceral afferents on a common population of spinal interneurons. These interneurons may release transmitters, such as NO, endogenous opiates, or VIP, which inhibit micturition (120). In addition, activation of inhibitory sympathetic pathways to the bladder has been demonstrated with some electrostimulation methods (332).

Intermittent or continuous electrical stimulation can be performed using implantable or nonimplantable devices. Implantable devices involve placement of electrodes on the bladder, urethra, pelvic striated musculature, and spinal nerves or roots. Nonimplantable devices include rectal, vaginal, and transcutaneous stimulators.

Bladder inhibition with implantable devices is optimized when stimulation intensities evoked contractions of the striated urethral sphincter or pelvic floor musculature, resulting in a reflex afferent discharge back to the spinal cord (581). However, this stimulation can be associated with a variety of unwanted side effects. Patients with an intact spinal cord may have pain when spinal nerves rather than anterior roots are stimulated (554). Autonomic dysreflexia can be seen during spinal nerve stimulation in patients with high spinal cord injuries. Koldewijn and associates (289) reported on 17 patients in whom compliance was increased 1 year after S-2 to S-5 posterior root sectioning and electrostimulation. Similarly, Gasparini and colleagues (196) reported good results in 24 patients with up to 4 years of follow-up.

Results with spinal nerve or root stimulation for detrusor hyperreflexia in highly selected patients are encouraging, with up to 90% cure or improvement (289,499). The stimulation parameters, however, may have to be altered over time to maintain maximal results.

A variety of nonimplantable anal or vaginal stimulators differing in design and stimulation parameters are available. Eriksen and Mjolernod (160) reported a 71% cure rate for stress, urge, or mixed incontinence with anal electrostimulation. Bent and colleagues (44), while noting that patients reported a 70% improvement with transvaginal stimulators, were unable to document any objective improvement in leak episodes or pad weighing. A technique known as acute maximal functional electrical stimulation requires stimulation of the vagina, perineum, or anus on a monthly outpatient basis to achieve long-term bladder inhibition (448). Early data on acute maximal functional electrical stimulation indicates a 20% to 80% cure or improvement rate in selected patients. However, the inability to predict those patients that will respond to therapy, combined with poor patient compliance, has prevented the widespread use of nonimplantable stimulators. There is no shortage of short-term, uncontrolled, invalidated studies supporting dramatic successes with peripheral electrostimulation. Yet few clinicians embrace this approach, and most question outcomes.

In an effort to improve comfort or compliance, transcutaneous posterior tibial nerve stimulators have been used clinically to inhibit bladder activity and improve urinary continence (374). Several new techniques based on the acupuncture site for the bladder and posterior tibial nerve stimulation have shown promise. In a report of preliminary subcutaneous nerve stimulation (SANS; urosurge), 75% of patients with bladder overactivity and documented detrusor instability reported improvement (334). Despite these abundant reports of success in the literature, a consensus panel from the American Urological Association charged with reviewing behavioral regimens concluded that peripheral nerve stimulation could not be recommended as routine therapy based on the equivocal data. In some patients, electrostimulation may help them identify or improve pelvic floor contractions.

Sacral Root Stimulation. Beginning with the pioneering work by Tanagho and Schmidt, the use of implantable sacral nerve stimulation for bladder overactivity has gained acceptance (559). The precise physiologic basis of this therapy is unclear, but it most likely works through stimulation of somatic and visceral afferents (directly and by reflex stimulation of pelvic floor muscles), which in turn inhibit pain and micturition pathways in the spinal cord. This isanalogous to the gate theory of pain. Although it is recognized that the Medtronic Interstim can result in cure or improvement in symptoms of urgency, frequency, and urge incontinence, the use of sacral nerve root stimulation must be viewed realistically (Fig. 26B.26). If one reviews the literature with over a dozen clinical trials, the following observations can be made. First, a home trial of percutaneous stimulation of the sacral roots is needed to select patients who are refractory to conventional drug therapies who might respond to neuromodulation. Second, the definition of success varies, but more than a 90% improvement in symptoms and dry rates can be achieved. Third, the cost is high, both financial and in terms of manpower. Fourth, a significant reoperation rate and learning curve is reported. Of all subjects with overactive bladders or incontinence having failed pharmacologic therapy, roughly 50% respond during the trial period. Of these, only 50% achieve a greater than 90% improvement, at a cost of $20,000 and with up to a 35% reoperation rate. The cost-benefit ratio of this modality must be carefully weighed, but if appropriately selected, this device can achieve a significant improvement or cure in a very difficult patient. Chai and colleagues (90) also report success in controlling urinary frequency and pain in women with interstitial cystitis. Reports of long-term durability with a low dropout rate are now appearing. However, as with most implantable biomechanical devices, eventual reoperation is likely.

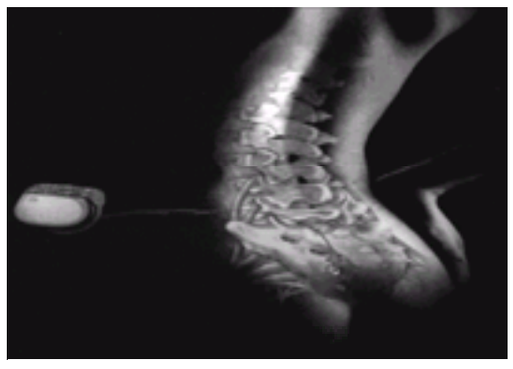

FIGURE 26B.26. Interstim sacral nerve root stimulation for overactive bladder.

Denervation Techniques

Denervation techniques have been used to disrupt the sensory or motor pathways to the bladder in the hope of eliminating the micturition reflex and, thereby, the uninhibited bladder contractions associated with urge incontinence. This assumes that all urge incontinence and overactive bladder is due to an unstable bladder. Moreover, it assumes instability due to reflex contractions generated by nerves.

Denervation can be accomplished by selective blockade with local anesthetics, alcohol, or phenol; or by surgical transection, which has been performed at different sites in the nervous pathways to the bladder (Fig. 26B.27). Denervation at the level of the bladder by prolonged hydrodistention, bladder transection, or myotomy has had initial encouraging results, with a 65% to 75% cure rate (188,619). However, long-term failures are common.

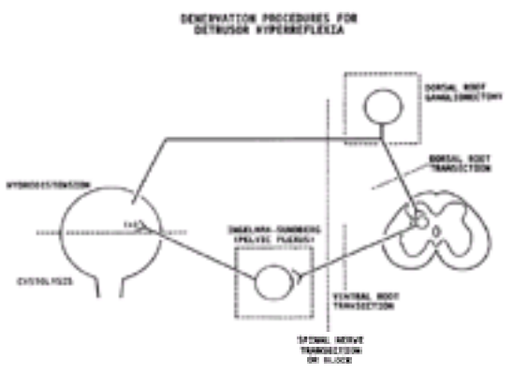

FIGURE 26B.27. Methods of bladder denervation. (From Steers WD. Mechanisms and management of detrusor hyperreflexia with spastic disorder. *State of Art Reviews in Neurosurgery* 1989;4:333, with permission.)

Sectioning the pelvic nerve or subtrigonal plexus is possible (Ingleman-Sundberg procedure) but technically difficult in men due to the relative inaccessibility of these nerves. Furthermore, bowel and sexual dysfunction are often produced by pelvic neurectomies. Subtrigonal injections of alcohol or phenol have been used (239), but a 30% fistula rate has been reported. A simple subtrigonal neurolysis has also been used to treat refractory detrusor instability in women. Anecdotally, many clinicians cannot document efficacy for this technique.

The sacral nerves or roots are relatively accessible and are the most easily identified site for transection. The sacral nerves can be electrically stimulated with bipolar electrodes while monitoring bladder and rectal pressures, as well as striated urethral EMG activity (499,554). Therefore it is useful to intraoperatively identify motor pathways to the lower urinary tract before nerve sectioning to identify the major bladder pathways. Therapy for detrusor hyperreflexia has been especially successful with superselective sectioning of the spinal roots—especially the S-3 anterior spinal root—while lessening the chances of unwanted side effects (339,567). Early cure or improvement rates have been reported in 30% to 100% of patients, and satisfactory long-term results have been achieved in up to 50% of patients. Differences in cure rates and duration of response have been attributed to variations in surgical techniques.

Another surgical procedure used to abolish detrusor hyperreflexia has been dorsal root ganglionectomy (372). In a study comparing dorsal root ganglionectomy with selective spinal nerve sectioning, only ganglionectomy consistently produced low-pressure bladder and urinary continence. Care must be taken before embracing denervation techniques. Nearly all experimental studies reveal devastating effects of depriving muscle of its innervation. Thepropensity of the nervous system to adapt and provide alternative routes of neural input bears remembering.

Augmentation Cystoplasty

Enterocystoplasty has been reported to be beneficial for the treatment of storage failure secondary to bladder dysfunction. The procedure was initially used for bladder contracture secondary to tuberculosis. Some patients with neurogenic bladder dysfunction who had failed more conservative management benefited from this therapy (330).

Although controversy exists regarding the optimal method of bladder reconstruction and amount of bladder to be removed, successful results have been reported by a number of clinicians, as long as the technique used avoids making a diverticulum and achieves detubularization of the augmenting bowel patch (399). Goldwasser and Webster (216) reviewed the subject and categorized success rates by cause of dysfunction. Initial positive results have been obtained in 80% to 90% of patients with tuberculous cystitis, interstitial cystitis, and neurogenic bladder dysfunction. The success rate in a small number of patients with radiation injury to the bladder has been in the neighborhood of 50%. Long-term results with interstitial cystitis, however, have been disappointing.

Luanghot and associates (338) reported on 21 incontinent adults with refractory detrusor hyperreflexia secondary to neurologic disorders. Using tubularized ileocecal patch, 95% of patients were dry and not on anticholinergics at a mean follow-up of 3 years. For small, poorly compliant neurogenic bladder, augmentation seems reasonable. For idiopathic instability, less encouraging results are commonplace. More recently, autoaugmentation has been achieved by merely stripping off muscle fibers and leaving mucosa to create, in effect, a wide-mouthed diverticulum (550) (Fig. 26B.28). Many of these patients experience emptying failure afterward, although in most of these, preoperative prediction of this phenomenon is possible by careful urodynamic evaluation. Sphincter weakening procedures may then be used, or intermittent catheterization may be used to obviate this problem. Storage failure secondary to bladder dysfunction and a significant sphincter component may be safely managed with augmentation cystoplasty in combination with the use of an artificial urinary sphincter or periurethral bulking agent. Intermittent catheterization can even be performed safely under these circumstances per urethra or via Mitrofanoff mechanism using appendix or ureter. An algorithm for managing patients with poor bladder compliance, with or without detrusor-sphincter dyssynergia, culminating in augmentation cystoplasty is shown in Fig. 26B.29. Contraindications for augmentation cystoplasty include renal insufficiency, bowel disease, and inability to perform intermittent catheterization. Patients should bewarned of the rare but possible problem of increased rate of malignancy. Spontaneous rupture can also occur, especially in children. In this regard, it is important to realize that radiographic evidence of rupture using a fluoroscopic or computed tomography cystogram may be lacking. Finally, if any reservoir or augmentation is performed, the patient or caregiver must irrigate at least three times per week to lessen the chances of stone formation.

Increasing Outlet Resistance

Physiotherapy

By periodically performing various pelvic floor exercises for several months, it is possible for females, at least, to increase pelvic striated muscle tone and to control minor degrees of prolapse and sphincteric incontinence (81). Kegel's exercises are designed to improve the functioning of the pubococcygeal muscles. These exercises involve voluntary tensing of the perineal muscles approximately 20 times in the morning, afternoon, and evening to strengthen the perineal muscular, fascial, and elastic tissues. Patients are instructed to contract their perineal muscles as though interrupting the flow of urine and to squeeze the vaginal muscles while drawing up the perineum and rectum as though interrupting a bowel movement. Every effort should be made to motivate the patient to learn the exercise routine correctly and to practice it conscientiously on a daily basis. In uncomplicated urinary stress incontinence, consistent exercise is said to bring symptomatic improvement within 6 weeks, although several months are required to bring all supportive and sphincteric structures to optimal capacity. Only minor degrees of sphincteric incontinence can be significantly improved in this fashion.

Electrical Stimulation

Intravaginal and anal electrical stimulation have been used to treat storage failure by increasing outlet resistance and decreasing bladder contractility (160). The mechanism involves indirect stimulation of the striated pelvic floor musculature through branches of the pudendal nerve (165). In cats, additional urethral closure is provided by a pudendal to hypogastric reflex that stimulates the smooth muscle of the bladder neck and proximal urethra by means of an a-adrenergic effect. In properly selected cases, initial cure or improvement rates range as high as 50% to 80%, figures that many have not been able to reproduce. One must remember to select the proper unit, because parameters for this type of stimulation differ from those used to inhibit bladder contractility. Overall, electrostimulation appears to be more effective for urge than stress incontinence except in those patients unable to contract their pelvic floor voluntarily.

Pharmacologic Therapy

a-Adrenergic Agonists (Table 26B.16)

Ephedrine	25-50 mg q.i.d.
Pseudoephedrine	30-60 mg q.i.d.
Phenylpropanolamine	50 mg t.i.d.
Phenylpropanolamine SR	5 mg b.i.d.

TABLE 26B.16. a-AGONISTS FOR FAILURE TO STORE

The bladder neck and proximal urethra contain a preponderance of a-adrenergic receptor sites that, when stimulated, produce smooth muscle contraction. Such stimulation alters the urethral pressure profile by increasing maximum urethral pressure (MUP) and maximum urethral closure pressure (MUCP) (149). Various orally administered pharmacologic agents are available to produce a-adrenergic stimulation with relatively mild side effects. Potential side effects of all the agents that produce a peripheral a-adrenergic sympathetic effect include blood pressure elevation, anxiety, and insomnia caused by central nervous system stimulation. They may also cause headache, tremor, weakness, dizziness, respiratory difficulties, palpitations, and cardiac arrhythmias. All of these agents should be used with caution in patients with hypertension, cardiovascular disease, or hyperthyroidism (606).

Ephedrine is a noncatecholamine sympathomimetic agent that owes part of its peripheral action to the release of norepinephrine but that also directly stimulates both a- and b-adrenergic receptors (607). The oral adult dosage is 25 to 50 mg four times daily. Some tachyphylaxis develops in response to its peripheral actions, probably as a result of depletion of norepinephrine stores. Pseudoephedrine is a stereoisomer of ephedrine that is used for similar indications with similar precautions (600). The adult dosage is 30 to 60 mg four times daily, and the 30-mg dosage form is available in the United States without a prescription. Norephedrine chloride in a dosage of 75 to 100 mg was shown to increase short-term MUP and MUCP in women with urinary stress incontinence (149). At a 300-mL bladder volume, MUP rose from 82 to 100 cm H_2O, and MUCP rose from 63 to 95 cm H_2O. The functional profile length did not change significantly. A 14-day double-blind crossover study comparing the effects of norephedrine to placebo showed that reduction of urinary leakage with the drug as compared with placebo occurred in 12 of 22 patients. Diokno and Taub (136) reported a good to excellent response in 27 of 38 patients with sphincteric incontinence treated with ephedrine sulfate. They noted that beneficial effects were most often achieved in those with minimum to moderate wetting and that little benefit was achieved in patients with severe stress incontinence. Obrink and Bunne (415) noted that 100 mg of norephedrine chloride twice daily did not improve severe stress incontinence sufficiently to offer an alternative to surgical treatment. They further noted that in their group of ten such patients, MUCP was not influenced at rest or with stress at low or moderate bladder volumes.

Phenylpropanolamine hydrochloride shares the pharmacologic properties of ephedrine and is approximately equal in peripheral potency, while causing less central stimulation (608). With dosages of 50 mg three times daily, Awad and colleagues (25) found that after 4 weeks of therapy, 11 of 13 females and 6 of 7 males with stress incontinence (severity not noted) were significantly improved. MUCP was increased from a mean of 47 to 72 cm H_2O in the empty bladder and from 43 to 58 cm H_2O with a full bladder. Fifty milligrams of phenylpropanolamine was combined with 8 mg of chlorpheniramine (an antihistamine) and 2.5 mg of isopropamide (an antimuscarinic) as a sustained-release capsule (Ornade) used primarily for relief of symptoms of allergic rhinitis. Stewart and colleagues (544) prescribed one capsule twice daily and found that of 77 women with urinary stress incontinence, 18 were completely cured, 28 were much better, 6 were slightly better, and 25 were no better. In 11 men with postprostatectomy stress incontinence, the numbers in the corresponding categories were 1, 2, 1, and 7. Subsequently, Montague and Stewart (390) performed urethral profilometry in 12 women with moderate to marked stress incontinence and six women with no history of incontinence. MUP increased more than 20% in 11 of the incontinent women and in only 1 of the continent group. Rees and Ransley (463) reported on the use of Ornade in 83 children with daytime wetting from a variety of causes. Of 24 children with bladder neck incompetence, 41% were cured, 29% had minimum symptoms, and 12% were improved. Interestingly, of 31 patients with bladder instability, the corresponding improved percentages were 24%, 24%, and 20%. The latter beneficial effect may have been caused by the anticholinergic agent in the preparation. Treatment had to be discontinued in 8 children because of side effects; 23 other children had mild and transient sideeffects.

Major surgery was avoided by drug treatment in four children. The formulation of Ornade has now been changed so that each capsule contains only 75 mg of phenylpropanolamine and 12 mg of chlorpheniramine. It is also available as a liquid.

In a rare placebo-controlled study of sustained-release phenylpropanolamine (5 mg twice daily) on 24 women with stress incontinence evaluated subjectively and with a voiding log and urodynamics, maximum urethral closure pressure increased by 12% over placebo, and episodes of incontinence decreased by nearly 50% (108). Scrutiny of all controlled data on the use of a-adrenergic agonists for all types of stress urinary incontinence reveals an overall cure rate of 0% to 14% and a 19% to 60% rate of improvement. No studies have stratified patients on the basis of hypermobility (type II) or intrinsic sphincter deficiency (type III), although mild, moderate, or severe categories are mentioned.

Phenylpropanolamine is no longer a drug that can be obtained only by prescription in the United States. It is readily available as a component of many appetite suppressants, and patients can be instructed to obtain an inexpensive brand that contains 50 to 75 mg of phenylpropanolamine with no caffeine and a minimum of extra ingredients.

Recent concern by the U.S. Food and Drug Administration has arisen over health concerns with a $_{1}$-adrenergic agonists. More specifically, cardiac arrhythmias and associated deaths from nonprescription drugs demand advising the patient of risks and side effects.

In an effort to reduce side effects and increase efficacy, selective a $_{1A}$-adrenoceptor agonists are being investigated. A-204176 contracts urethral tissues *in vitro* and raises urethral pressure in humans *in vivo* (75). Unfortunately, it also raises blood pressure, which is the first proof that a $_{1A}$-adrenergic receptors are expressed by the human vasculature and have a physiologic effect.

b-Adrenergic Antagonists

Theoretically, b-adrenergic blocking agents might be expected to “unmask” or potentiate an a-adrenergic effect, thereby increasing outlet resistance. In one of the only studies of b-blockers for voiding dysfunction, Gleason and colleagues (212) reported success in treating certain patients who had stress urinary incontinence with propranolol, a b-adrenergic blocking agent, using oral dosages of 10 mg four times daily. The beneficial effect, however, became manifest only after 4 to 10 weeks of treatment, a difficult fact to explain on an acute pharmacologic basis. Although such treatment has been suggested as an alternative method of drug therapy in patients with hypertension and sphincteric incontinence, few if any subsequent reports of such efficacy have appeared, and others have reported no significant changes in UPPs in normal women after b-adrenergic blockade (140). Although 10 mg four times a day is a relatively small dosage of propranolol, it should be recalled that the major potential side effects of the drug are related to its therapeutic b-blocking effects. Heart failure may develop, as well as an increase in airway resistance, and asthma is a contraindication to its use.

Estrogen

Estrogens may act through several mechanisms to improve stress incontinence. Salmon and colleagues (493a) first reported the use of estrogen in the treatment of stress urinary incontinence in 1941. Raz and colleagues (457) found that a daily dose of 2.5 mg of conjugated estrogens (Premarin) improved stress incontinence and increased urethral pressures in postmenopausal patients, effects that they attributed to mucosal proliferation, with a consequently improved “mucosal seal effect.” A beneficial effect was also attributed to enhancement of the a-adrenergic contractile response of urethral smooth musculature to endogenous catecholamines. Schreiter and colleagues (500) reported similar benefits after 10 days of treatment with daily divided doses of 6 mg of estriol. They showed also that the effects of estrogen and exogenous a-adrenergic stimulation were additive. Hodgson and associates (249) reported that the sensitivity of the rabbit urethra to a-adrenergic stimulation was estrogen dependent, because castration caused a decreased sensitivity, and treatment with low levels of estrogen reversed the defect. Ekstrom and co-workers (151) substantiated both acute and chronic effects of estrogens on a-adrenergic receptors in the bladder outlet.

Despite experimental enthusiasm, urodynamic evidence for estrogen effects on bladder and urethral function is not convincing. Rud (482) studied the effects of 4-mg daily doses of estradiol and 8-mg daily doses of estriol on 30 women with an average age of 61 years, 24 of whom had stress urinary incontinence. Small but statistically significant changes occurred in MUP (59 to 63 cm H_2O), functional urethral length (25 to 28 mm), and actual urethral length (33 to 37 mm). No statistically significant change occurred in urethral closure pressure (37 to 39 cm H_2O). Eight of the 24 incontinence patients experienced subjective and objective improvement, nine experienced subjective improvement only, and seven experienced neither subjective nor objective improvement. There was no correlation between subjective or objective improvement and the previously mentioned urodynamic measurements. However, in 18 patients, pressure transmission to the urethra was recorded during cough, and in 7 of these patients this condition improved. All of these patients had subjective improvement, and 5 were shown to be objectively dry. Rud (482) pointed out that it is hard to believe that the small changes in urodynamic measurements, even though statistically significant, were directly related to resumption of continence. He noted also that the increased pressure transmission ratio might have been caused by factors outside the urethra—either in the striated musculature of the pelvic floor or in the periurethral vasculature or supporting tissues. Interestingly,he found no changes in urodynamic measurements in five continent and three stress-incontinent females who had cystic glandular hyperplasia treated with a single injection of 1,000 mg of intramuscular progesterone, except that the pressure transmission ratio was lower in the three patients in whom this was measured.

Levin and colleagues (322) have shown that parenteral administration of estrogen can change the a-adrenergic receptor content and the autonomic innervation of the lower urinary tract of immature female rabbits. Whether these experiments have any clinical significance is unknown. Estrogen therapy seems capable of facilitating urinary storage in some women by increasing outlet resistance, and there is evidence of an augmentative or perhaps additive effect with a-adrenergic therapy in this regard. Whether the levels achieved by commonly used oral or parenteral estrogen preparations or by estrogen vaginal creams actually increase the a-adrenergic receptor content of the smooth muscle of the bladder outlet or the “mucosal seal effect” is unproven. Bhatia and co-workers (48) showed that 6 weeks of conjugated vaginal estrogen cured or significantly improved 54% of women with stress incontinence. Women who failed to respond did not demonstrate an increased functional length or maximum closure pressure. In a 3-month prospective study of postmenopausal women with stress incontinence who received piperazine estrogen for 3 weeks and were assessed with a voiding diary, no statistically significant improvement was noted over placebo (617). Results of combined a-agonist and estrogen therapy may be somewhat better, with cures up to 23% and reduction in episodes 38% at most (247,589). Some clinicians have the impression that intravaginal conjugated estrogen for 2 to 3 months is more effective than oral agents. Cardozo and associates (85) performed a meta-analysis on 77 studies of estrogen for symptoms related to atrophic vaginitis and concluded that estrogens are efficacious in this group of women. A reduction in irritative voiding and recurrent urinary tract infections has been most notable. An estrogen-impregnated ring (Estring) has also been evaluated. A reduction in symptoms of urge and stress incontinence occurred in 48% and 50% of women, respectively, compared with 11% of controls (161). The potential long-term effects of such treatment must be carefully considered, however, in light of the current controversy over whether estrogen therapy predisposes the patient to the development of endometrial carcinoma. Furthermore, all women placed on estrogens should be advised of the need for an annual mammogram.

Vesicourethral Suspension

Fixation of the vesicourethral junction in a physiologic position was initially reported to correct genuine stress urinary incontinence in females in 85% to 90% of cases (Table 26B.17). A review of the world literature reveals that significant overlap exists in improvement and cure rates for stress incontinence. Most data show that the Marshall-Marchetti-Krantz procedure provides the most durable results. However, it also has significant morbidity. Innumerable modifications of the Marshall-Marchetti-Krantz procedure, and other procedures designed to fix the vesicourethral junction in a physiologic position, have been described. In general, there is not one dominant procedure for correcting genuine stress urinary incontinence. Whether genuine stress urinary incontinence is due to hypermobility or arises from intrinsic sphincter deficiency will influence the success of surgery.

	Subjective Response		Objective Response	
Procedure	No. of Patients	% Success	No. of Patients	% Success
MMK	6,837	93	443	89
Burch	1,726	90	2,300	84
Needle suspension	1,888	78	446	70
Pubovaginal sling	1,712	82	720	85
Periurethral injections	319	56	133	63

TABLE 26B.17. SURGERY FOR STRESS INCONTINENCE

Choice of a specific procedure is based on experience; type of stress incontinence; presence of pressure of pelvic floor deformities such as cystocele, enterocele, or rectocele; previous procedures; concomitant surgery; patient preference; and medical condition. All effective operations restore the physiologic position of the bladder neck–proximal urethral area. More important, they anchor the vagina and urethra, preventing hypermobility and allowing transmission of intraabdominal pressure to the urethral and bladder neck.

The Marshall-Marchetti-Krantz (MMK) operation (Fig. 26B.30) approximates the periurethral and vaginal fascia to the posterior surface of the cartilaginous portion of the pubic symphysis. If we envision the suspension of the vagina and urethra as a bridge, a cable of fascia (pubocervical) extends from the pubis or either side to the ischial tuberosity. The pubocervical fascia is strung from this fascial cable and fixed to the vagina, cervix, and urethra. Anycondition that lengthens or attenuates (aging, vaginal childbirth), weakens (collagen disorder), or destroys (trauma) these tissues can produce hypermobility and stress incontinence.

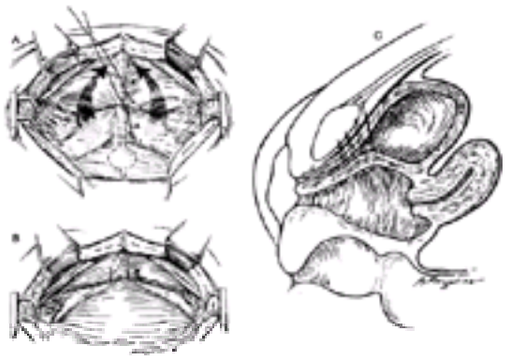

FIGURE 26B.30. Marshall-Marchetti-Krantz procedure. This procedure corrects stress urinary incontinence by approximating the periurethral and vaginal fascia to the underside of the pubis symphysis with three or four pairs of sutures. **A:** The placement of the sutures in the periurethral and vaginal fascia and at the level of the vesicourethral junction. The *large, stippled upward curved arrows* point out the sites of suture attachment on the underside of the pubic symphysis. The orientation of this view is retropubic, as the surgeon would see it. Accurate placement of the sutures is important to achieve satisfactory suspension, and to ensure good fixation it is helpful to take a double bite through the periurethral fascia and anterior vaginal wall, taking care not to put the suture through the vaginal mucosa. Insertion of the sutures is facilitated by elevation of the anterior vaginal wall. It is usually helpful for the surgeon to use the left hand to do this while placing the sutures with the right hand. **B:** Retropubic view after the sutures have been tied individually, commencing with the more distal pair. While the surgeon is tying the sutures, it is useful to have the assistant elevate the vaginal wall. The most proximal suture may need to be passed through the insertion of the rectus abdominus muscle. **C:** Lateral view showing correction of the anatomic abnormality contributing to stress urinary incontinence by the Marshall-Marchetti-Krantz procedure. Here the most proximal sutures are shown passing through the insertion of the rectus abdominus muscle. (From Webster GD. The urethra. In: Paulson DF, ed. *Genitourinary surgery*. New York: Churchill Livingstone, 1984, with permission.)

Although the original procedure was done through a horizontal suprapubic incision, a vertical incision may yield better exposure in patients who represent failures of previous pelvic surgical procedures. The original procedure (354) involved mobilization of the urethra to within 1 cm of the meatus, and it used three no. 1 doubled chromic sutures inserted equidistantly from each other on either side of the urethra, the sutures catching the deep vaginal wall and the lateral wall of the urethra. A similar suture was placed lateral to the vesicourethral junction, and additional sutures were placed in the vaginal wall to bolster the repair. Sutures were also placed between the musculature of the lower and lateral bladder and the posterior rectus sheath to further close the space of Retzius. Most surgeons who perform this operation use absorbable sutures. Some surgeons prefer to open the bladder to facilitate suture placement; some use nonabsorbable sutures; and others, who consider urethral lengthening to be the primary therapeutic goal, place sutures only between the bladder and rectus fascia (304). In an attempt to prevent sutures from detaching from the pubis, some surgeons anchor sutures using drills to secure fixation. The downside of the MMK procedure is the development of osteitis pubis, occasional urinary retention due to obstruction, and the need for open pelvic surgery.

Retropubic colposuspension (vaginal suspension), first described by Burch in 1961, fixes the vesicourethral junction without retaining sutures in the pubis (Fig. 26B.31). The suture placement generally commences distally at the level of the vesicourethral junction, although some surgeons prefer a midurethral level. Fixation is to Cooper's ligament.One concern, however, is that aggressive elevation of perivesical tissues can kink the ureters, causing bilateral ureteral obstruction. Some believe that this operation gives broader support to the urethra and bladder base and avoids the risk of urethral compression and obstruction. Potential enteroceles in Douglas's pouch must be obliterated by successive purse-string sutures in this area (527). A modification of the Burch technique with placement of sutures through the vaginal wall has been reported, with a success rate of 92% as a first procedure, and 89% cure rate for recurrent stress incontinence (281). Numerous studies have now appeared confirming durability of response for the Burch procedure, with dry rates between 65% and 75% after 5 to 10 years (10,113,312). The overall complication rate is as high as 41% (113). Infections, obstruction of the bladder outlet and ureters, and need for open surgery are potential complications of the Burch colposuspension. This procedure may not correct urinary incontinence due tointrinsic sphincter deficiency. Failures of the Burch procedure are noted to possess intrinsic sphincter deficiency. A pubovaginal sling procedure can “rescue” these patients. However, a prospective study examining the response of patients with documented ISD has yet to be performed to settle this controversy.

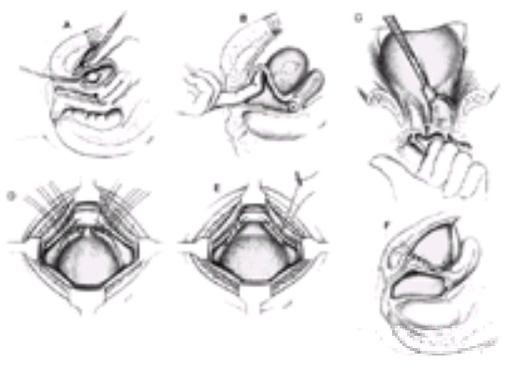

FIGURE 26B.31. Burch colposuspension. **A:** Sagittal section showing blunt finger dissection in the retropubic space of Retzius, between symphysis pubis and anterior surface of bladder and urethra. **B:** Sagittal section showing upward pressure in the lateral vaginal fornix to aid the surgeon in the abdominal section. **C:** Retropubic view from area of pubis but with the pubis removed. With the operator's finger still in the vagina and elevating the lateral vaginal fornix, the bladder base is dissected medially off the paravaginal fascia. **D:** Retropubic view, as seen by surgeon, showing three pairs of sutures in place but not tied. Some surgeons use heavy absorbably sutures, whereas others use nonabsorbable sutures. The sutures are inserted into the paravaginal fascia and then to the nearest point on the ipsilateral iliopectineal ligament. The most distal (caudal) sutures are inserted opposite the bladder neck and not lower. The next two sutures are inserted more proximally (cephalad) alongside the bladder base. The lateral vaginal fornix should be elevated toward the iliopectineal ligament as the corresponding suture is being placed through the ligament so as to position the suture accurately. **E:** The tying of the sutures, showing approximation of the paravaginal tissue to the iliopectineal ligaments. **F:** Sagittal section showing elevation of the bladder neck and bladder base on a shelf of paravaginal fascia, sutured to the iliopectineal ligament. (From Stanton SL. Colposuspension. In: Stanton SL, Tanagho EA, eds. *Surgery of female incontinence.* Berlin: Springer-Verlag, 1986, with permission.)

The needle suspension procedure was first introduced by Pereyra in 1959. Numerous modifications of this procedure have evolved, and currently there are several in use that involve endoscopic control to make sure that the suspending sutures are not passed through the lumen of the bladder or urethra. The Stamey procedure uses the intact tissues lateral to the vesicourethral junction as the primary source of support for suspension of the bladder neck. As initially described, the surgeon was to watch the bladder neck close with tightening of the suprapubic sutures. This is now recognized as too tight. The Raz needle suspension perforates the retropubic space between the pubic bone and the endopelvic fascia, freeing the endopelvic fascia from its lateral pubic attachments. The suspension sutures are placed through the edge of the lateral vaginal wall, incorporating the endopelvic fascia in this area (233). Several modifications of the Raz technique have been made over the years. In a long-term follow-up of over 200 patients, Raz and co-workers (460) reported a durable cure or only rare incontinence in 90% of these individuals. Others report failure at 7 years as high as 40% (109). A modification of the Raz technique to correct small to moderate (grade I to II) cystoceles includes the four-corner (461) suspension.

The Gittes technique (210) relies on a helical suture through the vaginal mucosa and submucosa. A Stamey or Raz needle is passed from two small suprapubic incisions. The technique has been successful in 97% of women with grade I (leakage only with severe abdominal straining) stress incontinence, but only 42% effective with grade III (total, possibly intrinsic sphincter deficiency) (299). The Gittes procedure can be accomplished on an outpatient basis under local anesthesia (210). Thus this technique can be performed on patients categorized as high operative risk.

Each of these modified Pereyra procedures had a large number of ardent supporters. Although the results in the treatment of stress incontinence, when performed by experienced operators, seemed to approach the best results achieved by modifications of the Marshall-Marchetti-Krantz or the Burch procedures, long-term data reveal an alarmingly high failure rate. Needle procedures have largely been abandoned because of long-term data revealing poor durability of this surgery. Only 30% to 40% of women remain dry with needle suspensions after 48 months (312).

Interest in laparoscopic surgery has led to evaluation of this technique to suspend the urethrovesical junction using a Burch technique, in an effort to decrease patient discomfort and allow earlier return to full activity. Initial reports suggested that a laparoscopic Burch technique is feasible, with results approaching the open abdominal procedure (300,561). Operative times vary with experience of the laparoscopist, and success depends on type of suture material or staples, experience, and whether previous abdominal or suprapubic surgery has been attempted. Long-term results in prospective trials are needed to assess the durability of this procedure for treating urethral hypermobility. However, long-term durability remains of concern. McDougall and colleagues (361a) compared the laparoscopic Burch procedure with a transvaginal suspension in 100 patients. Only 15 of 50 patients (30%) remained completely continent after laparoscopic Burch colposuspension.

Bladder Outlet Reconstruction

Reconstruction of the bladder neck is one method of restoring sphincteric continence in patients with a fixed, open bladder outlet. Other alternatives involve mechanical compression of the bladder outlet and include sling procedures, submucosa urethral tunneling, periurethral bulking agents, and the use of an artificial sphincter. Bladder neck reconstruction for the treatment of urinary incontinence was introduced by Young in 1907 and subsequently modified by Dees (119) and Leadbetter (313). Procedures using the Young-Dees principle involve reconstruction of a neourethra from the posterior surface of the bladder wall and trigone. In the male, the prostatic urethra affords additional substance for closure and for increase in outlet resistance. The Leadbetter modification involves proximal reimplantation of the ureters to allow more extensive tubulization of the trigone. Long-term success rates of between 60% and 70% have been achieved (314). Tanagho (557) and Tanagho and co-workers (560) described a procedure based on a similar concept, but using the anterior bladder neck to create a functioning neourethra sphincter. A success rate of 70% was reported. Despite these encouraging reports, others have had difficulty reproducing these dramatic successes.

Surgical Mechanical Compression

Submucosal Tunnel

In cases of sphincter incompetence, Nill and associates (405) described a technique of creating a bladder tube and reimplanting it submucosally to achieve continence (Fig. 26B.32). Of 38 patients (mean age of 10 years, range of 6 months to 46 years) with neurogenic intrinsic sphincter deficiency, all were dry. Difficulties with catheterization or stricture represent the major morbidities.

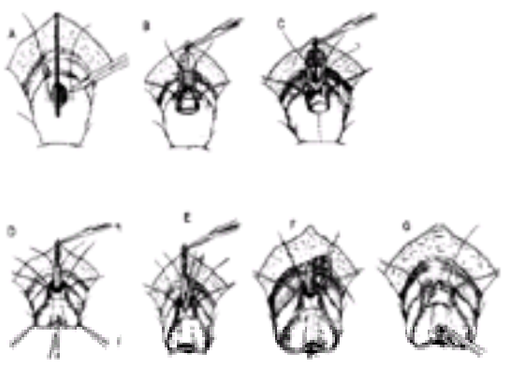

FIGURE 26B.32. Kropp technique for submucosal tunnel. **A:** Bladder strip harvested. **B:** Ureteral orifices identified. **C:** Tubularization begun at bladder neck. **D:** Bladder is bivalved to help create submucosal tunnel. **E:** Tunnels are connected. **F:** Red rubber catheter used to pull urethral tube through tunnel. **G:** Bladder neck and wall closure are then performed. (From Kropp K. Suburethral tunnel for correction of urinary incontinence. *R Surg Tech Urol* 1991;4:1, with permission.)

Gracilis Myoplasty

A novel approach to urethral compression has been the experimental surgery involving intact gracilis muscle transposition with electrostimulation using intramuscular electrodes(97). Early results appear to be promising, but long-term follow-up is needed.

Periurethral Injections

The injection of Polytef paste periurethrally to increase urethral resistance has been developed and promoted primarily by Politano and protégés (449,585). Most clinicians inject the Polytef paste transurethrally, and an ingrowth of fibroblasts is stimulated, which produces a bolstering effect but does not stricture the urethra. Good results were reported by Politano's group in up to 70% of patients. Deane and associates (115) described four cures and two improvements in 6 females with genuine stress incontinence and five cures and size improvements in 22 females with bladder neck incompetence at rest. They were able to achieve only one improvement in 8 males with postprostatectomy incontinence. Malizia and colleagues (347) expressed concern regarding the potential of distal embolization of the Polytef particles, which they observed in laboratory animals and humans. Migration of Polytef to skin in a woman treated for incontinence has also been reported. Reference is also made to blood-vessel, pulmonary, and lymph nodes after vocal cord injections of Polytef.

To improve efficacy through reduced viscosity, and to reduce potential morbidity of Teflon migration or malignancy, other agents have been used to increase bladder leak-point pressure and treat intrinsic sphincter deficiency. These agents include glutaraldehyde cross-linked (GAX) collagen, fat, and silicone. Fat, readily accessible and without cost, is initially successful in 82% of patients (494). However, a high failure rate in the long term, due to autolysis, is thought to occur.

Periurethral GAX collagen has been reported to cure 88% of women and children with stress incontinence due to intrinsic sphincter deficiency (279,549,591) (Fig. 26B.33). Results are much more disappointing in men after radical prostatectomy, with cure rates as low as 20% (245). At 2 years, up to 20% of patients may require a repeat injection. Long-term data indicate durable cure rates in 12% to 20% of men and 40% to 50% of women. Resorption or extrusion of the material is problematic.

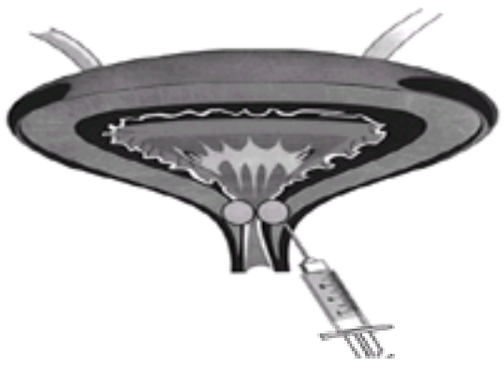

FIGURE 26B.33. Periurethral bulking agent.

To improve durability yet avoid the mechanical properties of a thick paste, three new materials have appeared. Autologous chondrocytes and myoblasts have been injected periurethrally and are undergoing clinical trials. A carbon slurry (Durasphere) has been approved for use as an injectable agent for incontinence. Published clinical trials with adequate follow-up are lacking.

Pubovaginal Sling

Since 1907, a considerable number of procedures utilizing a suburethral sling technique have been described, using either autologous or alloplastic material. A Dacron, Marlex, collagen-coated woven polyester (ProteGen) or fascial (autologous versus cadaveric donor) sling is placed underneath the proximal urethra under no tension and secured to or over the rectus fascia. Alternatively, the use of bone anchors has been advocated. Slings are effective following failed retropubic suspensions, suggesting a different pathology and mechanism of action for this procedure. Dry or dramaticimprovement in incontinence at before 2 years with fascial slings is more than 90%, and 60% to 80% after 2 to 7 years has been reported (91,111,312). The advantages of fascial slings include avoiding erosion, pain, fistulae, and irritation (286). Cadaveric (allograft) fascial slings avoid the discomfort of autologous harvesting. Tensile strengths of certain cadaveric materials are comparable to autologous fascia (316). A recent report of human DNA on the cadaveric fascia raises the theoretic possibility of disease transmission (e.g., prions) (103). The risk of HIV transmission from properly screened tissue donors is 1 in 667,600, which is lower than with transplantation. There are six suppliers of fascia lata allograft in the United States. Costs range from $60 to $1,200 for varying sizes. However, several studies reveal a reduction in operating time and hospital staff (512).

These procedures have been used for patients with all types of stress incontinence and have been very effective in patients with recurrent stress incontinence, obesity, and pelvic floor weakness, and especially after repeated unsuccessful surgeries. The fascial sling suspension is ideal for women with a combination of urethral hypermobility and intrinsic sphincter deficiency. The technique elevates and fixes the urethra in a normal retropubic position. However, the noncircumferential compression afforded by the sling is optimal treatment for patients with little urethral closing function and those with poor urethral smooth muscle function resulting in intrinsic sphincter deficiency (58,369,553). Although originally described through a retropubic approach, a combined vaginal and abdominal approach (Fig. 26B.34) often facilitates the procedure. The vaginal access to and dissection of the retropubic space for sling placement is similar to that provided by the Raz-type suspension procedure. In general, urge incontinence can be corrected in more than one-fourth of patients following the sling procedure. However, the biggest drawback to pubovaginal slings is the reported *de novo* detrusor instability of 10% to 20%. Pain from the sutures is seen early and occurs in roughly 15% of women. Urinary retention is uncommon, occurring only 5% of the time.

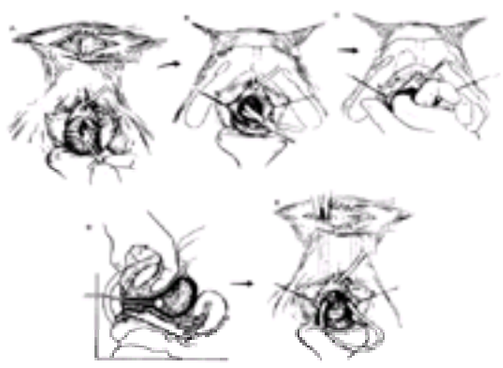

FIGURE 26B.34. Fascial sling procedure. **A:** In this variation, a combined vaginal and abdominal approach is used. **B:** After reflecting the vaginal wall from the urethra, the paraurethral musculofascial tissue is dissected into the retropubic space at the level of the bladder neck. The approach is similar to that used in the Raz suspension procedure. **C:** This space is further digitally dissected, as in the Raz procedure. **D:** Rarely, a retropubic dissection is also necessary, as pictured. **E:** The fascial sling, which may be obtained from rectus or external oblique fascia, or fascia lata, is looped around the urethrovesical junction and fixed to the rectus fascia suprapubically. The tension of the sling must be carefully adjusted to provide the minimum necessary to achieve the desired goal of elevation or compression. (From Webster GD. The urethra. In: Paulson DF, ed. *Genitourinary surgery*. New York: Churchill Livingstone, 1984, with permission.)

The use of bone anchors for suspensions, slings, and laparoscopic surgeries raises several issues. First, efficacy does not appear to be enhanced. Suspension surgeries usually do not fail because the sutures pull out from above. Second, these devices add cost to the procedure without proven increased efficacy. Third, morbidity is increased. Despite arguments that orthopedic appliances are readily tolerated, few metallic devices are placed into bone via the vagina. Pain is an increasingly common complaint following bone anchors, and reports of osteomyelitis are now appearing (159).

In an effort to avoid prosthetic slings or harvesting of fascia, Raz and co-workers (461) have used a buried vaginal wall sling. Most patients have difficulty resuming volitional voiding immediately after surgery. Rarely, permanent self-intermittent catheterization may be required after any compressive sling procedure. More commonly, detrusor instability occurs in up to 25% of women after the procedure or may be exacerbated if it already exists. Adjustment of proper sling tension requires considerable operator experience. Prosthetic materials such as Marlex are to be avoided because of the significant incidence of erosion. An increase in urethral pressure in the area of the urethra adjacent to the sling of 10 cm H_2O has given consistently good postoperative results.

In an effort to further reduce morbidity and discomfort, a tension-free vaginal tape procedure has been developed (Fig. 26B.35). Three-year data from more than 100 women reveal a dry rate of 86% to 90% (420). Anecdotal reports of bladder perforation, hemorrhage, and even one death in Europe will be clarified once long-term prospective studies are performed.

A three year follow up of tension free tape for the surgical treatment of female stress urinary incontinence. *Br J Obstet Gynecol* 1999;106:345, with permission.)

Artificial Urinary Sphincter

Control of sphincteric urinary incontinence with implantable prosthetic devices has improved. The most significant contribution was the introduction in 1973 of a totally implantable artificial sphincter mechanism that could be used in adults and children of both sexes (505). Through biomechanical evolution, improvements have led to the currently used device, which is composed of an inflatablesnap-on cuff, a pressure–balloon reservoir, and a control assembly (Fig. 26B.36). Constructed of silicone rubber, this hydraulic device is filled with normal saline or an iso-osmotic contrast medium. Cuff closing pressure is regulated by the elasticity in the wall of the balloon and is partially dependent on the volume of fluid within the balloon. Fluid flow through the system is mediated by the pump and a series of unidirectional valves within the control assembly. On the side of the control assembly is a small button that allows manual activation and deactivation of the sphincter mechanism. Balloon pressures are manufactured that, under normal clinical situations, provide enough cuff closing pressure to ensure urinary continence, but do not damage the underlying tissue of the urethra or bladder neck.

FIGURE 26B.36. AS 800 artifical sphincter mechanism.

Excessive pressure produces tissue ischemia and ultimately pressure necrosis, with erosion of the cuff into the lumen of the underlying urethra or bladder neck. Thisgenerally is manifested by recurrent incontinence and concurrent infection around the implanted sphincter. Device removal is required for adequate healing; however, another device may be implanted later.

Identification of candidates for artificial sphincter implantation requires a thorough neurourologic workup to properly establish the unique aspects of the patient's incontinence. Specific criteria for implantation have been established (214,352), with most patients having intrinsic sphincter deficiency with normal detrusor contractility and compliance. Usual candidates are men with incontinence related to radical prostatectomy or transurethral resection of the prostate, and neurogenic causes such as myelomeningocele or previous pelvic trauma; and females.

Surgical implantation of the device involves implantation of the cuff around the bulbous urethra of adult males (Fig. 26B.37). Bladder neck cuff placement may be technically challenging in patients with previous bladder neck or pelvic surgery. The pressure–balloon reservoir is placed in a pocket underneath the fascia of the anterior abdominal wall, or in the peritoneal cavity if extensive scarring is present. The pump control assembly is positioned in a convenient location in the subcutaneous tissues of the scrotum or labia.

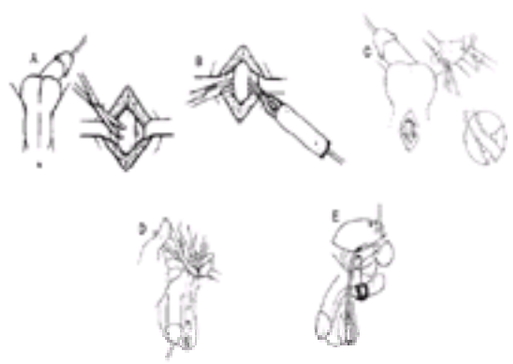

FIGURE 26B.37. A–E: Implantation of the artificial sphincter cuff around the bulbous urethra.

The device remains in a deactivated configuration for 6 to 8 weeks to allow complete healing around the pump and cuff. Device activation is performed manually by merely compressing the pump chamber firmly. The device may be deactivated by pressing the button on the side of the control assembly.

Results of implantation on 221 patients with the AS-800 device who had follow-up for up to 3 years indicated that 95% of the patients were socially dry. The patient must haverealistic expectations of this device. Significant rises in intraabdominal pressure will trigger leakage during vigorous exercise or lifting. The more incontinent the patient, the more satisfactory the outcome. Mechanical reliability based on life-table analysis projects a 97% survivorship at 3 years. Although initial results appear reasonable, long-term results will help establish more accurately the exact role of the artificial sphincter in treating severe incontinence. An algorithm for testing a nonfunctioning artificial sphincter is presented in Fig. 26B.38. Overall, reoperation rate approaches 30%. Placement of a more distal second cuff may be needed if incontinence recurs. In the long term, problems with fibrosis underneath the cuff causing a recurrence in incontinence have necessitated double cuff revisions in some patients. If the patient lives long enough, the device will undoubtedly have to be replaced some years after implantation.Use of the artificial urinary sphincter (AUS) following external beam radiotherapy is associated with a high reoperation rate approaching 55%.

FIGURE 26B.38. Algorithm for the investigation and treatment of problems with the AUS. Evaluation starts with testing the pump. (Courtesy of Dr. Erik Schick.)

Nonsurgical occlusive devices for the male are external and compress the penile urethra by squeezing the penis from two sides. Their main disadvantages include bulk, discomfort (in those with sensation), and potentially, pressure necrosis of the urethra, especially in those patients with impaired sensation.

Urethral compression is feasible only in patients with low-pressure bladders. Although any pressure system can theoretically be occluded, continued obstruction of a high-pressure system can result in disastrous lower and upper urinary tract sequelae.

Antidiuretic Hormone–like Agents

A novel approach to the treatment of urinary frequency occurring within a specific period of time has been the use of synthetic antidiuretic hormone (vasopressin) analogues. Desmopressin acetate (DDAVP) has been used effectively in patients with central diabetes insipidus. For diabetes insipidus, the usual adult dosage is 2 to 4 µmg subcutaneously daily as a single or divided dose. For children, the usual dosage range is from 0.5 to 3.0 µmg daily. Large doses may cause transient headaches, nausea, and a slight increase in blood pressure. Fluid intake should be adjusted during this therapy to avoid hyponatremia and water intoxication.

The drug has been used to decrease the frequency of nocturnal enuresis (Table 26B.18). Hilton and Stanton (246) used a nighttime dose of 20 µmg intranasally in a double-blind placebo study of 25 women with nocturnal urinary frequency. The number of mean episodes per night decreased from 3.17 in the pretreatment group to 1.94 in the group treated with active drug, compared with 2.61 in the placebo-treated group. The nocturnal urinary output, as expected, also decreased significantly in the drug-treated group. One patient already receiving treatment for hypertension with a diuretic became hypertensive, with a diastolic pressure of 110 mm Hg (entrance pressure was 80 mm Hg). The authors emphasize that hypertension, ischemic heart disease, and congestive failure should all be considered contraindications to the use of this type of medication. A double-blind, placebo-controlled study was also performed in a group of 21 males with benign prostatic hypertrophy and significant nocturia (350). Active treatment consisted of 20 mg of drug administered intranasally. This produced a mean decrease in nocturia from 2.60 episodes during the control period to 1.93, statistically significantly better than the response to placebo (2.31) but hardly a significant clinical change.

Author	No. of Patients	Age (yr)	Dose DDVAP (µg)	Success
Tuvemo	18	6–12	20	89
Delaere	23	7–43	20	68
Terho	52	5–13	20	67
Miller	55	6–17	40	65
Ramsden	21	18–older	20	76

TABLE 26B.18. DESMOPRESSIN FOR NOCTURNAL ENURESIS

Rittig and associates (471) and Djurhuus and co-workers (138) demonstrated an abnormal diurnal variation of vasopressin and suggest this mechanism as a cause for enuresis. Although it explains increased nightly output, this hypothesis fails to explain why individuals with enuresis fail to awaken and void. A large number of placebo-controlled clinical trials using desmopressin have been reported (Table 26B.18). Success rates range from 68% to 89% in a usual daily dose of 20 µmg. An oral preparation of DDAVP has been released. Efficacy is only slightly lower due to somewhat reduced bioavailability. These studies are remarkable for the lack of adverse effects reported. The major limitation is the cost of the desmopressin regimen. However, care must be taken in the elderly, who are prone to hyponatremia and confusion. If hyponatremia is to occur, it appears very soon after initiation of therapy. Thus serum sodiums are recommended 24 hours after the first dose, several days later, and then at 2 weeks. If used for nocturia, an attempt should be made to determine the cause before initiation of drug therapy. Medications, sleep apnea, and fluid consumption are common culprits (267). Desmopressin has even been evaluated in men with symptoms of BPH (350).

Vasopressin has also been successful in treating urgency and incontinence in patients with multiple sclerosis (284). Overall results with this type of agent in patients other than those with central diabetes insipidus enuresis and detrusor hyperreflexia seem more statistically than clinically significant. However, this class of treatment may prove to be useful on a long-term basis in the occasional case of nocturia or enuresis that has proved refractory to all other forms of therapy, or in short-term situations in which a decrease in intravesical volume and consequent urinary frequency is desired for a limited period of time.

External Collection Devices

No satisfactory external collecting device has been devised for the female because of the difficulties of fixation and leakproof collection. Absorptive padding, a collection device of sorts, is a last resort for many patients. The ideal substance is one that is highly permeable and absorbent. Immediately next to the patient is generally a layer of hydrophobic material.

External collecting devices for the male (Texas or condom catheter) are generally successful insofar as urine collection is concerned, but are unacceptable to many patients because of the visible equipment required, the incontinence,and the “leaks” of often foul-smelling urine that can result. Some of these leaks can be prevented by using self-ventilating systems that prevent siphoning (124). Compressive collective devices can also cause severe pressure necrosis of the penis and urethrocutaneous fistula, especially in patients with impaired sensation (217). For this reason, a collecting device without a single discrete roller band or application ring would seem to offer at least a theoretic advantage. Newer silicone devices with better seals and internal tissue adhesive are available that are better tolerated.

Assessing Outcomes

One of the greatest difficulties in the management of patients with voiding dysfunction is comparing treatments and assessing outcomes. In this regard, experts have proposed various parameters to measure and report when evaluating treatment modalities based on disorder, sex, and age of the patient (177,336,359,412). Measurements should include symptom scores, diaries, pads, urodynamic tests, and quality-of-life instruments. If experts could validate and combine questionnaires, diary forms, and quality-of-life assessments for neurogenic bladder patients, men and women with voiding complaints, incontinent patients of both sexes, children, and the elderly, better studies of therapeutic efficacy with cross comparisons could be designed.

VOIDING DYSFUNCTION AND NEUROLOGIC DISEASE

The bladder is the only visceral organ that requires central neural input for total function and survival of the individual. Thus it is not surprising that many neurologic lesions generally affect bladder filling, urine storage, and bladder emptying in a relatively consistent fashion, dependent on the area affected (Table 26B.19). Neurologic lesions anywhere along the neuraxis can result in involuntary bladder contractions, with changes in the smooth-sphincter and striated-sphincter areas analogous to those that occur in normal micturition (185). Patients with complete lesions of the spinal cord above spinal cord level S-2, after they recover from spinal shock, generally exhibit involuntary bladder contraction with smooth-sphincter synergia but striated-sphincter dyssynergia. Patients with spinal cord trauma caudal to that level generally do not manifest involuntary bladder contractions per se. Detrusor areflexia is the rule initially, and depending on the extent of neurologic injury, various forms of decreased compliance during filling may occur. Damage to the neurologic outflow from the lower thoracic and upper lumbar levels may result in an open smooth-sphincter area, whereas the area of the striated sphincter generally retains a residual resting sphincter tone but is not under voluntary control. Discrete lesions of the spinal cord often elicit involuntary bladder contractions with variable degrees of striated-sphincter dyssynergia or synergia, depending on the severity of the disease and the intactness of the cortical and pontine-mesencephalic regulatory tracts (Fig. 26B.39). In this section, the most common types of voiding

dysfunction that occur with specific neurologic diseases or trauma are discussed. Throughout this discussion, it becomes apparent that the lower urinary tract can serve as a window to the nervous system.

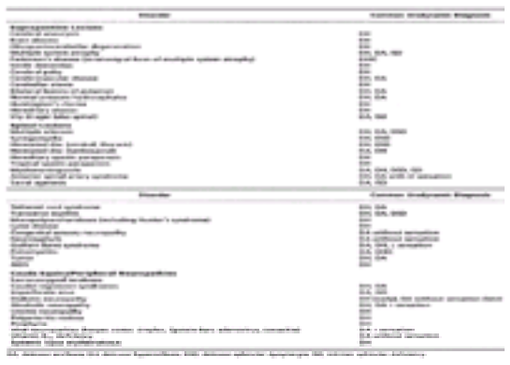

TABLE 26B.19. URODYNAMIC FINDINGS WITH SELECTED NEUROLOGIC DISORDERS

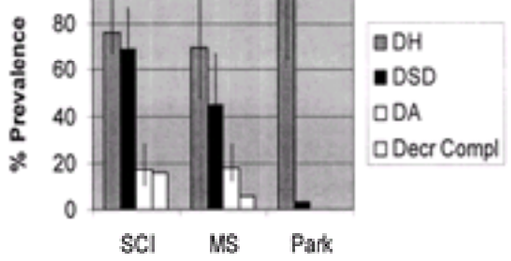

FIGURE 26B.39. Examples of urodynamic abnormalities and prevalence among selected groups of neurogenic bladder patients based on several recent urodynamic reports. DA, detrusor areflexia; DH, detrusor hyperreflexia; DSD, detrusor-sphincter dyssynergia; MS, multiple sclerosis; PARK, Parkinson's disease; SCI, spinal cord injury.

At or Above the Brainstem (Supraspinal)

Cerebrovascular Disease

Transient ischemia associated with cerebrovascular disease has not been associated with any particular type of bladder dysfunction, but after an occlusive or a hemorrhagic episode of a cerebral vessel, focal neurologic deficits often occur, and voiding dysfunction of a particular type may result (571,631). Bladder symptoms are present during the acute phase in 70% of individuals, but are persistent in only 10% of victims. During the first weeks and months, the symptoms of bladder dysfunction may become apparent. The most common long-term expression of lower urinary tract dysfunction after cerebrovascular accident is detrusor hyperreflexia. Sensation is variable but generally intact, and thus the patient has urgency. An ice water test is positive in 63% of patients (258). The appropriate response is to try to inhibit the involuntary bladder contraction by forceful contraction of the striated sphincter. Gelker and associates (198) evaluated 51 patients undergoing rehabilitation after a stroke and found that 37% had urinary incontinence. Urodynamics evaluation revealed that 37% had detrusor hyperreflexia and 21% had areflexia. Incontinence in these stroke victims correlated with large infarcts, aphasia, cognitive impairment, and functional disability, not with age or site of lesion.

Sakakibara and co-workers (490) reported on 72 stroke victims assessed at 3 months. Fifty-three percent had urinary symptoms, most notably nocturia (36%), urge incontinence (29%), and hesitancy (25%). Six percent presented following stroke in urinary retention. Voiding dysfunction correlated with hemiparesis but not hemianopia. Sixty-eight percent of symptomatic victims exhibited detrusor hyperreflexia on urodynamics, and 14% had detrusor-sphincter dyssynergia.

Concussion

Generally, when voiding dysfunction occurs after a closed head injury or spinal cord contusion, there is an initial period of detrusor areflexia followed by recovery of unstable reflex detrusor dysfunction. This is not a common sequela of cerebral concussion, but when it occurs, the same considerations apply as for voiding dysfunction secondary to cerebrovascular disease.

Brain Tumor

Both primary and metastatic brain tumors have been reported to be associated with disturbed bladder function. The most commonly involved area that results in bladder dysfunction is the superior aspect of the frontal lobe (55). Resultant voiding dysfunction consists of detrusor hyperreflexia and urinary incontinence without dyssynergia.

Parkinson's Disease

Parkinson's disease primarily affects the pigmented neurons of the substantia nigra. This results in a relative dopamine deficiency and a predominance of cholinergic activity in the corpus striatum. Dopaminergic projections to the prefrontal cortex synapse may inhibit micturition. The net result of loss of dopaminergic input is tremor in motor systems and detrusor hyperreflexia expressed by the bladder. Classic neurologic symptoms include bradykinesia, tremor, and skeletal rigidity. Voiding dysfunction occurs in 25% to 75% of patients, but as with cerebrovascular disease, there may be preexisting detrusor or outlet abnormalities, and the symptoms may be affected by the various treatments that are instituted (578).

Symptoms generally consist of urgency, frequency, nocturia, and urge incontinence. The most common urodynamic correlate is detrusor hyperreflexia (46,434). Dopamine agonists (L-dopa and apomorphine) improved voiding by reducing detrusor hyperreflexia (21). In primates with experimental parkinsonian condition, dopamine agonists similarly increased volume of the micturition and reduced hyperactive voiding (630). True striated-sphincter dyssynergia with detrusor hyperreflexia does not occur, but it is less clear whether these patients retain voluntary striated-sphincter control (55,523) (Fig. 26B.40). Slow relaxation of the striated sphincter may occur (bradykinesia). Araki and Kuno (20) found that symptoms in 203 Parkinson's patients correlated with disease severity rather than disease duration. Their incidence of symptoms based on questionnaires in a neurology clinic was 27%, substantially lower than previous reports from urology clinics. The IPSS in patients correlated with a Hoehr and Yahr staging of Parkinson's disease severity. Urinary symptoms rose and quality of life fell with a score of 3 or higher. No correlation was observed between symptoms and whether patients were receiving anticholinergics and dopamine receptor agonists.

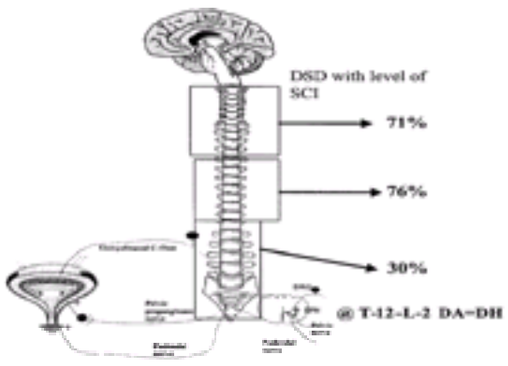

FIGURE 26B.40. The prevalence of detrusor-sphincter dyssynergia *(DSD)* with level of injury in spinal cord injury *(SCI).* DA, detrusor areflexia; DH, detrusor hyperreflexia.

One dilemma in dealing with parkinsonian men is deciding if they have outlet obstruction secondary to prostatic enlargement, and whether prostatectomy is indicated. Men with Parkinson's disease and symptoms, and urodynamic findings identical to those with BPH, do not respond to prostatectomy. Even combined pressure/flow studies are not predictive of outcome after surgery in these patients. Poorly sustained bladder contractions, sometimes with slow sphincter relaxation, may occur as a result of the neurologic disease, and in these individuals prostatectomy may result in no change or even worsening of the voiding symptoms. Thus many experts wonder whether any men with Parkinson's disease should ever undergo surgery for obstruction. Acontractile bladders are unusual in Parkinson's disease and are generally seen only in women, in which case the situation is probably representative of a preexistent problem and unrelated to the Parkinson's disease per se.

Shy-Drager Syndrome

Shy-Drager syndrome is an uncommon degenerative disorder that results in atrophy of areas in the cerebellum, brainstem, peripheral autonomic ganglia, and thoracolumbar preganglionic sympathetic neurons (46,55). Patients generally have parkinsonian symptoms coupled with orthostatic hypotension and anhidrosis. Voiding dysfunction similar to Parkinson's disease consists of detrusor hyperreflexia (67%). Unlike with Parkinson's disease, a bladder neck that is open at rest (100%) and denervation of the striated sphincter (61%) also occur. Areflexia or poorly sustained bladder contractions may develop, however. Combined with diminished smooth- and striated-sphincter tone, management of the voiding dysfunction may be quite difficult.

Spinal Cord Lesions

Suprasacral Spinal Cord Lesions

Only recently have bladder overactivity and pyramidal signs been reported with cervical myelopathy (486,487). Syringomyelia, a benign condition once causing neurologic symptoms, is associated with voiding difficulties, especially retention (489).

Traumatic spinal cord injury results from a high-velocity missile, from fracture or fracture dislocation of the spinal column, or after sudden or severe hyperextension. Spinal cord bony segments are numbered by the vertebral level, and these have a differing relation to spinal cord segmental level at various locations. The sacral spinal cord begins at about the spinal column level of T-12 to L-1. The spinal cord terminates in the cauda equina at the spinal column level of approximately L-2. In addition to trauma, spinal cord damage may be produced by vascular disease, arteriovenous malformations, myelopathy, arachnoiditis, or myelitis.

Over the past 30 years, the survival of patients with spinal cord injuries has dramatically improved. This has resulted from the development of specialized centers for the care of such patients, resulting in a decreased number of potentially significant complications of all types. Urologic care and urologic surveillance have undergone decided improvements. Renal failure has been replaced by pulmonary problems as the most common late causes of death, at least in male patients. Amyloid disease of the kidneys may cause death, and bladder and outlet dysfunction and urinary tract infection with urosepsis are still substantial problems. Controlled and coordinated bladder emptying depends on an intact neural axis. Bladder contractility and the occurrence of reflex bladder contractions depend on an intact conus medullaris (sacral spinal cord segments) and its afferent and efferent connections. Complete lesions above this area but below the area of the sympathetic outflow generally result in detrusor hyperreflexia, absent sensation below the level of the lesion, smooth-sphincter synergia, and striated-sphincter dyssynergia. Lesions above the spinal column level of T-6 (spinal cord level of T-7 or T-8) may result in smooth sphincter dyssynergia as well. After a significant spinal cord injury, “spinal shock” occurs. This refers to a decreased excitability of spinal cord segments below the level of the lesion (235,367). This is synonymous with absent somatic reflex activity and a state of flaccid muscle paralysis below this level. Although classic teaching refers to generalized areflexia, most peripheral somatic reflexes of the sacral cord segments (the anal and bulbocavernosus reflexes) may never disappear or, if they do, return within minutes or hours of the injury. Spinal shock includes a suppression of autonomic activity, and the bladder is acontractile and areflexic. The smooth-sphincter mechanism generally functions, however, and EMG activity can generally be recorded from the striated sphincter (269). Because sphincter tone exists, urinary incontinence does not result, urinary retention is the rule, and intermittent catheterization (or continuous catheterization in some instances) is necessary to circumvent this problem. If the distal spinal cord is intact but simply isolated from higher centers, there will eventually be a return of detrusor contractility. At first, such reflexactivity is poorly sustained and produces only low-pressure changes, but the strength and duration of such involuntary contractions increases, producing involuntary voiding, usually with incomplete bladder emptying. The return of reflex bladder activity in such patients is generally manifested by involuntary voiding between intermittent catheterizations, and occurs along with recovery of lower-extremity deep tendon reflexes. In evolving lesions, every attempt should be made to preserve bladder pressure storage as low as possible, often by the combination of intermittent self-catheterization and anticholinergic therapy (375). Any measures that might impair this, such as indwelling catheter drainage, are to be avoided. Surgery designed to decrease outlet resistance can be useful.

The urodynamic picture that results when a patient has a complete lesion above the sacral spinal cord is detrusor hyperreflexia, smooth-sphincter synergia (with lesions below T-6), and striated-sphincter dyssynergia. Neurologic examination shows spasticity of skeletal muscle distal to the lesion, hyperreflexic deep tendon reflexes, and extensor plantar responses. There is impairment of superficial and deep sensation. Incomplete bladder emptying generally results, usually because of striated-sphincter dyssynergia. The neurologic center responsible for coordinating bladder and striated-sphincter activity is in the pontine-mesencephalic formation (68,69,121,223,490,491). Any lesion between this area and the sacral spinal cord can interfere with this coordination. True dyssynergia, either continuous or intermittent, often develops, but in some instances there is simply a failure of relaxation without an increase in sphincter activity over baseline. In one study, only 6% (*n* = 34) of spinal cord–injured patients did not have dyssynergia.

Occasionally, incomplete bladder emptying may result from poorly sustained detrusor contractions. This seems to occur more commonly in lesions close to the conus medullaris than with more rostral lesions (235). Poorly sustained contractions may also be caused by locally functioning reflex arcs, which result in detrusor inhibition from strong striated pelvic floor muscle contractions, or result from a loss of higher center–mediated detrusor facilitation, which normally occurs after the initial increase in intravesical pressure during a bladder contraction.

Sacral Spinal Cord Lesions

After recovery from spinal shock, there is usually a depression of deep tendon reflexes below the level of the lesion, with varying degrees of flaccid paralysis. Sensation is absent below the level of the lesion. Detrusor areflexia is common initially and accompanied by a competent but nonrelaxing smooth sphincter. The striated sphincter retains some tone, although it is not under voluntary control. Absent or diminished EMG activity is seen. The bulbocavernosus reflex may be retained and is the first reflex to return with recovery from spinal shock (221,232,269,326). Although the classic description of this problem is that of an adequate-capacity bladder with high compliance, in many instances decreased compliance develops. As with other neurologic lesions distal to the sacral spinal cord (200,232), this represents a response to decentralization. At a point at which bladder pressure becomes greater than urethral pressure, leakage results, and if this leak-point (detrusor leak-point pressure) is high enough, upper tract deterioration may occur. It is not uncommon for incomplete lesions to result at this level or for various degrees of reorganization to develop. Thus varying degrees of bladder and sphincter dysfunctions or combinations thereof are seen.

Attempts to correlate completeness of lesion or level with upper tract deterioration are contradictory. Hackler and colleagues (232) found that patients with lower motor lesion were more likely to have poorly compliant bladders. Conversely, Gerridzen and associates (200) found that quadriplegics were more likely to have upper

tract deterioration. Kaplan and associates (269) have warned that neurologic findings do not uniformly correlate with deteriorating renal function. Grainger and co-workers (221) found that women with spinal cord injury rarely had upper tract deterioration without infection. They also found that more of the women developed autonomic dysreflexia. Weld and co-workers (610), using a logistic regression analysis on 316 spinal cord–injured patients, found that incomplete and sacral lesions were associated with poor bladder compliance, which in turn correlated with reflux, pyelonephritis, and calculi. Older age at injury and use of a Foley catheter also correlated with poor compliance. Therefore neurourologic evaluation should help characterize each of these patients, and management modalities must be consistent with the goals and practicalities previously mentioned. Assigning risk of hydronephrosis merely to physical examination, level of lesion, or urodynamics exclusively cannot be done consistently. Thus vigilant follow-up is mandatory.

Multiple Sclerosis

Multiple sclerosis is one of the most common neurologic diseases causing voiding dysfunction (47,56,184,356,398,513). The disease is caused by focal neural demyelination, which impairs nerve conduction. It affects the spinal cord in nearly 75% of patients (Fig. 26B.41). The demyelinating process characteristically involves the posterior and lateral columns of the cervical spinal cord, which is the site of pathways that subserve bladder and outlet function. From 50% to 88% of patients with this disease complain of voiding symptoms at some time (39). Bladder involvement is part of the presenting symptom complex in approximately 10% of patients and may constitute the sole initial complaint, either in the form of acute urinary retention of an unknown cause, or in the acute onset of involuntary bladder contractions with urgency and frequency. Detrusor hyperreflexiais the most common urodynamic abnormality detected and occurs in 50% to 90% of cases (39,47,56,513). Of patients with detrusor hyperreflexia, 30% to 65% also have striated-sphincter dyssynergia. Bladder areflexia may also occur and has been reported in 1% to 40% of cases, but of these, a substantial proportion progress to detrusor hyperreflexia. Smooth-sphincter synergia is the rule.

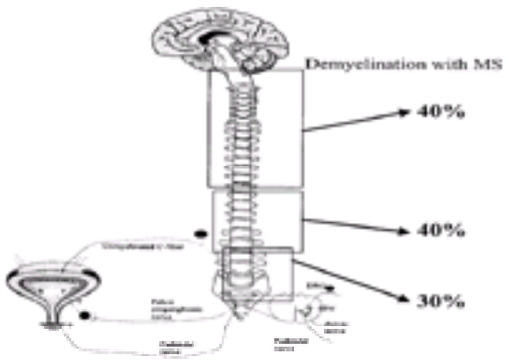

FIGURE 26B.41. Level of spinal involvement with multiple sclerosis *(MS)*.

Blaivas and Barbalias (57) have identified certain risk factors for voiding dysfunction in patients with multiple sclerosis. These include an indwelling catheter, detrusor striated-sphincter dyssynergia in men, and decreased compliance, resulting in sustained intravesical pressures greater than 40 cm H_2O. Betts and co-workers (47) found that severity of voiding complaints correlated with exacerbation of neurologic symptoms. Because sensation is frequently intact, one must be careful to separate pseudodyssynergia from true striated-sphincter dyssynergia. Also, there are some varieties of striated-sphincter dyssynergia that are more worrisome than others (65). For example, sustained DSD results in high bladder pressures of long duration that are most associated with urologic complications. Betts and colleagues (47) found that only men with multiple sclerosis and chronic paraplegic men (longer than 5 years) developed dyssynergia and upper tract changes. Sirls and associates (513) noted that medical management alone is nearly always effective in preventing upper tract deterioration. Fortunately, unlike spinal cord injury, progressive neurologic conditions such as multiple sclerosis rarely cause renal deterioration due to detrusor-sphincter dyssynergia unless an indwelling catheter is used in management. The reason for this disparity is unknown.

Peripheral Nerve Lesions

Diabetes Mellitus

Peripheral and autonomic neuropathies are common in diabetes. Diabetic neuropathy has been attributed to segmental demyelinization and impairment of nerve conduction (269). Neuropathy tends to develop in middle-aged and elderly patients with long-standing or poorly controlled diabetes (478). Surprisingly, few large, well-documented studies of voiding dysfunction in diabetics have been published. The exact incidence of diabetic cytopathy is uncertain, because unselected patients generally do not complain of bladder symptoms. If specifically questioned, 5% to 50% report symptoms of voiding dysfunction. Frimodt-Moller (190,191) coined the term *diabetic cystopathy* to refer to involvement of the lower urinary tract in this disease. The insidious onset of impaired bladder sensation can be the first manifestation of such involvement. Likewise, in early diabetic neuropathy, detrusor hyperreflexia can develop (7). A gradual increase in the time interval between voiding then develops, which may progress to a point at which the patient urinates only once or twice a day without ever sensing any urgency. Ultimately, bladder decompensation may occurdue to impaired detrusor contractility, which necessitates abdominal straining to initiate and maintain the voided stream, the strength and force of which are impaired.

Typical urodynamic findings include impaired bladder sensation, increased cystometric capacity, decreased bladder contractility, impaired uroflow, and residual urine (41). Yet these findings are surprisingly uncommon even in patients undergoing renal or pancreatic transplantation (41,537). Norden and co-workers (408) found that of 27 patients with diabetic nephropathy who were followed for over 30 months, only 7% had residual urine. Furthermore, presumed diabetic autonomic dysfunction failed to correlate with progression of renal insufficiency. Interestingly, diabetic men tend not to undergo as many prostatectomies for BPH, possibly because of impaired sensation, and in turn, lack of irritative voiding symptoms (511). The main differential diagnosis is outlet obstruction, because both conditions can produce a low flow rate. The flow pattern in diabetics reflects abdominal straining. Pressure/flow studies are easily able to differentiate the two conditions. The secondary manifestations of resultant bladder decompensation are seen and may be prevented by early awareness of the problem and the institution of strictly timed voiding.

Guillain-Barré Syndrome

Guillain-Barré syndrome is an immune-mediated peripheral neuropathy. It elicits voiding difficulties—both detrusor hyperreflexia and areflexia—in nearly one-fourth of patients (492). Bladder symptoms appear after the weakness is established.

Tabes Dorsalis (Neurosyphilis)

Luetic involvement of the posterior sacral roots and the dorsal columns of the spinal cord may result in the loss of bladder sensation and resultant voiding dysfunction (162). Although rare in the postpenicillin era, tertiary syphilis is classically associated with detrusor areflexia with decreased or absent bladder sensation. Garber and associates (194) have demonstrated not only detrusor hyperreflexia, but detrusor-sphincter dyssynergia that was attributed to suprasacral involvement with neurosyphilis. Pernicious anemia (vitamin B_{12} deficiency) may also result in a similar type of “sensory neurogenic bladder” (251).

Viral Infections

An assortment of viral disorders can trigger voiding dysfunction, including herpes simplex genitalia (469), herpes zoster (261), herpes varicella (404), Epstein-Barr virus (524), cytomegalovirus (381), human T-lymphotropic virus (HTLV-1) (590), and HIV (275). Bladder symptoms appear days to weeks after the primary viral manifestations of flulike symptoms, arthralgia, fever, and cutaneous lesions. Herpes infections, when associated with cutaneous lesions in the sacral dermatomes, are most commonly found with urinary retention secondary to detrusor areflexia from involvement of sacral dorsal root ganglia. These viruses appear in the urine and can be taken up by nerves in the bladder wall and anterogradely transported to the sacral cord.

Transverse myelitis, even causing quadriplegia, is often associated with complete neurologic recovery; yet urinary symptoms may be the only residual sequelae (488).

Endoscopic examination in a patient with herpes zoster may reveal a similar type of vesicles within the bladder mucosa. This condition is usually self-limited and

resolves spontaneously within a month or two. Tropical spastic paraparesis (HTLV-1) represents a somewhat unique viral cause of neurogenic bladder in which most patients have detrusor-sphincter dyssynergia (590). Dasgupta and colleagues (114) found thickening of nerves in the lamina propria of the bladder in this disease. Nearly 60% of patients with this rare disorder have urinary complaints.

Disc Disease

Most disc protrusions compress the spinal roots in the L-4 to L-5 or L-5 to S-1 disc interspaces. Voiding dysfunction due to a prolapsed or herniated disc correlates with the usual clinical manifestations of low back pain radiating in a girdlelike fashion along the involved spinal root areas (244,363). The most consistent urodynamic finding is detrusor areflexia. However, a herniated disc may initially irritate nerve roots and cause detrusor hyperreflexia. The striated sphincter may be normal or show evidence of denervation. In patients with cervical myelopathy due to disc disease or spondylosis, detrusor-sphincter dyssynergia has been reported (241). Patients with voiding dysfunction from a disc typically have difficulty urinating, straining, or urinary retention. Laminectomy may not improve bladder function, and it may be difficult to separate causation as a result of the disc sequelae from changes secondary to the surgery. In a prospective assessment of bladder function after lumbar decompressive laminectomy for disc or spinal stenosis in an elderly group of 20 patients, Deen and co-workers (118) reported improved bladder function in 60% by 1 year. In experimental work in animals, Delamarter and colleagues (127) found that a 75% constriction of the cauda equina was required before a flaccid neurogenic bladder developed.

Pelvic Surgery

Voiding dysfunction is relatively common after pelvic plexus injury. This often arises after abdominoperineal resection and radical hysterectomy (167,192,514). Neurologic dysfunction after these procedures is reported in 10% to 60% of patients, and voiding dysfunction is permanent in 15% to 20% (363,366). The type of voiding dysfunctionthat occurs is dependent on the specific nerves involved, degree of injury, and the pattern of reinnervation or altered innervation that results over time. Urinary retention, with varying degrees of sensory preservation, is generally the initial manifestation of such voiding dysfunction. The permanent pattern is generally a failure of voluntary bladder contraction, or impaired bladder contractility, with obstruction by residual striated-sphincteric tone, which is not subject to voluntarily induced relaxation. Often, the smooth-sphincter area is open and nonfunctional, attributed to destruction of the terminal sympathetic nerve supply to this area. Alternatively, such an appearance in a patient whose bladder neck has not been operated on may result from increased intravesical pressure and obstruction at the level of the striated sphincter. Decreased compliance is common, and with the obstruction caused by fixed residual striated-sphincter tone is the paradoxic occurrence of both storage and emptying failure. These patients often leak across the distal sphincter area and, in addition, are unable to empty their bladder because, although they have increased intravesical pressure, they have nothing that approximates a true bladder contraction. Thus they represent a combined problem of filling or storage and emptying. They often have urinary incontinence with increases in intraabdominal pressure. This is usually most obvious in females, because the prostatic bulk in males often masks a deficit in urethral closure function. Alternatively, patients may have variable degrees of urinary retention. Urodynamic studies may show decreased compliance, poor proximal urethral closure function, loss of voluntary control of the striated sphincter, and a positive bethanechol supersensitivity test (514). Upper tract risk factors are related to the leak-point, and the therapeutic goal is low-pressure bladder storage with periodic emptying. A prostatectomy should not be performed unless a clear demonstration of outlet obstruction is possible (363). Prostatectomy will often simply decrease urethral sphincteric function and thereby result in occurrence or worsening of stress urinary incontinence.

OTHER NEUROLOGIC CAUSES OF VOIDING DYSFUNCTION

A wide array of central and peripheral neurologic disorders have been associated with failure to store or empty urine. Many supraspinal disorders, including normal pressure hydrocephalus (4) and cerebellar ataxia (311), can cause detrusor hyperreflexia and urge incontinence. Similarly, urodynamic evaluations in other neurodegenerative disorders and para-autonomic failure have revealed detrusor hyperreflexia or, rarely, areflexia (243,493).

Inherited disorders such as familial spastic paraparesis and congenital type II neuropathy cause voiding dysfunction. The disorder is associated with inability to relax the external urethral sphincter and detrusor hyperreflexia (82). The latter is associated with loss of bladder sensation (29). Of interest, the receptor for nerve growth factor is abnormal, resulting in loss of sensory nerves.

Disorders causing vasculitis or inflammation of the bladder or its innervation can also disturb micturition. Lyme disease (95), periarteritis nodosa (10), systemic lupus erythematosus (586), Rocky Mountain spotted fever (252), and porphyria (462) have been linked with either hyperactive voiding (detrusor instability) or urinary retention (detrusor areflexia). In these instances, it is difficult to distinguish bladder symptoms resulting from vasculitis or neural involvement. The paucity of reports of voiding problems, and rather circumstantial evidence for autonomic involvement, suggest that these associations are probably rare.

Myotonic dystrophy does not affect the external sphincter. Yet detrusor hypocontractility is common, suggesting involvement of bladder smooth muscle or autonomic nerves (419,486,487).

Bladder Outlet Obstruction

General Pathophysiology

Bladder outlet obstruction remains one of the most commonly encountered but overdiagnosed disorders in urology. Surgical treatment of benign enlargement of the prostate once constituted the most frequently performed operative procedure within the specialty. With the advent of medication (a-adrenergic blockers, 5a-reductase inhibitors) and less invasive surgical procedures (e.g., laser, hyperthermia, stent), transurethral resection of the prostate is no longer performed as frequently. Bladder outlet obstruction can be divided into fixed anatomic or functional causes. Functional in this case does not mean psychogenic, but simply indicates increased urethral resistance to the forces of bladder emptying by neuromuscular phenomena, which may be involuntary or voluntary. Anatomic causes of bladder outlet obstruction include prostatic enlargement (benign or malignant), bladder neck contracture, urethral stricture, and meatal stricture. Functional causes of bladder outlet obstruction include dyssynergia and loss of relaxation at the level of the smooth sphincter and at the level of the striated sphincter.

Bladder Response to Obstruction

The bladder responds unpredictably to obstruction, producing hyperactivity or impaired contractility. Whether these sequelae take place along a continuum or are independent is unclear. Abrams (3) summarizes data that strongly suggest that outlet obstruction causes detrusor instability. Consistent with this notion, bladder suspension surgery in women that obstructs the outlet (proven on urodynamics) produces detrusor instability. Abrams (3) cites evidence that the incidence of detrusor instability in patients with outletobstruction secondary to prostatism ranges from 53% to 80%, with a mean of 62%. Postoperatively, the incidence ranged from 0% to 55% in these same series, with a mean of 24%. The fact that outlet obstruction in the form of prostatic enlargement is a major cause of bladder instability in males is supported by the high rate of preoperative instability (50% to 75%) in such patients and the high reversal rate of this phenomenon after prostatectomy (70%). Although the proof of cause and effect consists of retrospective correlation of the disappearance of this phenomenon after the relief of outlet obstruction, this nevertheless seems to be a reasonable argument. Disappearance of irritative voiding and instability takes between 1 and 6 months. Reversion to a normal cystometric accommodation limb and disappearance of all irritative symptoms may take as long as 12 months. When the involuntary contractions seem to result from outlet obstruction, the pathophysiology has been attributed to myogenic changes, denervation supersensitivity, or neurogenic causes (323). Abrams (3) has pointed out that no series has demonstrated an association between the incidence of instability and the severity of obstruction. He also noted an increasing incidence of detrusor instability in asymptomatic elderly men. Chalfin and Bradley (92) have presented evidence that there may be a change in sensory input that triggers detrusor reflex activity in the area of obstruction. Moore and colleagues (391) report an increase in presumptive sensory nerves in patients with detrusor instability. However, Chapple and co-workers (100) found evidence of decreased sensory neuropeptides in the bladder in men with detrusor instability, due to obstruction from BPH. In contrast, Harrison and associates (240) and Mattiason and colleagues (358) demonstrated an increase in total sensory neuropeptides in obstructed animals. Steers and colleagues (534,538) found that anatomic changes in sensory nerves correlate with levels of nerve growth factor (NGF) in the bladder. NGF is known to sensitize afferents and reduce their threshold for firing and could theoretically play a role in irritative sensory symptoms. Perhaps the tension receptors in the bladder wall have a reduced threshold for firing when the bladder wall is under stress. Blockade of NGF receptors in animals prevents changes in afferents and bladder hyperactivity. Prostatic enlargement could distort or compress the abundant nerve endings in its capsule. Reversion to normal voiding after prostatectomy could thus be explained by a decompression phenomenon or by decreased NGF and subsequent reversal of neural change. However, local anesthesia of the prostatic urethra in men with detrusor instability fails to abolish irritative symptoms, although bladder capacity increases (629). Furthermore, Tammela and colleagues (555) could not find that the temperature threshold decreased in men with detrusor instability due to BPH. These involuntary contractions may also occur on an irritative or a neurologic basis.

Although detrusor instability can occur in response to outlet obstruction alone, its etiology is probably multifactorial, a response to a combination of aging, neurologic,

architectural, and strictly urodynamic factors related to pressure or volume changes within the bladder. This must be true because age-matched women and elderly men with obstruction often have the same degree of irritative symptoms (88). The phenomenon is much less common in response to urethral stricture disease, although it may be manifested in the presence of smooth- or striated-sphincter dyssynergia. Recently, it has been recognized that patchy denervation occurs in bladder from obstructed men. Animal models reveal that obstruction and aging are associated with ischemia (27,485). Thus ischemic mechanisms may play a role in neural and myogenic processes.

Decreased bladder compliance during filling without discrete involuntary contractions is another interesting phenomenon that can likewise be caused by or coexist with outlet obstruction. The possible relationship of this phenomenon to outlet obstruction has been the subject of much investigation. Benson and colleagues (42) showed that increasing the degree of stretch on muscle strips from the bladder body changed the response to norepinephrine from the usual b (relaxation) response to an a (contractile) one. Rohner and colleagues (475) recorded the same type of change of response to adrenergic stimulation after producing chronic bladder outlet obstruction in dogs. Perlberg and Caine (441) showed that muscle strips from the bladder dome of 23% of patients with prostatic enlargement requiring surgery showed an a-adrenergic response instead of the normal b-adrenergic response. Therefore it is not surprising that a-adrenergic blockers increase urine flow and decrease obstructive symptoms (318,319). It is less clear how irritative symptoms are reduced. Shapiro and co-workers (510) were able to correlate the effect of a-adrenergic blockers with the amount of smooth muscle in the prostate. The clinical significance of all these forms of detrusor hyperactivity that occur in response to outlet obstruction is that they—and not the simple phenomenon of residual urine with a decreased functional bladder capacity—are often responsible for the clinical correlates of frequency, nocturia, urgency, and urge incontinence.

Detrusor hypocontractility, as opposed to hyperactivity, may also occur in response to significant infravesical obstruction. The finding of residual urine is more a sign of detrusor decompensation than of the outlet obstruction that caused it. For this reason, the relief of outlet obstruction more commonly leads to satisfactory urodynamic resolution in patients with a low—as opposed to a large—residual urine volume (201).

Morphologically detectable changes to bladder outlet obstruction include bladder muscle hypertrophy followed by connective tissue replacement with increased collagen deposits within the bladder wall (208). Smooth muscle hypertrophy and hyperplasia develop in response to outlet obstruction, along with collagen deposition. Although theabsolute amount of collagen increases, the collagen concentration decreases (574). What regulates the degree of cellular hypertrophy in response to obstruction is unknown, but Gilpin and associates (208) reported that the largest increases in cell size were observed only in patients with concomitant connective tissue infiltration. Whether the endoscopic appearance of trabeculation is more related to collagen deposition or muscular hypertrophy is a matter of discussion. Regardless, trabeculation does not correlate with symptoms or presence of detrusor instability (12,13). Experimental models of bladder outlet obstruction vary with respect to the species used and the degree or duration of the obstruction. Even so, general response patterns exist.

Outlet Obstruction in the Male

Prostatic obstruction may be caused by hyperplasia, carcinoma, or inflammation. Obstruction is defined by an elevated intravesical pressure and a subnormal flow rate during voiding. Many asymptomatic elderly males satisfy this definition but without the usual symptom complex known as “prostatism” (88). When symptoms are associated with prostatic obstruction, they fall into two general categories: obstructive and irritative. The obstructive symptoms consist of hesitancy, a slow stream, prolonged urination, and a feeling of incomplete emptying. They are clearly distinct from the irritative symptoms, which consist of frequency, nocturia, urgency, and urge incontinence. These findings are statistically related to detrusor hyperactivity. Frequency and nocturia can also occur on the basis of a substantial residual urine volume, with a resultant decrease in functional bladder capacity. Bladder trabeculation develops in response to either detrusor hyperactivity or obstruction without such hyperactivity (12,13).

The optimal neurourologic evaluation for patients with suspected outlet obstruction secondary to prostatic enlargement differs markedly from center to center, and it may vary from a history, physical examination, and endoscopic examination to sophisticated combined pressure/flow studies. Despite this lack of consensus, a national guideline has been developed that outlines the minimum evaluation necessary and absolute indication for treatment and offers an alternative approach for BPH. Flow rates alone are insufficient to screen for obstruction. Significant outlet obstruction can exist in the presence of relatively normal flow rates, and diagnoses can be made in this subgroup of patients only by pressure/flow studies that show grossly elevated intravesical pressures (497) (Fig. 26B.42).

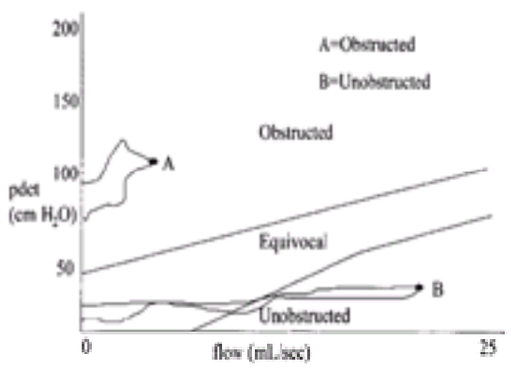

FIGURE 26B.42. Pressure/flow nomogram after Abrams-Griffith. Patient A is clearly obstructed based on peak micturition pressure and flow rate. Patient B is not obstructed.

Other anatomic causes of bladder outlet obstruction in the male include sclerosis or fibrosis of the bladder neck, urethral stricture disease, and urethral valves. Neurologic causes of sphincter dyssynergia have already been discussed. Functional causes of outlet obstruction in the male include smooth-sphincter dyssynergia (sometimes called *bladder neck dyssynergia* or *dyskinesia*) and striated-sphincter dyssynergia. Each of these can be secondary to neurologic or nonneurologic causes. The former syndrome characteristically occurs in males between ages 30 and 55 years who complain of long-standing obstructive and irritative symptoms. Many of these patients have seen several urologists and have been diagnosed as having psychogenic voiding dysfunction because of a normal prostate on rectal examination, a negligible residual urine volume, and a normal endoscopic bladder appearance. In this group of patients, objective evidence of outlet obstruction is easily obtainable by pressure/flow studies (Fig. 26B.43). Secondary bladder changes may occur, manifested by detrusor hyperactivity or decompensation with residual urine volumes. Once obstruction is diagnosed, it is localized at the level of the bladder neck in these individuals by micturitional urethral profilometry, formal videourodynamic study, or cystourethrography during a bladder contraction that shows obstruction at the level of the bladder neck, prostatic enlargement having already been excluded endoscopically. The diagnosis may also be made indirectly in such a patient bythe finding of outlet obstruction in the absence of a distal urethral stricture, prostatic enlargement, or evidence of striated-sphincter dyssynergia. The cause of this problem is unknown. Its occurrence in young, anxious, high-strung individuals and its partial relief by a-adrenergic blocking agents have prompted some to speculate that it may in some way be related to sympathetic hyperactivity (295). This theory is unproven. Exacerbation of these symptoms occurs during a relatively short and early period of prostatic enlargement, and marked relief in these cases is generally effected by a small prostatic resection. Interestingly, the spontaneously hypertensive rat exhibits urinary frequency and unstable bladder contractions, suggesting either a genetic component or a heightened sympathetic nervous system (107).

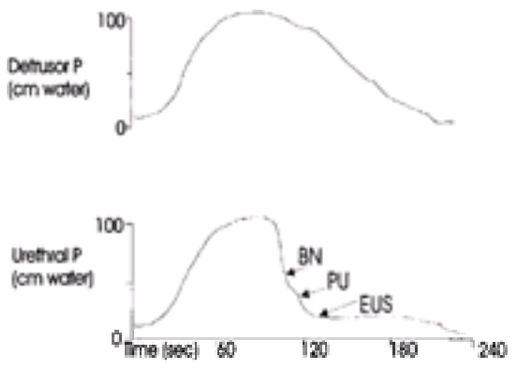

FIGURE 26B.43. A 25-year-old white male diagnosed with obstruction on a combined pressure/flow study has a 70 cm H_2O pressure drop across the bladder neck during a static urethral pressure profile, indicating site of functional obstruction.

Functional obstruction at the level of the striated sphincter in males and females occurs most commonly in association with neurologic disease; such dysfunction has been discussed previously. It is easy to produce obstruction voluntarily in this area and to stop voiding on command. This is one form of pseudodyssynergia (601), which must be distinguished from true involuntary functional obstruction at this level. Many believe that true detrusor striated-sphincter dyssynergia, implying involuntary contraction of the striated sphincter during the emptying phase of micturition, occurs only in patients with neurologic disease. The existence of this entity in individuals without neurologic disease seems to be reported most commonly in children, but it is reported in some adults as well, in whom the entity has been postulated to cause problems ranging from obstructive or irritative symptoms of an obscure cause to recurrent urinary tract infection. It is difficult to prove urodynamically. Unequivocal demonstration of this entity, in our opinion, requires pressure/flow EMG evidence of bladder emptying occurring simultaneously with involuntary striated-sphincter contraction in the absence of any element of an abdominal straining component, either in an attempt to augment bladder contraction, or as a response to discomfort during urination. Such reports do exist (266) and seem to confirm the existence of the syndrome. The cause is uncertain; it may represent a persistent transitional phase in the development of micturitional control, or persistence of a reaction response to the stimulus of urethral pain during voiding long after the problem has disappeared (266).

Outlet Obstruction in the Female

The most common cause of outlet obstruction in women is probably bladder neck suspension surgery. The frequency of infravesical obstruction in nonoperated females is rare when compared with incidence in males. Farrar (168) cites a figure of 10% of females referred to urodynamic centers as having outlet obstruction. He reports that the most common site of urodynamically proven outlet obstruction in these women is in the distal urethra and that this condition usually results from a failure of this area to fully attain its potential caliber during voiding. Groutz and associates (227) evaluated 587 consecutive women and found that 6.5% were obstructed using pressure/flow studies. Half of these women had antiincontinence surgery. Stricture occurred in 13%, primary bladder neck obstruction occurred in 85%, 5% had a learned disorder, and 5% exhibited detrusor-sphincter dyssynergia. Other causes of outlet obstruction include benign and malignant urethral masses, severe bladder prolapse, and rarely, uterine pathology such as large fibroids (Fig. 26B.44).

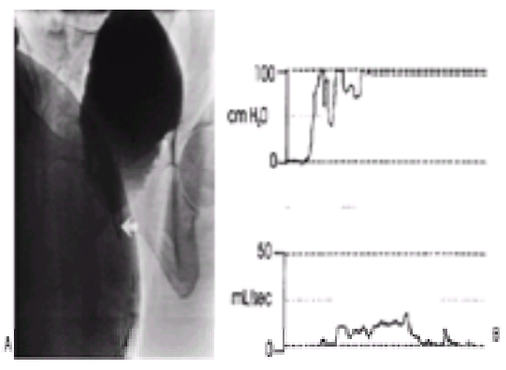

FIGURE 26B.44. A: Bimanual examination and fluoroscopy of a 40-year-old woman detects a large uterine fibroid displacing and compressing the bladder outlet *(arrow)* on anteroposterior view. **B:** A urinary retention pressure/flow study documents elevated voiding pressure (greater than 100 cm H_2O) with low to normal flow.

Bladder neck obstruction in females remains rare except after surgeries for stress incontinence. Diokno and colleagues (134) have clearly defined this entity in a small number of patients without a history of surgery, on the basis of urodynamic video pressure/flow criteria. They point out that the diagnosis of obstruction in this situation must be based on the demonstration of a relation between pressure and flow, and it should not be made on the basis of a single isolated parameter or any study that does not include simultaneous measurements of such parameters (Fig. 26B.45). Furthermore, following suspension surgery, urodynamics can often be equivocal. Awad and colleagues (26) and Nitti and Raz (407) have clearly shown that suspension procedures can cause obstruction with low flow rates, detrusor instability, or retention. Once the diagnosis of obstruction has been made (only equivocally one-third of the time), the site of obstruction can be localized further, either by simultaneous periurethral EMG recording and fluoroscopic monitoring during flow or by micturitional urethral pressure profilometry.

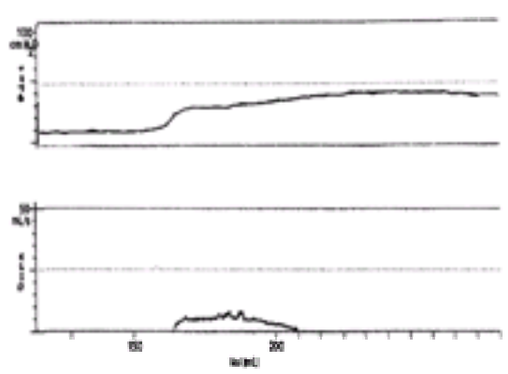

FIGURE 26B.45. A 45-year-old woman 1 year after Marshall-Marchetti-Krantz (MMK) bladder suspension. Severe urge incontinence and straining to void developed immediately after surgery. A combined pressure/flow study shows normal voiding pressure for female with low flow rate. Relief of symptoms and residual urine occurred after urethrolysis.

Treatment of obstruction after suspension surgeries requires urethrolysis. The most common preoperative complaint is urge incontinence; 13% are in retention and 51% possess residual urine (111). Resolution of urge incontinence and complete emptying varies from 65% to 93%.

Urinary Incontinence

Definitions

The ICS has defined *urinary incontinence* as involuntary loss of urine, which is a social or hygienic problem that is objectively demonstrable (256). Loss of urine can occur through the urethra and other routes. The terminology used to describe various types of urethral urinary incontinence is somewhat confusing because symptoms, signs, physical conditions, urodynamic findings, and anatomic factors are sometimes mixed together. The International Continence Society's Committee on the Standardization of Terminology is responsible for most of these definitions, and this committee now has input from the American-based Society for Urodynamics and Female Urology (SUFU), formerly known as the Urodynamics Society. Clinical practice guidelines have also been presented by the Agency for Health Care Policy and Research (361). In addition, SUFU is developing its own incontinence guidelines.

Stress incontinence can denote a symptom, a sign, or a condition. The symptom of *stress incontinence* indicates the patient's statement of involuntary loss of urine when exercisingphysically. The sign denotes the observation of involuntary loss of urine from the urethra immediately on an increase in abdominal pressure. *Genuine stress incontinence* denotes involuntary loss of urine when the total intravesical pressure exceeds the maximum urethral pressure in the absence of detrusor activity.

Urge incontinence refers to the involuntary loss of urine associated with a strong desire to void. Urge incontinence may be subdivided into motor urge incontinence, which is associated with involuntary bladder contractions, and sensory urge incontinence, which is not associated with involuntary bladder hyperactivity. *Reflex incontinence* applies to the involuntary loss of urine resulting from abnormal reflex activity in the spinal cord in the absence of sensation. Overflow incontinence is the involuntary loss of urine when intravesical pressure exceeds the maximum urethral pressure, caused by an elevation of intravesical pressure associated with distention of the bladder in the absence of detrusor activity. The term *total or continuous incontinence* is descriptive and can be associated with any combination of the aforementioned conditions.

Epidemiology

True prevalence figures for urinary incontinence vary widely. Based on a survey in England, the prevalence of urinary incontinence ranges from 2.5% to 5% in men and 10% to 25% in women. Burgio and associates (80) found a disturbingly high prevalence of incontinence, approaching 31% of healthy middle-aged women. As many as 58% of women have had urinary incontinence at some time. In the elderly (defined as over age 60), 15% to 30% are incontinent (132). Elderly women are twice as likely as men to be incontinent. The average period before patients seek treatment has been reported to be as long as 8 years. In nursing homes, the problem of incontinence exceeds 50% (361). After radical prostatectomy, the prevalence of urinary incontinence varies with surgical technique, documentation, age of patient, preexisting bladder dysfunction, and extent of disease. Incontinence after radical prostatectomy ranges from 5% to 80% given these variables. The cost of caring for patients with incontinence in the United States is $7 billion in the community and $3.3 billion in nursing homes (1987 dollars) (253). Thus few urologic conditions affect so many lives socially and financially.

Pathophysiology

Discounting individuals with cerebral disease and dementia, who do not recognize a need to urinate in a socially acceptable manner or place, the pathophysiology of urinary incontinence involves the bladder, the outlet, or both. Bladder hyperactivity may be manifested either as discrete involuntary contractions or as a more tonic decrease in the volume–pressure curve during filling (decreased compliance). Bladder-related incontinence may also occur in an individual without hyperactivity, but with such hypersensitivity on filling that urinary incontinence results from an uncontrollable need to rid oneself of a painful bladder sensation that has occurred in response to filling. Incontinence primarily related to the outlet most commonly results from intermittent decreases in urethral pressure below that of bladder pressure, which occur during abdominal straining and are unrelated to bladder hyperactivity. Rarely, episodic decreases in outlet pressure without a bladder contraction may also be responsible for urinary incontinence (urethral instability). Finally, the bladder outlet may simply have lost its closure potential and be nonfunctional, defined as *intrinsic sphincter deficiency.* Virtually any combination of bladder- and urethra-related causes may exist, compounding the complexity of finding an adequate solution and necessitating a diagnostic evaluation.

Outlet-related Incontinence in the Female

Under this category, we consider genuine stress incontinence, the nonfunctional bladder neck and proximal urethra (ISD), and urethral instability. Delancey (128) and Raz and Smith (459) have eloquently reviewed the structural basis for stress incontinence due to urethral hypermobility. *Urethral instability* refers to a seemingly reflex-caused total loss of urethral closure pressure provoked by bladder filling without a corresponding increase in intravesical pressure (364). This term is probably a misnomer, because the drop in urethral pressure probably represents a component of a normal voiding reflex in which afferent input from the bladder triggers urethral relaxation just before micturition. In the absence of a detrusor contraction, because of myogenic or motor-neuron disease, this fall in urethral pressure is expressed as stress incontinence. This is an entity that cannot be diagnosed by conventional urodynamic study but requires sophisticated urethral pressure recordings. In addition, there have been no systematic investigations regarding the treatment of this entity, but conceptually it would seem to make sense to try to raise the urethral pressure well above the threshold at which a precipitous decrease results from whatever stimulus is involved. Treatment remains problematic. Pharmacologically blocking the neural-evoked relaxation would be ideal. The transmitter is unknown, although NO has been implicated (431,442). Therefore current theory relies on pharmacologically (a-adrenergic agonists) or surgically increasing outlet resistance.

Factors related to maintaining outlet continence fall under three general categories: those related to urethral closure pressure, those related to urethral length, and those related to support of the urethral trigonal anatomy. Urethral length has been considered an important factor by some in the prevention of stress urinary incontinence. Lapides (303) considered the normal functional urethral length in the female to be 3.0 to 4.5 cm and believed that stress incontinence occurred when and because the functional length ofthe urethra was less than 3.0 cm in the erect position. Although this may be correct much of the time, there is considerable disagreement about whether there is more than a minimum change in the resting UPP and functional urethral length after surgical correction of stress urinary incontinence. Also, there seems to be a minimum change in functional urethral length in the elderly between those patients who have stress urinary incontinence and age-matched control subjects. Factors such as these have led most people to believe that reduction of urethral length alone is rarely a factor in promoting stress urinary incontinence. Even in men after radical prostatectomy, continence cannot be entirely correlated with anatomic urethral length as measured radiographically (416). Urethral closure pressure contributes to a cough-competent outlet; and any decreases in factors that contribute to urethral closure pressure, although they may not cause stress incontinence by themselves, in combination can either result in stress incontinence or make a preexisting problem much worse. Alternatively, augmenting these factors may result in enough of an increase in urethral closure pressure to significantly ameliorate the problem.

The smooth muscle of the outlet is estimated to account for 30% to 50% of urethral closure pressure. The smooth muscle has inherent tonus and is responsive to pharmacologic stimulation, particularly a-adrenergic stimulation. Factors that decrease smooth muscle tone and responsiveness include overstretching, trauma, a-adrenergic blockade, b-adrenergic stimulation, progesterone administration, and age. Factors that increase smooth muscle tone and responsiveness include stretch (up to a certain point), a-adrenergic stimulation, b-adrenergic blockade, and estrogen administration.

The striated muscle of the outlet likewise has been estimated to account for 30% to 50% of urethral closure pressure. This striated muscle effect is not confined to the urethra in the area of the urogenital diaphragm, because the striated muscle extends along the urethra from this level for a variable distance to the bladder neck. Striated muscle also possesses an inherent tonus and is capable of voluntary or reflex activity. The factors that decrease striated muscle tone and responsiveness include a section of the pudendal nerve (and perhaps the pelvic nerve), skeletal muscle blockade, age, trauma, and overstretching. Factors that increase striated muscle tone and responsiveness include pudendal nerve stimulation and perhaps pelvic nerve stimulation.

The vascular cushion effect refers to the turgor of the blood vessels in the urethral submucosa and is estimated by Raz and colleagues (457) to account for 20% to 30% of urethral closure pressure, although others think its contribution is minor. Factors that decrease this effect include estrogen deficiency, trauma, and age. Factors that increase this effect include estrogen administration. This “inner urethral softness” (632) acts as a framework of spongy tissue that supplements the pliability and elasticity of the urethral mucosa. The “mucosal seal effect” is caused by the infolding of the urethral epithelium surfaces and complete apposition of the surface folds for which mucous secretion is necessary. Although the exact contribution of this mucosal seal effect to urethral closure pressure is unknown, the lack of it increases the amount of compression pressure required to form a complete seal. Factors that decrease this effect include estrogen deficiency, trauma, and age. Factors that increase this effect include estrogen administration in an estrogen-deficient female.

Several groups (128,393,529) have concisely summarized current concepts of the anatomic support and configuration of the urethral trigonal region. Pelvic support of the vesicourethral segment is contributed mostly by the pubourethral ligaments, which are condensations of the endopelvic fascia (128). The main support is from the posterior pubourethral ligaments, which extend from the inferior portion of the pubis to the midurethra. These prevent downward and posterior rotational displacement of the urethra. A “hammock” of levator ani muscle, covered by endopelvic fascia, supports the bladder and urethra in their intraabdominal position. The pubourethralis, a division of this muscle, forms a sling around the proximal urethra as it passes through the pelvic diaphragm and aids in preventing posterior displacement of the proximal urethra and bladder neck. The perineal musculature and fasciae provide additional inferior support, especially during abdominal straining. The fascia of the bladder and anterior vaginal wall fuse to form the pubocervical fascia. At the level of the bladder neck and proximal urethra, and at the level of the bladder and the fascial ring of the cervix, these two fasciae are densely adherent. Along the base of the bladder, the vesicovaginal space can be developed between these two fascial planes. The pubocervical fascia prevents herniation of the bladder and urethra into the vagina. The vagina provides a potential space for both anterior and posterior vaginal prolapse. Anterior vaginal prolapse may occur through the upper (cystocele), middle (trigonocele), or lower (urethrocele) third of the pubocervical fascia. The sacrouterine and cardinal ligaments support the uterus and cervix laterally and posteriorly, respectively, and provide direct and indirect supports to the bladder and urethra through these attachments. The primary function of these suspensory mechanisms is to support the upper urethra and urethrovesical junction and to provide a stabilizing effect to check the descent of these areas, which might otherwise be produced by an increase in intraabdominal pressure.

The one factor that seemed to be common to patients with genuine stress urinary incontinence was a failure of transmission of intraabdominal pressure increases so that these increases did not act to occlude the proximal urethra. Enhorning (158) was the first to urodynamically demonstrate this failure of abdominal pressure transfer to the upperurethra. The concept has been refuted by using microtip transducers in the urethra and extravesical space. The rise is greater and occurs in the urethra (446). Anatomically, the pathophysiology seems to involve downward and posterior rotational movement of the bladder neck and proximal urethra during

intraabdominal straining so that the bladder neck and proximal urethra descend to a position in which concomitant transmission of intraabdominal pressure to these areas does not occur. The urethra is in a dependent position with respect to the bladder base, and the tensile forces of the full bladder open the bladder neck with stress and permit flow into the proximal urethra (529). Whatever other factors contribute to decreases in urethral closure pressure, this abnormal descent of the bladder base and proximal urethra remains the only factor regarding which a consensus has been reached as a cause common to all patients with genuine stress incontinence. All effective vesicourethral suspension procedures correct this problem by anchoring the vesicourethral junction in a physiologic position and preventing its descent during abdominal straining.

The pathophysiology of classical stress urinary incontinence is corrected by any of the standard vesicourethral suspension procedures, all of which restore the anatomic and physiologic position of the proximal urethra in such a fashion as to allow transmission of intraabdominal pressure so that urethral closure pressure is enhanced to a similar and sometimes greater degree. In doing so, proper support is provided to prevent rotational descent of the bladder neck and proximal urethra. Such correction assumes that the factors responsible for urethral closure pressure in the first place are physiologically intact and capable of translating these intraabdominal pressure increases into increased urethral resistance.

Some patients have gross incontinence during abdominal straining; in such cases, a vesicourethral suspension may not be effective for correction. These patients, classified by McGuire and colleagues (371) as having type 3 (intrinsic sphincter deficiency) stress incontinence, have a nonfunctional bladder neck and proximal urethra. There is no pressure or poor closure pressure in this area. On an x-ray film with the patient erect and the bladder full, this area can appear fixed in an open or relatively open position. Alternatively, a small (less than 60 cm H_2O) increase in abdominal pressure forces urine through this region. The incontinence that is seen in patients with this finding is generally quite severe, although they often complain primarily of stress incontinence. Patients may state that they “leak” constantly or with any slight increase in intravesical pressure. Their abdominal leak pressures are uniformly less than 60 cm H_2O. Often, they complain particularly of gravitational incontinence that occurs simply on assuming the erect position. They often have a history of previous pelvic surgery, and the characteristic history includes three or more failed procedures for what was diagnosed as genuine stress incontinence. These patients have a particularly low urethral closure pressure in the first 1 to 2 cm distal to the bladder neck, and radiographically they exhibit a bladder neck and proximal urethra that never quite closes in the erect position with the bladder full. However, such patients do not exhibit an increase in subtracted bladder pressure. Treatment relies on increasing abnormal leak pressure with a periurethral bulking agent or pubofascial sling. Hypermobility of the vesicourethral segment is often not a problem in these patients, if this segment is fixed because of previous scarring and fibrosis. Likewise, combined hypermobility and intrinsic sphincter deficiency can coexist, requiring fixation using a pubofascial sling. Some authors advocate a pubovaginal fascial sling for all types of stress incontinence, quoting cure and improvement rates of 92% (91) with a mean follow-up of 3 years.

Bladder-related Incontinence in the Female

Bladder related incontinence in the female may be related to phasic rises in detrusor pressure, either of neurologic (detrusor hyperreflexia) or nonneurologic (detrusor instability) causation. Such incontinence may also be related to an abnormal tonic rise in intravesical pressure (decreased compliance). The neurologic causes of involuntary bladder contraction have already been reviewed. The cause of detrusor instability is obscure, especially in women, in whom outlet obstruction is uncommon (397,399). Some work has begun to elucidate neurophysiologic and neuromorphologic differences in detrusor muscle and micturition pathways between patients with bladder instability and normals; however, the cause of this troublesome and common clinical problem remains obscure.

One subject that should be mentioned is the simultaneous occurrence of bladder instability and stress urinary incontinence. Detrusor instability per se is a common cause of urinary incontinence in females. Instability has been cited as one of the most common causes of failure of a suspension operation for stress urinary incontinence (26). Whether preoperative urodynamic findings indicate that such an operation is likely to fail is an important question. A careful urodynamic evaluation in all such patients might well decrease the enthusiasm for corrective surgery in patients who also have genuine stress incontinence. Many have noted the occurrence of detrusor instability in patients with stress incontinence but have repaired the stress incontinence anyway, ideally to ameliorate the involuntary bladder contraction component of the incontinence by nonsurgical means. More often than not, however, this does not constitute a problem. McGuire and Savastano (373) have documented their long-stated position that only a small number of women with a combination of stress incontinence still have symptomatic urinary loss as a result of persistent detrusor abnormalities at 8 weeks after corrective surgery for the stress incontinence. They reviewed 603 women withurodynamically and radiographically diagnosed stress incontinence; 180 had associated detrusor instability or urge incontinence or both. The overall incidence of detrusor instability was 30%. By 8 weeks after surgery, only 25 patients (4%) of the entire group, and only 14 of those with detrusor instability or urge incontinence at any time, were still troubled with incontinence resulting from that condition. Thus, in McGuire's experience, women with both stress incontinence and detrusor instability fare worse after surgery than those with only stress incontinence, with respect to total freedom from incontinence. However, 90% of women with stress incontinence and detrusor instability or urge incontinence were totally relieved of urinary incontinence at 6 months by an operation designed to treat only the stress incontinence. These data also suggest that, at least in some patients, stress incontinence and detrusor instability are causally related. Patients with stress incontinence who also have bladder-related incontinence because of decreased compliance do not seem to fare so well after surgery to correct just the stress incontinence. Finally, the *de novo* development of stress urge incontinence due to instability should raise suspicion concerning bladder outlet obstruction.

Urgency-frequency Incontinence in the Female Without Detrusor Hyperactivity or Outlet Incompetence

There are patients who have symptoms that suggest involuntary bladder contractions, yet have no consistent cystometrically demonstrable rise in pressure during the filling phase of micturition. Most of these patients report symptoms of urgency, frequency, dysuria, pressure, and incontinence in varying proportions. The treatment of this symptom complex is, initially at least, usually empiric, and consists of one or a combination of the agents to decrease detrusor hyperactivity (598). The fact that most of these patients do not have involuntary contractions most likely accounts for the generally less than optimal results achieved only with this type of treatment (464). Urodynamic evaluation of these patients may be entirely normal, may show hypersensitivity only during filling, or may show variations in urethral pressures. Fossberg and colleagues (181) reported successful subjective results in 22 of 34 female patients with sensory urge incontinence, many of whom had wide urethral pressure variations during filling, using phenylpropanolamine 50 mg twice daily. The ideal pharmacologic treatment for at least the urgency, frequency, and dysuria component of this symptom complex, which seems to be more sensory than motor in origin, would be an agent that produces topical anesthesia or hypoesthesia of the bladder and urethral mucosa. Although there are agents that are reported to have this action as their primary effect, the clinical results that have been obtained with such compounds in these circumstances have been poor, at least in our experience. MacCaulay and colleagues (341) report that, compared to women with stress incontinence, those with sensory urgency scored higher on anxiety and hysteria scales. There is no doubt that in at least some of these patients the symptoms are psychosomatic. However, poor treatment results in this group probably reflect that state-of-the-art techniques and practices fail to detect pathophysiology from the myriad possibilities (Table 26B.20), and optimal treatment for some of these has not yet been defined.

Lower urinary tract or genital infection, bacterial or nonbacterial	Bladder carcinoma or carcinoma in situ
Meatal obstruction	Bladder stone
Bladder outlet or urethral obstruction	Estrogen deficiency
Detrusor hyperactivity	Interstitial cystitis
Smooth-sphincter dyssynergia	Radiation cystitis
Striated sphincter dyssynergia	Tuberculous cystitis
Urethral diverticulum	Emotional factors
Urethral caruncle	Decreased central or peripheral opioid/peptide influence
Urethral carcinoma	Nonlaminar turbulent distal urethral flow

TABLE 26B.20. POSSIBLE CAUSES OF URGENCY-FREQUENCY-INCONTINENCE SYNDROME

Bladder-related Incontinence in the Male

Detrusor hyperreflexia and instability in the male have been discussed, especially as they pertain to outlet obstruction secondary to prostatic enlargement. Likewise, decreased compliance as a cause of urinary incontinence in the male has been covered. Overflow incontinence represents another form of bladder-related incontinence that seems to be more common in males than in females, although it occurs in both. The primary pathophysiology is actually a failure of emptying, leading to urinary retention with “overflow” incontinence, which results from either continuous or episodic elevation of intravesical pressure over urethral pressure.

Overflow incontinence results from outlet obstruction or detrusor inactivity, either neurologic or pharmacologic in origin, or secondary to inadvertent overdistention of the bladder. Our subjective impression is that it develops in patients whose bladder neck and proximal urethral resistance is decreased, or in whom the detrusor is not totally decompensated. Treatment is directed at the primary cause of the failure to empty, or at circumvention if correction of the primary cause is not possible, or if irreversible bladder decompensation has occurred.

Outlet-related Incontinence in the Male

In theory at least, categories of outlet-related incontinence that are similar to those in the female should exist in themale; that is, urethral instability, stress urinary incontinence, and a nonfunctional bladder neck and proximal urethra. In reality, there is little, if any, information regarding the topic of urethral instability in the male, possibly because conditions that cause stress incontinence in the male must affect the distal sphincteric mechanism and are universally associated with damage to urethral nerves. Stress-related incontinence exists after neurologic injury (this is discussed in the section on voiding dysfunction after radical pelvic surgery and in the section on myelodysplasia).

The most common type of outlet-related incontinence in the male is postprostatectomy incontinence. However, postprostatectomy incontinence is not caused solely by outlet-related reasons. Twenty-five percent of these patients have bladder dysfunction (hyperactivity) that accounts for all or part of their symptoms (Fig. 26B.38). The incidence of bladder hyperactivity in patients with postprostatectomy incontinence has been variously reported (178,311,452,625). Although many of these patients had not been studied urodynamically before surgery, it can be assumed that—because of the high incidence of bladder instability secondary to outlet obstruction in the male—a substantial proportion of them actually had detrusor hyperactivity preoperatively. Thus, in most cases, it did not develop in response to the prostatectomy. Recognition of the abnormal bladder function is of utmost importance in the management of these patients, because satisfactory continence may most often be obtained with pharmacologic therapy alone when the patient has only a minimum amount or no element of sphincteric insufficiency.

Postprostatectomy incontinence is one of the most devastating complications that can befall the patient and urologist. The continence zone after a radical prostatectomy is located between the verumontanum and urogenital diaphragm. One can characterize the various types of prostatectomies, including radical prostatectomy, as to the potential antiincontinence mechanisms left intact, and therefore as to the probability of urinary incontinence (related to the outlet) after prostatectomy. All types of prostatectomies essentially ablate the proximal sphincter mechanism, consisting of the smooth muscle of the bladder neck and proximal prostatic urethra, as well as the nonmuscular elements of the wall of these structures. These surgeries ideally leave intact enough of the distal sphincter mechanism (the smooth muscle of the urethra from the level of the verumontanum to the urogenital diaphragm; the striated muscle between the leaves of the urogenital diaphragm; the striated muscle that is applied along the outer wall of the urethra for a variable distance from the urogenital diaphragm to and beyond the apex of the prostate; and the nonmuscular elements of the urethral wall in that area) to produce continence in the absence of bladder hyperactivity and sensory urgency. Radical prostatectomy has the greatest potential for significant distal sphincter mechanism destruction, whereas transurethral prostatectomy is less likely to disturb this mechanism. The primary pathology seems to be noncompliance of the urethra. This may result from ischemia rather than direct injury. If one considers the potential damage to proximal or distal sphincter mechanisms or their innervation with various types of prostatectomy, a correlation with the commonly quoted figures for severe incontinence after different types of prostatectomy is evident (Fig. 26B.46):

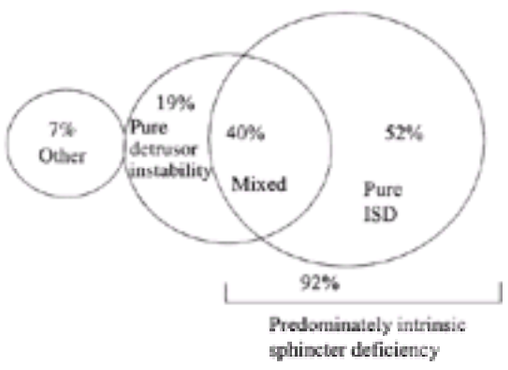

FIGURE 26B.46. Pathogenesis of urinary incontinence following radical retropubic prostatectomy. The pooling of urodynamic data from several recent large series reveals that intrinsic sphincter deficiency *(ISD)* is the most common cause. Other causes include reduced bladder compliance. Older series reporting predominant detrusor instability included obstructed patients.

Transurethral prostatectomy for benign prostatic hypertrophy, 0.2% to 1.4%
Transurethral prostatectomy for carcinoma, 10% to 20% (presumably because the distal sphincter mechanism is in some cases compromised by the carcinoma)
Suprapubic prostatectomy, 1% to 6%
Nonradical retropubic prostatectomy, 0.2% to 2.6%
Radical retropubic prostatectomy, 1% to 87% (depending on the definition of incontinence)
Simple perineal prostatectomy, 1.9% to 10.5%
Radical perineal prostatectomy, 2% to 15%

Given the evidence that postprostatectomy incontinence is related to age, coincident bladder or outlet dysfunction, site of surgery, and presence of stricture formation, one can postulate several mechanisms for postprostatectomy incontinence, including one or more of the following: (a) destruction of smooth muscle in the distal sphincter, (b) injury to nerves supplying the distal sphincter, and (c) ischemia with loss of muscle and neural function.

In a prospective comparison of perineal and retropubic prostatectomy, Doublet and co-workers (142) found that incontinence was more prevalent with the perineal approach, although not statistically different from the abdominal procedure. Attempts to preserve the bladder neck or create a neourethra have been advocated to help preserve continence (542). Although such techniques may help preserve continence, they could also facilitate future periurethral injection therapy if it should become necessary in the future.

Incontinence associated with detrusor hyperactivity or sensory urgency can resolve within months. Incontinence without urgency is more worrisome and less apt to dissipate spontaneously. Thus a urodynamic evaluation of patients with these problems is necessary to ascertain the exact contribution of outlet and bladder-related factors. Often, this evaluation is delayed for at least a year after surgery and just before institution of therapy.

Any patient whose proximal or distal sphincteric mechanism is already compromised is at greater risk from incontinence when another procedure in the area of the bladder neck and anterior urethra is performed. Postprostatectomy bladder neck contracture can also prevent closure of the outlet and produce incontinence. Any neuromuscular disease affecting the tone of the smooth or striated muscle of the distal sphincteric mechanism will predispose anindividual patient to a greater chance of urinary incontinence after even a well-done transurethral resection. This may include any neuromuscular disease, myasthenia gravis, Parkinson's disease, diabetic neuropathy, or alcoholic neuropathy. Moreover, a patient who has had a membranous urethroplasty or an abdominoperineal resection, or who has a rigid urethral stricture in this area, is at significant risk for urinary incontinence after a prostatectomy.

Incontinence in the Elderly

Incontinence in the elderly is a pervasive and distressing problem for patients, their families and friends, and health professionals. This subject is also of immense social and economic importance (427,466,467). Studies in Great Britain and Europe have fixed the prevalence of urinary incontinence in the hospitalized elderly at between 18% and 40% in men and between 24% and 46% in women. In community-dwelling elderly, the corresponding figures are 5% to 25% in men and 7% to 42% in women. In the United States, it is estimated that 28% to 50% of elderly nursing-home patients are incontinent of urine. It is estimated that over $3.3 billion per year in additional care is required for the 15% of incontinent elderly who are institutionalized (253).

The pathogenesis of incontinence in the elderly is multifactorial. Ischemia to areas of the prefrontal cortex has been demonstrated by Griffiths (224). Ischemia of the

bladder may also occur. Elbadawi and co-workers (152) stress the importance of changes in the bladder in the development of detrusor instability.

The subject of incontinence in the elderly requires different considerations than incontinence in other age groups (467). First, there is a large segment of the elderly with transient incontinence. Transient incontinence is most often associated with acute medical conditions, psychologic responses, or iatrogenic factors, particularly associated with the administration of various types of pharmacologic agents. Restricted mobility and impaction of stool are also common causes of transient incontinence (Table 26B.21). Appropriate early management can often prevent this type of incontinence from becoming an established pattern. Transient cause for incontinence may contribute to 50% of the total number of cases of incontinence in the elderly.

Delirium
Infection
Atrophic urethritis/vaginitis
Pharmaceuticals
Psychologic, especially depression
Excessive urine output (cardiac, DM)
Restricted mobility
Stool impaction

After Resnick NM, Yalla SV, Laurino E. The pathophysiology of urinary incontinence among institutionalized elderly persons. *N Engl J Med* 1989;320:1.

TABLE 26B.21. DIAPPERS MNEMONIC FOR TRANSIENT INCONTINENCE

Another type of problem, not specific to the elderly but more characteristic of this group, is functional incontinence. This refers to the inability of a normally continent person to reach the toilet in time to avoid an accident. The reason maybe an illness—commonly a musculoskeletal limitation—that prevents an appropriately quick response to a need to void, or it may be a failure—on an organic, cerebral, or psychologic basis—of the individual to appreciate the social necessity of voiding in the right place at the right time; or it may represent spiteful behavior associated with depression, suppressed hostility, or anger (426). Bladder hyperactivity, usually with sensation (urge incontinence), is the most common of urodynamically definable conditions contributing to incontinence in the elderly and is estimated to occur in between 40% and 70% of incontinent elderly patients. Involuntary voiding without stress or sensation (reflex incontinence) may occur as well, either because of interruption of sensory pathways, spinal cord disease, or cortical damage that can cause detrusor hyperreflexia and also diminish the awareness of bladder filling. Stress incontinence in the elderly is much more common in females than in males who have not undergone prostatectomy. Nonsurgical management is often beneficial and appropriate. Overflow incontinence represents an easily diagnosable problem in these patients. If this is secondary to outlet obstruction with an intact detrusor, surgical treatment is often successful. If the detrusor is decompensated, intermittent catheterization, if practical or available, will totally obviate the problem.

Painful Bladder and Urethra

Evaluation and management of patients afflicted with purely sensory disorders of the lower urinary tract is frustrating and challenging. These patients often complain bitterly of symptoms suggestive of lower urinary tract dysfunction, without an obvious infectious cause or urodynamic correlate, but occasionally with endoscopic abnormalities. However, cystoscopic abnormalities are not constant or diagnostic (199). Recognition that disorders of sensory nerves can occur is limited by inability to objectively measure responses.

Interstitial Cystitis and the Urethral Syndrome in the Female

Hunner (254) first described a painful bladder condition manifested by frequency, nocturia, urgency, and suprapubic pain in a group of young women whose endoscopic examination revealed ulcers on the vesical mucosa. Subsequently, it has become evident that the classical finding of a scarred, contracted bladder that splits and bleeds on distention is present only in approximately 10% of cases of interstitial cystitis (IC). The onset of the disease is commonly subacute, and full development of the symptom complex takes place over a relatively short time (236). Many women can pinpoint the onset of symptoms. Often, the symptoms initially seem to be similar to those of urinary tract infection, of which many of these women have a repeated history. Positive urine culture report is more difficult to verify. The symptom complex, however, although initially thought to be simply caused by another infection, “never disappears.” The most common symptoms of the patient with classic interstitial cystitis are pain, frequency, nocturia, and urgency because of suprapubic discomfort. In most cases, voiding relieves the pain somewhat, but the pain recurs with bladder filling. The patients are usually women between ages 30 and 70 years, although men and children of either sex constitute approximately 10% of cases (236). Abacterial prostatitis or prostatodynia may correspond to the male counterpart. Oravisto (422) found the occurrence of IC in Helsinki to be 18 per 100,000 women. Kinder and Smith (282) found only 27 cases in more than 17,000 urologic registrations in London.

One of the problems in gathering data about this disease entity is the total lack of an objective and agreed-on definition. The National Institutes of Health (NIH) has developed guideline criteria for inclusion and exclusion in NIH-supported clinical trials on IC (Table 26B.22) (207). Although originally meant to be criteria for entry into research protocols on IC, they have become the de facto definition. Some patients with IC clearly fall outside of these guidelines. In effect, this entity is a disorder of exclusion. The symptom complex is not specific. Urodynamic investigation is unrevealing except for the presence of hypersensitivity during filling. A potassium test has been advocated but merely demonstrates hypersensitivity (93). Its sensitivity is 69%,but specificity is only 50%. Occasionally, patients exhibit decreased compliance during filling; in our experience, these are usually chronic cases, with a long duration of disease, and with fibrosis of the bladder wall. Many of these changes may result from previous therapy or the response to minimal distention, similar to a defunctionalized bladder. Endoscopic findings vary widely. Classical Hunner's ulcers are rarely seen, but bleeding on refilling the bladder after cystoscopic distention is common. The bleeding may result from petechial hemorrhage, ecchymoses, or free bleeding from vessels, and is estimated by Hald and Holm-Bentzen (236) to occur in up to 90% of patients. Messing and Stamey (380) described the appearance of glomerulations (discrete rounded petechial mucosal hemorrhage) in response to cystoscopic hydrodistention and emptying as a manifestation of early interstitial cystitis. Such endoscopic findings are nonspecific and can be seen after filling and emptying of the bladder in patients with other inflammatory bladder conditions, including patients undergoing endoscopic examination for periodic surveillance (e.g., for bladder tumors) without either definable disease or symptoms. Conversely, the inability to demonstrate these findings does not exclude the diagnosis. A recent report demonstrating glomerulations in normal women before laparoscopic surgery and in men with prostatitis dispels the notion that cystoscopic changes are pathognomonic of IC (45).

Automatic Exclusion
Less than 18 years old
Bladder tumor
Radiation cystitis
Tuberculous cystitis
Uterine, cervical, vaginal, or urethral malignancy
Bacterial or fungal cystitis or prostatitis within 3 months
Vaginitis
Cyclophosphamide or other chemical cystitis
Urethral diverticulum
Active herpetic infection
Bladder or ureteral calculi
Waking urinary frequency <8 times
Absence of nocturia
Symptoms unrelieved by antibiotics, urinary antiseptics, and analgesics or anticholinergics
Duration less than 9 months
Involuntary bladder contractions on cystometry
Capacity greater than 350 ml. on cystometry in a conscious patient
Lack of intense urgency at 100 ml. volume (gas) on 150 ml. liquid cystometry at full rate of 80–100 ml./min
Required for Inclusion
1. Presence on cystoscopy of either glomerulations after distension or Hunner's ulcer
2. One of the following subjective symptoms: pain in bladder or urinary urgency

TABLE 26B.22. NIDDK-NIH CRITERIA FOR INTERSTITIAL CYSTITIS

The IC database initiated by the National Institutes of Health has been revealing (454). More than 90% of patients are Caucasian with a mean age of 43 years. Using pain-urgency-frequency scoring, 7% have mild, 44% have moderate, and 49% have severe symptoms. Severe urgency and frequency (more than 15 urinations per 24

hours) are seen more than severe pain (Likert score greater than 7) (29%). Although symptoms fluctuate, no indication of worsening over time has been seen.

The cause of the disease has variously been considered to be infectious (bacterial and nonbacterial), traumatic, autoimmune, and neural. Dixon and Hald (137) nicely summarized the varied pathologic findings and also attempted to implicate a defective bladder urothelium in the pathogenesis of this disease, an idea originally suggested by Gordon and colleagues (218). They summarized the available pathologic evidence, which suggests that the disease is associated with a pancystitis. The bladder wall is frequently thickened, and the perivesical tissues are infiltrated. There is frequent thinning of the mucosal lining, and in some areas the mucosa may be denuded. The areas of ulceration are frequently covered by a layer of fibrin. An intense reaction occurs in the subepithelial connective tissue beneath the areas of mucosal thinning. The lamina propria is edematous and congested and contains dilated capillaries and perivascular hemorrhages. A diffuse cellular infiltration of all areas of the bladder wall by lymphocytes exists, but this is most evident in the lamina propria. Mast cell infiltration in the muscle coat ("detrusor mastocytosis") has been proposed as a diagnostic feature by Larsen and colleagues (309). This observation or measurement of mast cell products in the urine, such as histamine and its metabolites, has been adopted by some as a diagnostic feature. However, there is no agreement as to this criterion among many other clinicians (380).

Parsons and associates (433) have proposed a theory of pathophysiology involving a defect in the protective layer of glycosaminoglycans lining the mucosa of the urinary bladder, allowing a marked increase in bladder urothelial permeability, which in turn allows "leakage of urine" into the bladder wall, thereby inducing a local inflammatory response. Dixon and Hald (137) could not support such a theory implicating a defective glycocalyx, because they detected no structural differences in the glycosaminoglycans layer between patients with interstitial cystitis and control subjects. However, they mention the possibility that abnormalities of bladder urothelial permeability may occur because of other reasons, perhaps defective "urothelial tight junctions," with resultant urine leakage into the bladder wall.

Circumstantial evidence suggests that remodeling of sensory pathways occurs in patients with IC. Immunohistochemical data reveal that patients with IC have more nerves in the submucosa and muscle of the bladder (105,250,340). Lundeberg and associates (340) postulate that the number of mast cells depends on innervation. Chemically induced bladder inflammation in animals has been shown to reduce the threshold of mechanoreceptive afferents (228) and to alter the micturition reflex (52). Therefore it is reasonable to suggest that, in IC, sensory remodeling (pain begets pain) could develop in the spinal nociceptive pathways from the bladder in response to irritative stimuli in the bladder, reinforcing or reflecting the proliferation of axons in the bladder. Sensory neuroplasticity or chronic pain has been documented in models using the endotoxin component (lipopolysaccharides) of gram-negative bacterial cell walls. Thus one or more minor urinary tract infections in women or men could give rise to a neuropathic condition and chronic pain. Similar irritative hypotheses have been put forth to explain irritable bowel syndrome and pain with rheumatoid arthritis. Lending credence to the neurogenic pathogenesis in response to irritation, infection, or injury is the finding of elevated NGF in the urine and bladder tissue from IC patients (337,417). IC patients also express greater levels of mRNA for a substance P receptor (351).

Consistent with altered sensory nerve function in IC is effectiveness of intravesical anesthetics such as lidocaine and DMSO; the sensory neurotoxin capsaicin (436); electrical stimulation of sacral nerve roots (165); or denervation by cystolysis (620), hydrodistention (146), or sacral rhizotomy (382). Intravesical vanilloids that diminish afferent activity have also been used. Intravesical capsaicin and resiniferatoxin show only moderate success, suggesting that painpathways rostral to the bladder in the spinal cord and brain are activated. All therapies have partial and often only temporary success. Insight into the possible explanation for failure of the therapies derives from the experience of patients undergoing radical cystectomy or partial cystectomy with bladder augmentation. Even in these cases, surgical removal of the bladder does not uniformly abolish the sensation of bladder pain (596). This phenomenon is similar to the phantom limb syndrome experienced by patients after amputation of an extremity. These findings also suggest that mechanisms central to peripheral bladder sensory nerves play a role in chronic dysesthesias and pain.

Attempts to formulate any sort of a meaningful review of this disease are hampered by the fact that there is absolutely no agreement on a definition of the disease, or any way to grade its severity. The disease is often defined on the basis of symptoms alone without endoscopic or pathologic findings. It may be defined on the basis of symptoms with endoscopic findings but without specific pathology, or on the basis of pathologic findings with symptoms but with or without typical endoscopic findings. It has been suggested that ulcerative and nonulcerative interstitial cystitis are two different pathologic and clinical entities. Responses to treatment differ among patients in these various categories, probably accounting for the wide variations and disagreements regarding successful results with hydrodistention, intravesical instillations of DMSO, sodium oxychlorosene (Clorpactin) or doxorubicin, surgically or laser-induced "denervation," synthetic glycosaminoglycan therapy, and biofeedback. Often, the most effective therapies are those used for any chronic pain disorder. These include biofeedback, transcutaneous electrical nerve stimulation, and tricyclic antidepressants. Reports of long-acting calcium channel and a-adrenergic blockers appear promising (174,238). The use of intravesical agents such as bacille Calmette-Guérin has shown some promise (443). With a mean follow-up of 27 months, patients have shown a 60% response rate compared with 27% for placebo. Responses have also correlated with changes in cytokines in the urine that suggest an immune mechanism of action.

The urethral syndrome in the female is another imprecisely defined entity that, to most urologists, is a diagnosis of exclusion for these patients with frequency, urgency, or dysuria without evidence of any disease process in the urinary or genital tract. George (199) summarized the clinical features. Frequency by day is the primary complaint of most patients, who describe a constant, unpleasant sensation in the area of the urethra that is only temporarily relieved by voiding. Nocturia is generally of mild degree and never reaches the levels experienced by most patients with true interstitial cystitis. Patients complain that their voiding is typically slow and hesitant, and in fact, the measured flow rate, even with adequate volume, may be low.

A diagnosis of obstruction cannot be made on the basis of flowmetry, but must rely on pressure/flow documentation. Any positive finding uncovered during a search for infectious, inflammatory, or urodynamically definable pathologic characteristics should be treated specifically. Unfortunately, this leaves a large number of patients who must be treated either by biofeedback, reassurance and encouragement (really a form of biofeedback, but simply practiced by the urologist during office hours), empiric pharmacologic therapy, and a host of other treatments, generally directed toward the urethra or the surrounding structures. Schmidt (498) and Tanagho and colleagues (559) have come up with an interesting theory of striated-sphincter dysfunction as a cause of the urethral syndrome. Treatment of such dysfunctional striated-sphincter activity in their hands has been successful in ameliorating the clinical condition, and such treatment has ranged from simple reeducation—with or without pharmacologic therapy—to various forms of neurostimulation to fatigue the presumed erratic behavior of the striated sphincter.

Prostatodynia/Prostatitis/Male Pelvic Floor Dysfunction

The terms *prostatodynia* and *abacterial prostatitis* describe a syndrome in the male that is somewhat similar to the urethral syndrome in the female (144) and may represent the male counterpart to interstitial cystitis. Likewise, recent reports of lack of inflammation on biopsy of these patients have led to reassessment of our beliefs (570). Similar to IC, glomerulations can be seen, NGF levels are elevated, and relative ischemia may be present (102). Classically, the patient has an ill-defined discomfort in the prostatic area, but with no evidence of true acute or chronic prostatitis and no evidence of infectious or inflammatory findings in the expressed prostatic secretions. The National Institutes of Health has recently proposed criteria for the diagnosis of prostatitis (335,403) This syndrome of chronic genital discomfort, which often includes symptoms of irritative voiding dysfunction, typically occurs in tense and anxious persons (425). In a series of 37 such patients in whom the diagnosis had been established by clinical, bacteriologic, and urodynamic screening (with no identifiable disease), Osborn (425) reported the somatic symptoms as consisting of perineal pain (76%), pain after ejaculation (56%), suprapubic discomfort (55%), penile pain (44%), orchialgia (35%), and loin pain (17%). Orchialgia may arise from the close proximity of testicular nerves to the prostate capsule. Zorn and associates (633) noted that injection of this region with local anesthetic transiently abolished testis pain. Voiding symptoms consisted of postmicturition dribble (35%), hesitancy (26%), persistent nagging urethral sensation (23%), and necessity of straining to void (17%). The pathophysiology is obscure, and causative considerations have ranged from undiagnosed bacterial, trichomonal, or chlamydial infections, to what is described as tension myalgia of the pelvic floor striated musculature, or increased adrenergictone, occurring primarily in persons with a tendency to a tense, neurotic personality (507). In patients without an identifiable cause—unfortunately, quite a large number—long-term therapy is frequently used to either decrease bladder contractility or decrease outlet resistance. As with interstitial cystitis, tricyclics and a-adrenergic blockers can be effective (238).

Enuresis

Enuresis is the nocturnal or diurnal incontinence of urine in a child older than age 4 years. Primary enuresis is present from birth, and secondary enuresis is preceded by a dry interval of 6 to 12 months. The incidence of enuresis has been estimated at 12% of children ages 4 to 5 years (180), and it is known to have a familial predisposition (613). Theories regarding the cause of enuresis include such factors as delayed central nervous system maturation, psychogenic and behavioral components, environmental influences, deep sleep, allergies, small bladder capacity, uninhibited neurogenic bladder, structural abnormalities of the urinary tract, and lack of diurnal variation in vasopressin (138,172,272,317,355). The incidence of underlying organic problems is higher in the older patient population. A history of enuresis is a risk factor for urge incontinence and detrusor instability in adult women (176,392). This discussion focuses on children with enuresis without neurologic or urologic disorders.

The extent of the urologic evaluation of enuretic children has recently undergone reevaluation. In the past, most children underwent intravenous urography, voiding cystourethrography, and endoscopy. However, current recommendations are for a much more selective and minimal evaluation, because organic pathology is rare.

The importance of history, physical examination, and results of urinalysis and urine culture in this evaluation are paramount. One should determine the pattern of incontinence, whether nocturnal, diurnal, or both; associated urinary frequency or urgency; fecal soiling or constipation; and a history of urinary tract infection and obstructive voiding symptoms. Careful examination of the spine, abdomen, and genitalia, and neurologic evaluation of sacral spinal cord segments, is necessary. The voided stream should be observed. A urinalysis and urine culture, if indicated, are performed. A history or laboratory findings suggestive of urinary tract infection, or evidence suggestive of a hyperactive external urethral sphincter, urinary tract obstruction, or neurologic problem, mandate further evaluation. Determination of the uroflow rate, possibly combined with surface perineal EMG, may be indicated (32).

Many investigators have performed urodynamic evaluations of enuretic children in an attempt to identify any specific abnormality of vesicourethral function responsible for their incontinence. Overall, urodynamic abnormalities alone in children with nocturnal enuresis are unusual. Whiteside and Arnold (613) studied 50 patients who had normal urinary flow rates and complete bladder emptying. In 13 patients with nocturnal enuresis only, 15% had detrusor instability approaching what may be seen in a normal population. In contrast, 97% of 37 patients with both diurnal and nocturnal enuresis had detrusor instability. Blaivas and associates (59) evaluated 13 children with diurnal and nocturnal enuresis and found two with neurogenic bladder dysfunction. Seven of the remaining 11 patients had decreased bladder capacity. Firlit and associates (172) performed pressure, flow, and EMG urodynamic studies on 34 children with diurnal and nocturnal enuresis and found 13 patients with uninhibited bladders, 17 with hyperactive external sphincters, and 4 with normal results. Kass and associates (272) urodynamically evaluated 65 children with primary enuresis. Forty-two of these patients had either a history or evidence of a urinary tract infection. Among these, 30 had uninhibited detrusor contractions, 10 were normal, and 2 had mixed types of neurogenic bladder dysfunction. Of the remaining 23 patients, 5 had uninhibited detrusor contractions, and 18 were normal. Smey and colleagues (518) reported a subgroup of enuretic children who had hyperactive external urethral sphincters as a contributing factor to incontinence. Diurnal enuresis, urinary frequency and urgency, urinary tract infection, and fecal soiling or constipation appear to correlate with the presence of uninhibited detrusor contractions, hyperactive external urethral sphincters, or both.

Various treatments have been used for enuretic children, including reassurance, psychotherapy, alarm conditioning, behavior modification, hypnotherapy, pharmacologic manipulation, and various surgical techniques. The preponderance of evidence currently suggests that the history, physical examination, and basic laboratory findings will indicate the appropriate extent of evaluation and initial management of most nocturnal enuretic children. Children with past or present urinary tract infection, evidence of lower urinary tract obstruction, or abnormalities on physical or neurologic examination should undergo thorough urologic evaluation, including imaging, followed by appropriate treatment. Meatotomy may be helpful in the male child with documented meatal stenosis (overdiagnosed), but may be associated with a high relapse rate. The routine use of meatotomy or urethral dilations is to be condemned. Children with none of the aforementioned findings, or those who have had a negative urologic evaluation, may be managed in a more conservative manner.

When deciding whether to initiate therapy, it is important to assess the effect of the problem on the patient and the family as a whole. When some parents and children are informed that no significant organic or psychologic problem is causing enuresis, reassurance and fluid restriction before bedtime may be the only treatment required. Many are quite willing to wait for the spontaneous resolution of enuresis that occurs at a rate of 15% per year in patientsbetween ages 5 and 19 years (180). If treatment is desired, a conditioning device such as a pad-and-bell bed alarm is successful in up to 60% of patients, and behavior modification therapy, aimed at making the patient responsible for changing his or her behavior, and complemented by positive reinforcement, is helpful in up to 70% of patients (355).

For patients who are unable to accept or who fail these approaches, pharmacologic therapy may be effective. The results of the thorough study by Kass and associates (272) suggest that successful empiric pharmacologic treatment of these patients can be instituted on the basis of historical information, physical examination, and urinalysis. Eighty-five percent of patients with nocturnal enuresis and daytime urgency and frequency respond well to anticholinergic medication. Seventy percent of patients with nocturnal enuresis only are successfully treated with imipramine hydrochloride. Nortriptyline hydrochloride may be efficacious in those patients who do not respond to imipramine hydrochloride. Tricyclics in these circumstances probably work by increasing spinal levels of monoamines during sleep, which inhibit micturition. Imipramine has the additional benefit of a more rapid onset of action and shortened half-life if undesirable side effects are encountered, such as hyperactivity or lethargy. Tricyclics are contraindicated in children with a seizure disorder.

Some reports indicate that desmopressin 20 µmg intranasally is effective in decreasing or eliminating enuresis in children and adults who have failed behavioral and pharmacologic therapies (138,260). The primary limitation of this treatment is cost. Side effects include weight gain, headache, stomachache, and rarely, epistaxis. A high relapse rate can be expected if drug therapy is withdrawn early, particularly in younger children. Pharmacologic therapy is more effective if it is suggested in a positive manner and combined with a program of behavior modification and positive reinforcement techniques.

Myelodysplasia

Myelodysplasia (spinal dysraphism) is a congenital anomaly occurring in 1 to 2 per 1,000 births in the United States. Multifactorial genetic and environmental influences are thought to be responsible for the unfused neural arches and associated spinal cord defects (155). Prenatal screening involving ultrasound or amniocentesis can be used to identify these patients. Although early neurosurgical intervention has decreased the incidence of meningitis and hydrocephalus in infancy (310), urologic complications resulting from neurogenic vesical dysfunction (NGVD) remain the leading cause of morbidity and death in survivors (519). For most, urinary incontinence is a formidable social handicap; and, in some, vesicoureteral reflux, hydroureteronephrosis, chronic pyelonephritis, and urolithiasis ultimately result in renal failure (329). In recent years, sophisticated urodynamic evaluation of these children has permitted more precise and rational treatment. In a study by Roach and associates (472), initial urodynamics were predictive of future clinical course in 55% of children. Conversely, the bladder may change over time and necessitate close follow-up. Teichman and colleagues (563) reported that urodynamics did not predict renal deterioration in many myelodysplastic children and argued for an early aggressive approach based on number of urinary infections and presence of vesicoureteral reflux. During the first 3 years of life, changes in the external sphincter may lead to upper tract deterioration (525). Pharmacologic therapy—often in conjunction with intermittent catheterization—and application of new surgical techniques have rendered many of these patients continent and promoted the preservation of renal function. Other children require bladder reconstruction with continent stoma or periurethral injections to achieve continence.

Spinal dysraphism encompasses a spectrum of anomalies, from the more occult dermal sinus, lipoma of the spinal cord, aberrant roots or fibrous traction bands, and abnormal filum terminale, to the more apparent and generally more serious lesions of the meningocele and myelomeningocele (15). Although the occult forms may be associated with significant NGVD, this discussion is concerned primarily with the more common form encountered by the urologist, which is myelomeningocele. The location of myelomeningoceles is most commonly lumbosacral (42%), thoracolumbar (27%), and sacral (21%); only 10% are in a thoracic or cervical location (268). Some investigators maintain that the level of vertebral defect largely determines the degree of neurologic damage (34), but most studies suggest no correlation between vertebral level and the NGVD. Significant NGVD has been associated with minimum bony defects (15). These disparities can be explained by the various possible neuropathologic lesions, or reorganization of pathways of the spinal cord, which include hydromyelia, syringomyelia, failure of upward migration or tethering of the cord, and dysplasia of the cord. Further, these changes may extend several segments above and below the site of the myelomeningocele. The importance of urodynamic evaluation to determine the precise vesicourethral dysfunction present in an individual patient is apparent.

Caudal Regression Syndrome

The syndrome of caudal regression was described by Duhamel (145) and is currently referred to as VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limbs). In VACTERL syndrome, sacral agenesis, imperforate anus, fusion of the lower extremities, and absence of the genitourinary tract except for the gonads can occur. The disordered embryogenesis appears to occur at the fourth to fifth week of fetal life, when the lumbosacral spine and nephrogenic masses are forming, and the cloacal septum is separating the genitourinary sinus from the rectum. Fortunately, the mostsevere form is rare, but imperforate anus and sacral agenesis are relatively common. Nearly 73% of children with caudal regression syndrome have neurogenic bladder-sphincter dysfunction of sacral agenesis (70). The combination of sacral agenesis and imperforate anus is highly associated with voiding dysfunction.

Imperforate Anus

Several classifications of imperforate anus have been proposed, and that of Santulli and colleagues (495) remains widely used. They classified imperforate anus into four major groups based on the level of the imperforation in relation to the puborectalis muscle or the pelvic floor: low or translevator lesions, intermediate lesions (which are uncommon), high or supralevator lesions, and miscellaneous lesions. In nearly all males with supralevator lesions, a fistulous communication exists between the prostatic urethra and the blind end of the rectal pouch; in females, a rectovaginal fistula is common. Patients with translevator lesions do not have fistulae between the intestinal and urinary tracts; rather, the rectal fistula opens near the posterior scrotal raphe in males and the distal vagina or posterior fourchette in females. Combined openings of the urinary and gastrointestinal tracts also occur.

Patients with supralevator lesions are managed with a diverting colostomy shortly after birth, with the definitive rectal pull-through and repair of rectourethral fistula performed when the child has grown to approximately 25 pounds. Those who have infralevator lesions are treated with a primary anoplasty. All patients should have

uroradiographic studies to detect associated genitourinary anomalies. Patients with supralevator lesions have a 52% to 67% incidence of genitourinary anomalies, but those with infralevator lesions have a 16% to 18% incidence (432).

Sacrococcygeal Teratoma

Sacrococcygeal teratoma is the most common germ cell tumor of infancy. It is associated with vesicoureteral reflux, obstruction of the bladder, and neurovesical dysfunctions. In one series, 12% of children had a neurogenic bladder (465). Nearly 81% of children with presacral involvement have urologic complications. Urodynamics should be performed in all children at presentation to compare with postresection findings because a high incidence of neurovesical dysfunction after surgery has been noted (465). Treatment is based on previous strategies for failure to store or empty.

Cerebral Palsy

For many years, it was believed that cerebral palsy per se did not cause neurovesical dysfunction. However, McNeal and associates (378) and later Decter and colleagues (116) found that up to one-third of children have voiding dysfunction. Urodynamic findings correlated somewhat to neurologic findings, with involuntary bladder contraction being the most common finding. Treatment has been based on symptoms and urodynamic findings. Occult spinal cord pathology has been suggested in the basis of detrusor-sphincter dyssynergia in a few patients. However, this finding may be artifact. Anticholingeric drugs are commonly used, but problems with constipation are especially prevalent. Intermittent catheterization is used for failure to empty.

Nonneurogenic Voiding Dysfunction

A major challenge to the pediatric neurourologist is determining the cause of vesicourethral dysfunction in the child who has no neurologic deficits. These children are seen by the clinician only after voiding difficulties have led to either urinary tract infection or significant social disability. The spectrum of voiding abnormalities is not unlike that of patients with true neurologic disease (5). Thus to label this type of vesicourethral dysfunction as nonneurogenic speaks only to the general neurologic state of the child and not to the problem of vesicourethral dysfunction. Because these patients have no outward indicators for the potential of underlying vesicourethral problems, it becomes important for all clinicians to assess carefully the subtle changes in voiding mentioned by the child or the parents. When in doubt as to the significance of a particular symptom, a simple noninvasive test such as uroflowmetry may better define its importance.

When voiding dysfunction is identified without outward neurologic disease or evidence of spinal dysraphism, confusion abounds as to its cause. Some investigators have suggested an underlying psychologic defect, and others emphasize an occult neuropathy (265,616). Lack of progression and absence of any other neurologic involvement argue against neurologic pathology. Regardless of origin, many of the voiding abnormalities are thought to be related to a disorder of coordination between the detrusor contraction and external sphincter relaxation. Support for a nonneurologic acquired abnormality comes from Bauer and associates (36), who failed to show denervation potentials on raw EMG data obtained from the external sphincter in such children. In addition, many such voiding abnormalities are associated with acquired bowel defects such as encopresis. Also supporting an acquired cause is the fact that many such voiding abnormalities can be corrected by a period of bladder retraining, which may include biofeedback. The full spectrum of voiding dysfunction may be seen, and the diagnostic characteristics are the same as those seen with true neurologic disease (599). Many such patients have subtle but sustained irreversible damage to the detrusor, resulting in myogenic decompensation. In others, vesicoureteral reflux may have developed, and surgical repair will be necessary to ensure adequate bladder emptying (521). In all such patients, therapy should be designed to promote adequate bladder emptying and an acceptably low voiding pressure to protect the upper urinary tracts.

Those with urgency, frequency, and wetting related to vesicourethral incoordination are ideally suited to bladder retraining with the biofeedback methods. However, those with significant failure-to-empty defects may be better managed with conventional techniques of intermittent catheterization, with or without the use of adjunctive pharmacologic agents. The length of therapy in both categories of patients is dependent on the degree of detrusor decompensation, upper tract disease, and the likelihood of relapse into a vesicourethral incoordination state. Regular follow-up is necessary in these patients to ensure that relapse has not occurred and that the upper tracts are being protected.

Psychogenic Voiding Dysfunction

Voiding dysfunction in the absence of organic disease has been classified as psychogenic (294,295). All types of voiding problems are associated with psychologic manifestations. However, which came first—the voiding dysfunction or the psychologic problem—is not always clear. Voiding abnormalities are obviously organic, psychogenic, or indeterminate. Voiding symptoms related to psychologic disturbances range from urinary retention to marked urgency, frequency, and enuresis (341).

Psychogenic Retention

For those patients with defects related to a “failure to empty,” the symptoms may range from acute retention to those suggesting a more chronic course, such as urinary infection or overflow-type incontinence (28,30,141,451). Acute retention is often temporally related to some catastrophic psychologic stress in the patient's life. These patients are often young or middle-aged women. However, some males and children may also demonstrate this phenomenon (274). Such patients may exhibit a propensity for repeated episodes of acute retention with essentially normal voiding in between. In a prospective study from Denmark, the annual incidence of retention in women was estimated to be 7 in 100,000 (285). Only 2 of 18 patients had obstruction, and 9 of 18 had hypocontractility. The cause was indeterminate and possibly psychogenic.

Fowler and co-workers (182) described a syndrome of urinary retention in exclusively premenopausal women, often with polycystic ovaries and urinary retention. EMG recordings from the external sphincter resembled myotomia. Impaired sphincter relaxation has been shown (125). Fowler (185) postulates a local, hormone-dependent channelopathy.

Patients with a chronic pattern continuously maintain considerable residual volumes. A propensity toward urinary infection may be seen, and depending on the degree of retention and presence of incontinence, upper tract disease may develop. The patient may give a history of having been toilet trained at an early age and may exhibit excellent urinary control. Many will be lifelong infrequent voiders and require voiding only one to four times daily. Micturition in such patients may require straining, pushing, or a Credé maneuver to augment emptying. The sensation to void becomes impaired, and the desire to void is noticed only when large volumes occupy the bladder. Periodic “treatments,” such as urethral dilation or internal urethrotomy, may transiently benefit the patient; however, excessive residual urine generally returns.

The pathophysiology of psychogenic retention is open to controversy, but it is much easier to accept in patients with acute retention. It is important to exclude other causes; often viral illnesses are overlooked (451). Theoretically, excessive stimuli, either excitatory or inhibitory, originate in centers above the brainstem and influence coordinated micturition. Speculation exists as to the point at which impairment leading to retention occurs in the cascade of events that takes place during normal micturition. The two most plausible explanations are as follows:

1. Excessive stimulation of the centers of the pyramidal tracts that directly innervate the skeletal muscle urethral sphincter, resulting in a failure of the sphincter to relax in preparation for voiding
2. Inhibition of the autonomic motor nucleus in the brainstem that innervates the bladder body, resulting in decreased detrusor contractility

Urodynamic parameters in patients with acute urinary retention generally reflect decreased detrusor contractility, normal compliance, and slightly elevated urethral closing pressure. After the acute phase resolves, the parameters, including uroflow rate, may be normal. Those with a long-term history of urinary retention will have decreased detrusor contractility, increased compliance, increased intraabdominal pressure during voiding, and reduced average flow rate.

The diagnosis of psychogenically induced urinary retention is one of exclusion, and subtle neurologic or metabolic disease must be excluded (31). It becomes the responsibility of the urologist to coordinate this evaluation and exclude other pathologies. Also, management of the voiding problem must be undertaken along the lines outlined earlier for patients with failure to empty. Psychologic consultation is required when patients have overt psychologic disease or when they fail to understand the potential for a psychologic disturbance as a cause of voiding abnormalities.

Uroradiography, endoscopy, and urodynamics are normal in most of these patients. In a select few, however, micturition may be impaired by functional outflow obstruction (169). Cystometry reflects normal compliance but a decreased functional capacity (464). Occasionally, detrusor instability is seen. Uroflow reflects a small voided volume, and the average rate is decreased. Combined studies including fluoroscopy are best for detecting the functional outlet obstruction syndrome. Voiding

pressure is high and flowrate decreased. There is little if any bladder neck funneling during the detrusor contraction. Thus the condition suggests dyssynergia of the bladder neck and proximal urethra.

It is unclear whether this extreme version of the urgency-frequency syndrome is truly psychogenic, but the lack of associated neurologic disease in most of these patients makes the diagnosis plausible (395). Even in females with detrusor instability, at least one-third of patients who failed to respond to any treatment demonstrate psychoneuroticism on psychiatric evaluation (392). Many of these patients respond, at least temporarily, to measures designed to reduce outflow resistance (459). Internal urethrotomy or bladder neck resection is a last resort and should be performed only in the presence of data substantiating outlet obstruction (157). Even then, results tend to be poor. Botulinum toxin injections into the external urethral sphincter and NO cream have been used without success (183). Results with sacral nerve stimulators have met with some success (163). The goal of such therapy is to reduce voiding pressures and reverse the stimulus that provokes the sensation of urgency. The psychodynamics of the psychogenic urgency-frequency abnormality are similar to the retention syndrome, in that inhibitory or excitatory stimuli from the central nervous system above the brainstem alter the micturition sequence in such a way that either sensation or contraction is impaired.

UROLOGIC MANIFESTATIONS OF SPINAL CORD INJURY

Due to recent improvements in medical care, the outlook for patients with spinal cord injury (SCI) has undergone a transformation. Complete cervical myelopathy was described in the 5,000-year-old Edwin Smith Surgical Papyrus as an “ailment not to be treated” (170). Even at the beginning of the twentieth century, the 2-year mortality rate was 80%. However, the current 12-year survival rate is 85%, a figure that approaches the noninjured survival rate (87). Better urologic care, achieved by improved diagnostic capabilities and better management strategies, has been a major factor in the improved survival. As significant progress has been made in urinary tract management, sexual function and fertility have become prominent concerns (Table 27.1).

TABLE 27.1. PERCENTAGE OF SPINAL CORD–INJURED PATIENTS INDICATING GREAT INTEREST IN AN EDUCATIONAL TOPIC

This chapter begins with a brief overview of SCI, reviews the acute and chronic phases of injury, and introduces the options for management of the neurogenic bladder. The role of urodynamic testing in SCI is then discussed, followed by sections that comprehensively discuss each major method of bladder management. The succeeding sections address the common urologic complications of SCI. The concluding sections address the subjects of sexual dysfunction and infertility in SCI.

Epidemiology of Spinal Cord Injury

Spinal cord injury is surprisingly common, with approximately 10,000 new cases annually. Patients are more often male (82%) and young (59% between 16 and 30 years). The most common causes are motor vehicle accidents (45%), falls (22%), violence (16%), and sports injuries (13%). Midcervical and thoracolumbar injuries are the most common (48).

Level of Injury

The level of SCI is usually described by the neurologic level of injury and the degree of functional impairment. By convention, the neurologic level of injury is the most caudal spinal cord segment with good motor and sensory function (Table 27.2). *Complete* injury exists if there is absent function below the level of injury or only partial preservation of neurologic function no more than three segments below the level of injury. Injury is considered *incomplete* if nonreflex neurologic function is preserved more than three segments below the level of injury. Overall, approximately 50% of spinal cord injuries are complete, and approximately 25% of all patients with SCI fall into each of the following categories: incomplete quadriplegic, incomplete paraplegic, complete quadriplegic, and complete paraplegic. Two classification schemes are commonly used to describe neurologic impairment: the Frankel system and the American Spinal Injury Association (ASIA) Impairment Scale (Table 27.3). Motor strength is usually graded on a five-point scale (Table 27.4). The level of injury is the major determinant of functional capability and independence (Table 27.5).

Key Muscles Determining Motor Level	
C-5	Elbow flexors (biceps, brachialis)
C-6	Wrist extensors (extensor carpi radialis longus and brevis)
C-7	Elbow extensors (triceps)
C-8	Finger flexors (flexor digitorum profundus to the middle finger)
T-1	Small finger abductors (abductor digiti minimi)
L-2	Hip flexors (iliopsoas)
L-3	Knee extensors (quadriceps)
L-4	Ankle dorsiflexors (tibialis anterior)
L-5	Long toe extensors (extensor hallucis longus)
S-1	Ankle plantar flexors (gastrocnemius, soleus)
Key Areas Determining Sensory Level	
C-2	Occipital protuberance
C-4	Supraclavicular fossa
C-5	Top of the acromioclavicular joint
C-6	Lateral side of the antecubital fossa
C-6	Thumb
C-7	Middle finger
C-8	Little finger
T-1	Medial (ulnar) side of the antecubital fossa
T-2	Apex of the axilla
T-3	Third intercostal space (IS)
T-4	Fourth IS (nipple line)
T-5	Fifth IS (midway between T-4 and T-6)
T-6	Sixth IS (level of xiphisternum)
T-7	Seventh IS (midway between T-6 and T-8)
T-8	Eighth IS (midway between T-8 and T-10)
T-9	Ninth IS (midway between T-8 and T-10)
T-10	Tenth IS (umbilicus)
T-11	Eleventh IS (midway between T-10 and T-12)
T-12	Inguinal ligament at midpoint
L-1	Half the distance between T-12 and L-2
L-2	Midanterior thigh
L-3	Medial femoral condyle
L-4	Medial malleolus
L-5	Dorsum of the foot at the third metatarsophalangeal joint
S-1	Lateral heel
S-2	Popliteal fossa in the midline
S-3	Ischial tuberosity
S-4–5	Perineal area (taken as one level)

TABLE 27.2. KEY MUSCLES DETERMINING MOTOR LEVEL AND KEY AREAS DETERMINING SENSORY LEVEL

Frankel System (classifies injury by level of function below the neurologic level of injury)

A. Complete
B. Preserved sensation
C. Preserved but useless voluntary motor function
D. Preserved, useful voluntary motor function
E. Normal sensory and motor function

American Spinal Injury Association (ASIA) Impairment Scale

A. Complete: no sensory or motor function preserved in sacral segments S-4 and S-5
B. Incomplete: sensory but not motor function preserved below neurologic level, extending through sacral segments S-4 and S-5
C. Incomplete: motor function preserved below neurologic level and muscle grade less than 3 in majority of key muscle groups below neurologic level
D. Incomplete: motor function preserved below neurologic level and muscle grade 3 or greater in majority of key muscle groups below neurologic level
E. Normal: normal sensory and motor function

From Maynard FM, et al. International standards for neurological and functional classification of spinal cord injury. rev. Chicago: American Spinal Injury Association, 1996, with permission.

TABLE 27.4. GRADING SCALE FOR MUSCLE POWER

Level of injury	Self-care	Transfers Between Bed and Wheelchair	Mobility
C1-C4 (high tetraplegia)	Dependent on others	Dependent on others	In a manual wheelchair, dependent on others; independent in a motorized wheelchair
C5-C8 (low tetraplegia)	Partially independent with adaptive equipment or totally independent	Dependent on one person with a transfer board or totally independent	Independent in a manual wheelchair either for short distances only or for longer distances outdoors; able to drive an automobile with adaptive equipment
T1-T10 (high paraplegia)	Totally independent	Totally independent	Independent in a manual wheelchair; ambulatory with knee-ankle-foot orthoses, walker, and assistance, for exercise only
T11-L5 (low paraplegia)	Totally independent	Totally independent	Ambulatory for short distances only with knee-ankle-foot orthoses and a walker, or ambulatory for longer distances outdoors with ankle-foot orthoses and canes

[a]The level of injury refers to the last normal root above the injured portion of the spinal cord. Self-care refers to feeding, dressing, and bathing. From DiBenna JF Jr, Formal CS. Chronic spinal cord injury. N Engl J Med 1994;330:550, with permission.

TABLE 27.5. EXPECTED LEVEL OF FUNCTIONING ACCORDING TO THE NEUROLOGIC LEVEL OF INJURY[a]

Spinal Cord Syndromes

Several syndromes exist with unique and characteristic features. *Central cord syndrome* results from hemorrhagic necrosis of central gray matter and medial white matter with relative preservation of laterally located distal tracts. This produces sacral sensory sparing and motor weakness that is typically greater in the upper extremities—sometimes called *upside-down quadriplegia.* It is seen with cervical extension injuries, particularly in the elderly, and in patients with cervical stenosis. *Brown-Séquard syndrome* results from asymmetric lesions and produces contralateral defects in pain and temperature sensation and motor weakness. *Anterior cord syndrome* results from a lesion in the region supplied by the anterior spinal artery. This can be seen in flexion injuries, acute central herniations of the nucleus pulposus, and vascular insults. Sparing of the posterior columns and dorsal horns produces weakness and loss of pain and temperature sensation below the level of injury. *Cauda equina–conus medullaris syndrome* results from injuries below the thoracolumbar junction. It involves injury to the sacral cord (conus) and lumbosacral roots and produces flaccid weakness due to lower motor neuron dysfunction. Sacral reflexes are lost (63).

ACUTE PHASE

Acute spinal cord injury is followed by a period of spinal shock lasting 2 to 12 weeks. During this period, patients exhibit detrusor areflexia. Most patients are initially managed by urethral catheter drainage. Once the patient is stabilized, alternative forms of management may be initiated. In the 1980s, there was a period of enthusiasm for early placement of a suprapubic (SP) tube (111), but this is no longer a common practice. One study suggests that short-term management choice during the recovery period produces no real difference in the long term (91), but most think that clean intermittent catheterization is preferable. Intermittent catheterization is usually done every 4 hours with the goal of maintaining maximum bladder volumes less than 500 mL (167). As the spinal shock phase resolves, patients usually display an evolving pattern of bladder dysfunction. Significant changes may continue to occur up to 6 months after injury. Because of recent trends toward shorter hospitalization, the challenge of accommodating the changing pattern of function often extends past the time of discharge (49).

CHRONIC PHASE

The upper motor neuron (UMN) lesion produces an initial flaccid paralysis of the bladder and lack of reflex activity below the level of the lesion. Some sphincter activity appears to persist throughout the acute period, accounting for the maintenance of resting urethral sphincter pressure and continence (125). Recovery of detrusor function usually follows return of the bulbocavernosus reflex and deep tendon reflexes below the level of injury. During the recovery phase, detrusor reflex activity manifests as poorly sustained low-pressure contractions. Depending on the integrity of the sphincter, contractions of increasing pressure may or may not

cause leakage between catheterizations. Over time, the pattern of reflex activity may progress to higher-pressure contractions and the patient may begin to void (174). Some patients with incomplete SCI recover the ability to void voluntarily. However, in the absence of perineal pinprick sensation and position sense of the great toe, recovery of voluntary bladder control is unlikely (165). Loss of pons-mediated coordination between the detrusor and sphincter can produce functional obstruction with diminished and interrupted urine flow and incomplete emptying (16,112,167,171).

The appearance of reflex detrusor activity appears to involve a complex reorganization of the micturition reflex. In the neurologically intact individual, A-delta fibers are the afferent pathway activated by bladder distention. C-fiber afferents exist and are activated by cold or chemical irritation; however, they are normally quiescent (43). Following SCI, there is hypertrophy of the C-fibers and emergence of a short-latency, C-fiber–mediated reflex contraction of the detrusor in response to bladder filling. The emergence of the C-fiber afferents appears to be a major factor in development of reflex detrusor activity and is probably the reason that ice water instillation can trigger detrusor contraction in the chronic SCI bladder and why capsaicin, a neurotoxin specific for the C-fiber afferents, can inhibit this reflex detrusor activity (174).

The lower motor neuron (LMN) lesion also produces initial areflexia. In contrast to the upper motor neuron lesion, areflexia typically persists even after the resolution of spinal shock. This may be complicated by sphincteric deficiency or the development of diminished compliance (64,99,162).

The chronic phase of SCI is not necessarily a static phase. Over time, there may be a continued evolution of bladder dysfunction. The marked thickening and trabeculation of the bladder that occurs in a patient with uncontrolled detrusor activity is a finding familiar to all urologists. An emerging concept is that changes in the end-organ function may influence the neural regulation of the bladder (Fig. 27.1). This provocative concept suggests that uninhibited detrusor activity, functional obstruction or loss of compliance, and elevated bladder pressures may contribute—by a mechanism of neural plasticity—to progressively worsening hyperreflexia and loss of compliance. Both UMN and LMN lesions can produce an evolving pattern of bladder dysfunction, and for this reason all patients with SCI require lifelong urologic follow-up. Patients should be seen at least annually for the first several years after injury. Those who are considered at low risk for upper tract deterioration and are stable over the first several years may be followed biannually. Those who are at higher risk of upper tract complications because of a high-pressure bladder or indwelling catheter, those who exhibit progressive changes in the pattern of bladder dysfunction on annual cystometry, and those with new bladder symptoms or symptomatic infection require more frequent evaluation. The annual evaluation should include an upper tract study (ultrasound), urinalysis, urine culture if a urea-splitting bacterial infection is suspected on the basis of an alkaline urine pH, and appropriate urodynamic testing.

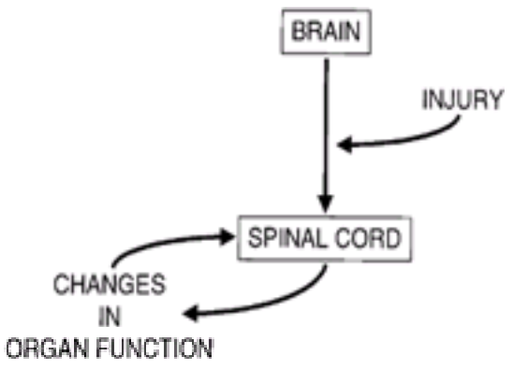

FIGURE 27.1. Reciprocal influences between the bladder and spinal cord below the level of injury contribute to reorganization of the spinal reflex circuitry following spinal cord injury. OPTIONS FOR BLADDER MANAGEMENT: AN OVERVIEW

Many SCI patients are managed by an indwelling urethral catheter. Others elect to have a suprapubic catheter placed, some wear external catheters, and others perform clean intermittent catheterization. Sekar and colleagues (132) reported the method of management at discharge in 913 patients: indwelling catheter (20%), condom catheter (31%), Credé (5%), intermittent catheterization (33%), and normal voiding (12%). Usually, the method of management is determined by the motivation and functional limitations of the patient, the availability of caregivers, and the counseling provided by the rehabilitation team (Table 27.6). The management options and important ancillary measures for patients with UMN and LMN bladder dysfunction are summarized in Table 27.7. Men and women with neurologic impairment face different challenges in the selection of long-term management strategies and therefore are discussed separately. The details of each management strategy, associated issues, and potential complications are discussed later in this chapter.

TABLE 27.6. CONSIDERATIONS IN SELECTING METHOD OF BLADDER MANAGEMENT: PATIENT FACTORS AFFECTING OUTCOME

TABLE 27.7. OPTIONS FOR LONG-TERM BLADDER MANAGEMENT[a]

Men

In the 1970s and 1980s, it was said that the "ultimate goal of bladder management in the SCI patient is the resumption of a balanced bladder" (112). The so-called balanced bladder was one defined as having low voiding pressures, no outlet obstruction, and low residual volume (less than 100 mL). This was considered an

achievable goal in 80% of SCI patients (112). Patients were usually managed by intermittent catheterization until spontaneous voiding returned and balanced bladder function was achieved. Men managed this way usually wear a condom catheter. Others transfer to toilet and either initiate a voiding reflex with suprapubic tapping (UMN injury) or, because of detrusor areflexia and diminished sphincter tone (LMN injury), empty by Valsalva or Credé maneuver (62,101). Despite the observation that a catheter-free state was associated with a lower rate of urologic complications than with indwelling catheter or diversion (113,127), enthusiasm for the balanced bladder diminished because of frequent problems with incomplete emptying, infection, vesicoureteral reflux, and hydronephrosis. Intermittent catheterization has become the strongly preferred long-term management option for patients who can perform intermittent catheterization independently or who have a dedicated caregiver available and willing to perform catheterization. This preference is based on the finding that well-managed patients performing intermittent catheterization have a higher quality of life and lower incidence of serious urologic complications than patients managed by other methods. The indwelling Foley catheter or suprapubic tube is often a last resort for patients with high spinal cord lesions who are unable to perform intermittent catheterization or wear an external catheter. The potential complications associated with a permanent indwelling catheter are myriad. A suprapubic tube offers selective advantages in minimizing risks of urethral injury, recurrent epididymitis, and prostatitis, but it does not reduce the incidence of symptomatic urinary tract infection (UTI), stones, or bladder cancer. For properly selected patients, urinary diversion by ileocystostomy (bladder chimney) is a superior option.

Women

Women with SCI pose a particular challenge because of the relative inaccessibility of the urethra and the lack of external collecting devices. Spontaneous voiding is used by some women despite the lack of a usable external collection device (21). Some patients are able to transfer to the toilet and void by induced reflex, Credé maneuver, or straining or with the use of an implantable neurostimulator. Patients who either cannot transfer or who cannot establish a predictable voiding schedule elect to wear absorbant pads. This clearly has drawbacks, including chronic wetness, *Candida* rashes, and risk of skin breakdown. Intermittent catheterization is the preferred option, but many patients need to transfer in order to perform urethral catheterization. Construction of a continent abdominal stoma makes intermittent catheterization an option for many patients for whom it would not otherwise be possible (8,98,135). Use of an indwelling urethral catheter in women is associated with the same risks and complications as in men. In addition, urethral erosion and loss of sphincter function occurs frequently and results in chronic leakage around the catheter (8,98,135). Suprapubic cystostomy may offer an advantage in avoiding this specific complication. In several reported series, the percentage of patients managed by the different methods varied significantly: reflex voiding (39%); intermittent catheterization (10% to 65%); and indwelling catheter (31% to 48%) (98,135).

Urodynamics

Why Test?

Urodynamic testing is the basis for understanding and managing neurogenic bladder dysfunction. The insights it has provided have led to revolutionary changes in bladder management over the past several decades. In current clinical practice, the use of information provided by urodynamic testing to optimize bladder management is the primary means to eliminate leakage, reduce the incidence of symptomatic UTI, and avoid upper tract deterioration. This section presents the rationale for routine urodynamic testing, reviews the important methodologies, identifies the risk factors for upper tract deterioration, and describes the role of urodynamic testing in patient management.

Most patients with SCI are attended primarily by physicians specialized in physical medicine and rehabilitation. In many centers, urologic consultation and urodynamic testing are not routine elements of the rehabilitation program. Patients are managed empirically. In patients managed with a condom catheter, bladder emptying is assessed by either bladder scanning or catheterization. In patients managed with intermittent catheterization, symptoms such as autonomic dysreflexia or leakage between catheterizations often prompt treatment for a presumed UTI and empiric anticholinergic therapy. Urologic consultation and urodynamic testing are reserved for patients who continue to have problems with leakage, recurrent symptomatic infections, worsening spasms or autonomic dysreflexia, or hydronephrosis. Although this approach works reasonably well for many patients, there is a compelling argument that *proactive* bladder management guided by urodynamic testing maximizes quality of life, preserves bladder function, and reduces long-term risks. This argument is based on three principles.

1. The first principle is that bladder behavior cannot be accurately predicted from the level of injury. The spinal cord micturition center is located between S-2 and S-4 and is focused primarily at S-3. This is generally located anatomically at vertebral level L-1, although there is some individual variation in the correlation of cord level to vertebral column anatomy. In general, complete suprasacral cord injury results in detrusor hyperreflexia (DH). This is often accompanied by striated-sphincter dyssynergia [detrusor external-sphincter dyssynergia (DESD)]. Smooth muscle sphincter dyssynergia [detrusor bladder-neck dyssynergia (DBND)] may also occur. Complete sacral spinal cord injury below the micturition center usually produces detrusor areflexia (DA), a competent but nonrelaxing smooth muscle sphincter, and a striated sphincter that may retain tone but is not under voluntary control (Fig. 27.2). However, these generalizations cannot be relied on for individual patient management (16,75,164). Among 284 patients with spinal cord lesions, 15% of patients with cervical lesions had detrusor areflexia and 24% of patients with sacral cord lesions had detrusor hyperreflexia (Table 27.8). The proposed reasons for the lack of correlation include individual anatomic variation, the presence of incomplete lesions, and the presence of occult secondary cord lesions.

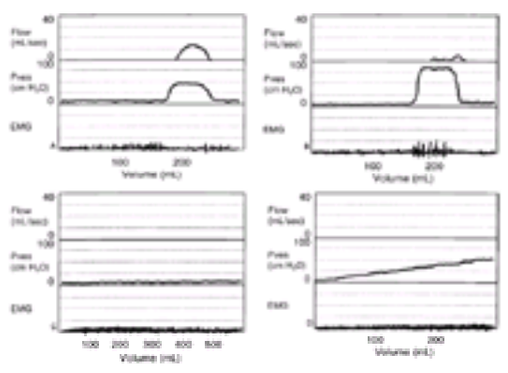

FIGURE 27.2. Major forms of neurogenic bladder dysfunction. **A:** Detrusor hyperreflexia (DH). Uninhibited detrusor contractions during bladder filling or uninhibited voiding reflex with synergistic relaxation of the external sphincter during voiding. **B:** Detrusor hyperreflexia with detrusor external-sphincter dyssynergia (DH/DESD). Uninhibited detrusor contractions during bladder filling or uninhibited voiding reflex with dyssynergic behavior of the external sphincter. This is seen in most patients with cervical and thoracic spinal cord injury. DESD may coexist with dyssynergia of the internal sphincter (bladder neck). **C:** Detrusor areflexia (DA) occurs most often in those with lumbar and sacral-level injuries. **D:** Diminished compliance may occur in combination with either DH or DA. It is most common in patients with thoracolumbar injuries.

Spinal Cord	Normal (%)	Detrusor Hyperreflexia with Detrusor External-sphincter Dyssynergia (%)	Detrusor Hyperreflexia Without Detrusor External-sphincter Dyssynergia (%)	Detrusor Areflexia (%)
Cervical (n = 104)	1	55	30	15
Thoracic (n = 87)	1	90	10	0
Lumbar (n = 61)	1	30	30	40
Sacral (n = 32)	12	12	12	64

TABLE 27.8. URODYNAMIC FINDINGS IN 284 SPINAL CORD–INJURED PATIENTS

2. The second principle is that “the bladder is an unreliable witness” (15). The gross clinical measures of bladder function—voided volume, postvoid residual, and continence—are not reliable indicators for detecting serious underlying problems. Diminished compliance, for example, may be completely asymptomatic yet

cause hydronephrosis and irreversible renal insufficiency. Low compliance has been estimated to occur in as many as 17% of patients and is more common in patients with thoracolumbar injuries (65). Similarly, elevated voiding pressures may also be relatively asymptomatic and yet predispose a patient to upper tract changes, infection, and reflux. Reliance on clinical impression can be particularly misleading in patients with thoracolumbar injuries where diminished compliance and significant voiding dysfunction may exist with minimal neurologic deficit (160,161).

3. The third principle is that urodynamic testing can identify patients with increased storage pressures or increased outlet resistance for whom early intervention will avert upper tract complications and prevent a progressive deterioration in bladder function. In patients who void involuntarily or by reflex voiding (e.g., suprapubic tapping), the key goals are to maintain low storage pressure (less than 40 cm H_2O) at capacity, low voiding pressures, and acceptable bladder emptying (100). Urodynamic testing identifies potential risk factors and allows tailored intervention (e.g., sphincterotomy) to optimize bladder function. In patients performing intermittent catheterization, urodynamic testing identifies those with dangerously high storage pressures (greater than 40 cm H_2O at capacity), as well as those with more modest degrees of diminished compliance or significant uninhibited detrusor activity. Early intervention to address these problems may prevent progressive hypertrophy, bladder wall fibrosis, gradual loss of functional capacity, and worsening compliance.

When to Test

Urodynamic testing has little practical value during the acute and recovery phases of SCI. The initial selection of a long-term management strategy is generally made according to the patient's preference, neurologic level of function, and level of support at home. Because significant changes in bladder function may occur between 3 and 6 months after injury (125), testing is reasonably deferred until 6 months after injury.

How to Test

Urodynamic testing is an invasive test that should be done only in the absence of bacteriuria. For patients who are chronically colonized, pretreatment with antibiotics is necessary to clear bacteriuria before testing. This is ideally based on culture and sensitivity obtained before testing. When this is not feasible, the patient may be treated for 2 days before testing with a fluoroquinolone antibiotic and the urine examined before testing (41).

The nature of the urodynamic testing performed will depend on the equipment available (160). Cystometry performed with water is the single most useful test, allowing evaluation of compliance and capacity. When combined with electromyographic (EMG) monitoring, DESD can usually be identified as well. Fluoroscopy is a valuable adjunct that permits the examiner to make an unequivocal diagnosis of DESD by narrowing of the membranous urethra and dilation of the prostatic urethra (Fig. 27.3), to rule out bladder neck obstruction, identify bladder diverticula, and demonstrate vesicoureteral reflux. Transrectal ultrasound imaging of the bladder outflow tract has been used in lieu of fluoroscopic imaging to identify DESD but has not achieved great popularity (13). Rectal pressure monitoring is useful in patients who void voluntarily to evaluate the component of straining, but it is not required for most patients with SCI. Similarly, urethral pressure profilometry is generally unnecessary. Endoscopic evaluation is not a routine component of urodynamic evaluation but is sometimes required for evaluation of hematuria, stricture, or false passage or to rule out bladder stone. It may be performed at the same visit. In men, both cystometry and flexible cystoscopy can be performed with the patient seated in a wheelchair (7,53,121). It is important to recognize the potential for autonomic dysreflexia to occur in patients with high SCI, to appropriately monitor for this and to stop testing and decompress the bladder if signs or symptoms of dysreflexia occur.

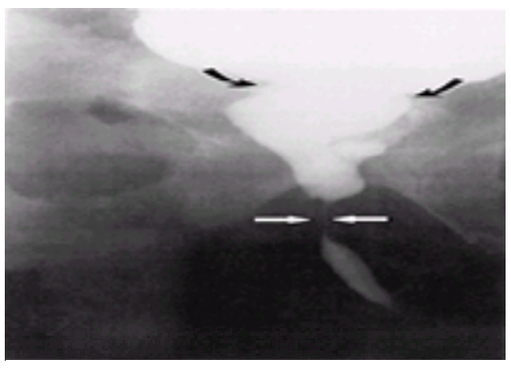

FIGURE 27.3. Detrusor external sphincter dyssynergia. Voiding cystourethrogram demonstrating detrusor external-sphincter dyssynergia (DESD) without bladder neck obstruction. *Straight arrows* denote the narrowed external sphincter. *Curved arrows* point to the open bladder neck. (From Chancellor MB, Rivas DA, Abdill CK, et al. Prospective comparison of external sphincter balloon dilatation and prosthesis placement with external sphincterotomy in spinal cord injured men. *Arch Phys Med Rehabil* 1994;75:297, with permission.)

Filling cystometry is used to determine sensation to bladder filling, compliance, and capacity. A gradual but progressive increase in intravesical pressure indicates significantly diminished compliance. For patients with diminished compliance, intravesical pressure may rise gradually and progressively to the point where leakage occurs (i.e., where detrusor pressure exceeds sphincteric resistance). The detrusor pressure at which leakage occurs is termed the *detrusor leak-point pressure* (DLPP). If detrusor contractions occur during filling, the pressure and duration of the contractions, the volume at which these occur, and the presence or absence of associated urine flow are noted. Patient perceptions (urge, symptoms of dysreflexia, or lower extremity spasm) should be recorded. If a patient voids reflexively, filling is continued until voiding occurs and voiding pressure, flow rate, and postvoid residual (PVR) are noted. EMG or fluoroscopy can be used to identify sphincter dyssynergy. The urodynamic evaluation is often tailored to address a patient's specific clinical issues. If the patient experiences leakage between catheterizations, the integrity of the sphincter may be assessed by determining the Valsalva leak-point pressure (VLPP) at 150 to 200 mL of filling. This may be done by having the patient cough, perform the Valsalva maneuver, or lift up as during self-transfer. For patients with cervical or upper thoracic injuries who cannot cough or perform the Valsalva maneuver adequately, the examiner may apply direct pressure over the bladder and determine the Credé-induced leak-point pressure. Leakage during these provocative maneuvers usually indicates sphincteric deficiency, and by a series of graded efforts, the VLPP can be estimated.

Risk Factors for Upper Tract Deterioration

Upper tract deterioration occurs in 9% to 40% of patients with SCI (90). This usually occurs from obstruction at the ureterovesical junction (UVJ). Increased resistance at the UVJ from muscular hypertrophy or fibrosis is uncommon, and it can be distinguished by resolution of the hydroureteronephrosis with stenting and catheter drainage but not catheter drainage alone. More commonly, obstruction at the UVJ results from increased bladder pressure. An intravesical pressure of approximately 40 cm H_2O impairs upper tract emptying. Hydronephrosis develops when intravesical pressure exceeds this threshold for significant periods of time either as a result of diminished compliance or from sustained, high-pressure detrusor contractions (Fig. 27.4). Wyndaele (170) suggested that maximum detrusor pressures of 70 cm H_2O or greater caused upper tract damage. Gerridzen and colleagues (58) found that among patients with areflexia, those showing upper tract changes had an average maximum detrusor pressure of 58 cm H_2O compared with 24 cm H_2O in those without changes. They also found that among patients with hyperreflexia, elevated voiding pressures were associated with upper tract changes (115 versus 72 cm H_2O). Linsenmeyer and colleagues (90) reviewed 84 consecutive patients managed by reflex voiding and found that a longer duration of detrusor contraction was significantly correlated with upper tract stasis.

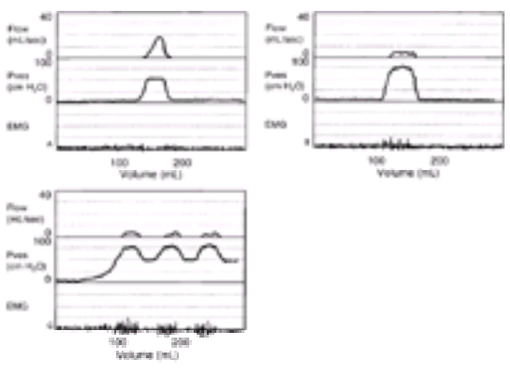

FIGURE 27.4. Cystometry reveals relative risk for upper tract deterioration. Three voiding patterns are observed during cystometry. **A:** Patient 1 exhibits detrusor hyperreflexia (DH) with voiding at modest pressures. **B:** Patient 2 exhibits DH with detrusor external-sphincter dyssynergia (DESD): Voiding occurs at high detrusor pressure. **C:** Patient 3 exhibits DH with DESD in combination with diminished compliance. Patient 3 is at greatly increased risk for upper tract deterioration because poor emptying (due to DESD) combined with diminished compliance results in persistently elevated storage pressures.

The reported incidence of vesicoureteral reflux in the SCI population ranges from 13% to 25% (90). Reflux is often attributed to increased intravesical pressure, but anatomic predisposition may be a critical factor. Linsenmeyer and colleagues (90) found no difference in any urodynamic parameter between four patients who voided reflexively with reflux as compared with patients who did not reflux. Three of the four were considered to have abnormal-appearing ureteral orifices on cystoscopy. Anatomic predisposition to reflux may be either congenital or acquired as a result of chronic inflammation, infection, bladder hypertrophy and fibrosis, or denervation of bladder and ureter. From these observations, it may be inferred that some patients have reflux that will resolve with lowering of bladder pressures, and others have reflux that may persist even at low intravesical pressures.

Role of Testing in Patient Management

The purpose of urodynamic testing is to identify patients at risk for upper tract deterioration and to optimize bladder management. Among patients with so-called balanced bladder managed by spontaneous voiding, urodynamic evaluation will identify patients with diminished compliance, elevated DLPP (greater than 40 cm H_2O), or incomplete bladder emptying. These findings may be used to direct pharmacologic or surgical intervention to moderate uninhibited detrusor activity, eliminate high-pressure storage, and improve bladder emptying (Table 27.9).

Compliance	Detrusor Leak-point Pressure (DLPP)	Postvoid Residual	Risk of Hydronephrosis
Normal	Low (<40 cm H_2O)	Low	-
Normal	Low	High	+
Normal	High (>40 cm H_2O)	Low	+
Normal	High	High	++
Low	Low (<40 cm H_2O)	Low	+
Low	High (>40 cm H_2O)	Low	++
Low	High	High	+++

In patients with normal compliance, the risk of hydronephrosis is greater with the combination of high DLPP and incomplete emptying. This combination can result in frequent, high-pressure contractions that produce chronically elevated intravesical pressure. In patients with low compliance, the risk of hydronephrosis is substantial whenever sphincteric resistance (DLPP) exceeds 40 cm H_2O. The risk is greatest when patients do not void the bladder by discrete detrusor contraction but simply "overflow" at the DLPP.

TABLE 27.9. IMPLICATIONS OF URODYNAMIC FINDINGS FOR BALANCED BLADDER/REFLEX VOIDING

Among patients managed by intermittent catheterization, cystometry will identify patients at risk for upper tract deterioration because of diminished compliance, a competent sphincter (DLPP greater than 40 cm H_2O), or sustained high-pressure detrusor contractions during filling. Urodynamic evaluation can direct intervention to prevent leakage between catheterization. Cystometry may identify uninhibited detrusor activity amenable to pharmacologic treatment (e.g., anticholinergic). In other patients, cystometry may reveal diminished compliance as a major factor and direct alternative pharmacotherapy (e.g., a-adrenergic blocker) or surgical intervention (augmentation cystoplasty). In still others, testing will identify sphincteric weakness as the cause of leakage (Table 27.10).

Compliance	Detrusor Hyperreflexia	Detrusor Leak-point Pressure (DLPP)	Risk of Hydronephrosis	Risk of Incontinence
Normal	No	High (>40 cm H_2O)	-	-
Normal	Yes	High	+	++
Normal	No	Low (<40 cm H_2O)	-	+++
Normal	Yes	Low	-	++++
Low	No	High (>40 cm H_2O)	++++	-
Low	Yes	High	++++	++
Low	No	Low (<40 cm H_2O)	+	+++
Low	Yes	Low	+	++++

In patients with normal compliance, the risk of upper tract deterioration is generally low. Reflux or upper tract changes may occur in patients with sustained, high-pressure detrusor contractions and a competent sphincter (high DLPP). Incontinence results either from uninhibited detrusor contractions or from sphincteric deficiency (low DLPP).
In patients with low compliance, the risk of hydronephrosis is substantial when the sphincteric resistance (DLPP) exceeds 40 cm H_2O. Low-sphincteric resistance protects against hydronephrosis but results in greater incontinence.

TABLE 27.10. IMPLICATIONS OF URODYNAMIC FINDINGS FOR INTERMITTENT CATHETERIZATION

I am not aware of any published data showing a value of routine urodynamic studies in patients with an indwelling catheter. Many patients with a long-term catheter show diminished compliance or capacity. One study suggested a benefit of anticholinergic medication in maintaining more favorable urodynamic characteristics (increased compliance, lower leak-point pressure) (78). Cystography can identify patients with reflux, a finding that may be relevant in patients with repeated febrile UTI, but there are few published data to support surgical correction of reflux in this situation.

METHODS OF BLADDER MANAGEMENT

This section discusses the major forms of bladder management, including reflex or balanced voiding, intermittent catheterization, indwelling catheter drainage, and continent and incontinent urinary diversion. Each section provides detailed information on management issues, common complications, and strategies to reduce patient risk.

Balanced Voiding

Reflex or induced voiding remains a widely used method of bladder management. It is most appropriate for men with reflex voiding who are able to wear a condom catheter and for both men and women who can transfer to toilet and initiate a voiding reflex by suprapubic tapping (101). It may also be used in selected patients with detrusor areflexia and diminished sphincter tone who can empty by Valsalva or Credé maneuvers (62). However, reflex voiding as a method of bladder management is associated with a number of problems. Bacteriuria is common, especially in men using a condom catheter. In one study, a catheterized specimen revealed bacteriuria in 53% of patients. One-third of those with positive cultures grew multiple isolates (110). Incomplete emptying combined with bacteriuria creates the potential for symptomatic UTI and stone formation. There is a 3% to 30% incidence of cutaneous complications, including redness, excoriation, swelling, and ulceration of the penile skin. The frequency of condom change (daily versus alternate day) does not appear to affect the incidence of cutaneous or urologic complications (140). There are often problems keeping a condom catheter in place. Some men develop a retracted penis or a protruding suprapubic fat pad. Placement of a semirigid penile prosthesis can help, but this increases the risk of complications due to patients' limited mobility and impaired sensation (155). Women who use pads as a means of urine collection are at risk for skin breakdown and decubitus ulceration (8). In one study, more than 10% of patients managed by reflex voiding developed severe hydronephrosis or reflux (152). This occurs because of diminished compliance or from a combination of detrusor hyperreflexia and DESD. If patients void by Credé or Valsalva maneuver, intravesical pressures during voiding must exceed the resistance of the bladder outlet, which may increase paradoxically (4). Voiding pressures can be very high (95 to 160 cm H_2O) in patients with a functional continence mechanism and can produce vesicoureteral reflux

and hydronephrosis (62).

Patients managed with balanced bladder function require diligent annual follow-up. Patients who have detrusor hyperreflexia without DESD, low-pressure voiding, and low residual are at low risk for complications. Patients who have detrusor hyperreflexia with DESD or low compliance are at higher risk for upper tract complications or poor bladder emptying (Table 27.9). All patients should be followed annually with urinalysis, renal ultrasound, and postvoid residual urine measurement. Annual urodynamic evaluation is recommended for all patients, but it is particularly critical for those at higher risk. In cases of high-pressure storage or voiding, early intervention to reduce storage or voiding pressures should be considered (137).

In summary, this is a convenient and workable option for the patient who maintains low intravesical pressure during urine storage and empties well. However, enthusiasm for this form of management has to be tempered. Over the long term, many patients develop problems with incomplete emptying and elevated intravesical pressures that cause recurrent UTI, vesicoureteral reflux, and hydronephrosis. External sphincterotomy has traditionally been used to correct this, but the long-term success rate of sphincterotomy is disappointing. Many patients continue to empty poorly after sphincterotomy or require repeat sphincterotomy, and many patients abandon condom catheter drainage on long-term follow-up.

A number of topics relevant to balanced or reflex voiding are addressed in the following sections. These include external sphincter and bladder neck dyssynergy; treatment of dyssynergia by sphincterotomy, sphincteric stenting, and botulinum toxin injection; and the use of an implantable anterior root neurostimulator in combination with posterior rhizotomy to restore volitional voiding.

Sphincter Dyssynergy

In patients with SCI, discoordination between the sacral and pontine mesencephalic micturition centers can produce dyssynergia between the bladder and sphincter. Early testing of patients after suprasacral SCI reveals that sphincter muscle activity is present very early after injury but shows an evolving pattern of interaction with the detrusor over the first several months after injury. Voiding efficiency is maximal at 12 weeks and diminishes thereafter (125). DESD has been termed an *abnormal continence reflex,* a variant of the normal increase in sphincter activity that accompanies bladder filling (125). Blaivas and colleagues (17) postulated that DESD results when the increase in intravesical pressure that accompanies a detrusor contraction increases firing of the pelvic nerve afferents and triggers contraction of the external sphincter. Electromyographic recordings from patients with DESD confirm that increased sphincter EMG activity occurs with an increase in intravesical pressure and abates during the negative slope (decrescendo) phase of the detrusor contraction (125). Clinically, three major patterns of DESD are recognized (Fig. 27.5). DESD can produce high-pressure voiding and incomplete emptying. DESD associated with elevated maximum detrusor pressure has been associated with at least a 50% incidence of urologic complications, including sepsis, hydronephrosis, reflux, stones, and renal insufficiency (29).

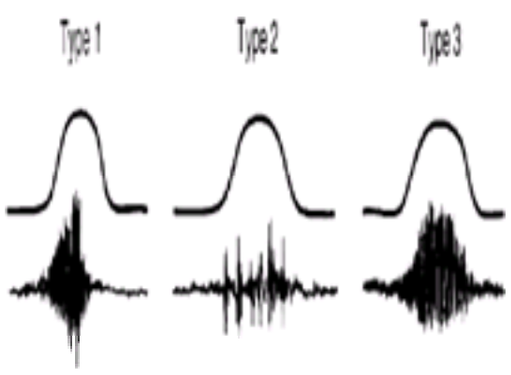

FIGURE 27.5. Three types of detrusor external-sphincter dyssynergia. Type 1 dyssynergia is characterized by a crescendo increase in electromyographic activity that reaches its maximum at the peak of the detrusor contraction. As the detrusor pressure began its decline, there was sudden complete external-sphincter relaxation. Voiding occurs only during the downslope of the detrusor pressure curve. Type 2 dyssynergia is characterized by clonic contractions of the external urethral sphincter interspersed throughout the detrusor contraction. These patients usually void with an interrupted, spurting stream. In type 3 dyssynergia, the external urethral sphincter contraction persisted throughout the entire detrusor contraction. These patients void with an obstructive flow or do not void at all. (From Blaivas JG, Sinha HP, Zayed AAH, et al. Detrusor external sphincter dyssynergia: a detailed electromyographic study. *J Urol* 1981;125:545, with permission.)

DBND may coexist with DESD. Schurch and colleagues (129) evaluated 34 patients with upper motor neuron lesions and found that 32 had DESD and 25 had DBND. DBND coexisted with DESD in all cases but persisted even when DESD was abolished by pudendal nerve block. It is usually stated that DBND occurs only with complete suprasacral cord injury above T-6; however, Schurch and colleagues (129) found that DBND was not confined to patients with lesions above T-6. They found a high incidence among patients with cervical lesions, but also observed it in patients with both upper and lower thoracic lesions. In a study of 43 patients, Krongrad and colleagues (82) found a higher incidence of DBND in both high and low thoracic lesions (approximately 25% each) than in cervical lesions (7%).

Role of Sphincterotomy

Transurethral procedures to relieve functional outlet obstruction in SCI were introduced over 50 years ago (39,52,124). Currently, DESD is surgically treated by transurethral sphincterotomy (Fig. 27.6). This is usually performed by a single incision completely transecting the sphincter muscle at 12 o'clock (79). This requires an incision at least 2 cm long and 6 mm deep (155). The 12 o'clock position has been found to be associated with fewer complications of hemorrhage and impotence. Completeness of the sphincterotomy may be assessed intraoperatively by performing the bulbocavernosus reflex and demonstrating loss of the sphincter contraction. Because DBND and DESD may coexist, some have recommended empiric transurethral resection or incision of the bladder neck in combination with external sphincterotomy (1), but this is controversial. Most reserve treatment of the bladder neck for patients who are diagnosed with bladder neck obstruction on videourodynamic study either initially or following a previous external sphincterotomy. Although Schurch and colleagues (129) found that DBND always coexists with DESD, Al-Ali and Haddad (1) reported good results when bladder neck resection was performed without external sphincterotomy in patients with incomplete, low thoracic lesions.

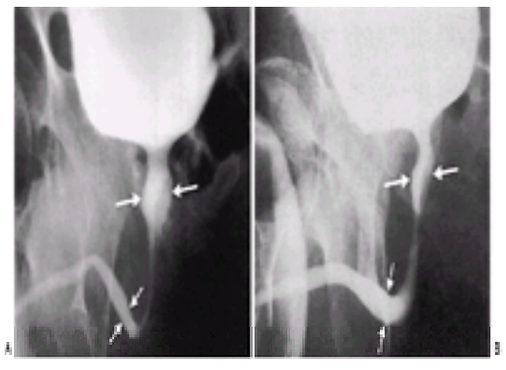

FIGURE 27.6. Effect of sphincterotomy. Comparison of voiding cystourethrogram before **(A)** and after **(B)** transurethral external sphincterotomy. Postoperatively, there is an increase in urethral diameter in the region of the external sphincter. Also note the decrease in dilation of prostatic urethra *(large arrows)* and slight increase in diameter of the infrasphincteric bulbous urethra *(small arrows)* following surgical ablation of the external sphincter. (From Fontaine E, Hajri M, Rhein F, et al. Reappraisal of endoscopic sphincterotomy for post-traumatic neurogenic bladder: a prospective study [see comments]. *J Urol* 1996;155:277, with permission.)

There has been considerable debate over the indications for sphincterotomy and the appropriate measure(s) for judging the success of the procedure. Many have

used a high PVR as an indication for surgery and judged success or failure by the change in PVR (155). Others have argued that febrile infections and upper tract complications are more likely related to high intravesical pressures and pointed out that sphincterotomy may be successful in reducing high intravesical pressures without necessarily decreasing the PVR (155). Several authors have found an increased rate of complications in patients with DLPP greater than 40 cm H_2O, suggesting that the primary goal of sphincterotomy should be to reduce outlet resistance to less than 40 cm H_2O (74,79). Regardless of which measure is used, most patients show improvement after sphincterotomy. In a prospective study of 92 patients with a 20-month mean follow-up, Fontaine and colleagues (55) reported an overall 84% objective improvement after sphincterotomy. Mean voiding pressure decreased from 82 to 41 cm H_2O, and mean PVR decreased from 210 to 101 mL.

Some patients fail to improve after sphincterotomy, and others show only temporary improvement. Early failure is most often due to poor detrusor contractility. In a review of 60 patients who underwent sphincterotomy, Lockhart and colleagues (93) reported 15 failures. Detrusor acontractility or hypocontractility was the cause of failure in 11 of the 15 patients. Urodynamic testing can identify some patients with areflexia or detrusor hypocontractility preoperatively; however, some patients appear to develop hypocontractility or acontractility *de novo* after sphincterotomy (93). Yang and Mayo (173) reported that 3 of 37 patients with detrusor contraction greater than 30 cm H_2O preoperatively developed *de novo* hypocontractility after spincterotomy. The loss of contractility after sphincterotomy has been attributed to the loss of Barrington's urethrovesical reflex (106). Light and colleagues (86) noted that detrusor hypocontractility after sphincterotomy appeared to result from afferent dysfunction of the lumbosacral cord and postulated that the presence of obstruction is necessary to maintain a positive feedback mechanism for the detrusor contraction. Although the mechanism is still debated, the consensus is that some patients will unpredictably lose detrusor contractility after sphincterotomy. With respect to this issue, paraplegics may be at an advantage because they can assist emptying if necessary by Valsalva or Credé maneuver. Other causes of immediate failure include persistent high outlet resistance due to DBND and recurrent or persistent DESD. This was reported as the reason for failure in 2 of 15 patients by Lockhart and colleagues (93) and 6 of 18 patients by Yang and Mayo (173). The mechanism for DESD after sphincterotomy may be incomplete surgical division of the sphincter or scarring and contracture of the divided muscle. Whatever the mechanism, the incidence of repeat operation ranges between 15% and 50% (79). In a 10-year retrospective analysis, Santiago (126) reported that 9 of 25 patients required repeat sphincterotomy and also noted a relatively high failure rate for repeat procedures. Laser sphincterotomy has been proposed to reduce the need for repeat procedures, but Perkash (115) reported that 7 of 76 patients with laser sphincterotomy required repeat within 1 year. Similarly, Rivas and colleagues (122) observed recurrent obstruction within 1 year in 3 of 22 patients.

Contrasting with the generally good success rate of spincterotomy in the short term are disturbing reports of high long-term failure rates. In their review of 37 patients (1987 to 1993) all with detrusor contraction greater than 30 cm H_2O preoperatively, Yang and Mayo (173) reported 18 failures. The shorter mean follow-up in patients considered to be successful as compared with patients deemed to be failures (26 versus 49 months) suggests increasing failure with time. Reporting on 16 patients with median 39 months of follow-up after sphincterotomy, Vapnek and colleagues (155) found only 8 still using condom catheter drainage. Because of a risk of initial failure, a frequent need for repeat sphincterotomy, and the long-term failure rate, patients should be counseled about the possibility of failure and subsequent need for an alternative form of bladder management. Sphincterotomy irreversibly destroys sphincteric competence and creates dribbling incontinence even if it fails to improve emptying. This obviates other options, such as intermittent catheterization, that require a competent sphincter. For this reason, sphincterotomy has been considered a last resort in the patient who could perform intermittent catheterization (71).

Sphincteric Stent

Placement of a wire mesh stent across the external sphincter has proven to be an effective method to relieve functional obstruction by DESD. The indications for stenting are the same as for sphincterotomy. The advantages of the stent are reduced risk of hemorrhage or adverse impact on potency and the possibility of reversing the procedure. Generally, a 3-cm stent is used and is placed with the proximal end at the verumontanum (Fig. 27.7). In a prospective randomized trial, patients undergoing standard external sphincterotomy were compared over a 2-year follow-up with patients treated by stent placement. Both treatments yielded comparable decreases in maximum detrusor pressure. More than half of the patients in both groups reported resolution of autonomic dysreflexia (29a). Follow-up studies showed that urodynamic improvement is maintained. The stent becomes epithelialized after insertion, with greater than 90% coverage in most patients within 6 months. Even so, stent removal is possible without significant long-term complications, and sphincter behavior reverts to prestent condition (31,32). Stent removal is required in approximately 15% of patients, most commonly for migration. Stones, encrustation, and obstruction by fibrosis or hyperplasia are relatively uncommon problems (32).

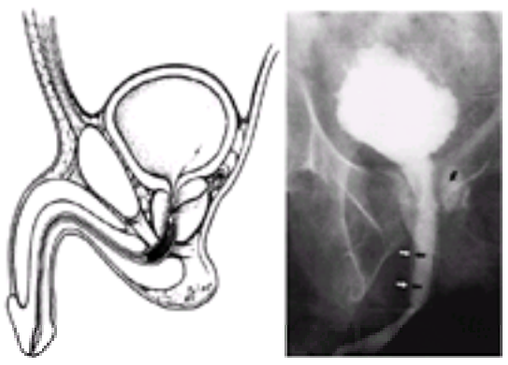

FIGURE 27.7. A: Treatment of detrusor external-sphincter dyssynergia (DESD) by stenting. Diagram of a wire mesh stent placed across the region of the external sphincter. (From Chancellor MB. Urinary sphincter prosthesis. In: Olsson CA, ed. *Current surgical techniques in urology.* Wilmington, DE: Medical Publishers, 1991, with permission.) **B:** Voiding cystourethrogram 12 months after stent placement demonstrating widely open external sphincter. Mild urothelial hyperplasia and intraprostatic reflux are noted (*small* and *curved arrows,* respectively). (From Chancellor MB, Rivas DA, Abdill CK, et al. Prospective comparison of external sphincter balloon dilatation and prosthesis placement with external sphincterotomy in spinal cord injured men. *Arch Phys Med Rehabil* 1994;75:297, with permission.)

Botulinum Toxin

Botulinum toxin, injected transurethrally or transperineally into the region of the external sphincter, has been used to weaken the effect of sphincter dyssynergy (51,128). The effect on maximum detrusor pressure is more modest than either sphincterotomy or stent and is temporary (3 to 9 months), necessitating repeat injection. Medical therapy for DESD has been disappointing. Continuous intrathecal baclofen decreases dyssynergia in up to 40% of patients (138), but oral baclofen has not proven effective. Centrally acting muscle relaxants such as diazepam cause sedation and have not proven useful. Clonidine was reported to inhibit vesicosphincter reflexes in patients with SCI (70), but this was only a preliminary study. a_1-Adrenergic antagonists such as terazosin have no demonstrable effect on the external sphincter, but they decrease resistance at the bladder neck and can be used both diagnostically and therapeutically in patients with persistent voiding difficulty following external sphincterotomy (30).

Neuromodulation

In an attempt to restore normal voiding in the SCI patient, investigators have explored the feasibility of electrical stimulation of the detrusor muscle, the conus medullaris, and the anterior sacral nerve roots. The best results have been obtained by combining sacral posterior root rhizotomy with implantation of an externally controllable anterior sacral root stimulator (Fig. 27.8). Posterior rhizotomy is done to increase bladder capacity and compliance. Anterior sacral root stimulation produces simultaneous detrusor contraction and external sphincter activation; however, the timing of stimulation is adjusted so that the peaks of detrusor contraction and sphincter activation are out of phase and micturition occurs between bursts of stimulation (38). There is a large collective experience with the anterior root stimulator, accrued even as the technique of sacral rhizotomy was being refined. Brindley (20) reported the mean 4-year follow-up of his first 500 patients. He reported that 86% of surviving patients continued to use the device for micturition and that upper tract deterioration occurred in only 2 of 365 patients who had undergone complete posterior rhizotomy (20). In a subgroup analysis of 184 patients in that same cohort, Van Kerrebroeck and colleagues (153) reported that 156 of 184 patients (69 males, 87 females) used the stimulator alone for micturition. In a more recent series of 52 patients, Van Kerrebroeck and colleagues (154) reported complete continence in 73%. Although suitable for both male and female paraplegics and tetraplegics, the ideal candidate for the implantable neurostimulator is a patient with complete thoracic SCI who can transfer to the toilet and either cannot or prefers not to perform intermittent catheterization. Possible complications of the procedure include device-related complications, new or worsened SCI, loss of erectile function, and altered bowel function or continence.

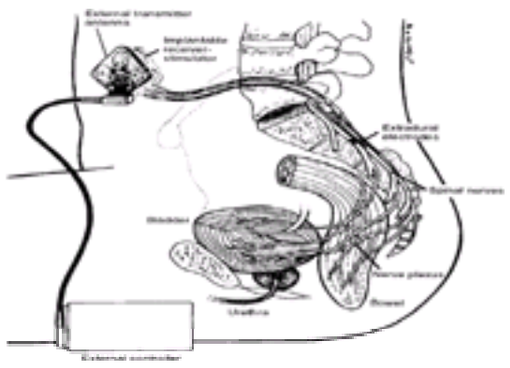

FIGURE 27.8. Restoration of voiding by posterior rhizotomy and neurostimulation. In select patients, voiding function may be restored by use of an implantable neurostimulator. A complete posterior rhizotomy is performed to provide sufficient bladder capacity. A surgically implanted neurostimulator is connected to the anterior sacral roots through extradural electrodes. Voiding is accomplished by activation of neurostimulation using a handheld external control device.

Intermittent Catheterization

Intermittent catheterization is the preferred long-term management option for most patients. The standard guidelines are a daily fluid intake of 1800 mL and catheterization every 5 to 6 hours for volumes of approximately 300 mL (87). Of course, there is considerable individualization in patterns of fluid intake and catheterization. Most patients use a clean rather than sterile method of self-catheterization (Table 27.11). One prospective study demonstrated a high rate of bacteriuria with intermittent catheterization by either method and suggested that the incidence of symptomatic UTI was the same (80). The key variables determining patient acceptance of intermittent catheterization are functional capability and continence (117). Functional capability, broadly defined, includes the patient's intrinsic capabilities or the presence of a dedicated caregiver who can perform catheterization. Frequently, an occupational therapist can offer patients with cervical injury and limited hand function splints and practical modifications that facilitate self-catheterization. Women tetraplegics present a difficult challenge because of their inability to transfer and access the urethra. In selected patients, a continent abdominal stoma can make intermittent catheterization a realistic option. Incontinence—leakage between catheterizations—is the number one reason that patients discontinue intermittent catheterization (148). Sometimes this is related to sphincteric weakness, but usually it is related to uninhibited detrusor activity. With aggressive management to achieve complete continence, excellent long-term compliance with intermittent catheterization is obtained. In a series of 89 patients initially managed by intermittent catheterization with a mean follow-up of 6 years, Chai and colleagues (27) found that 71% continued to be managed by intermittent catheterization. In their mean 5-year follow-up of 40 patients on intermittent catheterization at the time of discharge, Maynard and Glass (96) found that 80% continued to perform intermittent catheterization.

TABLE 27.11. CLEAN INTERMITTENT SELF-CATHETERIZATION

The assertion that intermittent catheterization is a superior method of bladder management has not gone unchallenged. One study that is often cited as evidence that a catheter-free state confers no advantage in terms of long-term complications is the retrospective study of 57 patients in a Veterans Administration Medical Center (47). With a mean follow-up of 12 years, the authors found no difference in renal or bladder calculi, pyelonephritis or urosepsis, gross hematuria, urethral or penile erosion, or urethral stricture in patients managed with or without a chronic indwelling catheter. However, the 25 catheter-free patients in this study included only 11 patients managed by intermittent catheterization. Thirteen were managed by spontaneous voiding or condom catheter, and one was status post urinary diversion. Because no subgroup analysis was done, this study does not allow a valid comparison of intermittent catheterization to management by an indwelling catheter.

The preponderance of evidence indicates that intermittent catheterization, particularly when combined with diligent efforts to control bladder pressure, affords a much lower rate of urologic complications than is usually associated with either an indwelling catheter or reflex voiding. In comparing the complication rate in 22 women managed by intermittent catheterization with those in 13 managed by urethral catheter drainage, McGuire and Savastano (98) reported a much lower complication rate with intermittent catheterization. Advantages were realized in the incidence of intravenous pyelogram (IVP) changes (0% versus 54%), autonomic dysreflexia (0% versus 54%), stone recurrence (0% versus 100%), nonfunctional urethra or urethral erosion (0% versus 54% and 46%, respectively), urine leakage (27% versus 92%), and febrile UTI (32% versus 92%). This study is noteworthy for the authors' stated efforts to maintain bladder storage pressures less than 30 cm H_2O. Bennett and colleagues (8) also reported a significantly lower incidence of complications in women managed by intermittent catheterization as compared with either catheter drainage or spontaneous voiding with use of incontinence padding. A number of other studies have demonstrated very low complication rates on long-term follow-up of patients managed by intermittent catheterization (27,83). Chai and colleagues (27) attributed the low complication rates in their series to their efforts to maintain low-pressure storage. The low complication rates observed in series like these are clearly superior to the complication rates that attend chronic indwelling catheter drainage (Table 27.12). Likewise, patients managed by intermittent catheterization had lower incidence of hydronephrosis, reflux, and kidney stones than patients managed by either reflex voiding or Credé maneuver (59).

Complications	Intermittent Catheterization (*n* = 31; mean follow-up, 5.9 years)*	Indwelling Catheter (*n* = 32; mean follow-up, 12 years)*
Renal stones	3%	25%
Bladder stones	16%	41%
Pyelonephritis	0%	25%
Gross hematuria	3%	6%
Urethral erosions	0%	12.5%
Urosepsis	0%	6%
Urethral stricture	0%	9%
Epididymitis	6%	6%
Difficulty catheterizing/ false passage	3%	0%

TABLE 27.12. COMPLICATION RATES WITH INTERMITTENT CATHETERIZATION VERSUS INDWELLING CATHETER

Patients managed by intermittent catheterization should undergo routine urodynamic monitoring with intervention as necessary to maintain continence between catheterization and keep storage pressures below 40 cm H_2O (27). Leakage between catheterization is most often due to uninhibited detrusor activity and low bladder capacity. Some patients eliminate leakage by restricting fluid intake and increasing the frequency of catheterization, and others may wear a condom catheter to

manage leakage between catheterizations, but these are awkward and tedious solutions (117). Medication to increase bladder capacity and decrease the amplitude of uninhibited detrusor contractions provides continence to most patients (50). Useful medications include anticholinergics, tricyclic antidepressants, and occasionally a-adrenergic blockers (27). It has been postulated that muscular hypertrophy, diminished compliance, and increased intravesical bladder pressures may develop over time and that pharmacologic intervention to suppress uninhibited detrusor activity diagnosed by urodynamic testing may help prevent this progression. In patients in whom diminished compliance exists despite maximal anticholinergic therapy, a-adrenergic blockers such as terazosin have been shown to improve compliance (146). Less commonly used measures to treat uninhibited detrusor activity include intravesical instillation of oxybutynin (114,163) and intravesical instillation of capsaicin (42,46,169). For patients with incontinence between catheterization and high-pressure uninhibited detrusor contractions, some have advocated sphincterotomy to reduce the elevated bladder pressures (116), but this commits the patient to both intermittent catheterization and a condom catheter—a condition that does not promote long-term compliance. If intravesical pressures remain elevated despite maximum tolerable medical therapy, surgical intervention is appropriate. Surgical augmentation of the bladder can provide a large-capacity, low-pressure bladder (54,94,134,158). In general, bowel augmentations such as ileocystoplasty have yielded larger increases in bladder capacity than detrusor myomectomy (autoaugment) (142). Rhizotomy as an isolated procedure to increase bladder capacity was done more frequently in the past than currently (57,100).

Some patients experience nocturnal enuresis related to excessive urine output at night. This has recently been shown to occur in patients with SCI because of the absence of normal diurnal pattern of antidiuretic hormone secretion (77). DDAVP has been used successfully in selected patients (33). Sphincteric weakness is the problem in some patients. Penile clamps are rarely used because of risk of injury, but implantation of an artificial urinary sphincter is a well-defined remedy (131,170). Collagen injection has also been used with some success (10).

Among men performing intermittent catheterization, urethral strictures can occur from repeated instrumentation. The reported incidence ranges from 3% to 19% of patients managed by intermittent catheterization for more than 5 years (27,117). Low-friction hydrophilic catheters might decrease stricture occurrence, but this has yet to be demonstrated (157). Occasionally, patients do not have a true stricture but experience episodic difficulty passing the catheter through the sphincter. If a gentle pressure of the catheter tip against the sphincter is maintained, the sphincter will usually relax and permit catheter passage. If not, a gloved finger in the anus may induce relaxation of the sphincter and facilitate passage of the catheter. Some patients develop hypertrophy of the smooth muscle at the bladder neck that creates a ledge, which can interfere with catheterization (116). Passage may be facilitated either by using a coudé catheter or administering a-adrenergic blockers to decrease bladder neck tone (71).

Indwelling Catheter

A chronic indwelling catheter is an option of last resort, and the complications associated with it are well documented. Jacobs and Kaufman (73) reported on 19 veterans with SCI managed by an indwelling catheter for a mean of 21 years. Abnormal upper tracts on IVP (hydronephrosis, stones, pyelonephritic scarring, or absent kidney due to nephrectomy) were found in 76%. Major complications requiring hospitalization (pyelonephritis, stones, need for nephrectomy, hemorrhagic cystitis, bladder cancer, and serious urethral complications) occurred in 96%. The rate of major complications was 0.25 per year. Other series have shown similar complications. Chao and colleagues (34) provided data on patients managed by an indwelling catheter for 20 years or more. Among 32 patients, there was a high incidence of renal stones (8 patients), bladder stones (7 patients), upper tract scarring and caliectasis (14 patients). Three patients developed carcinoma of the bladder, including squamous cell carcinoma (one patient), transitional cell carcinoma (one patient), and adenocarcinoma (one patient). Dewire and colleagues (47) reported a comparably high incidence of complications (Table 27.12). It has been reported that regular use of oxybutynin in patients with an indwelling catheter may preserve bladder compliance and reduce the incidence of hydronephrosis (78). Similarly, some authors have recommended daily clamping of the catheter for 2 hours to maintain bladder capacity (133). However, neither measure has been validated by prospective studies.

Despite the many urologic complications associated with chronic catheterization, renal function is usually preserved. Sekar and colleagues (132) found no significant influence of the method of bladder management on preservation of renal function. A total of 1,114 patients with SCI were followed annually with effective renal plasma flow determined by renal scan. Twenty percent of the patients had been followed for at least 10 years; 40% had been followed at least 5 years. Changes in renal function were compared among patients managed by indwelling Foley catheter, condom catheter, intermittent catheterization, and suprapubic catheter. No significant deterioration in renal plasma flow was seen with any method of bladder management, and no differences could be demonstrated. This observational study is not without methodologic weaknesses, but it is an important study showing that long-term management with an indwelling catheter is not generally associated with an inexorable decline in renal function.

Indwelling urethral catheters are particularly problematic in women because of urethral complications (150). In a series of 13 women managed by chronic Foley drainage for a mean of 7 years, McGuire and Savastano (98) reported development of a nonfunctional urethra in 54% and urethral erosion in 46%. This was in addition to other complications, including IVP changes (54%), autonomic dysreflexia (54%), stone recurrence (100%), urine leakage (92%), and febrile UTI (92%). In a series of 22 patients with catheter drainage for a mean of almost 17 years, Bennett and colleagues (8) found a similarly high incidence of urethral incompetence (9 patients), as well as other complications, including hydronephrosis (6 patients), reflux (10 patients), and bladder stones (16 patients). When severe urethral incompetence occurs in a woman with an indwelling urethral catheter, surgical intervention is usually required to provide effective drainage and eliminate leakage. In many cases, a pubovaginal sling tied with moderate tension will suffice and can be combined with suprapubic catheter placement. In other cases, surgical closure of the bladder neck may be necessary.

Foley Versus Suprapubic Tube

Long-term suprapubic catheterization as an alternative method of bladder drainage has been viewed with varying enthusiasm. Some older series (65) suggested a much higher incidence of serious complications with a suprapubic tube than with a urethral catheter. Recent series are more encouraging. In 185 patients managed by suprapubic catheterization for a mean of 2 years, the most common problems were catheter blockage (18%), leakage (8%), and recurrent symptomatic UTI (4%). Bladder stones requiring intervention were present in nearly half of those patients experiencing these problems (133). MacDiarmid and colleagues (95) reviewed 44 patients in whom a suprapubic catheter was used with a mean follow-up of nearly 5 years. No patient experienced renal deterioration. Incontinence occurred in 11%, most often in women with urethral incompetence due to long-term use of a urethral catheter. Symptomatic infections were common (52%) as were bladder stones (41%) and catheter blockage (36%). This experience suggests that suprapubic catheterizations is an acceptable alternative to chronic urethral catheterization. In women, it may avoid the urethral complications associated with Foley catheters (148).

Catheter blockage occurs frequently with both urethral and suprapubic catheters. The occluding sediment is usually calcium and magnesium phosphate, a composition similar to that of infection stones. Bacterial urease activity and urinary calcium concentration are considered the most important factors (23). Treatment to eradicate urea-splitting organisms, avoiding drug- or diet-induced increases in pH or urinary calcium, and maintaining adequate hydration and generous urine output are measures that may reduce the incidence of catheter blockage.

Indwelling catheters are associated with metaplastic and neoplastic changes in the bladder urothelium, particularly squamous metaplasia and squamous cell carcinoma. The risk is greater with an indwelling catheter than with intermittent catheterization, suggesting that chronic irritation plays a causal role (166). Nitrosamines produced by infecting bacteria may also contribute to neoplastic transformation (141). Bejany and colleagues (6) reported a 2.3% incidence of tumors among their patients. Squamous cell carcinoma predominated (9 of 11 patients). One patient had transitional cell carcinoma and one had mixed transitional and squamous cell carcinoma. Locke and colleagues (92) prospectively screened 25 patients catheterized for a minimum of 10 years by urine cytology and bladder biopsy. Two cases of squamous cell carcinoma of the bladder were identified (92). Trop and Bennett (150) reported that screening biopsy of 32 patients managed with an indwelling catheter for 4 to 36 years showed squamous metaplasia in 27 patients, transitional cell carcinoma in three patients, and squamous cell carcinoma in two patients.

Although some have argued against routine screening (172), screening for bladder cancer in high-risk patients has been recommended because tumors identified by screening are usually lower stage and have better survival rates than those that cause symptoms (108). Various screening protocols have been suggested. MacDiarmid and colleagues (95) recommended routine cystoscopic screening of patients with an indwelling catheter for more than 5 years. However, patients with indwelling catheters often have chronic inflammatory changes in the bladder mucosa that make the cystoscopic appearance nonspecific. Cytology may be a useful adjunct (143). Although it may be sufficient to perform annual screening with cystoscopy and cytology, and to biopsy only those patients with suspicious findings, some have recommended routine cystoscopy, cytology, and random biopsy in all patients who have had an indwelling catheter for 10 years (73).

Incontinent Urinary Diversion

Ileal conduit urinary diversion was a popular management strategy in the past, but the complications associated with long-term reflux of chronically colonized urine have diminished enthusiasm for its use (102). Ileocystostomy (Fig. 27.9), or “bladder chimney,” is currently the preferred method of incontinent urinary diversion

because reflux is prevented by the integrity of the native ureterovesical junction (105,123,130). This reconstruction is suitable for the patient who has not done well with catheter drainage and in whom no management strategy, other than incontinent urinary diversion, is a realistic option. Proper patient selection is essential to avoid postoperative issues of incontinence due to sphincteric deficiency or large-volume “residuals” with stasis and sediment or stone formation. In female patients in whom sphincteric incompetence exists due to long-term Foley catheter drainage, a pubovaginal sling may be performed simultaneously to eliminate leakage from below (123).

FIGURE 27.9. A–E: Incontinent ileovesicostomy. A segment of ileum long enough to reach without redundancy from the bladder to a predetermined stoma site is isolated, spatulated, and anastomosed to the bladder. (From Schwartz SL, Kennelly MJ, McGuire EJ, et al. Incontinent ileo-vesicostomy urinary diversion in the treatment of lower urinary tract dysfunction. *J Urol* 1994;152:99, with permission.)

Continent Urinary Diversion

A continent stoma can facilitate intermittent catheterization in patients with an inaccessible or damaged urethra. Usually, this is combined with creation of a large-capacity, low-pressure reservoir (139). This type of reconstruction can be used even by patients with limited hand function and has a substantial positive impact on quality of life and sexuality (104,161). Reconstruction may involve cystectomy performed for erosion, fistulization, or tumor, with creation of continent urinary diversion. More commonly, augmentation of the existing bladder is combined with creation of a catheterizable stoma. A variety of reconstructions have been used with good success and excellent continence rates. The recently described Monti procedure combined with ileocystoplasty provides the advantages of bladder augmentation using small bowel with a narrow-caliber catheterizable channel of generous length (Fig. 27.10) (26,103). If urethral incompetence exists, it may be addressed by either pubovaginal sling or formal bladder neck closure (11,35,69,85,104,119,139,145,147,110).

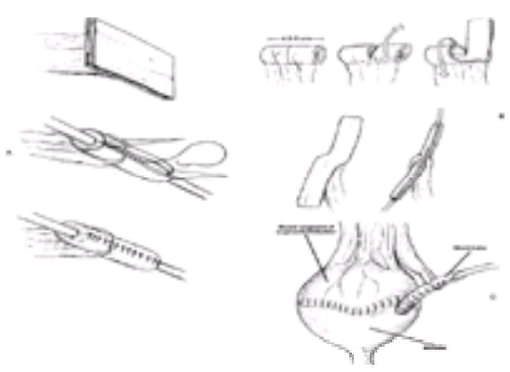

FIGURE 27.10. Monti procedure. **A:** A catheterizable tube is created from a 2- to 3-cm segment of ileum opened longitudinally and then tubularized along the perpendicular axis. **B:** If a longer catheterizable channel is required, a double Monti tube can be created. **C:** Implantation of the catheterizable channel into the bladder to provide a continent stoma can be combined with simultaneous ileocystoplasty to provide a large-capacity bladder. (From Labbi A, Gosalbez R, Lince LF. Monti procedure: refashioned short bowel segments for construction of catheterization channels. *Curr Surg Tech Urol* 2000;13:1, with permission.)

UROLOGIC COMPLICATIONS OF SPINAL CORD INJURY

Urinary Tract Infection

UTIs and stones are the most common urologic complications of spinal cord injury. Although the overall incidence of UTI is not known, one prospective study of patients managed by either intermittent catheterization or condom catheter showed an incidence of significant bacteriuria associated with fever and chills of 1.82 episodes per person per year (156). Another retrospective study reported an annual incidence of UTI in spinal cord patients of 20% (168). The increased incidence of UTI in the spinal cord population results from a number of factors: elevated intravesical pressures, bladder overdistention, vesicoureteral reflux, outlet obstruction, large postvoid residuals, instrumentation, and urinary tract stones. Other influences may include pattern of fluid intake, reduced host defenses due to chronic illness, local tissue trauma, and personal hygiene (156).

The relative risk of UTI with different methods of bladder management has not been subject to rigorous controlled studies; however, there is a general consensus that patients with an indwelling catheter are at greatest risk for developing UTI. Patients with an indwelling catheter are almost uniformly bacteriuric. The daily incidence of bacteriuria accrues at the rate of 5% to 10% per day, and the vast majority of patients with a catheter in place for more than 30 days are bacteriuric (56,159). The infection rate with suprapubic tubes and Foley catheters is equivalent (109). Bacteriuria is common in men managed with a condom catheter. The incidence of bacteriuria has been found to be greater than 50% in one study (110). Factors that predispose to bacteriuria are kinking of the catheter and colonization of the urine from skin flora (24). Occasional catheterization may also serve as an inoculating event. Sphincterotomy may reduce the incidence of symptomatic UTI by reducing outlet resistance and decreasing intravesical pressures (25). Intermittent catheterization may reduce the incidence of symptomatic UTI as compared with an indwelling catheter, but most patients maintained on intermittent catheterization are also bacteriuric. Studies comparing sterile versus nonsterile methods of catheterization are inconclusive. Some studies have shown a significant effect on the rate of UTI, but others have not (120). Bacterial colonization of the perineal skin and distal urethra is thought to be an important source of urinary pathogens (60). A sterile method of intermittent catheterization has been developed that uses an introducer tip to bypass the distal 1.5 cm of the urethra. A prospective study of spinal cord–injured patients performing intermittent catheterization with or without the introducer tip showed significant decrease in UTI with the use of the urethral introducer tip (9).

The criteria for diagnosis of significant bacteriuria and distinguishing colonization from infection are issues of clinical importance. The National Institute on Disability and Rehabilitation Research (NIDRR) Consensus Statement recommended the following criteria, based on colony-forming units (cfu) per milliliter of urine, for the diagnosis of bacteriuria in patients with spinal cord injury (107). For patients on intermittent catheterization, 10^2 cfu/mL or greater was considered significant. A value of greater than 10^4 cfu/mL was considered significant for clean void specimens from catheter-free males using collecting devices. Any detectable trace of uropathogens from indwelling catheters or suprapubic aspirates was considered significant, because the vast majority of patients with an indwelling catheter and low-level bacteriuria showed an increase to greater than 10^5 cfu/mL within a short period of time (24). Asymptomatic bacteriuria is generally not treated. Occasionally, individuals in an immunocompromised state or with vesicoureteral reflux may be considered for treatment or prophylaxis. Patients with alkaline urine due to otherwise asymptomatic infection with urea-splitting organisms such as *Proteus mirabilis* are a special case because of the potential for stone formation. In these patients, the bacteriuria should be treated with appropriate antibiotics based on culture and sensitivity testing and follow-up cultures obtained to ensure eradication of the urea-splitting organism.

The significance of pyuria remains controversial. Pyuria is commonly observed in patients with SCI in the absence of overt symptoms. In some patients, this may

occur from irritative effects of the catheter on the bladder wall. In others, it may be related to the bacteriuria. One small study suggested that more than 50 leukocytes per high-power field predicted a higher likelihood of developing symptoms related to UTI (118). On the other hand, a small prospective study failed to confirm the predictive value of pyuria. Although mean level of pyuria was almost tenfold higher in symptomatic versus asymptomatic infection, changes in level of pyuria did not predict progression to symptoms (40). The significance of pyuria in patients with spinal cord injury remains to be clarified by further research.

The issue of prophylaxis to prevent UTI has been exhaustively examined. Antibiotic prophylaxis will decrease the incidence of bacteriuria and UTI in the short term, but a long-term benefit is doubtful. Because of the potential for antibiotic prophylaxis to elicit antimicrobial resistance, it is not generally recommended. However, prophylaxis might be considered for selected patients. This may include patients in whom symptomatic infection recurs with the same organism despite proper treatment and in whom thorough evaluation reveals no specific nidus for bacterial persistence. This may occur more commonly than generally acknowledged. In one study, two-thirds of patients treated for UTI showed the same organism to be present days to weeks after the completion of the antibiotic course (40). In men, this may be related to prostatic colonization (76).

A number of studies have suggested that bladder irrigation with antimicrobial agents may reduce bacteriuria; however, the use of such agents has been limited because of allergic reactions and hematuria (24). Methenamine is a well-tolerated oral medication that is converted to formaldehyde in nonalkaline urine. It shows no effect on gastrointestinal flora, has minimal side effects, is inexpensive, and does not produce resistant organisms (3). Several studies have suggested that methenamine may decrease the incidence of bacteriuria and UTIs in patients managed by intermittent catheterization (3,81,144). However, the long-term efficacy of methenamine in reducing UTI has not been convincingly demonstrated. It is important to note that methenamine is not active in alkaline urine, a condition that is associated with urea-splitting organisms.

UTI is the most common cause of fever in the spinal cord–injured patient (12). Because of loss of sensation, many patients do not experience frequency, urgency, or dysuria. More commonly they report abdominal or back discomfort, leakage between catheterizations, increased spasticity, autonomic dysreflexia, malaise, lethargy, and cloudy or malodorous urine. The most common uropathogens in catheter-associated UTIs are *Escherichia coli, Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, *Providencia* species, enterococci, and staphylococci, including methicillin-resistant species. Infection with multiple organisms is common. When possible, a urine culture should be obtained before empiric treatment is initiated. A broad-spectrum antibiotic such as a fluoroquinolone is the agent of choice for empiric therapy (24). Amoxicillin, nitrofurantoin, and trimethoprim-sulfamethoxazole are generally not recommended because of high prevalence of resistance to these agents in the SCI population. Patients with fever or hemodynamic changes are generally hospitalized and treated with empiric broad-spectrum therapy such as aminoglycoside and ampicillin or a penicillin derivative (24). Patients treated with antibiotic to which the urine cultures demonstrates sensitivity should show a response within 24 to 48 hours. If not, repeat urine culture should be obtained and imaging studies performed to rule out obstruction. Invasive procedures such as cystograms or urodynamic studies are delayed until the acute infection is resolved. The duration of therapy in spinal cord–injured patients has not been established. Treatment for 7 to 14 days is usually recommended; however, shorter regimens of 4 to 5 days are probably effective in the mildly symptomatic patient (24). The role of a follow-up culture is unclear because asymptomatic bacteriuria may not be a cause for treatment. However, in a patient with recurrent UTIs, follow-up culture may be appropriate to rule out bacterial persistence, which would trigger urologic investigation. Likewise, a patient treated for infection with a urea-splitting organism should have a follow-up culture to ensure its eradication.

Patients with recurrent, symptomatic UTI should undergo urinary tract imaging and review of their bladder management program, with particular attention to their frequency of intermittent catheterization or voiding schedule, the use of recommended drugs, and catheterization techniques (24). Recurrent symptomatic infection may be related to high storage pressures and should prompt urodynamic evaluation. Intervention to decrease storage pressures will usually decrease the incidence of symptomatic infection.

Stones

Kidney and bladder stones occur in the SCI population with a reported incidence of 7% to 32% (66). In a study of 898 SCI patients, there was a 14.8% incidence of renal stones and a 29% incidence of bladder stones requiring cystolitholapaxy (66). Chronic UTI and hypercalciuria associated with immobilization are the primary etiologic factors (22). The presence of a chronic indwelling catheter is associated with a much higher rate of stone formation. In the study by Hall and colleagues (66), the risk of stone was 57% among patients with an indwelling catheter versus 28% in those without. The presence of vesicoureteral reflux was associated with a much higher rate of kidney stone formation (38% versus 11%).

Autonomic Dysreflexia

Autonomic dysreflexia is an acute syndrome of massive reflex sympathetic discharge in response to noxious stimuli. It occurs in patients with SCI at or above the T-6 level (37,149). Bladder distention is the most common cause of autonomic dysreflexia. Other causes include bowel distention or any of a range of intense (e.g., sexual activity) or noxious stimuli (149). These stimuli elicit a cord-mediated sympathetic response that is isolated from supraspinal inhibition and results in generalized sympathetic activity below the level of injury. Hypertension resulting from this response elicits a limited parasympathetic response, including reflex bradycardia and vasodilation above the level of injury (Fig. 27.11).

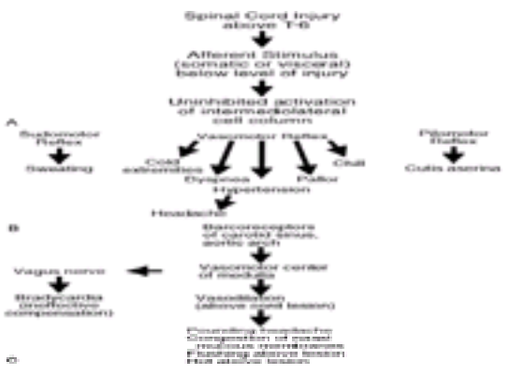

FIGURE 27.11. Pathophysiology of autonomic dysreflexia. **A:** Mechanism of reflex induction. **B:** The autonomic reflex. **C:** The inhibitory response to the reflex. (From Trop CS, Bennett CJ. Autonomic dysreflexia and its urological implications: a review. *J Urol* 1991;146:1461, with permission.)

Patients may complain of headache, shortness of breath, blurred vision, anxiety, agitation, chest pain, and nausea. Pallor, piloerection, somatic and visceral muscle contraction, and spasticity are observed below the level of the lesion, and flushing and intense sweating are seen above. Systemic changes include hypertension and bradycardia or sometimes tachycardia. Uncorrected, autonomic dysreflexia can produce life-threatening complications. The first order of treatment is to remove the initiating stimulus, if possible. When necessary, nifedipine can be administered sublingually to treat the acute episode (2). Terazosin has been recognized as an effective prophylactic therapy for patients with recurrent symptoms of autonomic dysreflexia (151). Some patients with reflex voiding experience dysreflexia related to increases in bladder pressure during voiding. In selected patients, sphincterotomy or stenting may decrease voiding pressures and ameliorate the symptoms of dysreflexia (5,29,32,115).

Anesthetic Risks

Patients with SCI present a unique anesthetic challenge. Perioperative issues include autonomic dysreflexia, bradycardia, hypotension, respiratory inadequacy, and muscle spasms. Patients with low, complete lesions and no history of dysreflexia undergoing surgery below the level of the lesion may not need anesthesia for pain control but should have anesthetic monitoring. In patients with higher lesions, autonomic dysreflexia may be precipitated by bladder distention, as well as other surgical maneuvers. General anesthesia can be used; however, spinal anesthesia is being increasingly recognized as a safer and more effective method of anesthesia that effectively protects against autonomic dysreflexia (67). Respiratory function is often a major perioperative concern in patients with high SCI. Lesions above C-6 may affect diaphragmatic function. Abdominal and intercostal muscle function may be severely compromised by high thoracic lesions, making effective coughing impossible without assistance (2).

SEXUAL DYSFUNCTION

Sexual function is an important concern for both male and female SCI patients and their partners (14,36,44). In one study of women with SCI, 69% were satisfied with their postinjury sexual experiences but considered self-confidence, spasticity, and lack of spontaneity to be significant issues (36). Sexual function in men with SCI is generally more problematic and includes issues of impotence, ejaculatory dysfunction, and failure to achieve orgasm. Following recovery from spinal shock, men may display reflexogenic erections or psychogenic erections (14). Reflexogenic erections are typically brief erections induced by stimulation below the level of the lesion and require an intact sacral (S-2 to S-4) reflex arc. If the lesion is above T-11, complete rigidity of the penis can be obtained, but if the lesion is below that level, erection will involve the corpora cavernosa while the spongiosum remains nontumescent. Psychogenic erections induced by cortical outflow involve discharge from the sympathetic center (T-11 to L-2) and are observed in patients with lesions below L-2. Erections occur in more than half of SCI patients, but the frequency of successful coitus is less. Reports of successful coitus range from 5% to 75% (19). Erectile dysfunction has been successfully treated in men with SCI with a range of options, including use of an elastic band to maintain a spontaneous erection, vacuum devices, intracavernous injection of papaverine or prostaglandin, and penile prostheses (14,72). Recently, sildenafil has been shown to be an effective and well-tolerated treatment option for erectile dysfunction in SCI (45,61,97).

INFERTILITY

Women with SCI may experience amenorrhea that lasts for 6 to 12 months after injury. Subsequently, most women with SCI are able to conceive. Pregnancy may be complicated by issues of impaired sensation, autonomic dysreflexia, and increased risk of premature labor and low birth weight, but most patients are able to successfully bear children (19). Fertility in men is more seriously compromised. The estimated incidence of successful pregnancy achieved through intercourse by men with SCI ranges from 1% to 10%. Pregnancy rates of 1% and 6% have been observed in men with complete and incomplete upper motor neuron lesions, respectively. The comparable rates in lower motor neuron lesions are 5% and 10% (88). The causes of infertility include both erectile and ejaculatory dysfunction and poor semen quality.

Hypothalamic neural output travels in the anterolateral columns to terminate in the intermediolateral columns between T-10 and L-3. Sympathetic outflow regulates seminal emission and mediates bladder neck closure during ejaculation. The S-2 to S-4 cord segments provide genital afferent innervation and somatic motor innervation of the striated sphincter and perineal musculature. Bors and Comarr (18) reported that ejaculation occurs in 5% and 32% of men with complete and incomplete UMN lesions, respectively. The rates in complete and incomplete LMN lesions were higher—18% and 70%, respectively. Many patients exhibit a diminished, dribbling ejaculation. In addition to the neurologic dysfunction caused by SCI, confounding influences may exist such as external sphincterotomy and the use of a-adrenergic blockers, which may cause retrograde ejaculation and impaired vasal and seminal vesical peristalsis (88).

Methods of assisted ejaculation have been used to obtain semen for insemination. These include administration of anticholinesterases, vibratory stimulation, and electroejaculation. Intrathecal prostigmine, which was reported to produce erections and ejaculations, was associated with severe side effects (89). Vibratory stimulation is delivered by placement of a vibrator on the base or glans of the penis and administering stimulation until ejaculation occurs. This technique is most successful in men with incomplete lesions or lesions above T-10. Electroejaculation, achieved by using a rectal probe, is the most popular method of assisted ejaculation because of a high success rate and low incidence of significant side effects. It has been reported to be successful in obtaining semen in 85% to 100% of men with SCI (136). In the event of retrograde ejaculation, the sperm can be retrieved by catheterization and centrifugation. In men who do not ejaculate even with stimulation, sperm can be retrieved by direct aspiration of vasal fluid (89).

Poor semen quality is the rule in men with SCI. One review reported that only 13% of men with SCI had a sperm concentration exceeding the lower limit of normal (20 million/mL) and less than 1% had motility greater than 40%. The average motility of semen obtained by electroejaculation has been reported to be 25%. Lumbar injuries are associated with the lowest motility (89). Factors that have been considered as possible contributors to poor semen quality include UTI, method of bladder management, stasis of prostatic fluid, testicular hyperthermia, abnormal testicular histology, changes in the hypothalamic-pituitary-testicular axis, antisperm antibodies, and side effects of chronic medications (89). A simple and comprehensive, yet nonspecific, explanation put forth by Brackett and colleagues (19) is that poor semen quality in patients with SCI results from a disturbance of the autonomic nervous system. Even though sperm quality may be preserved during the acute phase of injury, most men cannot ejaculate during the acute phase even with vibratory stimulation or electrostimulation, and sperm banking is not generally recommended or attempted (88). Despite all of these issues, fatherhood is possible for many SCI patients through assisted reproductive techniques (19). Techniques of assisted reproduction may include techniques such as artificial insemination or *in vitro* fertilization, and Brackett and colleagues (19) reported over a 50% pregnancy rate in couples who wished to pursue parenthood.

SUMMARY

Over the past century, patients with spinal cord injury have been a driving force in the development of sophisticated urodynamic testing and novel strategies for lower urinary tract management. The impact on the prognosis and quality of life of patients with neurogenic bladder dysfunction has been profound. The investigative techniques, insights, and strategies developed for treatment of these patients have had added value for their general relevance to the evaluation and treatment of nonneurogenic voiding dysfunction in the pediatric and adult population. Basic and clinical research continue to keep spinal cord injury at the forefront of advances in the understanding of bladder function and the neurophysiology of micturition, the development of new drug therapies for bladder dysfunction, and the possible role of the central nervous system in spermatogenesis and fertility.

Inflammatory diseases of the bladder result from specific infectious causes or chemical, radiation, or unknown factors. Uncomplicated urinary tract infections (UTIs) typically occur in young women with normal urinary tracts. Thirty-five percent of women 20 to 40 years of age experience at least one UTI, and acute cystitis affects 4 to 6 million women, resulting in more than 7 million office visits and more than 100,000 hospitalizations annually in the United States (164,165). Cystitis is rare in males, except in uncircumcised boys and adult homosexual men (97).

Complicated UTIs occur in persons with congenital anatomic genitourinary (GU) abnormalities, in those with urologic conditions such as “infection” stones or obstruction, or following urologic surgery and/or urinary catheterization. Bacterial drug resistance is common in complicated UTIs, as are Gram-positive and polymicrobial bacteriuria (147). Complicated UTIs require extended courses of treatment, and recur unless underlying anatomic or functional defects are corrected.

Although *Escherichia coli* is the most common organism in UTIs, complicated UTIs are frequently caused by Enterobacteriaceae such as *Proteus*, *Providencia, Klebsiella, Serratia, Pseudomonas,* and *Enterococcus* species (147). The treatment of complicated UTIs has improved with the introduction of the fluoroquinolones. These drugs have broad-spectrum antimicrobial activity, achieve high urinary levels following oral administration, and have long half-lives and a low incidence of side effects and bacterial drug resistance (74).

EPIDEMIOLOGY OF URINARY TRACT INFECTIONS

The prevalence of UTIs varies according to age and gender (Table 28.1). Boys have a higher rate of neonatal UTIs than girls (8). Following the neonatal period, the proportion of females to males with UTIs increases to approximately 25:1, and this female preponderance continues into adulthood (166). In the elderly and institutionalized, the prevalence in both sexes is nearly equal (146).

Age Group	%	Ratio (Male:Female)
Neonatal	1	1.5:1
Preschool	2–3	1:10
School-age	1–2	1:30
Reproductive age	2–5	1:50
Elderly	20–30	1:5–10

TABLE 28.1. PREVALENCE OF URINARY TRACT INFECTIONS

Congenital GU tract disorders, such as vesicoureteral reflux or posterior urethral valves, occur in approximately 40% of male bacteriuric infants—a rate two times higher than that in bacteriuric girls (8). Uncircumcised boys are 10 to 40 times more likely than their circumcised counterparts to develop UTIs in the first year of life because of bacterial colonization of the prepuce (97,161). Bacteriuria in men is rare until the fourth to fifth decades when prostatic diseases and lower urinary tract instrumentation increase the risk. The 5% prevalence rate of bacteriuria in women of childbearing age is due to bacterial colonization of the vaginal introitus and distal urethra (48,165). Three percent of women experience more than one UTI per year, with the majority having a fairly constant rate of infection, averaging three UTIs annually (165).

Relapse of a UTI (Table 28.2) with the isolation of the original bacteria following antimicrobial therapy occurs within weeks of completion of therapy and is due to bacterial persistence or unresolved bacteriuria (165). The latter results from bacterial resistance from prior antibiotic therapy or R-factor mediated resistance, poor antibiotic delivery, azotemia or medullary concentrating defects, or a large bacterial “inoculum.” Bacterial persistence occurs with “infected” renal calculi (both sexes) and chronic bacterial prostatitis (men) (97,147). These conditions are the only urologically correctable causes of recurrent UTIs, and patients with bacterial persistence require a complete urologic evaluation.

	Bacterial Persistence	Bacterial Reinfection
Time interval	Weeks	Months–years
Bacterial species	Same	Different
Source of bacteria	GU tract	Outside GU tract
Frequency	Uncommon	Common
Evaluation	All patients	Men, children
Causes	Chronic bacterial prostatitis, Infected calculi (renal, prostatic)	Bacterial adherence (introitus, prepuce)
Surgically correctable	Often	No

GU, genitourinary.

TABLE 28.2. BACTERIAL PERSISTENCE VERSUS REINFECTION

The most common cause of recurrent UTIs is reinfection—isolation of a new bacterial strain following eradication of the original infecting bacteria (Table 28.2). Such infections recur at longer time intervals compared with bacterial persistence, and the bacteria arise from outside of the GU tract, that is, the perineum and vagina in women (48,153) or the colonized prepuce in uncircumcised boys (161).

PATHOGENESIS OF URINARY TRACT INFECTIONS

A critical balance exists between bacterial virulence factors and host defense mechanisms (Table 28.3 and Table 28.4). Virulence factors are important in patients with normal (anatomic, functional) urinary tracts, whereas altered host defenses are more important in complicated UTIs. The short length of the female urethra and its frequent bacterial colonization contribute to the high frequency of UTIs in women. In men, the longer urethra and the antibacterial activity of prostatic fluid blunt bacterial urethral ascent and reduce the risk of UTIs (97,162).

Bacterial adherence	Aerobactin production
Bacterial adhesions	Capsular K antigen
Uroepithelial cell receptors	Bacterial lipopolysaccharide
Bacterial biofilm	(O antigen)
Hemolysin production	

TABLE 28.3. BACTERIAL VIRULENCE FACTORS

Mechanical effects of voiding	Antiadherence mechanisms
Bacterial inhibitory properties of urine	Bacterial interference
Immune mechanisms	Uromucoid (Tamm-Horsfall Protein)
Ureteral peristalsis	Mucosal glycosaminoglycans (GAGs)
	Secretory IgA (SIgA)

TABLE 28.4. HOST DEFENSES

Bacterial adherence is mediated by fimbriae or pili (typically 150 to 200 per cell), proteinaceous cell surface appendages that attach to disaccharide moieties on epithelial cells (167,171). Type 1 mannose-sensitive fimbriae are expressed by bacteria colonizing the vaginal introitus and lower urinary tract, whereas bacteria associated with pyelonephritis, bacteremia, and urosepsis more frequently express P (mannose-resistant) and other (e.g., X, S, G, M) fimbriae (153). Increased vaginal cell receptivity occurs in women during and between episodes of recurrent UTIs and is paralleled in buccal mucosal cells, suggesting a genetic predisposition (153). Genetic factors associated with an increased risk of UTIs include the P1 blood group, with an increased risk of pyelonephritis in children, and blood group (e.g., Lewis) nonsecretors, with an increased risk of recurrent cystitis in women (155).

Other virulence factors contribute to the pathogenesis of UTIs (Table 28.3). Bacterial strains causing acute pyelonephritis are more likely to produce hemolysin, aerobactin, express O and K antigens, and show increased adherence to uroepithelial cells compared with strains causing simple uncomplicated cystitis (114). Certain bacterial species, such as *Pseudomonas,* produce a bacterial biofilm on mucosal or foreign body (catheter, prostheses) surfaces. This biofilm is derived from bacterial expolysaccharide and host extracellular matrix proteins (139). Bacteria growing within the biofilm (sessile bacteria) are protected from the effects of antibiotics (139), which may explain the difficulty in eradicating infections associated with indwelling catheters and GU prostheses.

Host defense mechanisms counteract the propensity of uropathogenic bacteria to cause UTIs (Table 28.4). High postvoid residual urine volumes favor bacterial growth and proliferation in patients with bladder outlet obstruction and neuropathic bladder dysfunction (22,171). Tamm-Horsfall protein (uromucoid), produced in the ascending limb of the loop of Henle, helps to bind *E. coli* to uromucoid, and elimination of the latter during voiding is an efficient antibacterial defense (114,167). Emptying mechanically interferes with bacterial adherence because of the shearing forces associated with voiding. Normal urine inhibits bacterial growth and is bactericidal against small numbers (inocula) of uropathogens (114). Factors contributing to this inhibitory defense mechanism are high osmolality, high urea concentration, low urinary pH, and the high organic acid content of urine (171).

Commensal lactobacilli adhere to vaginal epithelial cells and competitively prevent adherence of pathogenic bacteria (167). The glycosaminoglycan (GAG) moiety of the mucopolysaccharide lining of the bladder wall discourages bacterial adherence (114).

Urinary IgA and IgG antibodies exert a protective effect by coating infecting bacteria and interfering with urothelial attachment. Children susceptible to recurrent bacteriuria have lower baseline levels of urinary IgA. Bladder immunoglobulin levels can be increased experimentally by immunization, leading to faster clearance of infection (181).

UNCOMPLICATED CYSTITIS

E. coli is responsible for most community-acquired UTIs. *Staphylococcus saprophyticus,* a Gram-positive, coagulase-negative, novobiocin-resistant, nonhemolytic coccus, accounts for 10% to 20% of UTIs in sexually active women (165). Other aerobic, Gram-negative bacteria causing cystitis include *Klebsiella* species,

Enterococcus, Proteus mirabilis, and *Pseudomonas.* Less common infecting organisms include *Staphylococcus epidermidis,* fungi, *Gardnerella vaginalis, Lactobacillus,* and *Ureaplasma urealyticum.*

Diagnosis of a UTI is based on the presence of symptoms and confirmation of the infection. Dysuria is the main symptom associated with frequency, urgency, nocturia, pain, and voiding in small amounts. Acute pyelonephritis causes flank, back, and abdominal pain, and systemic symptoms, such as fever, malaise, nausea, vomiting, and sweats. Upper tract UTIs are more difficult to treat, have higher complication rates, and require prolonged treatment and frequent hospitalization. Clinical evaluation cannot reliably delineate lower from upper tract infections (9). Many patients (10% to 50%) with cystitis have subclinical pyelonephritis, as shown by sophisticated localization culture techniques. Definitive techniques to localize infections such as ureteral catheterization (Stamey test) and the bladder washout (Fairley test), are invasive and not commonly used.

Pyuria, greater than 10 white blood cells (WBCs) per high-power field (HPF) is a sensitive indicator of infection. Pyuria also can be detected by dipstick chemical detection of leukocyte esterases or a hemocytometer cell counting chamber (52). Bladder urine is normally sterile, but voided urine can be contaminated by distal urethral and perineal organisms. Following its initial description in acute pyelonephritis, significant bacteriuria has been defined as greater than 10^5 bacteria per milliliter of urine (83). However, recent studies in acutely dysuric women with symptoms of cystitis show that one-third have colony counts of 102 to 104 colony-forming units (CFU) per milliliter of urine (164). Significant bacteriuria is now defined as greater than 102 colonies of bacteria per milliliter in a symptomatic patient. Reasons for low counts include urinary frequency, diuresis, fastidious organisms, and slow-growing bacteria (165).

Direct microscopic examination of a Gram-stained, uncentrifuged urine showing one bacterial organism per oil-immersion field or an unstained centrifuged urine showing any bacteria correlates with a colony count of greater than or equal to 105 CFU/mL of urine. The bacterial enzyme, nitrate reductase, produces nitrite from urinary nitrates and is the basis of a quick dipstick test for bacteriuria. These rapid methods for the detection of bacteriuria are specific but not very sensitive.

In sexually active young women, symptoms of cystitis can be mimicked by sexually transmitted diseases (STDs) or vaginitis. Vaginitis can be caused by candidal fungal species, trichomonas, genital mycoplasmas, or *Gardnerella vaginalis* (175). The common STD pathogens are *Neisseria gonorrhea, Chlamydia trachomatis,* and herpes simplex viruses. In the past, symptomatic women with “low count” bacteriuria and urethritis were diagnosed as having the “urethral syndrome” (164).

Chronic bladder inflammation may lead to cystitis cystica, which is characterized microscopically by lymphoid follicles or cysts (Fig. 28.1). Cystitis cystica, cystitis glandularis, and Brunn's nests are related conditions, commonly seen in chronic inflammation. Brunn's nests are invaginations of transitional cell epithelium that grow down from the bladder surface and become separated. Central cavitation of the infolded mucosa results in cystitis cystica. The cysts in cystitis cystica are lined by low cuboidal cells, which may differentiate into columnar epithelium and formation of cystitis glandularis. These lesions are not associated with neoplasia, although they suggest mucosal instability.

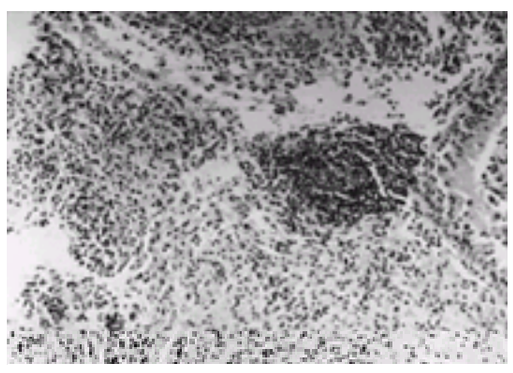

FIGURE 28.1. Cystic follicularis. Bladder biopsy in a 67-year-old woman with recurrent cystitis and the cystoscopic appearance of cystitis cystica. Sections of a trigonal biopsy show inflammation, fibrosis, and lymphoid follicles in the lamina propria.

The bladder trigone in women frequently reveals whitish patches that show squamous metaplasia on biopsy. The term “pseudomembranous trigonitis” is mistakenly used to describe this squamous metaplasia. Leukoplakia is also a whitish patch that infrequently involves the trigone. Lesions suspicious for leukoplakia should be biopsied because squamous cell develops in approximately 25% of cases of leukoplakia (137).

Cystitis associated with pneumaturia suggests bowel fistulization into the bladder. Enterovesical fistulae appear as reddened edematous areas in the posterior bladder wall. A shaggy necrotic center may be visualized, with bowel contents emanating into the bladder. Sigmoid diverticulitis is the most common cause of enterovesical fistulae (96). A computed tomography (CT) scan is recommended in all cases of suspected enterovesical fistulae. Vesicovaginal fistulae occur primarily after gynecologic surgery and vesicouterine fistulae after cesarean section (126).

Uncomplicated cystitis is treated with antibacterial agents that achieve high urinary concentrations. Conventional 7- to 10-day treatment with trimethoprim-sulfamethoxazole (TMP-SMX), amoxicillin, and nitrofurantoin is safe and effective (165). In enterococcal UTIs, *in vitro* TMP-SMX sensitivities are misleading because *in vivo* the organisms can incorporate exogenous folates and escape the antibacterial action of TMP-SMX (55). Uncomplicated UTIs, especially in women, are often treated with single-dose or short-course (3 to 5 days) therapy (113). This results in better patient compliance, less cost, fewer side effects, and less chance of bacterial resistance (165). The widespread use of TMP-SMX and ampicillin has led to the development of chromosomally and plasmid-mediated bacterial resistance (140,163,188).

COMPLICATED URINARY TRACT INFECTIONS

Recurrent Urinary Tract Infections in Women

Simple cystitis responds to antimicrobial therapy in more than 90% of cases. However, 20% of women develop recurrent cystitis as a result of reinfection by bacteria from the colonized perineum or introitus (165). GU tract abnormalities are not a significant factor in causation of these UTIs. A genetic predisposition to increased bacterial adherence to urothelial cells is linked to HLA phenotypes (HLA-A3) and blood group nonsecretor status (Lewis and ABO groups) (Table 28.5) (155).

Inherited	Acquired
Blood group nonsecretors	Sexual activity
HLA-3 phenotype	Diaphragm usage
	Spermicidal use

TABLE 28.5. RISK FACTORS FOR URINARY TRACT INFECTIONS IN WOMEN

Acquired risk factors include sexual activity and the use of the diaphragm and spermicidals (Table 28.5) (45,75). Bacterial colonization of the vagina is more notable in

women using spermicidal foams and diaphragms. Nonoxynol-9, an active ingredient in spermicides, has significant antimicrobial activity against sexually transmitted bacteria and lactobacilli but little activity against *Enterococcus, Klebsiella,* and *E. coli* (75). Diaphragms may partially obstruct the urethra, interfere with normal voiding, and increase the risk of urinary stasis and infection (45).

Treatment of recurrent cystitis includes postintercourse voiding and long-term, low-dose or postcoital oral antimicrobial prophylaxis. Continuous, low-dose antibiotic prophylaxis for 3 to 12 months reduces infection rates from 2 to 3 to less than or equal to 0.15 infections per patient year (164,165). Prophylactic antibiotics need to be safe and inexpensive, and they should not select resistant bacteria from the bowel flora. Common antimicrobial regimens used for prophylaxis are nitrofurantoin (100 mg daily), TMP-SMX (one-half double-strength tablet daily), or trimethoprim (100 mg daily) (135). With TMP-SMX, bacterial resistance, enterococcal superinfections, and yeast vaginitis are problematic (165). Norfloxacin also has been used for prophylaxis (116). However, the fluoroquinolones are not the drugs of choice for prophylaxis, unless the bacteria are resistant to the commonly used antibiotics. The cost of quinolones makes them less attractive for long-term prophylaxis compared with nitrofurantoin, TMP-SMX, or trimethoprim.

Antibiotic prophylaxis is recommended for patients with more than three UTIs per year. If the infections are temporally related to sexual intercourse, postcoital prophylaxis can be used. Temporary discontinuation of diaphragms and/or spermicidals may be needed in some women to break the vicious cycle of recurrent UTIs (45). In postmenopausal women, intravaginal estrogen reduces the frequency of recurrent UTIs by altering the vaginal flora and pH (138). Intravaginal lactobacilli instillation has been used to prevent recurrent UTIs. Lactobacilli increase vaginal acidity, produce hydrogen peroxide (some species), and interfere with attachment of uropathogenetic bacteria. Cranberry juice also may play a role in reducing pyuria and recurrent cystitis (79). Bacterial immunization protocols also have been used to reduce the chance of recurrent UTIs.

Urinary Tract Infections in Pregnancy

Asymptomatic bacteriuria occurs in 5% of pregnant women—a rate similar to that in nonpregnant women (21,147). Asymptomatic bacteriuria predisposes to pyelonephritis. The hormonal and mechanical changes that occur in pregnancy increase the risk of pyelonephritis (147). Hyperestrogenism causes “hydroureter of pregnancy” by the eighth week of gestation, with greater frequency on the right side because of mechanical factors (e.g., right-sided placenta). Ureteral peristalsis is reduced, and bladder capacity increases as the bladder moves out of the pelvis into the abdomen. Urinary stasis, reduced renal concentrating ability, aminoaciduria, and gestational glycosuria increase the risk of pyelonephritis, especially in the third trimester.

Thirty percent of women with asymptomatic bacteriuria develop acute pyelonephritis later in pregnancy and pyelonephritis is the most common (1% to 2%) medical complication in pregnant women (172). Pyelonephritis is associated with maternal and fetal risks (198). Premature labor is more common because of bacterial liberation of prostaglandins from phospholipids in the amniotic and chorionic membranes. Treatment of asymptomatic bacteriuria prevents the development of acute pyelonephritis in more than 90% of patients. Women should be screened at their first prenatal visit, and bacteriurics should be treated to reduce the risks of prematurity, premature labor, low birth weight, and other fetal complications. Penicillin and ampicillin are relatively safe for both the mother and the developing fetus (17). Despite many years of clinical use, these drugs are still classified as class B in the U.S. FDA safety rating for drugs used in pregnancy. Nitrofurantoin, although classified as a class C drug, is generally regarded as safe in all trimesters of pregnancy as are the cephalosporins (186). The use of quinolones in children and pregnant or nursing women is not recommended (74).

Recurrence or persistence of infection following antibiotic treatment suggests the presence of anatomic abnormalities, bacterial persistence, stones, or renal parenchymal infection and should lead to a full urologic evaluation following parturition. Up to 20% of patients so evaluated will have structural abnormalities of the kidney, ureter, or bladder (147).

Urinary Tract Infections in the Elderly

By the sixth decade of life, bacteriuria is present in 20% of women and 10% of men (41). The prevalence is higher for patients in nursing homes, extended care facilities, and hospitals. Although *E. coli* is the most common infecting organism, there is an increased rate of infection with *Proteus, Klebsiella, Enterobacter, Serratia, Pseudomonas,* and *Enterococcus.* Elderly men have a high frequency of Gram-positive bacteriuria (40% to 50% of all UTIs) related to the more frequent use of urethral catheterization, cystoscopy, and antimicrobial usage (163). Infections are frequently polymicrobial in hospitalized or institutionalized patients.

Numerous factors contribute to the high rate of bacteriuria in the elderly (Table 28.6). Micturition is impaired as a result of prostatic enlargement in men or bladder prolapse in women and levels of prostatic antibacterial factor (PAF) decrease with age. Perineal soiling from fecal incontinence, reduced host defense mechanisms (e.g., T-H protein), and indwelling and condom catheters all predispose to bacteriuria. Urine cultures in the elderly with symptomatic UTIs do not always show greater than or equal to 105 bacteria per milliliter of urine—a situation similar to that in sexually active women. Pyuria is not as significant a marker for bacteriuria in the elderly as it is in the young.

Prevalence: 20%–50%
Female to male ratio: 2:1–3:1
Risk Factors
Immobilization, instrumentation
Hospitalization, age, systemic disease
Fecal incontinence, neurogenic bladder dysfunction
Catheters (Foley, condom)
Men
Benign prostatic hyperplasia
Prostate cancer
Loss of prostatic antibacterial factor
Women
Bacterial colonization introitus, perineum; pH changes
Bacteriology
Polymicrobial; intermittent bacteriuria
More noncoliform infections
Gram-positive infections in men

TABLE 28.6. URINARY TRACT INFECTIONS IN THE ELDERLY

Asymptomatic bacteriuria in the elderly does not contribute to excess mortality or morbidity (41,146). Because of the risks of adverse drug reactions and bacterial resistance, routine antibiotic treatment of asymptomatic bacteriuria is unwarranted. Treatment should be started if patients become symptomatic, in immunosuppressed/neutropenic patients, or when urease-producing bacteria cause the infection.

Aging affects the pharmacokinetic disposition of drugs in the elderly because of changes in body composition and diminished function of organs, such as the kidney and the liver. The risk of drug interaction is greater because the elderly use multiple concurrent drugs more frequently than their younger counterparts. The fluoroquinolones generally are tolerated well by elderly patients, and the indications for their use parallel those in younger patients (74,130). Because of the high tissue levels obtained after oral administration, the fluoroquinolones are attractive for the treatment of tissue (e.g., kidney, prostate) infections in the elderly. Judicious use of these agents can reduce the need for hospitalization in patients with pyelonephritis and allows earlier hospital discharge (158).

Catheter-associated Urinary Tract Infections

Catheter-associated UTIs account for 40% of hospital-acquired (nosocomial) infections (Table 28.7). Catheterization (indwelling or in and out) and lower tract instrumentation account for 80% of these infections (163). Between 15% and 20% of all hospitalized patients undergo catheterization, and 1% to 3% develop bacteriuria with a mortality rate of approximately 10% (188). The incidence of bacteriuria with indwelling catheters averages 5% per day and bacteriuria is universally present in all catheterized patients after 3 to 4 weeks.

Catheter-associated UTIs account for 40% of all nosocomial infections.
Significant Causes
Periurethral migration
Bacterial biofilm
Altered bladder defenses (e.g., glycosaminoglycans)
Less Significant Causes
Retrograde spread from distal urethra
Drainage bag contamination
Break in closed drainage system

TABLE 28.7. CATHETER-ASSOCIATED URINARY TRACT INFECTIONS (UTIs)

Because bacteria colonize the distal urethra, catheter insertion results in bacteriuria in 1% of ambulatory patients and 20% of hospitalized patients. Intraluminal contamination may occur by ascending infection from the drainage bag or by breaks in the system of closed drainage. However, the main route of infection is the extraluminal periurethral space (173). Once bacteria reach the bladder, their persistence and proliferation depend on factors, such as bacterial adherence, the antibacterial effect of surface glycosaminoglycans, and the development of "bacterial biofilms" on the catheter surface (115). Poorly fitted condom catheters cause urethral obstruction and impaired bladder emptying (81) and bacteria from the perineum and scrotum may colonize the condom portion of the catheter and act as a reservoir for infection.

Risk factors for bacteriuria in catheterized patients include duration of catheterization, inadequate care of the drainage bag and closed drainage system, female gender, diabetes mellitus, renal failure, and systemic immunosuppression (163). Certain bacteria, such as *Providencia stuarti*i and *S. epidermidis,* readily adhere to catheter surfaces and are frequent causes of catheter-associated bacteriuria. Urease-producing bacteria, such as *Proteus* species, hydrolyze urea to ammonia, increase urinary pH, and predispose to the formation of struvite and apatite stones.

Catheter-associated UTIs can be reduced by limiting the duration of catheterization and by using alternative methods of drainage, such as intermittent catheterization (clean or sterile), or suprapubic tubes (147). Instillation of antibacterial agents into the bladder or urinary drainage bag and rigorous meatal cleansing are of little benefit in reducing the risk of catheter-associated UTIs (145). Use of catheters coated with silver alloy may reduce the risk, as does short-term systemic oral antibiotic therapy for up to 14 days especially in patients undergoing transurethral surgery or renal transplantation.

Catheter-associated UTIs are a major reservoir of antibiotic-resistant organisms in the hospital, but they are rarely symptomatic (approximately 10%), and infrequently cause bloodstream infection (174). Symptoms referable to the urinary tract, fever or peripheral leukocytosis have little predictive value for the diagnosis of catheter-associated UTI (174). The fluoroquinolones are excellent for treatment of catheter-associated UTIs because of their activity against the *Enterobacteriaceae* and *Pseudomonas* sp. It is extremely rare for *E. coli* to develop resistance but *Pseudomonas* resistance has been reported in 5% to 27% of patients treated with the fluoroquinolones (74).

TUBERCULOSIS

GU tuberculosis occurs as a result of hematogenous spread from pulmonary tuberculosis. Over the last few years, the prevalence of tuberculosis has increased in the Western world as a result of changing immigration patterns and the "epidemic" of HIV infections with associated immunosuppression (25). Urologists should consider the diagnosis of GU tuberculosis in patients with irritative voiding symptoms of unclear etiology and sterile pyuria.

Bladder tuberculosis results from downward seeding from a renal focus, and symptoms follow at varying time intervals after the onset of pulmonary or renal tuberculosis (56). Women and children may present earlier with frequency, dysuria, and hematuria—characteristics of bladder implantation of tubercle bacilli. Men more commonly present with epididymitis (134). Men predominate over women (2:1 ratio) and the common age group is 20 to 40 years. Bacterial cystitis is superimposed on bladder tuberculosis in approximately 20% of patients. However, the majority of patients have sterile pyuria (57).

Cystoscopically, tuberculosis appears as patchy erythematous ulcerations with exudates. These lesions mimic transitional cell carcinoma or carcinoma *in situ* (CIS) and biopsy. The ureteral orifices and bladder base are most inflamed in the acute phase. In untreated cases, fibrosis and contracture may occur. Because the trigone contracts less, the ureteral orifices may assume a position in the angle at the top of the bladder making ureteral catheterization difficult if it becomes necessary to evaluate or treat (stent) the hydronephrosis associated with healing tuberculous ureteritis (26).

For diagnosis, at least three consecutive early-morning urine specimens should be cultured, each on two types of media, plain Lowenstein-Jensen medium for *Mycobacterium tuberculosis* and a pyruvic egg medium containing penicillin for *Mycobacterium bovis* (57). Routine guinea pig inoculations are no longer required. Drug sensitivity should be checked whenever mycobacteria are cultured (124). Recently, rapid diagnosis of GU tuberculosis using the polymerase chain reaction (PCR) and DNA hybridization has shown high sensitivity and specificity as well as the capacity for rapid detection using urine samples (110).

Treatment of tuberculous cystitis is based on the premise that pulmonary and renal involvement also is present. Most patients can be treated on an ambulatory basis if their chemotherapy is closely supervised (56). Multidrug oral therapy is currently preferred. Short-course therapy prevents the emergence of resistant organisms because of the rapid bactericidal and sterilizing properties of the drugs used (57). The main antituberculous drugs currently in use are isoniazid, rifampin, streptomycin, pyrazinamide, and ethambutol. Isoniazid (10 to 30 mg/kg per day) is the most effective and important antituberculous agent, and its use requires pyridoxine supplementation. The introduction of rifampin (10 to 20 mg/kg per day), an oral drug, has eliminated the need for parenteral therapy and significantly shortened the course of therapy from the previously accepted 2 years to 4 to 9 months (57).

Short-course, multidrug chemotherapy is based on the following principles: (a) Rifampin and pyrazinamide are potent sterilizing agents, (b) isoniazid and pyrazinamide or isoniazid and rifampin are excellent sterilizing combinations, and (c) streptomycin or ethambutol adds little to the sterilizing ability of the previous combinations. Ethambutol (15 to 20 mg/kg per day) has largely replaced the use of paraaminosalicylic acid, but it is not recommended for children because of the risk of optic neuritis. Patients receiving ethambutol should have monthly visual examinations. Streptomycin and other drugs are needed occasionally when the patient has problems with the preferred drugs or in treating drug-resistant cases.

The most used combination is pyrazinamide, isoniazid, and rifampin administered daily (usually in one dose at night) (191). Streptomycin is added if the infection is severe or the patient is highly symptomatic. Steroids are indicated in patients with severe tuberculosis cystitis or lower ureteral strictures. The main adverse drug reactions are hypersensitivity (usually with streptomycin and rifampin) and hepatotoxicity (isoniazid and rifampin), with jaundice and elevated serum transaminase and alkaline phosphatase levels. Two years of therapy is still recommended by some authorities, although 9-month therapy is less costly and equally effective (56). Bladder fibrosis and contracture are generally preventable by medical therapy. Bladder augmentation or urinary diversion seldom is necessary (57).

VIRAL CYSTITIS

Viral cystitis causes irritative voiding symptoms and hematuria. The usual causative viruses are adenovirus types 11, 21, and 35, papovavirus, and influenza A (89,156). Children and immunocompromised adults typically are affected (111). Cytomegalovirus cystitis has been reported to occur in AIDS.

Viral cultures are not generally available, and diagnosis is usually made clinically. Definitive diagnosis requires viral isolation from acute phase urine cultures and serum antibody titers (complement-fixing and specific-neutralizing antibodies). Ultrasound examination of the bladder may document the characteristic thickening and irregularity of the bladder wall in viral cystitis. The symptoms and the hematuria typically resolve in 2 to 3 weeks. If the ultrasound changes resolve, diagnostic cystoscopy, usually employed for the evaluation of hematuria, may be omitted selectively. If the symptoms and ultrasound changes persist or if there is a palpable bladder mass on rectal or abdominal examination, further evaluation with cystoscopy is warranted. There also may be transient vesicoureteral reflux (107). Because viral cystitis is usually hematogenous in origin, a diagnostic evaluation for obstruction or other anatomic abnormalities is usually not indicated.

Acute viral hemorrhagic cystitis may occur after renal and bone marrow transplantation (197). The disease is usually self-limiting, although serious complications such as pneumonia can occur in immunosuppressed individuals. Patients can be managed successfully without the need to reduce immunosuppressive drug dosing. Intravenous ribavirin and ganciclovir have been used to treat acute adenovirus-associated hemorrhagic cystitis (15).

FUNGAL INFECTIONS

Fungal inflammations of the GU tract are becoming more prevalent because of increased broad-spectrum antibiotic use and the increasing number of patients receiving immunosuppressive drugs and chemotherapy (194). GU fungal infections are commonly caused by *Candida albicans,* but also may be due to *Aspergillus fumigatus, Cryptococcus neoformans, C. glabrata,* and others (159). Symptoms vary widely from the asymptomatic patient with a fungus-colonized bladder catheter to the patient with severe urgency, frequency, and dysuria. *Candida* is a saprophyte in the urinary tract, vagina, external genitalia, or perineum. Antibiotics suppress normal bacterial flora (aerobic, anaerobic, Gram-negative, and Gram-positive bacteria) and encourage colonization and infection with fungal species (141). *Candida* is usually an opportunistic pathogen associated with diabetes mellitus, obstructive uropathy, neuropathic bladder dysfunction, neoplasia, systemic antibiotic/steroid/immunosuppressive therapy, and indwelling urinary catheters.

Most candidal UTIs represent candiduria—lower tract colonization (159). Risk factors for the development of candiduria include female gender and ICU location. Patients receiving oral fluconazole and quinolones are at increased risk of developing *C. glabrata* candiduria (67). Invasion of the bladder wall may lead to candidal cystitis, disseminated candidal infection, and candidemia. Differentiation of colonization from infection relies on the use of urinalysis, urine culture, blood culture, and appropriate serologic and imaging studies. Budding forms and pseudohyphae are seen on careful urinalysis. Blood cultures are positive in only 50% of patients with invasive or renal candidiasis. Serologic testing for the antibody response to candidal antigen is useful for diagnosing serious infection (159).

Candidal species (except *C. glabrata*) form fungus balls or bezors that can obstruct the urinary tract. CT of the bladder may delineate filling defects and bladder wall thickening (Fig. 28.2). Ultrasonography is useful for demonstrating fungus balls (Fig. 28.3). The number of organisms required to constitute a “significant infection” is different for fungal cystitis as compared with bacterial cystitis. In patients without indwelling catheters, colony counts of 10,000 to 15,000/mL of urine on a clean-voided or straight-catheterized specimen are significant and require further investigation (194).

FIGURE 28.2. Computed tomography scan of the bladder in a 15-year-old girl with a fungus ball on the posterior wall of the bladder and severe fungal cystitis.

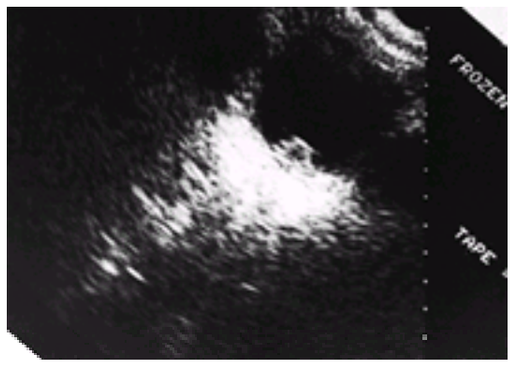

FIGURE 28.3. Same adolescent as in Fig. 28.2. Fungus ball and posterior bladder wall thickening and inflammation as seen on ultrasound of the bladder.

In candidal cystitis, the bladder mucosa is hemorrhagic and covered by a whitish pseudomembrane or elevated white plaques similar to those seen in fungal stomatitis. Fungus balls appear as gray, shaggy aggregations in the bladder that may be adherent to the bladder wall.

The most common clinical scenario in urologic practice is persistent candiduria in patients with indwelling urinary catheters. Therapy is based on laboratory sensitivity tests. Treatment of fungal cystitis with intravesical irrigations of amphotericin B is preferable to systemic therapy, if renal or systemic involvement is absent (196). Irrigation for 5 days with a solution of 50 mg amphotericin B suspended in 1 L of sterile water eradicates candiduria in 90% of patients. Ambulatory patients with chronic candiduria can be treated with daily bladder instillations of amphotericin B or miconazole (194). Improvement in host defenses (e.g., better nutritional status) and correction of predisposing factors (e.g., discontinuation of broad-spectrum antibiotics or removal of indwelling catheter) are also important.

Systemic candidiasis requires parenteral therapy with amphotericin B, flucytosine (5-FC) or the imidazoles (e.g., miconazole, ketoconazole, fluconazole) (195). Parenteral administration of amphotericin B requires attention to prescribing guidelines because of its nephrotoxicity. 5-FC is not available for parenteral administration but reaches high urinary levels after oral administration (150 mg/kg/ per day in divided dosages with reduced dosages for patients with reduced renal function). Oral fluconazole is safe and effective for short-term (up to 2 weeks) eradication of candiduria, especially following catheter removal (157).

MALACOPLAKIA

Malacoplakia is an uncommon, benign granulomatous disease of the GU tract. It commonly involves the bladder (i.e., 40% of reported cases), although the kidney can be involved (40,99). Malacoplakia causes severe irritative voiding symptoms and hematuria and needs to be distinguished by biopsy from other benign and malignant bladder conditions. The term derives from the Greek “malakos” (soft) and “plakas” (plaque). Cystoscopically, malacoplakia consists of yellow-brown, soft plaques with a smooth surface and raised margins surrounded by peripheral hyperemia.

Microscopically, malacoplakia consists of infiltrates of large macrophages mixed with lymphocytes and plasma cells. Large, eosinophilic histiocytes contain abundant PAS-positive Michaelis-Gutmann bodies—rounded intracytoplasmic inclusions with a concentric “owl-eye” or “birds-eye” appearance, containing incompletely digested mineralized bacterial components (99) (Fig. 28.4). Normal lysosomal phagocytosis and digestion relies on the integrity of intracellular microtubules that are under the control of intracellular cyclic nucleotides (cGMP/cAMP ratio). Abnormally low levels of cyclic 3',5'-guanosine monophosphate (cGMP) have been demonstrated in patients with malacoplakia (99). Bethanechol raises intracellular cGMP levels, and ascorbic acid reduces cAMP levels (199). The association of malacoplakia with recurrent UTI suggests an immunologic deficiency.

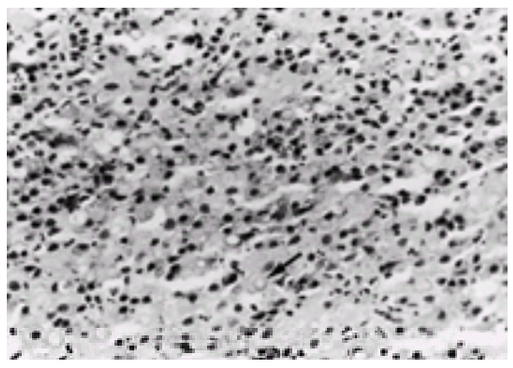

FIGURE 28.4. Malacoplakia of the bladder. Bladder biopsy in a 2½-year-old boy with an *Escherichia coli* urinary tract infection and hematuria; inflammatory reaction with Michaelis-Gutmann body *(arrow)* seen in lamina propria. (From Witherington R, Brannan WJ, Wray BB, et al. Malacoplakia associated with vesicoureteral reflux and selective immunoglobulin: a deficiency. *J Urol* 1984;132:975, with permission.)

Malacoplakia commonly presents with chronic UTIs and is associated with a 40% incidence of systemic diseases such as carcinoma, immunodeficiency, and autoimmune disease (27). The female-to-male ratio is 2:1 to 4:1. After renal transplantation, malacoplakia has particularly serious implications and may be associated with graft loss and mortality. It may be necessary to stop azathioprine in cases of bladder involvement after transplantation and to consider early transplant nephrectomy in cases of renal parenchymal (transplant) involvement (170).

Treatment of malacoplakia is based on the current theories of pathogenesis. Medical treatment consists of bethanechol, ascorbic acid, and antibiotics such as TMP-SMX, rifampicin, or the fluoroquinolones (185). Because of the effective medical regimens, total endoscopic removal of the bladder lesions of malacoplakia may not be necessary (99). If bladder lesions persist despite medical therapy, transurethral or (rarely) open excision may be indicated. Prolonged antibiotic treatment and close follow-up are needed. Long-term antibiotic treatment of the associated UTI is a cornerstone of therapy (23). TMP-SMX may play a special role because of its lipophilic quality, postulated cell-membrane binding, and cell-entry capacity, all of which facilitate macrophage phagocytosis.

CYCLOPHOSPHAMIDE CYSTITIS

The oxazaphosphorine alkylating agents, cyclophosphamide and isophosphamide, are widely used to treat lymphoproliferative disorders, solid tumors, certain nonmalignant diseases, and as conditioners before bone marrow transplantation (143). Urologic side effects include frequency, dysuria, urgency, suprapubic discomfort, and both microscopic and hematuria. Rarely, mucosal necrosis, bladder fibrosis, contracture, vesicoureteral reflux, and tumor formation occur. The incidence of GU side effects ranges from 2% to 40% in patients on long-term, cyclophosphamide therapy (95). The risk of hemorrhagic cystitis is dose related. Patients who are dehydrated or receiving intravenous rather than oral treatment are at increased risk.

The urotoxicity of these alkylating agents is due to acrolein, a liver metabolite of the oxazaphosphorines (143). The bladder is most affected because of its reservoir function, which allows prolonged contact (dwell times) between acrolein and the bladder mucosa (95). Cystoscopically, the bladder initially appears edematous with multiple punctate hemorrhages. Later, diffuse telangiectasia, reduced capacity, and trabeculation occur. Histologically, the early lesion is that of edema, ulceration, and hemorrhage heading to chronic inflammation and fibrosis.

Therapeutic approaches to the prevention of cyclophosphamide-induced hemorrhagic cystitis are aimed at neutralization or detoxification of acrolein (169). Hydration combined with frequent voiding or indwelling bladder catheterization reduces the urotoxicity of acrolein. Two drugs, *N*-acetyl cysteine (Mucomyst) and 2-mercaptoethane sulfonate (Mesna), form nonurotoxic stable thioesters by binding to the carbon-to-carbon double bonds of acrolein. *N*-acetyl cysteine can be administered orally, parenterally, or intravesically (143). However, it reduces the antineoplastic and immunosuppressive effects of cyclophosphamide when given systemically and is cumbersome and expensive to use as a bladder irrigant. Mesna binds specifically to acrolein without affecting the therapeutic effects of the oxazaphosphorine alkylating drugs (35). It is oxidized to a stable inactive disulfide within minutes of parenteral administration and becomes activated when excreted in the urine. Excretion is rapid with a half-life of 1.5 hours. Mesna also enhances renal excretion of cysteine, thereby increasing the number of sulfhydryl groups available for attachment to acrolein. Routine prophylactic administration of Mesna with cyclophosphamide has been recommended (127). An oral form of Mesna has been developed. Once the bladder complications have occurred and bladder hemorrhage is present, the cyclophosphamide should be stopped if possible because this allows the toxic cystitis and hematuria to subside in most cases. Bladder cancer has been reported to occur with a higher incidence after cyclophosphamide therapy (127). The management of cyclophosphamide-induced hemorrhagic cystitis is described later.

RADIATION CYSTITIS

Approximately 20% of patients who receive pelvic irradiation suffer bladder complications, half of these being hemorrhagic cystitis (29,143). Hemorrhagic cystitis secondary to radiation therapy occurs after treatment of prostate, bladder, and cervical cancers. Hematuria may be acute or chronic and is accompanied by urgency, frequency, and dysuria. Hematuria may develop acutely during radiation therapy or occur months to years later.

Pathologically, radiation injury to the bladder involves progressive obliterative endarteritis with resulting telangiectasia, submucosal hemorrhage, and smooth muscle and interstitial fibrosis. Mucosal ischemia results from the endarteritis, causing hypoxic surface damage, ulceration, and bleeding. Acute radiation cystitis occurs either during or shortly after the radiation therapy has been given. Histologically, edema and inflammation of the mucosa and lamina propria characterize it. Most cases of acute radiation cystitis subside spontaneously during the 12 to 18 months after completion of therapy. Late sequelae occur up to 8 to 10 years after radiation and result from endarteritis, which leads to inflammatory cell infiltrates, fibrosis throughout the bladder wall, and increased mucosal vascularity. Factors that contribute to radiation cystitis are bladder outlet obstruction, infection, previous radiation or surgery, and excessive radiation dosage (29).

Unlike cyclophosphamide cystitis, there are no effective preventive measures for radiation-induced hemorrhagic cystitis, although sodium pentosan polysulfate (PPS), a semisynthetic heparin-like compound, may be uroprotective (61). This drug is not yet approved for clinical use in the United States. Reports on the use of hyperbaric oxygen for established, clinically significant radiation cystitis are encouraging (11,29). Hyperoxia reverses the radiation-induced tissue damage by promoting neovascularization, healthy granulation tissue, and generalized vasoconstriction. Hyperbaric oxygen therapy may be the preferred treatment for radiation-induced hemorrhagic cystitis because cessation of hematuria is achieved in 90% of patients (11). Conjugated estrogen (either parenteral or oral) recently has been shown to be effective treatment in a small number of patients with cyclophosphamide or radiation-induced hemorrhagic cystitis (98).

There is little reason to cystoscopically document early, acute radiation cystitis. Treatment is directed at prevention of infection and control of bladder spasms. In chronic and severe cases, cystoscopy shows diffuse telangiectasia and reduced bladder capacity. Symptomatic treatment of radiation cystitis consists of anticholinergic and antispasmodic agents for frequency and urgency. As in the case of troublesome bleeding from cyclophosphamide, a progressive treatment sequence may be needed (143).

TREATMENT OF HEMORRHAGIC CYSTITIS

Most cases of hemorrhagic cystitis are due to chemotherapeutic agents or pelvic irradiation. Uncommon causes include viral, bacterial, fungal or parasitic infections, drugs (e.g., the penicillins, danazol), and chemical toxins (e.g., busulfan, aniline, toluidine derivatives and ether). The best treatment of hemorrhagic cystitis is prevention, especially for cyclophosphamide-induced cystitis. However, once hemorrhagic cystitis is established, treatment is the same irrespective of the cause (Table 28.8).

General Measures	Specific Measures *(continued)*
Hydration	Prostaglandin irrigation
Continuous bladder irrigation	Conjugated estrogens
Clot irrigation	Hyperbaric oxygen
Cystoscopy	Sodium pentosan polysulfate (PPS)
Clot evacuation	Arterial embolization
Fulguration bleeding points	**Surgery**
Specific Measures	Arterial ligation
Epsilon aminocaproic acid (Amicar)	Diversion
Alum irrigation	Cystectomy
Silver nitrate	
Phenol instillation	

TABLE 28.8. MANAGEMENT OF SEVERE HEMORRHAGIC CYSTITIS

The mainstay of therapy is clot evacuation. This can be done at the bedside using a multiple hole, wide lumen catheter (Robbins catheter). If this is unsuccessful, cystoscopy with clot evacuation and fulguration of visible bleeding points is necessary. Hydration with or without epsilon aminocaproic acid (Amicar) is the usual next step. Amicar, given orally or parenterally, inhibits clot lysis by urinary urokinase. Amicar may cause existing clots to become dense and adherent, and its use is contraindicated in upper tract bleeding because it may cause renal failure secondary to clot obstruction.

If hematuria continues, bladder irrigation with 1% silver nitrate (an astringent) via a three-way indwelling Foley catheter may be successful. Alum (potassium or ammonium aluminum sulfate) is an astringent that acts by protein precipitation over the bleeding surfaces. Systemic absorption is minimal, and continuous bladder irrigation with a 1% to 2% solution is employed without anesthesia and even in the presence of vesicoureteral reflux. This treatment is painless, nontoxic, and inexpensive. Alum precipitation may cause catheter blockage and dense mucosal precipitates. Encephalopathy and acidosis can occur, especially in patients with renal insufficiency in whom serum aluminum levels should be monitored (95).

Prostaglandins are effective in the treatment of hemorrhagic cystitis. Prostaglandins used include PGE_1, PGE_2, and carboprost tromethamine (prostaglandin F2) (95). Prostaglandins are cytoprotective and have antiinflammatory and vasoconstriction properties. Their advantages include ease of administration (intravesical, parenteral), no anesthesia requirements, lack of a coagulum/precipitate to block catheters, tolerance by very ill patients, and lack of systemic side effects other than bladder spasms. The prostaglandins usually are instilled intravesically. Recently, intravesical epsilon aminocaproic acid has been used to control bladder hemorrhage (93).

For severe, intractable hemorrhage, formalin instillation is an effective treatment (30). It hydrolyzes proteins and coagulates superficial bladder mucosal tissue. The concentration of formalin is the most critical factor relative to effectiveness and complication rate (e.g., perforation, bladder fibrosis) (30). Generally, a 2.5% to 4.0% solution is utilized for 20 to 30 minutes, using passive instillation at a volume of one-half of the bladder capacity, followed by continuous bladder irrigation with normal saline. Instillation is painful and requires general or regional anesthesia. An intraoperative cystogram should be done to exclude vesicoureteral reflux as inadvertent formalin reflux into the upper tracts can lead to fibrosis, obstruction, papillary necrosis, and other complications (152). If reflux is present, occlusive balloon catheters are inserted into the lower ureters and the patient is placed in the reversed Trendelenburg position.

Patients with severe hemorrhagic cystitis refractory to formalin instillation may require selective hypogastric artery embolization, percutaneous nephrostomy drainage, ileal loop diversion, cutaneous ureterostomy, cystectomy, or other procedures. Urinary diversion may become necessary as a lifesaving maneuver (143). Open surgical exposure of the bladder and application of phenol to actively bleeding points has been successful in a child with cyclophosphamide cystitis (32).

EOSINOPHILIC CYSTITIS

Eosinophilic cystitis is a rare bladder entity associated with an eosinophilic infiltrate in the lamina propria and muscle layers (184). The presentation of eosinophilic cystitis is nonspecific with the most common symptoms being dysuria, frequency, lower abdominal discomfort, and hematuria. Occasionally, a mass may be palpable and mistakenly suspected as bladder sarcoma in children (180). A history of allergies and peripheral eosinophilia is common, especially in women and children.

An IgE-mediated allergic cause is suggested by the strong allergic histories of the patients and the bladder histology. The characteristic cystoscopic findings are yellow raised plaques, necrotic ulcerated lesions resembling bladder tumors, and generalized edema and erythema (58). Often, the mucosa overlying the bladder mass may be cystoscopically normal and the diagnosis of eosinophilic cystitis missed, unless deep biopsies are obtained. Because of the clinical presentation and cystoscopic findings, the disease has been confused with malacoplakia, tuberculosis, interstitial cystitis, and bladder neoplasms. The diagnosis is made by bladder biopsy. Bladder ultrasound may show a thickened and irregular bladder wall, and vesicoureteral reflux occurs in approximately 33% of cases.

Treatment of eosinophilic cystitis is nonspecific. Steroids and antihistamines are the mainstays of treatment. Other treatment modalities include intravesical dimethylsulfoxide (DMSO), intravesical steroids, nonsteroidal antiinflammatory drugs (NSAIDs), radiation, and chemotherapy (184). Although it is believed that eosinophilic cystitis is a self-limiting disease in children, relapses and progression are common in adults. The synthesis and secretion of interleukin (IL)-5 might explain the chronicity of the lesions of eosinophilic cystitis by activated eosinophils (31). Because healing may lead to fibrosis with loss of renal function, surveillance for upper tract dilation is important.

Cystectomy and urinary diversion are seldom indicated (184). Hydronephrosis and ureteral dilation occur in approximately 25% of patients. In rare cases of severe bleeding and upper tract dilation, radiation to the bladder, extensive cystoscopic fulguration, and partial or total cystectomy have been utilized.

EMPHYSEMATOUS CYSTITIS

Emphysematous cystitis is an uncommon disorder characterized by gas in the bladder wall and surrounding tissues. Its clinical manifestations are protean, ranging from the relatively asymptomatic, predominantly radiologic presentation to life-threatening cystitis associated with significant mortality (76).

There is a female preponderance (female-to-male ratio of 2:1). The glycosuria of diabetes mellitus acts as a fermentation substrate for gas-forming bacteria in patients with emphysematous cystitis, and up to 50% of patients are diabetic. Acute renal infection with *E. coli* or *K. pneumoniae* in patients with diabetes mellitus and/or urinary tract obstruction is the cornerstone for the development of emphysematous pyelonephritis (76). Immunocompromised patients and patients with liver disease are also at increased risk. There are increasing reports of cases caused by anaerobic gas-forming *Clostridium* and *Candida* species, especially in severely ill, immunocompromised, and elderly patients (84).

Patients present with lower abdominal pain, fever, hematuria, and pyuria with a plain abdominal roentgenogram confirming the presence of gas (in a linear distribution or multiple “bubbles”) in the bladder wall. In severe cases, symptoms can be suggestive of acute intraabdominal or pelvic pathology as a result of severe bladder inflammation with mucosal sloughing and gangrene. Such patients have signs and symptoms of systemic sepsis and require urgent antibiotic and surgical treatment. Most patients with emphysematous cystitis have mild forms of the disease that respond to appropriate antibiotic therapy, despite the sometimes alarming radiologic appearance of the bladder.

Plain abdominal roentgenograms are usually diagnostic. CT confirms the diagnosis, localizes the site and extent of the gas collection, and excludes abscess formation or fistulae. Intravenous urography, although not essential for the diagnosis, may demonstrate extension of the gas up the ureters, into the kidney, or around the adrenal gland. Such extension is associated with significant mortality and morbidity. Cystoscopy reveals the characteristic submucosal bubbles and free air within the bladder. However, the risk of cystoscopy in a patient with grossly infected urine limits its usefulness.

Most patients with emphysematous cystitis survive in spite of their usually frail medical status and associated illnesses. Management includes appropriate antibiotics, control of diabetes (if present), and establishment of adequate urinary drainage. The serum creatinine level is a reliable predictor of outcome in patients with emphysematous pyelonephritis, with azotemic patients having an increased risk of morbidity and mortality (187). Surgical exploration with debridement or cystectomy

is used only in severely ill patients who are not responding to medical and supportive measures. Antibiotic therapy combined with CT-guided percutaneous drainage is an acceptable alternative in select patients with associated emphysematous pyelonephritis (16).

OTHER INFLAMMATIONS

Trichomonas vaginalis, flagellate protozoa, may cause cystitis but usually presents as urethritis or prostatitis. Because the frequency and urgency may be the same as cystitis, microscopic examination and culture of urine and genital secretions should include this possibility. Similarly, *Chlamydia trachomatis* primarily causes urethritis, epididymitis, and prostatitis. Chlamydial infections are transmitted by sexual exposure. *Ureaplasma urealyticum* is recovered infrequently in patients with UTI but needs to be considered in the differential diagnosis of patients with frequency, dysuria, and negative bacterial urine culture (175).

Parasitic GU tract infections cause intensive bladder inflammation and symptoms. *Schistosoma haematobium* is endemic in Egypt, and in infected patients, the ova enter the bladder wall from pelvic veins (125). This causes an eosinophilic inflammatory response that becomes chronic and eventually results in fibrosis and calcification. As the ova are excreted in the urine, an epithelial reaction occurs with severe mucosal hyperplasia and subsequent dysplasia, bladder stones, and squamous cell carcinoma (51). Children with schistosomal cystitis may have nodular filling defects in the bladder, vesicoureteral reflux, and obstructive uropathy. These all improve significantly with praziquantel therapy (44). *Echinococcus granulosus* infestation of the urinary tract typically causes calcified cysts of the kidney, but it also may infiltrate the bladder and cause hematuria, cystitis, bladder cysts, and hydronephrosis (50).

INTERSTITIAL CYSTITIS

Interstitial cystitis (IC) is diagnosed with increasing frequency in modern day urologic practice (24). The “elusive” or Hunner's ulcer (77) is a misnomer that has led to the underdiagnosis of IC because many patients lack ulcers. Messing and Stamey (10) described the “nonulcer” variety of IC in 1978 and emphasized its prevalence, which led to the more frequent diagnosis of IC and the recognition of two subtypes of the disease—Hunner's ulcer and the more common nonulcer type (151).

Epidemiology and Natural History

The reported prevalence data for IC reveal wide variations due to varying assessment methods and diagnostic criteria (24). The prevalence of IC in Finland was estimated to be 18.1 per 100,000 women (120). Held and co-workers (69) estimated the prevalence of IC in the United States to be 30 cases per 100,000 total population, based on a questionnaire survey. Data from the 1989 National Household Interview Survey estimated that IC affects 0.5% of the population after adjustments for age, race, and gender—a prevalence of more than 500 cases per 100,000 total population (82). The Nurses' Health Studies (NHS) I and II conducted in 90,000 female registered nurses estimated the prevalence of IC to 60 per 100,000, equivalent to 750,000 women in the United Sates (24). This study relied on self-reporting of IC but used an additional questionnaire and a medical record check to confirm IC, based on the National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases (NIH/NIDDK) diagnostic criteria for research studies (53).

Most patients with IC are female and white, with a female-to-male ratio of 9 to 10:1 (92). More than 25% of women are younger than 30 years of age at first diagnosis. In patients with Hunner's ulcers (“classic” IC), only 18% were diagnosed before age 30 years, compared with more than 30% in patients with nonulcer IC. The quality of life of IC patients is poor and compares unfavorably to those with other chronic diseases such as chronic renal failure and arthritis because of pain, suffering, and inability to work (106). The disease affects blacks and other ethnic minorities, as well as children and adolescents (20,148). A history of allergy (drug hypersensitivity, bronchial asthma, allergic rhinitis) is present in up to 25% to 40% of IC patients (92,178).

The natural history of IC is variable. Symptoms tend to develop subacutely, progress to the classic symptom complex over a short period of time, and plateau within approximately 5 years (92). A minority progress to a small, shrunken, “end-stage” bladder. Hunner's ulcers tend to occur in middle-aged or older women with reduced bladder capacities and accounts for 57% of cases in Europe (43). In the United States, the ulcer variety of IC is uncommon, accounting for less than 10% of cases (92). Chronicity is a hallmark of the disease, punctuated by periods of exacerbation (flares) and remission. Spontaneous remissions occur in 10% to 15% of patients, but these figures need cautious interpretation because of the lack of a specific disease marker and the subjective nature of IC symptoms (38).

Underdiagnosis of Interstitial Cystitis

Although current estimates of the prevalence of IC put the number of affected individuals in the United States at approximately 750,000, this is probably a considerable underestimate (64). Factors contributing to the underdiagnosis of IC include the variable urologic and nonurologic symptoms associated with IC; their similarity to symptoms associated with other disorders; and a lack of awareness of IC, especially in men (151). Four main groups of patients with IC are commonly misdiagnosed (151) (Table 28.9). Patients with cystitis that remain symptomatic after two or three courses of antibiotic treatment are likely candidates for IC, as are individuals with symptoms of overactive bladder that do not respond to anticholinergics. Many men diagnosed with chronic pelvic pain or prostatitis also are likely to have IC. Women with chronic pelvic pain, a negative laparoscopy, and concomitant bladder symptoms are also potential IC patients.

Men with nonbacterial prostatitis/prostatodynia (chronic pelvic pain syndrome)
"Overactive bladder" symptoms in both sexes unresponsive to anticholinergics
Women with undiagnosed chronic pelvic pain
Women with "cystitis" unresponsive to antibiotic therapy

TABLE 28.9. UNDERDIAGNOSIS OF INTERSTITIAL CYSTITIS

Population surveys estimate the proportion of male patients with IC at approximately 10% of the total. This is an underestimate. Over an 8-year period, Novicki and others (117) reported that men comprised 21% of newly diagnosed IC patients at their clinic. Common misdiagnoses were prostatitis (48%) and benign prostatic hyperplasia (38%). IC must be considered in the differential diagnosis of irritative voiding symptoms and pelvic pain in men. IC is clearly more prevalent in men than previously accepted.

There are many similarities between the symptoms of nonbacterial prostatitis—irritative voiding, pain, sexual dysfunction, and lack of response to antibiotics—and prostatodynia in men and IC in women. Of 60 men, 35 (58%) with nonbacterial prostatitis/prostatodynia and negative bacterial cultures had moderate to severe petechiae, similar to that seen in women with IC, following cystoscopy and hydrodistention under general or regional anesthesia (4). This strongly suggests that the majority of men with nonbacterial prostatitis and prostatodynia have IC.

In women, IC is also commonly misdiagnosed as gynecologic disorders (149) such as chronic pelvic pain or endometriosis. Idiopathic sensory urgency (the presence of urinary frequency and urgency without obvious cause) presents with similar symptoms to IC. Frazer and associates (49) showed an increase in mast cell density in a subset of women with idiopathic sensory urgency compared with normal. As mast cell levels also are increased in IC, many patients with idiopathic sensory urgency may have early IC.

Although the NIDDK criteria were designed primarily for use as research criteria (53), the lack of a suitable diagnostic paradigm has led to their use for clinical diagnosis. Rigorous application of these guidelines is not suitable for clinical diagnosis of IC because 60% of patients considered clinically to have IC would not be diagnosed (64).

Associated Diseases

Many patients with IC have associated diseases such as allergies, autoimmune diseases, fibromyalgia, other rheumatic diseases, irritable bowel syndrome (IBS), and so on. Urinary frequency/urgency and detrusor instability (urodynamically confirmed) are common in women with irritable bowel syndrome (IBS) compared with controls (109). In a questionnaire survey of patients with temporomandibular joint (TMJ) disorders, 46% reported associated IBS, and 19% IC (90). The overlap between these various conditions suggests a common pathophysiology mediated by immune, endocrine, and neurologic (sensory afferent and autonomic) dysfunction.

IC is an uncommon manifestation of systemic lupus erythematosus (SLE). Patients with IC often have associated allergies. Systemic diseases, such as chronic fatigue syndrome and fibromyalgia, also are linked to IC (19).

Clinical Features

Urinary frequency, urgency, and nocturia are common, and suprapubic or pelvic pain is usually prominent. The pain is usually related to bladder filling and relieved by voiding, although some patients complain of pain at the end of voiding. Dyspareunia is common, whereas dysuria and incontinence are infrequent (151). A typical IC patient has seen many urologists, gynecologists, family practitioners, and internists (usually between three to five) before being diagnosed (69,92).

Gynecologic evaluation, although usually normal, may reveal focal vulvitis, an inflammation of the introital vestibular glands characterized by marked dyspareunia. The coexistence of IC and vulvitis or vulvodynia in some patients suggests a common etiologic mechanism (104). Many IC patients report prior gynecologic surgery (hysterectomy, laparoscopy), and up to 40% experience “perimenstrual” symptom exacerbation, suggesting a pathophysiologic role of the female sex hormones (149).

Patients with “mixed” incontinence (frequency, urgency, pain, incontinence) may have IC and genuine stress incontinence (168). Urodynamic evaluation is an important part of the evaluation in such patients. Patients have been labeled as neurotic or psychotic, and shunted to psychotherapists, pain clinics, and psychiatrists before urologic evaluation and definitive diagnosis (88).

Diagnostic Considerations

In the past, the diagnosis of IC was based on the triad of (a) presence of irritative voiding symptoms and pain, (b) exclusion of known bladder diseases, and (c) the presence of glomerulations or Hunner's ulcers at cystoscopy. The National Institutes of Health consensus research criteria for the diagnosis of IC (53) had become the “*de facto*” clinical diagnostic criteria. Recently, there is an evolving consensus that the diagnosis may be made clinically based on the presence of irritative voiding symptoms and pain and exclusion of known bladder diseases or by the newly described potassium sensitivity test. (Table 28.10).

Clinical diagnosis	Potassium sensitivity test
Exclusion of urinary tract	Cystoscopy and hydrodistention
infection and cancer	Under anaesthesia
Local cystoscopy	Possible biopsy
Cystometrogram	Combinations of above

TABLE 28.10. DIAGNOSTIC CONSIDERATIONS IN INTERSTITIAL CYSTITIS

Approximately 10% of IC patients have greater than 10 WBCs or greater than 5 red blood cells (RBCs) per HPF (105). An uncommon presenting feature of IC is gross, painless hematuria. The diagnosis of IC should not be made in the presence of bacterial cystitis, although a prior history of UTI does not exclude it. CIS and mucosal dysplasia of the bladder can mimic the irritative voiding symptoms and cystoscopic appearance of IC (182). A negative urine cytology or bladder biopsy is required, particularly in men, before a diagnosis of IC is made.

Patients with significant incontinence, urgency, or the lack of pain benefit from urodynamic evaluation. Radiographic imaging, including ultrasonograms, intravenous urograms, CT scans, and plain radiographs are usually unrevealing and noncontributory. A thorough patient history, physical examination, urine analysis, and urine cytology provide key information for diagnosis of IC. Urodynamics, cystoscopy, and biopsy offer important supportive additional information (177).

Although biopsies are used to rule out CIS and other specific diseases, they do not provide a definitive diagnosis of IC (72,80). Analysis of the tissue samples allows the degree and type of inflammation to be evaluated and the presence of mast cells to be assessed (129,179), which help determine whether antihistamine treatment is appropriate for IC. Staining for the presence of substance P and other mediators of neurogenic inflammation may identify patients who respond to pharmacologic treatment targeted at neurotransmitter blockade.

Hydrodistention and cystoscopy under anesthesia provide useful information regarding prognosis and treatment (Table 28.11). Bladder capacity provides an indication of how well patients are likely to respond to therapy; those with smaller capacity bladders prove harder to treat. Up to 20% to 30% of patients get transient—2 to 3 months—relief of their symptoms following hydrodistention (136). Bladder capacity is determined by *passive gravity filling* of the bladder at a hydrostatic pressure of 70 to 80 cm H_2O for 2 to 3 minutes. Drainage of the bladder following filling results in a terminal blood tinge (terminal hematuria) of the draining fluid in 90% of patients because of bleeding from the areas of glomerulations (Fig. 28.5) (105). In a few patients, distention causes mucosal cracks and fissures (Fig. 28.6). Occasionally, a true Hunner's ulcer is encountered. Urethral calibration usually reveals a urethra of normal size. Most patients have normal or increased bladder capacities under anesthesia, glomerulations, and terminal hematuria, while approximately 10% have shrunken bladders with fissures, scars, or ulcers. The cystoscopic findings are summarized in Table 28.10.

Normal urethral lumen	Nonulcer disease (90%)
Anesthesia (general, spinal)	Capacity >400 mL
Glomerulations	No ulcers, scars, mucosal
Hematuria (terminal blood	cracks
tinge)	Classic disease (Hunner's ulcer)
Biopsy	(10%)
Exclusion of specific disease	Capacity <400 mL
Prognosis	Ulcers, scars, etc.

TABLE 28.11. INTERSTITIAL CYSTITIS: ENDOSCOPIC FEATURES

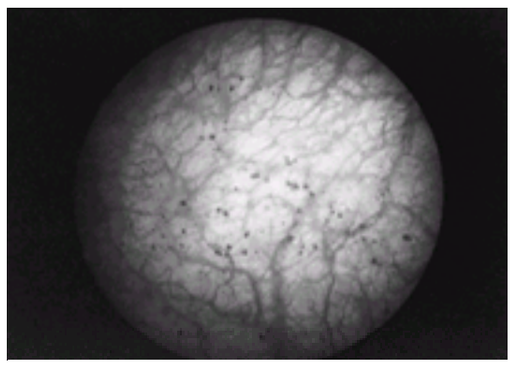

FIGURE 28.5. Cystoscopic view of diffuse “glomerulations” in patient with interstitial cystitis. Note discrete, punctate submucosal capilar tufts following passive bladder hydrodilation.

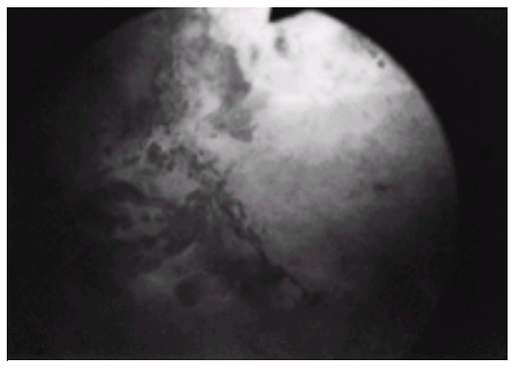

FIGURE 28.6. Interstitial cystitis. Marked mucosal hemorrhage and bleeding following hydrodistention.

Glomerulations are not pathognomonic of IC. Glomerulations may occur in inflammatory bladder conditions caused by radiation, toxic chemicals, and neoplasms. Conversely, some patients show all the symptomatology and urodynamic characteristics associated with IC, but their cystoscopic findings are normal. In a prospective cohort study of 20 urologically asymptomatic women undergoing tubal ligation, glomerulations were present in 40%—a similar incidence to that found in patients with suspected IC (190). This intriguing study needs to be repeated in a larger group of patients with carefully documented voiding logs and gynecologic symptom questionnaires because IC can present with nonurologic symptoms such as chronic pelvic pain, irritable bowel syndrome, and so on (149).

The recently introduced potassium sensitivity test identifies IC patients with bladder-related pain. Approximately 70% of patients with IC experience hypersensitivity to a potassium solution introduced into the bladder (121) because of a bladder epithelial dysfunction that allows potassium ions to diffuse across the epithelium and depolarize sensory nerves and smooth muscle. A positive test helps the physician localize patients' pain to the bladder although a negative test does not reliably exclude IC. Recent therapy for IC, such as hydrodistention, DMSO treatment, and PPS can all significantly reduce the response to potassium.

A recent study (14) has reported a lower correlation between the potassium assay and cystoscopy. In all, 66% of patients with a positive potassium test had IC, based on a positive cystoscopic test, while 46% of patients with a negative potassium test had IC based on a positive cystoscopic test. The potassium sensitivity test may identify patients likely to respond to heparinoid treatments for IC (176). Diagnostic tests for IC under investigation include urinary antiproliferative factor (AFP), bladder surface factors, and proteins such as GP51 (10,86).

Nerve fiber proliferation and expression of substance P and its receptor (Neurokinin 1) have been demonstrated in IC (6,18,103). Changes in the T-cell subpopulations in patients with classic IC indicate a possible role for the immune system in pathogenesis (66,133). Histopathologic typing of the inflammatory infiltrate (e.g., mastocytosis, nerve fiber density) may allow tailored approaches to treatment as the pathogenesis of IC becomes better understood (151).

Etiology and Pathogenesis

Several theories have been proposed regarding IC causation, including infection, vascular obstruction, autoimmunity, lymphatic obstruction, neurogenic and hormonal factors, genetic defects in bladder cytoprotection, toxic urine substances, and even psychiatric causes (Table 28.12). Most certainly, the etiology is multifactorial (38,151), and IC is best regarded as a syndrome of heterogenous causation rather than as a single disease (43).

Infection	Allergic/immune/autoimmune causes
Dysfunctional bladder epithelium	Neurogenic inflammation
Defective glycosaminoglycan cytoprotection	Bladder mastocytosis
Abnormal intercellular junctions	Psychosomatic
Changes in extracellular matrix	Other
Toxic substances in urine	Food intolerance
	Endocrine
	Hormonal
	Genetic

TABLE 28.12. ETIOLOGIES OF INTERSTITIAL CYSTITIS

An infectious (bacteria, mycobacteria, fungi, or viruses) etiology has not been proven (38), although some studies implicate fastidious bacteria such as *Gardnerella vaginalis* and *Lactobacillus* species (193). Studies of *Helicobacter pylori* and *Borrelia burgdorferi* have been negative (37,60). A sensitive PCR assay (2-round amplification using nested primers from a highly conserved region of the bacterial 16s rRNA gene) showed no difference between IC patients and controls with respect to PCR positivity or the type(s) of bacteria present (85). The bacterial flora of the lower urinary tract in IC and the urethral syndrome was found to be considerably different from that of healthy women (59). The significance of these findings is uncertain because it is possible that the inflamed, damaged bladder and urethral mucosa in these conditions can cause increased bacterial adherence and colonization.

Bladder permeability is increased in IC as demonstrated by the intravesical potassium sensitivity test, which is also positive in acute cystitis (100%), detrusor instability (25%), radiation cystitis (100%), IC (75%), and “controls” (4%) (121). A recently described test of bladder epithelial permeability using inert sugars may find application as a less painful method to intravesical potassium in evaluating patients with suspected IC (39). The bladder permeability defect in IC has not been definitively characterized, but it is believed to be multifunctional—surface GAGs, intracellular adhesion molecules, extracellular matrix, and so on (151).

A low-molecular-weight peptide—antiproliferative factor (APF)—identified in the urine of IC patients inhibits *in vitro* proliferation of normal bladder epithelial cells (86). This inhibition of epithelial regeneration following bacterial or chemical damage promotes further assault by microorganisms, urinary antigens, and potassium, and leads to chronic inflammation. Stress and heat-shock proteins are increased in IC suggesting that “toxic” urine upregulates genes involved in stress protein production

(160). Triggers for mast cell activation such as stress, infection, and chemicals induce the “stress response” (“heat shock response”) in mammalian cells (129,179).

A sulfonated GAG deficiency has been suggested as a cause of IC (123) and is the rationale for treatment with sodium PPS (Elmiron)—a highly sulfated, exogenous, orally administered glycosaminoglycan (78,112). Altered GAGs are associated with increased bladder surface permeability, the presence of Tamm-Horsfall (T-H) protein in the submucosa, and increased urea absorption (“leaky” urothelium) in IC (38,121). Substances in the urine, such as food, metabolites, food additives, drugs, environmental pollutants, and antibiotics, may leak across the altered bladder mucosal lining and cause bladder inflammation, which can be toxic, allergic, or immunologically mediated (7).

Oral antibiotics have not been convincingly implicated as a cause of IC (94). However, NSAIDs can cause IC (68). The high incidence of IC in women, chronic inflammatory cell infiltrate, response to steroid therapy, and periods of exacerbation and remissions suggest an autoimmune etiology (183). Circulating autoantibodies directed against bladder tissue lack sensitivity or specificity for IC, suggesting that they are epiphenomena (118).

Potassium diffusion stimulates mast cell activation and causes upregulation of the sensory bladder afferent nerves with neuropeptide (e.g., substance P) release and of neurogenic inflammation, leading to the pain of IC. Increased levels of substance P neurokinin 1 (NK1) receptor has been demonstrated in women with IC (103) and in cats with IC (5,6). The neurokinin-1 receptor is required for mast cell–induced cystitis in experimental models (144). Polymodal, nociceptor activation may cause unmyelinated C fibers in the submucosa of the bladder to release neuropeptides, such as substance P (101), which induce inflammation and degranulate mast cells. Mast cells are intimately related with autonomic nerve fibers (129,179). Neurogenic inflammation probably plays a role, either primary or secondary, in the pathogenesis of IC.

Mastocytosis is present in 30% to 50% of patients, and this represents a subgroup of IC patients (179). The strategic location of mast cells at host-environment interfaces suggests a potential role for bacteria in the pathophysiology of IC (102,179). Mast cells modulate the immune response to infectious agents, and bacteria or bacterial products are known to cause mast cell activation. Increased urinary excretion of mast cell products, such as 1,4-methyl-imidazole-acetic-acid, methylhistamine, tryptase and histamine, has been demonstrated in IC (36,179). Nerve-growth factor (NGF) and neurotrophin-3 (markers of neuronal plasticity and sensory nerve activation) also are increased (119). Estradiol and psychologic stress trigger mast cell activation (179), and stress is a well-known cause of flares in IC patients. Tyrosine hydroxylase immunoreactivity (THIR) in the central nervous system was found to be significantly greater (p <.05) in cats with IC than in healthy cats. These findings point to a role for mast cells, hormones, and the autonomic nervous system in the pathogenesis of IC (5,6).

The p65 subunit of nuclear factor kappa B (NF-KB), a key regulator of genes involved in response to infection, inflammation, and stress, is increased in IC (1). The inflammatory and/or immune response in IC may be exacerbated by the persistent activation of this nuclear factor. The cytokine profile of human uroepithelial cells was assessed in a number of diseases. IL-8 and transforming growth factor-b (TGF-b) were constitutively produced in all patients, whereas IL-1b, IL- 4, IL-6, and interferon (IFN)-g expression varied according to the disease. IL-1b and IL-6 staining was detected in IC and cancer, and IFN-g and IL-4 staining was only observed in IC (62).

An animal model of immediate bladder hypersensitivity/inflammation induced by local application of ovalbumin (OA) in OA-sensitive female Wistar rats was recently described (2). The early inflammatory response and alterations in smooth muscle reactivity to OA challenge in actively sensitized animals are dependent on mast cell degranulation and activation of sensory C-fibres in the bladder.

TREATMENT

General Measures

The treatment of IC is largely empirical. The use of many of the common therapies is based on old noncontrolled studies, using clinical and subjective impressions in small groups of patients. Placebo-controlled, blind studies using validated outcomes measures are needed to assess the efficacy and benefits of treatment. The placebo response rate in IC is high because of the intermittency and subjectivity of its symptoms and the chance of spontaneous remission.

Patients can expect symptomatic relief even though treatment is nonspecific and frequently noncurative. They need education and continuing reassurance that IC is not a harbinger of systemic disease or malignancy (192). Acid foods, such as alcohol, citrus juices, and carbonated beverages, and foods rich in tyrosine, tryptophan, and aspartate may cause bladder irritation (54). Patients are advised to identify their dietary provocation factors and to modify their diets accordingly. Behavior modification with increasing intervals between voids is useful in some patients, and referral to a therapist is indicated in depressed or anxious patients. Patients with significant pain that is unresponsive to the usual therapies benefit from referral and management in a multidisciplinary pain clinic.

Rationale for Multimodality Treatment

Our current understanding of the pathogenesis of IC suggests a vicious cycle of changes in the bladder-epithelial membrane barrier, sensory nerve endings, mast cells, and so on and is represented in Figure 28.7. Epithelial dysfunction due to hereditary or acquired causes (e.g., prior UTI, hormonal changes) means leads to influx of potassium and other urinary constituents into the bladder wall with resultant chemical inflammation, activation and degranulation of mast cells, release of substance P and other tachykinins and neurotransmitters, and neurogenic inflammation (144,151). The latter process is relayed to the dorsal root ganglia in the spinal cord with substance P upregulation in the spinal cord (5,6). This may well contribute to the pelvic pain symptoms, such as irritable bowel syndrome, dyspareunia, pelvic and perineal pain, associated with IC. It also may explain why some IC patients continue to experience pelvic pain even after cystectomy and diversion procedures.

FIGURE 28.7. Postulated pathogenesis of interstitial cystitis. GAG, glycosaminoglycan.

Multimodality treatment aims to target the specific biologic perturbations in IC; for example, the dysfunctional bladder epithelium with sodium PPS, mast cell activation with hydroxyzine, neuropeptide upregulation with antidepressants (tricyclic and serotonin-uptake inhibitors), nerve depolarization with membrane-stabilizers (gabapentin–neurontin), and detrusor muscle hyperactivity with anticholinergics (e.g., tolterodine, oxybutynin).

Administration of the drugs in combination addresses the multiple pathogenetic biologic factors and allows for smaller doses of individual drugs, shorter time to response, and more acceptable side effect profiles. Common drug combinations include sodium PPS and hydroxyzine, for a patient with a history of allergies and/or mast cell activation on biopsy, and sodium PPS and amitriptyline. Currently the benefits of combination therapy are being investigated in an NIH-sponsored multiinstitutional study, The Interstitial Cystitis Clinical Trials Group (ICCTG), comparing Elmiron versus placebo versus hydroxyzine versus Elmiron with hydroxyzine.

Systemic Therapy

Many of the drugs used to treat IC have been inadequately evaluated in controlled studies, show disappointing results, or have low benefit-to-risk ratios (Table 28.13).

H_1-antihistamines (diphenhydramine hydrochloride, dexchlorpheniramine, and hydroxyzine) are effective in some patients, but their sedative effect may limit their use (178). The poor response rate is due to the pharmacokinetic properties of the drug and the effects of absorption, renal excretion, and drug metabolism. Only a small proportion of the active drug or inactive metabolites reaches the inflamed bladder.

Systemic	Intravesical Therapy
Antihistamines	Silver nitrate
Corticosteroids	Heparin
Antiinflammatories (NSAIDs; COX-1 and COX-2)	Oxychlorosene sodium (Clorpactin WCS 90)
Anticholinergics, antispasmodics	Corticosteroids
Immunosuppressives	Sodium bicarbonate
Heterocyclic antidepressants	Doxorubicin
Sodium pentosan polysulfate (PPS; Elmiron)	Elmiron
L-Arginine	Lidocaine/Marcaine
Cimetidine	Disodium cromoglycate
Misoprostol	BCG (bacille Calmette-Guérin)
Heparin	Hyaluronic acid
Calcium channel blockers	? Capsaicin or resineferatoxin (RTX)

NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 28.13. DRUG TREATMENT OF INTERSTITIAL CYSTITIS

Antiprostaglandins (e.g., aspirin) or NSAIDs (e.g., ibuprofen) inhibit prostaglandins (cyclooxygenase pathway) and leukotrienes (lipoxygenase pathway) released by activated mast cells. Antimuscarinic drugs (e.g., probanthine) and musculotropic relaxants [e.g., oxybutynin (Ditropan), flavoxate (Urispas)] are used for their anticholinergic and antispasmodic properties to reduce frequency and urgency.

The tricyclic antidepressant drugs, such as amitriptyline, nortriptyline, imipramine, desipramine, doxepin, and trazodone, cause meaningful symptomatic responses, especially pain control in approximately half the patients (63). The drug is given at bedtime in gradually increasing doses. The true efficacy of antidepressants in IC has not been studied in placebo-controlled studies.

The use of sodium PPS (Elmiron), a synthetic, highly sulfated polysaccharide similar to heparin but with less anticoagulant activity, is based on the putative deficiency of bladder surface GAGs in IC. Elmiron, one of the few drugs for IC evaluated through prospective, blinded, and randomized studies is the only oral drug approved by the FDA. PPS sodium resulted in overall improvement in approximately 30% of patients who had not responded to intravesical therapy or other oral agents. This rate was approximately twice the placebo response rate (78,112). Mild adverse reactions (e.g., diarrhea, nausea, headache) occur in 6% of patients. The drug is inexpensive; less than 10% of the drug is excreted in the urine, and this accounts for the long time lag (3 months or more) before clinical improvement (73).

A meta-analysis of PPS conclusively demonstrated its efficacy over placebo in controlling pain, frequency, and urgency in IC (78). PPS (100 mg orally three times daily) takes approximately 3 to 6 months to achieve full therapeutic benefit (70) because of the low levels of PPS getting into the bladder. Ongoing dose-escalation studies are under way in the United States to determine whether higher oral dosages result in a shorter time to response without an increased incidence of side effects. Clinical experience that a positive potassium sensitivity test may be a predictor of response to PPS is emerging (176).

Electroanalgesia from transcutaneous electrical nerve stimulation (TENS) is useful to control pain in patients with the ulcer type of IC. Long periods of treatment, usually months, are required before patients show improvement (42). However, TENS is nondestructive and safe and deserves consideration before invasive or surgical therapies. Subcutaneous heparin, a glycosaminoglycan that restores the defective mucous layer of the bladder wall, has been used (100). However, inconvenience, logistical problems associated with administration, and the potential side effects of bleeding (menstrual, ecchymoses) are reflected in the near-universal lack of adoption of this therapeutic approach.

Approximately 40% of IC patients treated with hydroxyzine self-report symptom improvement, and this rate rises to 55% in patients with bladder mastocytosis on biopsy and/or a history of allergies (178). The ability of hydroxyzine to inhibit neurogenic activation of bladder mast cells explains its effectiveness in IC (108).

Immunosuppressive drugs have been used to treat IC. Cyclosporine reduces urinary frequency and bladder pain, but the symptoms recur when treatment is discontinued (47). The therapeutic role of immunosuppressive drugs such as cyclosporine and methotrexate need to be assessed in well-designed prospective, randomized, placebo-controlled studies. Oral steroids and immunosuppressive drugs [azathioprine (Imuran), chloroquine, and oxychloroquine] have not achieved widespread use because of their potential side effects of infection and bone marrow suppression (65).

Misoprostol, an oral prostaglandin analogue, was used to treat IC. In an open label study in 25 patients receiving 600 mg daily for 3 months, 56% had significant symptomatic improvement, although incidence of side effects (64%) was high (87). Calcium channel blocking agents, such as nifedipine, have been reported to be useful in select IC patients (46).

Decreased urine levels of nitric oxide (NO) and high levels of bladder luminal NO have been reported in IC. L-arginine (a nitric oxide donor) was studied in a randomized, double-blind, placebo-controlled study. An “intention to treat” analysis demonstrated no statistical difference between the groups (91). Other studies have confirmed the lack of efficacy of L-arginine in the treatment of IC (12,34). A regimen of sequential antibiotic therapy has been used but does not seem to offer any advance in treatment outcomes (189).

Intravesical Therapy

Intravesical therapy (Table 28.13) is often used in IC treatment (150). Short dwell times in the bladder reduce the chance of systemic absorption and deliver high drug concentrations to the inflamed bladder. DMSO (Rimso 50) is the only intravesical drug approved by the FDA for IC.

Various dosage and treatment schedules of silver nitrate are used, ranging from a dilute 1:5,000 to a 1:100 (1%) concentration administered with local or general anesthesia, with an overall success rate of approximately 50% (65,150). Vesicoureteral reflux needs to be excluded and biopsies should not be performed at the time of treatment because of the risk of silver nitrate extravasation.

DMSO has many pharmacologic properties—antiinflammatory, analgesic, muscle relaxant, and collagen dissolution—that are useful for treatment of IC. The number and timing of instillations are empirical. DMSO usually is given at 1- to 2-week intervals for four to eight treatments. Fifty milliliters of RIMSO-50 are instilled, the catheter is removed, and the patient is instructed to hold the medication in the bladder for 15 minutes before voiding. Patients experience a temporary garliclike breath odor and a similar taste in their mouths for approximately 24 hours. Extensive studies have not demonstrated changes in the ocular refractive index or the development of lens opacities in humans. Individuals can be taught self-intermittent catheterization and instillation of DMSO. Many patients require maintenance therapy for relapsing symptoms, and the timing of treatment is empirical.

Other drugs augment the therapeutic benefit of DMSO therapy (150). Hydrocortisone (100 mg) promotes the antiinflammatory effects of DMSO. Heparin (5,000 units) can be added because of its antiinflammatory and surface-protective action, and sodium bicarbonate enhances steroid activity in the DMSO-steroid mixture. Intravesical heparin (10,000 IU monthly) reduces relapses in patients who respond to DMSO and can be used for maintenance therapy (122).

Oxychlorosene sodium (Clorpactin), a mixture of hypochlorous acid and the sodium salt of dodecylbenzene sulfonic acid, exerts a “detergent” action on the bladder mucosa, and the initial rationale for its use in IC was the similarity between classic IC with small, scarred bladders and tuberculosis of the bladder (150). A 0.4% solution is used for intravesical instillation under general or regional anesthesia because administration is painful. Vesicoureteral reflux is a contraindication to its use because of the risk of ureteral fibrosis. After treatment with oxychlorosene sodium, patients initially require oral narcotics and anticholinergics for control of frequency, pain, and other symptoms. Other intravesical agents include disodium cromoglycate (cromolyn sodium), an inhibitor of mast cell release; intravesical lidocaine (200 mg lidocaine in 40 mL normal saline); intravesical doxorubicin (Adriamycin); and intravesical hyaluronic acid (Cystitat) (38,150).

A single-institution prospective, double-blind, placebo-controlled trial of intravesical Tice strain bacille Calmette-Guérin (BCG) demonstrated a 60% response rate

compared with a 27% placebo response in IC (131). BCG is a strong stimulus of the immune system and its efficacy may be due to stimulation of type 1 (TH1) helper cell response (133). Longitudinal follow-up of the BCG responders from that initial study revealed that 8 of 9 (89%) patients maintained symptomatic improvement without long-term adverse events (132). BCG is currently being studied in a multicenter prospective, randomized, placebo-controlled study in the United States. Its role in treatment of IC will depend on the results of this study and the risk-benefit ratio of BCG used for nonmalignant bladder disease.

Electromotive drug administration (EMDA) utilizes the technique of iontophoresis to promote active transport of ionized drugs by application of an electric current. Patients (NIH-NIDDK criteria) treated with intravesical electromotive administration of lidocaine and dexamethasone followed by cystodistention (142) achieve significant symptom relief with increases in bladder capacity. This outpatient treatment approach holds promise as a novel therapy for IC.

Surgery

Surgery is needed in 2% to 3% of patients for control of intractable symptoms or to circumvent the functional effects of a severely limited bladder capacity (Table 28.14). Bladder hydrodistention, an integral part of the diagnostic evaluation, affords transient (3 months) relief of symptoms in approximately 20% of patients (150). A greater degree of distention can be achieved with the Helmstein intravesical balloon (33) in patients with reduced (less than 300 to 400 mL) bladder capacities. The duration of response is usually short, repeat hydrodilations are needed, and the risk of bladder rupture is approximately 8% (150).

Bladder distention	Sacral neuromodulation
Simple hydrodilation	Substitution
Helmstein balloon	enterocystoplasty
Transurethral electrocautery	Cystourethrectomy/urinary
Laser photoirradiation	diversion
(Nd:YAG laser)	

TABLE 28.14. SURGERY FOR INTERSTITIAL CYSTITIS

Transurethral resection (TUR) or fulguration of discrete ulcers controls pain in many patients with classic IC (71). Ulcers and fissures heal within 4 to 6 weeks following laser photoirradiation with the neodymium:yttrium aluminum garnet (Nd:YAG) laser (154), and pain relief is significant. Because of the rarity of Hunner's ulcers and the risk of small bowel perforation, laser treatment has not gained widespread use.

Less than 10% of IC patients require lower urinary tract surgical reconstruction (Table 28.15) for intractable symptoms (e.g., small capacity, pain), failure to respond to medical therapy, or lack of tolerance for standard pharmacotherapy. The outcomes following subtrigonal or supratrigonal cystectomy and orthotopic bladder substitution with an ileocecal pouch (Mainz pouch) were assessed. Both supratrigonal and subtrigonal cystectomy gave similar relief of symptoms (mean follow-up of 31.5 months), although the supratrigonal cystectomy group had better functional bladder rehabilitation (71).

Indications
Intractable symptoms
Failure of nonsurgical treatment
Presence of ulcers
Small bladder capacity (<400 mL)
Required in small number of patients (2%–3%)
Proper patient selection to ensure success
Cystolysis if capacity >350–400 mL
Substitution cystoplasty if capacity <300–350 mL
Cystourethrectomy
For failed cystolysis, enterocystoplasty
Better control of pain symptoms

TABLE 28.15. OPEN SURGERY IN INTERSTITIAL CYSTITIS

Supratrigonal cystectomy with ileocystoplasty resulted in a good clinical outcome in “classic” IC, whereas pain continued in patients with nonulcer IC. Identification of the IC subtype is crucial in the selection of patients for subtotal cystectomy and ileocystoplasty (128). Anterior vaginal wall hernias may develop in women who undergo simple cystourethrectomy and urinary diversion for intractable IC (3). An extended simple cystectomy, as compared with a radical cystectomy that includes a partial vaginectomy, may well result in weakening of the anterior vaginal wall and resultant anterior enterocele formation.

Another interesting treatment approach is that of sacral neuromodulation using sacral nerve stimulation. A small pilot study showed good responses, and parallel changes decreased levels of urinary antiproliferative factor. This study needs to be validated in a larger multiinstitutional study before it gains widespread acceptance (13). Ongoing studies of neuromodulation using the Stoller afferent nerve stimulator (SANS) and the ANS spinal cord device should shed light on the role of neuromodulation in IC.

Conclusions

Ongoing research into the causes and pathogenesis of IC continues to identify a multiplicity of dynamic pathophysiologic processes involving the various layers and components of the bladder. The initial insult or insults that lead to IC remain unknown. However, an altered bladder epithelial permeability results in a complex cascade of changes and interactions involving urinary cations (e.g., potassium), sensory nerves, activated mast cells, detrusor muscle overactivity, and spinal cord sensitization. The resultant vicious cycle of inflammation and nerve sensitization leads to the chronicity that is the hallmark of IC.

New drug treatments for IC will follow as a result of a better understanding of disease pathogenesis. There is now an emerging consensus favoring multimodality drug treatment for IC. This is based on the roles of the bladder surface urothelium, mast cells, and nerve endings in the pathogenesis of IC. Hopefully these multidrug therapies will lead to better treatment outcomes with patients responding in weeks rather than months.

IC is more prevalent than currently realized. This increasing recognition in men with symptoms of prostatitis and women with chronic pelvic pain has been a notable advance in recent years. Likewise, the recognition that IC patients frequently have a variety of associated diseases lends credence to the hypothesis that a subset of IC patients may have a systemic aberration in their immune, endocrine, or nervous systems.

Descriptions of urinary fistulae in both sexes appear in ancient texts, some of which are attributed to Hippocrates and Rufus. Such fistulae, although seldom life-threatening, can severely compromise the quality of life. Appropriate evaluation and timely correction is paramount. Treatment requires diligence, technical versatility, and supportive handling of the patient, family, and others involved. J. Marion Sims, although not the first to perform a surgical cure for fistula, changed history with the unique observation of vaginal anatomy when he examined patients in the knee–chest position. He described a surgical approach using three basic principles of urinary fistula repair: (a) excising all scar tissue, (b) obtaining fresh viable margins, and (c) closing the tract without overlying suture lines (60).

In developed countries, urinary fistulae are largely iatrogenic in etiology. Other inciting events or agents include direct invasion by malignancy, radiation therapy, trauma, pelvic inflammatory conditions, infections, granulomatous disease, the presence of foreign bodies, and traumatic delivery. Contributing factors that are critical in the etiology and successful repair of these abnormal communications include poor vascular supply, distal obstruction, poor nutrition, and continued inflammatory or infectious processes. Regardless of the type or location of fistula, the approach to repair should specifically address (a) the extent, number, and location of the fistula(e) and (b) the most likely cause, excluding complicating cofactors such as foreign body, malignancy, inflammatory or infectious conditions (including tuberculosis), and distal obstruction. Consideration of secondary comorbidities such as poor nutrition and previous radiation are critical because they influence the choice of procedure, timing of surgery, and probable outcome. Regardless of the type of fistula, most patients can be managed successfully without permanent supravesical diversion. Some fistulae require innovative techniques. It is crucial for urologists to be versatile and conversant with a broad range of procedures.

The principles of closure include appropriate urinary and fecal diversion. Well-vascularized, healthy tissue should be utilized for repair, and closure should be accomplished without tension and without overlapping suture lines. Infection should be treated adequately before repair. If possible, well-vascularized, noninvolved tissues should be interposed between the suture lines to provide an additional buttress. The operative area should be drained adequately after anatomic reconstruction has been performed.

VESICOVAGINAL FISTULA

Etiology

In medically underdeveloped countries, obstetric trauma remains the leading cause of vesicovaginal fistulae (15,162) (Table 29.1). In Africa, the common etiologic factors are obstructed labor with pressure necrosis (84%) and “gishiri cutting” (13%), involving an anterior vaginal wall cut to prevent pressure necrosis (31). The prevalence is highest among young primigravida (63%) during unassisted vaginal deliveries (176). The length of labor in these cases ranges from 1 to 6 days (mean 3.9 days). The destruction caused by the long periods of labor extend to the fetus as well because stillbirths are recorded in 93% of cases (76). In countries with more advanced obstetric care, the incidence of childbirth-related vesicovaginal fistulae has declined significantly, for example, from 39% in Judd's series (1920) to fewer than 6%, as reported by Massee and colleagues (105) in 1964 from the same clinic. More current studies from Europe and North America suggest an incidence as low as 0.01% (32,184). In developed countries, the most common cause of vesicovaginal fistula remains iatrogenic injury during gynecologic surgery, usually hysterectomy (27,51,74,178). The pathophysiology of vesicovaginal fistula is thought to be secondary to avascular necrosis of the bladder from suture placement and erosion into the vaginal cuff. A fistula also may follow an uncomplicated operation as the result of a pelvic hematoma that ruptures into the bladder during the postoperative period. Additional mechanisms of iatrogenic fistula include crushing, ligating, cutting, or devascularizing the bladder and vaginal cuff with surgical instruments. A thorough understanding of the relevant anatomy, strict hemostasis, and proper mobilization of tissue planes between bladder and uterus/vagina could minimize these causes. An awareness of predisposing risk factors such as previous radiation, cesarean section, endometriosis, prior pelvic surgery or pelvic inflammatory disease, inflammatory bowel disease, diabetes, concurrent infection, and atherosclerosis also is necessary (71,83,87,152).

Congenital (rare)	Abdominal hysterectomy
Inflammatory	Vaginal surgery
Infection, such as tuberculosis and schistosomiasis	Urologic procedures
Foreign body in bladder or vagina	Obstetric trauma
	Prolonged labor
	High forceps delivery
Prolonged indwelling urethral catheter	Cesarean section
	Direct injury
Endometriosis	Neoplastic
Trauma	Carcinoma of cervix, bladder
Pelvic surgery	Radiation induced

TABLE 29.1. CAUSES OF VESICOVAGINAL FISTULAE

Fortunately, fistulae following aggressive transurethral resection of the bladder neck or transurethral resection of posteriorly based bladder tumors are now rare. Radiation-induced fistulae are commonly associated with carcinoma of the cervix, and several have been reported after radiotherapy of other pelvic malignancies. Fistulae may appear during the course of radiotherapy or after treatment is completed. Those occurring during therapy are probably secondary to necrosis of tumor in the wall of the vagina or bladder. Those that appear later are likely secondary to excessive radiation, which leads to endarteritis obliterans and eventual necrosis of the vesical or vaginal wall. These fistulae usually appear during the first 2 years of treatment and have become less common with improved radiation therapy techniques. Reports of new onset of fistulae secondary to remote irradiation continue to appear suggesting that clinicians should remain diligent in their evaluation of patients whose bladder symptoms evade a clear etiology (111).

Other less common causes of vesicovaginal fistulae are the destruction of tissue by other malignant tumors, ulceration resulting from a foreign body, (i.e., retained pessary) direct trauma (especially automobile accidents associated with pelvic fractures), tuberculosis, schistosomiasis, calculi, and endometriosis.

Clinical Features

The most common presenting symptom of vesicovaginal fistula is continuous leakage of urine from the vagina. Incontinence developing from operative trauma usually occurs 5 to 14 days postoperatively (74,184). Leakage of urine is directly related to the size and position of the fistula. Patients with small fistulae may void reasonable amounts of urine and notice only slight, position-dependent drainage. Patients with large fistulae have total incontinence and may not void through the urethra at all. Leakage of urine causes irritation of the vagina, vulva, and perineum and usually produces an unpleasant, ammoniacal odor. In neglected cases, phosphatic encrustations may be noted. The posthysterectomy fistula is typically located in the vault of the vagina (164). An obstetric fistula is usually located at a lower level, is larger in size, and is more commonly associated with urethral injury.

Graham (53) described the painful syndrome of postradiation urinary vaginal fistula. He noted that 40% of patients with radiation-induced fistulae developed pain, usually associated with an alkaline urine and deposition of triple-phosphate crystals, which further irritate compromised tissue. Urinary leakage can make the patient a social recluse; disrupt sexual activity; and lead to significant mental depression, insomnia, and low self-esteem (61,74).

Diagnosis

In most patients, the diagnosis is obvious (Table 29.2). However, a complete urologic investigation is mandatory, especially to rule out ureterovaginal fistula. This investigation should include a urinalysis, urine culture, and intravenous urogram. Other tests, such as a retrograde ureteropyelogram, can be performed as necessary. In one series, 12% of patients with vesicovaginal fistulae had associated ureterovaginal fistulae (51). Overlooking additional fistulae continues to perplex even the most experienced urologists (93). Such patients are a continual source of consternation as well as surgical failures.

Urinalysis	Retrograde ureteropyelogram
Urine culture	Cystoscopy and vaginoscopy
High vaginal swab	Computed tomography scan or magnetic resonance imaging
Intravenous urogram	
Dye test	

TABLE 29.2. INVESTIGATIONS FOR URINARY VAGINAL FISTULAE

All patients with fistulae should undergo cystoscopy and vaginoscopy. Every attempt should be made to determine the exact location (in relation to ureteral orifices), size, and underlying cause of the fistula. Successful repair depends on identification of these factors. At examination under anesthesia, it is often possible to palpate the vaginal opening of the fistula. A diligent search should be made for additional communications because many treatment failures have occurred because less obvious fistulae were overlooked. It is also worthwhile to determine the status of the bladder neck and note whether there is any associated loss of urethral tissue. In addition, a careful examination should be done with the patient anesthetized, and a biopsy sample should be obtained from any suspicious lesion to rule out malignancy. In advanced cases with a positive biopsy for carcinoma in the fistula tract, Wein (178) has recommended pelvic exenteration or palliative urinary diversion rather than fistula repair. In equivocal cases, a simple double-dye test can be performed at the bedside (143). The vagina is packed with four sterile, wet gauze pads—one in the left and one in the right vaginal fornix, one at the midvaginal level, and one at the vaginal outlet. The bladder is filled with a 1% carmine solution (red), and 5 minutes later 5 mL of indigo carmine (blue) is injected intravenously. The swabs are removed 10 minutes after the injection. A red stain (carmine) in the midvaginal pack indicates a vesicovaginal fistula, a blue stain on the upper swabs placed in the vaginal fornices indicates a ureterovaginal fistula, and a red stain in the swab at the vaginal outlet indicates leakage through the urethra. Sometimes the findings can be misleading. The amount of indigo carmine excreted

depends on renal function, and occasionally, carmine solution can reflux up a ureter and gain entry into the vagina by means of a ureterovaginal fistula, providing a false-positive result for a vesicovaginal fistula. Recently, a simplified double-dye test has been used to diagnose various types of vaginal fistulae with oral phenazopyridine administered until the urine is stained orange. The patient is then instructed to insert a vaginal tampon. The bladder is catheterized, emptied, and filled with saline/methylene blue mixture. After 10 minutes, the bladder is emptied and the tampon removed. An orange stain at the top of the tampon indicates a ureterovaginal fistula, and a blue stain is consistent with a vesicovaginal fistula (124).

The use of computed tomography (CT) scanning with intravaginal contrast has been used in a small number of patients with limited success (60% detection rate). CT findings that suggest fistula include radiation changes, contiguous pelvic mass, and adherent bowel. The use of such imaging techniques may be most beneficial in trying to ascertain the underlying etiology and the extent of prior disease before attempting a surgical repair (82). The use of magnetic resonance imaging (MRI) has been reported largely in the case report format only; thus recommendations are difficult to assess. However, the use of a T_2-weighted image looking for fluid within the fistula is suggested as a useful characteristic (121). The multiple plane image reconfigurations and tissue characterizations of this technique are also useful (167). In a prospective study of ultrasonographic evaluation of vesicovaginal fistula, Adetiloye and others (1) noted its demonstration in only 29% (7 of 24) compared with examination under anesthesia in 87%. Sonography appears to function as complimentary examination at best. There is no substitute for a diligent search on the part of the clinician to establish the site or sites of fistulae (Table 29.3).

Vesicovaginal fistula	Severe stress or urge incontinence
Ureterovaginal fistula	Vaginitis or enterovaginal fistula

TABLE 29.3. DIFFERENTIAL DIAGNOSIS OF URINARY VAGINAL FISTULAE

Preoperative Care

Medical and psychologic support are necessary in afflicted women. Cystitis, vaginitis, and perineal dermatitis should be treated with appropriate antimicrobials. Local care is important, with meticulous cleansing and frequent pad changes to minimize inflammatory edema and vulvar irritation. Protective creams or ointments are occasionally helpful in reducing vulvovaginitis. Keeping the area as dry as possible, at times by the innovative use of collection or drainage devices, is often helpful. Nutritional supplementation may be of benefit in this group of patients. Video urodynamics is a key diagnostic tool providing information about bladder storage function and urethral continence mechanisms. This issue should be addressed prospectively in fistula at the bladder neck and urethra, irradiated tissue, and in patients with a previous history of or recurrent incontinence (184).

A small fistula may close with catheter drainage alone or after electrocoagulation and catheter drainage (128,130,184). Denuding the fistula tract with a metal screw curettage has resulted in successful healing (8). Nonsurgical treatment of the vesicovaginal fistula has been reported in the past, and reports continue to appear. Davits and Miranda (31) reported their experience with spontaneously healing fistulae with the use of prolonged Foley catheterization. In their four cases, the diagnosis was made easily and prompt conservative treatment was begun. Although this study confirms that this method can be used, the success rate is low. Such techniques require continuous drainage, with some patients on constant suction often for extended periods of hospitalization. The successful closure of small fistula using a fibrin clot following debridement of the tract has been successfully used (64,139). Estrogen replacement also can be used provided there are no medical contraindications in patients who are castrated or postmenopausal. Hyperbaric oxygen treatment also has been used as an adjuvant treatment in radiation-associated fistulae (155). Fistulae associated with the use of adjuvant radiation therapy will not heal spontaneously, and surgical correction is required (144).

Timing of Repair

Controversy remains over the timing of repair. Most surgeons agree that there should be a waiting period of at least 3 to 4 months before surgical repair is performed (27,74,115,178). The rationale for this relates to the acute inflammatory response and edema, which will have a chance to subside. Waiting also allows the tissues to develop an improved blood supply and become more pliable, allowing for greater ease of defect closure without tension. This observation also allows an opportunity to treat any infection that may be present. It should be noted that this sage advice to delay repair is based on the historically more prevalent obstetric fistula, which etiologically and prognostically is different from the more straightforward iatrogenic fistulae seen in the Western world. Several series report excellent results with early operative intervention in patients with vesicovaginal fistula that result from iatrogenic injury (9,14,138,146). Using the transabdominal approach, Blandy reported 100% successful treatments of iatrogenically induced ureteral and vesicovaginal fistulae in 40 patients (14). Ideally, fistula that are to be repaired early should be done within the first 2 weeks before inflammation and fibrosis make reconstruction difficult. Unfortunately, many fistula are not detected until after this period. Regardless, this early aggressive treatment has not received wide acceptance. Wein and associates (178) attributed two of their failures to inadequate delay between the initial surgical procedure and the subsequent attempt at fistula repair. Collins and associates (24) have recommended a 10-day course of cortisone to decrease inflammation, followed by early repair of the vesicovaginal fistula. Because steroids may adversely affect healing, this approach appears hazardous. In their reported series of 38 patients who had repair 4 weeks after diagnosis, a 28% failure was seen.

Every patient should be examined at regular intervals, and treatment decisions should be individualized rather than using arbitrary timelines. The optimal time for repair is when all necrotic tissue has disappeared, tissue pliability is acceptable, inflammatory edema has subsided, the fistula size has stabilized, and all acute inflammatory changes have resolved. In making this judgment, the surgeon should not allow objective judgment to be swayed by a patient's emotions and the referring physician's consternation. There is no question that the planned delay in treatment results in physical discomfort and emotional stress with patients enduring the discomfort and humiliation of having continuous urinary leakage or catheterization for a 3- to 6-month period. Presented with an incontinent and angry patient, one needs to remember the admonition of Dr. V.J. O'Conor, Jr., that “a surgeon must stand firm in his conviction that an impatient patient is easier to manage than a surgical failure” (126). The failure rate for repair of the fistula will be higher if the tissue is acutely inflamed, edematous, ischemic, or necrotic. Some fistulae recognized in the immediate postoperative period or after trauma with minimum inflammatory changes may lend themselves to early repair. In cases of complex or radiation-induced fistulae, a longer waiting period is usually required to optimize tissue status and assess surgical options.

Operative Management

A vesicovaginal fistula can be repaired through a vaginal, abdominal, or combined approach. The vaginal approach is often used, and a success rate close to 90% is achieved with this technique (27,105,115). Compared with the abdominal approach, the vaginal repair of a fistula is a less extensive procedure, avoids a cystotomy, is associated with less blood loss, results in less discomfort and disability to the patient, and requires a presumed shorter hospital stay (74,115,176). The disadvantage of the transvaginal approach is the relative lack of familiarity with the surgical anatomy by many urologists and the relative lack of versatility in surgical options should the fistula “suddenly” become complex in nature. Furthermore, the abdominal approach often provides better access to the fistula. Improved exposure decreases the likelihood of ureteral injury. If necessary, an omental pedical graft can be interposed between the bladder and vaginal wall (125,128,129,130 and 131,169,178).

Indications for a transabdominal approach include (a) limited access because of a high retracted fistula in a narrow vagina, (b) proximity of the fistula to the ureteral orifices or a need for a ureteral implantation, (c) associated pelvic pathology, (d) complex fistula with multiple fistulous tracts or previous radiation, (e) narrow introitus, (f) poorly estrogenized or scar tissue that does not respond to preoperative estrogen replacement, and (g) morbid obesity. Despite the recent interest in transvesical or transvaginal approaches, the O'Conor technique is time-tested, enjoys a high success rate and is still regarded as the gold standard (122). A combined vaginal and abdominal approach also can be helpful in instances of complicated fistulae with pelvic malignancy or previous radiotherapy (182). This allows for full mobilization of the omentum and its interposition between the vagina and the bladder or urethra (169).

Using a vaginal or abdominal approach to an individual fistula depends on the findings and the surgeon, but the principles of repair are the same. Success is determined by a watertight, multilayered closure without tension and without overlapping suture lines. Maintenance of blood supply, removal of all necrotic tissue, identification and separation of surgical planes (vaginal wall and bladder wall), obliteration of dead space, good bladder drainage, control of infection, and interposition of healthy tissue when appropriate are important technical considerations (115,138). The best chance at closure of the fistula is the first chance. In troublesome incontinence from vesicovaginal fistulae in patients who are not operative candidates secondary to terminal disease, urinary diversion via percutaneous nephrostomy with or without ureteral occlusion can be considered. Occlusion with Gianturco coils and gelatin sponges is safe and reliable in obtaining long-term, if not permanent, supravesical diversion (42).

Vaginal Repair

The inverted lithotomy position provides excellent exposure of the ventral vaginal wall. The bladder is then in a dependent position, and the fistula is more easily dissected. Many surgeons, however, prefer the conventional lithotomy position (74,115,138). A description of how to repair the fistula with the patient in a lithotomy position follows (Fig. 29.1).

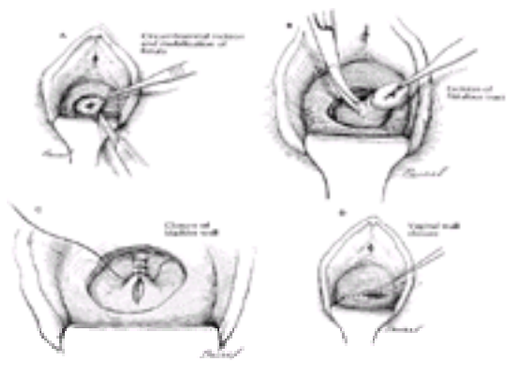

FIGURE 29.1. Schematic representation of a vaginal repair of a vesicovaginal fistula. **A:** Circumferential incision around fistula track with mobilization of the fistula. **B:** Fistula is excised. **C:** Bladder is closed, and then the vagina is closed in multiple separate layers with avoidance of overlying suture lines. **D:** Closure of vagina wall.

After careful evaluation, the ureteral orifice may be catheterized cystoscopically if there is any concern about the ureters. The labia minora are sewn laterally, and a weighted posterior vaginal retractor is placed. Stay sutures are placed in healthy tissue on each side of the fistula because they are helpful in identifying the fistula's opening at a later stage in the operation, when bleeding and excision of tissue may make identification more difficult. Additional Babcock or Allis clamps may bring the fistula tract closer to the surgeon. A Foley or Fogarty catheter also can be placed through the fistula track. This maneuver can greatly aid dissection of a fistula, especially one high in the vagina. If the vagina is small, an incision can be made through the dorsal lateral vaginal wall, similar to an episiotomy incision, to provide better access (52). A circumferential incision is made around the defect, and all scar tissue is excised. Adequate separation of bladder and vaginal wall is attempted to obtain a tension-free closure. In some instances, the separation may be difficult and lead to unnecessary bleeding and devascularization of tissue (115,136). On the other hand, it must be remembered that if basic surgical principles are even slightly compromised in these cases, the failure rate is much higher. Caution is also exercised in the posthysterectomy fistula to avoid opening Douglas's pouch and inadvertently creating a bowel fistula because small bowel may be closely adherent. In high vaginal fistulae, inadvertent injury to the ureters is also possible. After excision of the fistula tract with adequate separation of the bladder and vaginal wall, a three-layer closure is performed (74,131) with absorbable sutures on an atraumatic needle. If there is tension on the closure, relaxing incisions have been recommended, but in such a case, the operation has probably been performed inadequately. A vaginal flap advancement or other maneuver to create a tension-free anastomosis would be a better alternative. Occasionally, bleeding may be profuse, but vaginal packing generally controls it.

One can advance a vaginal flap rather than totally excising the tract, especially in patients with a simple, small fistula. In more difficult cases, the Latzko technique of partial colpocleisis can be performed (86,101,102). This method involves denudation of an elliptical portion of the vaginal wall surrounding the tract, with the bladder portion left untouched. Partial colpocleisis is performed in three layers, without sutures entering the bladder wall. This enables the posterior vaginal wall to become the posterior bladder wall with eventual reepithelialization with transitional epithelium. The overall success rate of 93% (40 of 43 patients) is comparable to more standardized vaginal approaches (40,164). This method may cause loss of vaginal length and interfere with sexual function but has been particularly effective in patients who have had previous radiation (101,102).

Various flaps have been increasingly utilized in recent years (63,70,103). In patients with a large defect, a pedicle flap enhances the cure rate, presumably because of additional blood supply, improved lymphatic drainage, and better separation of suture lines. With a low or midlevel fistula, the graft of a pedicle flap of labial fibrofatty tissue (103) can easily be performed. The use of this flap is so convenient and well tolerated that its routine use should be encouraged. By careful dissection and preservation of its anterior- or posterior-based blood supply, the labial fat pad can reach high-level fistulae. Conversely, a higher fistula with a large defect may require a buttock flap (66), or a gracilis muscle or rectus abdominus muscle flap in patients who have undergone radiation (52,53,70,136,154). For fistulae that involve the trigone or lie close to the ureteral orifices, a bladder rotation flap or bladder advancement flap with interposition of omentum often suffices (25,80,142,160). The use of such flaps does not excuse the surgeon from strict adherence to the principles of repair outlined earlier. The use of various tissue interposition maneuvers are discussed later in this chapter. At the end of the operation, the bladder is irrigated and all clots removed. A Foley catheter is left in place, and the vagina is packed with gauze.

Abdominal Approach

The always useful abdominal approach (transperitoneal transvesical) begins by exposing the bladder through a lower midline abdominal incision (Fig. 29.2). The advantage of this incision is that it can be readily extended upward and a pedicle flap of omentum can be mobilized. A limited transvesical approach has been advocated by some for simple vesicovaginal fistula in cases where the vaginal approach is not possible, and the surgeon wishes to avoid the associated morbidity of the traditional transabdominal approach (48,184). In complicated cases, a transperitoneal approach is preferable.

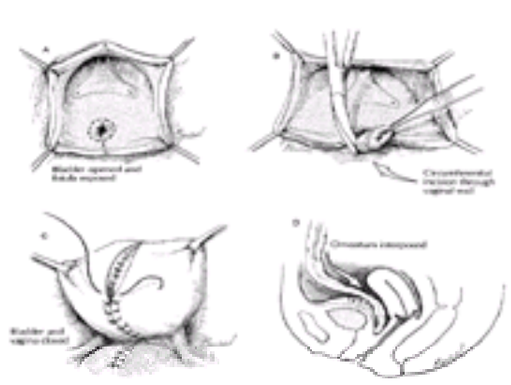

FIGURE 29.2. Abdominal repair of vesicovaginal fistula. **A:** Transabdominal, transperitoneal exposure of fistula track reveals fistula above trigone after the bladder is opened. **B:** Bladder wall is divided and the fistula, including the vaginal wall, is excised transvesically. **C:** Bladder and vagina are closed in multiple separate layers. **D:** Omentum is interposed between bladder and vagina to provide a vascularized pedicle to prevent further fistula formation.

The principles of repair are the same. The peritoneum is opened high above the umbilicus as adhesions are freed and the omentum mobilized for later use. The

bladder is opened between Allis clamps, and stay sutures are held with clamps. The bladder incision is extended downward posteriorly, with stay sutures placed on each side. The proposed incision effectively bisects the bladder and extends around the fistula to create a tennis racket appearance. The key is to bisect the bladder and vagina so that closure can be effected using viable, freely movable flaps that come together easily without tension.

As the fistula is approached, it is often helpful to place a balloon catheter or Young prostatic retractor to elevate the area. A circumferential incision is made through the full bladder wall. All firm scar tissue at the fistula is excised until the edges bleed freely. Once these bladder flaps are developed, the upper vagina is well exposed and hemostasis is excellent. The vaginal part of the fistula is excised and cut back until viable vascular edges are obtained. Any hard, fibrous tissue that does not bleed should be excised. The vagina is closed transversely in two layers, the bladder is closed longitudinally in multiple layers with absorbable sutures, and the omentum is brought down and fixed to the vagina. If adequate omentum is not available, the short gastric arteries are divided, with care taken to preserve arteries from the gastroduodenal source. Although many quote that O'Conor invented the use of omentum for this purpose, it should be emphasized that its use in vesicovaginal fistula repair was initially described by Waltman Walters (175). Closures can be reinforced with a peritoneal flap of the lateral parietal peritoneum (36) if omentum is not available. If the defect cannot be closed without tension, the flap should be used to plug the defect, which can then be used to allow reepithelialization (184). Other alternatives include an advancement flap derived from the posterosuperior wall of the bladder as a means of covering large defects (48). Alternative flaps include the gracilis muscle, island myocutaneous flaps, myofascial flaps, bladder mucosa, appendices epiploicae, and seromuscular intestinal patches (see later for interposition flaps details). A urethral and occasionally a suprapubic catheter ensure continuous drainage.

Recently, surgeons have adopted the use of the versatile bladder mucosa graft in the treatment of vesicovaginal fistula (16,134). This technique consists of a transvesical approach with an incision in the anterior bladder wall above the fistula site. The fistula is removed, including a 3- to 5-mm edge of tissue free of fibrosis. A bladder mucosa graft proportional to the size of the defect is dissected from the muscle. The free graft is positioned so that the submucosal tissue faces the bladder and the mucosa surface faces the vagina. The serosal vaginal surface is sutured through the vesicostomy incision using absorbable sutures. Investigators report a remarkable 96.3% success rate with no late failures (16). It has been proposed that the graft acts as a biologic dressing avoiding scar tissue formation that could result in a new vesicovaginal fistula. A second potential advantage of this procedure is that the suture lines are not directly overlying each other because the graft covers the bladder suture line and produces an extra layer of tissue. The bladder mucosa autograft technique offers a very promising alternative for the treatment of small and well-visualized vesicovaginal fistulae.

The recent reports of a laparoscopic approach to vesicovaginal fistula is not surprising given its application in other areas (114). However, its role as a dependable form of therapy depends on adherence to fistula repair principles and studies that move beyond the case report format.

Postoperative Care

The vaginal pack is removed after 24 to 36 hours. The patient is encouraged to be ambulatory as early as possible to minimize thromboembolic complications, which have been reported in most large series (27). Antimicrobials are used intraoperatively and frequently postoperatively until all tubes are removed. Unobstructed vesical drainage is mandatory for success. Anticholinergics and sedation often reduce bladder spasms. The urethral catheter is removed 7 to 10 days postoperatively, after a cystogram verifies there is no extravasation. It is recommended that the patient abstain from sexual intercourse for at least 6 to 8 weeks postoperatively.

URETHROVAGINAL FISTULA

Etiology

Urethrovaginal fistula is an uncommon condition that usually results as a complication of such operative procedures as urethral diverticulectomy, anterior colporrhaphy, transurethral resection of the bladder neck, or trauma. In these cases, the most common causes are interference with blood supply leading to tissue slough or nonhealing secondary to infection. In medically deprived countries, obstetric trauma secondary to obstructed labor with pressure necrosis of the anterior vaginal wall is by far the most common cause of urethral destruction. A fistula may result after trauma, especially with pelvic fractures and urethrovaginal lacerations. In addition, vaginal and urethral neoplasms treated with radiotherapy may undergo necrosis and create a fistula. Pressure necrosis also can occur with a prolonged indwelling urethral catheter. Transsexual surgery and drainage of a periurethral abscess are other rare causes of fistulae. Finally, urethrovaginal fistulae can be seen on a congenital basis (101,102).

Clinical Features

Fistulae involving the bladder neck and proximal 2 cm of the urethra may produce continuous incontinence, whereas a fistula distal to the external sphincter may be entirely asymptomatic. A distal fistula also may create a spraying-type split stream. Usually, bothersome urine will drain via the vagina, especially when the patient stands. Of patients, 20% to 40% will have associated stress incontinence. Generally, the defect is obvious on examination, but occasionally, it may be hidden by the rough, irregular vaginal surface. As many as 19% of patients with this type of fistula may have a secondary communication between the bladder and vagina (92).

Diagnosis

The differential diagnosis includes vesicovaginal fistula, ureterovaginal fistula, severe stress or urgency incontinence, and a copious vaginal discharge. A complete urologic investigation with cystourethroscopy and vaginoscopy reveals the type and size of the defect. In select patients, urodynamic studies, urethral pressure profile, voiding cystourethrogram, and the Bonney test provide additional useful information.

Management

An efficient bladder neck mechanism is critical in females to maintain continence. Studies have shown that the proximal 2 cm of bladder neck and urethra represents the continence zone (85). Unfortunately, as many as 49% of continent postmenopausal women have an incompetent bladder neck mechanism and depend on an intact proximal urethral mechanism to maintain continence (88). The fistula may compromise the urethral closure mechanism, causing the patient to experience stress incontinence in addition to the difficulties from the fistula.

The principles of management are similar to those of vesicovaginal fistula. Treatment depends on symptoms, cause, size, and location of the fistula, as well as other local factors. If stress incontinence is noted, the evaluation should include an assessment for urethral hypermotility, scarring, and fixation. If atrophic tissue is present in the vagina, estrogen replacement may be of benefit provided no medical contraindications are present. For this type of fistula, video urodynamics have an important role in preoperative assessment. In patients with type III stress incontinence, the use of concurrent fascial sling at the time of transvaginal closure warrants serious consideration (13,184). Its role as a reinforcing layer as well as a continence procedure does not preclude alternative interpositions as well (i.e., Martius flap).

In cases of bladder neck destruction, the Young-Dees-Leadbetter (89) repair may be useful in reconstruction. The transpubic approach, as advocated by Waterhouse and colleagues (177), may provide additional exposure, but complication rates are higher. Labial fat pad repair (38,88,103), gracilis muscle flap interposition (70,136), pedicle perineal flap (66), island bulbocavernosus musculocutaneous flap (19), and full-thickness skin graft have been successfully used in reconstruction of the female urethra.

In the small fistula, the Martius procedure, using the fibrofatty labial tissue, may suffice. This tissue is mobilized on a pedicle, preserving its vascular supply on its posterior aspect, and is passed through a subcutaneous tunnel into the vaginal lumen, where it is sutured over the repaired urethra. The ease of usage and other advantages of this flap are so numerous that we recommend it for routine use. The pedicle buttock flap, as described by Hendren (66), however, provides better vascularized tissue and ensures a greater likelihood of success, especially in larger fistulae (Fig. 29.3A and Fig. 29.3B). Success rates of repair vary from 75% to 100%, although some patients require more than a single operation (54,74,136,164). If stress incontinence is associated with a urethrovaginal fistula, a simultaneous continence procedure can be performed once the fistula repair has been completed (88,184). Preoperative planning of urethrovaginal fistula correction must consider bladder neck competency or risk residual stress incontinence as high as 40% (127,136). This issue is critical in those with prior irradiation, bladder fibrosis or multiple previous surgeries. Fistulae induced by irradiation seem to be the most difficult to repair successfully because this group has bladder compliance difficulties in addition to the urethral pathology (38,165). Sophisticated urodynamics are necessary for addressing both bladder and urethral pathology. Tissue interposition is mandatory if a surgical approach is considered. The bladder is then drained suprapubically for several weeks.

FIGURE 29.3. URETEROVAGINAL FISTULA

Etiology

The ureter is especially susceptible to injury during vascular, gynecologic, urologic, and colonic operations. Gynecologic surgery remains the most common cause of ureterovaginal or ureterocutaneous fistulae (91). Total abdominal hysterectomy is the most common operation responsible for ureteral injury (120,174). Endometriosis, obesity, and pelvic inflammatory disease appear to be complicating factors (161). Injuries are more common if the patient has received preoperative radiation. Postoperative radiotherapy does not appear to be associated with an increased incidence of stricture or fistula formation.

Clinical Features

In the postoperative period, a ureteral injury is suggested by the presence of unexplained abdominal pain, flank tenderness, abdominal mass, or fever. Subsequent urinary drainage occurs days or weeks after the injury and is often detected as copious drainage through a postoperative drain site. The patient usually voids normally. However, the presence of associated continuous urinary leakage from the vagina should raise the question of a ureterovaginal fistula. The symptoms are often similar to those in patients with congenital extravesical duplicated ureters.

Diagnosis

An intravenous urogram demonstrates some degree of ureteral obstruction in most cases (9,120,169). Retrograde pyelography usually delineates the nature and extent of the injury. Ureteral catheterization usually reveals obstruction. In equivocal cases, a dye test can be helpful and is quite sensitive (120).

Occasionally, a preexistence abnormal communication may exist between an ectopic ureter and the vagina but may not be demonstrated by the usual tests (90). The upper pole of the kidney may not be visualized on the intravenous pyelogram (IVP) because its function is impaired. Presence of a duplication may be suspected from a “drooping lily” configuration of the lower-pole pelvis. Meticulous cystourethroscopy and careful inspection of the vagina are mandatory because an ectopic orifice can be missed. Occasionally, a mass can be seen in the region of the trigone (15). A mass along the wall of the vagina can be examined by needle puncture and instilled with contrast medium.

Management

The primary goals include renal preservation and prevention of urosepsis. Primary nephrectomy was frequently performed in the past, but Goodwin and Scardino (51) reported a reduced nephrectomy rate of 5%. If a ureteral injury is suspected and diagnosed, the patient will rarely require a nephrectomy for ureterovaginal fistula. However, the management of the ureterovaginal fistula is controversial. Early repair has been advocated to prevent irreversible damage to the kidney. On the other hand, a retrograde catheter or stent can be placed to establish drainage, or a percutaneous nephrostomy also can be placed with a stent (84). The percutaneous nephrostomy is more easily tolerated than a retrograde ureteral catheter and provides better drainage. In select patients, a conservative approach using a ureteral stent and a percutaneous nephrostomy allows the ureter to heal if done in a timely fashion (22). This endourologic management is recommended, particularly if the injuries are recent (less than 3 weeks), if minimal loss of ureteral length (less than 2 cm) is involved, and if some continuity of the ureteral wall remains (26). Several groups of investigators report a 25% to 50% success rate in managing postoperatively discovered ureteral injuries using these techniques (34,37,171). This type of drainage may have a role in preserving renal function even if open surgery is planned.

If urinary extravasation or obstruction persists after removal of the ureteral stent, a formal repair can be performed as soon as the inflammation has subsided and any infection is under control. A psoas hitch ureteral reimplant has been successful for us in these cases. With the sutures placed intravesically, the mobilized bladder can be displaced superiorly and anchored in position, so no dissection is necessary in the scarred pelvis. We insert a finger intravesically to “push” or position the bladder high on one side and then anchor it extravesically. We commonly continue to use intravesical pressure to help introduce and anchor the ureter. Preoperative, purposeful self-distention of the bladder may help secure necessary mobility to reconstruct the urinary tract. The pedicle on one side of the bladder can be sacrificed to gain additional bladder mobility. If a larger segment of ureter has been damaged, Boari flap procedures can be used as well. If these maneuvers fail to surmount the distance needed to reestablish ureteral continuity, then renal descensus, renal autotransplantation, or ileal substitution may be needed. Successful management of ureteral fistula repair using a single, open procedure approximates 100% in select series (99,133). Nephrectomy or renal embolization and percutaneous ureteral occlusion should be used for those who are poor surgical risks (97,148).

ARTERIOURETERAL FISTULA

Etiology

Fistulae between the urinary system and major arterial vessels (usually iliac) have emerged as a troublesome phenomenon within the last 15 years. Recently, the association between ruptured iliac aneurysms and arteriovesical fistula has been identified (49). Although they were previously considered rare, reports are appearing in the vascular and urologic literature with increasing frequency, presumably secondary to the widespread practice of stenting ureteral pathology (strictures, stones). The mechanism of fistula development has been postulated to require irradiation or previous surgery on the major abdominal vessels, causing injury to the vaso-vasorum (45,46). This phenomenon, combined with the leakage of blood, causes fibrosis and adherence of the ureter to the artery. Once a ureteral stent has been placed, it may create a localized necrosis of the wall (33). The addition of radiation acts as a sclerosing agent and contributes to fibrosis, ureteral obstruction/fixation, and eventual fistulization. This phenomenon is supported by a marked absence of arterioureteral fistula without the presence of ureteral stents. The relationship between arteriourinary fistula following the rejection of pancreas transplants with bladder drainage also has been noted (151). It has been proposed that the inflammatory response in rejection leads to reabsorption of the graft placing the bladder in close proximity with the iliac artery leading to subsequent erosion and fistulization.

Diagnosis

Profuse intermittent hematuria should increase the suspicion of ureteroarterial fistula. The presence of a stented or irradiated ureter or history of previous surgery should suggest a consideration of this condition. The diagnosis is particularly difficult to make at the time of presentation because the patient is usually critically ill. Imaging studies such as arteriography or CT scanning are rarely helpful but appropriate if time permits. In a recent review, 15 of 22 cases were not diagnosed until the time of surgical exploration (35). Cystoscopy is helpful in lateralizing the side of hemorrhage, and retrograde ureterograms can demonstrate the fistula in a minority of cases (7). The development of hematuria in a patient with a rejected pancreas transplant with bladder drainage should be aggressively evaluated for such

a fistula.

Management

Surgical management is the only reasonable alternative for treating these fistulae. Conservative measures are associated with an 83% mortality rate. Goals in the surgical care include (a) control of hemorrhage, (b) maintenance of a vascular continuity, (c) provision of adequate urinary diversion, (d) removal of all infected prosthetic material (graft and stent), and (e) salvage of the kidney if possible. The management of the involved ureter depends on the location and extent of the fistula. Potential urologic maneuvers include ureterectomy, ureteral reimplantation, transureteroureterostomy, cutaneous ureterostomy, and excision of the fistula with primary ureteral repair. Any interposition of healthy tissue that is available (ideally omentum) is advisable. Renal salvage has been successful in 67% of patients (35). Vascular management has required repair of the iliac artery in 48% of patients, all of whom required subsequent bypass procedures (35). Mortality rates before 1980 exceed 50%, but recent reviews report improved postoperative care as the major factor in lowering mortality to 15% (172). Recently, a minimally invasive management of this problem has emerged in which endovascular stent grafting is used (43,58). This promising technique appears to be able to manage the fistula without the need for extracutaneous vascular bypass. This technique obviously requires early recognition, medical stabilization, and angiographic evaluation. Whether this approach becomes a predominant method in treating this potentially fatal problem remains to be demonstrated.

RECTOURETHRAL AND PROSTATIC FISTULA

Etiology

A rectourethral or prostatic fistula may be congenital or acquired (Table 29.4). The congenital fistula is uncommon and usually occurs in boys in association with congenital anorectal anomalies (28). A rectourethral communication is present in 80% of patients with a high- or intermediate-level imperforate anus. Treatment is usually associated with anorectal pull-through operations.

Congenital	Inflammatory
Iatrogenic	Prostatic abscess
Prostatectomy	Urethral stricture
Transurethral resection of prostate	Tuberculosis
	Crohn's disease of colon
Urethral dilation	Neoplastic
Anorectal surgery	Prostate
Direct trauma, especially associated with fractured pelvis	Urethra
	Rectum

TABLE 29.4. CAUSES OF RECTOURETHRAL FISTULA

The acquired fistula is usually a postprostatectomy complication. In the past, perineal prostatectomy was the most common cause. Most patients developed a fistula after a simple prostatectomy or, less frequently, after a radical prostatectomy or an open prostatic biopsy (28,29,78,108,132,173,181,185,187). It also may occur as a complication of suprapubic prostatectomy, retropubic prostatectomy, radical retropubic prostatectomy, radiation therapy of the prostate, or overzealous transurethral resection of the prostate (TURP). Several factors appear to predispose a patient to rectal injury during prostate surgery, including a history of TURP, previous radiation, or rectal surgery (108). Rarely, a prostatic abscess may rupture into the rectum. A rectourethral fistula also has been described in association with Crohn's disease or inflammatory disease of the colon as well as carcinoma of the rectum or prostatic carcinoma (18). Direct trauma also may result in rectourethral fistula, especially in association with a fractured pelvis (168). Rarely, stricture disease or tuberculosis may create a fistula (62).

Clinical Features and Diagnosis

A rectourethral fistula may be strongly suspected from the patient's history. The patient may have pneumaturia or fecaluria with leakage of urine from the rectum during micturition. Urinary drainage via the rectum may lead to diarrhea. Urinary tract infections and epididymitis are common (28), as are urethral stricture and perineal fistula (28,168).

The diagnosis can usually be made by careful inspection of the rectum. Occasionally, the opening can be palpated or visualized directly by proctoscopy. A biopsy is performed when necessary to rule out carcinoma. The fistula also is usually visible on careful cystourethroscopy. Radiographic studies of the bowel and colonoscopy should be performed to verify that no additional colonic disease is present.

Management

The variety of methods recommended for the treatment of rectourethral fistulae bears ample testimony that there is no single accepted method of treatment for this uncommon lesion (Table 29.5).

Adequate urinary and fecal diversion
Maintenance of infection-free environment
Adequate drainage
Adequate exposure of the operative field
No tension on the suture lines
Transfer of healthy vascular tissue to the site of repair in appropriate cases
Nonapposition of suture lines
Closure of nonedematous, healthy tissue

TABLE 29.5. PRINCIPLES OF URETHRORECTAL FISTULA CLOSURE

Rectal injury in association with a surgically or traumatically disrupted lower urinary tract is a serious complication and, if not recognized at the time of surgery, may result in severe pelvic infection and urosepsis. Diversion of the fecal and urinary stream has been the standard practice in the past. However, several authors describe repair of rectal injury without a diverting colostomy as long as the injury is small, the bowel was prepared preoperatively, and the repair is closed in two layers under good visualization (81,108). Previous pelvic irradiation diminishes the chances of successful primary single-stage repair; thus a suprapubic cystostomy and a diverting colostomy are recommended in this circumstance. After meticulous control of bleeding, the rectum is closed in two layers (the outer layer is closed with silk suture). The urinary tract is reapproximated appropriately for the surgical procedure or injury. Every effort is made to separate the rectal and urinary suture lines. The wound should be irrigated with saline or appropriate antimicrobial solution. Interposition of healthy vascularized tissue between the suture lines is advisable if possible. A Penrose drain is left *in situ* for 5 to 10 days to drain the perirectal tissue.

A proximal colostomy reduces the risk of failure. Allen (4) successfully managed two cases by primary closure supplemented with rectal tube decompression and

neomycin irrigation of the bowel. Manual dilation of the anal sphincter should be carried out in an attempt to reduce rectal pressures by temporarily defunctionalizing the sphincter. When in doubt, the clinician should strongly consider a colostomy. Postoperatively, a liquid or low-residue diet should be instituted and maintained for several days. Systemic antibiotics effective against aerobic and anaerobic organisms should be used.

Occasionally, a fistula may occur or first be recognized weeks or months after the original operation. Successful treatment depends on the cause and the general condition of the patient. Controversy remains regarding single-stage and multistage repairs. Wood described a single-stage repair (modified York-Mason) in a series of seven patients with 100% cure and no fecal incontinence (185). All cases were corrected within 2 weeks of the fistula creation. For patients in good general condition a single-stage repair may be effective, but it still carries a higher risk of failure than a multistage repair. For poor-risk patients or patients with major fecal drainage, perineal infection, and inflammation, a multistage procedure is mandatory. Whatever repair is performed, it is imperative that basic surgical principles be rigorously followed (Table 29.5).

In the multistage procedure, a suprapubic cystostomy and a diverting colostomy (29,77,104) are done as the initial procedures. With this therapy alone, approximately one-third of patients may undergo spontaneous resolution of their fistulae (132). Once infection is controlled and the inflammation has subsided, the defect is closed. Adequate bowel preparation is essential for a successful outcome. Intraoperative and postoperative antibiotics are important. Intravenous fluids and an elemental diet are utilized postoperatively. When a postoperative cystogram shows there is no leakage of contrast material, the cystostomy catheter is removed. The colostomy is closed at a later date.

Surgical Techniques

A urethrorectal fistula may be closed by a transrectal, perineal, posterior, or abdominal approach (Table 29.6). Urethral stricture is a common postoperative complication (166). This complication can be avoided by suturing the urethral defect transversely or suturing scrotal skin to the edges of the urethral fistulous opening, as in the Johansson technique (166).

Transrectal approach	Posterior approach
Vose procedure	York-Mason procedure
Parks procedure	Kraske procedure
Perineal approach	Abdominal approach

TABLE 29.6. SURGICAL TECHNIQUES

Transrectal Repair

In 1949, Vose described a simple technique for the closure of urethrorectal fistulae with the transrectal approach. The patient is placed in the lithotomy position. After dilation of the anal sphincter, a bivalve anal speculum is placed to expose the defect. The fistulous track is excised and the defect closed in layers. This procedure is suitable for small fistulae lying close to the anal verge.

A variation of the transrectal approach is the rectal advancement flap popularized by Parks, which is simple and suitable for low fistulae (168). A bivalve anal speculum or a self-retaining anal retractor is inserted, and 1:300,000 epinephrine-in-saline solution is injected beneath the mucosa distal to the fistula. An ellipse of rectal mucosa including the fistula is removed. A full-thickness, inverted U-shaped rectal flap is raised above the fistula, brought down over the fistula, and sutured in two layers to the rectal wall (168).

The transrectal repair is often the only feasible approach in the early postoperative period. Its disadvantage is that it provides limited exposure to the fistula and therefore is reserved for low-lying, small fistulae.

Perineal Repair

In the perineal approach, the patient is placed in the lithotomy position. The fistula is exposed by an inverted U-shaped perineal incision. The fistula is excised, and the dissection is carried well above the fistulous site to obtain good exposure (28,181). The urethra is closed with a single layer of 4-0 absorbable suture. A urethral catheter is used as a stent for 10 to 14 days. The rectal defect is closed in two layers. The outer layer is closed with silk. Normal vascularized tissue is interposed between the urethra and rectum. The levator ani muscle is readily available and can be approximated in the midline.

For radiation-induced fistulae, the gracilis muscle can be rotated through a subcutaneous tunnel to the perineum and interposed between the urethra and rectum (150). Some surgeons recommend adequate dissection of the rectum and rotating the rectal fistula site away from the midline or bringing the rectal repair to a level lower than the opening in the prostate, but this dissection is difficult because of the extensive scarring present around the fistula. Recently, a useful adjunct to this exposure using a perineal subcutaneous dartos pedicled flap was described for fistula following gunshot or pelvic trauma (188). The advantage of this interposition is the familiarity of scrotal anatomy to urologists (Fig. 29.4). How this method will perform in the face of previous radiation is not known.

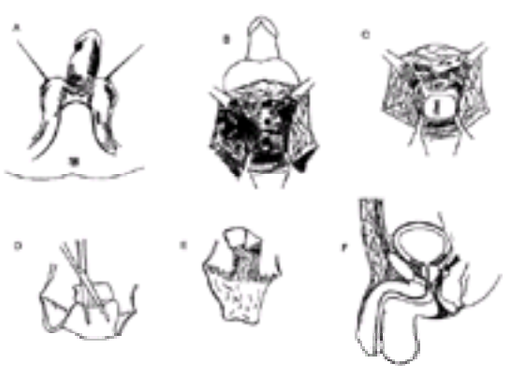

FIGURE 29.4. Creation of a perineal subcutaneous Dartos flap for urethrorectal interposition. **A:** U-shaped perineoscrotal incision is made. **B:** The fistula tract is exposed, and excised, and margins of fistula are freshened. **C:** Rectal wall is repaired in several layers. **D:** Dartos flap is made by incising the apical portion of the perineoscrotal flap and dissecting skin away from Dartos fascia. **E:** The Dartos muscle and fascia flap are mobilized to obtain adequate length. **F:** The Dartos flap is interposed between the rectal repair and the urinary tract.

The Young-Stone technique is a variant of the perineal method (187). The prostatic-rectal fistula is divided, and the entire lower portion of the rectum is mobilized and drawn through the anal sphincter; the redundant rectal wall including the fistulous area is then excised. The resultant cuff of healthy rectal mucosa is anastomosed to the skin edges after the urethral defect is closed in layers. This operation is technically difficult to perform (181), and fecal soiling has been a troublesome

complication (94,181).

Posterior Approach

In 1962, Kilpatrick and Thompson described six patients in whom a successful rectourethral repair was performed using the posterior Kraske approach. The Kraske approach involves excision of the coccyx and has been clearly described by Wiseman and Decter (183). York-Mason successfully repaired fistulae in four patients with the posterior transsphincteric approach with no residual incontinence. Beneventi and Cassebaum (10) modified this technique with a rectal flap, thus avoiding neurologic and vascular structures. Recent studies report successful use of this technique in 6 of 7 rectourethral fistulae following radical prostatectomy and cystoprostatectomy (123).

York-Mason Procedure

In the York-Mason procedure, the patient lies in the prone jackknife position (104,185). The incision is begun at the level of the anal margin to the left of the midline and extended upward and laterally to the level of the midsacrum (Fig. 29.5). The mucocutaneous junction is marked with stay sutures. The sphincters are marked with sutures so that they can be easily identified at the end of the operation. The incision is deepened, and the rectal mucosa is divided to expose the defect. The fistulous track is excised. The urethral opening is closed transversely, and the rectal wall is closed in layers. The sphincter muscles are identified and carefully reapproximated. This approach provides excellent exposure, and careful reconstruction of the sphincters has produced complete anal continence (29,71,141,185). Fecal and urinary diversion may induce a spontaneous repair in 46% of posttraumatic, small, less fibrous fistulae not associated with previous radiation or malignancy (2). Combining a Parks anterior wall advancement with a York-Mason transsphincteric approach was utilized successfully in 11 of 11 patients, although urethral stricture developed in 25% (2).

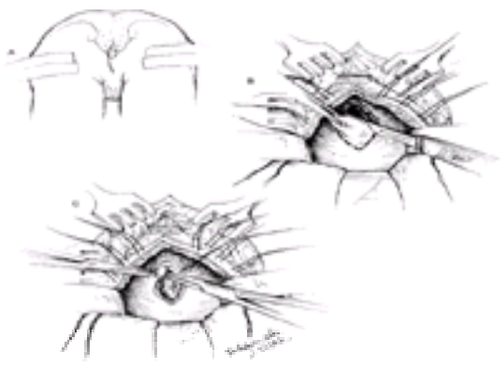

FIGURE 29.5. York-Mason procedure. **A:** Incision to the left of midline. **B:** Transrectal excision of fistula. **C:** Closure of posterior rectal wall after closure of urethra and ventral rectum at fistula site. (From Dahl DS, Howard PM, Middleton RG. The surgical management of recto-urinary fistulas resulting from a prostatic operation: a report of 5 cases. *J Urol* 1974;111:514, with permission.)

Abdominal Approach

Interposition of an omental pedicle graft is indicated for large fistulae, radiation-induced fistulae, and complex fistulae with posterior multifocal strictures (65). The omentum is freed from the gastric margin, and the highly vascularized omental pedicle is interposed between the rectal and urethral walls. The rectal defect is closed in a single layer, but no attempt is made to close the urethral defect. Neoepithelialization occurs on the interposed omentum.

VESICOENTERIC FISTULA

The four categories of vesicoenteric fistula—colovesical, rectovesical, ileovesical, and appendicovesical—are grouped together because of the similarities in clinical features and management.

Etiology

An abnormal communication between the bowel and bladder was first described in the second century A.D. by Rufus (116), but the common causes of acquired vesicoenteric fistula have changed from diseases of the past such as typhoid, amebiasis, syphilis, and tuberculosis (73) to diverticulitis, malignancy, Crohn's disease, and trauma (158,170,180) (Table 29.7). Less common causes include ovarian abscess (153), small bowel lymphoma with or without the presence of AIDS (47,37), Meckel's diverticulum (69), pelvic actinomycosis (21), and foreign bodies in the bowel (68). Congenital vesicoenteric fistulae are rare and are often associated with an imperforate anus.

Congenital (rare)	Carcinoma of bladder
Inflammatory	Carcinoma of prostate
Diverticular disease	Radiation enteritis
Crohn's disease	Lymphoma
Tuberculous ileitis	Trauma
Fungal and parasitic disease of colon	Gunshot wounds
Perforated viscus—duodenal ulcer	Pelvic fractures with bony spicules
Neoplastic	Penetrating injuries
Adenocarcinoma of colon and rectum	Iatrogenic
Carcinoma of cervix	Foreign bodies in bowel, such as fish and chicken bones

TABLE 29.7. ETIOLOGY OF VESICOENTERIC FISTULA

A colovesical fistula is the most common form of vesicointestinal fistula and is most often associated with diverticular disease of the colon but can result from colorectal carcinoma (73,118,157). It is more common in males, with a ratio of 3:1 (73,157). The lower incidence in women is thought to be due to the interposition of the uterus and adnexa between the urinary bladder and colon (20,79,163,180). Diverticular disease accounts for approximately 50% to 70% of vesicoenteric fistulae (73,140). Malignancy and Crohn's disease account for another 20% and 10%, respectively. Colorectal carcinoma is the most common malignancy associated with a vesicoenteric fistula. Occasionally, carcinoma of the bladder, cervix, prostate, and ovary are implicated (79,140,180). The site of the enteric fistula is influenced by etiology. Colovesical fistula between the sigmoid and dome of the bladder is the most common type of enterovesical fistula (79,140). Ileovesical fistulae are more prevalent in association with cancer and Crohn's disease. Diverticular fistulae are almost entirely colovesical, and rectovesical fistulae result from cancer or trauma (140).

Crohn's disease is the most frequent cause of an ileovesical fistula (55,73,163). The mean duration of Crohn's disease at the time of first symptoms of enterovesical fistula formation is 10 years (55,73), and the average age of the patient is 30 years (73). Ileovesical fistulae develop in 10% of patients with regional ileitis (73). Appendicovesical fistulae are occasionally reported (30,56).

Clinical Features

The presenting symptoms and complications of enterovesical fistula occur primarily in the urinary tract. However, the pathologic process is almost always intestinal (55,73,79,157,163). Suprapubic pain and complaints associated with chronic urinary tract infection are common. Chills, fever, and diarrhea are less common. Patients may notice passage of urine through the rectum or passage of mucus in urine. *Escherichia coli* is the most common offending organism, and nearly one-third of patients have a mixed-organism infection (163).

Pneumaturia and fecaluria may be intermittent and must be sought carefully in the history. Pneumaturia occurs in approximately 60% of patients but is nonspecific because it can occur in infections with gas-forming organisms such as *Clostridia,* fermentation of diabetic urine, or urinary tract instrumentation. Fecaluria is pathognomonic of a fistula and occurs in approximately 40% of cases (140).

Symptoms of the underlying disease causing the fistula may be present, but in about one-third of patients, no symptoms referable to the underlying bowel disease are noted at the time of diagnosis of the fistula (157). Patients with diverticulitis or Crohn's disease are more likely to have pneumaturia than patients with cancer (64% and 57% versus 30%) (140). Abdominal pain is most common in patients with Crohn's disease (50%). These patients also are more likely to have abdominal tenderness or mass (140).

Greenstein and colleagues (55) noted an abdominal mass and abscess more frequently among fistula patients than in a control group of patients with Crohn's disease without a fistula.

Diagnosis

A high index of suspicion is essential for making a diagnosis of vesicoenteric fistula. In most series, patients have been treated for recurrent urinary tract infections extending 4 to 12 months before a diagnosis of fistula is made. Hafner and colleagues reported that a patient's history is at least as important as any diagnostic test in the diagnosis of ureterovesical fistula (57). Enterovesical fistula is thus a clinical diagnosis, and preoperative studies should be used to delineate the bowel disease and search for malignancy.

Cystoscopy remains the most reliable diagnostic test. The presence of a localized area of edema and congestion is a typical finding in the early stage of a fistula. As the fistula matures, it is surrounded by bullous edema and mucosal papillomatous hyperplasia. Fecal material or mucus may be observed in the bladder. Cystoscopy can be useful in ruling out other causes in the differential diagnosis and permits biopsy of the fistula if one is identified. Charcoal, oral contrast, chromium-151 or indocyanine green Chromagen dye administered by mouth and identified in the urine provides confirmatory evidence of the presence of a fistula (96,159). An attempt can be made to catheterize the suspected tract with a ureteral catheter. Retrograde injection of contrast material can confirm the presence of a fistula. A cystogram may demonstrate contrast outside the bladder at times identified clearly on CT scan. In diverticular disease and Crohn's colitis, the lesion is most commonly on the left posterior wall or the left dome of the bladder, whereas in Crohn's ileitis and in an appendicovesical fistula, the lesion is found in the right posterior wall or right dome of the bladder. A biopsy of the lesion is important to rule out malignancy.

Urinalysis may reveal undigested intestinal food residue. A urine culture may disclose an *E. coli* or mixed-organism infection.

Cystography is the most useful radiologic examination. The “herald” sign, seen best in oblique views, is a crescentic defect on the upper margin of the bladder and represents a perivesical abscess. A “beehive on the bladder” radiographic configuration may be noted (72).

Barium enema, flexible sigmoidoscopy, and colonoscopy rarely reveal the fistula but are useful in delineating diverticular disease from colorectal carcinoma. Radiography of the urinary sediment after a nondiagnostic barium enema may enhance the yield of the test (5). Barium detected in the urine sediment can confirm the presence of a fistula. CT scan often can reveal abnormalities that suggest fistula and can show associated abscesses and tumor masses, but it rarely shows the fistula itself (50). MRI may delineate fistulae better because of its excellent soft tissue contrast and ability to modify the image to ensure visualization of the proper plane of the fistula (135).

Management

A thorough and accurate preoperative evaluation helps in planning the treatment. Both single-stage and multistage procedures have been used in the management of these patients, depending on the underlying disease process and general condition of the patient. A single-stage procedure may be inappropriate in the presence of extensive inflammation, abscess, multiple organ involvement, postradiation changes, or poor-risk patients (79).

In the presence of inflammatory bowel disease, a proximal colostomy does not prevent the development of a fistula (157). Unlike prostatic-rectal fistula, spontaneous closure of vesicoenteric fistula is rare. In conjunction with Crohn's disease, approximately 95% of patients ultimately require surgery (55,109). To prevent recurrence of fistula, excision of the diseased segment of the intestine is essential (6,79).

After adequate bowel preparation, a single-stage procedure is recommended for patients in a good nutritional state in the absence of abscess or severe inflammation and multiorgan involvement (79,152,157). Otherwise, a multistage procedure is appropriate.

In the absence of malignancy, simple closure of the bladder is usually adequate. When possible, omentum is interposed between intestinal and bladder suture lines. A urethral catheter is left *in situ* for 2 weeks. A cystogram is usually performed to verify that the bladder is intact before the catheter is removed. In poor-risk patients and in patients with cancer or complex fistulae, a diverting colostomy affords some palliation. A partial cystectomy may be necessary if a colonic carcinoma is present. If a fistula has developed in this setting, an attempt to resect all carcinoma may be undertaken; however, the prognosis is often poor.

RECTOVAGINAL FISTULAE

Etiology

Rectovaginal fistulae occur most often after pressure necrosis from obstructed labor (first-degree perineal tears) and are uncommon in this country. Occasionally, rectovaginal fistulae may follow surgical trauma or direct injury to the perineum. Inflammatory fistulae are principally caused by diverticular and Crohn's diseases. Rarely, ulcerative colitis, lymphogranuloma venereum, tuberculosis, or actinomycosis may result in a fistula. Malignant disease and irradiation injury also are rare causes of rectovaginal fistulae.

Diagnosis

Even though the presence of a fecal fistula may be obvious, an evaluation and an examination with the patient anesthetized should be performed in all cases. Barium enema, sigmoidoscopy, and colonoscopy are helpful in evaluating the underlying bowel disease and in determining whether there is stenosis at or below the fistula site. A fistulogram may determine whether a fistula is a simple communication between the vagina and rectum or whether there is an associated abscess cavity. A biopsy specimen of all suspicious lesions should be taken to rule out malignancy. In one large series, a rectovaginal fistula was noted in 18% of patients who had a vesicovaginal fistula (75). Thus complete evaluation of vaginal comorbidities is worthwhile. Spontaneous closure of small rectovaginal fistulae have been reported in about 10% of cases (75).

Management

The principles of repair are the same as discussed earlier for repair of urinary vaginal fistulae. They include accurate diagnosis, fecal and urinary diversion, adequate operative exposure, excision of the fistula, multilayered closure, maintenance of blood supply, and interposition of such tissues as omentum. High obstetric fistulae are often associated with a urinary fistula. The urinary fistula should be treated first, and the cure rate will be enhanced if fecal diversion is performed before closure of the urinary fistula. A preliminary colostomy is often recommended but is elective during the repair of a straightforward rectovaginal fistula. There is conflicting opinion regarding early versus late repair. Conservative management would suggest an interval of at least 2 to 3 months from causative injury to repair. If the patient

has a history of radiotherapy, waiting at least 1 year is advised. There are several approaches through which a fistula can be repaired, including abdominal, vaginal, anal, and transsphincteric. The choice of approach depends on the experience of the surgeon, the site of the fistula, and the condition of the patient.

RENAL AND UPPER URINARY TRACT FISTULAE

Etiology

Upper tract fistulae constitute a broad group of nonanatomic communications between the upper urinary collecting system and adjacent organs or body surfaces. These fistulae include nephrobronchial, nephrocutaneous, nephroenteric, pyeloenteric, and ureteroenteric. In the past, a tuberculous etiology was the most common cause of renal fistulae. However, the incidence of these infections has decreased, and iatrogenic (percutaneous surgery) and trauma are becoming more common causes (11).

Nephroenteric fistulae originating in the renal pelvis are the most common type and involve the left or right colon and duodenum. Unusual cases involving perforated viscus (i.e., duodenal ulcer) are occasionally reported (186). The nephrocolic fistulae are the most common. Fistulae involving the stomach (41) and jejunum (39) are rare. Although nephroenteric fistulae resulting from trauma, surgery, or malignancy of both intestinal and renal origin are increasingly reported, chronic and acute renal inflammatory disease remains the principal cause (3,59,110,117,149).

It has been noted radiographically that atrophy of the perinephric fat is a prerequisite to fistula formation (113). Bacterial pyelonephritis or pyonephrosis is found in 80% of cases and stones in 65% (11). Ureterointestinal fistulae, generally related to inflammatory bowel disease or diverticulitis, are caused by Hodgkin's disease, colon carcinoma, or xanthogranulomatous processes (145). Chronic inflammatory or infectious disease accompanied by distal stones and obstruction is the most common cause of spontaneous nephrocutaneous fistulae. Xanthogranulomatous disease and actinomycosis are the most common etiologies, and tuberculosis is of historical interest. Kidneys involved in such fistulae are generally associated with calculous disease, pyonephrosis, perirenal abscess, and nonfunction (172).

Clinical Presentation

Symptoms of nephroenteric fistula vary from marked gastrointestinal (GI) complaints (nausea, vomiting, and diarrhea) to recurrent urinary tract infections with flank pain and fever, depending on the location and underlying etiology. Spontaneous drainage of urine from the flank is the classic sign of nephrocutaneous fistula.

Diagnosis

Radiographic studies may not be helpful in making the diagnosis. Barium enema and IVP are reasonable; however, an IVP is likely to be uninformative because approximately 80% of fistulae are associated with a nonfunctioning kidney. A CT scan is helpful in the diagnosis of related renal and GI inflammation or malignancy. Retrograde ureterography is generally needed to illustrate this fistula.

Management

Iatrogenic or traumatic fistula associated with reasonable renal function may be treated conservatively with ureteral stenting and/or percutaneous nephrostomy. Success has been reported in 90% of a selected group of patients (98). The standard treatment for renal units that are diseased is nephrectomy with removal of the fistula tract and bowel resection. Attempts to conserve the kidney when stones and abscess are present lead to persistent morbidity and no improvement in renal function. The treatment of nephrocutaneous fistula is generally nephrectomy because of irreversible nephron loss (172).

FISTULA OF URINARY DIVERSION

Etiology

The use of a portion of the intestine as a substitute for ureter or bladder has been widely reported and is uniformly regarded as safe and dependable. However, urinary leakage does occur and is one of the most distressing early complications of diversion. Ureterointestinal leakage may occur as an early or late complication of this surgery. Most fistulae occur within the first 7 to 10 days postoperatively, with a reported incidence of 2% to 9% (95,107). These are considered to be secondary to technical error. Later-occurring fistulae may be related to subsequent necrosis at the anastomosis. Mortality rates from this complication range from 5% to 50% (67,95).

Clinical Features

The patients who have external drainage near the ureterointestinal anastomosis are identified earlier secondary to the increase in drainage output with a corresponding decrease in conduit efflux. If drains are not used, the diagnosis is harder. Classically, such patients will develop an elevated blood urea nitrogen level, signs of sepsis, bowel obstruction, and urine drainage via the incision (67). Diagnosis is generally made by the combination of loopogram, IVP, and significantly increased urea or creatinine levels in the drainage fluid.

Management

If a minor leakage occurs early, it can be safely observed for 2 to 3 days provided drainage has been established and there are no signs of sepsis. Spontaneous closure has been reported in 20% to 60% of patients (95). The use of nutritional support is routine if the leak is major or persists beyond the initial few days. Percutaneous nephrostomy and ureteral stenting across the anastomosis can be used to aid closure of the fistula (22). Because unrecognized stomal stenosis may contribute to fistulization, stomal catheterization with a red rubber catheter allowing conduit decompression should be tried. If conservative therapy fails to cure the fistula, one should consider revision of the ureterointestinal anastomosis with careful attention to the vascular integrity of the ureter using frozen sections to assess the presence of tumor and tissue necrosis. The ureters can be reanastomosed at a different site in the conduit using a Bricker technique. The use of ureteral stents and external drainage is encouraged.

Late-occurring fistulae are treated similarly, with external drainage, proximal urinary diversion with nephrostomy tubes, ample nutritional support, and exact localization of the leakage site. Definitive surgical options include a transverse colon conduit or the addition of a segment of ileum (in series) with the existing conduit. The use of a transverse colon conduit is encouraged in the face of pelvic abscess, extensive loss of ureteral length, previous pelvic irradiation, or previous ileal conduit repair (95). The judicious use of nephrectomy should be considered if the leak is unilateral or if the patient cannot tolerate a major intraabdominal procedure.

MANAGEMENT AND OPERATIVE CARE OF PLANNED INTERPOSITIONS

Unexpected technical difficulties found during fistula repair should not surprise the urologist who treats these conditions. Because of unforeseen problems or findings, the surgeon must be prepared for alternative maneuvers to ensure operative success. As previously mentioned, the interposition of well-vascularized tissue between suture lines is one key to this success. Complicating factors such as poor tissue quality, prior irradiation, or prior surgery require the urologist to be prepared with a host of additional techniques of tissue interposition to maximize healing and fistula repair. Discussion of tissue interposition is divided anatomically into transabdominal and transvaginal procedures; however, these various procedures often have interchangeable potential applicability.

Transabdominal Repair

Omental Interposition and Substitutes

In any transabdominal fistula repair, the generous use of omentum is recommended. The omentum, with its rich blood supply, (a) offers an excellent vascular bed for proper healing; (b) adequately separates opposing suture lines; and (c) resorbs blood, lymph, and surgical debris. Commonly, the omentum is draped between tissue planes to prevent fistula recurrence. Securing its position with absorbable sutures is important to prevent inadvertent displacement. Occasionally, the omentum has insufficient length to reach the area of need; under these circumstances, mobilization based on the right gastroepiploic artery should be performed. The right artery is used because its consistent vascular supply comes from gastroepiploic arch on the greater curve of the stomach. The right branch is larger and lower, allowing it to

reach the pelvis. For proper mobilization, the omentum is first dissected free from the transverse colon. The left gastroepiploic vessels are then divided at their splenic origin, and the short gastric branches are divided if needed. The omental pedicle is then rotated downward and secured between tissue planes. The use of absorbable sutures for mobilization and securing is preferred to prevent precipitation of urinary salts on permanent sutures. Not uncommonly, the omentum is not available because of previous gynecologic surgery; thus the use of pericolonic or mesenteric fat may be necessary. If a radiation field has not altered the peritoneum significantly, creation of a flap of peritoneal membrane from the lateral parietal aspect of the pelvis may be considered (36). Appendices epiploicae of the sigmoid colon have been reported as an acceptable interposition flap (48). One needs to be aware of the potential problems associated with the use of this tissue because insufficient length may cause tension, induce colonic distention, or promote involvement of future colonic disease.

Rectus Abdominis Flaps

In cases of more extensive fistulae or recurrent fistulae or when omentum and adjacent tissues are not available, use of the more elaborate rectus muscle flap is possible. These can be used for both the vesicovaginal or urethrovaginal fistula provided adequate length is harvested (17,154). This long muscle receives its blood supply from both superior and inferior epigastric arteries. It is mobilized through a careful midline incision by dissection from its anterior and posterior fascia (Fig. 29.6A,Fig. 29.6B and Fig. 29.6C). The inferiorly based muscle is transected at its transverse tendinous intersection and pulled through a peritoneal window. Once the fistula tract is repaired as previously discussed, the muscle flap is interposed and secured with absorbable sutures (112,156). If being used for a urethrovaginal repair, after muscle flap mobilization, the muscle is passed through the endopelvic fascia and fixed to the opposite tendinous arch or Cooper ligament to support the urethra and bladder neck (Fig. 29.6C).

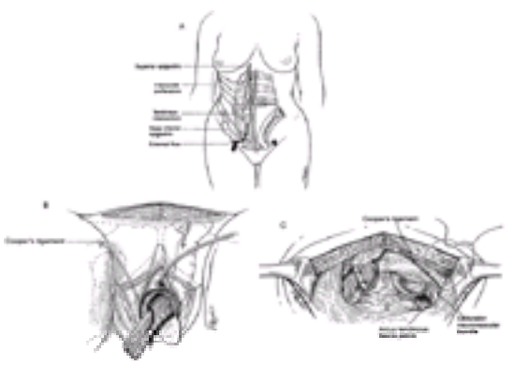

FIGURE 29.6. Rectus abdominis musculoperitoneal flap for closure of bladder or urethral fistula. **A:** Harvest of the rectus abdominis muscle above the first tendinous intersection followed by preservation of the inferior vascular pedicle. The muscle is then tubularized around the inferior epigastric vessels. **B:** The rolled muscle is passed through the endopelvic fascia lateral to the bladder neck to the vaginal exposure site near the previously excised fistula tract and repaired urethra. The flap is interposed and covers the repair site. **C:** The muscle flap is brought back through the contralateral endopelvic fascia site once covering the fistula. This is secured to the contralateral Cooper's ligament or arcus tendinous fascia.

Transvaginal Repair

Gracilis Muscle Flaps

Although it requires additional planning, the gracilis muscle flap interposition has many advantages, including limited exposure to previous irradiation, ease of flap rotation for fistulae below the genitourinary diaphragm, and avoidance of intraabdominal exposure when perineal or vaginal surgery is sufficient. The use of this muscle and its overlying skin (if necessary) is based on (a) its proximal vascular supply from the profunda femoris arteries, (b) the ease of mobilization after transection of its attachment to the proximal skin, (c) its lack of adherence to other muscles of the thigh adductor group, and (d) its minor role in anteromedial adduction of the thigh (Fig. 29.3C). In transabdominal surgery, one can use the gracilis by tunneling the muscle flap via a midthigh plane through a genitourinary diaphragm incision while taking care to avoid pelvic bleeding, sphincter injury, or damage to the ureters (44). This flap can be used successfully with transabdominal or perineal exposures (rectal fistulae) but has bulkiness problems when used with vaginal surgery unless it is swung as a myocutaneous unit. If additional length is needed, the distant two branches may be sacrificed.

Martius Labial Fat Pad Flap

The Martius labial fat pad is an excellent source of interposing tissue for repairing fistulae from the vaginal approach. This tissue has a prominent fibrous component, making it a strong graft that is not nearly as fragile as adipose tissue from other areas. Anatomic studies revealing its ample blood supply from the ventral aspect (external pudendal artery) and dorsal aspect (internal pudendal artery) suggest that it is possible to detach the flap at its superior or inferior end without vascular compromise (38). In most cases, this fat pad does not include the underlying bulbocavernosus muscle. Incorrectly considered synonymous, the labial fat pad interposition and bulbocavernosus flap interposition are two different procedures (19). The use of the Martius flap is recommended routinely but may be applicable only if there is sufficient vaginal epithelium (Fig. 29.3A and Fig. 29.3B). Complications include excessive dissection of the anterior or posterior pedicle or small tunnel aperture causing constriction of the vascular supply. If the vaginal epithelium is insufficient for primary closure of the vaginal defect, the labial flap also may be used to supply skin from the labial majorum. If the flap is not wide enough, the buttock flap based on the cutaneous branches of the inferior rectal artery should be considered (66,176). Use of the buttock flap results in less asymmetry of the anterior vaginal introitus than the use of the Martius flap but runs a risk of impaired blood supply or injury to the anal sphincter (Fig. 29.3C).

A peritoneal flap may be used for smaller fistulae that lie high in the vault and out of reach of the Martius fat pad. Its interposition is created by posterior dissection of the anterior vaginal wall between the vaginal wall and the bladder (147). This exposes the edge of the peritoneum in the pouch of Douglas without the need to enter the abdominal cavity. The edge of the peritoneum mobilized from the posterior wall of the bladder is moved inferiorly and secured over the repaired fistula. One can prevent possible bladder or ureteral injury by avoiding prevesical fascia and remaining just beneath the vaginal wall. Information on the use of intestinal seromuscular flaps is limited (23). This technique has been used in vesicovaginal fistula as well as rectovaginal fistula when omentum is not available. The judicious use of this technique is advised because animal models have developed flap contractions that may compromise any fistula repair (23).

NUTRITION

The nutritional support of the surgical patient is a commonly overlooked component in urologic care. In the patient with urinary fistula, this aspect is particularly important. The metabolic sequela of a surgical procedure is characterized by hypermetabolism secondary to the response of systemic catecholamines. This results in increased tissue breakdown, decreased body mass, and the loss of essential intracellular components. There is recognition that severe malnutrition can exist in 50% of hospitalized patients, which effects morbidity and mortality and increases the length of hospital stay (12,119,179). Malnutrition also (a) increases the risk for nonhealing of wounds, (b) increases the incidence of respiratory infection, (c) increases the incidence of clean wound infection, (d) decreases immunocompetence, and (e) prolongs the postoperative ileus.

All patients undergoing fistula repair must have their nutritional status assessed because it effects the outcome of the procedure. Important assessments of nutritional status include recent lean body weight loss, reactivity to skin antigen testing, creatinine excretion index, lymphocyte count, serum albumin level, serum transferrin level, and triceps skinfold measurements (106). Once this assessment has been made, the caloric requirements can be calculated and replenished via enteral or parenteral feedings.

It is estimated that approximately 55,000 new cases of bladder cancer will be diagnosed in 2000 and that approximately 12,500 patients will die from this disease (192). The appropriate management of patients with bladder cancer depends on an appropriate understanding of contributing factors to the etiology of bladder cancer, its natural history, and sound clinical judgment regarding selection of the best therapeutic modality for management of the individual patient. Currently, assessment of the grade and stage of the initial bladder tumor; evidence of multicentricity; and important histologic features, such as the presence or absence of carcinoma *in situ* (CIS), lymphovascular invasion, and an assessment of molecular markers, are important factors that help determine management.

Bladder cancer produces clinical symptoms, the first of which usually remains fixed as a definitive episode in the life of a patient. Urologic consultation is usually sought promptly thereafter. Asymptomatic incidental bladder cancer is rarely encountered either in life or autopsy finding. Only one incidental bladder cancer was found in 2,805 consecutive male autopsied patients, and Kretschmer (180) reported that in none of 902 consecutive patients diagnosed with bladder cancer was a tumor found before symptoms occurred.

It is difficult to determine the relative incidence of various grades and stages of initial bladder tumor in any consecutive series of patients managed by any of the various therapeutic options because of referral patterns. However, it can be inferred that approximately 70% of all new patients with bladder cancer will present with disease that is not deeply invasive. Jewett and Strong's classic article in 1946 (156) described a relationship between the depth of infiltration of the bladder wall and the potential morbidity of bladder cancer. Based on their autopsy study of 107 cases, 100% of patients with superficial tumors confined to the mucosa should be curable; 80% of those whose tumor was confined to the muscularis had localized disease, whereas only 26% of patients whose tumor had penetrated into the intravesical fat were thought to be potentially curable when first evaluated. However, 5-year survival reports for patients with all stages of bladder cancer indicate that the potential curability indicated by Jewett and Strong is seldom realized. In fact, in 1974, Caldwell (43) reported that 50% of patients with invasive bladder cancer die within 18 months of their initial presentation, regardless of therapy. High-grade, invasive bladder cancer is clearly a lethal disease. Prout and Marshall (271) reported that only 15% of 101 untreated patients, who presented with high-grade bladder cancer, survived 2 years regardless of the form of therapy. This clearly underscores the need for the physician to have a good understanding of the pathophysiology of the disease and appropriate knowledge of the treatment schemes.

This chapter summarizes current available knowledge in all areas of bladder cancer, ranging from epidemiology, pathology, staging, management of superficial and invasive disease, and chemotherapy in the management of advanced urothelial cancer. It is hoped that this information will be useful to the clinician in the future management of patients who develop bladder cancer.

EPIDEMIOLOGY AND ETIOLOGY OF BLADDER CANCER

Bladder cancer does not have the same high profile in terms of either public concern or federal research support as other cancers. Nonetheless, it is an extremely

important disease, ranking fourth in incidence among all cancers in the United States in men and ninth in the United States in women. Although no subgroup of the general population is immune to bladder cancer development, the highest-risk demographic subgroup is white, well-to-do males (287). Men have a risk of bladder cancer that is approximately four times higher than that of women. Non-Hispanic white men have a bladder cancer rate that is twice that of any other numerically important racial-ethnic group in the United States. Women show a relatively comparable pattern in terms of race-ethnicity, as do men, albeit at much lower absolute rates. Non-Latino white women have the highest rate among the most common racial-ethnic groups in the United States. There is a clear relationship between bladder cancer incidence and socioeconomic indicators. For example, in Los Angeles, men in the highest quintile of socioeconomic status (based on a combined measure of income and education level) have 1.3 to 1.4 times the rate of bladder cancer compared with men in the lowest quintile (287).

Bladder cancer incidence and mortality rates have shown sustained declines extending over several decades. Declines have been particularly prominent among non-Latino whites. Rates in the middle to late 1990s are roughly 60% of what they were in the late 1970s (287). Despite their much lower absolute rates, both men and women have shown similar patterns of decline. However, other racial-ethnic groups of either gender generally have not shown declines of similar magnitude (316).

Although bladder cancer typically is believed to be a disease that is well understood epidemiologically, it is troubling that the main demographic risk factors for bladder cancer (high risk in non-Latino white males of high socioeconomic status) are not readily explicable on the basis of the epidemiology of the most prevalent and best-established risk factors. Dozens of epidemiologic studies have established cigarette smoking to be the most important risk factor for bladder cancer around the world (288). Cigarette smoking alone is typically described as explaining perhaps as much as 50% of all male bladder cancer in the United States (i.e., 50% of bladder cancer in men is “caused” by this single exposure). Cigarette smokers, as a group, have two to three times the risk of bladder cancer of nonsmokers. As expected, this risk is substantially higher among long-term heavy smokers compared with short-term, less frequent smokers (48). Risk factors for the former category of smokers may be as much as fivefold to sixfold higher than among otherwise comparable lifelong nonsmokers. Interestingly, smoke-induced bladder cancer is almost exclusively due to cigarette smoking. Pipe smoking and cigar smoking appear to be at most only weakly related to bladder cancer incidence, and smokeless tobacco use appears unrelated to bladder cancer altogether (288). Although bladder cancer risk in ex-smokers probably never reverts back to the rate of lifetime nonsmokers, the risk declines relative to that of active smokers in direct proportion to the time since cessation. Furthermore, inhalation patterns and use of filters have not been shown to substantially modify any smoking-related increase in bladder cancer incidence. Women sustain at least as great an increase in incidence as men for comparable intensity of smoking (48).

The first well-established risk factor for bladder cancer was occupational exposure to a class of chemicals known collectively as the *arylamines.* Epidemiologic “proof” that one particular arylamine, b-naphthylamine (2-naphthylamine), used in the manufacture of synthetic dyes, caused bladder cancer was established by the early 1950s (46). Much circumstantial data accumulated as early as the late 1800s had already strongly implicated b-naphthalamine as a bladder carcinogen. Although potent bladder carcinogens, occupational exposure to arylamines is primarily of historical importance (these chemicals have largely been eliminated from industry through government regulation and/or industry initiatives). However, arylamines themselves are not solely of historical importance. Exposure to these chemicals may occur through other environmental sources. In fact, they provide the most likely explanation for the association between cigarette smoking and bladder cancer. Cigarette smoke contains small amounts of a whole series of arylamines, including 2-naphthylamine and aniline (260), another proven bladder carcinogen in occupational settings. Currently, a major focus of bladder cancer epidemiologic research is to better understand the mechanism by which cigarette smoking causes bladder cancer. In particular, there is current interest in examining differences in how individuals metabolize arylamines, which might help further define bladder cancer risk as it relates to cigarette smoking.

It has been hypothesized that genetic differences across racial-ethnic groups might also help explain epidemiologic difference in bladder cancer. It is clear that among various populations across the world, with highly concordant smoking patterns, vastly different underlying rates of bladder cancer exist. This discrepancy even exists among populations living in the same geographic location. In Los Angeles, although African American, Chinese, Japanese, and non-Latino white men have had relatively comparable smoking patterns for many years, bladder cancer rates among these same populations vary by approximately threefold (highest in whites and lowest in the two Asian American populations) (289). Although a number of the enzymes involved in the activation or detoxification of the arylamines present in cigarette smoke have been identified, the precise detailed pathways and the range of genes involved have not been totally elucidated. It is possible that a better understanding of these enzymatic pathways may help explain some of the discrepancies between the epidemiology of cigarette smoking and that of bladder cancer.

Among those enzymatic pathways that have been investigated epidemiologically, the best studied are the *N*-acetyltransferases (NATs), particularly the NAT-2 isozyme, and certain members of the glutathione S-transferase (GST) family of enzymes, especially GSTM1.

NAT-2 is a totally genetically regulated enzyme system, encoded by a single polymorphic gene (26). Aberrant alleles are associated with reduced enzyme activity. Individuals possessing two such “mutant” alleles are phenotypically characterized as “slow” acetylators, meaning they are able to detoxify carcinogenic arylamines through this pathway at a relatively slow rate. The results of a combined analysis of the 12 studies that had evaluated the relationship between NAT-2 slow acetylation and bladder cancer risk have been reported (125). As hypothesized, slow acetylators have an approximately 50% higher risk of bladder cancer than so-called fast acetylators. Furthermore, studies have suggested that smokers, or those occupationally exposed to arylamines, are at particularly high risk of bladder cancer if they have slow acetylator phenotypes (125).

Non-Latino white populations, at particularly high risk for bladder cancer, have the highest prevalence of slow acetylator phenotypes, with African Americans showing an intermediate rate (393). Low-risk Asian populations have a very low prevalence of slow acetylators, approximately one-fourth that of whites.

The GSTs detoxify various toxic chemicals by promoting their conjugation to glutathione, thereby facilitating their excretion. Nearly half of the U.S. white population lacks either copy of the gene-encoding one of these enzymes—GSTM1 (29). Several studies have found that GSTM1-null individuals (i.e., those lacking both gene copies) have between a 40% and threefold higher risk of bladder cancer than individuals who possess at least one copy of the gene (26,36). Most studies of GSTM1 also note a higher risk in smokers than in nonsmokers.

OTHER RISK FACTORS

Bladder cancer is a relatively well-studied cancer epidemiologically. A number of potential risk factors have been evaluated and have been eventually dismissed as major contributors to bladder cancer occurrence. Artificial sweeteners, for example, received much attention in epidemiologic studies in the 1970s and 1980s because of their role in experimental bladder cancer development. Currently, there is no clear or consistent evidence that these substances modify bladder cancer risk in humans (288). Coffee consumption has been even more extensively studied as a possible bladder cancer risk factor. With the possible exception of very extreme categories of consumption (approximately 5 to 6 cups per day or more, which may be associated with a modest increase in risk), again no clear pattern of risk has emerged (288).

Analgesics, particularly those with phenacetin as an active ingredient, although other formulations are probable as well, are a recognized cause of upper urinary tract transitional cell cancers (149). Because bladder cancer, like cancer of the renal pelvis, also presents primarily with a transitional cell histology, there is reason for concern that heavy consumption of analgesics might also increase risk of bladder cancer. However, one recent study found that the nonsteroid antiinflammatory drugs (NSAIDs) might actually reduce bladder cancer risk (47), possibly through its ability to inhibit the cyclooxygenase-2 (COX-2) enzyme system (250). Substantial supportive evidence exists for bladder cancer prevention by NSAIDs experimentally (250) and for other cancers (especially colon cancer) in humans (280).

Persistent urinary tract infections also increase the risk of bladder cancer, probably through a mechanism involving chronic inflammation and repair. These bladder cancers are primarily of squamous cell histology (165). The best documented relationship between chronic infection and bladder cancer development occurs in Egypt, where chronic infection with *Schistosoma haematobium* has made squamous cell bladder cancer the principal histologic cell type (353).

Recently, there was epidemiologic confirmation of a longstanding bladder cancer etiologic hypothesis, that is, that frequency of micturition will reduce bladder cancer risk by reducing exposure of bladder mucosa to carcinogenic substances in the urine (256). This interesting study tested this hypothesis indirectly by showing rather convincingly that a surrogate measure of micturition frequency—fluid consumption—was inversely related to bladder cancer risk. This study demonstrated that this relationship was “dose” related and that the inverse association was consistently observed across all major categories of beverages (225). Confirmatory studies performed with equal care are needed to more firmly establish this relationship.

Substantial progress has been made in better understanding the molecular genetic pathways of bladder cancer, leading from normal bladder mucosa to a fully malignant phenotype. It appears that two rather distinct pathways are involved in the development of transitional cell bladder carcinoma. One pathway traverses through CIS to a highly invasive form of the disease, whereas an alternative pathway results in the common low-grade papillary transitional cell malignancy, which

uncommonly progresses to a more lethal form (162). Although low-grade papillary transitional cell lesions and the more invasive higher-grade bladder cancers appear to have similar demographic profiles, commonality or differences in environmental risk factors have not been evaluated sufficiently.

Pathobiology

In the United States, it is estimated that approximately 55,000 new bladder carcinomas will be diagnosed in 2000, with transitional cell carcinomas accounting for 90% of all bladder tumors, squamous carcinomas accounting for 7%, and adenocarcinomas accounting for 2% (192). Depending on the population of patients, these proportions can vary. For instance, in regions where *S. haematobium* is a common disease, squamous carcinoma is the most common bladder tumor (76,115). A diverse group of unusual tumors, such as sarcomas and lymphomas, represent less than 1% of newly diagnosed bladder tumors (87,184).

Tumors can metastasize to the bladder but rarely do without evidence of disease elsewhere. The most common mode of spread to the bladder is by direct extension from either the colon, prostate, or cervix. Other tumors that metastasize to the bladder are melanomas and gastric, breast, kidney, lung, renal, and pancreatic carcinomas (317). On the other hand, primary bladder carcinomas spread most commonly to regional lymph nodes, bone, lung, and liver (18,304).

Certain anatomic and histologic findings are important to understand the pathologic aspects of bladder cancer. In the adult, the bladder is located within the pelvis, with the posterior surface or the base lying in a posterior and inferior position. The rectum lies just beyond the soft tissues of the bladder base. In women, these soft tissues contain the cervix and proximal portions of the vagina. In men, these soft tissues between the rectum and posterior bladder are occupied by the seminal vesicles. These relationships are important for two reasons. First, these are the organs most commonly involved by contiguous spread of primary bladder cancers. Second, they explain the pattern of spread of the most common metastatic tumors to the bladder.

Histologically, the bladder mucosa has three layers, including the superficial or umbrella cell layer that is in contact with the urine within the intervesical space. The intermediate cell layer is between the umbrella cells and a basal layer, which are the cells that are in contact with the basement membrane, and are the apparent germinal cells. The superficial umbrella cells have a unique surface membrane that was named the *asymmetric urothelial membrane* by Koss (177) and now has been shown to be composed of transmembrane proteins called *uroplakins* (231). These proteins appear to be specific to the bladder mucosa and are concentrated in the umbrella cells.

Underlying the basement membrane and separating the transitional mucosa from the muscularis propria is the lamina propria. It is important to recognize that within the lamina propria is a thin band of smooth muscle fibers that is variable in its extent (74,283). This band of muscle is a muscularis mucosa that in a few is complete, but in general is incompletely present. These delicate bands of smooth muscle are easily distinguished from the underlying muscularis propria in sections from cystectomy specimens, by the difference in the extent and size of the muscle fibers, as well as in the presence of prominent thick-walled vessels that course along their path. These same venous channels are not associated with the muscularis propria. On occasion, this thin, delicate muscular layer can be difficult to recognize in biopsies that are involved by invasive carcinoma or are artifactually distorted by the biopsy itself. The remaining tissue in the lamina propria generally is loose connective tissue associated with small, delicate vessels and occasionally inflammatory cells. It also is important to recognize that fat can be found in the lamina propria and muscularis propria, sometimes in significant amounts (30).

The muscularis propria consists of a complex of interlacing smooth muscle bands that, in the area of the bladder neck, can be separated into three layers. The central portion of the muscle wall appears to be circular, and the inner and outer walls appear longitudinal. In other areas, these muscular coats are difficult to separate. Again, fat can be fairly prominent and interlaced throughout this muscular portion of the bladder. In addition, these muscle fibers are separated and supported by connective tissue–containing blood vessels, lymphatics, and delicate nerves. On occasion, paraganglia may also be seen.

The muscularis propria varies in thickness from region to region of the bladder. This recognition becomes important because the T_2 tumors are defined by invasion of this muscular wall. No distinct anatomic structures separate this muscle wall to allow this determination. Therefore, proper orientation of histologic sections is necessary to measure the exact extent of invasion. In addition, bladder diverticula possess a particularly thin and attenuated muscular wall, requiring special consideration in evaluating the depth of invasion.

UROTHELIAL CARCINOMA

The most common histologic type of carcinoma arising in the bladder is transitional or urothelial carcinoma. This cell type accounts for at least 90% of all bladder cancers in the United States. Transitional cell carcinomas have two basic morphologic expressions: a papillary lesion accounting for 70% to 80% of these tumors and a flat lesion accounting for the other 20% to 30%. Classifications of both papillary and flat carcinomas have broad areas of agreement and understanding, but they also have differences in their definitions, particularly with regard to grade. These differences, although apparently subtle at first look, often can result in difficulty comparing groups of patients from one institution with those of another.

The World Health Organization (WHO)/International Society of Urologic Pathology Consensus Classification published in 1998 (the most recent classification) makes great strides in removing these differences (80). Already, several papers specifically applying this classification's criteria to large patient populations are demonstrating its utility (51,52 and 53).

PAPILLARY NEOPLASMS

The most common transitional neoplasm is the papillary neoplasm. In the WHO classification (80), these tumors are divided into five categories, including papilloma; inverted papilloma; papillary neoplasm of low malignant potential; papillary carcinoma, low grade; and papillary carcinoma, high grade. Papillary neoplasms are classified on the basis of their architectural and cytologic features. The numbers of categories in this group of papillary tumors is about the same as prior classifications; however, the names are now more reflective of the morphologic appearance and clinical behavior of these lesions.

The papilloma; papillary neoplasm of low malignant potential; and papillary carcinoma, low grade all have good clinical outcomes, but they tend to recur at multiple sites over long periods. It is difficult to separate this group of lesions in a way that all agree upon. On one hand, many argue that the low end of this spectrum should be called *papillomas,* with as many as 20% being classified as such (163). Others point out that when the group is classified in this manner, there is a subpopulation that develops recurrences and may progress to invasive and even fatal carcinomas.

The definition of a papilloma in the WHO classification is that of a discrete papillary growth, surfaced by urothelium of normal thickness, whose cytology is not atypical. The number of cells surfacing the fibrovascular cores is generally of normal number, but exact numbers of cell layers is unnecessary to count. This lesion is believed to be usually small and isolated and occurs most frequently in young patients (Fig. 30.1).

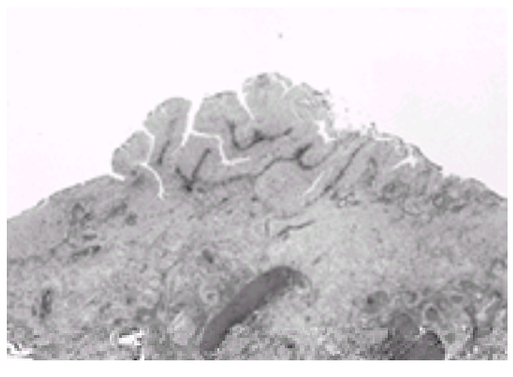

FIGURE 30.1. Low-power view of a urothelial papilloma.

Inverted papilloma is a nodule most often found in the region of the trigone, which, on rare occasions, can have a few papillary structures on the surface but is usually smooth. The tumors grow as nests and trabeculae of epithelium that cytologically comprise normal transitional epithelial cells (Fig. 30.2). The trabeculae tend to resemble reversed papillary processes, where the small vessels and stroma separate basal layers. The epithelial cells differentiate centrally to create merged, mature surface cords that sometimes contain lumens or even cysts. Both glandular and focal squamous differentiation have been identified in these trabecular layers of transitional epithelium. There can be pleomorphism; however, it should be minimal. Mitoses, although present, are usually uncommon.

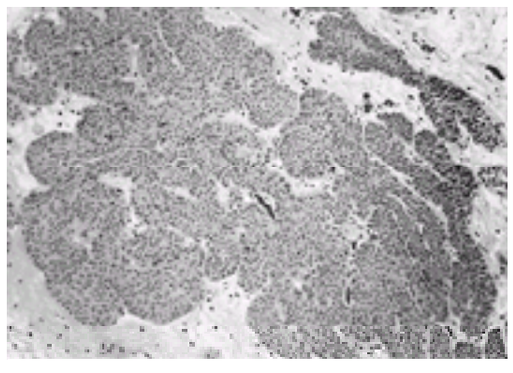

FIGURE 30.2. Inverted urothelial papilloma characterized by anastomosing trabeculae of normal urothelial cells in the lamina propria.

The third category, or papillary neoplasm of low malignant potential, is a papillary tumor in which the papillae are orderly with only slight architectural abnormalities (Fig. 30.3). The surface transitional epithelium is thicker, and a mild degree of nuclear atypia can exist, including nuclear enlargement. Mitoses may be present but are uncommon and usually are found in the basal layers. The main distinction from the papilloma, then, is the increase in cell numbers on the surface and the presence of cytologic atypia. These lesions are found to recur more often and can, on occasion, recur as higher-grade lesions. Some argue that more of these lesions should be in the papilloma group (163), whereas others believe that it is important to delineate this group and ensure that urologists do not minimize its significance. Recurrences of these lesions have occurred many years after the initial removal.

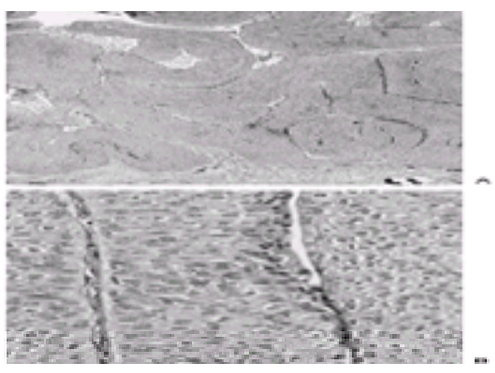

FIGURE 30.3. Papillary urothelial neoplasm of low malignant potential. **A:** Low power. **B:** High power.

Papillary carcinoma, low grade, is a papillary tumor in which there is greater architecture and cytologic variation than the papillary tumor of low malignant potential (Fig. 30.4). The architectural abnormalities include fused papillary cords and fusion of adjacent papillae. In evaluating fusion of cords, one must examine histologic sections that are cut perpendicularly to the base, as opposed to tangential sectioning. Cytologically, these lesions have variation of polarity and nuclear size, shape, and chromatin texture. Again, mitotic figures are uncommon but can be found throughout all levels of the surface epithelial layer. However, they are usually in the lower half of the epithelial surface. Local areas of neoplastic cells can appear overtly malignant. This is as opposed to papillary tumors of low malignant potential in which the cells should display only nuclear enlargement. These tumors again frequently recur but have a lower risk of progression to an invasive or high-grade carcinoma. The risk of progression is believed to be less than 5%.

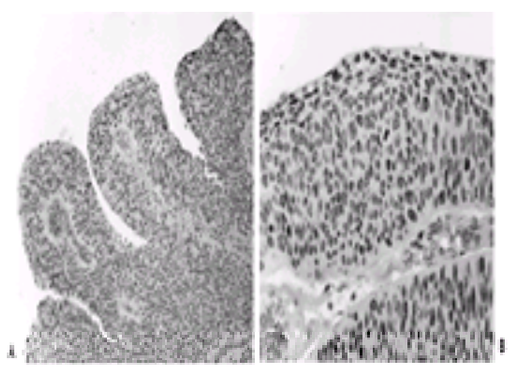

FIGURE 30.4. Papillary carcinoma, low grade. **A:** Low power. **B:** High power.

Last, the papillary carcinoma, high grade, are tumors in which there are distinct architectural and cytologic abnormalities (Fig. 30.5). These tumors have blunted and usually fused papillae, composed of cytologically abnormal cells. The cells are enlarged, and the nuclei are irregular with clumped chromatin and often prominent nucleoli. Mitoses generally are easily identified, occur throughout the urothelium, and are atypical. Clearly, some tumors have both low-grade and high-grade areas, and a clear cutoff has not been defined regarding when to make this distinction. These tumors often are invasive at the time of diagnosis and, if they are not invasive, have a high risk of progression to invasive disease. This group of papillary tumors often has CIS in areas away from its site of involvement.

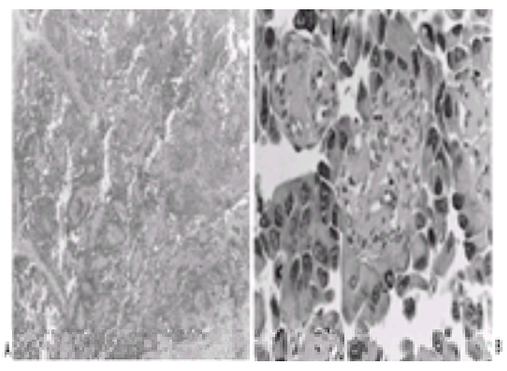

FIGURE 30.5. Papillary carcinoma, high grade. **A:** Low power. **B:** High power.

FLAT LESIONS WITH ATYPIA

CIS, or high-grade intraepithelial neoplasia, is a rare lesion when occurring alone, but it is relatively common when seen in association with papillary tumors, particularly the papillary carcinoma, high grade (83,84,117,178,222,241). In its most easily recognized or classic form, this tumor is composed of overtly neoplastic cells throughout the thickness of the mucosa. These cells are generally large, usually have high nuclear-to-cytoplasmic ratios, and have irregular and hyperchromatic nuclei often with nucleoli. Mitotic activity is seen throughout the lesion. Cells comprising this lesion are loosely cohesive, which often leads to a histologic appearance of loosely attached or discohesive cells (Fig. 30.6). There is commonly an increase of small delicate vessels in the lamina propria directly beneath the basement membrane of areas with CIS. Less commonly, carcinomas may demonstrate a pagetoid pattern where the overtly neoplastic cells are scattered throughout the urothelium (361). Occasionally, in areas adjacent to overt CIS, the neoplastic cells can undermine the normal urothelium, creating a layer of CIS beneath a layer of more normal mucosa. On occasion, because of the discohesive properties of the CIS cells, the lesions can be disrupted when viewed microscopically. In these instances, only a few neoplastic cells are left attached to the basement membrane, creating a so-called “clinging” pattern (99).

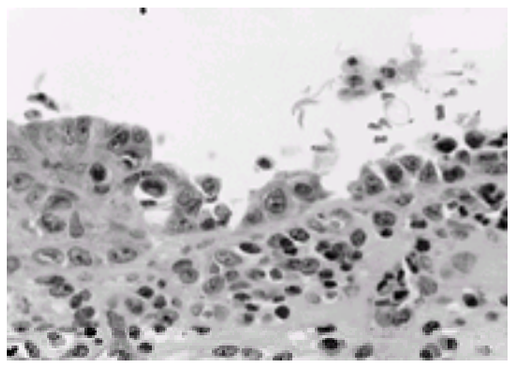

FIGURE 30.6. Carcinoma *in situ* showing discohesion adjacent to full thickness carcinoma *in situ.*

A related group of important lesions are those that are believed to be dysplastic. These lesions have cytologic features that fall short of transitional cell CIS but have some of its features (Fig. 30.7). These lesions can be recognized because they lack the orderly structure of the normal transitional mucosa and they lack the cytologic atypia of CIS. The lack of precise diagnostic criteria makes it difficult to classify this group (309). Biologically, however, this remains an important group because it probably represents a precursor to CIS. An important finding with CIS that may distinguish it from the dysplasias is the finding of small vessels immediately beneath the basement membrane that are associated with CIS.

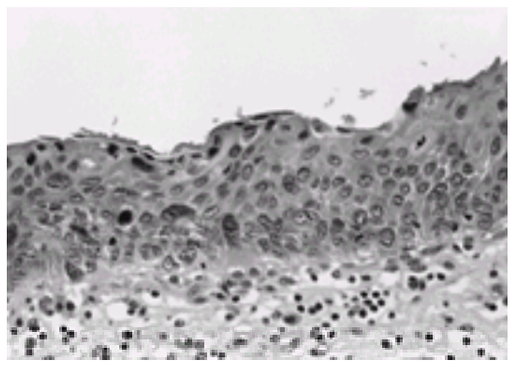

FIGURE 30.7. Dysplastic urothelium showing maturation but also significant cytologic atypia.

Papillary carcinomas, especially high-grade lesions, are often associated with CIS. This observation was first made by Melicow, who noted the presence of CIS between grossly apparent papillary tumors in cystectomy specimens (83,222,223). Eisenberg subsequently demonstrated the increased likelihood of recurrent bladder tumors in patients having papillary carcinoma with CIS. Others have demonstrated the clinical importance of these observations, pointing out that partial cystectomy or segmental resection were contraindicated in surgical management of those patients (321).

INVASIVE UROTHELIAL NEOPLASMS

Invasive carcinomas usually arise from flat lesions, but papillary neoplasms can become invasive as well (178). Probably the single most important determinant in predicting the behavior of a papillary tumor or flat carcinoma recurrence in this population is the demonstration of tumor invasion. Unfortunately, the diagnosis of early invasion can be difficult to determine (1,205). The first site of invasion is the lamina propria (Fig. 30.8 and Fig. 30.9) (12). The patterns of invasion of papillary tumors and the flat carcinomas often differ. Low-grade papillary tumors tend to have a pushing border without a clear-cut invasive appearance, until a significant degree of invasion is present (Fig. 30.10 and Fig. 30.11) (9,390). These nests should not be confused with von Brunn's nests. Higher-grade papillary tumors and flat carcinomas often invade as single cells or small irregular nests that may elicit a desmoplastic or an inflammatory response. Once invasion is established in the lamina propria, its extent should be evaluated. Established lamina propria invasion usually results in a desmoplastic inflammatory reaction to the tumor. Therefore it is important to distinguish the thin delicate fibers and prominent vascular channels of the muscularis mucosa from the muscularis propria. This distinction is easier when adequately biopsied, in that the muscle fibers of muscularis propria are large and compact. Several groups have demonstrated that substaging these lamina propria invasive tumors has allowed separation into groups with significantly different prognoses (Fig. 30.12) (14,386). Furthermore, it is important to recognize vascular space invasion within the lamina propria because it may predict a higher likelihood of involvement of paravesical lymph nodes (209).

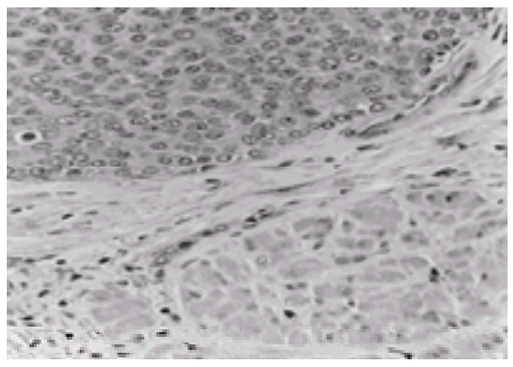

FIGURE 30.11. High-power view of the pushing margin of a low-grade carcinoma.

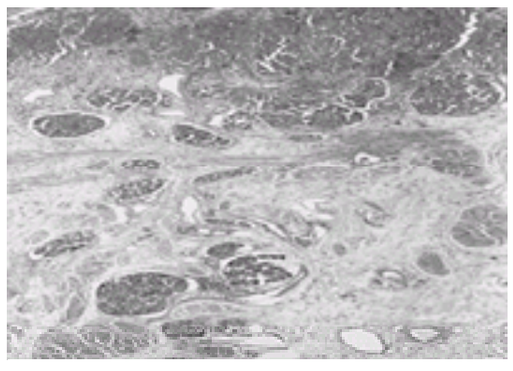

FIGURE 30.12. Significant vascular space invasion associated with a high-grade transitional cell carcinoma.

The papillary and nonpapillary carcinomas of the bladder can also present with a mixed pattern. The mixed pattern is defined as the presence of typical transitional or urothelial carcinomas associated with areas of glandular or squamous differentiation. Some have referred to these areas as *metaplastic;* however, metaplasia by definition refers to replacement of one type of epithelium with another and usually is not applied to malignant tumors. The incidence of squamous or glandular differentiation in transitional cell carcinomas is approximately 10%. There appear to be no prognostic implications to this morphologic finding.

Recently, several groups have described a deeply invasive variant of transitional-cell carcinoma that displays a microcystic pattern (Fig. 30.13 and Fig. 30.14)(261,392). This pattern is usually found in areas of conventional transitional carcinoma but may be found as the dominant pattern as well. These tumors are characterized by small cysts up to 1.2 mm in size. In the lamina propria, they may be morphologically similar to areas of cystitis cystica and cystitis glandularis. These tumors are clinically aggressive. A second bland-appearing transitional carcinoma has been called the *nested variant* (239,258,352,390). These tumors are also infiltrating but comprised bland nests and tubular formations that resembled von Brunn's nests or cystitis cystica. The bland histologic appearance may be confusing and delayed their correct diagnosis (239,352,390). Morphologically, these tumors can also resemble an inverted papilloma. Importantly, these tumors have a more aggressive course than their bland histology would suggest.

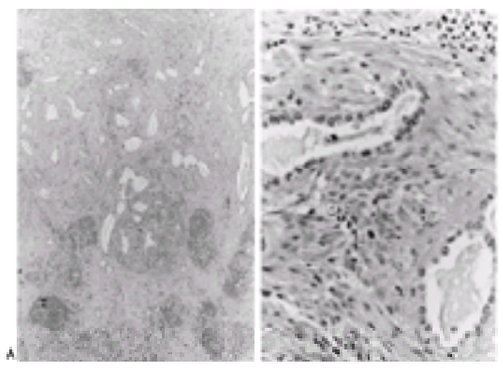

FIGURE 30.13. A: Low-power view of a microcystic variant of transitional cell carcinoma invading deeply into the bladder *(left).* **B:** High-power view of microcystic carcinoma revealing the bland cytologic features of the malignant cells *(right).*

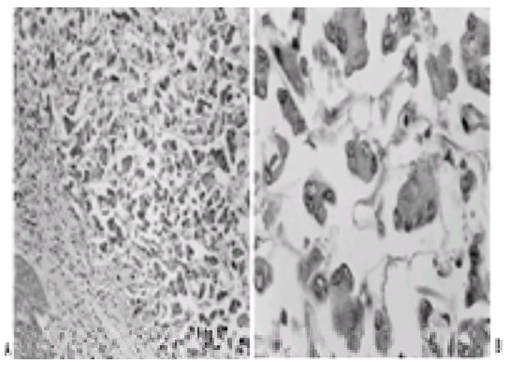

FIGURE 30.14. A: Invasive micropapillary carcinoma composed of small nests of cells with retraction artifact. **B:** High-power view of micropapillary carcinoma, a clinically aggressive variant.

Another clinically aggressive morphologic variant of transitional cell carcinoma is the micropapillary variant (Fig. 30.14). This tumor is described as resembling a papillary serous carcinoma of the ovary. It is composed of slender, delicate, filiform processes or, when invasive, is composed of tight papillary clusters (9). The cases described with this morphologic pattern were almost always found in association with more typical transitional cell carcinoma. This pattern may be associated with noninvasive surface carcinoma, with invasive carcinoma, and in metastatic sites. The presence of this pattern usually suggests muscle invasive disease. This pattern is also commonly associated with vascular space invasion, high stage, and poor clinical outcome.

A number of other malignant tumors have morphologic features that may disguise their urothelial origin (160,305). The most troublesome is the so-called sarcomatoid carcinoma, which has a distinct resemblance to carcinosarcoma. These tumors both occur in the same age range and generally present grossly as large ulcerated, polypoid masses. The major distinction between a carcinosarcoma and sarcomatoid carcinoma is the ability to find an area of urothelial CIS or more clear-cut urothelial carcinoma in sarcomatoid carcinoma. Microscopically, the sarcomatoid carcinoma demonstrates spindled areas that blend imperceptively into the more epithelial areas, as opposed to the distinct separation of epithelial and sarcomatous areas found in carcinosarcoma. Recently, Jones and Young (160) described variants of sarcomatoid carcinoma that have myxoid and sclerosing features. This tumor has been described by various names, including *spindle cell* and *giant cell carcinoma.*

On occasion, a transitional cell tumor can have areas that resemble a choriocarcinoma, including the production of human chorionic gonadotropin (hCG), as demonstrated by immunohistochemical techniques (Fig. 30.15) (73,148,323). More often, the areas of choriocarcinomatous differentiation are identified focally within urothelial or squamous carcinomas. With these tumors, patients can develop gynecomastia and breast tenderness related to hCG production. The hCG may be elevated in the serum and can be used as a tumor marker to follow patients for recurrent disease.

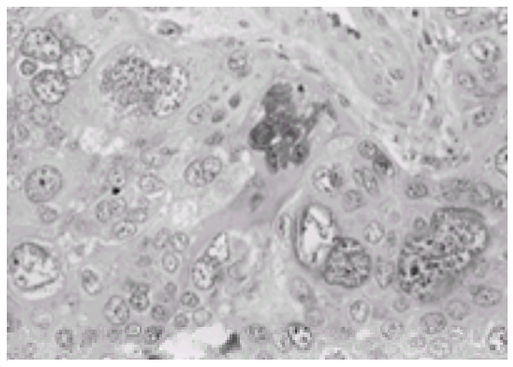

FIGURE 30.15. High-grade transitional cell carcinoma with syncytiotrophoblastic giant cells stained with human chorionic gonadotropin (hCG) by immunohistochemistry.

Transitional cell carcinomas sometimes can mimic lymphoreticular tumors (Fig. 30.16) (398). These tumors may resemble multiple myeloma or lymphoepithelial carcinoma. The recognition of lymphoepithelial carcinoma usually is not difficult if adequate biopsy material is obtained. However, when biopsies are small, the neoplastic epithelial component can be missed or masked by a prominent lymphoid proliferation. Rarely, a carcinoma can appear as a myeloma due to the cytoplasm being filled with intermediate filaments, giving the cells the cytologic appearance of a neoplastic plasma cell (294).

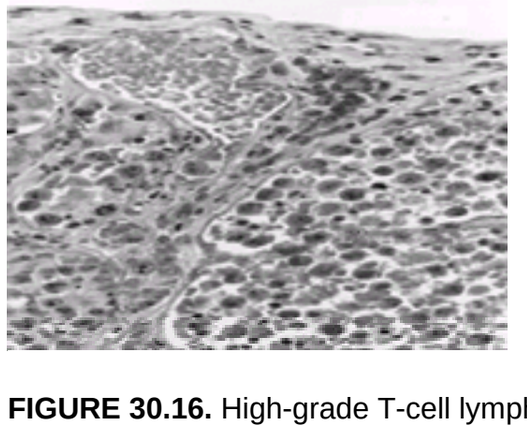

FIGURE 30.16. High-grade T-cell lymphoma characterized by loosely cohesive primitive cells invading the lamina propria of the bladder.

A recent important variant of transitional cell carcinoma is the transitional cell carcinoma with areas of neuroendocrine differentiation (2,28,114,228,255). Morphologically, these tumors have areas of more distinct transitional cell carcinoma or, rarely, adenocarcinoma or carcinoid tumors in which there is a distinct tumor-component morphologic similarity to an oat cell carcinoma of the lung. These cells have dense core granules by electron microscopy and have immunohistochemical markers of neuroendocrine carcinoma. The group is important to recognize in that these tumors have an aggressive clinical course. These tumors are commonly associated with transitional cell carcinomas, but they also may occur in a pure form.

SQUAMOUS CARCINOMA

Squamous carcinomas of the bladder are tumors that display squamous differentiation in all areas. Tumors that demonstrate areas of transitional features are placed into the category of mixed transitional cell carcinoma with squamous differentiation. Pure squamous carcinomas are the second most common histologic type, representing between 5% and 7% of bladder carcinomas in the United States and 1% to 3% of bladder carcinomas in the British Isles (292,293). In regions where *S. haematobium* is prevalent, squamous carcinomas represent the most common form of bladder cancer (Fig. 30.17) (76,115). Squamous carcinoma presents as large exophytic masses. They often have a gray-white surface caused by surface keratinization. Squamous metaplasia, especially atypical squamous metaplasia, often is associated with these tumors, and its presence adjacent to less differentiated tumors is a clue about the squamous origin of the tumor.

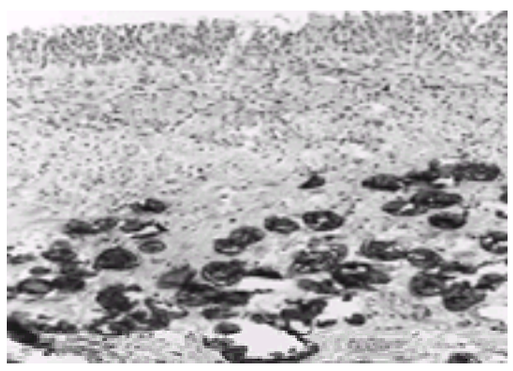

FIGURE 30.17. Calcified ova of *Schistosoma haematobium* within the vessels of the bladder's lamina propria.

Microscopically, squamous carcinomas consist of neoplastic cells with intercellular bridges and keratinization. Areas of keratin pearl formation are common (Fig. 30.18). Cytologically, the cells have abundant amounts of eosinophilic cytoplasm and nuclei, often with prominent nucleoli. These tumors are graded in a different manner than are transitional carcinomas. The degree of keratinization and nuclear pleomorphism are the segregating features. They generally are placed into three categories; well, moderate, and poorly differentiated carcinomas, or grade 1, 2, or 3. Squamous carcinomas associated with schistosomiasis are usually well differentiated. When the tumors are associated with *S. haematobium,* the eggs of the schistosomal organisms can be identified within the vessels or connective tissues of the lamina propria and muscularis propria. Often, these eggs are calcified, making their recognition somewhat difficult.

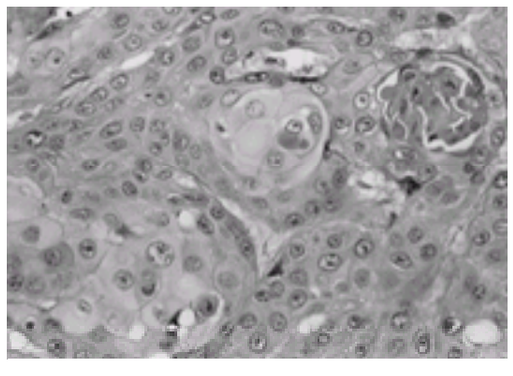

FIGURE 30.18. A squamous pearl within a moderately differentiated squamous carcinoma.

A rare variant of squamous carcinoma, *verrucous carcinoma,* also may occur in the bladder (Fig. 30.19) (383). Grossly, verrucous carcinoma is an exophytic tumor with a warty appearance. When this tumor invades, it has rounded, pushing borders with a slight desmoplastic and inflammatory response. Microscopically, the tumor is composed of papillary structures with acanthotic surfaces. Cytologically, the cells have very little pleomorphism and lack atypia. Although rare in the United States, verrucous carcinoma is found commonly in patients from populations where schistosomiasis is associated with bladder cancer.

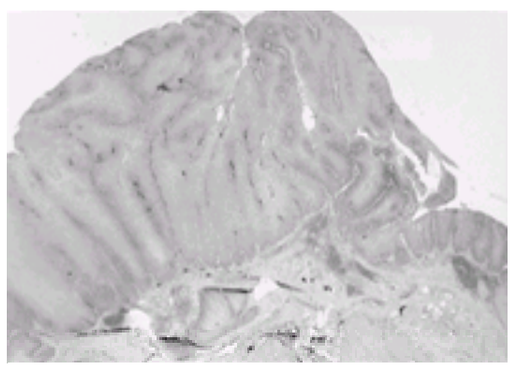

FIGURE 30.19. A verrucous carcinoma, an exophytic neoplasm with a blunt pushing margin.

ADENOCARCINOMA

Primary adenocarcinoma of the bladder, the third most common epithelial tumor, accounts for 0.5% to 2% of bladder carcinomas (Fig. 30.20) (13,112,158,237,356,373). Transitional cell carcinomas often demonstrate areas of glandular differentiation and must not be confused with a primary adenocarcinoma. Adenocarcinomas appear to arise from the urachus in approximately one-third of cases and from the bladder mucosa in the remainder (112). Nonurachal adenocarcinomas often are associated with metaplastic enteric bladder mucosa and cystitis glandularis.

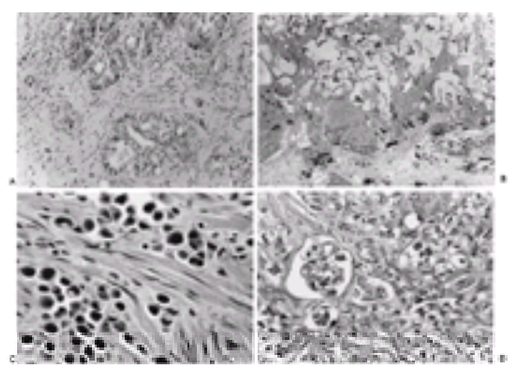

FIGURE 30.20. A: Primary adenocarcinoma of the bladder, enteric type. **B:** Primary mucinous adenocarcinoma of the bladder characterized by small clusters of

neoplastic cells in lakes of mucin. **C:** High-power view of a primary signet cell adenocarcinoma of the bladder. **D:** High-power view of a primary clear cell adenocarcinoma of the bladder.

The distinction between urachal and nonurachal tumors often requires clinicopathologic correlation. In 1954, Wheeler and Hill (373) proposed five criteria that identify urachal adenocarcinoma. These criteria include location in the dome of the bladder; absence of cystitis cystica or glandularis; predominant involvement of the muscularis propria rather than the submucosa, with an intact or ulcerated bladder epithelium; demonstration of a urachal remnant connected with the neoplasm; and the presence of a suprapubic mass. Some believe the criteria of Wheeler and Hill are too restrictive (158). It has been suggested that tumors within the dome or anterior wall, tumors in which there is a clear distinction between the surface mucosa and the underlying adenocarcinoma, and tumors occurring in patients with no evidence of an adenocarcinoma elsewhere (i.e., metastatic) should be considered of urachal origin. Unfortunately, no clear or distinctive microscopic features separate urachal from nonurachal tumors.

For the most part, adenocarcinomas arising within the bladder are indistinguishable microscopically from those arising in the colon. In the largest series of adenocarcinomas (112), these tumors were segregated into five histologic types. In this series, adenocarcinomas not otherwise specified accounted for 27.8% of cases, mucinous 23.6%, enteric 19.4%, signet ring 16.7%, and the mixed type 12.5%. When evaluated from the standpoint of urachal or nonurachal tumors, the majority of the urachal tumors were mucinous (50%), as opposed to 10% of the nonurachal tumors. However, the signet cell carcinomas were largely nonurachal, comprising 23% of this group compared with only 4% of the urachal tumors (112). The behavior of these tumors was different for the sites of origin as well, with the nonurachal tumors having the greatest mortality within the first several years and the urachal tumors having a more gradual mortality spread over 10 years. The stage of the tumors was the best predictor of outcome for both urachal and nonurachal tumors. Grading of the tumors was of little clinical significance. The histologic type was a good predictor only in signet cell–type tumors, which have a poor prognosis.

Histochemical staining for mucin within the cells of these tumors, or their immunohistochemical characterization, was of little help in distinguishing adenocarcinomas arising from the urachus versus those arising elsewhere. Furthermore, these stains were of little help in recognizing adenocarcinomas arising within the bladder from those arising elsewhere and metastasizing to the bladder.

A sixth form of adenocarcinoma arising in the bladder is the clear-cell adenocarcinoma (147,207,391). This type of tumor is rare. Young and Scully (391), in a review of the literature, found that clear-cell adenocarcinomas were most common in women, and of 19 patients having this tumor, 6 tumors were in the bladder and 13 in the urethra. These tumors are similar to clear-cell adenocarcinomas of the female genital system, having a varied appearance including tubular glands, cysts, papillae, and diffuse areas. Hobnail cells almost always are present focally. In the bladder, they generally occur in the area of the trigone or posterior wall. Their importance is distinction from nephrogenic adenomas, metastatic renal cell carcinomas, clear-cell carcinomas arising elsewhere in the female genital tract, and a variety of reactive or inflammatory lesions (147).

MALIGNANT MELANOMA

Most malignant melanomas identified in the bladder are the result of metastases (3,172,338). In autopsy series of patients dying from melanoma, bladder metastases are common, with as many as 20% of patients having such a metastasis. Primary melanomas arising in the bladder are rare, with no large series and only 11 reported cases. The patients are mostly women ranging in age from 46 to 81 years. When identifying a melanoma within the bladder, it is important to exclude the presence of a cutaneous melanoma, including a regressed cutaneous melanoma or ocular melanoma, because metastasis from these sites is far more common than a primary tumor.

Those cases identified in the bladder resemble melanomas elsewhere. They normally have atypical melanocytes in the mucosa adjacent to the tumor mass. As one would expect, these tumors reveal immunoreactivity with S100 protein and HMB-45. In addition, when evaluated by ultrastructure, they have typical premelanosomes or melanosomes present.

Paraganglioma

Paragangliomas, or pheochromocytomas, typically are distinct, well-circumscribed submucosal or intramural lesions (113). Their size and location are variable. They usually have a lobular growth pattern with a tan to yellow-brown cut surface. Histologically, these tumors grow in nests of cells that are separated by a delicate vascular network, a feature called *zellballen.* The tumor cells generally have moderate to abundant amounts of eosinophilic cytoplasm, ovoid nuclei, and central nucleoli. Nuclei can vary in size, and even though they have atypia, including bizarre forms, this feature is not useful in predicting metastatic potential. Immunohistochemical stains including S100, synaptophysin, and somatostatin have been useful in diagnosing this tumor (238). Studies to identify pathologic predictors of behavior in the bladder paragangliomas have not been fruitful. Predictors of potential metastases include an increase in mitotic figures, necrosis, and vascular invasion. Although these findings are useful in predicting an increased risk of malignancy, the only true predictor is actual metastases.

Unusual Tumors of the Bladder

There is a group of tumors that is uncommon in the bladder, but important because it challenges the clinician and pathologist to ensure their accurate recognition and diagnosis. Benign mesenchymal tumors of the bladder include hemangiomas, lymphangiomas, ganglioneuromas, granular cell tumors, benign fibrous histiocytomas, lipomas, and adenofibromas. Malignant soft tissue tumors that have fewer than ten case reports in the literature include liposarcoma, angiosarcoma, hemangiopericytoma, rhabdoid tumor, malignant fibrous histiocytoma, and both osteosarcoma and chondrosarcoma. Unusual germ cell tumors also reported are yolk sac tumors and dermoid cysts. Choriocarcinomas have been identified; however, these most commonly are foci of choriocarcinoma associated with transitional cell carcinomas and may be considered a variant of transitional cell carcinoma. Last, carcinoid tumors have presented in the bladder on rare occasions (369).

Primary tumors of the hematopoietic system have been reported in the bladder and usually represent systemic disease at the time of their presentation (350). Less than 50 non-Hodgkin's lymphomas have been described as primary bladder tumors, and they represent the entire morphologic spectrum of the non-Hodgkin's lymphomas (16,91,108,119,266). Hodgkin's disease has been reported in the bladder as primary presentation in only a single case report (213). In autopsy series, the bladder is more frequently involved by non-Hodgkin's lymphomas, with 7% to 19% of cases having bladder involvement. Hodgkin's disease had only a 4% incidence of bladder involvement at autopsy. Multiple myeloma often involves the bladder at some time over its course. This involvement is usually microscopic and rarely important clinically. Plasmacytomas can present in the bladder (385). The importance of this histologic entity is distinguishing it from an unusual and recently described variant of transitional cell carcinoma that has plasma cell features (294). This distinction can be accomplished easily by applying immunohistochemical stains. Last, leukemias can involve the bladder and are often found at autopsy (108). The acute leukemias appear to involve the bladder slightly more frequently than the chronic leukemias.

Neurofibromas are another unusual tumor presenting in the bladder. Almost all cases of neurofibroma in the bladder have been associated with von Recklinghausen's disease. One-third of neurofibromas occur in children. Most neurofibromas have been of the plexiform type and are often in the region of the distal ureters and bladder neck, resulting in ureteral obstruction. Occasionally, these tumors undergo apparent malignant transformation to a neurofibrosarcoma. These tumors usually reveal areas of neurofibroma with focal areas of neurofibrosarcoma.

Soft Tissue Tumors of the Bladder

One of the most common and significant sarcomas presenting in the bladder is the rhabdomyosarcoma. The average age at presentation is 5 years. The tumor is rarely found in adults (126,129,159). Five percent of cases submitted to the Intergroup Rhabdomyosarcoma Study presented within the bladder. These tumors occur slightly more commonly in males (3:2 ratio) and present most commonly in the trigone. Clinically, the patients present with hematuria or bladder neck obstruction. Rhabdomyosarcomas that grossly present as multiple polypoid masses are called the *botryoid type. Botryoid* is derived from a Greek word meaning a “bunch of grapes.” Grossly, the tumors present as multiple polypoid masses or a single large mass replacing the bladder wall and sometimes extending within the bladder lumen. When the tumors are large and bulky, their exact site of origin is difficult to ascertain. Common sites of origin that involve the bladder secondarily are the prostate, vagina, and retroperitoneum.

The usual histologic pattern is that of embryonal rhabdomyosarcoma. This appearance reveals polypoid projections comprising proliferating small cells in an

edematous stroma. The characteristic pattern is one in which the collections of small neoplastic cells create a layer immediately beneath the mucosa, which has been likened to the cambium layer of a plant. Because the botryoid pattern is found superficially, it is seen in biopsies from cystoscopy. In these cases, the deeper patterns of tumor often will be spindle cell or alveolar. This tumor has also been reported in adults; however, occurrence is much less common, with fewer than 30 reported cases. The diagnostic features of rhabdomyosarcomas in both children and adults are typical morphologic features that may include the presence of cross-striations within the cytoplasm of neoplastic cells. Difficult cases are now usually confirmed by immunohistochemical stains, including myoglobin and desmin.

The other common sarcoma occurring in the urinary bladder is the leiomyosarcoma (Fig. 30.21) (227,351). They are the most commonly reported sarcomas in adults, but overall represent less than 0.5% of all bladder cancers. They can occur in all age groups but tend to be more common in adults. Males are slightly more commonly affected by this tumor, and they are most likely to occur in the dome or lateral walls. Their gross appearance can be varied but often includes a polypoid mass that extends into the lumen of the bladder that may fill the entire lumen. Their cut surface can vary but includes fibrous white or tan myxoid surfaces that may be focally hemorrhagic with areas of necrosis. Microscopically, these tumors are also varied in appearance and resemble leiomyosarcomas elsewhere, being composed of spindle cells with increased cellularity, nuclear pleomorphism, and an increased number of mitoses. A feature seemingly more common in the bladder is prominent myxoid stroma. When features of leiomyosarcoma, which include increased mitoses, pleomorphism, necrosis, and infiltrative borders, are present, these lesions are relatively easy to diagnose. However, in borderline cases, distinct criteria to distinguish them from their benign counterpart, the leiomyoma, have not been established, and this distinction therefore can be difficult. These tumors must be distinguished from sarcomatoid carcinomas, which have been confused with them, particularly on biopsies. Immunohistochemical stains, especially low-molecular-weight keratins, have helped make this distinction. In addition, two pseudotumors that resemble these lesions are the postoperative spindled-cell nodule and the inflammatory pseudotumor. Unfortunately, immunohistochemical stains have not proven helpful in their differential diagnosis, but clinicopathologic correlation has.

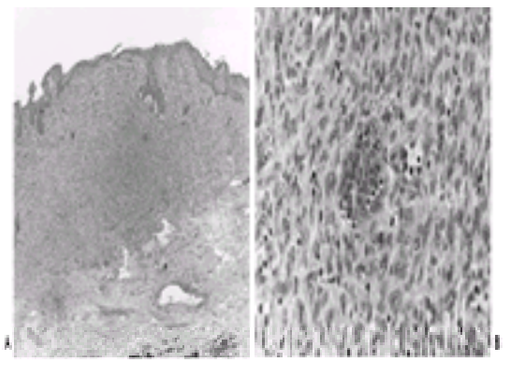

FIGURE 30.21. A: Recurrent low-grade leiomyosarcoma involving the lamina propria. **B:** High-power view of a low-grade leiomyosarcoma surrounding a nest of urothelium.

The benign counterpart of leiomyosarcomas, the leiomyoma, is the most common benign tumor presenting in the bladder. This tumor occurs more frequently in middle-aged women and grossly resembles its counterpart in the uterus. They can occur throughout the wall of the bladder, including the lamina propria and bladder wall. Their site of origin often determines their gross appearance, with those in the lamina propria often presenting as polypoid masses extending into the bladder lumen. These tumors usually are nonulcerated, which can distinguish them from leiomyosarcomas that often ulcerate. As in other locations, these tumors are often large, and on unusual occasions, weigh several kilograms. Microscopically, they resemble leiomyomas in the uterus, that is, having interlacing smooth muscle bundles separated by a delicate vasculature. Mitoses should be rare to absent; however, a few borderline cases with an increase in mitoses have been reported. These cases fall into a borderline group because distinct criteria distinguishing the benign from malignant smooth muscle tumors have not been established.

CARCINOSARCOMA

Carcinosarcomas are unusual tumors that occur in many sites, including the bladder. On gross examination, these tumors, when in the bladder, are usually large and generally present with exophytic or polypoid masses. Some pathologists have included this tumor with sarcomatoid carcinomas, which have both spindled and epithelial neoplastic elements. Others treat the carcinosarcoma as a distinct and separate group of tumors. There is little question that, given strict criteria, tumors from the two groups can be separated. In addition, there is little question that there is a group of tumors that has both neoplastic spindled components and epithelial components that are difficult to place in either category. Carcinosarcomas should lack areas of CIS or transitional cell carcinoma elsewhere in the bladder mucosa. Carcinosarcomas are tumors that have intimate association of both a high-grade sarcoma as well as a high-grade carcinoma. The two elements generally stand out one from another, with little merging of the two elements as occurs in sarcomatoid carcinoma. Carcinosarcomas often have distinct malignant mesenchymal components, including chondrosarcoma, osteosarcoma, and rhabdomyosarcoma, a feature that confirms the tumor as a carcinosarcoma. On the other hand, when the sarcomatous portion resembles a leiomyosarcoma or fibrosarcoma, these tumors can be difficult to distinguish from a sarcomatoid carcinoma. In general, these tumors are locally aggressive; however, distant metastases have occurred in a few. These patients have a poor prognosis, with more than 50% of patients dying of their tumor within 1 year. A recent publication by Lopez-Beltran and others (199) demonstrated that, although carcinosarcomas and sarcomatoid carcinomas are usually distinct morphologically, they both have a poor prognosis. Their study demonstrated that the stage best predicted the prognosis in patients with either of these tumors.

Mimics of Carcinoma

A variety of lesions that are broadly classified as inflammatory, metaplastic, or developmental can mimic carcinoma of the bladder, both clinically and pathologically. The importance of these lesions to the pathologist is to avoid their confusion with neoplastic lesions and consequential overtreatment. The urologists' awareness will help in their clinical recognition.

The most common morphologic changes occurring in the bladder that may be considered pseudoneoplastic are von Brunn's nests, cystitis cystica, and cystitis glandularis (10,377). Von Brunn's nests are small, spherical clusters of urothelium that in some cases are connected to the surface mucosa; however, in others, they are just below the mucosa. The incidence of these lesions is high, with an autopsy study revealing that 86% of bladders had these lesions present. Von Brunn's nests are seen frequently in biopsies and can occasionally mimic carcinoma when they are found in distorted biopsy specimens. These nests of cells can be involved by CIS and, in those cases, especially on biopsy, mimic microinvasive carcinoma.

Often, these urothelial-lined nests develop a central lumen, in which case they are called *cystitis cystica.* Cystitis cystica has been reported in 60% of bladders in an autopsy study (10). In a significant proportion of patients, glandular epithelium is found in these nests, in which case the entity is called *cystitis glandularis.* The cells lining the surface in cystitis glandularis are usually simple columnar cells that are associated with transitional type epithelium (Fig. 30.22). On occasion, the lining cells take on both the morphologic and histochemical characteristics of intestinal epithelium. This form of cystitis glandularis has been recognized for many years and is best designated as *intestinal type of cystitis glandularis* (Fig. 30.23). Cystitis glandularis of the intestinal type is a metaplastic change, and some have suggested that its presence has a higher association with invasive carcinomas. A study of 53 patients who had intestinal metaplasia (Fig. 30.24) associated with exstrophy for greater than 10 years seems to dispel this theory, in that none developed adenocarcinomas and only one developed a transitional carcinoma (63). Cystitis glandularis is also a common lesion found in autopsy series.

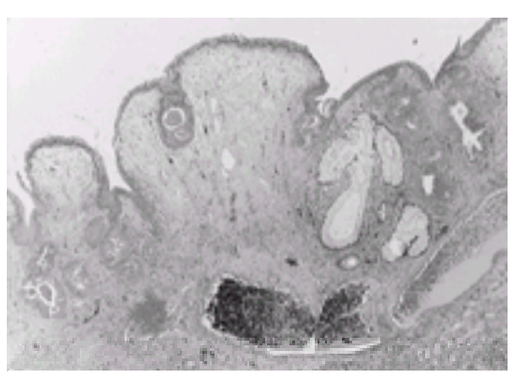

FIGURE 30.23. Chronic cystitis with cystitis glandularis of the typical type and the intestinal type.

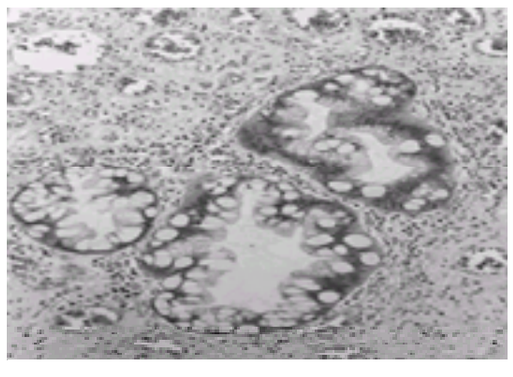

FIGURE 30.24. Intestinal metaplasia that is atypical because of the presence of adenomatous change.

All of these epithelial proliferations are more common around the trigone but occur elsewhere in the bladder. They are often indistinct and not recognized cystoscopically; however, occasionally, they can present with a slightly raised surface and, rarely, even become nodular in appearance.

A more troublesome but less common mimic of carcinoma is *nephrogenic adenoma,* a lesion originally described in a paper by Friedman and Kuhlenbeck (102) (Fig. 30.25). Its name arises from its morphologic appearance, which is most frequently characterized by collections of small tubules lined by cells with clear cytoplasm that resemble the nephron. More recent studies have emphasized additional patterns common to nephrogenic adenoma: cystic, papillary to polypoid, and more rarely, diffuse (252). These lesions are usually associated with an inflammatory reaction, and their irregular contour can give an infiltrative pattern. Fifteen percent of Oliva and Young's cases had glands intermingled with muscle fibers of the muscularis mucosa (252). Most cases of this lesion have been identified in the bladder; however, they do occur elsewhere in the genitourinary system, including the urethra and ureter. The lesions have been seen in children, and males more commonly have this lesion than females, with a ratio of 2:1. These lesions are associated with previous operations or a chronic irritant, such as bladder calculi. Of interest is that a number of patients with renal transplant have developed these lesions. More recently, similar changes have been found throughout the bladder, and in that context, the lesions have been designated *nephrogenic metaplasia.*

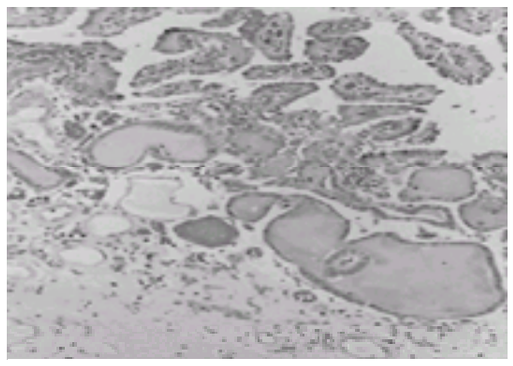

FIGURE 30.25. Nephrogenic adenoma comprising papillae and tubules lined by a single layer of cuboidal epithelium.

One of the most important reasons for recognition of this lesion is distinguishing it from adenocarcinoma, particularly a clear-cell adenocarcinoma (252). Clinically, patients with nephrogenic adenoma are young males with a predisposing factor such as trauma or previous surgery, whereas patients with clear-cell adenocarcinomas are older women without a history of previous bladder problems. Pathologically, nephrogenic adenomas are distinguished from clear-cell carcinoma in that they are small and, although clear cells are present, they are less common than in clear-cell carcinoma. In addition, the cytologic atypia of nephrogenic adenoma and the numbers of mitoses are less than in clear-cell adenocarcinoma. Oliva and Young (252) found that the presence of mitoses in nephrogenic adenoma was rare, with no mitoses found in 76 cases and only a single mitosis in 20 high-power fields found in 4 cases.

A last metaplastic change that is relatively common in the bladder but that can sometimes be confusing histologically with carcinoma is squamous metaplasia (377). It should be remembered that in the area of the trigone, nonkeratinized squamous mucosa is a normal finding in women and should not be referred to as *metaplasia* (Fig. 30.26) (377). Elsewhere in the bladder of women and throughout the bladder of men, both keratinizing and nonkeratinizing squamous mucosa is considered metaplastic change. Squamous metaplasia, especially when it is keratinized, is not difficult to diagnose pathologically but can sometimes be found extensively throughout the bladder, making adequate sampling and identification of carcinomas difficult. In these cases, the identification of a well-differentiated squamous

carcinoma can be difficult for the clinician because the malignant area of squamous carcinoma cannot be identified in the extensive areas of squamous metaplasia.

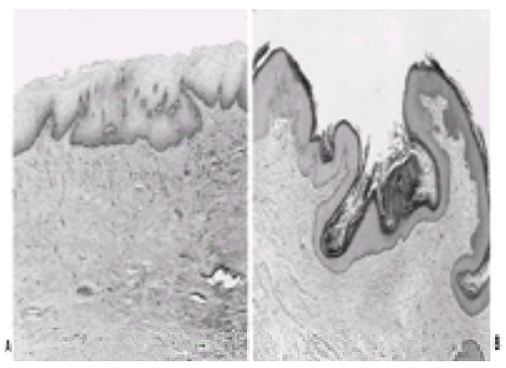

FIGURE 30.26. A: Nonkeratinizing squamous metaplasia—a normal finding when identified in the trigone of women. **B:** Keratinizing squamous metaplasia—an abnormal finding in the bladder.

A variety of papillary or polypoid lesions that are benign and are reactive can occur in the bladder (282). One of the more troublesome polypoid lesions that can occur from a diagnostic pathologist's viewpoint is prostate mucosa. When present, this prostatic epithelium creates a polypoid lesion, usually in the region of the trigone. In most cases, the prostatic tissue is benign in appearance, and its prostatic origin can now be documented by localizing prostate-specific antigen, or prostatic acid phosphatase, with immunohistochemical techniques (282).

A rare polypoid lesion in the bladder is the fibroepithelial polyp (388). These polyps appear to be composed of proliferating mesenchymal cells within the lamina propria. Often, their stromal cells are atypical, a feature commonly seen when these lesions occur at other sites. On occasion, this atypia can reach a point that it raises the question of sarcoma.

Papillary and polypoid cystitis are clinically more common lesions that present as inflamed short papillae or polyps throughout the bladder (39,387). The lesions appear to arise because of an inflammatory process in which there is edema, chronic inflammation, and vascular proliferation in the lamina propria, creating elevated polypoid structures. When not much edema is in the lamina propria, the lesions are more papillary in appearance. Clinically, these lesions are associated with chronic bladder irritation such as an indwelling catheter or fistula. Pathologically, they must be distinguished from papillary neoplasms. This is most easily done by their lack of complex architecture at low power and bland cytologic appearance.

Occasionally, there can be a proliferation of lymphoid tissue in the lamina propria of the bladder. This is a relatively common finding in the region of a transitional cell carcinoma (296) but is also seen as the sole lesion in rare patients (142,179). Typically, these lesions are small, gray-white nodules, giving the bladder mucosa a cobblestone appearance. On occasion, they are associated with erythema, which can resemble CIS when seen at cystoscopic examination. Microscopically, these lesions are composed of aggregates of lymphocytes, often with germinal centers. Occasionally, they can resemble a lymphomatous infiltrate, but the reactive germinal centers are usually most helpful in distinguishing them from neoplastic infiltrates.

The bladder is the most common site of endometriosis presenting in the urinary tract (314). Patients generally have had a history of endometriosis elsewhere or previous pelvic surgery. When present and seen cystoscopically, the lesions appear as raised cystic structures that are reddish-brown or blue-black, depending on where a patient is in her menstrual cycle. Their gross appearance often leads to the suspected diagnosis of a neoplasm. Because the lesions are often within the wall of the bladder, they can be difficult to biopsy. Microscopically, if a lesion is excised completely, the morphologic appearance is similar to endometriosis elsewhere, in that there are bland-looking, endometrial-type glands surrounded by stroma. There is often congestion hemorrhage and hemosiderin deposition within the lesions. This finding is often associated with a chronic inflammatory infiltrate in and around the stroma. The glands may also be filled with blood and necrotic debris. There are reports of cases composed primarily of endocervical glands rather than endometrial glands, and in some cases, not all glands are associated with stroma. The term *endocervicosis* has been used to diagnose a lesion composed primarily of endocervical glands (54).

Two important pseudosarcomatous lesions involve the bladder, both of which were described in the 1980s. Clinically, these lesions occur as masses that are sometimes pedunculated or ulcerated and, at cystoscopy, appear as neoplasms. Pathologically, they are similar and are confused with leiomyosarcomas because they have many features that overlap with myxoid leiomyosarcoma. The first of these was described by Nochomovitz and Orenstein (245), and then by Ro and associates (284,285). The first authors referred to this lesion as an *inflammatory pseudotumor,* possibly related to nodular fasciitis, and the second group of authors called it *pseudosarcomatous myxoid tumor.* The second of these mimics of sarcoma was reported first by Proppe and colleagues (268) as a postoperative spindle cell nodule of the genitourinary tract. One of their cases presented in the bladder, with three of them presenting in the prostatic urethra. These lesions were as large as 4 cm. All patients in this group had had recent transurethral resections of the prostate or bladder.

In both cases, the lesions are characterized by a proliferation of intersecting fascicles of spindle cells associated with a myxoid background that includes chronic inflammatory cells. In some cases, the lesions have borders that infiltrate surrounding stroma and smooth muscle of the bladder wall. The intersecting fascicles of spindle cells are separated by a thin, delicate, blood vessel network. Collagen is focally deposited in these lesions, and inflammatory cells tend to occur in areas of ulceration or deep within the lesions. The neoplastic cells are generally enlarged without hyperchromatism but often have prominent single nucleoli. In some cases, mitoses have been reported to be increased in number. Immunohistochemical stains have typically shown expression of vimentin and muscle-specific actin, and most have lacked expression of cytokeratin in their critical cells. When cytokeratin is seen, it probably represents cross-reactivity of the cytokeratin antibody with actin filaments.

Both of these lesions are rare, and their distinction from sarcomas can be difficult. Many have been treated by wide excision; however, at least a few have been treated by transurethral resection only. Management of these lesions can be difficult because of the uncertainty of diagnosis and inability to clearly distinguish it from a low-grade leiomyosarcoma.

In summary, a number of pathologic lesions can mimic bladder neoplasms. Both the mucosa and stromal elements of the bladder have diverse proliferative and reactive responses. Recognition of these lesions is important to prevent unnecessary therapy.

STAGING

The current staging system for bladder cancer evolved from dual origins initially described more than 50 years ago. In 1946, Jewett and Strong (155) first proposed and described a classification of bladder cancer based on the relationship of depth of penetration of the bladder wall to incidence of local extension and metastasis. In 1950, based on Denoix's classification of bladder cancers (71), the Union Internationale Contre le Cancer (UICC) recommended adopting the tumor node metastases (TNM) staging system, which classifies tumors based on the assessment of the extent of the primary tumor (T), the condition of the regional lymph nodes (N), and the presence or absence of metastases (M). Today's TNM classification of bladder cancer by the American Joint Committee on Cancer (AJCC) is based on the evolution of these original staging systems (4).

Jewett and Strong (155) first analyzed 100 autopsy cases of patients with bladder cancer. They discovered that the primary bladder tumor could be segregated into three pathologic stages with increasing incidence of concomitant lymph node involvement, or hematogenous metastases with increasing tumor invasion of the bladder wall. No patient with a stage A bladder tumor (confined to the mucosa) was found to have evidence of metastases, compared with 13% of patients with stage B bladder tumors (involving the muscularis propria), and 74% of those with stage C bladder tumors (involving the perivesical fat). In 1951, Jewett further refined this system based on a clinical study of 80 patients (153). It was suggested that stage B tumors should be divided into superficial (B_1) and deep (B_2) categories (depending on the depth of muscularis invasion). Tumors in the B_1 category behaved much like stage A tumors, whereas those in the B_2 category resembled stage C tumors. In fact, in this report, 14 of 19 patients (74%) with stage A or B_1 tumors survived 5 years compared with only 2 of 61 patients (3%) with tumors involving the deep muscle or perivesical fat. Unfortunately, the separation of stage B into B_1 and B_2 was based on only 18 patients (4 of 5 with B_1 disease survived 5 years

compared with only 1 of 13 with B_2 disease).

Nearly 30 years later, in a follow-up editorial entitled, “Comments on the Staging of Invasive Bladder Cancer—Two B's or Not Two B's: That is the Question,” Jewett astutely stated, “It seems probable that our arbitrary dividing line drawn 30 years ago at the halfway level to separate B_1 from B_2 tumors was too superficial. If placed at a deeper level, many of the currently reported B_2 cases would fall into stage B_1, which they often resemble, suggesting that penetration of the muscle rather than the depth of infiltration is the most important determinant of the treatment of patients with bladder cancer” (154).

A modification of the Jewett and Strong staging system was presented in 1952 by Marshall (214), who added stage 0 to include tumors not infiltrating the lamina propria, patients without evidence of tumor in the cystectomy specimen, and those with CIS. Furthermore, stage D was included to define those with evidence of metastatic disease. This was divided into two categories: stage D_1 lesions were confined to the pelvis (including invasion of pelvic walls or rectus muscle below the sacral promontory), and stage D_2 lesions were beyond the limits of the pelvis, including distant metastases of lesions above the sacral promontory. The aortic bifurcation was chosen arbitrarily instead of the sacral promontory to segregate stage D_1 from D_2 lesions when lymph node tumor involvement was present.

In 1968, the UICC published their first edition on the classification and staging of 23 tumor sites (44). Subsequently, in 1977, the AJCC published the first edition of their TNM staging system. It became obvious that a uniform staging system was required. Through a collaborative effort, the recommendations in the publications of the UICC and the third edition of the AJCC's manual became identical in 1987 (362). The TNM staging and classification in the most recent edition (the fifth, published in 1997) of the AJCC system corresponds exactly to the UICC TNM classification (4).

When comparing the Marshall (214) system with that of the current AJCC (4), the Marshall system considers both papillary noninvasive tumors and CIS as stage 0. The AJCC system classifies them as T_a and T_{is}, respectively. Tumors with submucosa (lamina propria) involvement are classified as stage A in the Marshall system and as T_1 in the AJCC system. Marshall subclassifies B_1 as representing superficial muscle penetration, and B_2 as representing deeper muscle involvement. This system currently corresponds to the subclassification of the AJCC system: T_{2a}—tumor invades superficial muscle (inner half), and T_{2b}—tumor invades deep muscle (outer half). This classification is a modification of the 1987 AJCC, in which deep muscle–tumor involvement was designated as T_{3a} (362). Tumors involving the perivesical fat in the Marshall system are classified as stage C, which corresponds to T_3 in the current AJCC system (4). Furthermore, T_3 has been subclassified in the current AJCC system; T_{3a} is microscopic perivesical invasion, and T_{3b} is macroscopic tumor involvement (extravesical mass) (4). This is a modification of the previous AJCC system, which designated extravesical tumor involvement as T_{3b} only. In the recent 1997 AJCC system, T_4 tumors invade contiguous structures (prostate, uterus, vagina, pelvic wall, and abdominal wall). These are subclassified as T_{4a}—involving prostate, uterus or vagina, and T_{4b}—involving pelvic or abdominal wall (4). This corresponds to the D_1 tumors of the Marshall system (214).

Regarding lymph node involvement, the current AJCC system classifies lymph nodes as regional (within the true pelvis) and distant (outside the true pelvis) (4). These are then subclassified as N_1, in a single lymph node (2 cm or less in greatest dimension); N_2, in a single lymph node (more than 2 cm but not more than 5 cm in size) or multiple lymph nodes (none more than 5 cm in greatest dimension); and as N_3, in a lymph node more than 5 cm in greatest size. The Marshall classification considers patients with regional lymph nodes as D_1, and patients with distant nodes (above the aortic bifurcation) as D_2 (214). Distant metastases are designated as M_1 in the TNM system, and as D_2 in the Marshall system.

It must be emphasized that accurate clinical staging of bladder cancer is critical and necessary, because tumor stage is the most important determinant of therapy. However, despite the best clinical efforts, even with modern imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI), considerable clinical staging errors still occur in patients with bladder cancer; nearly 40% to 50% of patients are being understaged and 10% to 20% of patients are being overstaged. Freeman and associates (94) found that 34% of patients with superficial bladder cancer (T_a, T_1, T_{is}) who underwent cystectomy were pathologically upstaged to muscle-invasive disease or metastatic disease. Of these, only 50% had organ-confined disease, with 8% demonstrating metastatic tumors. Pagano and colleagues (257) reported an overall clinical staging error of 44%, which increased with increasing clinical stage. Similarly, Lerner and associates (195) reported a significant understaging in patients with muscle-invasive, clinically organ-confined disease; 68% of muscle-invasive tumors (T_2, T_{3a}) demonstrated extravesical tumor extension (P_{3b}). The current problem of clinical staging is that the system is only as good as the techniques available to assess the extent of the disease. Furthermore, understaging appears to be increased with higher clinical stages. Despite improvement in various radiographic modalities, the ability to evaluate the extent of the primary bladder tumor as well as the regional lymph nodes remains significantly limited (320). Therefore it must be emphasized that obtaining clear and accurate histopathologic information of the tumor and other sites of the bladder should include the degree of invasion, the grade of the tumor, and the presence or absence of CIS.

The optimal management of bladder cancer requires the early detection, precise clinical staging, and the true assessment of the tumor's biologic potential. Currently, histologic evaluations (including determination of tumor grade and stage) are the primary prognostic variables that dictate treatment strategies for patients with bladder cancer. Although these two conventional histopathologic variables provide a certain degree of stratification of a tumor's biologic potential, a significant degree of tumor heterogeneity remains, even within various prognostic subgroups of bladder cancer. This makes the accurate and reliable prediction of the tumor's aggressiveness difficult. The future of clinical staging, with a more accurate determination of the aggressiveness of a specific bladder tumor, ultimately may involve the application of various molecular or prognostic tumor markers (208,341). The ability to better predict the true biologic potential of an individual tumor would, in turn, facilitate treatment-selection decisions. This would identify those patients who may benefit from adjuvant therapy or more aggressive therapy, and also identify those patients who may require less aggressive treatment strategies. Advances in molecular biology have led to the discovery of certain suspected tumor markers that may influence cancer development and progression. These could clearly influence treatment decisions.

Clinical Staging of Bladder Cancer

Nearly 80% of patients present with some form of hematuria, which may be visible (gross) or discovered on routine urinalysis (microscopic) (88). The hematuria seen in patients with bladder cancer is classically painless and may be intermittent. Furthermore, although the degree of hematuria does not correlate with the extent of the disease, the presence of hematuria requires urologic evaluation. This may be particularly important in patients older than 50 years of age or in those with a known predisposing factor for bladder cancer. Known predisposing risk factors for bladder cancer include a smoking history, known exposure to industrial carcinogens, or having had an indwelling catheter in the bladder for an extended period of time.

Irritative bladder or voiding symptoms are the second most common form of presentation seen in approximately 25% of patients with bladder cancer. Such voiding symptoms may include urinary urgency, frequency, and dysuria and are usually seen in patients with CIS or with an invasive bladder tumor (82,363). Furthermore, patients with irritative voiding symptoms and bladder cancer generally have associated hematuria. Although irritative voiding symptoms are more commonly suggestive of bacterial or interstitial cystitis, the physician must always consider a bladder tumor in any patient with irritative voiding symptoms without an obvious bladder infection.

Although uncommon, patients with bladder cancer may also present with symptoms of bladder outlet obstruction, including urinary retention, pelvic fullness, or suprapubic pain or discomfort with a suprapubic or pelvic mass. Ipsilateral flank pain may occur secondary to ureteral obstruction. Less commonly, when bilateral ureteral obstruction is present, the patient may present with flank pain or renal insufficiency. Evidence of advanced or metastatic disease may present with constitutional symptoms including anorexia, weight loss, and generalized weakness. Patients with bone metastases may present with bone pain or even anemia if there is extensive bone involvement.

The physical examination is usually unremarkable in most patients with bladder cancer. Patients with superficial bladder cancer confined to the mucosa or the submucosa generally have a normal physical examination. A careful physical examination is always necessary to exclude coexistent pathology. All patients should undergo a careful bimanual pelvic examination to determine the presence of a palpable mass, as well as any induration or fixation of contiguous organs or the pelvic side wall. In the female patient, the vaginal examination allows evaluation of the entire urethra and vagina. Patients with large or advanced bladder tumors may have abdominal tenderness, a bladder mass, or induration on physical examination.

An excretory urogram (intravenous pyelogram [IVP]) is generally performed first to evaluate radiographically the upper urinary tract. This test should be performed before cystoscopy. Radiographic abnormalities of the upper urinary tract may include a cortical defect, hydronephrosis, a poorly functioning or nonfunctioning kidney, and a filling defect identified anywhere along the collecting system (calyces, renal pelvis, or ureter). Any filling defect or abnormality identified on IVP, or if the entire upper urinary tract is not well visualized, can then be further assessed at the time of cystoscopy with retrograde ureteropyelography. Patients allergic to intravenous

(IV) contrast material, or with a history of renal insufficiency, may alternatively undergo an ultrasonography of the kidneys, followed by bilateral retrograde ureteropyelography at cystoscopy. This ensures complete radiographic evaluation of the upper urinary tract, and will identify any synchronous upper urinary tract urothelial tumors, which occur in approximately 5% of patients with bladder cancer (251).

Bladder filling defects are identified on IVP in approximately 50% of patients with bladder tumors (140). Large tumors are identified more easily, and are characterized by nonspecific filling defects of the bladder wall. In addition, nonsymmetric bladder wall expansion during the filling phase of the IVP may also suggest a bladder wall tumor (72). Other causes for a bladder filling defect include a blood clot, a bladder fold in a nondistended bladder, or as the result of extrinsic compression from an adjacent organ. To improve the diagnostic evaluation of the bladder, IVP images should be obtained during early bladder filling, along with a distended bladder film, and a postevacuation film.

Bladder tumors associated with ipsilateral hydronephrosis generally suggest an invasive lesion of the bladder (121,123). In fact, Hatch and Barry (123) found ureteral obstruction to be associated with muscle invasion in more than 90% of patients with transitional cell carcinoma and hydronephrosis.

A retrospective analysis of 415 consecutive patients who underwent radical cystectomy for invasive bladder cancer from 1983 through 1993 was recently performed (121). The specific variable of hydronephrosis (unilateral and bilateral) was evaluated as determined by preoperative radiographic imaging studies with regard to pathologic stage and clinical outcome. Of these patients, 299 (72%) demonstrated no preoperative evidence of hydronephrosis, 94 (23%) had unilateral hydronephrosis, and 22 (5%) had bilateral hydronephrosis. All 415 patients were uniformly treated and pathologically staged. A significant correlation between hydronephrosis and advanced cancer stage and decreased patient survival was identified. Of the 116 patients with either unilateral or bilateral hydronephrosis, 85% had muscle-invasive tumors or more advanced disease (in excess of P_2). Of the 94 patients with unilateral hydronephrosis, 83% demonstrated bladder tumors with pathologic evidence of muscle invasion of the bladder (in excess of P_2). This confirms previous reports that patients presenting with unilateral hydronephrosis and bladder cancer generally have muscle-invasive tumors. Furthermore, when evaluating patients with bladder cancer who present with bilateral hydronephrosis, more than 90% of patients demonstrated advanced disease pathologically, with extension outside the bladder (more than P_{3b}, or lymph node–positive disease). Moreover, the 5-year survival for patients with no hydronephrosis was 62%, compared with 45% and 30% for those with unilateral and bilateral hydronephrosis, respectively.

These data obviously suggest that patients with unilateral hydronephrosis have muscle-invasive tumors, whereas those patients presenting with bilateral hydronephrosis have a more ominous prognosis. Obviously, the presence of hydronephrosis (unilateral or bilateral) as determined by preoperative radiographic imaging is an important piece of clinical information that may help dictate therapy and provide prognostic information.

Urinary Cytology

Urinary cytology should be performed in all patients diagnosed with or suspected to have bladder cancer. The evaluation of a voided urine specimen for exfoliated cancer cells may be particularly useful in patients with high-grade bladder tumors, or when CIS is present (19). The limitations of urinary cytology are a result of the normal cystologic appearance of well-differentiated tumor cells, and the fact that well-differentiated tumors cells are more cohesive and less commonly shed into the urine. Cytologic results have been disappointing in patients with low-grade bladder tumors, with an overall sensitivity of approximately 30% (394). In addition, approximately 20% of high-grade tumors or CIS will have a false-negative urinary cytology. A negative voided urinary cytology does not exclude the presence of a bladder tumor. In fact, because most low-grade bladder tumors have a normal urinary cytology, a positive urinary cytology in the context of a low-grade bladder tumor should raise the suspicion of a concomitant high-grade tumor. Even in the presence of a normal radiographic evaluation, a positive urinary cytology should alert the physician to a bladder tumor somewhere along the urinary tract.

Ideally, urinary cytology should *not* be obtained from a first-voided morning specimen, but rather from a well-hydrated patient, to optimize the appearance of the cancer cell. Cellular degeneration occurs in urine that has remained in the bladder for an extended period of time and should be avoided (176). Other factors that may artifactually alter the urinary cytology result include urinary tract infection, indwelling catheters, bladder instrumentation, radiation therapy, and intravesical immunotherapy or chemotherapy. To improve the accuracy and sensitivity of urinary cytology, saline bladder washings may be used (219). This mechanical action (barbotage) enhances tumor cell shedding and provides better cytologic evaluation. A cytology specimen obtained by barbotage has been reported to be positive in 10% of patients with grade I bladder tumors, in 50% of those with grade II tumors, and in 90% of those with grade III tumors (332).

Recently, a urine antibody test for bladder-tumor antigen (BTA, Bard Diagnostic Sciences, Redmond, WA) has been developed to improve and add to the diagnostic capabilities of routine urinary cytology. The BTA test is an assay for the qualitative detection of BTA in the urine (297). The antigen is composed of basement membrane complexes that have been isolated and characterized from the urine of patients with bladder cancer. In a large, well-designed, prospective, multicenter trial involving 499 patients, the BTA test was found to be more sensitive than urine cytology; the BTA was found to have an overall sensitivity of 40% compared with only 16% for urine cytology in detecting recurrent bladder cancer in patients with low-grade and low-stage tumors (297). Its sensitivity for low-grade tumors is approximately 30%. When stratified by stage, the BTA assay was more sensitive than urinary cytology for T_a tumors (31% versus 4%) and T_1 tumors (48% versus 22%). Furthermore, for grade 2 tumors, the BTA assay was also more sensitive. Clearly, further evaluation of this assay is needed to define its true role in the initial evaluation of patients with bladder cancer. However, because the BTA test is a simple, rapid, and inexpensive adjunct to cystoscopy, and because it is more sensitive than routine urinary cytology for low-grade and low-staged tumors, it may be an attractive method along with urinary cytology for the initial evaluation and surveillance of patients with bladder cancer.

Cystoscopic Evaluation

The diagnosis of bladder cancer is ultimately made on cystoscopic examination of the bladder, and pathologic evaluation of the resected tumor specimen. However, when a bladder tumor is suspected from previous radiographic imaging studies or is identified cystoscopically, or abnormal cells are reported on urinary cytology, a careful bimanual examination is first performed. This should be performed in the lithotomy position with good pelvic relaxation under general anesthesia. This helps determine the presence, extent, and fixation of a palpable bladder mass. If a bladder tumor is palpable before resection, bimanual examination also should be performed following resection of the bladder tumor. The presence of a palpable bladder mass after transurethral resection implies extravesical tumor extension. Conversely, resolution of any induration or a palpable mass following complete transurethral resection suggests a more superficial tumor confined to the bladder. Fixation of the bladder is suggestive of advanced disease. It must be kept in mind that this bimanual examination is very subjective, and is certainly difficult to perform and interpret in obese patients, patients with a previous operation in the lower abdomen, and patients with tumors located posterior to the pubic symphysis. Nonetheless, a bimanual examination should always be performed because it can provide some clinical information.

Cystoscopic evaluation begins with careful inspection of the entire urethra, prostate, and bladder neck. Examination of the bladder should be comprehensive and methodical. Mapping of the entire bladder should be performed before resection or biopsy of any bladder tumors. The number, location, size, and configuration (papillary, flat, sessile, or nodular) of all tumors, and of any associated mucosal abnormalities, should be accurately recorded. The mucosa must be evaluated for areas of irregularity or erythema, which may be consistent with CIS. Retrograde pyelography should first be performed when the upper urinary tract has not been adequately evaluated or is suspicious for a concomitant lesion seen on previous radiographic imaging studies. If an upper urinary tract lesion is identified, ipsilateral ureteral cytology, saline lavage, brushing biopsy, or ureteroscopy may be performed for complete evaluation.

Once the entire urinary tract has been completely evaluated (either radiographically or endoscopically), transurethral resection or deep biopsy of the tumor is next performed. This is important to establish a pathologic diagnosis with determination of tumor grade and depth of tumor invasion. The accurate pathologic determinants of the resected bladder tumor are critical in the clinical staging and treatment decision process of the patient with bladder cancer. Care must be taken during resection or biopsy to ensure an accurate histologic evaluation. The use of cautery should be minimized to preserve the architectural structure of the tissue and to avoid cautery artifact.

Directed bladder biopsies of adjacent and normal-appearing bladder mucosa remote from the primary tumor should also be performed in conjunction with transurethral resection. Mucosal biopsies are best performed with the use of cold cup biopsy forceps. Mucosal biopsies should include (in addition to suspicious lesions) four uniform sites: lateral to both ureteral orifices, the trigone, and the dome of the bladder. Biopsies need not be deep because only the mucosa requires histologic examination. The results of these biopsies are an important adjunct that may influence treatment decisions, particularly in the presence of low-grade superficial tumors. The presence of CIS associated with a low-grade tumor is known to increase the recurrence rate and may warrant early institution of intravesical immunotherapy or chemotherapy (324). In addition, transurethral biopsy of the prostatic urethra and stroma should be performed for complete staging purposes in men; nearly 30% of men with CIS will have prostatic involvement with tumor, which may also alter treatment recommendations (111).

The ideal method to resect a bladder tumor is to first resect the superficial portion, followed by resection of the deeper portion, along with a portion of the muscularis

propria. These specimens should be submitted separately to the pathologist. Care must be taken during the resection of any tumor to prevent a bladder perforation and potential tumor spill. To minimize bladder perforations, resection of the tumor is best performed with the continuous-flow resectoscope while the bladder is only partially distended or filled. In addition, resection must be performed with the patient completely paralyzed under general anesthesia. It should be kept in mind that resecting bladder tumors on the lateral bladder wall may stimulate an obturator nerve reflex with violent contraction of the adductor muscles of the thigh and possible bladder perforation. Once the tumor is completely resected, the site should be fulgurated.

Complete transurethral resection of a small papillary lesion should be performed. Alternatively, electrocautery can be used with papillary lesions after appropriate biopsies have been taken for histopathologic evaluation. Complete resection of an obvious invasive bladder tumor (broad based, sessile), particularly when radical cystectomy is anticipated, should be avoided. Bladder tumors that encroach or involve a ureteral orifice can be completely resected. However, fulguration of the ureteral orifice following resection should be avoided. If resection of a ureteral orifice is necessary, placement of a stent may be prudent to prevent acute ureteral obstruction secondary to edema. Care must also be taken when a bladder tumor is identified in a bladder diverticulum. These tumors should be biopsied rather than resected. This reduces the risk of perforation of the thinned wall diverticula, which by definition lack any muscularis propria. Furthermore, patients with bladder tumors located in a bladder diverticulum are probably best treated with radical cystectomy, and therefore an extensive resection is unnecessary; only a tissue diagnosis is required.

Clinical and Radiographic Modalities in the Staging of Bladder Cancer

Abdominal and transurethral ultrasonography have been used to evaluate the local extent of the primary bladder tumor. Transabdominal ultrasound suffers from poor definition of bladder wall invasion, and has been superseded by other imaging techniques. Transurethral ultrasound may provide a more accurate assessment of the bladder wall and gross depth of tumor invasion, but in reality will provide no additional clinical information over transurethral resection.

Complete clinical and radiographic staging should evaluate the most common metastatic sites for bladder cancer, including the lungs, liver, and bone. A chest radiograph should be performed on all patients. A CT scan of the chest is obtained only when pulmonary metastases are suspected either by history, or because of an abnormal chest x-ray examination. In addition, liver function tests and serum alkaline phosphatase should be obtained routinely on all patients with bladder cancer. All patients with an elevated serum alkaline phosphatase or with complaints of bone pain should undergo a bone scan. A CT scan of the abdomen and pelvis should be performed in patients with suspected metastases, elevated liver function tests, a bladder tumor associated with ipsilateral or bilateral hydronephrosis, or in patients with a T_4 primary bladder tumor. The results of these tests may impact the decision for neoadjuvant therapy. A CT scan of the abdomen and pelvis may also provide some clinical information regarding the pelvic and retroperitoneal lymph nodes, as well as the presence of any liver lesions. The ability of CT to detect lymph node tumor involvement generally depends on the enlargement of the involved nodes. However, as previously mentioned, CT scanning of the pelvis strictly for staging of the primary bladder tumor should not routinely be performed, because it is neither sensitive nor specific enough to evaluate the degree of primary bladder wall–tumor invasion (244). The general agreement is that CT scanning cannot differentiate between superficial and invasive bladder tumors, owing to the similar density values of tumor and normal bladder wall. Furthermore, the evaluation of a bladder tumor extravesical extension with CT scanning is also poor. CT scanning cannot detect microscopic infiltration of the tumor beyond the bladder wall. It should be understood that benign perivesical changes (scar formation following previous operation or transurethral resection) cannot be differentiated from tumor growth on the imaging study (193). This is particularly true following a transurethral resection of a bladder tumor, or following irradiation therapy where edema and artifactual changes in the bladder wall make interpretation difficult. The limitations of CT scanning in the clinical staging of patients with primary bladder tumor must be kept in mind (249).

Commonly, CT scanning is performed to evaluate the regional (pelvic) and the retroperitoneal lymph nodes. However, CT scanning of the abdomen and pelvis may be limited in accuracy, because it may detect only obvious gross extravesical tumor extension, and large (in excess of 2 cm) pelvic or retroperitoneal lymph nodes (249). Furthermore, a reactive or an enlarged pelvic or retroperitoneal lymph node (particularly following resection of a bladder tumor) is not diagnostic of tumor involvement. CT scanning can detect only the presence of enlarged lymph nodes; neither the internal architecture nor the pathologic contents are revealed.

The diagnostic value of CT scanning to stage patients with bladder cancer must be carefully considered. If the clinical investigation suggests an operable bladder tumor, it is not unreasonable to proceed and pathologically stage the patient with a pelvic lymphadenectomy and radical cystectomy. However, despite the limitations of CT scanning, some will argue that it is not unreasonable to perform an abdominal and pelvic CT scan, which is more sensitive than physical examination in grossly evaluating the regional and metastatic extent of the disease. Furthermore, proponents for neoadjuvant chemotherapy in the treatment of invasive bladder cancer may also argue there is a role for CT scanning of the abdomen and pelvis for staging purposes (301).

MRI studies currently play little role in the evaluation of patients with bladder cancer. The resolution of the pelvic and retroperitoneal lymph nodes and anatomy is not as clear as CT scanning. However, MRI may have a role in the evaluation of suspected bone metastases, because it appears to be more sensitive than both CT and bone scans for this purpose.

Management of Superficial Bladder Cancer

As previously mentioned, most (70% to 80%) newly diagnosed tumors of the bladder are classified as superficial lesions. Superficial bladder cancers comprise a heterogeneous group ranging in both histologic grade (I to III) and depth of invasion (stage). Superficial cancers of the bladder consist of tumors that are either confined to the mucosa (T_a) or invasive into the lamina propria (T_1). CIS of the bladder epithelium is also classified as a superficial lesion. The natural history of superficial bladder cancer is predicted based on a variety of tumor characteristics that estimate the risk for disease recurrence or progression to a more advanced stage. These characteristics include tumor stage at presentation, histologic grade, tumor size, configuration (papillary versus solid), multifocality, associated positive urinary cytology following resection of all visible disease, associated mucosal dysplasia, and failure to respond to intravesical treatment (67,127,163,203,210,359). The heterogeneity of the underlying molecular alterations in superficial bladder cancer further underscores the dramatic differences in their natural history and clinical behaviors (253,335).

Selection of appropriate therapy for a given superficial bladder tumor is largely based on the combination of known risk factors obtained at the time of initial transurethral resection. The information provided by endoscopic resection is necessary to determine the need for, and subsequent therapy following, tumor resection or fulguration. Tumor grade has demonstrated a strong correlation with the risk of progression, the development of metastatic disease, and overall survival (100,163). Although able to maintain the ability to recur throughout a patient's life, low-grade tumors (grade 1) exhibit an exceedingly low risk of progression to muscle invasion (106,270,271). Endoscopic excision or ablation followed by close observation is all that is required for most of these lesions. In contrast, high-grade lesions (grade 3) portend a more ominous outcome, because they are associated with a significantly greater risk of tumor progression, observed in approximately 50% of patients (57,94,127). Moderately differentiated (grade 2) tumors comprise a group of heterogeneous lesions that demonstrate an intermediate risk for both recurrence and disease progression.

Depth of tumor invasion also provides valuable prognostic information and should be used to guide therapeutic recommendations (67,106,151,156,378). Whereas T_a lesions rarely (less than 5%) progress to muscle invasion, nearly half of all T_1 tumors, many of which are also high grade, proceed to invade the muscularis propria if treated with endoscopic resection alone (106,127,151). Superficial tumors that are associated with dysplasia of the surrounding mucosa or CIS demonstrate a more aggressive behavior than lesions of the identical stage without the associated mucosal abnormalities (8). Other tumor characteristics associated with a high risk of tumor progression include large tumor size (89,127), tumor multifocality (67,194,203), lymphovascular invasion (12,94), nondiploid DNA content, high cellular S-phase fractions (20,22,117,118,307), and the absence of tumor cell–surface blood-group antigens (59,60,211,311).

Local Treatment Modalities

Transurethral Resection of Bladder Tumors

Endoscopic resection remains the mainstay of current diagnostic approaches to superficial bladder lesions and plays a central role in management. Complete removal of solitary or multifocal disease can be performed endoscopically to provide valuable material for pathologic grading and staging. Resection into the muscle layer of the bladder allows for definitive identification of invasive disease and proper assignment of therapy. Endoscopic resection or fulguration of initial or recurrent papillary, low-grade lesions can also serve as definitive treatment. Complete endoscopic removal or destruction of all visible tumors should be attempted at the time of cystoscopy and will provide the best chance for success when subsequent intravesical therapy is needed. Although the long-term survival of patients with low-risk superficial bladder cancer treated by endoscopic resection alone is excellent, the limitation of transurethral resection of bladder tumors (TURBT) as definitive therapy for higher-risk lesions is evident from the high incidence (approximately 50%) of recurrent disease and subsequent progression following transurethral resection

alone.

Endoscopic evaluation of the bladder is critical in the initial assessment of patients with superficial bladder cancer because it identifies tumor characteristics that will guide initial therapy, provide a risk assessment for disease progression, and determine the need for additional therapy. At the time of all endoscopic evaluations, the location, number, and configuration of all tumor(s), should be documented carefully. The location of the ureteral orifices and the quality of the efflux (clear or bloody) also should be noted. The entire mucosa of the bladder and prostatic urethra should be examined carefully, with the site and description of all mucosal changes documented. The instrumentation used for biopsy includes the cold-cup forceps and the resectoscope with electrical cutting loop. The cold-cup forceps are used to avulse small samples of mucosa or sections of tumors, usually measuring less than 0.5 cm. Once grasped, the forceps are twisted and pulled to remove the desired specimen. The forceps typically are unable to obtain material from below the lamina propria, and usually do not lead to significant bleeding or perforation. Biopsy forceps equipped with cautery capabilities are available to provide additional hemostasis when required. Alternatively, a Bugbee electrode can be used to control postresection bleeding. The resectoscope is the instrument of choice for removing most bladder lesions. To allow for effective electrical conduction to the resecting loop, an irrigant, such as water, is used with either a continuous or noncontinuous flow set up. The initial pass at the tumor with the resecting loop should be aimed at excising the tumor down to its base. Pure cutting current is preferred to limit coagulation artifact to the biopsy material. Because tumor staging plays an important role in risk assessment and the assignment of therapy, a separate biopsy of the tumor base should be taken. This should include a sample of muscle layer of the bladder wall to provide information regarding the depth of tumor penetration. Once all material for pathologic evaluation has been removed, electrocautery may be applied to obtain complete hemostasis at the biopsy/resection sites. Lesions overlying the ureteral orifices also should undergo complete resection, although resection of the intramural ureter may lead to vesicoureteral reflux. A minimal amount of coagulating current in this region is preferred. This will limit the risk of subsequent obstruction of the resected orifice. During resection of lateral wall tumors, particular care must be taken to eliminate the effects of obturator nerve stimulation. Electrical stimulation of the obturator nerve during resection may lead to a violent adduction of the thigh and result in a bladder wall perforation and potential tumor spill. Complete muscle paralysis may be needed during resection of lateral wall–based tumors to prevent obturator spasm.

Surveillance of other regions of the bladder that are not obviously involved by tumor will aid in identifying field changes (epithelial dysplasia or CIS) associated with an increased risk of disease recurrence (8). Approximately 25% of superficial lesions, and up to 70% of invasive tumors, will have dysplasia or CIS associated with the primary tumor or identified at other sites within the bladder. Although suspicious regions of erythema should always be sampled, random biopsies of more normal-appearing mucosa are less likely to yield positive findings; less obviously involved areas of dysplasia may be identified. Cytologic evaluation of bladder washings obtained at the time of cystoscopy can provide evidence of occult mucosal abnormalities because dysplastic cells are less adherent and more readily dislodged. Some have suggested that cytologies are more useful than random bladder biopsies and may eliminate potential implantation sites provided by denuding regions of mucosa (170). A careful examination of the prostatic urethra, particularly in patients with a positive urinary cytology and no apparent lesion within the bladder, or in patients who are candidates for bladder-sparing protocols, should be included in each evaluation. Loop biopsy of the prostatic urethra using the resectoscope provides information on the status of the prostatic ducts and stroma, as well as the mucosa, and is useful in evaluating high-risk patients. Bimanual examination at the time of resection is mandatory and provides information that may alter therapy or surgical management if a mass is palpable, fixed within the pelvis, or involving surrounding structures such as the rectum.

Complications of TURBT are uncommon, but must be recognized at the time of resection to limit overall morbidity. Bleeding following tumor resection is dealt with appropriately upon completion of the resection with the various forms of available cautery devices. Unrecognized regions of bleeding may become evident postoperatively as the bladder decompresses and relieves the tamponade effect provided when distended. Clot retention that occurs after resection may lead to bladder distention and an increased risk of bladder rupture of the already thinned wall. Perforation of the bladder at the time of tumor resection may occur and can be recognized by visualization of fat within the depths of the resected region. Small extraperitoneal perforations usually can be managed with catheter drainage alone. Following a larger perforation of the bladder, significant amounts of irrigation fluid may extravasate into the pelvis, which can be identified on physical examination as abdominal or suprapubic fullness. Open repair and drain placement may then be necessary. Intraperitoneal perforations, if small, may be managed safely with catheter drainage; however, larger intraperitoneal perforations will require open repair and suprapubic catheter placement. Injuries to intraabdominal structures, such as bowel, requires open exploration and repair. Vesicoureteral reflux may occur after resection of tumors at the ureteral orifices. Less commonly, obstruction of the ureteral orifice occurs, and can be avoided by the use of pure cutting current when resecting orifice-based lesions. Urethral strictures and bladder contractures are uncommon complications following TURBT.

Follow-up after endoscopic resection usually consists of a surveillance cystoscopy and cytologic evaluation every 3 months for the first 2 years. If no recurrence is identified after 2 years, the frequency of cystoscopic evaluations may be decreased to every 6 months, and annually thereafter. Although it is justifiable to decrease the intensity of follow-up over time, the need for long-term follow up, even in patients with low-risk disease, continues throughout a patient's life. Several series have reported at least a 20% recurrence rate in patients who have gone 5 years without evidence of recurrent disease, many of whom have invasive disease at the time of recurrence (236,357). Flexible endoscopic equipment is well suited for surveillance cystoscopy because it provides visualization of the bladder comparable with that obtained with rigid scopes and provides improved patient comfort, allowing outpatient office evaluation (370).

Upper tract studies, usually consisting of an IVP, are included as part of the initial patient workup. The low risk (5%) of developing upper tract tumors following resection of a superficial bladder lesion suggests that regular IVPs after TURBT are not warranted (79,371,395). The presence of CIS or other high-grade lesions and tumors adjacent to the ureteral orifices increases the risk of upper tract tumors and is an indication for a more stringent follow-up regimen (68,226). Annual upper tract studies are recommended for 2 years, followed by biennial examinations if no evidence of disease is found. The higher rate of upper tract lesions in high-risk patients mandates that long-term surveillance of the upper collecting systems be performed.

Laser Therapy

Laser surgery for superficial bladder cancer is an effective means of destroying superficial bladder tumors (143,326,329). The wavelength emitted by a laser fiber determines the tissue effects, depth of penetration, and degree of tissue ablation. Although a variety of lasers, including the argon (328), holmium (157), and potassium thianyl phosphate (KTP), have been tested to treat superficial bladder tumors, the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser has been the most widely used with an end-fire, noncontact fiber (143,291,308,329). In the noncontact mode, the Nd:YAG leads to a coagulative necrosis of tissue with minimal vaporization, limiting the potential for bladder wall perforation. The argon laser also has been used to treat superficial bladder tumors; however, its use is restricted by the low energy output of available surgical fibers, which provides a limited depth of penetration. The KTP laser also demonstrates a lesser degree of penetration than the Nd:YAG. The holmium:YAG laser provides an increased cutting and vaporization ability due to the increased absorption by water. This serves to limit its depth of penetration and may decrease its hemostatic properties. The CO_2 laser, with its longer wavelength, is strongly absorbed by water and currently is not of practical use for endoscopic treatments.

Several advantages in favor of the laser over standard electrocautery resection have been reported and include the coagulation effects of the laser, which lead to minimized bleeding during the procedure and postoperatively. This may therefore limit the need for posttreatment catheter placement. Because no electrical energy is delivered to the bladder, obturator nerve stimulation does not occur with laser use and the stimulation of pain fibers is minimized, potentially decreasing the anesthetic requirements for this procedure. An additional use of the lasers includes the ability to deliver light energy during photodynamic therapy. Another theoretic advantage is the decreased manipulation of the bladder tumor, which may limit the number of cells dislodged and minimize the risk of implantation recurrences. Although theoretically beneficial, implantation of tumor cells at the time of resection is thought to represent only one possible mechanism for disease recurrence. Current information suggests that overall recurrence rates following laser ablation of superficial tumors is not superior to transurethral resection, whereas local recurrence rates are similar to those observed following transurethral resection (25,325).

Disadvantages limiting the use of the laser for the treatment of superficial disease include the risk of perforation of adjacent viscera, particularly the small intestine following absorption of forward scatter of the laser energy. Bowel perforation may occur in the absence of symptoms of a bladder perforation or urinary extravasation. A negative cystogram does not necessarily exclude injury to the bowel. Following laser injury, peritonitis typically develops within 24 hours and requires laparotomy and resection of the injured segment. Additional disadvantages include the loss of valuable staging information because no histologic material is retrieved for pathologic evaluation, and the increased cost associated with equipment and training.

Intravesical Therapies

The well-documented failure of endoscopic resection alone to provide long-term disease control, and the availability of well-recognized, high-risk tumor characteristics, has provided the basis for the development of intravesical treatments. The low absorptive capacity of the bladder, relatively noninvasive access to the bladder lumen, and ability to avoid systemic exposure with intravesical instillation of therapeutic agents has made this a favored approach in the treatment of superficial bladder cancer. Intravesical treatment has the advantage of accessing the entire bladder mucosa, treating multifocal areas of dysplasia or CIS. It provides

a means to place the therapeutic agent and the dysplastic or neoplastic cell into direct contact, an absolute requirement for most intravesical agents.

Established roles for intravesical therapy in the management of superficial bladder cancer includes treatment of residual, unresected disease (therapeutic); prevention of subsequent recurrences and tumor progression (prophylaxis); and prevention of tumor implantation perioperatively (adjuvant). The most common indication for intravesical treatment for high-risk patients involves instillations to prevent recurrences following complete endoscopic resection in hopes of eliminating or at least delaying the need for more aggressive therapy. Multiple instillations, delivered at varying dosing schedules, are typically used with or without long-term maintenance therapy, which may continue for several years. Although so-called field changes consisting of genetic alterations to large areas of the mucosa are largely thought to be responsible for the predisposition to develop subsequent tumors, another proposed mechanism responsible for the high rate of disease recurrence following transurethral resection of superficial tumors is implantation of cells that are dislodged at the time of resection (372). Several studies have demonstrated a beneficial effect of a single perioperative intravesical instillation of chemotherapy to decrease recurrence rates following TURBT (254,396). Although seeding of dislodged cells remains of potential concern, patients undergoing resection of bladder tumors and simultaneous transurethral resection of the prostate (TURP) have not demonstrated an increased risk of seeding in the field of resection within prostatic urethra.

Chemotherapy

Intravesical agents used for the treatment of superficial disease include a variety of chemotherapeutic substances thought to directly mediate tumor cell death. Randomized and nonrandomized studies have demonstrated a role for intravesical chemotherapy in the treatment of superficial bladder cancer. Dosing schedules have varied greatly, and empiric regimens remain in use. The toxicity of intravesical agents manifests as both local and systemic symptoms. Systemic effects are directly related to the extent of absorption of the agent through the bladder. Important factors that determine the absorptive characteristics of a chemotherapeutic agent primarily are related to the molecular weight of the substance. Drug concentration and pH of the intravesical solution, as well as the integrity of the bladder mucosa and drug dwell time, may also effect drug absorption and systemic toxicity. Although animal studies suggest the possibility of secondary malignancies following long-term exposure to intravesical chemotherapeutic agents (6,101,175), no documented direct carcinogenic activity of long-term (maintenance) therapy has been established in humans. Although no direct link is established, some have reported an increased incidence of secondary hematologic malignancies after intravesical treatment with triethylenethiophosphoramide (TEPA, thiotepa) or mitomycin (333). The rationale for long-term chemotherapy has also been questioned, based on the mechanism of action of current chemotherapeutic agents requiring tumor cells to be present for the drug to be effective. This would suggest however, that patients at higher risk of recurrence from multifocal disease or those with a positive cytology after complete endoscopic resection would be appropriate candidates for multiple-dose or maintenance-type protocols.

Studies have examined the efficacy of immediate postresection, single instillation and multiple postresection regimens alone, or in combination with maintenance dosing, that may continue for up to several years following initial resection. A variety of agents have demonstrated the ability to decrease short- and intermediate-term recurrences; however, most large, controlled trials have failed to confirm the ability of intravesical chemotherapy to reduce the long-term recurrence risk following surgery or report a significant decrease in the advantage afforded by such treatment with longer follow-up.

Triethylenethiophosphoramide

The use of thiotepa in the 1960s ushered in the era of intravesical chemotherapy for the treatment of bladder cancer (161). Thiotepa is an alkylating agent, whose cytotoxic effects are based on the ability of the drug to form covalent bonds with DNA, leading to cross-linking of strands and inhibition of protein synthesis. Delivered intravesically at a concentration of 1 mg/mL, the usual dose of thiotepa consists of 30 to 60 mg in sterile water. The drug is left in the bladder for a dwell time of 1 to 2 hours. Typical treatment regimens consist of 4 to 8 weekly instillations, followed by monthly treatments, which are continued for up to 1 year.

As with all chemotherapeutic agents, thiotepa can be used as treatment for residual disease, or as a prophylaxis against disease recurrence, following complete endoscopic excision of all visible disease. Studies evaluating the ability of thiotepa to treat residual, unresected superficial disease (T_a, T_1, and CIS) have reported a complete response in approximately one-third of patients (174,367). Although encouraging, many of the patients defined as complete responders had positive postresection cytologies (174), which has been reported as an ominous prognostic marker following thiotepa therapy (331). Postresection prophylactic instillations of thiotepa can be administered immediately following endoscopic resection as a single dose or as a series of postresection instillations. A single instillation of thiotepa given soon after complete TURBT was reported to demonstrate a 40% reduction in early recurrences compared with endoscopic resection alone. A similar benefit was not observed in patients with CIS (396). The most common indication for intravesical thiotepa has been as a prophylaxis to decrease recurrences and prevent disease progression after complete resection (161,174,367). Multiple instillation regimens of thiotepa used as a prophylaxis have been studied extensively (15,17,41,42,128,246,273,303,396). The National Bladder Cancer Collaborative Group studied 90 patients with superficial bladder cancer, and demonstrated a 35% decrease in early tumor recurrences in patients treated with thiotepa as a prophylaxis (273). Improved outcomes were observed mainly in patients with low-grade tumors (grade 1), whereas patients with high-grade lesions demonstrated no significant benefit. Furthermore, a high rate of disease progression was observed in patients with associated CIS, further suggesting that alternative therapies should be considered in high-risk patients. Lamm and colleagues (190) reviewed nine controlled studies, which included 1,130 patients treated with thiotepa for prophylaxis, and combined these data to determine the long-term ability of intravesical thiotepa to reduce recurrences. A statistically significant reduction in recurrences was noted, although at 5-year or more follow-up, the overall reduction was approximately 12% in the thiotepa-treated patients compared with those treated by surgery alone. Only five of the nine studies revealed a statistically significant improvement in favor of the thiotepa-treated group, whereas two studies demonstrated a more favorable outcome in the control group. In a randomized study from the European Organization for Research and Treatment of Cancer (EORTC), thiotepa was not shown to be more effective than doxorubicin as a prophylaxis (32). In a comparative evaluation between thiotepa and *Mycobacterium bovis* bacille Calmette-Guérin (BCG), thiotepa was found to be inferior to BCG in the treatment of superficial disease (217). No evidence is available to suggest that thiotepa treatment lowers the progression rates for patients with superficial bladder cancer.
