An understanding of the embryology of the ureteral bud facilitates comprehension of the spectrum of ureteral anomalies to be presented in this chapter. Associated renal abnormalities result from differences in induction of renal tissue from the metanephric ridge produced by ureteral buds arising at various levels from the mesonephric duct. Normally, the ureter begins development at approximately the end of the fourth week of embryonic life as a bud originating from the mesonephric (Wolffian) duct where the duct bends sharply ventrally (the elbow) (Fig. 48A.1). The ureteral bud grows rapidly to penetrate the metanephric blastemal ridge. By 5 weeks of gestation, the renal pelvis can be discerned. As subsequent renal differentiation takes place, the ureteral bud produces the entire renal collecting system: ureter, renal pelvis, calyces, papillary ducts, and collecting ducts.

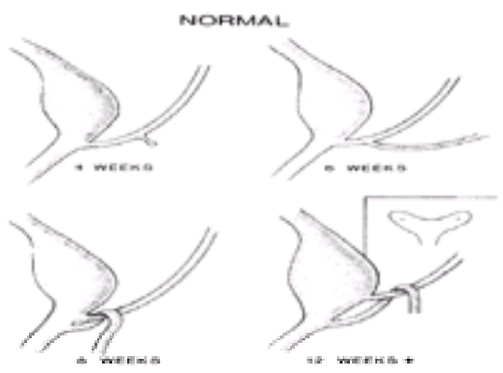

FIGURE 48A.1. Normal embryology of ureteral bud from the mesonephric duct.

The "common excretory duct" consists of that portion of the mesonephric duct between the origin of the ureteric bud and cloaca. This segment, along with a short segment above the ureteral bud, expands and inverts into the urogenital sinus by the eighth week of development forming half of the trigone. As development proceeds, the ureteral orifice migrates cephalad and laterally while the mesonephric duct moves distally and medially. By the twelfth week of gestation, the mesonephric duct reaches its final entry position in the posterior urethra at the level of the verumontanum in the male. The mesonephric duct becomes part of the epididymis, seminal vesical, and vas deferens in the male and becomes Gartner's duct in the female. This migration explains why the vas crosses over the ureter ventrally.

In normal embryology, the point at which the distal mesonephric duct joins the urogenital sinus indicates the eventual location of the bladder neck. As the common excretory duct (mesonephric duct below the point of origin of the ureteral bud) is incorporated into the expanding urogenital sinus, it forms the tissue of the bladder trigone. After ureteral bud and mesonephric duct migration is complete, the final positions of the ejaculatory duct and the ureteral orifice are roughly equidistant from the bladder neck.

Incomplete ureteral duplication results from a ureteral bud that bifurcates shortly after its origin from the mesonephric duct (Fig. 48A.2). If division of the ureteral bud occurs late (fifth week), following the interaction of the ureter with the metanephric blastema, a bifid pelvis occurs. Before the fifth week, bifurcation of the ureteral bud will lead to varying degrees of ureteral duplication but with fusion distally to form a single ureter entering the bladder. A complete duplication with double ureters requires two ureteral buds arising from the mesonephric duct.

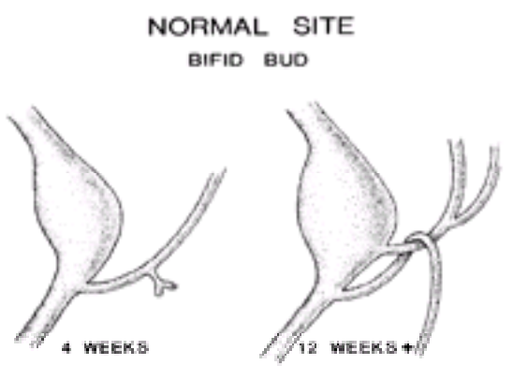

FIGURE 48A.2. Bifid ureteral bud at normal site leading to incomplete duplication of ureter.

A more lateral and cranial placed ureteral orifice is often associated with primary vesicoureteral reflux. This abnormal location of the ureter results from a ureteral bud originating at a lower-than-normal position on the mesonephric duct (Fig. 48A.3). A popular hypothesis holds that the early incorporation of this ureteral bud into the urogenital sinus permits it to migrate more laterally and cranially than normal. In this position, less trigonal support for the ureter might be expected, permitting vesicoureteral reflux. This embryologic explanation would account for what is found clinically in primary reflux: a lateral ureteral orifice with a shortened submucosal tunnel that permits vesicoureteral reflux (7,162,169).

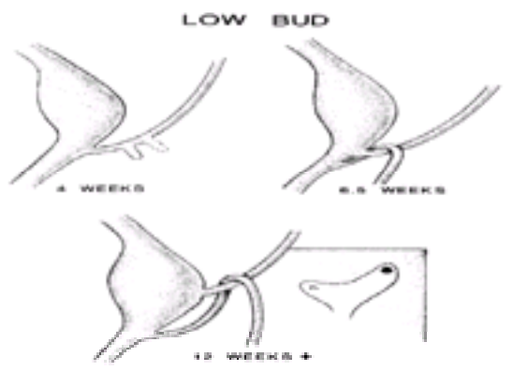

FIGURE 48A.3. Low origin of the ureteral bud from the mesonephric duct causing laterally ectopic ureteral orifice and vesicoureteral reflux.

When a ureteral bud originates slightly higher than normal on the mesonephric duct, it is incorporated into the urogenital sinus later than normal. This results in a shorter cranial and lateral migration resulting in a minor displacement of the ureteral orifice toward the bladder neck (Fig. 48A.4). However, if the ureteral bud originates very high on the mesonephric duct, it fails to be incorporated into the bladder altogether and ends in the urethra or mesonephric remnants (Fig. 48A.5). These remnants constitute the epididymis, vas, and seminal vesical in men and Gartner's duct in women. Gartner's duct runs from the broad ligament of the uterus along the lateral wall of the vagina to end at the hymen. A very high origin of the ureteral bud in the female could end anywhere along this duct and with secondary rupture of the duct into the vagina, resulting in a vaginally ectopic ureter. This explains the main sites of ectopic ureters in males and females. The important difference between the two sexes is attributed to the fact that in the male, all ectopic ureters terminate above the level of the external urethral sphincter so that urinary incontinence is uncommon. By contrast, in the female, ectopic ureters commonly exit below sphincteric control, which accounts for the history of constant wetting from the ectopic ureter despite normal voiding of urine from the ureter(s) terminating in the bladder.

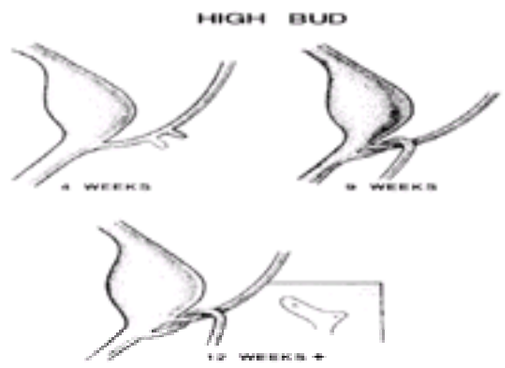

FIGURE 48A.4. High origin of the ureteral bud from mesonephric duct leading to mild degree of ureteral ectopia toward the bladder neck but still on trigone.

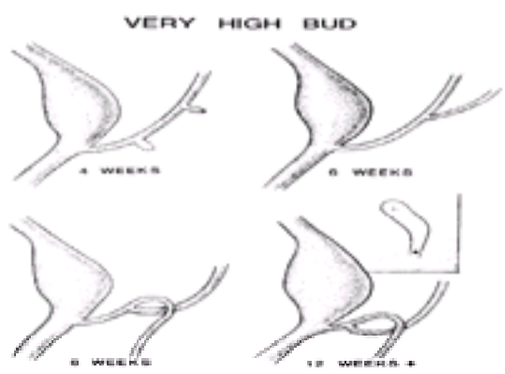

FIGURE 48A.5. Very high origin of ureteral bud from mesonephric duct causing ectopic ureter to maintain contact with mesonephric remnants (vas, epididymis, or

seminal vesicle).

The presence of two ureteral buds having independent origin from the mesonephric duct explains some of the most fascinating of ureteral anomalies. If the two buds arise close to the normal point of ureteral origin from the mesonephric duct, a complete ureteral duplication may result without any significant consequence (Fig. 48A.6). By contrast, if two buds are present, with one located normally and one low, the result would be complete duplication with vesicoureteral reflux into the ureter, which during migration was carried most cranially and laterally, that is, the lower pole ureter (Fig. 48A.7). This anomaly is a common clinical finding (8). With a duplication of the ureteral bud with one in a normal location and one high, the high ureter ends more caudally and medially than normal (Fig. 48A.8). Thus the upper pole ureter is the one that ends ectopically. This embryologic review explains the Meyer-Weigert law: When complete ureteral duplication exists, the medial and distal ureteral orifice is that of the ureter to the upper pole of the kidney (120,181). Occasional exceptions to this law have been reported (109).

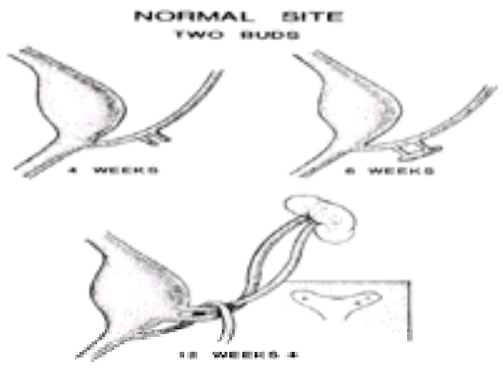

FIGURE 48A.6. Two ureteral buds at normal site on mesonephric duct leading to complete duplication of the ureter without pathologic sequelae.

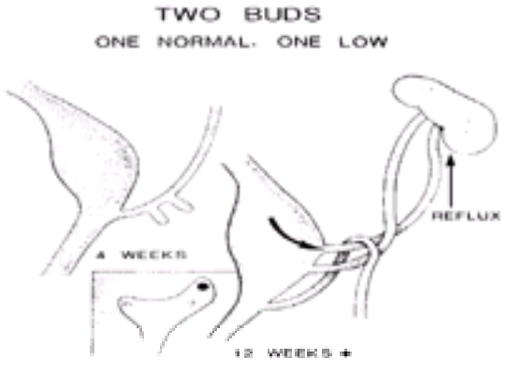

FIGURE 48A.7. Two ureteral buds, one normal and one low on the mesonephric duct, leading to complete ureteral duplication with lower pole vesicoureteral reflux.

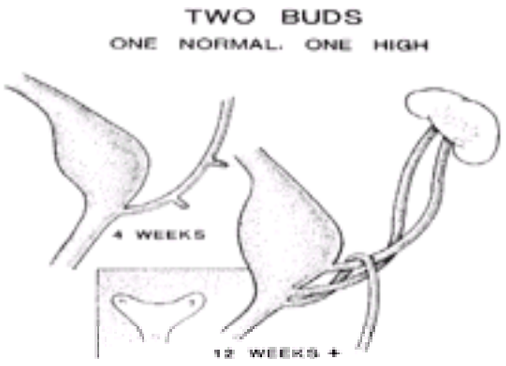

FIGURE 48A.8. Two ureteral buds, one normal and one high on the mesonephric duct, leading to complete ureteral duplication with ectopic upper pole ureter.

Ureteroceles can be defined as a cystic dilation of the terminal portion of the ureter. Ureteroceles associated with a single ureter are seen in children, usually as intravesical ureteroceles; however, ureteroceles associated with complete ureteral duplication are more common. In this situation, they are at the distal end of the ureter. They drain the upper pole collecting system and are most commonly ectopic ureteroceles, that is, a ureterocele with some portion situated permanently at the bladder neck or in the urethra.

The embryology of all ureteroceles cannot be explained by one hypothesis. Chwalla (34) pointed out in the embryo a two-cell-layer ureteral membrane that is present at the time the ureteral bud arises from the mesonephric duct. If this membrane did not completely break down, an obstructed ureteral orifice could result, leading to the formation of a ureterocele. Ureteroceles seen with stenotic orifices or associated with muscular hypertrophy of the ureteral wall support Chwalla's model. However, Stephens (164) and others have described cases in which ureteroceles are found to have large ureteral orifices. Alternatively, some suggest that the distal ureteral segment may be acted on by the same force that causes the expansion of the urogenital sinus to form the bladder (163,170,171). If this model were an adequate explanation for ureterocele formation, all caudal ectopic ureters should be associated with a ureterocele, which is not the case. Tanagho's hypothesis (Fig. 48A.9) suggests that delay in establishing the lumen of the ureteral bud with that of the mesonephric duct could result in ureteral expansion secondary to the same process that results in expansion of the urogenital sinus into the bladder (170,171).

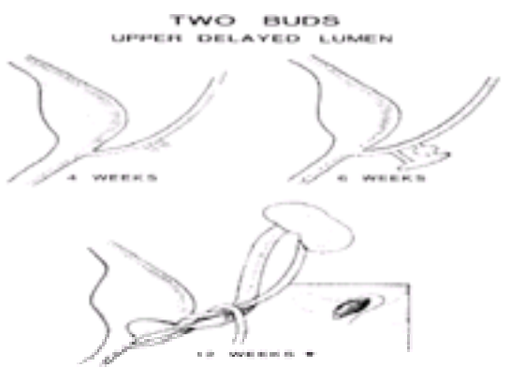

FIGURE 48A.9. Two ureteral buds with delayed establishment of lumen of upper ureteral bud leading to development of upper pole ureterocele.

Relation of Ureteral Bud Position to Renal Morphology

Renal tissue associated with ectopic ureters and ureters joining ureteroceles is often dysplastic or hypoplastic and has minimal, if any, function. In 1975, Mackie and Stephens suggested that this finding could be associated with an abnormal origin of the ureteral bud from the mesonephric duct, which, as we have seen, may account for the caudal embryologic explanation for ectopic ureters and ureteroceles (Fig. 48A.10). According to this theory, the metanephric ridge is made up of blastema with variable potential for the formation of normal renal tissue. The best potential exists in the central zone of the ridge, which would be the area normally penetrated by a ureteral bud having origin from a normal location on the mesonephric duct. This normal ureteral bud would thus be expected to induce a kidney from the metanephric blastema with the best potential to form a normal kidney. On either side of the central zone of the metanephric ridge, the blastema may have a lesser potential to form normal renal tissue. Thus, if the ureteral bud is located above or below the normal point of origin, it may grow to induce renal tissue from blastema with an increased propensity for dysplasia or hypoplasia. This hypothesis appears to hold best for the upper pole ureters seen in complete duplications associated with ectopic ureters or ureteroceles. Less often, lateral ectopic ureteral orifices associated with vesicoureteral reflux may also be found attached to ureters draining dysplastic or hypoplastic renal tissue. Thus the Mackie and Stephens hypothesis provides an attractive explanation for abnormal renal tissue associated with a ureteral orifice, either cranial or caudal, from the location of a normal ureteral orifice at the corner of the trigone.

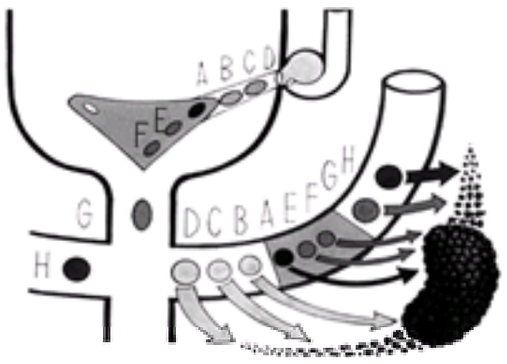

FIGURE 48A.10. Stephens' theory that an abnormal origin of the ureteral bud from the mesonephric duct leads to induction of metanephric blastema with limited potential for the formation of normal renal tissue. Composite diagram showing how a ureteral bud with near-normal origin *(A, E, F)* from the mesonephric duct will induce the kidney from the main mass of metanephric blastema and for a good kidney associated with a ureteral orifice on the trigone. Ureteral buds with an abnormal origin will induce blastema with limited potential and will be associated with an ectopic ureteral orifice.

PHYSIOLOGY OF THE URETER

The ureter consists of a syncytial type of smooth muscular tube with a urothelial lining that transports urine from the renal pelvis to the bladder. The normal ureterovesical junction prevents reflux of urine. The number of smooth muscle cells increases from birth at least to the age of 12 (44).

The transport of urine begins in the minor calyces, where pacemaker cells cause a contraction of the calyces. The smooth muscle cells of the ureter are in continuity with the calyces and renal pelvis. The contraction of the calyces is propagated along the smooth muscle cells to the renal pelvis. At normal urine flow rates, some of these contraction waves are blocked at the ureteropelvic junction (UPJ); however, most are propagated to the ureter. In children, the renal pelvis contracts an average of four times per minute, and ureteral contractions occur an average of 3.7 times per minute (52). In states of diuresis, there may be a 1:1 relationship between the pacemaker contractions of the calyces and the ureteral contractions (38). Although the nervous system may modulate the contractions, the fact that a transplanted kidney and ureter continues to contract demonstrates that peristalsis may occur without extrarenal innervation.

When a bolus of urine is pushed into the proximal ureter through the UPJ, it must be propagated to the bladder. The UPJ closes after a bolus of urine, preventing back-pressure and backflow of urine into the renal pelvis from the elevated ureteral contraction pressure (69). A contraction ring forms in the proximal ureter, and this ring of contraction migrates toward the bladder, pushing the bolus of urine distally. The pressure generated by this wave of contraction in children is approximately 30 cm H_2O (similar, but slightly less than in the adult), whereas the resting pressure in the ureter is 0 to 5 cm H_2O (52). In states of high urine output, the size of the bolus increases, and the pressure in the bolus may be greater than the contraction ring ahead of it, in which case the ureteral walls cannot coapt and urine is transported as a single column of fluid.

The intravesical ureter courses obliquely through the bladder wall. There is a normal elevation in resting pressure (10 to 15 cm H_2O) in this segment that increases with bladder filling and helps prevent reflux. In refluxing ureters, this pressure gradient has been shown to decrease (124,182). The histologic structure and autonomic innervation do not appear different in refluxing ureters relative to nonrefluxing ureters (50).

A decreasing compliance of the ureter with age suggests that more ureteral dilation occurs in neonates and young children in response to obstruction than in the adult. With dilation of the ureter, the intraluminal pressure generated by a given contractile force decreases inversely with the radius according to the Laplace equation (pressure = stress × wall thickness/radius). Therefore dilated ureters do not transport urine as well as nondilated ureters despite relief of obstruction (182).

URETERAL DUPLICATION

Incidence, Genetics, and Associated Anomalies

Ureteral duplication is the most commonly seen ureteral anomaly. In an autopsy population, ureteral duplication appears to occur in approximately 1 in 125 patients, or 0.8% (28,126). The right and left kidneys are affected equally. Bilateral duplication occurs in approximately 40% of cases (174). In clinical series, there are twice as many women with duplications as men. In series in which urography has been done for urinary symptoms, there is a much higher incidence of duplication: 2% to 4% (73). Urinary infection is the most common associated finding.

A genetic analysis of duplication indicates this anomaly may be transmitted as an autosomal-dominant trait with incomplete penetrance (35). When an index child with a duplication is found in a family, the frequency of a sibling being found with a duplication rises from 1 in 25 to 1 in 8 or 9 (11,13,185).

Patients with ureteral duplication have an increased incidence of other urinary tract anomalies. In the radiographic review of Privett and colleagues (139), 29% of the duplex units reviewed exhibited scarring, hydronephrosis, or both. Histologically, renal hypoplasia or dysplasia and pyelonephritic scarring occur more frequently. Clinically, one would expect to see an increased incidence of childhood urinary tract infections when duplications are present because of associated reflux or obstruction, and indeed, this increase is what has been found (28,101).

Incomplete Ureteral Duplication: “Y” Ureter

A ureteral bud that bifurcates early results in a partial duplication. A bifid renal pelvis is the result of the highest level of bifurcation and occurs in approximately 10% of the population. Of the other incomplete duplications, approximately 25% are found to divide in the distal or proximal third of the ureter and the remaining 50% divide in the middle section. Most partial duplications are discovered accidentally; however, with a “Y” junction in the ureter, it is possible for urine to be passed down to the junction and then, in a retrograde fashion, up the other side of the Y (27,176). This ureteral reflux, or “yo-yo,” on occasion leads to stasis and ureteral dilation (Fig. 48A.11). It is most common when the bifurcation is at a low position but is rare if the duplication ends in the intramural portion of the ureter (106). It has been reported in a blind-ending bifid ureter (99). When ureteral reflux is present, there may be associated infection or flank discomfort.

FIGURE 48A.11. Yo-yo reflux: incomplete ureteral duplication and ureteroureteral reflux.

Diagnosis is made by intravenous pyelography (IVP), particularly if fluoroscopic observation is used to observe the ureteral reflux (91). A voiding cystourethrogram (VCUG) is essential to eliminate ureteral dilation due to simple vesicoureteral reflux, which is much more common. When surgical treatment is required, the technique depends on the level of the duplication. With a low duplication, a reimplantation of the ureters into the bladder with separate ureteral orifices may be possible (5). When the duplication is higher, ureteropyelostomy or ureteroureterostomy at the renal level with excision of most of the distal duplicated ureter is curative (6).

On occasion, ureteropelvic junction obstruction may be found in association with incomplete duplex systems and may pose interesting reconstructive problems (131). Because the upper pole usually has no true ureteropelvic junction, it is almost always the lower pole collecting system that is obstructed. Usually, the lower pole ureter is short (Fig. 48A.12), and a side-to-side anastomosis of the obstructed lower pole pelvis to the upper pole ureter is required.

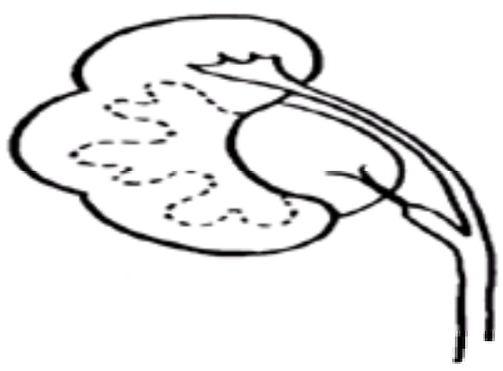

FIGURE 48A.12. Ureteropelvic junction obstruction in lower pole of duplex kidney. Usually, the lower pole ureter is too short for a ureteropyelostomy, and accordingly, a side-to-side anastomosis of the pelvis to the upper pole ureter is performed.

Incomplete Ureteral Duplication: Blind-ending Ureter

If a ureteral bud bifurcates, but only one limb induces the associated metanephric blastema, a rare form of incomplete duplication with a blind-ending ureteral stump is generated (2,135,151). Most of these duplications are in the middle or distal ureter. Women are three times more likely to exhibit this, and it is seen most frequently on the right side. A ureteral diverticulum may be confused with this entity (141). Culp's (43) somewhat arbitrary criteria help better define the true blind-ending bifid ureter: those blind-ending structures whose lumen joins that of the ureter at a clear angle, whose length is at least twice the width, and whose histologic characteristics resemble the ureter. Occasionally, a blind-ending ureteral duplication may end in the bladder and be confused with a periureteral diverticulum because of the frequent association of vesicoureteral reflux in this situation (116). The blind-ending ureter rarely causes symptoms but may generate flank pain associated with infection or calculi. A retrograde ureterogram may be required for diagnosis because the blind duplication may not fill on IVP. Treatment consists of surgical excision of the duplication.

Incomplete Ureteral Duplication: Inverted “Y” Ureter

The inverted “Y” ureter is the rarest of all anomalies of ureteral branching. The embryologic explanation presumably lies in two separate ureteral buds arising from the mesonephric duct but fusing before penetrating the metanephric ridge. This anomaly has been seen almost exclusively in females (97). If one limb is distally ectopic, urinary incontinence may result. Treatment is directed at problems caused by the ectopic limb. Usually resection of this limb is required. An inverted Y ureteral duplication with one blind-ending ureter has been reported (23).

Complete Ureteral Duplication and Vesicoureteral Reflux

When a complete ureteral duplication is present, vesicoureteral reflux is the most common cause of acquired renal disease. Reflux typically occurs into the lower moiety of a duplicated kidney (8). The upper pole ureter with its orifice medial (Meyer-Weigert law) has a longer submucosal tunnel and usually does not reflux. When reflux into both upper and lower pole ureteral orifices is seen, cystoscopy usually reveals that both orifices are side by side in a laterally ectopic position. This anomaly is embryologically explained by two ureteral buds close to one another, having an origin in a position caudal to normal on the mesonephric duct. Reflux into the upper pole ureter also may occur if its orifice is ectopic in the bladder neck or urethra. The child with duplication and reflux presents most commonly with urinary tract infection, as does the child with single-system reflux. Fehrenbaker and co-authors (59) found reflux in more than two-thirds of children with duplex systems who had a urinary tract infection. Renal Ultrasound or IVP and VCUG establish the diagnosis by showing a duplex renal system with vesicoureteral reflux usually only into the lower pole collecting system (Fig. 48A.13).

FIGURE 48A.13. Complete ureteral duplication and vesicoureteral reflux. **A:** Intravenous pyelogram showing completed duplication of ureters. **B,** Voiding cystourethrogram showing bilateral lower pole vesicoureteral reflux.

The treatment of duplicated ureters with reflux adheres to the same principles that govern the single-system ureter with reflux. When the grade of reflux is low,

spontaneous resolution with linear growth of the child accompanied by lengthening of the submucosal tunnel of the ureter usually avoids the need for surgery (105,132,180). Antibiotic prophylaxis and radiographic monitoring intermittently suffice for treatment. Surgical management may be more appropriate when the grade of reflux is high and the likelihood of spontaneous resolution is small. In a complete duplication, the distal 2 to 3 cm of the two ureters usually is bound in a common muscular sheath, making their separation dangerous to one or both ureters. Surgical correction of reflux thus involves mobilization of the common sheath and reimplantation of the common sheath, even though reflux has been observed in only one ureter (14,87). The success rate for common sheath reimplantation is similar to that reported for single systems (55). When the lower pole parenchyma is very diminutive, a common sheath reimplant generally suffices unless there is major ureteral dilation. This approach avoids the need for a renal operation.

Ureteral Triplication

Ureteral triplication is one of the rarest anomalies of the upper urinary tract. In their review of the literature in 1978, Kohri and colleagues could find only 75 cases. The embryologic explanation for ureteral triplication would be the presence of three ureteral buds originating separately on the mesonephric duct. If the ducts divide early, partial triplication would result as has been reported. In most cases, all three ureters drain through a single orifice (98). The left side appears to be affected most commonly, and trifid ureters are seen more often in females (133). Symptoms may be infection, incontinence, or pain (108). Ureteral triplication in association with an ectopic ureter (192,194) and ureterocele (62) has been reported. Surgical treatment must be individualized. Ureteral quadruplication is most rare but has been described by Soderdahl and colleagues (161).

URETEROCELE

Terminology and Definitions

A *ureterocele* is a cystic dilation of the intravesical submucosal ureter. According to the Committee on Terminology of the Urologic Section of the American Academy of Pediatrics, ureteroceles contained entirely within the bladder are *intravesical ureteroceles,* and a ureterocele that is partially situated permanently at the bladder neck or urethra, regardless of the position of the orifice, is an *ectopic ureterocele.* A *single-system ureterocele* is associated with a kidney with only one ureter, whereas a *duplex-system ureterocele* is associated with the upper pole of a kidney with a complete ureteral duplication. Usually, the wall of a ureterocele exhibits attenuated muscle and collagen (166,175). Ureteroceles vary greatly in size from ones so small that may be difficult to see to ones that are so large as to fill virtually the entire bladder (Fig. 48A.14). The orifice of a ureterocele may be stenotic, normal in size, or occasionally even patulous. They may be located intravesically or extravesically.

FIGURE 48A.14. A: Small ureterocele. Lower pole ureteral orifice is elevated by the ureterocele. **B:** Large ureterocele. Catheters are in the orifice of the ureterocele and ipsilateral lower pole ureteral orifice.

Incidence and Diagnosis

Campbell (29) reported the incidence of ureteroceles to be 1 in 4,000 autopsies of children. Malek and co-authors (114) report an incidence between 1 in 5,000 and 1 in 12,000 general pediatric admissions. Both of these estimates are probably low, suggesting that small ureteroceles were missed. Uson and colleagues (177) reported a much higher incidence of 1 in 500 autopsies. Ureteroceles occur most commonly in whites and are unusual in blacks. Although females are affected four to seven times more often than males, the malformation is often more complex in the male (53). Some series have demonstrated a slight left-sided predominance; approximately 10% are bilateral (144). Of ureteroceles, 60% to 80% are ectopic (25,56,115), and approximately 80% are associated with the upper pole ureter of a duplex kidney (24,56,115,164). Intravesical ureteroceles associated with a single ureter are seen more in adults than in children and may be an acquired lesion (173). Although the severity of obstruction and hydroureteronephrosis is greater in children than in adults (140), single-system ureteroceles usually are associated with better function and less hydronephrosis than are duplex renal units and their more commonly associated ectopic ureteroceles. Single-system ectopic ureteroceles are rare, usually occur in men, and may be associated with cardiac and genital anomalies (85). Rarely, a ureterocele is associated with a blind-ending ureter (4). Associated urologic anomalies, especially renal anomalies of fusion and ectopia, often occur with ureteroceles. When the ureterocele arises from the upper pole of a duplex kidney, the upper pole frequently displays renal dysplasia (134,159).

Ericsson (56) was the first to try classifying ureteroceles. *Simple* ureteroceles were defined as ones contained entirely within the bladder, and *ectopic* ureteroceles were defined as ones that extended to the bladder neck or urethra. The clearer classification given earlier in the chapter eliminates the confusing term *simple.* Stephens (164) provided a more complex classification that was intended to better describe the pathologic anatomy of ureteroceles. He described *stenotic* ureteroceles (approximately 40%) as being located entirely within the bladder and having a small ureteral orifice. The orifice could vary from pinpoint size with a constantly tense ureterocele to larger orifices that permit some decompression of the ureterocele and with the ureterocele being visible only when a peristaltic wave fills it. The muscle is predominantly longitudinal in orientation. Stephens (164) classified *sphincteric* ureteroceles (approximately 40%) as ones with an orifice confined within the internal sphincter, making them a type of ectopic ureterocele. Compression by the internal sphincter obstructs drainage from the ureterocele, causing emptying to occur only during voiding. The size of the meatus may be normal or even large. This type of ureterocele may exhibit vesicoureteral reflux (9%) (154). Stephens' *sphincterostenotic ureteroceles* (approximately 5%) have a stenotic meatus located either at the bladder neck or more distally and are also a type of ectopic ureterocele. These ureteroceles tend to be large and tense. Because they do not decompress during voiding as sphincteric ones do, the tense ureterocele may act as a ball valve in the bladder outlet, producing urethral obstruction. In the female, it may prolapse through the urethral meatus. Stephens' fourth type of ureterocele is referred to as a *cecoureterocele* (Fig. 48A.15). Here, although the meatus of the ureterocele is in the bladder, a tongue of the ureterocele extends down the urethra. At the time of ureterocele excision, if this tonguelike projection is not carefully excised, a mucosal flap may be left capable of producing a valvelike obstruction of the urethra (9).

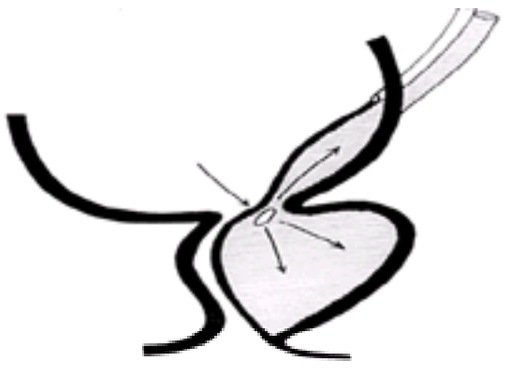

FIGURE 48A.15. Cecoureterocele: ureterocele with tonguelike projection extending down urethra submucosally.

The most common presentation of ureteroceles currently is by prenatal ultrasound, although infection continues to be a common presentation for ureteroceles after birth (26,71,88,113). This infected obstructed system may lead to the picture of full Gram-negative sepsis. At other times, infants may simply fail to thrive or show nonspecific gastrointestinal symptoms as seen with other obstructive uropathies in infancy. On occasion, an infant will have a palpable abdominal mass representing the bladder or the obstructed renal unit.

Prolapse of a ureterocele in the female may lead to bladder outlet obstruction, which constitutes the most common urethral obstruction seen in girls (96). Prolapsing ureteroceles can also occasionally obstruct the urethra in boys (49,127). Usually, this obstruction occurs with a duplex system ureterocele. The “ball-valving” obstructive ureteroceles tend to be tense large ones that Stephens would classify as stenotic. However, most ureteroceles are not obstructive because they are compressible during voiding. Hematuria may occur from minor trauma to the dilated system or rarely from the presence of a stone. At times, the only symptom is abdominal or flank pain. When incontinence is a presenting symptom, it is usually secondary to infection. Occasionally, a large ureterocele with an abnormal lax bladder neck may lead to incontinence before or after the ureterocele is surgically treated (80,102).

Although historically, in the diagnosis of a ureterocele, the most useful study has been the IVP (18,6,49,71,79,88,96,102,113,127,134,155,186), today, the diagnosis of a ureterocele relies predominately on ultrasonography (10,71,129,167). Ultrasound may demonstrate a well-defined cystic intravesical mass along the posterior bladder wall (Fig. 48A.16). The ultrasound appearance of a ureterocele can be deceiving, and accurate diagnosis requires an experienced radiologist. Because many ureteroceles are compressible with bladder filling, observation when the bladder is very full may obscure the mucosal irregularity of the bladder base. A dilated ureter behind the bladder may also be confused with an ectopic ureter or primary obstructive megaureter (Fig. 48A.17).

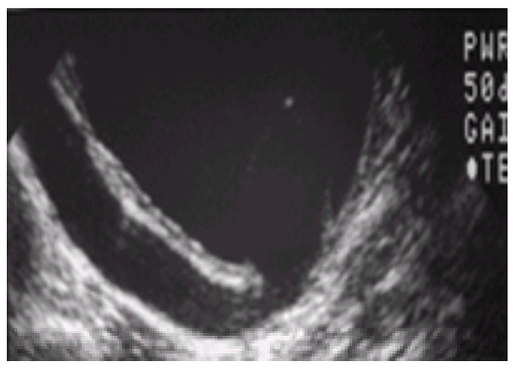

FIGURE 48A.16. Ultrasound demonstrating a dilated upper pole ureter posterior to the bladder, associated with a ureterocele.

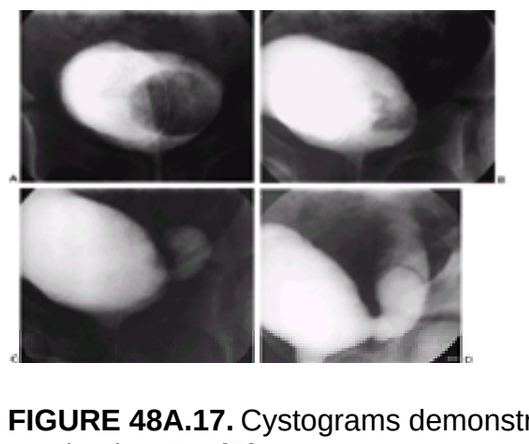

FIGURE 48A.17. Cystograms demonstrating large intravesical ureterocele **(A),** which prolapses through the ureteral hiatus **(B, C)** with subsequent reflux into more proximal ureter **(D).**

When the associated renal unit exhibits good function, an IVP demonstrates a characteristic “cobra head” or “spring onion” deformity of the distal ureter that is produced when opacified urine in the ureterocele is surrounded by a radiolucent halo that represents the wall of the ureterocele (Fig. 48A.18). Renal function adequate to produce this characteristic image is most frequently seen with single-system intravesical ureteroceles. Most ectopic ureteroceles are associated with the upper pole of a duplex kidney that exhibits minimal or no function, with reports of 74% to 90% (26). In these cases, the radiographic signs of a ureterocele are primarily negative, reflecting the displacement of the functioning lower pole renal unit and ureter by the hydronephrotic upper pole segment. The lower pole renal unit is often downward and laterally displaced, producing the characteristic “drooping lily” sign (Fig. 48A.19). The lower pole ureter may be tortuous and displaced away from the spine as it wraps around the dilated upper pole ureter. At the bladder level, a negative shadow may be seen, suggesting the presence of a ureterocele. The negative shadow can vary from a large, tense, round shadow occupying much of the bladder volume to a minor irregularity along the floor of the bladder. This negative shadow has to be differentiated from a bladder calculus, blood clot, bladder tumor, or gas in the rectum. In single-system ureteroceles, the absence of function or associated hydroureteronephrosis may help clarify the issue, but in a ureterocele associated with a duplex unit, especially if there is little hydroureteronephrosis, the diagnosis may be more difficult. The early films and the postvoid films from a urogram should be examined closely for the ureterocele because once the bladder is filled with contrast, the ureterocele may be obscured. Intravesical ureteroceles tend to be defined by contrast that nearly surrounds them as opposed to ectopic ureteroceles, which are poorly separated by contrast from the floor of the bladder.

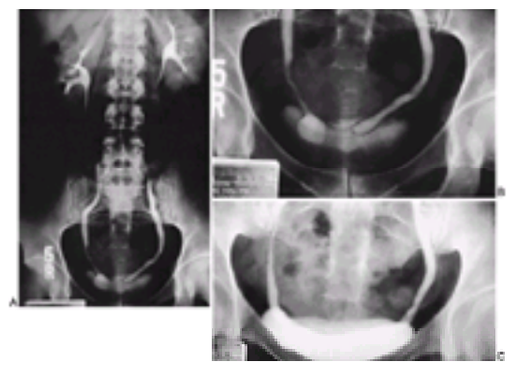

FIGURE 48A.18. Bilateral single-system simple ureteroceles. **A:** IVP showing normal kidneys and minimal obstruction. **B:** Bladder showing typical cobra head deformity of distal ureter with small ureterocele and good renal function. **C:** Bladder later in IVP showing how accumulation of contrast may obscure ureterocele.

FIGURE 48A.19. Large ureterocele associated with nonfunctioning upper pole of duplicated right kidney. Intravenous pyelogram shows right lower pole is pushed down and out (the drooping lily sign). A paucity of calyces is evident, and the upper pole infundibulum is absent.

A good quality VCUG constitutes a critical component in the evaluation of all ureteroceles (Fig. 48A.20). With duplex ureteroceles, reflux occurs in the ipsilateral lower pole in approximately 50% of cases (24,26,154). Most often, they are compressible ureteroceles that provide poor support for the submucosal course of the lower pole ureter. In approximately 25% of cases, there is contralateral reflux, and in approximately 10% of cases, there is reflux into the ureterocele itself (92,107,154) (Fig. 48A.17). Reflux into a single-system ureterocele is less common but can occur. This usually occurs into a wide-mouth sphincteric ureterocele, a ruptured one, or a cecoureterocele (22,154).

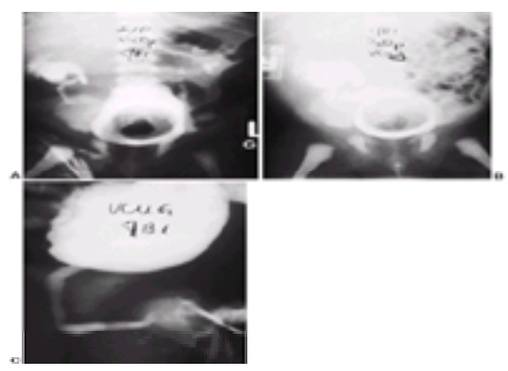

FIGURE 48A.20. Right renal duplication with ureterocele in infant presenting with sepsis. **A:** Intravenous pyelogram showing large ureterocele associated with nonfunctioning upper pole of right kidney. Lower pole shows drooping lily sign, and right lower pole ureter is tortuous as it wraps around the dilated upper pole ureter. **B:** Voiding cystourethrogram showing right lower pole vesicoureteral reflux. **C:** Voiding cystourethrogram showing that despite its size, the ureterocele does not obstruct the bladder outlet. Bladder full of contrast obscures the ureterocele.

The VCUG may help ascertain the degree of detrusor backing present for the ureterocele. If detrusor support is poor and the ureterocele prolapses through the detrusor with voiding, the ureterocele may mimic a bladder diverticulum (Fig. 48A.17 and Fig. 48A.21) (41,184). Prolapse may occur either into the dilated ureter associated with the ureterocele or through the hiatus paraureterally (100). Occasionally, following decompression of a ureterocele, detrusor backing may appear to improve. When tense, a ureterocele may obstruct the ipsilateral lower pole ureter or contralateral ureter as well as the bladder outlet. Occasionally, in males, an ectopic ureterocele can prolapse and produce an image that may be confused with posterior urethral valves (61).

FIGURE 48A.21. Illustration of how prolapse of a ureterocele through the ureteral hiatus may mimic a bladder diverticulum.

Cystoscopic detection of ureteroceles can be quite variable and frequently confusing. When a ureterocele is small, it may not be apparent until a peristaltic wave or flank compression causes it to fill. With very large ureteroceles, identification of any ureteral orifice in the bladder may be impossible. With a large ureterocele causing bilateral obstruction, it can be difficult to tell from which system the ureterocele originated. In this situation, the use of a small needle wedged into the end of a fine ureteral catheter can be used to puncture the ureterocele under direct vision at cystoscopy, and injection of contrast medium may permit an intraoperative radiograph defining the anatomy. An alternative approach is to use a spinal needle passed transabdominally into the bladder and then into the ureterocele under cystoscopic guidance with an intraoperative radiographic examination.

A compressible ureterocele can resemble only a minor mucosal fold with bladder filling, and one must examine the bladder carefully when it is nearly empty as well as when it is full. When the ureterocele has poor detrusor support and prolapses, one can misdiagnose it as a bladder diverticulum at cystoscopy (Fig. 48A.17) (160). As the bladder is emptied and the flank compressed, the ureterocele may fill again, permitting the correct diagnosis. Conversely, when the bladder is empty, the redundant mucosa of a periureteral diverticulum may be mistaken for a collapsed ureterocele. Once again, examination of the area in question when the bladder is full should permit recognition of a true diverticulum. Trigonal cysts are very rare but when present can be confused with a ureterocele at cystoscopy (168). Injection of contrast into the cyst, as previously described, or ultrasound should help diagnose these rare cases. Occasionally, the dilated lower end of an ectopic ureter may elevate the trigone, causing a “pseudoureterocele” by ultrasound, VCUG, or cystoscopy (Fig. 48A.22) (63).

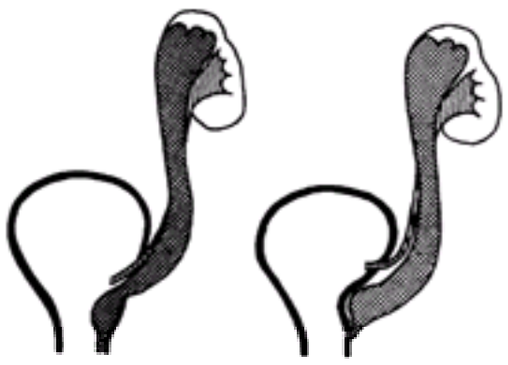

FIGURE 48A.22. Ureterocele **(left)** and “pseudoureterocele” **(right).** An ectopic ureter can occasionally elevate the floor of the bladder sufficiently to mimic a ureterocele **(right).** (From Gill B. Ureteric ectopy in children. *Br J Urol* 1980;52:257, with permission.)

Because contralateral duplications are common with ureteroceles, it is worth every effort to assess the contralateral anatomy at cystoscopy. In this way, possible damage to a nonapparent ureteral orifice may be avoided.

The Choice of Ureterocele Treatment

The goals of ureterocele treatment are control of infection, protection of normal ipsilateral and contralateral units, preservation of renal function, facilitation of subsequent reconstructive procedures, and maintenance of continence. Because the natural history of asymptomatic ureteroceles is unknown, the effect of any treatment option on asymptomatic neonatal ureteroceles remains difficult to determine. With the advent of successful ureterocele treatment by endoscopic incision, the algorithm for the management of ureteroceles has become more complex. A number of factors must be considered when determining which treatment approach is optimal for the child with a ureterocele. Treatment must be individualized because no one approach is appropriate for all ureteroceles.

The *age of the patient* is an important consideration. With a ureterocele detected antenatally, endoscopic incision has the advantage in the newborn of providing a simple and direct decompression of the obstructive uropathy. In the series reported from Great Ormond Street, there were no cases of urosepsis following decompression (57). An infant may tolerate a shorter, simpler endoscopic procedure better than a more complex upper pole partial nephrectomy. If excision of the ureterocele is later needed, this is facilitated by previous endoscopic decompression. After toilet training, bladder neck surgery causes a considerable degree of postoperative discomfort, thus treatment is best accomplished before toilet training. At this age, the attractiveness of a “simplified” approach with an upper pole partial nephrectomy avoids bladder surgery but is often not definitive because of associated reflux (26,154).

The *amount of functioning parenchyma* is another issue commonly considered when choosing treatment. If a child has never had pyelonephritis, salvage of functional renal parenchyma may be more successful. It is important to remember that usually the upper pole system serving the ureterocele typically makes up only the parenchyma subserved by the upper pole infundibulum (139), so in most cases, one should not let preservation of function be a paramount part of decision-making. On the other hand, a poorly functioning renal unit that is serving a decompressed ureterocele with no reflux has little or no reason to be removed.

A more important point is *whether the kidney is single or duplex.* In a single-system ureterocele, it would appear that a primary endoscopic approach would almost always be appropriate because open surgery would be directed at the bladder level. After endoscopic incision, one would have the advantage of reimplanting a smaller decompressed ureter should postendoscopic incision vesicoureteral reflux require an open operation. When the renal unit is duplex, the decision is more complex. Some of the issues to be subsequently mentioned may be more critical in this setting.

Consideration of the ureterocele as *intravesical* or *extravesical* is important because both the endoscopic and open surgical reconstructions vary. The endoscopic treatment of ectopic ureteroceles has not been as successful for definitive treatment as for intravesical ones (20,37,39,71,136,157). With long-term follow-up of ureteroceles treated endoscopically, 18% of patients with an intravesical and 64% of patients with an extravesical ureterocele required a second operation (37,136). Thus it would appear that for intravesical ureteroceles, whether associated with a single or duplex renal unit, a primary endoscopic approach is preferred. The high percentage of second operations required in children with extravesical ureteroceles managed with initial endoscopic treatment has become well established (37,78,84,136,157). However, prior endoscopic decompression should permit definitive surgery to be done with one open operation done through an incision at the bladder level (71). The decompressed ureter serving a ureterocele can be reimplanted with results approaching that seen for ureters without a ureterocele (i.e., greater than 90% success rate).

Detrusor backing is an important consideration in that a poorly supported ureterocele that everts during voiding and becomes a bladder diverticulum may be more likely to require secondary reconstruction of the trigone than one that is well supported. However, after ureterocele decompression, the support occasionally appears to improve, making it impossible to say that poor detrusor backing of the ureterocele is a firm predictor of the need for subsequent open-bladder surgery.

The degree of ureteral dilation is another factor. When there is a small ureter running to a small intravesical ureterocele that is detected when one is operating for what is felt to be primary reflux, reimplantation of the ureter from the poorly functioning upper pole with the refluxing lower pole ureter serves as very good definitive treatment (15). If, on the other hand, the ureter associated with the ureterocele is massively dilated, as is so often the case, attempts at reimplantation of such a system will be fraught with a greater complication rate than an ablative operation aimed at the upper pole of the kidney. After endoscopic decompression, the ureteral dilation will greatly diminish improving reimplantation results.

Associated vesicoureteral reflux appears to best predict the need for open surgery and emphasizes the importance of the VCUG . The review by Sen and colleagues (154) indicated that one can expect to see approximately 50% of ipsilateral lower pole ureters exhibit reflux. Approximately 25% of contralateral ureters reflux, and in about 10% of cases, reflux was seen in the ureterocele-bearing unit. In a review by Husmann and colleagues (80), it is evident that reflux was the major factor cause for subsequent surgery to decompress a ureterocele after an upper pole partial nephrectomy (the so-called “simplified” approach). In cases in which the ureterocele alone was present without reflux, no patient required additional surgery. If less than grade III reflux was present in only one ureter, 60% of patients did not require further surgery. In contrast, a higher grade reflux than this into one or more renal moieties almost invariably led to further surgery (96%). If high-grade reflux were associated with a ureterocele, it would appear that a primary endoscopic incision would be logical because subsequent surgery at the bladder level, while likely, will be facilitated by decompression of the ureterocele. The decompressed ureter to the ureterocele can usually be successfully reimplanted, and upper pole partial nephrectomy, even for a poorly functioning upper pole, is rarely needed. If there is no vesicoureteral reflux, then a “simplified” approach by an upper pole partial nephrectomy for an ectopic ureterocele is a reasonable treatment option. Unfortunately, ectopic ureteroceles without reflux are uncommon.

From this brief section, it can be deduced that there will not be one simple solution to all ureterocele problems. Minimizing the number of anesthetics and surgical procedures, as well as postoperative morbidity, becomes very challenging. With improved endoscopic techniques, one hopes when secondary open surgery is needed that it will be possible with one incision only, lessening surgical trauma to the child.

Endoscopic Treatment of Ureteroceles

Endoscopic decompression of ureteroceles was suggested initially by Zielinski (193) and by Hutch and Chisholm (81). Tank (172) advocated unroofing of ureteroceles without regard for reflux and found that 50% of patients showed improvement in function and that subsequent nephrectomy was not necessary. Lower tract reconstruction for recurrent infections was reported in only 10% of cases. Monfort and colleagues (122,123), Rich and colleagues (142), and Blyth and colleagues (20) suggested the current approach to ureterocele decompression: a small puncture placed low on the ureterocele to preserve a flap valve of the collapsed ureterocele and prevent reflux.

Several technical points concerning endoscopic treatment of intravesical ureteroceles may decrease complications. Because many ureteroceles are compressible with bladder filling, it may help to keep the bladder rather empty and massage the flank to distend the ureterocele to ensure a low incision on the front wall of the ureterocele just above the bladder neck. A 3-Fr Bugbee using the cutting current at a high enough level to ensure a clean incision is used. If a clean cut is not achieved, one may end up pushing the inner layer of the ureterocele away from the outer layer, thus not achieving decompression. A perpendicular approach to the

ureterocele is important to avoid a skiving incision that may likewise miss the lumen of the ureterocele. Although a low incision is preferred in efforts to create a flap valve mechanism of the decompressed ureterocele, it must be borne in mind that if one incises too low, the incision can be below the level of the ureterocele floor. A 2- to 3-mm incision is adequate in most cases because the thermal effect of the incision leads to subsequent enlargement in the hole. Only when the ureterocele appears to be very thick-walled is an incision any larger than this appropriate (71). Confirmation of adequate decompression can usually be assured from seeing a jet of urine emerge from the incision site in the ureterocele. This can be augmented by massage of the ipsilateral flank.

There are *technical considerations* in the *endoscopic incision of an ectopic ureterocele* that are different from those for an intravesical ureterocele. With the objective of achieving decompression of the ureterocele, a low puncture of the ureterocele to maintain a flap valve of the collapsed ureterocele continues to be a fairly uniform approach among different authors (39,148,157). Controversy exists about the treatment of the extension of an ectopic ureterocele into the urethra. Concern has been expressed that following decompression, an obstructing distal portion might remain. However, Schlussel and colleagues (148) and Smith and colleagues (157) report no problems with the urethral extension of the ureterocele after puncture at the intravesical level only. Care was taken to make a low, transverse, small incision that was within the bladder with the bladder neck closed. Technically, this can be accomplished by sweeping the cystoscope along the bladder wall lateral to the ureterocele and picking up the edge of the ureterocele just inside the bladder neck. An angled Bugbee facilitates a puncture perpendicular to the ureterocele wall. If the ectopic ureterocele is decompressed by intravesical puncture, the urethral extension will usually be adequately decompressed and will thus be unlikely to cause any difficulty. When one uses the technique described by Blyth and co-workers (20) of incising the intraurethral extension of the ureterocele upward until the incision is clearly within the bladder, the opening of the bladder neck may open the orifice of the ureterocele, leading to a greater incidence of reflux. This may account for the increased incidence of postpuncture reflux seen in Blyth's versus Schussel's series. This concern about the distal extension of the ureterocele may be more germane to open ureterocele excision when the urethral extension could remain as a cusp, catching urine during voiding and thus obstructing the urethra (9).

Follow-up after an endoscopic incision routinely involves a renal and bladder ultrasound 1 month after the procedure. Although residual hydroureteronephrosis often persists, a diminution of some degree indicates that decompression has been achieved. Subsequent imaging of the upper tracts and a VCUG 6 months following the procedure help direct further treatment.

Bladder-level Operation for Ureteroceles

In the open reconstruction of intravesical ureteroceles, if there is poor detrusor backing for the ureterocele, the bladder wall must be repaired at the time of ureterocele excision. In single-system ureteroceles that are decompressed, it is expected that the degree of ureteral dilation will go down to the point where a 5:1 ratio of submucosal tunnel length to diameter can be easily achieved to prevent vesicoureteral reflux. However, with massively dilated ureters associated with ureteroceles, even after decompression, a tailored reimplant may be required. Cohen's (36) technique of cross-trigonal advancement is generally used because it permits the reimplant to be done away from the area of bladder wall reconstruction.

In children who require ureterocele excision and lower pole ureteral reimplantation, it is usually delayed until the child is approximately 2 years old and is most commonly needed for persistent ipsilateral lower pole or contralateral reflux. As excision of the ureterocele and bladder neck reconstruction are considerably more symptomatic than a simple ureteral reimplant alone, it is preferable to perform the surgery before the age of toilet training. Several technical points in this procedure are worth bearing in mind. There are two basic methods for the intravesical excision for a ureterocele. If the detrusor backing for the ureterocele is solid, the back wall of the ureterocele can be left in place and the lower pole ureter tunneled beneath the mucosa. However, a bladder wall reconstructive procedure usually is warranted because of detrusor weakness behind the ureterocele. This may reflect an embryonic abnormality of the trigone, especially with ectopic ureteroceles (Canning DA, personal communication, 2000). It is usually possible to save a portion of the sidewalls of the ureterocele by separating the inner lining of the ureterocele to permit later mucosal coverage of the area of bladder wall reconstruction. If the ureterocele has a urethral extension, it is important not to leave a distal lip of mucosa that can be an obstructing flap valve. Either the entire urethral tongue of the ureterocele can be excised and the bladder neck area carefully reconstructed before closing the mucosa, or if the bladder neck and urethra have not been dilated by the ureterocele, merely removing the ureterocele roof as it extends down the urethra will suffice. It is technically a simpler procedure, but one must be certain that a functionally intact urethra and bladder neck are left behind because the primary reconstruction of these structures is easier than a secondary approach.

It is important to remember that in the series by Husmann and colleagues (79), 6% of the girls treated by an upper pole partial nephrectomy developed urinary incontinence after puberty, presumably due to a weakening of the bladder neck by the ureterocele, which persists after decompression. Because a ureterocele, especially ectopic ones, often widen the bladder neck, it is important to reconstruct this defect after ureterocele excision. The technique of “keeling” as described by Stephens (165) is particularly attractive (Fig. 48A.23). A series of sutures is used to evert the detrusor (“keeling”) until the bladder neck is reconstructed to a normal diameter. The mucosal edge of the ureterocele provides a good guide as to the amount of eversion needed. When the mucosa is reapproximated at the bladder neck, good bladder neck reconstruction can be ensured. To ensure that a small distal urethral mucosal cusp is not left to potentially obstruct the urethra (9), it is a simple matter at the end of the operation to use a small probe bent into a little hook and passed from the perineal end of the urethra to catch a distal lip of ureterocele, draw it externally, and nip it with a fine pair of scissors.

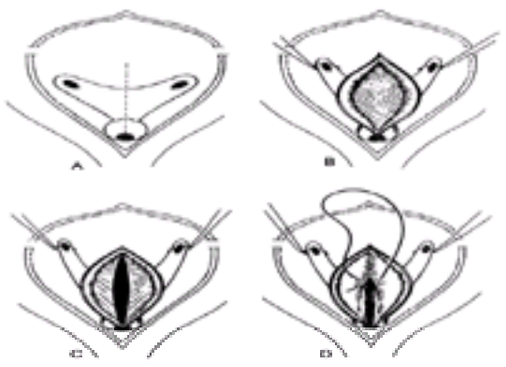

FIGURE 48A.23. Keeling repair of bladder neck after excision of ectopic (extravesical) ureterocele **(A, B).** Stephens' technique **(C, D)** involves a series of sutures placed to evert the detrusor at the bladder neck until the functional diameter of the bladder neck is restored to normal. The mucosal edge of the ureterocele provides a useful guide to the extent of eversion.

When one is operating at the bladder level for persistent reflux after upper pole partial nephrectomy (“simplified” approach), as the ureterocele is mobilized, the upper pole ureteral stump will be mobilized with the lower pole ureter. This dissection in most cases can be accomplished totally intravesically. After the lower pole ureter has been sufficiently mobilized for an adequate reimplant, the upper pole ureter stump is opened on its wall opposite the common one shared with the lower pole ureter. No effort is made to excise the portion of the wall of the upper pole ureter that is contiguous with the lower pole ureter. In this way, there should be minimal risk of injury to the lower pole ureter. A Cohen cross-trigonal reimplant is usually feasible and keeps the course of the ureter away from the area of recent bladder wall reconstruction. A ureteral stent is used only if the lower pole ureter is significantly abnormal.

On occasion, a surgeon will begin a ureteral reimplantation for what appears to be simple primary vesicoureteral reflux into a single system, and as the ureter is mobilized, a second small ureter is found running to a small nonobstructed ureterocele. It is the small size of the ureter and associated lack of function in the diminutive upper pole unit that may lead to this intraoperative discovery (15). Even though there is no function in the upper pole unit, treatment is usually satisfactory by a common sheath reimplant. The need for later removal of the upper pole renal unit is rare.

An intravesical ureterocele as part of a duplex unit rarely is associated with adequate function and a ureter small enough to permit ureterocele excision and a primary common sheath reimplant of the two ureters. More frequently, the associated ureter is too dilated to be reimplanted without tailoring. Here, if function justifies salvage, a renal level ureteroureterostomy or ureteropyelostomy may be used effectively (Fig. 48A.24). Today, a primary endoscopic puncture of the ureterocele and later a possible bladder level operation make these previous renal level operations rarely appropriate.

FIGURE 48A.24. Left ureteral duplication with ureterocele and function of upper pole treated by ureteroureterostomy. **A:** Preoperative intravenous pyelogram shows function of left upper pole and large ureterocele. **B:** After surgery, the left upper pole is well decompressed. The ureterocele collapsed and is no longer evident in the bladder.

If a bladder-level operation is needed after successful endoscopic incision of a ureterocele, it usually is for reflux associated with ectopic ureteroceles. An advantage of the endoscopic incision is that the decompressed ureter usually shrinks in diameter sufficiently to permit reimplantation into the bladder with results approaching that for normal refluxing ureters (71). Poor function of an associated upper pole renal segment is not an indication for a partial nephrectomy because when there is no associated persisting obstruction or reflux, follow-up has not demonstrated clinical problems.

Total Reconstruction

The first techniques developed for treatment of an ectopic ureterocele associated with a duplex renal unit was “total reconstruction” with excision of the ureterocele, reconstruction of the detrusor, and reimplantation of the ipsilateral lower pole ureter and the contralateral ureter if required. Following this bladder operation, a separate flank incision was made and an upper pole partial nephrectomy completed (75,76). If the upper pole had questionable function or the child was sufficiently ill to warrant a staged approach, the upper pole ureter could be exteriorized temporarily as a cutaneous ureterostomy. Monfort and colleagues (122) used this technique in 18 patients, with recovery of significant function in only 3, indicating that this approach is rarely indicated. Because most ureteroceles present in the very young, often before 1 year of age, the total reconstruction approach requires a technically challenging excision of a ureterocele, often with a urethral extension. Complications are not rare (46). As mentioned, the urethral extension of an ectopic ureterocele may act as a urethral valve and produce bladder outlet obstruction. Also, if the ureterocele is excised but the bladder neck imperfectly reconstructed, incontinence may follow (102). Incontinence can also rarely result from incomplete excision of a ureterocele that has an orifice beyond the sphincter mechanism, leaving a channel that bypasses sphincteric control (189). Proponents of this approach note that the majority of children can be treated with one operation, albeit two incisions. In one series, 14% of children with extravesical ureteroceles that underwent total reconstruction required subsequent intervention (145), indicating the significant risk of complications from a one-stage total reconstruction. It is our view today that a one-stage total reconstruction is rarely necessary.

Upper Pole Partial Nephrectomy: “Simplified” Approach

Because of potential complications secondary to a total reconstruction early in life, alternative methods of treatment for ureteroceles were undertaken. In duplex renal units with an associated ureterocele, the upper pole unit usually has not demonstrated sufficient function to warrant salvage (154,159), and a partial nephrectomy leaving the upper pole ureter open effectively decompresses the ureterocele. Because of this, a simplified “approach” based on a primary upper pole partial nephrectomy with ureterocele decompression and later a staged approach to bladder-level surgery were tried in several centers (26,30,32,94). The upper pole ureter was excised down to the level of the iliac vessels and left open to facilitate decompression of the ureterocele. The expectation was that decompression would simplify bladder surgery that would be carried out when the child was older or possibly eliminate the need for an operation at the bladder level completely. Ureterocele decompression by this technique was found to have the additional benefit that frequently ipsilateral lower pole reflux or obstruction and contralateral reflux or obstruction would subside. The ureterocele generally collapses so completely that it is difficult to subsequently visualize by a VCUG (16,26,32,60). Occasional cases with poor detrusor backing for the ureterocele have been observed to have an improvement in bladder support after decompression.

Husmann and others (78) noted that 30% of children without reflux developed reflux following partial nephrectomy. Half of these children spontaneously resolved their reflux, and the other half (15%) required additional surgery for reflux. Other series have found the overall need for eventual bladder surgery to range from 25% to 50% (26,32,94). Thus it must be acknowledged that while the “simplified” approach of an initial upper pole partial nephrectomy provides very effective decompression, an incidence of subsequent bladder-level surgery is likely to be significant, especially if there has been initial high-grade reflux.

Husmann and colleagues (79) point out a rare complication of the simplified approach. They saw 6% of their patients treated with upper pole partial nephrectomy alone develop a stress pattern of urinary incontinence after toilet training. In these cases, it would appear that the mass of the distended ureterocele distorted the bladder neck sufficiently to cause incompetence after decompression.

Experience with the simplified approach suggests that this approach to the treatment of ectopic ureteroceles with duplex systems permits the majority of children without reflux to avoid a secondary bladder procedure (Fig. 48A.26). Unfortunately, reflux is very common in association with ureteroceles, especially ectopic ureteroceles. As with endoscopic decompression of the ectopic ureterocele, most children with reflux treated by the simplified approach will require a second operation at the bladder level (78,79). The significant need for lower tract reconstruction has led some to suggest that in older children complete reconstruction may be a more definitive and efficacious treatment modality (78). However, many believe this is not necessary because endoscopic puncture for ureterocele decompression and possibly further operations at the bladder level constitute less surgical trauma for the child.

FIGURE 48A.26. Left ectopic ureterocele treated only by upper pole partial nephrectomy. **A:** Preoperative intravenous pyelogram (IVP) shows drooping lily sign, paucity of calyces, and absence of upper pole infundibulum. Ureterocele is just visible in the bladder. **B:** IVP 2 years after surgery shows an excellent left kidney. Voiding cystourethrogram shows no reflux.

Upper Pole Partial Nephrectomy

In the performance of an upper pole partial nephrectomy in a duplex renal unit, several technical points bear mentioning. A relatively short, transverse, flank incision just below the tip of the twelfth rib extending posteriorly to the erector spinal muscles permits complete mobilization of the kidney to facilitate surgery on the upper pole without difficulty in the majority of children. Because the upper pole renal vasculature is often anomalous and variable (21), when the kidney is mobilized, care should be taken to identify the small vessels that frequently course directly into the upper pole. If dissection is kept close to the upper pole, vessels running to this unit can be

identified before their division. This will reduce the chance of damaging the blood supply to the lower pole. The ureter to the upper pole usually runs posterior to the renal vessels, and no attempt is made to dissect out the hilar vessels. Occasionally, an aberrant vessel will be located behind the ureter. After identification and division of the ureter to the upper pole, gentle traction guides dissection of the upper pole parenchyma (Fig. 48A.25A). The upper pole capsule may be stripped back for later use in closure if not too adherent from previous inflammation (Fig. 48A.25B). Complete removal of the upper pole collecting system is the most important aspect of an upper pole partial nephrectomy. We make the parenchymal incision just on the upper pole side of the line of demarcation from the lower renal unit, which is usually evident following the division of the upper pole vessels. The hypoplastic or dysplastic upper pole can then be excised (Fig. 48A.25C and Fig. 48A.25D). Manual compression of the kidney provides adequate vascular control, and blood loss should be minimal.

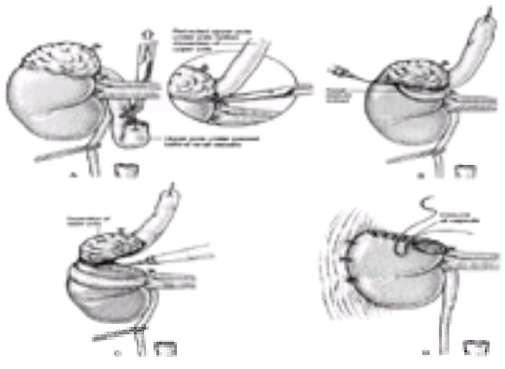

FIGURE 48A.25. A: Division and traction of upper pole ureter guide dissection of the upper pole along the collecting system. **B:** The upper pole capsule is incised and stripped back. **C, D:** Following complete removal of the upper pole collecting system, the capsule is closed.

Next, the distal end of the upper pole ureter should be dissected down to below the level of the iliac vessels, where it begins to assume a common adventitial sheath with the lower pole ureter. The upper pole ureter is usually dilated and tortuous; therefore it may appear to wrap itself around the more normal lower pole ureter. Dissection should be kept immediately on the wall of the upper pole ureter to prevent injury to the lower pole ureter. Patience with this often slightly tedious aspect of the dissection will gradually straighten the upper pole ureter, and the lower pole ureter will be well preserved. After dissection reaches the level of the iliac vessels, which is not difficult through the usual flank incision, the upper pole ureter is opened and the interior of the ureterocele gently irrigated with a feeding tube. If there is no reflux into the ureterocele, the stump of the excised upper pole ureter is left open. Occasionally, when the ureterocele is a large one, a small feeding tube may be left in the lumen of the upper pole ureter extending down into the ureterocele for a couple of days to act as a wick to help ensure that the ureterocele does indeed collapse. If reflux into the ureterocele is present, the upper pole ureter should be ligated. Here, there is an increased likelihood that a subsequent bladder operation to remove the ureterocele and upper pole ureteral stump may be required when the child is older. A small Penrose drain left in the area of the ureteral stump as well as one in the area of the removed upper pole renal parenchyma provides drainage.

Laparoscopic and Other Surgical Techniques for Treatment of Ureteroceles

The advent of the laparoscopic heminephroureterectomy presents another operative alternative that may be useful if partial nephrectomy is thought to be appropriate (72,82). It is our view, however, that with primary endoscopic incision it should be possible to carry out definitive open surgery with one procedure at the bladder level. Poor function of the upper pole does not require that it be removed. In rare cases in which the upper pole function is good and there is no initial vesicoureteral reflux present, a ureteropyelostomy or high ureteroureterostomy may be an alternative (Fig. 48A.24). This approach is less suitable if the lower pole pelvis is intrarenal or the lower pole ureter is nondilated. Today, endoscopic ureterocele puncture is typically the most appropriate primary approach.

Salvage of the upper pole renal unit by a primary bladder-level operation involving excision of the ureterocele and a common sheath reimplant has the disadvantage of requiring the reimplant of an often very dilated ureter into the small bladder of an infant. Amar and colleagues (3) have also suggested ureterocele excision, lower pole ureteral reimplantation, and a low ureteroureterostomy of the upper pole ureter into the lower pole ureter as alternative approaches. However, we propose that endoscopic decompression followed by an open operation at the bladder level with a duplex reimplant is preferable.

ECTOPIC URETER

An *ectopic ureter* is one that opens at the bladder neck or more caudally rather than at its normal location on the corner of the trigone. An ectopic ureter forms when the ureteral bud has an abnormally high origin from the mesonephric duct with delayed or no separation from the duct. There are multiple sites for an ectopic ureter in both males and females. However, in the male, the ectopic ureter is always above the external sphincter, which accounts for the prime clinical difference in presentation between the sexes (see later discussion).

Incidence of Single and Duplex Systems

Our estimation of the incidence of ectopic ureters may be low because not all cause symptoms. In autopsy series, the incidence of ectopic ureters is 1 in 1,900 (28). Occasionally, ectopy occurs in more than one family member (47,125). In 80% of cases, the ectopic ureter is attached to the upper pole of a duplicated renal system. The percentage of ectopic ureters associated with duplication in females is even higher than 80%. In males, an ectopic ureter drains a single system more commonly (86,150). Indeed, ectopic ureter is much more of a female clinical problem in general, with only approximately 15% of ectopic ureters having been reported in men (149). Approximately 10% of ectopic ureters are bilateral (54). When the ectopic ureter is part of a duplex system, the contralateral system is duplicated in approximately 80% of cases, and 21% will have duplication contralaterally with contralateral ectopy as well (114).

The most commonly encountered anomaly associated with an ectopic ureter is hypoplasia or dysplasia of the renal moiety. There is a fairly good correlation between the degree of ectopia and the degree of renal abnormality, although it appears to hold better for duplex systems with ectopy than for single systems with ectopy (147). Severe ectopia with an orifice in the genital system is almost always associated with nonfunctioning renal tissue (143,149). Some series (63) have shown a higher incidence of other associated anomalies, especially imperforate anus, in single-system ectopy.

A single ectopic ureter with a normal contralateral system usually does not result in any deficiency of the bladder neck. However, when two single ureters are ectopic, the bladder and bladder neck fail to form normally and incontinence is a problem (see later discussion). Interestingly, when one single ectopic system is at the bladder neck and one is more distal, an intermediate level of bladder neck abnormality is present. In the series from the Children's Hospital of Philadelphia (147), most of the children in this intermediate group were continent.

Ectopic Ureter in the Female

The fundamental difference between ureteral ectopia in the female and male is that in females, ectopic ureters can terminate at a level distal to the continence mechanisms of the bladder neck and external sphincter and thus may be associated with incontinence (Fig. 48A.27) (89,121). Approximately one-third of ectopic ureters open at the level of the bladder neck (Fig. 48A.28) or slightly more distally in the upper urethra (95). A higher orifice has a lower chance of associated urinary incontinence; however, obstruction is more common in higher ureters because they traverse a greater portion of the musculature of the bladder neck.

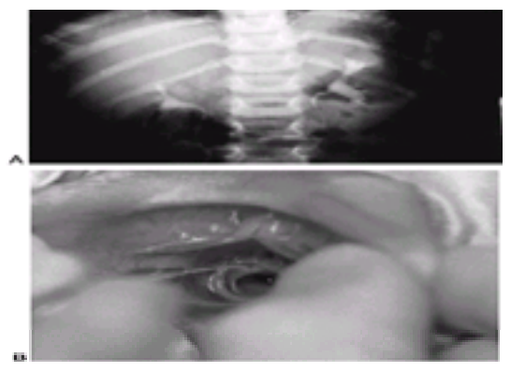

FIGURE 48A.27. Ectopic ureter in vaginal vestibule in female who presented with constant dribbling incontinence as well as normal voiding. **A:** Intravenous pyelogram shows right duplication with minimal upper pole function and down and outward displacement of lower pole (drooping lily sign). **B:** Ureteral catheter in ectopic ureter.

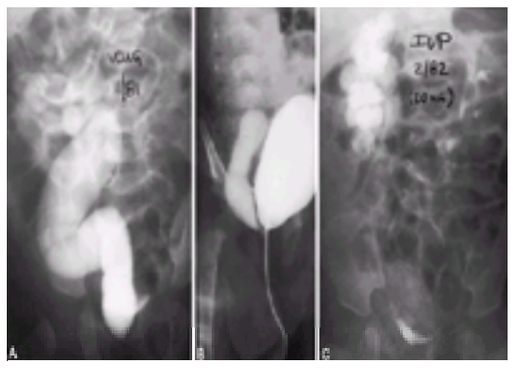

FIGURE 48A.28. Ectopic ureter at bladder neck in girl who presented at 4 months of age with sepsis. **A:** Voiding cystourethrogram showing vesicoureteral reflux into very dilated right ureter. **B:** Oblique view from cystogram showing ectopic ureter entering at bladder neck. **C:** Intravenous pyelogram 3 months following tapered reimplant of right ureter.

These more proximal ectopic ureters drain primarily during voiding when the continence mechanism is open. Vesicoureteral reflex occurs in 75% or more of these higher ectopic ureteral orifices, producing the paradox of both reflux and obstruction. By having the bladder neck repeatedly open, the cyclic VCUG described by Lebowitz and Wyly (190) provides an opportunity for the obstructed ectopic ureter to decompress before contrast is voided and thus increases the likelihood that the contrast will reflux into the ectopic system. When the ectopic ureter enters at the level of the external sphincter or more distally, reflux is less commonly seen.

One-third of ectopic ureters in the female terminate in the area of the vaginal vestibule immediately around the urethral orifice (Fig. 48A.27). This area marks the terminal end of Gartner's duct—the mesonephric duct remnant in the female. Occasionally, infant girls will present with an ectopic ureter entering what appears to be a urethral diverticulum but that is actually a Gartner's duct cyst (180). In approximately 25% of ectopic ureters in females, the orifice opens into the vagina. More rarely, an ectopic ureter can end at a higher site on Gartner's duct with an opening at the level of the cervix or even uterus (less than 5%). These uterine, cervical, and vaginal cases presumably are the result of a rupture of Gartner's duct into the urovaginal canal along their common wall. Ureteral ectopy into the rectum is rare and usually is noted incidentally at autopsy (178). Presumably, it must result from an abnormal division of the cloaca by the descent of the urorectal septum or from an abnormally placed mesonephric (Wolffian) duct that empties into the posterior half of the cloaca.

Historically, approximately half of females with ectopic ureters presented with a classic history of continuous dribbling incontinence despite what appears to be a normal voiding pattern (114,147,149). Today, antenatal detection of hydroureteronephrosis is increasing. If undetected, ectopic ureters in the female may go unrecognized until adulthood (68). If the associated ureter is very dilated, the child may be continent when supine, and the pattern may be one of daytime wetting only. This reservoir effect may lead to an erroneous diagnosis of stress incontinence. Occasionally, it is a persistent, foul-smelling, vaginal discharge that suggests an ectopic ureter. If the ectopic ureter ends in a Gartner's duct cyst, the child may present with a mass on the anterior vaginal wall. When the ectopic orifice is quite high and there is significant obstruction, reflux, or both, urinary infection is frequent and is a common form of presentation for an ectopic ureter in the small child. An infant may present with an abdominal mass resulting from a severely obstructed ectopic ureter (179) (Fig. 48A.29). There are well-documented cases of females with ectopic ureters entering the vestibule or distal urethra without incontinence, presumably due to obstruction of the ureter as it traverses the continence mechanism with emptying only during voiding (130). Flank pain may be the only symptom (48). In this type of case, incontinence has been reported to develop after puberty or childbirth (33,45).

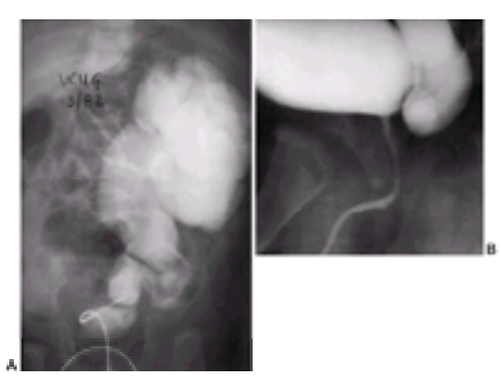

FIGURE 48A.29. Ectopic ureter to bladder neck in male infant who presented with an abdominal mass. **A:** Voiding cystourethrogram shows vesicoureteral reflux into massively dilated left renal unit. **B:** Oblique view shows ectopic ureter to bladder neck. Renal scan revealed the left kidney to constitute only 5% of total renal function. Treatment was by nephroureterectomy.

The diagnosis of an ectopic ureter in the female may be obvious or may be very difficult. Particularly when there is ectopy into the external genitalia, there is likely to be nonvisualization of the associated renal unit (70). Ultrasound can be especially useful for detecting the dilated ectopic ureter behind the bladder (Fig. 48A.30). If there is little hydroureteronephrosis of the ectopic upper pole system, diagnosis may depend on recognizing the absence of an upper pole calyx or an apparent excessive thickness of the renal tissue on the medial aspect of the upper pole. Tomography during urography or a computed tomography (CT) image of the kidney may aid in making this diagnosis (104). Magnetic resonance imaging (MRI) has been used to delineate the fluid-filled ureter and its anatomy (12). Bilateral ectopic ureters occur in approximately 10% of cases, and the radiographic findings may be very subtle, permitting one side to be easily missed (Fig. 48A.31).

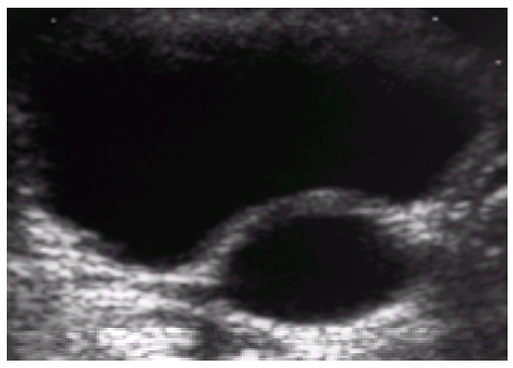

FIGURE 48A.30. Ultrasound demonstrating dilated ectopic ureter behind posterior bladder wall.

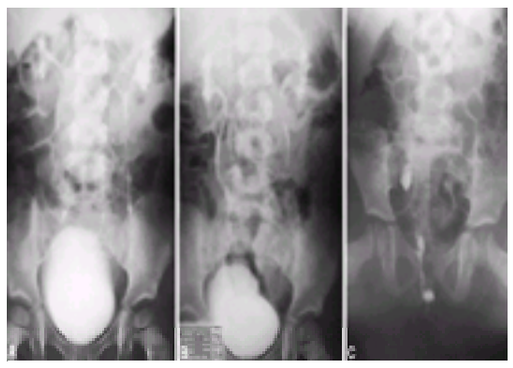

FIGURE 48A.31. Bilateral ectopic ureters in female who presented with constant incontinence as well as normal voiding. **A:** Initial intravenous pyelogram (IVP) shows down-and-outward displacement of left kidney and lateral displacement of ureter, suggesting duplication with ectopic ureter. Right kidney was not believed to be duplicated. Left upper pole partial nephrectomy did not correct incontinence. **B:** Follow-up IVP shows vertical axis to right kidney and mild tortuosity of right ureter, suggesting duplication with second ectopic ureter. **C:** Retrograde ureterogram of vestibular ectopic right ureteral orifice confirms suspicion of bilateral duplication with ectopia by showing upper pole ureter. Child was cured of incontinence by right upper pole partial nephrectomy.

If the ureter is single and beyond the continence mechanism, the associated renal tissue often is nonfunctional and the diagnosis may be made even more difficult by the fact that the associated kidney itself may be ectopic or even crossed and fused (183). Renal function may be inadequate to permit visualization by either intravenous urography or renal scan (152). The finding of a hemitrigone at cystoscopy may lead to the erroneous diagnosis of renal agenesis. Associated genital and anal anomalies occur in about one-third of cases (93) and may mask the presentation of single ectopia. Ultrasound used to detect a dilated ureter behind the bladder may be particularly useful in this situation (117). Vaginograms carried out by occluding the introitus with a Foley balloon may demonstrate reflux into a vaginal ectopic ureter. The ectopic ureter alternatively may be identified at vaginoscopy. Today, MRI will sort out many questions involving pelvic anatomy. However, there are cases in which exploratory surgery is required. Once the ureter is found, it can be traced upward to its associated renal unit.

When the physician is confronted with suspected ectopic ureters, dyes used to stain urine, such as indigo carmine and methylene blue, have a role. Because function of renal tissue associated with ectopic ureters is usually poor, intravenous administration of dye often is not successful in demonstrating an ectopic ureteral orifice. However, in the investigation of an incontinent child, the presence of an ectopic ureter would be strongly suggested if the bladder is filled with indigo carmine or methylene blue–stained saline via a Foley catheter and observation of the perineum reveals a continued slow drip of clear urine. Phenazopyridine hydrochloride (Pyridium) appears to be a better color marker excreted by poorly functioning renal tissue than methylene blue or indigo carmine (183), and thus if a cotton swab is left high in the vagina overnight and it is stained orange, it may suggest the diagnosis of a vaginally ectopic ureter.

Meticulous observation during physical examination of the area around the urethral meatus and distal vagina will many times reveal a recurring drop of liquid over a very small opening that can be probed and then retrogradely injected to confirm the presence of an ectopic ureter (Fig. 48A.32). Vaginoscopy with attention to the superior lateral aspect of the vagina may reveal vaginal ectopia. Sometimes, the orifice is large and obvious; at other times, it is hidden in a vaginal fold. Pressure on the anterior vaginal wall may produce a jet of cloudy fluid or pus from the ectopic orifice, revealing its presence.

FIGURE 48A.32. A: Ureteral ectopia in a male. Possible sites of ectopic ureter are above the external sphincter. **B:** Ureteral ectopia in a female. Ectopic ureter may be located beyond continence mechanism and produce incontinence. (From Johnston JH. Problems in the diagnosis and management of ectopic ureters and ureteroceles. In: Johnston JH, Scholtmejer RJ, eds. *Problems in pediatric urology.* Amsterdam: Excerpta Medica, 1972:57, with permission.)

The choice of surgical treatment of an ectopic ureter in a female depends on the associated renal parenchyma. Single-system ureteral ectopia to the genital system usually has such poor parenchyma that a nephroureterectomy is appropriate, but when single-system ectopia is to the bladder neck or urethra, there is often adequate function to justify a reimplantation of the ureter into the bladder (147). When the ectopic ureter is associated with the upper pole of a duplex renal unit, function of the upper pole is usually inadequate to justify salvage and a partial nephroureterectomy is most often performed. Several studies have demonstrated the incidence of histologic dysplasia in the upper pole ranges from 23% to 43%, which is less common than previously assumed (66,158). With increased perinatal detection of duplicated systems with an ectopic upper pole ureter, it may now be possible to salvage more renal function than before when this anomaly was recognized following a urinary tract infection.

Twelve percent of patients with ectopic ureters managed by upper pole nephrectomy alone will require subsequent distal ureteral stump removal secondary to infections (137). With either duplex or single ectopic ureters, the entire distal ureter associated with ectopia into the introitus or vagina usually need not be removed. The distal ureteral segment is a rare source of later problems in these patients with genital ectopia (42,147). If the distal segment becomes a source of stasis and infection, marsupialization of the ureter, usually a Gartner's duct cyst, into the vagina will correct the problem. More recently, the use of laparoscopic heminephroureterectomy for duplication anomalies has been reported to decrease postoperative discomfort and shorten hospital stay (72,191).

If, instead of ending genitally in the vagina or introitus, there is a urinary ectopic ureter ending in the bladder neck or urethra, reflux of voided urine into the residual ureteral stump is more likely to occur and require ureteral stump removal. This may present as a small amount of dribbling incontinence after micturition but more

commonly presents with recurrent urinary infection. In a series of 23 ectopic ureters managed by upper pole nephrectomy, subsequent stump removal was required due to infections in all patients with reflux into the ectopic upper pole ureter and in 40% of those with reflux into the lower pole ureter (137). This stresses the importance of a preoperative cyclic voiding VCUG in any patient with an ectopic ureter to assess the need for distal ureterectomy.

Although the dissection behind the bladder can be tedious when removing the distal portion of an ectopic ureter, if dissection is kept immediately on the wall of the ureter, there is no reason for the bladder neck or external sphincter to be damaged. The transtrigonal approach can be very useful. In a postpubertal girl, excision may be accomplished transvaginally. If the ectopic ureteral stump is not too large, its lining can be destroyed endoscopically using a Bugbee electrode, leading to obliteration of the ureteral lumen.

When enough function is present to merit salvage of the upper pole, a ureteropyelostomy or ureteroureterostomy to drain an upper pole ectopic system into the lower pole system at the renal level may be appropriate, although this is less feasible if the lower pole pelvis is intrarenal. An alternative technique for treatment of an ectopic upper pole ureter consists of ureteroureterostomy performed near the bladder level. This technique has been used to treat obstruction of the upper pole ureter as well as reflux (19,77,110). The ureter–ureter anastomosis is performed 3 to 5 cm above the bladder proximal to the common sheath. The distal upper pole ureteral stump is ligated or excised if it ends in the bladder neck or urethra. The concern about creation of iatrogenic “yo-yo” reflux appears more theoretical than real with no reports of this as a complication. This approach has the advantage of avoiding an open bladder operation. The ectopic ureter can also be primarily reimplanted into the bladder, although it may be sufficiently dilated to warrant tailoring. Rarely, a temporizing low end ureterostomy for decompression (especially in an infant) may permit a more simple later reimplant and additionally permits in a marginally functional unit time to see if recovery of function will justify a further reconstructive approach.

Ectopic Ureter in the Male

The ectopic pathway in the male extends from the bladder neck down the posterior urethra to the verumontanum and can lead to ureters ending in the mesonephric duct derivatives: epididymis, seminal vesicle, and vas deferens (Fig. 48A.32). The most common location of an ectopic ureteral orifice in the male is the posterior urethra, where approximately half of ectopic ureters will be found (Fig. 48A.33) (54). In approximately one-third of male patients, the ectopic ureter joins the seminal vesicle (67,153). Other ectopic sites are seen more rarely. Jona and colleagues (90) have described a case of single ureteral ectopia to the epididymis. Ectopic ureters to the male genital tract may present as epididymitis. Accordingly, any prepubertal boy with epididymitis requires evaluation for an ectopic ureter (156). A urine culture should always be performed. A bacterial urinary tract infection (UTI) and epididymitis is very likely to demonstrate pathology on VCUG and ultrasound. In some males, symptoms caused by a genitally ectopic ureter do not present until the onset of sexual activity. At that time, the male may present with epididymitis, prostatitis, seminal vesiculitis, or occasionally, an infected seminal vesicle cyst that may lead to pain with a bowel movement or be tender on rectal examination (17). Because ectopic ureters in the male enter above the external sphincter, they generally do not produce incontinence as they do in the female. Symptoms of flank pain and urinary infection are more common. Occasionally, there may be urgency or frequency due to the constant drip of urine into the posterior urethra. An occasional case of male incontinence may be caused by reflux of urine into a dilated ectopic ureter with drainage after voiding into the posterior urethra and subsequent leakage out through a relaxed external sphincter (188). A dilated single-system ectopic ureter into the prostatic urethra may elevate the bladder neck, causing outlet obstruction (118).

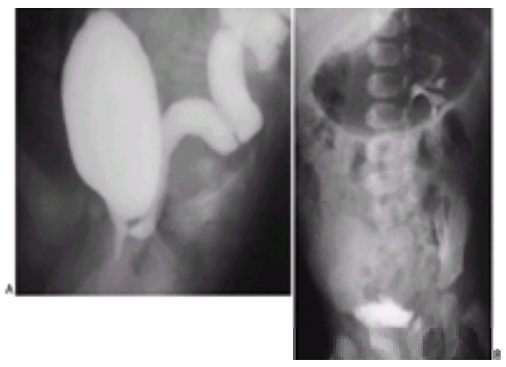

FIGURE 48A.33. Ectopic ureter to posterior urethra in a male who presented as an infant with sepsis. **A:** Voiding cystourethrogram shows vesicoureteral reflux into single ectopic ureter entering posterior urethra from solitary left kidney. **B:** Intravenous pyelogram after reimplantation of ectopic ureter into the bladder.

A high index of suspicion may be required to diagnose an ectopic ureter in the male. An ectopic ureter entering the genital tract is often single and drains a nonfunctioning renal unit (31,143,183). Ultrasound may show a dilated ureter and its associated renal element. In the case of an ectopic ureter associated with a duplex renal unit, the indirect signs of hydroureteronephrosis of the upper pole unit, described previously, with respect to ureteroceles again apply. The greatest diagnostic difficulties arise in duplex renal units when there is a tiny upper pole unit draining into a minimally obstructed ectopic ureter with little dilation (13).

Most ureters ectopic to the urethra or bladder neck will reflux (147), and thus careful examination of the oblique views from a VCUG and use of the cyclic voiding technique may enable the diagnosis to be made. In the male, as in the female, ectopic ureters at the level of the sphincters may demonstrate the paradoxical finding of both obstruction and reflux. Occasionally, when the ectopic ureter is outside the urethra, the ejaculatory duct will be so dilated as to permit reflux (188). MRI may be useful for diagnosing and demonstrating the ectopic ureteral anatomy (119). The advent of fast-scan MRI technology should improve the utility of this diagnostic study in the pediatric population.

Cystoscopy and examination with the patient under anesthesia are useful in establishing the diagnosis. A mass in the area of the seminal vesicle or an elevation of the bladder floor over a cyst (pseudoureterocele) may be noted during cystoscopy. The ectopic ureteral orifice may be seen at the bladder neck or urethra, or there may be an enlarged ejaculatory duct, permitting a retrograde study that will establish the diagnosis. When there is single ureteral ectopia, a hemitrigone is present. Occasionally, a vasogram is useful in defining the anatomy (150).

Treatment of ectopic ureters associated with duplex units in the male usually involves removal of the associated poorly functioning renal unit. When function is adequate, a ureteropyelostomy or ureteroureterostomy as previously discussed may be performed. Because the ectopic ureter is usually dilated, a reimplantation of the duplex ectopic ureter into the bladder is a less attractive alternative. These issues come up only rarely in the male because most duplex ectopic ureters occur in females.

In the treatment of single ureteral ectopy in the male, a functioning renal unit worthy of salvage is more likely to be present if the ectopia is to the urinary tract, namely, the bladder neck or urethra (147). When an ectopic ureter enters the male genital duct, it may be unfit for the passage of sperm, and ligation of the vas may be required to avoid recurrent epididymitis.

Bilateral Single Ectopic Ureters

Bilateral single ectopic ureters are rare (40,128,146,187). When bilateral single ectopic ureters are present at the level of the urethra or more distally, there is usually a poorly developed bladder with an absent trigone and poorly developed bladder neck. Rarely, there is associated bladder agenesis (65). Associated genital and anal anomalies are common with bilateral single ectopic ureters (93).

Females most commonly are found to have bilateral single ectopic ureters located in the distal urethra. Infant girls usually present with urinary infection and are noted, incidentally, to have constantly wet diapers. Older girls most commonly present with incontinence. Women in general have worse bladder function and more severe renal anomalies than men with bilateral single ectopic ureters (40,187). Although enough urine may enter the bladder in the male to permit some voiding to take place, males may also present with incontinence. Because some urine enters the bladder in the male, it is often slightly larger than the bladder seen in females.

This description represents the cases at the worst end of the spectrum of bilateral single ectopic ureters when bothureters are very distal from their normal point of entry into the bladder. When bilateral single ectopic ureters are present at the bladder neck level, the children may present with infection and upper urinary tract

dilation from obstruction, reflux, or both, but the bladder neck is generally better formed and continence more likely. When one ureter is ectopic to the urethra and one is ectopic at the bladder neck, there is an intermediate condition, but here incontinence is usually present (147).

A carefully executed IVP or ultrasound and VCUG usually establishes the diagnosis (138,190). The associated renal units may show very poor function. The VCUG shows a small bladder with an open bladder neck. If the ectopic ureters are in the urethra, reflux is commonly present, and the VCUG usually makes the diagnosis. If the ureters are further down the ectopic pathway than the urethra, they usually are not demonstrated by VCUG. Again, an ultrasound examination may be useful. Saline into the vagina may enable reflux into a vaginally ectopic ureter to be recognized by the presence of refluxed air bubbles into the ureter, which can be picked up by ultrasound. A retrograde flush vaginogram with a Foley balloon occluding the introitus may similarly detect refluxing, vaginally ectopic ureters. During cystoscopy, a child with bilateral single ectopic ureters usually has a poorly defined, funnel-shaped bladder neck and a small bladder capacity. In the male, the ureteral orifices are usually located in the distal bladder neck or urethra, but in the female, they may be more ectopic and thus more difficult to locate.

A child who is incontinent with bilateral single ectopic ureters presents a major challenge to reconstructive surgery. In the rare case in which bladder capacity appears to be adequate, reimplantation of the ureters into the bladder and a Young-Dees-Leadbetter type of reconstruction of the bladder outlet may be appropriate (103). If bladder capacity is inadequate, a primary continent reconstruction with bladder augmentation by bowel is wise. If the ureters are dilated, implantation into the bowel in an antirefluxing fashion is less likely to succeed. Thus the use of an ileocecal augmentation anastomosing the dilated ureters to the ileum and creating a nonrefluxing ileocecal valve (74) or use of the serosal-lined ureter to bowel anastomosis (Mainz) (1) may succeed in producing a nonrefluxing reservoir. The difficulty of creating a continent bladder outlet in this patient population often leads to eventual bladder neck closure and appendicovesicostomy to achieve continence (83).

Chapter References

The therapeutic approach to the widely dilated ureter varies regarding etiology and the pathologic significance associated with such dilation. The wide ureter lacks effective peristalsis owing to the inability of the ureteral walls to coapt, and thus it fails to properly propel a bolus of urine. This leads to urinary stasis and potential infection, predisposes to urinary calculi, and in the extreme, results in renal parenchymal destruction. However, not all wide ureters carry this poor prognosis, and in some cases, renal growth and development can proceed normally even in the presence of ureteral dilation. Because successful surgical therapy of the wide ureter is currently possible, it becomes important to identify patients with a dilated ureter who would benefit from such therapy. It also is equally important to identify those renal and ureteral units that will not benefit from surgery and can be safely observed. In this latter instance, surgical therapy can only serve as a source for potential complications and possible detriment without offering a significant change for benefit.

Much confusion has arisen as the debate regarding nomenclature for the wide ureter has continued. Caulk (8) first used the term *megaloureter.* His original term has been shortened to simply *megaureter,* but the term itself has come to mean different things to different observers. At its simplest, it means only “big ureter.” To achieve a more informed approach to the management of the widely dilated ureter, it is essential to clarify the terms used to describe such a ureter. Precise classification allows treatment based on etiology, thus permitting effective communication of the outcome of that treatment with colleagues. The term *megaureter* should not bring to mind a specific disease process nor imply an etiology, but rather it should be used as a general term for the wide ureter. Descriptive and modifying terms can then be applied as a classification scheme is adopted.

The precise definition of what constitutes an abnormally wide ureter can be elusive. The diagnosis of megaureter inevitably is established based on some form of radiographic demonstration. Technically, any ureter whose width exceeds that of the upper limits of normal for any particular age group can be designated a megaureter. Cussen (9) has established normal ureteral measurements in children from 30 weeks' gestational age to 12 years of age. Using this scheme, any ureter greater than 7 mm in diameter technically is a megaureter. However, practically speaking, there is little need to try to define megaureter in absolute diameter measurements. The radiographic appearance is usually striking, demonstrating more than just minimal ureterectasis. Marked ureteral dilation is the usual case. Ureteral tortuosity also may be present. Pelvocalyceal dilation is variable depending on the severity of the underlying disease process. Renal parenchymal scarring or loss may be present because of back-pressure atrophy or secondary to infection or calculi.

CLASSIFICATION

Several schemes for classifying the megaureter have been proposed (7,15,65). The most pressing practical matter has been to define the obstructive from the nonobstructive forms of megaureter, given that obstructive forms need surgical correction as early as possible. Most observers easily accepted the difference between the obstructed and the refluxing megaureter, but it became less clear how to classify or categorize the so-called nonobstructive, nonrefluxing megaureter. Inherent in any discussion of the classification of megaureter is that one must accept that a wide ureter can exist without significant reflux or obstruction being present. Considerable confusion developed as this problem of classifying the megaureter was examined, and there was initial failure to accept a uniform terminology. As the understanding and experience with megaureters grew, it became possible for a more uniform terminology to be proposed and accepted.

In 1976, an international pediatric urologic seminar was held in Philadelphia. This was a combined meeting of the members of the Urological Section of the American Academy of Pediatrics, the Society for Paediatric Urological Surgeons, and the Society for Pediatric Urology. A committee was formed to develop a standard nomenclature and classification of wide ureters. This was accomplished and has been the classification scheme most widely adopted and used up to the present (56). Although many observers disagree regarding specific clinical instances for inclusion in this scheme, it offers the opportunity for all patients with wide ureters to be classified within the system. Many less complex systems are appealing but lack the ability to classify all patients clearly. It appears that some degree of complexity will have to be accepted to ensure completeness with any classification system.

The three major categories of classification in the aforementioned scheme are (a) the refluxing megaureter; (b) the obstructed megaureter; and as noted earlier, (c) the nonrefluxing, nonobstructed megaureter (Table 48B.1). Each major category can be further divided into primary and secondary subcategories. A few pitfalls already have been pointed out. It is possible to have a wide ureter that shows both reflux and obstruction (29). This represents a special situation and should be kept in mind and specifically sought when evaluating the refluxing megaureter. Iatrogenic megaureter, the residual ureterectasis following urethral valve ablation, the prune-belly ureter, and other instances have been offered as examples for which classification is difficult or incomplete. It seems that with appropriate testing, most dilated ureters usually could be properly classified. One also would have to accept that it would be possible for the classification of the ureters to change depending on the results of therapeutic intervention. An example would be the secondary obstructive megaureter caused by urethral valves that improves following valve ablation and remains as a nonobstructive, nonrefluxing megaureter. Another instance could be the residual nonobstructive ureterectasis seen after successful ureteral reimplantation. Many patients may be properly classified only following serial evaluation or long-term observation. One should also remember that the testing procedures used to evaluate the wide ureter are prone to certain inaccuracies and may have to be repeated before proper classification can be achieved. Although imperfect, the international classification scheme seems to be the most comprehensive and widely accepted at present. This scheme is used in the discussion of the wide ureter in this chapter.

Refluxing Megaureter	Obstructed Megaureter	Nonrefluxing, Nonobstructed Megaureter
Primary (congenital reflux)	Primary (e.g., aberrant vessel, urethral valves)	Primary (idiopathic)
Secondary (e.g., urethral valves, neurogenic bladder)	Secondary (e.g., tumor, urethral valves, neurogenic bladder)	Secondary (diabetes insipidus, infection, residual dilation from surgery)

*Major categories within the international classification scheme for megaureter. Select examples are in parentheses. Note some conditions may appear in more than one category.

TABLE 48B.1. CLASSIFICATION OF MEGAURETER[a]

DIAGNOSTIC METHODS

General

All urologists are familiar with the fact that a ureter can appear normal on one testing circumstance and not on another. These differences can be accentuated further by different testing conditions; that is, the state of hydration, fluid load, or presence of urinary infection. The working party to establish the international classification agreed that any method that would demonstrate an abnormally wide ureter was sufficient to define the condition of megaureter. As mentioned previously, no definite measurement is used as an absolute point of definition for the diagnosis of megaureter because from a practical standpoint the diagnosis is usually quite clear radiographically.

The basic investigative procedure used by pediatric urologists today is the renal ultrasound to evaluate the upper tracts and the voiding cystourethrogram. If reflux is ruled out on the voiding cystourethrogram, the next two tests that can be used are the standard excretory urogram and/or the nuclear renal scan. The nuclear renal scan can define the severity of obstruction and the degree of renal function and is particularly helpful in the infant or young child, where concentrating ability for the contrast media is not yet mature. The excretory urogram is especially useful to identify anatomic features of obstruction, particularly to localize that obstruction if fluoroscopy is used during the excretory urogram. Using the aforementioned tests in their proper sequence usually will be sufficient to identify the majority of causes of megaureter, both primary and secondary.

Endoscopic techniques generally are used only as secondary procedures; more informative studies, which are discussed further in the text, are relied on initially. Cystoscopy can be appropriate in the initial management of the entities, such as posterior urethral valves, urethral stricture, or the evaluation of primary reflux, or may be best deferred until the time of any planned definitive surgical procedure. In the past, retrograde ureteral catheterization noting any “hydronephrotic drip” has been used to help confirm a diagnosis or to add information in equivocal cases. This is now primarily of historic interest only. Retrograde pyelography with drainage films also can be beneficial, particularly if drainage is delayed for a substantial time. Drainage films following administration of a diuretic also can add useful information.

Once reflux has been excluded, the diagnostic dilemmas arise when it is unclear whether the wide ureter is truly obstructed or represents a nonrefluxing, nonobstructive megaureter. Two procedures are now widely used to help establish further information regarding the presence or absence of obstruction. These are the diuretic renogram and the pressure perfusion study as advocated by Whitaker (4,34,48,49,64). Each test has advantages, disadvantages, and sources of error. In most settings, they can be considered complementary rather than competitive.

Diuretic Renogram

The diuretic renogram or furosemide-assisted nuclear renal scan attempts to quantitate or measure the ability of a system to empty following a diuretic challenge. It should be performed in a consistent fashion with standard tracer and diuretic doses and with the patient well hydrated. The most widely used radiopharmaceuticals are technetium 99m diethylenetriamine pentaacetic acid (^{99m}Tc DTPA) and technetium-99m mercaptoacetyl triglycine (MAG3). Early images are recorded and interpreted as the angiographic phase of the study, with renal blood flow being estimated. During the first 3 to 4 minutes after injection, images are taken that reflect renal perfusion and can be used to calculate relative renal function. Over the next several minutes, images are made and data are gathered to generate a renogram curve. When the collecting system is well filled with isotope, images are then taken after intravenous (IV) administration of 1 mg/kg of furosemide (Lasix). When evaluating the megaureter, the clinician must remember that areas of interest should include both the kidney and the lower ureter (32). In general, half-time clearance after furosemide should be accomplished in less than 15 minutes. If clearance is greater than 20 minutes, obstruction is likely. Clearance between 15 and 20 minutes is thought by many to represent equivocal test results.

Four types of renogram curves generally are recognized (Fig. 48B.1). The normal pattern shows spontaneous washout of the tracer without the need for furosemide. The dilated, nonobstructive pattern shows progressive accumulation of the radionuclide before furosemide administration, but prompt washout after its administration. The obstructed pattern shows no washout or progressive accumulation within the ureter and upper collecting system following administration of furosemide. In the equivocal pattern, there is some degree of washout following furosemide, but the rate of clearance is much slower than that in the nonobstructive system. Simultaneous imaging of the bladder and the ureter can be particularly helpful to define the point of obstruction if an abnormality at the ureterovesical junction is suspected (Fig. 48B.2).

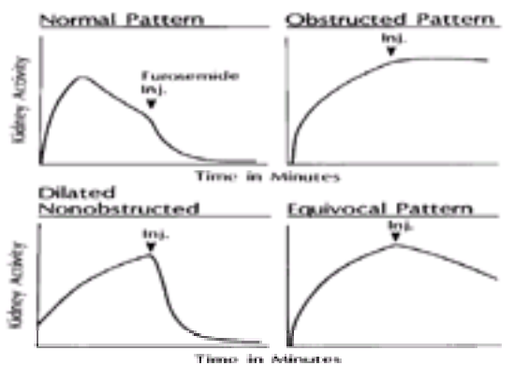

FIGURE 48B.1. Four major types of renogram curves generated during diuretic renography. Obstruction may be evidenced as a flat or even increased curve following furosemide injection.

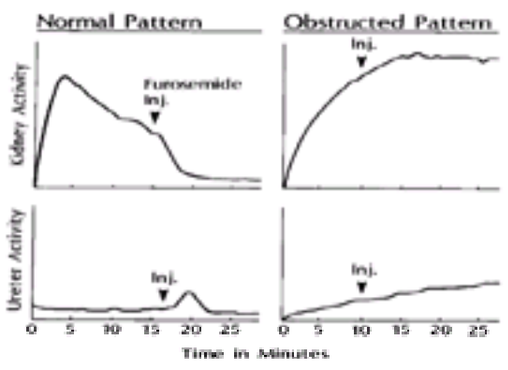

FIGURE 48B.2. Localization of the area of obstruction during diuretic renography by simultaneous renal and ureteral scanning. Note increased radioactivity in the ureteral region following furosemide injection when obstructed ureter is present.

Several factors affect the accuracy of this test. The doses of both tracer and furosemide should be standard so that adequate comparison of test results can be made. Adequate hydration is essential to ensure clearance of the tracer, and if the patient is not well hydrated, this can serve as a source of error for interpretation of the test. IV fluid administration can be helpful and is advocated by many as a routine part of the test to ensure adequate hydration. IV fluids are essential when evaluating

equivocal cases of obstructed megaureter. The degree of bladder filling influences the test; during the procedure, voiding should be initiated or catheterization performed to ensure evaluation with both an empty and a full bladder. This is especially important when evaluating specific conditions involving obstruction at the ureterovesical junction or determining whether a hypotonic, high-pressure bladder may be responsible for some degree of ureteral dilation. Poor renal function also can be an important source of error. The poorly functioning kidney may not generate enough of a diuresis to stimulate washout. By the same token, even a kidney with good function may not be able to diurese or empty an extremely capacious system if hydronephrosis is extreme (reservoir effect). In this situation, washout may be slow even if true anatomic obstruction is absent.

As we see increasing numbers of children with diagnosed prenatal hydronephrosis, it is especially important to remember that renal function immaturity in the newborn can significantly alter the results of the diuretic renogram. Low levels of glomerular function lead to slow diuretic responsiveness, and when the degree extends to the ureterovesical junction, it can make the timing of the diuretic and interpretation of the test difficult. When possible, it is best to obtain a diuretic renogram at 3 to 4 months of age, allowing time for renal maturity to occur and to avoid the possibility of a false-positive renal scan (31). This is especially important in the infant with either mild to moderate obstruction or an equivocal initial result as a newborn. The extraction factor component of the DTPA renal scan has been advocated as a means of measuring clinically significant obstruction (22). Although this appears to be a reliable test, broader experience is required to determine its usefulness in this setting.

The diuretic renogram has several advantages. It provides information for renal function measurement, is minimally invasive, can be performed with standard equipment, does not require anesthesia, and perhaps of greatest significance, can be easily used serially. The last advantage can be particularly useful in evaluation of the equivocally dilated-obstructed system or in the postoperative patient.

Pressure Perfusion Studies

The pressure perfusion study is an attempt to define obstruction in terms of pressures generated when subjecting the system to a set flow rate. By definition, in an unobstructed setting, a low pressure is maintained even when upper limits of normal flow are encountered. Thus a volume of fluid can move through the system without difficulty and without the requirements of high pressure. However, with obstruction, a high pressure is generated with the same flow rate when an attempt is made to move the same volume of fluid through the system. It is the high pressure required to move a volume of fluid through the system that is thought to produce renal damage. The pressure perfusion test was made popular by Whitaker (64) and is accepted as an accurate method of determining upper urinary tract obstruction. However, instances in which the results of the pressure perfusion study are difficult to interpret with certainty still remain.

The pressure perfusion study usually requires anesthesia in younger children, but it is possible with sedation and local anesthesia in the older, more cooperative child. It should be performed where the test can be monitored radiographically. The system is represented diagrammatically in Fig. 48B.3. Access to the upper urinary tract is established by a percutaneous nephrostomy. An appropriate-sized urethral catheter is placed in the bladder. The system is then connected through a length of manometer tubing and incorporates a pressure transducer and recording apparatus. A series of stopcocks allows measurement of renal pelvic and intermittent bladder pressure at different phases of filling of the urinary system. A dilute contrast agent is added to the fluid used to fill the system. This allows images to be taken during perfusion to ensure a completely filled system. A perfusion pump is used to establish a standard fast flow of 10 mL per minute, which is considered the upper limit of the physiologic range.

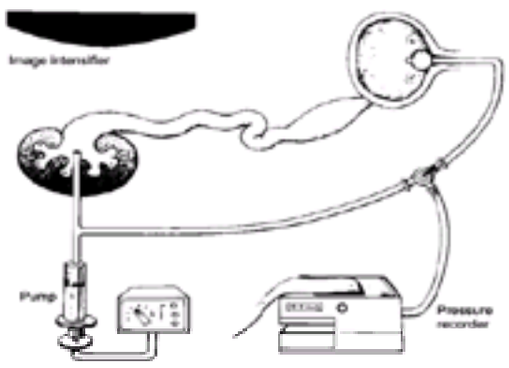

FIGURE 48B.3. Diagrammatic representation of pressure perfusion study.

Before perfusion of the system, a baseline pressure is established as that measured at the kidney level. The bladder pressure is then checked against a baseline and is usually somewhere between 3 and 5 cm H_2O pressure. Once perfusion of the urinary tract begins, spot radiographs are taken to afford anatomic information at various filling pressures; alternate renal and bladder pressures are recorded. When adequate measurements and radiographs have been obtained, the nephrostomy cannula can be removed or left, depending on the patient's therapeutic needs. To provide accurate calculation of the test results, the pressure generated when perfusing the cannula alone outside the body is measured and is subtracted from other readings. In essence, one obtains renal pelvic pressure as a relative value. This relative renal pelvic pressure is the recorded pressure minus the cannula resistance and minus the bladder pressure. A variation of the antegrade perfusion test is to fix the pressure in the renal pelvis and monitor the resulting flow into the bladder (fixed pressure perfusion). This ensures equilibrium and reduces artifact of rapid flows. In the unobstructed state, flow into the bladder is achieved at pressures below 7 cm H_2O.

A relative renal pelvic pressure less than 12 cm H_2O at a flow of 10 mL per minute is thought to be normal when assessing a point of potential obstruction, such as the ureterovesical junction. A pressure differential of 13 to 20 cm H_2O is thought to be equivocal and a greater-than-20-cm H_2O pressure difference is thought to represent true obstruction. The test usually is considered most helpful in instances in which impaired renal function and a large volume collecting system are present and the diuretic renogram is equivocal. When normal, the test is considered reliable. When equivocal or marginally elevated measurements are obtained, the results have to be interpreted with care.

Patients who are difficult to evaluate by this method are the same ones who are problematic by other methods. These include patients with noncompliant bladders, such as those with posterior urethral valves or refluxing ureters with residual ureterectasis following surgical correction. Such children may have normal relative renal pelvic pressures with the bladder empty but exhibit marked rises in pressure as the bladder fills. In these cases, the ureterovesical junction, by strict definition, is unobstructed; however, increasing bladder pressure with bladder filling results in a functional obstruction. The result is the same as localized obstruction, but the treatment is different and aimed at decreasing bladder pressures and increasing compliance as with augmentation cystoplasty. Occasionally, obstruction with filling also will be noted with little increase in bladder pressure. This can occur after reimplantation surgery with angulation of the ureter as it enters the bladder wall. Large-capacity systems also may have relatively low pressures even if obstruction exists. One must be certain that the urinary system to be tested is completely filled and at equilibrium (i.e., flow in equals flow out) to ensure accurate measurements. In addition, spot radiographs can ensure that no extravasation or leakage of fluid from the system has occurred, which could alter the accuracy of the results.

The main disadvantages of the pressure perfusion study are its invasive nature, the requirement for anesthesia in younger children, and that it is not easily applied in a serial fashion. It also gives no renal function information. As also noted previously, the results at times are difficult to interpret. It has been noted experimentally that renal pelvic pressures do not always accurately reflect obstruction (33). The determinants of the progression of hydronephrosis and possible renal damage include the rate of urine formation and the degree of duration of obstruction but, also importantly, must take into account the compliance of the pelvocalyceal and ureteral systems. A large-capacity collecting system can indeed tolerate larger volumes at lower pressures and thus give a certain measure of protection to an obstructed ureteral and renal unit once equilibration of urine formation and renal pelvic pressure has been reached. Thus low pressures can be measured within a compensated system even though obstruction does exist. In these instances, pressure perfusion measurements may not be able to predict whether hydronephrotic progression can or will occur.

Despite the drawbacks and inaccuracies mentioned, the pressure perfusion study still is considered to be a very sophisticated method of demonstrating obstruction and should be viewed as complementary to other methods, specifically the diuretic renogram. The test can be applied intraoperatively, although this seems to be applicable only in very selected instances to confirm a diagnosis or to check the immediate surgical result.

Comparisons of the diuretic renogram and Whitaker's pressure perfusion test have been made. Kass and associates (27) evaluated and compared the results of these two studies and found an excellent correlation. In their series of 42 kidneys, the majority could clearly be defined as obstructed or unobstructed by either study. False-positive and false-negative instances were encountered in both studies, although in less than 10% of the cases. Equivocal or indeterminate results also were obtained using both testing procedures, but again in less than 10%. It was through the complementary use of these tests and correlation with clinical, radiographic, and surgical findings that the final result could be established in these equivocal cases. Others have attempted to correlate the diuretic renogram and the pressure perfusion studies, with all investigators eventually concluding that there are certain limitations and technical considerations for each method (17). Both methods seem to have their advantages, disadvantages, and sources of error. These must be kept in mind as test results are interpreted and surgical decisions are made.

Most agree, following the standard renal ultrasound or excretory urogram, to proceed with the diuretic renogram in evaluating possible obstruction. Its noninvasive nature and ready availability make it attractive. If the diuretic renogram shows prompt washout, obstruction is unlikely. Particularly in the face of good renal function, hydronephrosis and delayed washout on renal scan argue strongly for surgical approach to an obstruction without the need for further studies. However, if the results of the study are equivocal, if renal function is poor, or if an error is suspected because of a capacious collecting system, then pressure perfusion studies can be considered. If the diagnosis of obstruction is still uncertain, repeat studies might have a role in the clinically stable young patient. There will still be the occasional case in which test results may remain indeterminate. Management should be based on clinical judgment, with the final diagnosis sometimes being made only at the time of surgery.

REFLUXING MEGAURETER

Primary

As shown in the earlier classification scheme, the refluxing megaureter may be divided into two basic categories: the primary and the secondary groups. *Primary reflux* refers to the circumstance in which only a ureterovesical junction malformation exists. Ureteral tunnel length is inadequate and free reflux is demonstrated on a voiding cystourethrogram (Fig. 48B.4). Primary refluxing megaureters are more likely to be bilateral as opposed to the unilateral occurrence in the primary obstructed megaureter. Patients with refluxing megaureters most often present with signs and symptoms associated with urinary tract infection. Some will present with renal failure and azotemia, and a significant number of patients will be neonates and infants. Refluxing megaureters seem to be encountered more often in boys than in girls. In addition to the classic symptoms of infection, presentation in older children also can involve findings associated with hypertension. Whereas most patients present in the classic symptomatic manner, some have been found to have refluxing megaureters without obvious clinical signs or symptoms. This usually has occurred as an incidental finding during other medical investigations, in prenatal screening, or in conjunction with screening for familial reflux (45,46).

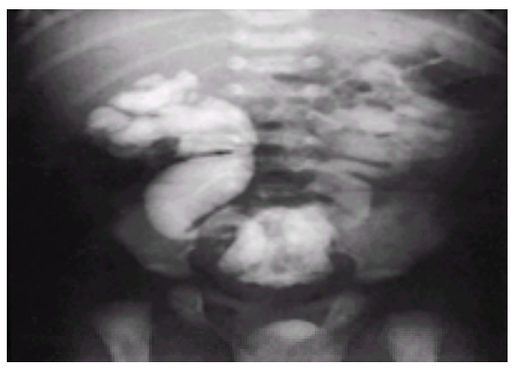

FIGURE 48B.4. Primary refluxing megaureter in a neonate presenting with urosepsis.

In many cases, the amount of renal parenchyma associated with the refluxing megaureter is reduced or renal scarring already is present at the time of discovery. Renal histology may show changes similar to those observed with obstruction, or it may demonstrate a degree of dysplasia. Secondary ureteropelvic junction obstruction can occur with severe reflux and a tortuous ureter (Fig. 48B.5). A nuclear renal scan is sometimes helpful to diagnose concomitant obstruction, which requires surgical repair with pyeloplasty. If the dilation proves simply to be nonobstructive and secondary to the reflux alone, it will usually correct with resolution of the reflux.

FIGURE 48B.5. Secondary ureteropelvic junction obstruction associated with reflux.

Management of the primary refluxing megaureter depends on several factors. Some children may be safely observed while on antimicrobial prophylaxis in hopes of spontaneous cessation. Realistically, however, with the more severe degrees of reflux (grades III to V), spontaneous cessation is less likely, particularly after the first year of life, and surgical management may be required. This is particularly true in children with associated abnormalities such as paraureteral diverticulum or gaping ureteral orifices.

Surgical management of the refluxing megaureter usually involves primary reconstruction. In the past, ureteral reimplantation was prone to a high level of complication and, for this reason, primary ureterostomy or permanent diversion was advocated. The latter is now thought to be inappropriate in most cases. Temporary diversion by cutaneous vesicostomy has proved useful in select situations because of its ready reversibility and ease of performance (3,12). This may be especially true in a sick neonate or in an infant with multiple congenital anomalies in whom definitive surgical correction is best delayed. Although it is possible for surgical correction and a reasonable success rate to be achieved even in neonates with high-grade reflux, experience has shown it is probably best to delay correction until the child is older. The bladders of neonates and young infants can present a hostile environment with high storage pressures and increase the likelihood of failure. Immediate or early surgery should be reserved for those children in whom breakthrough infections or deterioration of renal function is noted.

Older children with refluxing megaureters may present with severe renal compromise with or without hypertension. Ureteral reimplantation in these instances seems to offer little to improve renal function. However, surgery can be successful in controlling infection (by reducing postvoid residuals) and flank pain. Some have advocated this as a desirable alternative to later performance of pretransplant nephroureterectomy.

The unilateral refluxing megaureter can be associated with a degree of dysplasia or varying degrees of alteration of renal function, even to the point of nonfunction. A renal scan performed with an indwelling urethral catheter can determine the function in the kidney of a unilateral refluxing megaureter. If function is poor (less than 10%) and the contralateral kidney function is satisfactory, nephroureterectomy may be the therapy of choice in preference to ureteral tapering and reimplant.

Secondary

Secondary refluxing megaureters result from a functional or anatomic abnormality involving the bladder or urethra. The most common causes relate to neurogenic bladder dysfunction associated with myelodysplasia and outlet obstruction (and/or bladder dysfunction) associated with posterior urethral valves (Fig. 48B.6 and Fig. 48B.7). Other less common conditions resulting in secondary reflux include ureteroceles, urethral stricture, cyclophosphamide and radiation cystitis, and the "nonneurogenic neurogenic bladder." The approach to the secondary refluxing megaureter is more complex and initiated with treatment of the primary etiologic factors. For example, in the case of urethral valves, 50% of patients will have high-grade reflux at initial diagnosis (usually in the newborn period); more than one-third of these refluxes will spontaneously resolve following successful valve ablation, without the need for reimplantation surgery. Furthermore, persistent unilateral reflux following valve ablation, in many cases, is associated with a nonfunctioning kidney [vesicoureteral reflux dysplasia (VURD) syndrome]. The dilated ureter to a nonfunctioning renal unit can be used to augment a noncompliant bladder and potentially facilitate a complex reconstruction (43). In the patient with a secondary reflux megaureter, the character of the dilated megaureter may be highly variable—ranging from elastic with peristaltic activity to severely scarred with no elasticity or peristalsis and poor potential for reconstruction. Scarring is most common in the older patient with a history of urinary infections.

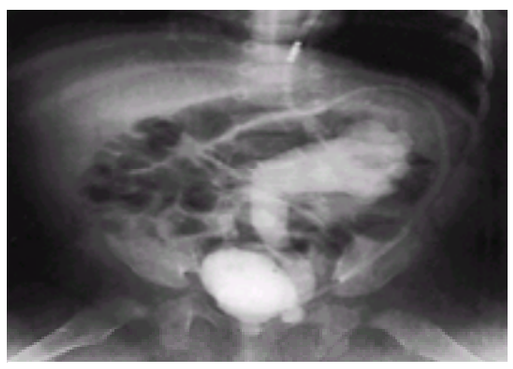

FIGURE 48B.6. Reflux associated with a neurogenic bladder.

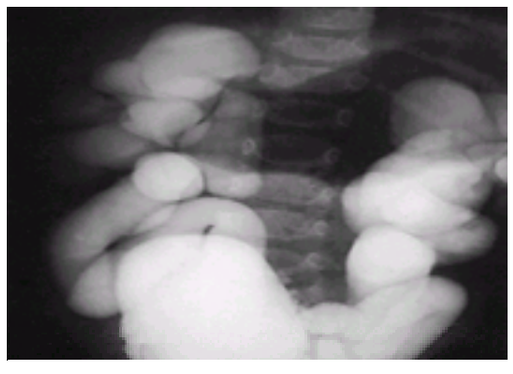

FIGURE 48B.7. Secondary refluxing megaureter attributable to posterior valves.

Similarly, management of severe reflux associated with a neurogenic bladder is initiated with a plan for bladder management. In the older child, this can involve clean intermittent catheterization with the appropriate pharmacologic manipulation and antimicrobial prophylaxis. In many cases, successful management of the bladder dysfunction will allow stabilization of the patient's condition and even lead to cessation of the reflux. In the neonate or infant, definitive bladder management may not be possible; in such cases, cutaneous vesicostomy has provided a temporary solution (3,12). Closure of the vesicostomy with management of the bladder by clean intermittent catheterization and pharmacologic means can then be attempted before a final decision is required regarding the reflux. Even the higher grades of reflux have been observed to cease in the neuropathic bladder after a period of vesicostomy drainage and with appropriate postvesicostomy bladder management (42). When required, ureteral reimplantation can be performed successfully in the presence of a neurogenic bladder. The success rate of ureteral reimplantation now has reached a level at which it plays an important role in the management of this situation (6,24,67). A cross-trigonal procedure is preferred because the trigone is usually less trabeculated and the chance of postoperative obstruction is minimized in these thickened, abnormal bladders (26). The improvement in the surgical management of even the refluxing megaureter in the neurogenic bladder makes it desirable, certainly in lieu of urinary diversion.

In the nonneurogenic neurogenic bladder or severe cases of voiding dysfunction with severe reflux, appropriate bladder or sphincter management (including voiding retraining and intensive counseling) should *precede* any attempt at surgical correction of reflux. Although the need for surgery is highly likely, this will allow the optimal chance of surgical success. Severe reflux associated with cyclophosphamide or radiation cystitis is usually best treated with augmentation cystoplasty or continent diversion because reimplantation alone has not proven successful (44).

Primary and Secondary Reflux with Accompanying Obstruction

One criticism of the international classification is that it provides no separate category for patients in whom reflux and obstruction coexist. Although this represents a small percentage of megaureters, this finding is of practical clinical importance in that ureters with both reflux and obstruction have been shown to be resistant to any form of treatment other than surgical correction (63). The obstructive component is thought to be more destructive because of chronic equilibrium with bladder detrusor pressure.

Subsequent obstruction results from ureteral wall fibrosis with muscle bundle disruption or fibrosis with fixed ureteral kinking as tortuosity develops. This process may be associated with paraureteral diverticula. This has been observed in both primary refluxing megaureters and in secondary refluxing megaureters associated with urethral valves.

The possibility of this entity of reflux and obstruction must be kept in mind by both the urologist and the radiologist during the evaluation of the wide ureter. At the time of the voiding cystogram, reflux may not be demonstrated until the patient voids or it may extend only into a dilated, tortuous lower ureter (Fig. 48B.8). Postvoiding films are important to obtain because they may show the rounded appearance of the distal obstructed ureter, with a space between this point and the bladder. This space usually represents the fibrosed or stenotic segment of the distal ureter (Fig. 48B.9). Other films may show a paraureteral diverticulum with reflux and poor drainage on delayed films. Diuretic renography or the Whitaker test may be necessary to define obstruction in selected patients.

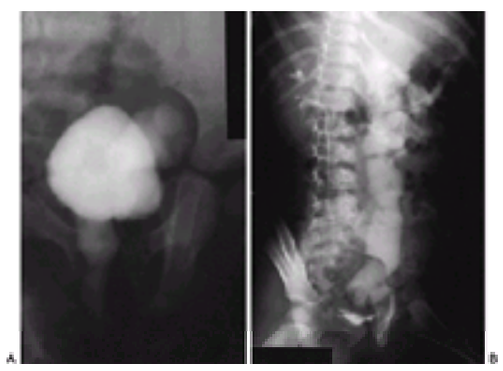

FIGURE 48B.8. A: Reflux into only the lower portion of a megaureter. **B:** Delayed intravenous pyelography film showing an obstructive element in addition to reflux.

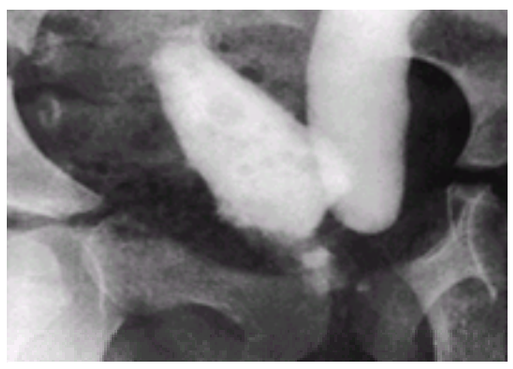

FIGURE 48B.9. Refluxing megaureter associated with secondary obstruction. (Note rounded appearance of the lower ureter characteristic of this finding on postvoiding film.)

OBSTRUCTIVE MEGAURETER

Primary

Primary obstructive megaureter has a congenital intrinsic form of obstruction at or above the ureterovesical junction. Causes include ureteral stenosis or stricture, valves, segmental atresia, ectopic orifice, and most commonly, an adynamic distal segment.

Congenital Ureteral Strictures

Congenital ureteral strictures or stenosis can occur throughout the length of the ureter. They occur primarily at the distal ureterovesical junction but are seen occasionally in the midureter in the region of the pelvic brim (Fig. 48B.10 and Fig. 48B.11). A ureteral stricture or stenotic area should be, by definition, an anatomic narrowing that is defined by calibration. Such areas have been shown histologically to contain normal transitional epithelium with sparse muscle and a relative increase in collagenous tissue. These strictures are thought to result from a vascular compromise in the eleventh or twelfth week of gestation resulting in the development of abnormal mesenchyme leading to decreased ureteral muscularization (2).

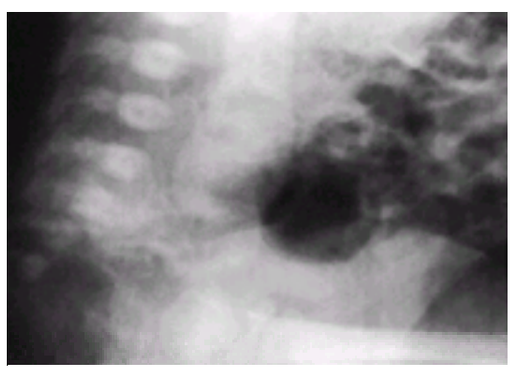

FIGURE 48B.10. Midureteral stricture in a solitary kidney discovered in a prenatal ultrasound. Lateral, delayed film during intravenous pyelography.

FIGURE 48B.11. A, B: Congenital distal ureteral stricture in child with solitary kidney. Child presented with flank pain and hematuria.

Ureteral Valves

Ureteral valves, like ureteral strictures, are rare. A true ureteral valve consists of a transverse fold of ureteral mucosa containing smooth muscle fibers above which are obstructive changes (Fig. 48B.12). These are annular valves that may occur in either the upper or the lower ureter.

FIGURE 48B.12. A, B: Annular valve of distal ureter. (From Noe HN, Scaljon W. Case profile: ureteral valves. *Urology* 1979;14:411, with permission.)

In the upper ureter, multiple transverse folds occur during normal fetal development (50). These folds normally disappear with growth, but many believe that it is their persistence that is the source of valvular obstruction in the upper ureter (1). Valvular obstruction in the lower ureter has been suggested to be secondary to persistence of Chwalla's membrane, but that theory will not account for the valves seen in the upper ureter.

Treatment of distinct ureteral valves will vary with the location. In the upper ureter, excision and either ureteropyelostomy or ureteroureterostomy is performed. Distal ureteral valves can be treated with excision and ureteral reimplantation.

In addition to the annular valves described previously, eccentric cusplike valves also have been described as possibly obstructive, particularly in the lower ureter (10). These cusplike folds are located at the junction of the proximal dilated ureter and the normal caliber distal ureter. Whether they are the primary source of obstruction or simply the result of a more distal obstruction is still unclear. A similar form of obstruction attributed to a tilt valve mechanism also has been described (14). This tilt valve occurs where the proximal dilated ureter joins a normal caliber juxtavesical ureteral segment. The distal ureteral lumen meets the proximal dilated ureter in an eccentric fashion. The portion of the wall of the proximal ureteral segment that overlaps the distal ureteral segment, including the lip of the eccentric distal lumen, acts as a flap and causes obstruction according to this concept. Once again, whether this is a primary process or a change secondary to more distal obstruction, as yet, is unclear. If indeed such a tilt valve mechanism exists, simple correction of the valvular obstruction could be performed and more extensive ureteral resection and reimplantation could be avoided because the distal ureteral segment may not be abnormal.

Ectopic Ureter

Ectopic ureters may prove to be obstructive. This is especially seen in the case of the ectopic ureter at the bladder neck in which compression of the ureteral orifice by the bladder neck musculature is obstructive (Fig. 48B.13). Intrinsic abnormalities of the distal ectopic ureter also may contribute to the obstruction.

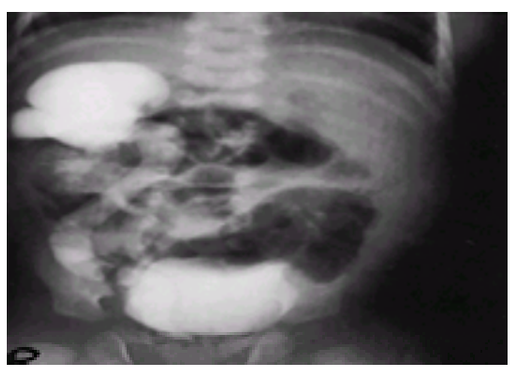

FIGURE 48B.13. Obstructive megaureter attributable to ectopic bladder neck insertion of upper pole ureter.

Distal Adynamic Segment

The distal adynamic segment is perhaps the best known of all the causes of primary obstructed megaureter. This segment consists of the terminal 3 to 4 cm of ureter that does not conduct a peristaltic wave and thus fails to allow passage of a bolus of urine through this portion of the ureter (Fig. 48B.14). This terminal ureteral segment is of adequate caliber anatomically and can be readily catheterized using the appropriate sized ureteral catheter. Thus the obstruction is functional rather than anatomic. Dilation appears proximal to this distal obstructive segment.

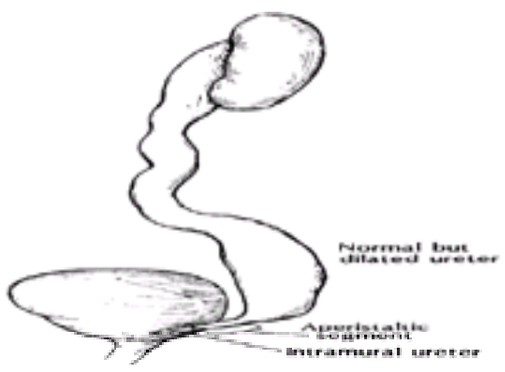

FIGURE 48B.14. Distal adynamic segment as found in primary obstructive megaureter.

Caulk's (8) original description likened this form of primary obstructed megaureter to Hirschsprung's disease. Although others attempted to further this concept, no neurologic deficit or absence of parasympathetic ganglia analogous to Hirschsprung's has ever been demonstrated. However, several histologic studies have been successful in demonstrating abnormalities in this distal adynamic segment. Increased collagenous tissue in the distal segment has been described (18). Others have described an area in this distal segment that is devoid of musculature (37), and some have described predominantly circular muscle in this area (41). Because the ureter is basically a smooth muscle meshwork of opposing helices, many have thought that the predominant circular pattern represents an exceptional tight helix formation at the distal end of the ureter, which has the same effect as a circular muscle. McLaughlin and colleagues (39) reported histologic studies on light microscopy of 32 such ureters. In their study, five ureters were normal, two showed primarily circular muscle, and three showed mural fibrosis with essentially absent muscle. The largest single category in this study included 22 ureters that showed muscular hypoplasia or atrophy of widely separated muscle bundles interspersed with fibrosis (Fig. 48B.15).

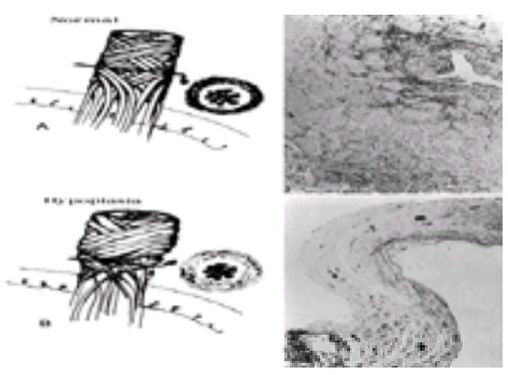

FIGURE 48B.15. Histopathologic findings in primary obstructed megaureter. **A:** Normal ureteral muscular orientation found in five ureters in McLaughlin's series. **B:** The most common abnormal finding of hypoplasia and atrophy of ureteral muscle seen in 22 patients in the McLaughlin series. (From McLaughlin AP III, Pfister RC, Leadbetter WF, et al. The pathophysiology of primary megaloureter. *J Urol* 1973;109:805, with permission.)

Electron microscopic studies of these ureters also have been performed (20,47,51,60,61). The early studies predominantly showed that collagenous tissue was observed in increased amounts between the muscle cells. It was thought that this would possibly alter the normal cell-to-cell contacts (intermediate junctions), thus disrupting electrical impulse propagation and peristalsis. More recently, quantitative histologic analysis of these dilated ureters has been performed (35). A color image analysis system was used to examine and compare collagen and smooth muscle components of the muscularis layers with more normal control ureters, primary obstructed megaureters, and primary refluxing megaureters. In patients with primary refluxing megaureters, a twofold increase in the tissue matrix ratio of collagen-to-smooth muscle was seen when compared with patients with primary obstructed megaureter. In those with primary obstructed megaureters, the amount of collagen was increased but did not appear to be statistically different from the control ureters. These differences in the structural components (collagen and smooth muscle) may account for the difference in surgical outcomes as will be discussed later. In addition, these histologic differences have been suggested to be a function of time. Harada and associates (21) performed an experimental study in 35 mongrel dogs in whom ureteral compliance and its relationship to histologic changes were studied over 26 weeks following the establishment of partial ureteral obstruction. This study demonstrated the initial response to be muscle hypertrophy with increased compliance up to 8 weeks following obstruction. Thereafter, the compliance significantly diminished and was proportional to the amount of connective tissue proliferation. Although most of these studies have mentioned altered collagen-to-smooth muscle ratio, to date, no specific or consistent intracellular abnormalities of the individual muscle cells have been shown in any of the ultrastructural studies. The distal thickened ureteral sheath also has been suggested as being partially obstructive and usually associated with bladder distention (60). A recent study has shown that a qualitative increase in apoptosis is present in congenitally obstructed megaureters compared with normal control ureters. The presence of apoptosis following the vascular supply into the fibromuscular areas of the megaureter could account for the characteristic alteration in the circular and longitudinal muscle fibers as well as in collagen deposition seen in these children (57).

All of the aforementioned studies seem to point clearly to the fact that the predominant mechanism of obstruction of the ureter is disruption of muscular continuity and the prevention of proper muscular propulsion of a bolus of urine. Whether this results from a single anatomic cause or multiple anatomic and/or functional causes at a tissue, cellular, or molecular level remain to be clarified.

Embryologically, the explanation of the distal adynamic segment is thought to rest with abnormal development involving the distal ureteral musculature. Tanagho (58) noted that the distal ureteral musculature was the last to develop and, in particular, noted that the earliest development occurred primarily in muscle with circular orientation. Arrest later in development, such as by vascular pressure in the female or by the vas deferens in the male, could lead to diminished longitudinally oriented ureteral muscle and could result in the histologic changes noted (59).

The degree of ureteral dilation proximal to the obstructing segment is variable. In many instances, only terminal ureterectasis is seen. In other instances, dilation of both the renal pelvis and calyces also is present. As the bolus of urine reaches the obstructed segment, retrograde flow from that point leads to increased urine volume in the terminal portion of the ureter. This increased volume results in the variable degree of dilation seen in the affected ureter. The ability of the upper ureter and pelvis to dampen this retrograde flow and maintain antegrade emptying determine the effect, if any, on the renal parenchyma.

Currently, megaureter is diagnosed most commonly by prenatal ultrasound as an incidental finding. In the past, clinical presentation of patients with this entity was variable but usually owing to the symptoms accompanying urinary tract infection (13,51,52,53,54,66). In some instances, the infection is clearly related to the affected renal unit, but in others, cystitis symptoms also may be present. With the latter, no relation to the ureteral anomaly is obvious and megaureter may be an incidental finding. Hematuria, abdominal pain, or abdominal mass also may be symptoms at presentation. Discovery also may be incidental during investigation for urinary incontinence or medical investigation for a nonurologic disorder. Fortunately, the signs and symptoms of renal failure are unusual modes of presentation in this disorder. The lesion appears to affect males more commonly than females except in the first year of life, when they are roughly equal. The left ureter is affected more often than the right, and involvement is bilateral in approximately 25% of the cases. Children younger than 1 year of age are more likely to have bilateral megaureters than are older patients. Contralateral renal agenesis occurs in approximately 10% of the cases. No hereditary basis is currently recognized for this entity.

Excretory urography or renal ultrasound is the means by which the diagnosis of primary obstructive megaureter secondary to the distal adynamic segment is made. Because the narrow distal obstructive segment is close to the bladder, oblique and postvoiding films may be helpful in visualizing this area (Fig. 48B.16 and Fig. 48B.17). Videofluoroscopic studies usually demonstrate active ureteral peristalsis down to the distal adynamic segment, where the urine bolus then floods back up the ureter for a variable distance (Fig. 48B.18). Upper ureteral or renal pelvic dilation may or may not be present. The diuretic renogram or pressure perfusion studies can be useful in select cases in which the decision for treatment is unclear. Endoscopy performed at the time of surgery usually demonstrates a normal ureteral orifice and trigone. Retrograde ureteral catheterization is performed with ease, and a “hydronephrotic drip” can be noted when significant obstruction is present. A retrograde ureterogram can confirm the diagnosis demonstrating poor emptying of the ureter, but this procedure usually is not required. If instrumentation is performed, it should be performed at the time of anticipated surgical correction to avoid introducing infection into a static system.

FIGURE 48B.16. Primary obstructed megaureter attributable to distal adynamic segment. **A:** Intravenous pyelogram showing terminal ureterectasis only, with otherwise normal renal unit. **B:** Oblique view of lower ureter showing area of distal adynamic segment.

FIGURE 48B.17. Longitudinal ultrasound of an obstructed megaureter. Real-time image showed ureter clearly obstructed just at the ureterovesical junction. B, bladder; U, ureter.

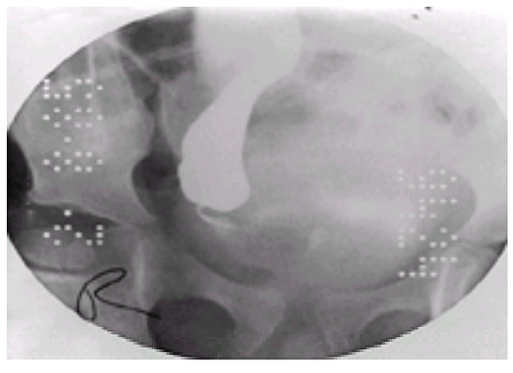

FIGURE 48B.18. Distal ureteral obstruction demonstrated on antegrade ureterogram at the time of percutaneous nephrostomy.

Treatment of these patients depends on the severity of the obstruction and the presence of symptoms. Those with only terminal ureterectasis and otherwise normal upper urinary tracts can be safely observed and usually do not progress. Surgical correction should be reserved for those with progressive or generalized hydronephrosis, parenchymal loss, calculus disease, or persistent flank pain in patients with proven significant obstruction. Persistent or recurrent infections, particularly those that can be related to or lateralized to the affected renal unit, also form an indication for surgical treatment.

Secondary Obstructive Megaureter

Secondary obstructive megaureter occurs as a result of urethral obstruction, neurogenic vesical dysfunction, ureterocele, extrinsic compression, or fibrosis.

Urethral Valves

Urethral valves are the most commonly seen form of urethral obstruction leading to secondary obstructive megaureter. They can be due to poor bladder compliance, relatively small bladder, associated nephrogenic diabetes insipidus, ureteral fibrosis, or fibrosis and kinking often associated with a paraureteral diverticulum. It should be remembered that ureteral dilation can remain following valve ablation but not be associated with true obstruction. Marked improvement in ureteral dilation and tortuosity can occur in a relatively short time following valve ablation (Fig. 48B.19). Significant residual dilation must be evaluated further. The diuretic renogram with a draining bladder catheter is usually the first study obtained. If this study demonstrates a dilated but nonobstructed pattern, distal causes such as poor bladder compliance, high urine volume state, or persistent bladder outflow obstruction must be considered. Serial studies, primarily by ultrasound but including renal function evaluation, often are helpful to confirm efficacy of a nonoperative approach. If the diuretic renogram is equivocal, the Whitaker test may be used. High perfusion pressures with an empty bladder indicate a potential obstruction at the ureterovesical junction, and surgical treatment is indicated. One of the major difficulties in interpreting the Whitaker test in patients with urethral valves has been the effect of the degree of bladder filling on relative renal pressures (16). If pressures are low with the bladder empty but become rapidly abnormally elevated with bladder filling, the patient is potentially at risk for progressive renal damage because of poor bladder compliance. Anticholinergic therapy, and rarely, augmentation of the noncompliant bladder should be considered before megaureter repair. Urodynamic evaluation with fluoroscopy is critical in such cases. Often, it is necessary to combine lower tract dynamic evaluation with antegrade perfusion to specifically define the nature of the cause of the ureteral ectasia.

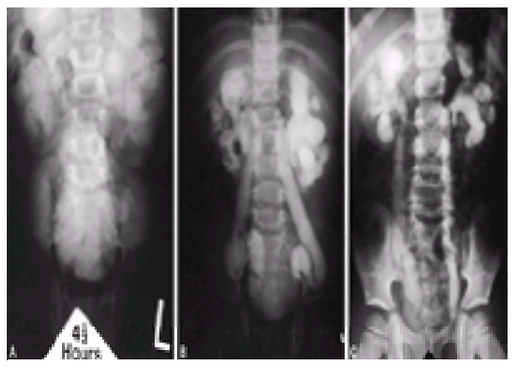

FIGURE 48B.19. A: Resolution of ureterectasis and hydronephrosis following valve ablation. Ureterectasis was present at diagnosis. **B:** Resolution of ureterectasis and hydronephrosis following valve ablation. Improvement was noted 12 months after valve ablation. **C:** Resolution of ureterectasis and hydronephrosis following valve ablation. There was further improvement 2.5 years later.

Neurogenic Bladder

Neurogenic vesical dysfunction can result in obstructive megaureter. Management of the bladder by vesicostomy, clean intermittent catheterization, or pharmacologic manipulation (anticholinergic and/or alfa-sympatholytic agents) usually results in resolution of the hydronephrosis without the need for diversion. In older children, augmentation may be required for long-term treatment of the noncompliant or small bladder.

Successful ureteral reimplantation can be undertaken in the neurogenic bladder. It is important to have the bladder stabilized in terms of function and emptying capabilities before considering reimplantation.

Ureterocele

Obstructed megaureter can be secondary to ureterocele. Ureteroceles can involve the ipsilateral ureter or, in some cases, also can be secondary to a contralateral ureter causing an element of obstruction. Simple ureteroceles generally are not encountered in children but have been noted to occur. Ectopic ureteroceles can be associated with massively dilated ureters. Four major types of ectopic ureteroceles have been described (55). Although ureteroceles are included here as a secondary form of obstructive megaureter, it is obvious that ureteroceles also could be considered in the primary obstructed category.

Mass: Vascular Compression

Extensive compression occurs with retroperitoneal masses or tumors (Fig. 48B.20). Treatment usually consists of management of the primary condition with observation for resolution of the ureterectasis. Persistent ureterectasis following successful tumor treatment may require additional studies to be performed to determine if true obstruction remains.

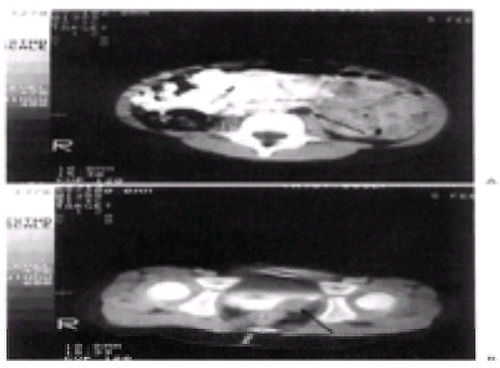

FIGURE 48B.20. A: Secondary obstructed megaureter owing to tumor. Computed tomography scan shows hydronephrosis and enlargement of left ureter *(arrow).* **B:** Tumor recurrent at bladder wall at ureterovesical junction *(arrow).*

Vascular compression can occur as a result of aberrant or accessory vessels. In these instances, treatment is influenced by the vessel involved and the degree and location of the obstruction.

Fibrosis: Iatrogenic Causes

Fibrosis can result in ureteral obstruction and can be caused by trauma or be associated with diverticula, but it is most often is the result of prior surgery, most commonly ureteral reimplantation. The assessment of postoperative residual ureteral dilation following reimplantation can be as challenging as in the similar situation involving posterior urethral valve patients. Diuretic renogram and/or pressure perfusion study and urodynamic evaluation should be utilized when the diagnosis is uncertain. As with valves, bladder compliance must be evaluated to ensure that accurate conclusions serve as a basis for treatment.

Occasionally, an unusual form of transient ureteral obstruction occurs following ureteral reimplantation. This is usually observed following surgery on the megaureter but also can be observed on ureters with less severe dilation. Although anatomically the distal ureter is open and can be catheterized, a very high-grade, if not almost complete, obstruction is observed postoperatively. This obstruction seems to be related more to ureteral dysfunction and altered peristalsis. A period of temporary drainage by double-J ureteral stent or short-term percutaneous nephrostomy usually allows a return of ureteral function and resolution of the abnormality. Once ureteral function has demonstrated recovery, tube removal is all that is required to allow proper return of function of the urinary system.

NONREFLUXING, NONOBSTRUCTED MEGAURETER

Primary

The cause of isolated primary nonrefluxing and nonobstructed megaureter is not known. It could represent an intrinsic abnormality of ureteral development or perhaps a resolved obstruction leaving residual ureterectasis. The entire ureter usually is dilated from the bladder proximally. The degree of dilation and the presence of caliectasis is variable. The distal ureter is not stenotic, nor is the remaining ureter especially tortuous. The diagnosis of a ureter in this category is, by definition, one of exclusion. In the absence of infection and with stable renal function, it seems safe to observe these patients. A case representative of this entity is shown in Fig. 48B.21.

FIGURE 48B.21. A: Nonobstructive, nonrefluxing megaureter. Intravenous pyelogram (IVP) of solitary kidney with ureteral dilation discovered on evaluation for hypospadias. **B:** Prompt washout shown 10 minutes after administration of furosemide. **C:** IVP 5 years later showing adequate renal growth without progression of hydronephrosis. Follow-up diuretic renograms have shown the system to be nonobstructed, and the creatinine clearance has remained stable.

In some cases, the prune-belly syndrome can be considered in this category. Ureteral dilation in the prune-belly syndrome is secondary to abnormal ureteral development, and the radiographic picture represents a degree of dysmorphism. This dysmorphism appears to be at its greatest in the distal portion of the ureter with the proximal-most portion of the ureter usually being less dilated. However, it should be kept in mind that ureteral dilation in the prune-belly syndrome may also be demonstrated to be secondary to either obstruction or reflux, and merits a full investigation. The particulars of the prune-belly ureter are discussed elsewhere.

The concept of a dilated but nonobstructed urinary system has been brought keenly to the forefront with the advent and widespread use of fetal and maternal ultrasound. It has been shown that spontaneous resolution of antenatal and postnatal urinary tract dilation does occur commonly (19,23,25). It recently has been demonstrated that up to 60% of these children will have resolution of this dilation and can be safely followed to between the ages of 12 and 36 months (40). The concept of spontaneous resolution or improvement has been extended to several groups of neonates prenatally discovered with megaureter who have been followed and evaluated (5,36,62). Keating and co-workers (28) first reported a large number of patients with megaureter discovered prenatally or serendipitously who were followed without surgery. Many of those renal units improved and were managed nonoperatively with preservation of renal function as measured by the extraction factor (22). This now has been confirmed in several other series. Although initially this might seem to go against the advice of those advocating early surgical correction of obstruction (30,38), it seems on reflection that the real dilemma may be in truly defining obstruction in the neonate or infant. There are numerous problems with precisely defining obstruction in this patient group, including the concept of renal functional maturity, which proceeds within the first few months of life (31). Thus it seems that when an asymptomatic mildly to modestly dilated system is discovered either serendipitously or through prenatal ultrasound, early diagnostic studies attempting to define the degree of obstruction should be obtained. There appears to be no ill effect to at least a modest delay in reconstructive surgery in most of these children while waiting for renal function to mature (11). If renal function is maintained and only mild to modest or improving obstruction is found, careful but frequent follow-up can be offered as an alternative to surgical correction. It should be noted that when significant obstruction with renal functional compromise is present, early surgical correction to preserve renal function and to prevent further damage is indicated. Whether the antenatally discovered, asymptomatic megaureter turns out to be a different entity than those discovered in the past because of symptomatic infections, stones, abdominal pain, mass, and the like, remains to be seen. It has been hypothesized that the fetal and neonatal ureter is more compliant with increased urinary output and that perhaps many of these children were simply unnoticed in the past because of their lack of symptoms. Only careful follow-up of such a series of patients such as those reported can shed new light on this problem.

Secondary

Ureteral dilation also can occur secondary to high urine flow and volume, as in diabetes insipidus or in the compulsive water drinker (Fig. 48B.22). Bacterial toxins also can affect ureteral muscular action leading to dilation and diminished peristalsis.

FIGURE 48B.22. Ureteral dilation secondary to high urinary output in patient with diabetes insipidus.

Other conditions included in this classification are the residual dilation following relief of the distal obstruction as in the patient with posterior urethral valves. Residual dilation following ureteral reimplantation also may be categorized in this designation (Fig. 48B.23). The classification of a dilated ureter can be a dynamic process. Successful treatment of the primary condition can still result in persistent ureteral dilation with no other clinical significance. However, these patients should definitely be followed over the long term to ensure that no late renal deterioration or increase in hydronephrosis occurs.

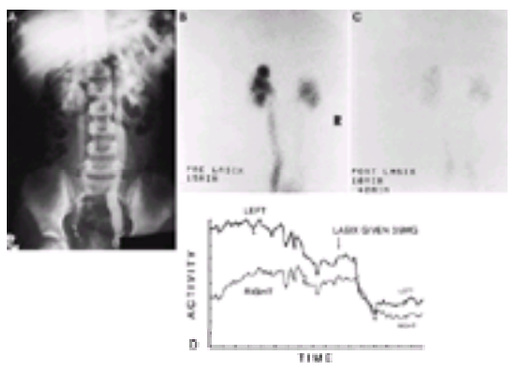

FIGURE 48B.23. A: Residual dilation following ureteral reimplantation. Intravenous pyelogram shows ureteral dilation postoperatively. **B:** Renal scan images before furosemide (Lasix) administration. **C:** Renal scan images showing prompt washout 10 minutes after furosemide administration. **D:** Renogram curves corresponding to images of the scan.

Urinary tract infection as a result of urinary stasis occasionally is seen in patients in this category. If this is true, nonrefluxing nonobstructive megaureter can serve as an indication for surgical treatment. If ureteral muscular failure is suspected or peristalsis is absent, surgical remodeling of the ureter may be of no benefit. In select instances, replacement of the ureter may be warranted.

MANAGEMENT OF THE MEGAURETER

The management of megaureter is evolving. In many cases, particularly those associated with prenatal hydronephrosis, simple observation may be warranted. Observation of children with dilation but no documented obstruction and good renal function may be appropriate, provided they are taking antibiotics. However, for children who exhibit persistent high-grade reflux, show proven obstruction, or have urinary tract infections, surgical management is the cornerstone of treatment. An intermediate response may be the placement of ureteral stents to temporize, as in the case of a sick neonate or young infant. However, in large part, if the megaureter secondary to either reflux or obstruction requires definitive treatment, it will require surgical correction. Such surgical correction usually takes the form of a tailored ureteral reimplantation directed at the lower ureter. The discussion of this treatment is provided in detail in the section of reconstruction techniques.

Prune-belly syndrome (PBS) consists of a constellation of three major findings and other commonly associated organ system anomalies. A deficiency of abdominal musculature gives the child's abdomen a wrinkled, prunelike, appearance (Fig. 48C.1). Bilateral, nonpalpable, undescended testes are present, and there is an abnormal urinary tract characterized by tortuous, dilated ureters, megalocystis, dilated prostatic urethra, and renal dysmorphism. Associated anomalies can involve the respiratory tract, gastrointestinal tract, cardiovascular system, and musculoskeletal system. Frolich first described it in 1839, and urologic interest began in 1895 with Parker's description (71).

FIGURE 48C.1. A, B: Typical newborn abdominal appearance. Note wrinkling in **A** and laxity in **B. C:** A 1-year-old child with renal failure on chronic ambulatory peritoneal dialysis. **D:** A 24-year-old man with typical potbelly. No surgery was done except for bilateral orchiopexies. Note pectus excavatum and prominent midline cutaneous infolding.

This syndrome has been called by many other names, including *Eagle-Barrett syndrome* (23), *absence of abdominal musculature* (13,54,60), *triad syndrome* (67), and *mesenchymal dysplasia syndrome* (48). Despite these many terms, the name *PBS* is the most widely accepted for this constellation of major and minor findings (6,34,20,96,107,109,127).

SPECTRUM

The manifestations of PBS are widely varied. In some infants, the disease is so severe that kidney development and urine production *in utero* are impaired. Subsequent oligohydramnios leads to pulmonary hypoplasia incompatible with life. These severely afflicted children may be stillborn or die shortly after birth. The most common postnatal cause of death is urosepsis. Before the 1970s, almost 50% of reported cases were postmortem reports (6,54,60). With aggressive management, including the judicious use of urinary diversion, peritoneal dialysis and transplantation, some of these children may survive. On the other hand, there are children with normal renal function even though the urinary tract has a markedly abnormal radiographic appearance. These children may grow up without much physical or physiologic impairment.

Attempts to correlate abdominal wall laxity with a degree of urinary tract abnormality or functional impairment have not been successful. The abnormal results of either the abdomen or the urinary tract imaging should not lead one to draw conclusions about long-term prognosis or treatment options without careful evaluation of the functional status of the child .

INCIDENCE

The incidence of PBS is estimated to be equal to that of exstrophy of the bladder (1 per 35,000 to 50,000 live births) (5,29). There are little data to support this

estimation, although approximately equal numbers of PBS patients and exstrophy patients are seen at large centers (118). The complete triad occurs only in males, but there is a subset of patients with two of three systems involved and some of these are female.

GENETICS

There is no evidence for a single gene or an autosomal-recessive inheritance in PBS (48). Riccardi and Grum (87) proposed a two-step autosomal-dominant mutation with sex-limited expression and also proposed that different gene abnormalities may result in an identical phenotype. Harley and colleagues (40) noted siblings with PBS and mosaicism, suggesting a genetic etiology. Subsequently, the occurrence of PBS in siblings has been reported many times. Frydman (27) reported a familial segregation of PBS anomalies that appeared to follow an X-linked inheritance. Amacker (3) and Hoagland (45) described an association between PBS and trisomy 21 and 18, respectively, whereas Watanabe (111) described two siblings with Beckwith-Wiedemann syndrome PBS. Despite the suggestion of chromosomal anomalies and associations with other syndromes, these still must be considered exceptions rather than the rule (29,37). However, parents should be counseled of the potential occurrence in subsequent offspring, and the chromosomal analysis of PBS patients is recommended.

There is a significant association between PBS and twin pregnancy. Among PBS patients, 1 of 23 is the product of a twin pregnancy (48). This is a much higher incidence than one would expect spontaneously (1 in 80). The majority of reported twins have been discordant for PBS, and this again speaks against a genetic etiology for PBS (48). The cause in twins may be the result of an uneven division of the mesenchyma at a critical time of primitive streak development during the third week of embryogenesis.

EMBRYOLOGY

The embryologic explanation for the development of PBS is unknown. Four theories have been suggested:

1. Wigger and Blanc (115) suggested that a primary myopathic or dysplastic process results in PBS. The predominant involvement of medial and lower abdominal wall muscles and the dysplasia that is observed histologically indicate a problem with the development and differentiation of mesenchyme into striated muscle. The lateral thoracic somites have migrated to the midline (i.e., midline defects like exstrophy and omphalocele are not present), but the somites either fail to differentiate into myoblasts or the myoblasts did not migrate ventrally and caudally. The bladder arises from the same lateral somites, so the same defect could lead to the bladder findings in PBS. Similarly, the deficiency of smooth muscle and fibrosis in the ureters might interfere with normal peristaltic propagation and result in ureteral dilation. This theory, however, does not explain the discrepancy in upper and lower ureteral dilation or the presence of undescended testicles.
2. It is possible that an intrinsic defect exists in the urinary tract that causes bladder and ureteral dilation. The consequent abnormal abdominal distention throughout embryogenesis would result in abdominal wall laxity and the characteristic appearance of a PBS patient. With this theory, the dilated bladder will mechanically block the testicle's descent into the scrotum. However, it does not explain the actual embryologic process of the urinary tract malformation, nor does the laxity of the abdominal wall necessarily correlate with the degree of urinary tract dilation.
3. PBS may result from an early, prostatic, membranous, urethral obstruction that causes bladder and ureteral dilation. Whether this is a functional (46,62) or anatomic (45) obstruction is unclear, but either might cause the abdominal musculature laxity and undescended testes, as explained previously. The overall incidence of urethral obstruction in reported cases is about 30% (58,115). I have seen a child with PBS abdominal wall and testicular findings but with a typical urethral valve urinary tract with a trabeculated bladder, bladder neck hypertrophy, and so forth. Prenatally, the fetus had ascites that may be a contributory factor in the development of abdominal wall laxity. Gonzalez and colleagues (1990) studied second trimester urethral obstruction in the fetal lamb. In one animal, this experimental manipulation resulted in musculoskeletal and genitourinary abnormalities and undescended testes as in PBS. It was hypothesized that the complete urethral obstruction in this model resulted in the findings that are distinctly different from the findings of the partial obstruction in posterior urethral valves. Outlet obstruction is clinically minimal in most patients at birth, so early urethral obstruction must recanalize later in development. This theory does not explain the more severe changes in the distal urinary tract and the milder changes in the proximal urinary drainage system.

   Two histopathologic studies support an obstructive etiology for PBS. Serial sectioning of the intact bladder and urethra in infants with PBS (45) revealed a short segment of obstruction in the prostatic urethra just above the membranous urethra in some patients. In another patient (46), the hypoplastic prostatic urethra was dilated and the angulation at the level of the internal sphincter caused a functional obstruction.

   However, Workman's (129) histologic evaluation of bladders from patients with PBS revealed two distinct groups. One group had marked muscle thickness consistent with obstruction, while the other group had thin bladders with increased connective tissue inconsistent with obstruction. This suggests either an obstructive or mesenchymal defect.
4. Stephens (100) suggested that the yolk sac perhaps could be at fault because it has a key relationship to the lateral folds of the discoid embryo as it enlarges and infolds into the chorionic cavity. If the yolk sac does not shrink and constrict, some may be retained inside the embryo, giving the abdominal wall redundancy. This theory would also explain the bladder and urachal anomalies encountered because they arise from the allantois and yolk sac. This theory does not address the ureteral changes or the undescended testes.

CLINICAL EVALUATION

Antenatal Diagnosis

Antenatal ultrasonography detects anatomic urologic abnormalities that may or may not require subsequent intervention. Bilateral dilation of the upper urinary tract in association with a large bladder that does not empty completely on real time ultrasound is suggestive of PBS, but a similar presentation would also be seen with posterior urethral valves. Scarborough and associates (89) suggested that the presence of fetal ascites early in gestation is suggestive of PBS. These anatomic abnormalities may be found as early as 15 weeks of gestation. Some have recommended *in utero* intervention for placement of a vesicoamniotic shunt to decompress the urinary tract and alleviate oligohydramnios (28,41,32,66). Others, on the basis of antenatal ultrasonographic evidence of PBS, have recommended pregnancy termination (77).

Antenatal ultrasound is associated with both false negative and false positive findings that make *in utero* diagnosis uncertain . There is no proof that relief of a functional obstruction *in utero* will affect renal function (12), although pulmonary function may be salvaged if oligohydramnios is reversed. Antenatal intervention or pregnancy termination for PBS is not indicated in the absence of oligohydramnios. The urinary tract dilation in PBS is not caused by obstruction but more often is the result of nonobstructive dilation in a functionally balanced system. There may be unusual circumstances in which abdominal distention or urinary tract dilation causes dystocia that may necessitate urinary tract decompression (28).

Diagnosis in the Newborn

Because of the typical features of a child with PBS, the diagnosis is usually obvious. Initially these patients should be monitored closely, with particular attention to their respiratory and renal function.

ELEMENTS OF PRUNE-BELLY SYNDROME

Abdominal Musculature

The abdominal musculature is unevenly involved. The lateral and inferior abdominal wall musculature is diffusely deficient, whereas the upper abdominal musculature and trunk musculature may be normal (83). The musculature, however, may be totally absent in some cases (58). The affected lower abdominal wall may consist of skin, subcutaneous fat, and condensation of fibrous tissue onto the peritoneum without evidence of organized muscle tissue (2,61). The whole muscle may be simply thinned out within the fascia, replaced by thick bundles of collagen surrounded by fascia, or consist of fragments of muscle interspersed in collagen (115). The abdominal organs can easily be palpated through the abdominal wall in these infants.

Over the first year, the wrinkled abdomen of the infant smoothes. As the child begins to stand, there is a pear-shaped, or pot-bellied, appearance to the abdomen (Fig. 48C.1). The abdominal musculature weakness makes it difficult for these children to sit from a supine position. They typically roll over and use their arms to assist them. Developmental delays in other motor activities may be associated with their difficulty in axial balance when standing to walk.

Cryptorchidism

In PBS, the undescended testicles are usually found at the level of the iliac vessels in the peritoneum on a long mesorchium. Kaplan and associates (1986) suggested a role for intraabdominal pressure in the process of testicular descent; however, Hutson and associates believe that the high intraabdominal pressure and bladder distension block descent (47). The underdevelopment of the inguinal canal may also contribute to the testicular nondescent (36). The fact that pseudoprune patients can have normally descended testicles and severe abdominal laxity sheds some doubt that mechanical forces are singly responsible for the cryptorchidism.

Histologic findings on testes biopsies vary. Case reports have described these testes as Sertoli cell-only (108), hypospermatogonia with Leydig cell hyperplasia (68), and normal for age-matched controls (36). The most comprehensive review of testicular histology is the review from Children's Hospital of Philadelphia (70). This study compared PBS testes, other intraabdominal cryptorchid testes, and testes of age-matched controls. There was no significant difference in germ cell counts, Adult Dark stem cell or Leydig cell counts found between intraabdominal testes in PBS and other intraabdominal cryptorchid testes. The observation that germ cell counts approach normal in PBS patients less than 1 year old suggests that PBS testes, like other cryptorchid testes, are not a congenital malformation but the outcome of a disease state.

Occasionally, the epididymis is detached from the testis, as noted in other circumstances of cryptorchidism. The ductus deferens may have a thickened wall of collagen with sparse musculature. The vas deferens may be tortuous and thin walled with atretic segments (105).

The risk of testis tumor in PBS patients is poorly defined. Certainly, the presence of germ cells in the young PBS patient testes places the patient at risk. Massad and co-workers (59) showed histologic similarities with intratubular germ cell neoplasia in three infants with PBS. Teratocarcinoma has been noted in intraabdominal testes after puberty (126), and a seminoma has been reported in a 30-year-old man who had undergone orchidopexy 6 years prior (72). Another PBS patient had a primary retroperitoneal embryonal cell tumor with normal testes biopsy results (88).

Orthopedic Anomalies

The oligohydramnios in PBS is believed to produce limited intrauterine space, which in turn leads to fetal compression and resultant musculoskeletal deformities. Some of these compression effects are mild (Fig. 48C.2). The incidence of orthopedic abnormalities ranges between 30% and 45%, and it is the most commonly affected system outside the genitourinary tract. The involvement may be congenital (clubfoot, limb deficiencies, hip dysplasia and dislocation, and vertebral anomalies) or developmental (renal osteodystrophy, scoliosis, and pectus deformities). Loder (1992) believes that the embryologic characteristics of the congenital musculoskeletal problems correlate with an aberration of mesenchymal development around 6 weeks of gestation, but Green (1993) believes that the anomalies are a direct result of the oligohydramnios based on the unilaterality of many of the deformities.

FIGURE 48C.2. Knee dimples seen in prune-belly syndrome. Dimples also may be seen on the elbows and are probably related to *in utero* compression.

Gastrointestinal Anomalies

Gastrointestinal anomalies are seen in 20% to 30% of PBS patients. Most anomalies (malrotation, volvulus, atresia, and stenosis) result from persistence of the wide embryonic mesentery with absent fixation to the posterior abdominal wall (94,130). The spleen has the same abnormal mesenteric attachment, and acute torsion has been reported in five patients (44,106). Gastroschisis (92,116), omphalocele (78), Hirschsprung's disease (11), and imperforate anus (64,110) have all been reported. PBS children may have problems with chronic constipation presumably secondary to the inability to generate intraabdominal pressure. This may require chronic intervention (30).

Respiratory Anomalies

Significant respiratory problems have been observed in PBS. These may result from a combination of pulmonary hypoplasia secondary to *in utero* oligohydramnios and disordered thoracic mechanics resulting from scoliosis, rib cage abnormalities, and abdominal weakness. Most patients have no baseline history of respiratory disease, although the majority had abnormal lung function when studied in a pulmonary function laboratory. Patients showed gas trapping secondary to poor expiratory effort, and half the patients showed significant restrictive lung disease that appeared to be secondary to musculoskeletal abnormalities rather than an interstitial lung problem. These pulmonary abnormalities must be considered before the elective treatment of PBS anomalies (i.e., musculoskeletal).

Cardiovascular Anomalies

Cardiovascular anomalies occur in approximately 10% of PBS patients (1). Atrial and ventricular septal defects as well as tetralogy of Fallot are the most common anomalies seen.

Cardiovascular, pulmonary, or other anomalies may have far greater significance in the newborn than the urologic manifestations of PBS. Urologists must individualize the approach for each patient's specific needs, realizing that the urologic anomalies are seldom a pressing problem in the newborn.

RADIOGRAPHIC EVALUATION

The introduction of infection during radiographic procedures is a real possibility because the PBS urinary tract is dilated and urine may be stagnant. Studies that require instrumentation are avoided unless they will significantly influence management decisions. Antibiotic coverage is recommended for radiographic instrumentation of the urinary tract.

Imaging of the urinary tract may be done with a voiding cystourethrogram, which usually fills the upper urinary tracts as a result of reflux. Some information about bladder functioning and emptying can also be gained from this study. The dilated, tapered, posterior urethra, so characteristic of PBS, may also be demonstrated.

Ultrasonography can be helpful in evaluating the size of ureters and the degree of the upper urinary tract hydronephrosis. It may also aid in distinguishing the amount of normal parenchyma from dysplastic parenchyma.

Upper urinary tract imaging is beneficial, but in the newborn, it should be delayed for 2 to 4 weeks to allow for better visualization of the kidneys. A renal scan obtained with technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc DTPA) measures only gross function. Because of the dilation and tortuosity, furosemide (Lasix) administration and measures of half-time excretion are not valid in the PBS to demonstrate obstruction (33).

Kidneys

Renal dysmorphism is a common finding. Cystic calyces are characteristic of PBS without narrowing of the infundibula. Incomplete renal rotation and irregular renal outline may be present. Most kidneys display some degree of hypodysplasia. Because PBS is potentially a mesodermal abnormality, the metanephric mesenchyme may not be normal or may be inadequately induced by an abnormal ureteric bud (56). Early fetal obstruction to urine flow may also influence or cause these developmental changes.

In postmortem specimens, Stephens (100) found hypoplasia and renal dysplasia (defined as any disorganization of the renal parenchyma consisting of embryonic tubules, cartilage, cysts, and mesenchymal connective tissue) in the majority of PBS patients. Renal cystic dysplasia is most commonly associated with some degree of distal obstruction (115), and those patients with urethral atresia usually have solid dysplastic kidneys as described by Potter (80). The involvement of the kidneys is variable and may be segmental, thus renal biopsy may not be accurately predictive of outcome. The autopsy patients evaluated by Stephens and Wigger were severely affected by the syndrome, and the prevalence of dysplasia in PBS patients with “normal” renal function is unknown.

Ureter

A radiographic hallmark of PBS is the characteristic ureteral redundancy, tortuosity, and dilation, with the distal portion being more involved than the proximal ureter (8,35) (Fig. 48C.3). Segmental dilations of the midureter are occasionally found. Rarely, an obstructed ureteral segment is discovered. Fluoroscopic examination shows an ineffective churning peristalsis. Over time the ureters may straighten somewhat, and the peristaltic activity may improve. Most of these ureters have free vesicoureteral reflux. It is difficult to incriminate an obstructive cause when the distal ureter is so much more involved with these changes than is the proximal ureter. Maizels and Stephens (57) noted “pleat valves” in the caudal portion of these ureters, which may be obstructing at times (15).

FIGURE 48C.3. A: Scaphoid megalourethra in a prune-belly syndrome (PBS) patient. **B:** Retrograde urethrogram of the scaphoid megalourethra in this PBS patient.

Histologic studies of the ureteral wall by Stephens (100) show fibrocytes, collagen, and smooth muscle in varying proportions. Other histologic studies show that the ureteral wall is composed primarily of a thick, hyaline ground substance that is acellular (24,38,69).

The poor quality of the distal ureter makes this segment a poor choice for reconstructive procedures or urinary diversion to the skin. Because the upper urinary tract dilation is nonobstructive, diversion is seldom required .

Bladder

The PBS bladder is enlarged and thick walled but not usually trabeculated. The dome of the bladder may have a pseudodiverticulum where the urachus is attached (Fig. 48C.4). Occasionally, the urachus is patent, especially when there is complete urethral atresia. The bladder is irregular, and diverticula may be present. The trigone is splayed, the ureteral orifices are laterally and superiorly displaced (100), and vesicoureteral reflux is present in 75% of the cases (20).

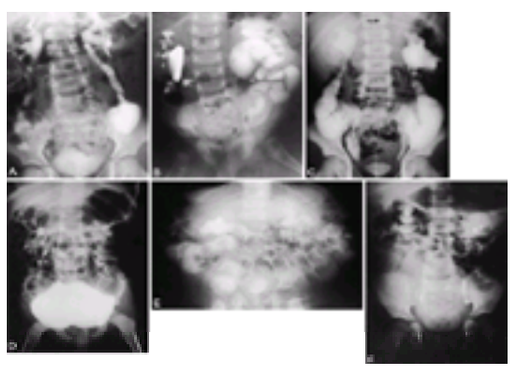

FIGURE 48C.4. A–E: Typical prune-belly syndrome urinary tract, representing a variety of cases with different degrees of dilation and tortuosity. All of these patients are being managed successfully without extensive reconstructive surgery. The patient in **B** is the same patient as in Fig. 48C.5. **B:** After excision of the urachal diverticulum and partial cystectomy. Note the typical distal tortuosity and more prominent dilation. **F:** Patient shows cystic changes in the calyces and a large bladder.

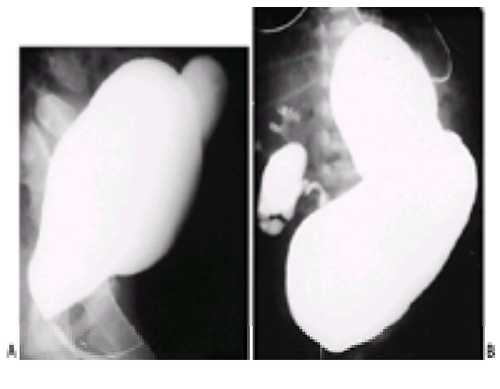

FIGURE 48C.5. A, B: Prune-belly syndrome bladders with urachal diverticula. Note the wide open bladder neck in **A** with narrowed area at membranous urethra.

The bladder has a variable histologic picture. Smooth muscle cells are intermixed with fibrocytes and collagen. Some portions of the bladder wall may be devoid of muscle cells completely. In some studies, actual muscle cell measurements show no evidence of hypertrophy (15,101). Workman (129) showed that some bladders display smooth muscle hypertrophy consistent with an obstructive etiology.

During voiding, the bladder neck opens widely and the intravesical pressures usually remain normal (67,98,119). Some patients are able to empty their bladders

completely; however, many have significant post void residuals. The latter may indicate abnormal bladder dynamics or a relative outflow obstruction (98). In an analysis of 34 patients with PBS (51), three distinct uroflow patterns were identified. These were normal initiation and peak flow, prolonged steady low flow, and an intermittent pattern. The pattern was not predictive of the ability to empty. Lee (55) found that some bladders improve their tone and emptying with age.

Prostatic Urethra

During voiding, the prostatic urethra markedly dilates, tapering down to the membranous urethra. These findings are characteristic of PBS (Fig. 48C.5). To the inexperienced observer, the PBS prostatic urethra may resemble posterior urethral valves (Fig. 48C.6). Valvular obstruction in conjunction with PBS is rare. Most of the prostatic urethral dilation is posterior, and there is occasionally evidence of a small utricle. The verumontanum can seldom be seen on the voiding studies. The membranous urethra is usually of normal caliber, and the distinct diminution of caliber from the prostatic urethra to the membranous urethra has led many to assume that there is obstruction at this point.

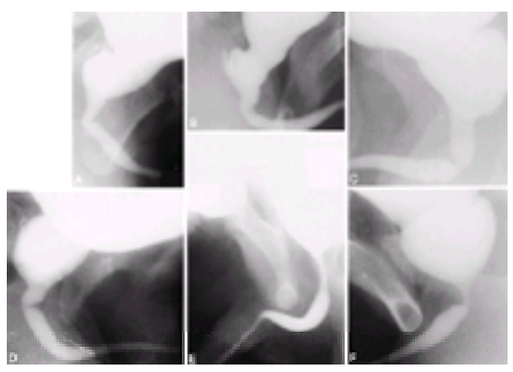

FIGURE 48C.6. Typical urethra of prune-belly syndrome. **A–F:** Six examples of the bladder neck, prostatic urethra, and anterior urethra.

Occasionally, obstructive lesions have been found in the prostatic urethra. An autopsy series search by Wigger and Blanc (115) revealed stenosis in 4 of 14 patients, atresia in 3 of 14 patients, and urethral valves in 4 of 14 patients. Manivel (58) found stenosis in 5 of 25 patients, atresia in 5 of 25 patients, and urethral valves in 4 of 25 patients. These findings are distinctly uncommon among living patients. Stephens (100) carefully studied the prostatic urethra and noted anterior folding of the mucosa, which in some cases overlapped the urethral outlet, having a valvelike effect.

Prostate

Prostatic maldevelopment in PBS is the rule. Few normal epithelial elements are found on histologic evaluation (16,62,79). The PBS patient also has an abnormal verumontanum and seminal vesicles. Because these structures are normal in urethral valve patients, this implies that the prostatic abnormality may be secondary to disturbed mesenchymal-epithelial development rather than obstruction (103).

Anterior Urethra

The anterior urethra in PBS patients is usually normal. Occasionally, a membranous urethral stenosis or atresia is present in the more severe cases; however, this is usually associated with a patent urachus. Without urethral or urachal patency, these patients usually are stillborn or die as newborns.

The occurrence of megalourethra is seen more frequently in PBS than in any other condition (4,65,93). Megalourethra occurs in two distinct types: fusiform and scaphoid (91,102). An absence of all three corporal bodies characterizes the fusiform type of megalourethra, which is the more severe defect. It results from a failure of the mesoderm in the urethral folds to develop, leading to an epithelium-lined urethra adjacent to a fibrous wall of the tunica albuginea (17). The fusiform type of megalourethra has been strongly associated with PBS and stillbirths (20,93). The scaphoid type of megalourethra is less severe (Fig. 48C.7) and results from failure of mesenchymal elements to invest the urethra. This explains the absence of spongiosal tissue in these patients. In a review of the literature (93), nearly 50% of patients with scaphoid megalourethra had PBS.

FIGURE 48C.7. Posterior urethral valve. This patient does not have prune-belly syndrome (PBS). This voiding study is shown to demonstrate the difference between posterior urethral valves and the typical PBS urethra.

Kroovand and associates (53) described milder urethral abnormalities, including a fusiform dilation of the bulbous urethra and similar dilation of the pendulous urethra. These abnormalities are usually not significant. In general, the phallus of PBS patients is long and slender with some curvature dorsally. Hypospadias has been reported.

MANAGEMENT

Therapeutic Considerations

Varied approaches to the management of the PBS patient have been advocated, ranging from watchful waiting with selective surgical intervention (20,120) to immediate newborn reconstruction without prior diversion (43,49,73,113,122).

In the 1950s, clinical outcomes with PBS were poor, and aggressive immediate surgical drainage followed by later reconstruction was the recommended management for PBS. This approach supposes that the urinary tract dilation is secondary to obstruction and that massive reflux and residual urine leads to further renal damage or both. This reconstruction includes excision of the distal half of the ureters with tapering reimplantation of the healthier upper portion of the ureters into the bladder. In addition, the size of the bladder is reduced, and the testes are brought into the scrotum without division of the spermatic vessels. This approach has been successful in achieving radiographic improvement and perhaps stabilizes renal function and decreases the incidence of infection (49,121).

Early intervention to create nephrostomy drainage, ureterostomies, or tube cystostomies may change a balanced though dilated urinary tract into one that will require reconstruction. Intervention may be prescribed in patients with rising blood urea nitrogen (BUN) and creatinine and acidosis. Although high diversion is rarely indicated, a cutaneous pyelostomy may be performed if the systems are redundant and stagnant (82,90). Cutaneous ureterostomies should be discouraged in these

patients because the upper ureter is more normal and should be used in subsequent reconstruction (123).

An approach of limited surgical intervention has been applied. The dilation in PBS is low pressure and nonobstructive, and reflux should not lead to renal damage without infection (19,21,97). This approach includes careful monitoring of the child during the first several days of life. The BUN concentration, creatinine level, and electrolyte values should be followed and should stabilize at acceptable levels (creatinine of 1.0 mg/dL or less). Spontaneous voiding should be observed for stream force and bladder emptying. Gentle bladder massage usually leads to a bladder contraction and allows evaluation of bladder function. With the urinary tract full of urine and easily palpable through a lax abdominal wall, it is difficult to avoid the temptation to achieve better drainage surgically. Catheter drainage should be discouraged because infection is likely to result. Selective surgical intervention is required if the child does not do well on prophylactic antibiotics.

A policy of watchful waiting can be very successful (Fig. 48C.8). The collecting system can distend to alarming proportions but without the significant pressure increase that would be associated with obstruction. Certainly, there are bona fide indications for surgical intervention. Before embarking on such a course; however, remember that there are quite a few reported and unreported technical failures leading to permanent diversion or rapid renal failure (18).

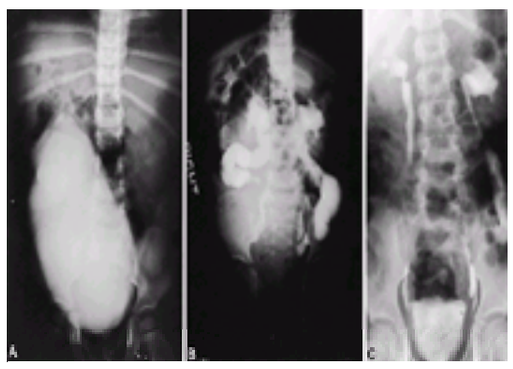

FIGURE 48C.8. A: Patient with prune-belly syndrome cystogram with large bladder but no reflux. **B:** Intravenous pyelogram with full bladder. **C:** Several years later when voiding dynamics balanced. No reconstruction was done.

There are several large clinical series showing that the management of PBS is variable and must be highly individualized with regard to timing and selection of surgical procedures (10,19,30,124,127). This probably reflects the spectrum of the PBS pathology. In general, the “good prunes” (good renal function and capacity for bladder emptying) do very well, but “bad prunes” (renal dysplasia, massive hydrouretero nephrosis, and poor bladder emptying) do poorly. As with posterior urethral valves, bladder function and emptying play an important role in upper tract outcomes. If bladder function is good, it is less likely that upper tract surgery will be required.

Infection

Infection can be devastating in the stagnant but balanced urinary tract of a PBS patient. Antibiotics in the neonatal period and long-term prophylactic antibacterial therapy with a sulfonamide or nitrofurantoin should prevent this complication. When urosepsis is present, the already poor ureteral peristalsis and bladder contractility are suppressed and surgical drainage may become necessary.

Anesthetic Considerations

These anomalies present particular problems with anesthetic management and sedatives (39,50). It is recommended that newborns have apnea monitors. A 25-year review of the Great Ormond Street experience (42) revealed a 6% incidence of postoperative upper respiratory infection. There were three postoperative deaths in 133 anesthetics. Only one of these was directly related to PBS. Normal doses of muscle relaxants may be used in these patients, but active physiotherapy is required postoperatively along with judicious use of analgesics.

Cutaneous Vesicostomy

When diversion of the dilated urinary tract is indicated, cutaneous vesicostomy is the diversion of choice (22). This procedure vents the entire urinary tract with a pop-off system of decompression. The dome of the bladder is secured to the abdominal wall through a small transverse incision midway between the symphysis and umbilicus. In PBS patients, in contrast to other patients with vesicostomies, a generous stoma is created because stenosis is a common occurrence. If a urachal pseudodiverticulum is noted, it is excised at the time of cutaneous vesicostomy. The urine is simply allowed to drain into a diaper, and prophylactic antibiotics are continued.

Reduction Cystoplasty

In some PBS patients, the bladder is enormous. Emptying is infrequent and incomplete. Some investigators have recommended a reduction in bladder capacity in hopes of improving bladder emptying (76). This procedure has been done in many ways. Generally, the dome and pseudodiverticulum of the urachus are excised, and the bladder is reapproximated in the midline (123). Williams and Parker (120) recommended bladder plication rather than excision, whereas Hanna and colleagues (38) proposed excision of bladder mucosa with overlapping detrusor flaps to augment the bladder emptying.

Urethrotomy

Despite the fact that the anterior urethra and membranous urethra in PBS patients are usually normal, a significant number of patients (30% to 50%) have difficulty with bladder emptying. Cukier (14) proposed urethrotomy of the membranous urethra (Fig. 48C.9) to improve bladder emptying. It is thought that the urethrotomy reduces the normal urethral outlet resistance that overbalances the diminished PBS detrusor contractile strength. Woodhouse (125) reported proper bladder emptying in four of five patients after urethrotomy, and Williams (117) reported urodynamic improvement following urethrotomy in most patients.

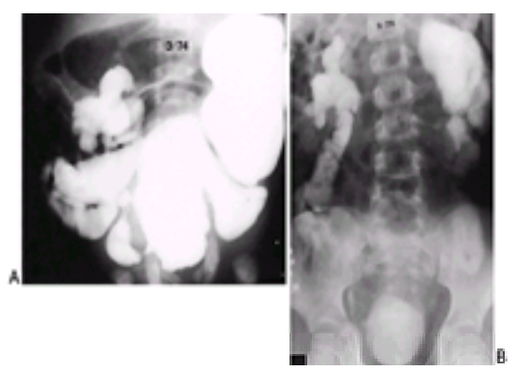

FIGURE 48C.9. A: Patient with prune-belly syndrome with cystogram at 1 month of age. **B:** Same patient 5 years later after a ureterocalycostomy of the left system and urethral sphincterotomy.

Anterior Urethra

PBS may be associated with either urethral atresia or megalourethra. Passerini-Glazel (75) reported the progressive soft dilation of the urethra (PADUA) resulting in a normal caliber urethra. When this is not successful or in cases of megalourethra, repair should be based on sound principles of hypospadias repair.

Vesicoureteral Reflux

Three-fourths of PBS patients demonstrate vesicoureteral reflux (20). However, the indications for antireflux surgery in the PBS patient should be different (21,114). Because the PBS patient has dilated ureters, the pressure from the vesicoureteral reflux is dissipated and does not reflect directly onto the renal papilla. It is technically difficult to prevent reflux and not cause some degree of obstruction at the ureterovesical junction because of the poor peristaltic function of the ureters. Reflux without infection does not lead to renal deterioration. If infection becomes a problem in the young patient, cutaneous vesicostomy is the preferred temporary surgical procedure.

If an individual patient requires antireflux surgery as a result of recurrent urinary tract infections, it is best to use the most proximal portion of the ureter that comfortably reaches the bladder and to excise the redundant distal ureter. If the reflux is unilateral, a transureteroureterostomy may be considered and can effectively bypass the ipsilateral reflux.

Abdominal Wall Plication

The abdominal wall laxity usually improves as the child matures. However, Ehrlich (25) and Parrott (74) believe that the appearance may be “psychologically crippling” in many patients. Children may wear a corset, but abdominal wall plication has been used to correct this deformity. Vertical abdominal wall plications are sometimes unsatisfactory because the laxity can return. Duckett (20) and Stephenson (104) reported that after vertical abdominal wall plication many of the patients returned to a more lax state. Ehrlich and colleagues (25) described a midline abdominal incision with plication of the fascia rather than excision. A subsequent modification by Monfort (63) allows preservation of the umbilicus.

Randolph and associates (83) studied the distribution of musculature and noted that the upper abdominal musculature was more normal. They used a transverse lower abdominal incision, removing the lower abdominal musculature, skin, and peritoneum. This technique nicely reconstitutes the patient's waistline, and in many patients has a pleasing cosmetic result (Fig. 48C.10). It can often be combined with orchiopexy or other reconstructive procedures when necessary.

FIGURE 48C.10. Plastic repair of abdominal wall. **A:** Abdomen of neonate with prune-belly syndrome. **B:** Elliptic portion of the lower abdominal wall to be excised. **C:** Early postoperative result. **D, E:** Preoperative and postoperative appearance in an older child.

Smith and associates (95) reported that abdominoplasty resulted in improved urinary tract emptying; however, the procedure was performed in conjunction with major urinary tract reconstruction and tailoring, and the relative contribution of the abdominoplasty must be questioned. It is possible that in the presence of repeated problematic pulmonary infections, plication may support a more effective cough.

Orchiopexy

All male PBS patients have bilateral undescended testes. The testicles are usually found in the abdomen on a broad mesorchium overlying the iliac vessels but may be found at any point along the pathway of normal testicular descent. In some patients, the testes may be placed in the scrotum with conventional orchiopexy techniques. Woodard and Parrott (121,122) recommended a transabdominal neonatal orchiopexy in which the spermatic cord vessels can usually be mobilized to allow the testes to be positioned dependently in the scrotum without vascular compromise. It may be performed in conjunction with neonatal reconstructive surgery or at the time of vesicostomy.

Fowler and Stephens (26) described a technique wherein the spermatic vessels are divided and the testicle is placed in the scrotum on a vas and peritoneal pedicle blood supply. The success rate with this technique is approximately 75% (9,31). This procedure allows the high intraabdominal testicles to be brought into the scrotum when the vessels are too short. The decision to do this procedure must be made before dissection around the testicle, which would disrupt the vasotesticular collateral blood supply. It has been recommended that the contralateral spermatic vessels be ligated at the time of the ipsilateral orchiopexy so that when the second orchiopexy is done at a later time, collateralization will have already developed. Microvascular autotransplantation, anastomosing the spermatic vessels to the inferior epigastric vessels, is feasible once the spermatic vessels are of sufficient size (at 5 years of age) with a success rate of approximately 80% (9).

SEXUAL FUNCTION AND FERTILITY

Woodhouse and Snyder (128) studied the sexual function of adult male PBS patients and found that erectile function was normal. Most patients had normal orgasm; however, seminal emission was absent in 7 of 8 patients. The fertility potential in these patients has always been in doubt (108,128). Before the advent of assisted reproductive techniques, no male PBS patient had documented fertility. This is most likely on the basis of poor prostatic function and seminal fluid, the abnormal configuration of the prostate and bladder neck, vasal anomalies and abnormal spermatogenesis. Both semen and postejaculate urine have been examined for the presence of sperm, and none was found (128). In the Woodhouse series, orchiopexy was done in late childhood or early adolescence The confirmation of germ cells in the PBS testes gives an indication for early efforts to place the testes in the scrotum (70). There is a reported case of sperm retrieval from a male with PBS, intracytoplasmic sperm injection, and twin live birth (52).

RENAL FAILURE AND TRANSPLANTATION

Approximately 25% to 30% of PBS patients will develop renal failure. This is either a developmental (renal dysplasia) or acquired (urinary tract infection and pyelonephritis) problem. A histopathologic evaluation (85,86) showed that the most severe renal changes in patients who developed renal failure after infancy were those of chronic inflammation and reflux nephropathy with lesser involvement of the kidneys with dysplasia when compared to infant kidneys. This stresses the importance of vigilant prevention of infection in these patients.

Reinberg (84) reviewed the Minnesota experience with renal transplantation. There was no significant difference in patient death, graft survival, or graft function between PBS patients and controls. Urinary tract undiversion was performed prior to transplantation, and intermittent catheterization was routinely used in the presence of chronic urinary retention. These results are in contrast to the results with renal transplantation from the same institution that show an adverse effect on allograft survival and function in posterior urethral valve patients.

INCOMPLETE PRUNE-BELLY SYNDROME

By definition, PBS must have the triad of an abnormal urinary tract, abdominal musculature laxity, and undescended testes. However, there is an occasional patient who has two of the three elements required for the diagnosis. Most commonly the abdominal wall is normal and typical urinary tract findings are present in conjunction with cryptorchidism, although the testes are often palpable. These patients frequently have a similar clinical course to PBS patients and need the careful follow-up demanded for patients with this syndrome. Renal failure occurs in up to 50% in some series (7).

Female patients with deficient abdominal musculature and the characteristic findings of the urinary tract have been seen (81,85,86). The frequent occurrence of bladder outlet obstruction in the Reinberg series suggests a role in the pathogenesis of the syndrome. The occurrence of associated anorectal anomalies is high (40%), and the perinatal mortality was 40%. In addition, two of four surviving patients developed renal insufficiency.

PROGNOSIS

In the past, PBS portended a poor prognosis, but PBS represents a wide spectrum of disease. The outcome greatly depends on the amount of renal hypodysplasia and renal function and the degree of respiratory embarrassment. The urinary tract is dilated and rarely obstructed, and, with better management of urinary tract infections, the outlook is brighter. Each patient must be dealt with on an individual basis. A course of watchful waiting with selective surgical intervention has been successful in many centers. Early reconstruction is technically challenging but can be safely performed despite the increased risks associated with megaureters and abnormal bladder dynamics.

In 1926, Keyes posed several questions that were prophetic in that they raised the same queries that we are faced with today in understanding the interaction of urinary tract infection (UTI) and reflux. These questions asked why some bacteria were pathogenic and others were not and how they get to and damage the kidney. Galen (147) in medieval times, recognized that reflux was abnormal when he observed the function of the ureterovesical junction in the dissected dog bladder. Others, including Pozzi (149), observed reflux in experimental animals and in humans but were unable to draw conclusions as to whether it was abnormal or not. Sampson (171) observed that the normal obliquity of the ureter through the bladder prevented reflux, and in one operated patient with an end-to-side ureterovesical anastomosis, reflux occurred. He further recognized that when reflux occurred, it could conceivably be a cause of renal infection. Sampson's work was reviewed by Young, who stated that he had come to a similar conclusion in 1898 regarding the normal ureter and that in patients who had a normal ureterovesical junction, there was no reflux, even when the bladder was forcibly distended through a catheter. It is of interest that, whereas reflux occupies a significant portion of a textbook on pediatric urology today, major texts on pediatric urology from the early 1950s from both the United States and Great Britain contained only one or two pages on reflux (32,68).

The point at which reflux became recognized as important had its genesis in Hutch's classic studies in 1952, demonstrating the effect of reflux in paraplegic patients and its relationship to chronic pyelonephritis. Before then, operations on the ureterovesical junction had been performed and the methodology of cystograms had been developed; however, the clinical implications of reflux were not recognized. This work of Hutch was followed by the observations of Hodson (74) that reflux was more common in children with UTI and that there was a high correlation between reflux and chronic pyelonephritis as seen on intravenous urogram (IVU). These classic studies ushered in a modern era of the development of surgical techniques to treat this disease and extensive studies on the natural history of reflux. More important, they laid the foundation for the development of the specialty of pediatric urology.

PEDIATRIC URINARY TRACT INFECTION

Etiology, Incidence, and Classification

The incidence of UTI is highest during childhood and decreases steadily until adolescence (Fig. 48D.1). In the first 2 years of life, UTI is a common problem, with the cumulative risk of having a UTI almost equal between boys and girls: 2.2% versus 2.1% (85). In uncircumcised boys, the risk of UTI is greatest in the first 6 months.

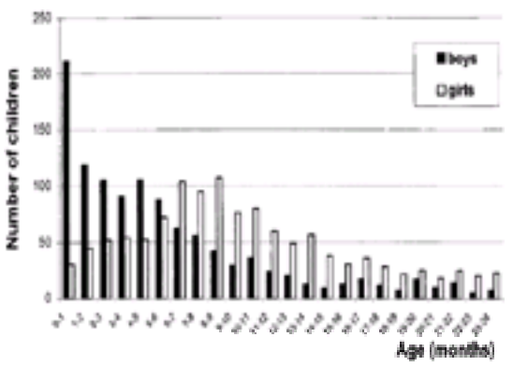

FIGURE 48D.1. Age and sex distribution of children presenting with first urinary tract infection. (From Jacobsson B, Esbjorner E, Hansson S. Minimum incidence and diagnostic rate of first urinary tract infection. *Pediatrics* 1999;104:222.)

UTI is a common presentation in children with abnormalities of the genitourinary tract. Indeed approximately 50% of children younger than 12 years of age who present with UTI are found to have such abnormalities (188). Traditionally, children have been classified according to whether they had a complicated or uncomplicated UTI, but the data that made this classification valid are changing. In the past, complicated infections were those associated with congenital abnormalities, most often reflux. The clinical symptoms associated with these infections included fever, lethargy, failure to thrive, and abdominal pain. Uncomplicated infections were not associated with congenital abnormalities and were more likely to be associated with lower tract symptoms. The primary factor in this changing classification has been the common use of newer imaging modalities that have altered the way we look at both UTI and reflux. The most important of these new modalities has been DMSA (dimercaptosuccinic acid with labeled technetium) scintigraphy, particularly when used with single-photon emission computed tomography

(SPECT) imaging. Current data suggest that most patients presenting with a febrile UTI who have DMSA scintigraphy evidence of acute pyelonephritis will not have reflux (119). On the other hand, renal scarring, as determined by DMSA scintigraphy, is commonly associated with vesicoureteral reflux (VUR) (36). The relationship, however, is loosely correlated because renal scarring also occurred in neonates, suggesting that some of the lesions seen are a congenital dysmorphic process. Indeed, Anderson and Rickwood (8) found that 71% of uninfected neonates with grade III or higher VUR had renal scarring on DMSA scintigraphy similar to that seen with older children, suggesting congenital renal dysmorphism as the possible cause.

Perhaps the classification of UTI that is the most important is that associated with renal scarring, as opposed to that without renal scarring. In 1997, an expert group of panelists performed a meta-analysis of the VUR literature and decided that renal scarring was the most important endpoint in the treatment and that its presence was the principal factor in deciding management (48).

A number of host and bacterial factors have been proposed as important in the etiology of UTI (160). Many of these host factors are genetically determined and thus cannot be altered as a form of management. It is important to discuss with the family those etiologic factors that can or cannot be altered with management. A major factor in the etiology of UTI has been the discovery of its association with functional elimination syndromes (99). Dysfunctional voiding problems include bladder instability, infrequent voiding, lazy bladder, and Hinman syndrome. Bowel symptoms include chronic constipation and encopresis. These symptoms are associated with an increase in the number of UTIs, an increase in breakthrough UTIs while taking prophylaxis, and delayed resolution of VUR. They are also associated with a higher complication rate from antireflux surgery (137). Loening-Baucke (110) found that the incidence of UTI decreased after bowel dysfunction was treated. The treatment of dysfunctional voiding, discussed more fully in another chapter, includes measures such as timed voiding and anticholinergic therapy. Bowel retraining and treatment of bowel disorders are equally important in reducing the incidence of UTIs. Treatment includes dietary increases in raw vegetables, fruits, and fruit juices; use of whole wheat breads; and a limitation on milk and milk products. Stool softeners, mild laxatives, and enemas are also used to establish regularity.

A controversial area is the relationship of UTI in male neonates to the presence or absence of foreskin. In 1985, Wiswell and associates (228) presented their initial report of a decreased incidence of UTI in circumcised versus noncircumcised male infants. A follow-up study reviewing a larger number of patients showed a tenfold increase in UTIs in uncircumcised male infants: 1.12% versus 0.11% (227). Of interest was that a large number of these infected infants required hospital admission for management of clinical pyelonephritis. This study was the impetus for these investigators to look further at the relationship of UTIs and circumcision with the finding that decreased numbers of routine neonatal circumcisions were being done and that this correlated with a rising number of neonatal male UTIs (225). Winberg and co-workers (222) suggested that perhaps the prepuce was a “mistake of nature”; but rather than suggesting circumcision as a cure, it was suggested that the prepuce be colonized with a nonpathogenic anaerobic gastrointestinal bacteria from the mother. Wiswell and Geschke (226) also have looked retrospectively at the sequelae of UTIs in the noncircumcised male infant. They found a much higher incidence of bacteremia, renal failure, and death. This retrospective study has a serious flaw in that the results do not state whether these patients had any other associated risk factors, such as obstructive uropathy or VUR. The intact foreskin has also been suggested as an etiologic factor in acute epididymitis in boys (19). A large study from the Department of Public Health in Toronto found an increased risk of UTI and hospitalization in noncircumcised boys but much less than previously published data. The study questioned the efficacy of routine circumcision as a means to protect boys from UTI (205). The Fetus and Newborn Committee of the Canadian Pediatric Society (52) did an extensive review of 122 articles on circumcision and came to the conclusion that “circumcision of newborns should not routinely be performed.” The Task Force on Circumcision for the American Academy of Pediatrics (6) made a similar policy statement indicating that although medical benefits did result from circumcision, they were not sufficient to recommend routine neonatal circumcision. The British Journal of Urology (28) recognized the tremendous emotional concerns about circumcision and devoted an entire supplement to the subject.

Although less controversial, labial adhesions in young girls have raised similar questions as to the relationship with UTIs. The relationship has a theoretical scientific basis on the grounds that it might promote abnormal perineal bacterial colonization, but there are no data to support this. Labial adhesions in young girls with UTIs should be treated. The initial form of treatment is estrogen cream applied daily after the child's bath for 3 weeks and then some mild ointment daily to prevent recurrence. For the latter, one can use vitamin A and D ointment. If estrogen treatment is not effective, the adhesions can most often be broken down in the office by applying EMLA cream for 45 minutes and painlessly forcing the adhesions apart. One can then follow with A and D ointment as just described. It is rare for a child to require surgical therapy of labial adhesions.

Pathogenesis

Bacteria that cause UTI are most often aerobic Gram-negative rods that are normal inhabitants of fecal flora. These organisms reach the bladder and kidneys through ascent from the rectum to the perineum, vagina, and urethra. The anatomic differences between males and females account primarily for the difference in the incidence of UTIs. These differences include the longer urethral length and the absence of the moist perineal-vaginal area in the male.

Bladder infection is the result of the relationship between virulent bacteria and the mucosal surface of the bladder. Factors that make bacteria virulent include the presence of pili, which may allow adhesion with uromucoid surfaces, and the nature of bacterial cell wall antigens and their association with hemolysin and colicin, which gives it a competitive advantage against other bacteria. Mutations on the surface of pili also may allow bacteria to adapt to changing conditions in the bladder.

Bacterial adherence is theoretically a vital link in the development of pyelonephritis. The subject is reviewed in the monograph by Schaeffer (174). It has been common knowledge among bacteriologists for some time that bacterial adherence is a property that allows colonization of surfaces. Recently, the role of adherence as a pathogenic phenomenon has been explored. Colonization of the alimentary tract and mucosa-lined orifices takes place within the first few weeks after birth. Colonization of the gut by pathogenic organisms is the first step in the process that eventually produces renal scarring. The adherence of pathogenic bacteria to the perineum, vagina, urethra, or bladder wall resists the natural action of those structures to wash the bacteria away. Adherence is, in part, due to the interaction between binding molecules on the bacteria (ligands) and receptors on the host cells. This bond between bacteria and host cells is so well developed that it is almost impossible to reverse. Bacterial ligands are located on fimbriae that provide the initial contact between bacteria and host cells. Fimbriae may be of several types, but any one bacterium will have only one type. Type 1, or mannose-sensitive fimbriae, are very common on nonpathogenic stereotypes of *Escherichia coli.* These fimbriae are so called because they react with a mannose sugar on the host cell surface. Mannose-resistant fimbriated bacteria are more likely to be pathogenic and have been implicated in pyelonephritis in children. Some mannose-resistant *E. coli* have fimbriae that possess P blood group bacterial adhesions and thus are referred to as *P pili bacteria.* The importance of these P pili bacteria is that they are implicated in a large number of children with clinical acute pyelonephritis. Kallenius and associates (90) found P pili *E. coli* in 91% of children with acute pyelonephritis. Acute pyelonephritis was defined as UTI with temperature greater than 38°C, elevated C-reactive protein level, and elevated erythrocyte sedimentation rate. Of the 150 strains of *E. coli* identified by O antigens, 9 are present in most UTIs (122).

The problem in relating this finding to renal scarring is that many of the children in both studies did not have reflux; conversely, the study by Lombard and associates (111) indicated that very few children with severe reflux and renal scarring have demonstrated infections with P pili bacteria.

Although renal scarring does occur in the absence of reflux (154), the rate at which it does so is unclear. Thus we are left with the conflicting data that suggest that the P pili *E. coli* is a very virulent strain, easily causing renal damage in experimental situations, and yet uncommonly is related to the renal scarring in children that is the focus of this chapter. Other types of adherence may occur in severely refluxing children and may account for the development of renal scars. It has been shown that both capsular K and cell wall O antigens can cause adherence, and these antigens are present in a large number of *E. coli* organisms. K antigen is present within the capsules of virulent Gram-negative organisms and is believed to protect against phagocytosis and inhibit host immune response.

These organisms also commonly have fimbriae that show mannose-resistant hemagglutination and fail to react with mannose on the host cell surface. Some mannose-resistant bacteria also express P blood group ligands on their fimbria, a property that further enhances bacterial adherence to the urothelium and renal epithelial cells (109,211). Some authors suggest that the adherence of bacteria to urothelial cells is independent of the P blood group antigen in the host (113), whereas others note that patients with the P1 blood group have a relative risk of pyelonephritis 11 times that of normals (159).

The ability of bacteria to adhere appears to also be affected by host epithelial cell surface receptors or soluble receptors in the urine. *E. coli* infections, for example, occur with greater frequency in children with Lewis (a-b-) phenotype, which is postulated to promote bacterial adherence (86). Tamm-Horsfall protein, which is secreted by the proximal renal tubules, binds to certain nonfimbrial adhesins and can prevent bacterial adherence to mucus (glycoproteins or glycosaminoglycans) that normally coats the urothelium (140). Differences in IgA (1), blood group antigens (25), and the amount of mucopolysaccharide (141) secreted by the bladder epithelium may also contribute to sexual and individual differences in the propensity to UTIs. However, no significant difference in genetic markers has been shown in children in the first year of life (3).

Other virulence factors, including hemolysin, aerobactin, and bacterial iron-binding capacity, contribute to the host inflammatory response and degree of tissue destruction (169). Bacteria that express three or more virulence factors are usually the cause of acute pyelonephritis in the absence of reflux. Less virulent bacteria can cause similar episodes in patients with reflux (112). In theory, once bacteria adhere to ureteral urothelium, endotoxins cause a decrease in ureteral motility,

ureteral dilation, and an alteration in papillary configuration, thus allowing intrarenal reflux (158).

The bladder defense mechanisms include the mucosal surface of the bladder and the emptying capacity of the bladder. The mucosal surface of the bladder, its glycosaminoglycan layer, and its propensity for infection may be determined genetically. Surface cells produce secretory IgA that may help prevent bacterial colonization (1). Bladders that do not empty effectively leave urine behind; this promotes greater contact with bladder mucosa, which fosters bacterial growth. Many conditions may allow poor emptying of the bladder, including neurogenic bladder, VUR, and obstructive uropathy. In the normal individual, other factors inhibit the growth of bacteria, including the osmolarity and acidity of the urine.

Bacteria that reach the kidney and cause pyelonephritis have a similar relationship to the surface of the renal pelvis and collecting ducts of the renal medulla as bacteria do to the bladder. These bacteria reach the kidney more commonly when reflux or obstruction is present, but they also can reach the renal pelvis in a perfectly normal system. Pyelonephritis occurs when there is an inflammatory response in the medulla; leukocytes are mobilized to combat the infection, and the resulting phagocytosis of bacteria, with the release of high oxygen radicals, is a factor in eventual renal scarring.

The renal scar may develop very quickly or take quite a long time. Ransley and Risdon (152) have proposed that some scarring in infants with intrarenal reflux takes place immediately after a severe pyelonephritic episode and have called it the “big bang” effect. They acknowledge that in some instances, the process takes longer, perhaps in a series of “little bangs.” Friedland (53) has indicated that the full growth of a renal scar may take place over as long as 2 years.

The actual process of scarring probably is due to the normal cellular response to the invading bacteria. The same processes that come into effect to kill the bacteria also damage the tubular cell wall. Roberts (156) has theorized that once bacteria adhere to renal tubular cells, an immune response is elicited. During phagocytosis, superoxide is released in a respiratory burst from the cell wall and damages both bacteria and tubular cells. This damage causes an interstitial inflammatory response that leads to renal scarring. In the monkey, administering superoxide dismutase (163) can block the scarring and inflammatory response. Furthermore, Roberts and co-workers (161) have been able to block adherence to tubular cells by immunization with an antifimbrial antibody. Immunization with a less purified *E. coli* mixture that had a mild protective effect against renal scarring also has been performed in piglets (207). New data from Langerman and colleagues (103) suggest that other factors might cause adherence against which immunization may provide protection. FimH, an adhesion, is necessary for colonization with *E. coli* of the bladder wall in some experimental animals, and immunizing with FimH may protect against repeat colonization. All of these findings suggest that immunization might be practical; however, in the long run, antimicrobial agents may provide less expensive and better protection (174).

Ischemic damage to renal tubular cells also can occur as a result of exposure to *E. coli.* Anaerobic metabolism of *E. coli* causes anoxia and consumption of the purine pool, leading to release of superoxide radicals. This process can be blocked by allopurinol (157). The complex mechanism of the development of renal scarring as described by Roberts is depicted in Fig. 48D.2.

FIGURE 48D.2. Schematic representation of pathogenesis of pyelonephritis scar formation. (From Roberts J. Vesicoureteral reflux and pyelonephritis in the monkey: a review. *J Urol* 1992;148:1721, with permission.)

Diagnosis

The diagnosis of UTI can be made on a urine culture obtained from a clean catch or a catheterized specimen. Clean-catch specimens are more likely to be contaminated, but if the growth is a single pathogenic bacteria, it is likely significant. Urine can be obtained easily from infants with a suprapubic bladder puncture or catheterization with an infant feeding tube. Colony counts of 100,000 colonies in a clean-catch urine are usually required to be significant, but any positive culture must be correlated with the symptoms that the patient presents with. Any urine culture greater than 5,000 colonies from urine obtained on a suprapubic puncture or catheterized specimen is significant.

Presentation

Infants and young children with UTIs are more likely to have nonspecific signs or symptoms. The most common serious presentation is with fever, which should trigger a strong suspicion of an underlying urologic abnormality. Other symptoms in young children include failure to thrive, vomiting, diarrhea, anorexia, and lethargy. Children of any age with renal scarring may present with hypertension. Older children and adolescents often have symptoms of bladder irritability, anorexia, or abdominal pain (186). Pain with sterile reflux may be colicky in nature. Older children may complain of flank pain with a full bladder. These symptoms are nonspecific as to localization of infection, but when associated with fever, they are suggestive of upper UTI.

Fever is a key presenting symptom that helps distinguish between children with pyelonephritis and those with cystitis, but it is not always a reliable determinant. Because children with pyelonephritis are more likely to have reflux, this presenting symptom, if reliable, would be helpful in predicting which children would have a positive radiologic evaluation. Woodward and Holden (230) evaluated 350 children with UTI and found that 90% of refluxing children had temperatures greater than 38.5°C, whereas only 40% of nonrefluxing children had similar temperatures. They noted that if only children with fevers had been evaluated, 10% of those with reflux would have been missed. Levitt and co-workers (105) examined the IVUs of children with upper or lower tract symptoms. Only 2 of 99 females with lower tract symptoms had abnormal IVUs, whereas 23 of 57 females with upper tract symptoms had abnormalities. The number of refluxing patients was not indicated in the study. Govan and Palmer (60) found a high correlation between historical evidence of pyelonephritis (presumably fever) and reflux; there was a positive history in 79% of refluxing patients but only 39% of nonrefluxing patients. In the refluxing patients, only 7% still had symptoms of pyelonephritis after successful antireflux surgery. In addition, it was noted that the children with reflux tended to present with UTI an average of 2 years earlier than those without reflux. Smellie and Normand (188) presented data that are in conflict with some of these findings. In their large series of children with UTI, there was no age difference in those with or without reflux. However, children with reflux were more likely to present with fever, and it was particularly evident if there was also renal scarring.

It is difficult to localize infection on a clinical basis, and although a number of laboratory tests have been suggested, most are not in standard use. These tests have included urine concentrating ability, leukocyte excretion rate, antibody-coated bacteria, lactate dehydrogenase (LDH), and the measurement of b_2-microglobulin (134). The clinical diagnosis of pyelonephritis is best made with criteria of fever (greater than 39°C), flank or costovertebral angle tenderness, and elevated white blood cell count. The National Children's Hospital group has advocated DMSA renal scanning as a means of making the diagnosis with a high degree of specificity (7,119). The addition of SPECT imaging allows for even more accurate diagnosis (118,203).

Radiologic Evaluation

The evaluation and management of children with UTI should allow initial treatment of the infection, followed by evaluation after the urine is cleared. The exception is the child in whom it is difficult to clear the infection or when obstructive uropathy is strongly suggested by history; in these instances, an early ultrasound (US) is appropriate. Ferrer and co-workers (51) found that for 99% of pediatric urologists, the two standard radiologic examinations for the child with UTI were renal US and voiding cystourethrography (VCUG). Belman (18) has suggested that all girls younger than 5 years old with UTI should have a US and VCUG as the initial studies, as should any older child with a *febrile* UTI. US by itself is not sensitive enough to diagnose most cases of VUR, particularly with lower grades of reflux (26). It has also been suggested that many children should have DMSA scintigraphy to quantify renal scarring, particularly those with a history of febrile UTI (200). As indicated

previously, the presence of renal scarring is the major determinant for long-term management of VUR. Stokland and co-workers (199) analyzed children 1 year after febrile UTI and found that 38% had renal scarring on DMSA scintigraphy; about 50% of these had VUR. There is no question that the sensitivity of DMSA scintigraphy with SPECT imaging allows for the most accurate diagnosis of renal scarring. In major centers, these studies have virtually eliminated the use of IVU for this diagnosis. The problem with DMSA scintigraphy remains the cost and the difficulty in separating the renal scars into those that are congenital in origin versus those that are acquired.

In addition to structural data, renal scintigraphy can also give functional information that can be used in following the patient or in comparing preoperative and postoperative function. Technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc DPTA) primarily is used to assess glomerular and tubular function; technetium-99m dimercaptosuccinic acid (^{99m}cDMSA) is best for visualizing cortical tissue and measuring renal function; and iodohippurate sodium ^{131}I is used to assess tubular function. MAGIII has recently been used to define renal function and obstruction but may not be as specific for renal scarring.

Nuclear cystograms provide an alternative for the patient who may require multiple or longitudinal studies annually. The study is also an alternative for the evaluation of the female with a first UTI. The methodology is similar to contrast studies and has the advantage of a lowered radiation dosage. Whether nuclear cystography is more sensitive than VCUG in detecting VUR is in question. A large study from Scotland did indicate better sensitivity (127), but a study in which patients were followed to see if VUR resolved spontaneously found that nuclear cystography was not as dependable as contrast VCUG (17). This might be related to the inaccuracy of grading with nuclear cystography as compared with contrast VCUG. The Children's Hospital of Philadelphia outline of evaluation and management of UTI, as depicted in Fig. 48D.3, has been updated to include the role of DMSA scintigraphy.

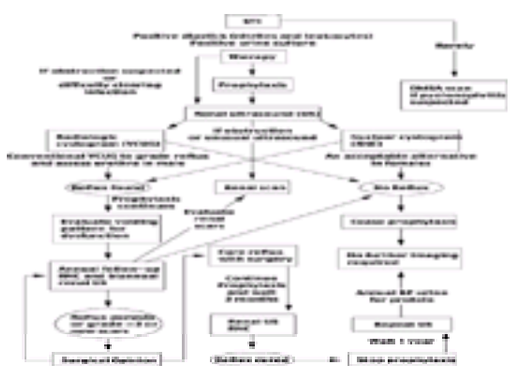

FIGURE 48D.3. Updated Children's Hospital of Philadelphia algorithm for urinary tract infection *(UTI).* BP, blood pressure; DMSA, dimercaptosuccinic acid with labeled technetium; RNC, radionuclear cystogram; VCUG, voiding cystourethrography.(Courtesy of John W. Duckett, M.D.)

Cystoscopy

In the past, cystoscopy has been considered part of the evaluation of UTI and the refluxing child, but this concept is no longer valid. There are several reasons for the decreased emphasis on cystoscopy, including low yield and the added risk and cost of an anesthetic. The likelihood that low grades of reflux (grades I and II, International Classification) will disappear spontaneously is so great that cystoscopic information adds little to the diagnosis or management. For the higher grades of reflux with clear indications for surgical intervention, cystoscopy may be done at the time of reimplantation of ureters. The continued evidence against bladder neck or significant urethral obstruction in female patients obviates cystoscopy performed solely for the purpose of ruling out obstruction. Dilation of the urethra as a routine treatment of UTI or reflux has no place in our current armamentarium and should be left for specific indications (48). A recent meta-analysis of articles dealing with this subject found no data to support urethral dilation or cystoscopy in most patients.

What then are the indications for cystoscopy in the refluxing child, and what information can be gained by the procedure? There are no absolute indications for cystoscopy in the refluxing child. Observation of the contralateral ureteral orifice in unilateral reflux at the time of surgery may be of help in deciding whether any procedure needs to be done to the contralateral side. The child with duplex ureters and reflux or an ipsilateral periureteral diverticulum may represent an indication for cystoscopy. Children with multiple breakthrough UTIs may require cystoscopy before a decision can be made about continuing medical therapy. Cystoscopy may be indicated in select children who also are having urodynamic studies.

The information gained at cystoscopy includes information about the urethra, bladder wall, ureteral orifices, and submucosal tunnels as well as about the external genitalia and vagina. Even though urethral obstruction is rare, the urethra should be calibrated. Visualization of the bladder neck from the urethra may indicate the raised, small, cystic-appearing lesions that are consistent with cystitis cystica. Children with cystitis cystica may have lower tract symptoms, such as urgency, frequency, and incontinence; however, associated reflux still has an excellent chance of spontaneous resolution (29). One of the major problems with cystoscopy in infants and children with reflux is the lack of consistency of observed findings among different examiners. The description by Lyon and associates (115) of orifice configuration is still widely used, although it does not correlate with spontaneous resolution. Duckett (41) found orifice configuration of only minimal value and indicated that even in the most abnormal orifices there was spontaneous resolution of reflux in 15% to 20% of patients. The tunnel length-to-ureteral diameter ratio can be measured nicely by using a 4-Fr whistle-tip ureteral catheter. The submucosal portion of the tunnel can be measured and an estimate of width obtained by comparing the width of the orifice to the width of the catheter (approximately 1 mm). Data should be obtained with both a full and an empty bladder and should indicate whether the orifice is patulous, the degree of development of the trigonal muscle, the degree of trabeculation of the bladder wall, and whether the orifice moves laterally as the bladder fills. The position of bladder diverticula should be noted, particularly in relation to the ureteral orifice. Spontaneous resolution of reflux may occur with periureteral diverticula unless the ureter enters the diverticulum (106). Vaginoscopy and inspection of the external genitalia also should be done at the end of the procedure; the pelvic organs can be palpated effectively with a rectal examination.

Urodynamics

Urodynamics, including cystometrogram, perineal or periurethral electromyogram (EMG), and urinary flow studies, may be helpful in select patients with VUR. These studies are particularly helpful in children with dysfunctional elimination syndromes. Taylor and co-workers (204) showed that 75% of refluxing girls had evidence of uninhibited bladder contractions. Allen (4) has indicated that these uninhibited contractions yield higher intravesical pressures and that, when associated with reflux, may lead to greater renal damage. This assertion, however, is not supported by the data of Taylor and colleagues (204). Koff and Murtagh (98) have treated such patients with anticholinergic therapy and indicate that it may be helpful in resolution of reflux. Cystometric studies are more easily interpretable in the child with low grades of reflux. If uninhibited bladder contractions are detected, appropriate pharmacologic control will often arrest the reflux and associated infection. The cystometrogram is also difficult to do and may be difficult to interpret in the very young child or infant. However, practicality would dictate that urodynamics is not cost-effective.

DEMOGRAPHY OF REFLUX

The demographic information that we have comes from three sources: (a) cystographic evaluation in normal children, (b) cystographic studies in children with UTI, and (c) the study of other animals. The first of these sources of information is largely closed to use because of ethical constraints in obtaining studies in normal children. Studies of children with UTI allow us to look at not only that population but their siblings. Comparisons of experimental animals to humans let us look at those who are close phylogenetically and those that have close anatomic resemblance.

Incidence

The incidence of VUR in normal infants and children is not known and probably varies depending on race and perhaps country of origin. Askari and Belman (10) have reported on the infrequency of reflux in African American children. In their studies of African American children investigated for UTI, the incidence of reflux was only 25% of that seen in infected white children. Extrapolating these data with the lowered incidence of UTI in African Americans, they concluded that the actual incidence of reflux in the normal African American population was 10% of its occurrence in a white population. Although the incidence of reflux was less in African American children, its natural history, once discovered, is the same. Skoog and Belman (184) described the distribution of grade of reflux and spontaneous resolution in African

American children and found it the same as in a larger group of white patients. A recent study evaluated neonates who presented with prenatal hydronephrosis; 58 were African American and 51 non–African American. Of the former, VUR occurred in none and in 17.6% of the latter (78).

The incidence of reflux in other races or national groups is not known, although all of the large reported studies on refluxing patients seem to come from northern Europe, including the Scandinavian countries, Great Britain, and Ireland, as well as North America, Australia, and New Zealand. Manley (121) suggested that reflux occurs more commonly in children with fair skin, blond hair, and blue eyes. Urrutia and Lebowitz (210) refute this and believe that only red-haired children have a higher incidence of reflux.A number of cystographic studies were done in normal children before the time at which human experimentation committees rightly placed constraints. Despite these constraints, the previously gained information is valuable. These studies must be examined critically because there was often no standardization of cystographic technique and the patient populations were not well defined. We know now that it is particularly important because of the racial differences in incidence, and it is likely that in many of these studies, the population chosen for study was unlike the population with UTI. In 1949, Gibson (56) did 43 cystograms in children, using syringe injection of contrast, and found two cases of reflux. Iannaccone and Panzironi (83) evaluated 50 infants without urologic disease and found only one instance of reflux. Although the patient population was not defined, they were all likely of Mediterranean origin. Jones and Headstream (89) evaluated 100 children and found one who had reflux. Race was not defined, and 70% of the patients were males. Lich and co-workers (108) did cystograms on 26 infants less than 48 hours old and found no reflux. Politano (146) had similar findings in 50 normal children. Peters and associates (144) defined race in 66 premature infants studied with cystography. They found no reflux in their group, 56 of whom were African American. In contrast to these studies, all of which showed a very low incidence of reflux, is the study of Kollerman (100), who found that reflux was more common. He examined 161 children with cystography. The technique was admittedly unphysiologic and involved filling the bladder with a syringe to capacities of 40 to 200 mL. No child had a history of UTI or of any urologic problem. Of the group, 18.5% had VUR.

The incidence of reflux in children with UTI is suspected of being much higher than in the normal population, despite our difficulty in defining incidence in this latter group. Shopfner (181) reviewed a large number of children defined as having a UTI by the culture of at least 100,000 colonies of bacteria per milliliter of urine. Reflux was present in 14% of 1,695 females and 29% of 523 males. Baker and colleagues (13) had shown previously that reflux was most common in younger children with UTI, occurring in 70% of children younger than 1 year of age, 25% of children at 4 years of age, 15% of children at 12 years of age, and 5.2% of adults. Compilation studies in children with asymptomatic bacteriuria yielded similar results: 29% of preschool-age females and 23% of school-age females had reflux (213).

Reflux is a commonly occurring phenomenon in some animals (Fig. 48D.4). It occurs in almost all rats and many rabbit species. Christie (34) found reflux in 80% of 3-month-old puppies, but it disappeared spontaneously and was present in only 10% of adult dogs. It is not present in piglets or adult pigs. Roberts (155) indicated that its presence in monkeys is variable and is both age and species related. In his studies on infant rhesus monkeys, reflux occurred almost all of the time in newborns but gradually disappeared, so by 36 months of age, it was uncommon. The disappearance curve was a gradual decline rather than a sharp change and was gone by the time the animal reached maturity. These studies are intriguing because the primates are close to us phylogenetically, and the disappearance curves closely parallel the disappearance of reflux in children with UTI. Figure 48D.5 depicts a comparison between the disappearance of reflux in infant and maturing rhesus monkeys (155) against the disappearance of reflux in a series of children with UTI (13).

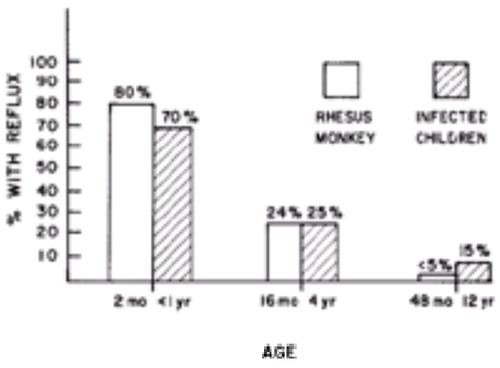

FIGURE 48D.5. Comparison of the disappearance of reflux in infant monkeys (162) to that of children with urinary tract infection (13).

Patterns of Inheritance

The observation that reflux occurs in siblings and parents of affected children has been known for the past two decades, but the actual mode of inheritance has not been determined. Stephens and colleagues (197) noted the occurrence of reflux in twins. Tobenkin (206) reported on a family in which three different generations had evidence of reflux. He suggested that the mode of inheritance might be sex linked, with incomplete penetrance. Mulcahy and co-workers (132) reported on three families in which two members had reflux and also noted that 18% of patients undergoing reimplantation had other family members with a history of UTI. Other investigators reported familial reflux in series ranging from 5 to 20 families (131,176,231).

Dwoskin (44) reviewed 125 families of probands with reflux and found that 26.5% of siblings had reflux. In a similar study, Jerkins and Noe (87) found 33% of siblings showing reflux. The conclusion from both of these studies was that the siblings of all children with reflux should be evaluated, particularly those younger than 2 years of age. This conclusion has been confirmed in studies that have gone on over a decade with the only change in recommendation being that aggressive screening should occur in all siblings younger than 5 years of age (135). A recent study from two centers evaluated siblings to 16 years of age and found largely low-grade reflux in 27% but evidence of reflux nephropathy in some older children. Their data supported screening children younger than 7 years of age (217).

Lewy and Belman (107) believed that a pattern of autosomal dominance was suggested by the occurrence of reflux in a large number of siblings, and that concept is actually supported by recent data (50). The wide variability of reflux in siblings actually gives credence to a polygenic or multifactorial mode of inheritance, as has been suggested by Burger and Burger (31). Polygenic modes of inheritance probably account for the variability of pathologic findings in many congenital urologic conditions, of which reflux and hypospadias may be two of the best examples. The variable factor determined by this mode of inheritance appears to be submucosal ureteral tunnel length. Experimental data in puppies with reflux have indicated that in addition to ureteral tunnel length, a paucity of adrenergic nerve fibers may relate to reflux. The suggestion was that with maturation of the autonomic nervous system and the increase in the adrenergic nerve fibers, there was a concomitant decrease in the incidence of reflux (96). The recent data from Noe and co-workers (136) indicate transmission of reflux from parent to child is significant in that 66% of the offspring of affected parents have VUR. These authors agree that the mode of transmission is almost certainly as a multifactorial genetic trait. However, reflux may be inherited as an autosomal-dominant trait in some instances.

CLASSIFICATION AND TERMINOLOGY

Classification of Reflux

The earliest attempts at classification of reflux tended to broadly quantify the amount of reflux to the kidney or to classify by what was happening physiologically in the bladder. Rolleston and associates (164) classified reflux as being slight, moderate, or gross. These investigators noted that gross reflux was almost always associated with renal damage. Hinman and co-workers (71) introduced the terms *high-pressure reflux* and *low-pressure reflux* to indicate reflux that occurred during bladder filling (low pressure) versus that which occurs during voiding (high pressure). The implication from this distinction was that low-pressure reflux was congenital and would not resolve, whereas high-pressure reflux was more likely to resolve with time. The pressure effect on the kidney was not an issue at that time.

More precise measures of reflux were proposed in both the United States and Europe and have provided the nucleus for the International Classification System that is in current use. Heikel and Parkkulainen (65) proposed a five-category classification system that gained use in northern Europe, whereas in the United States, the Dwoskin-Perlmutter (43) classification system was commonly used. The International Classification System represented one of the first cooperative efforts of the International Reflux Study. It was the belief of the original members of the study group that there were deficiencies in both the Heikel-Parkkulainen and the Dwoskin-Perlmutter systems that could be addressed only by a new system. Rather than discard the other two systems, the best characteristics of each were incorporated in the new system. Particular emphasis was placed on the fornices and calyces, and the anatomy of these structures provided the basis for classification. The International Classification System is shown in Fig. 48D.6. Despite the sophistication of this classification system, it was quickly recognized that clinical patterns of reflux were not neatly compartmentalized; the subtle variation in each grade is illustrated in Fig. 48D.7.

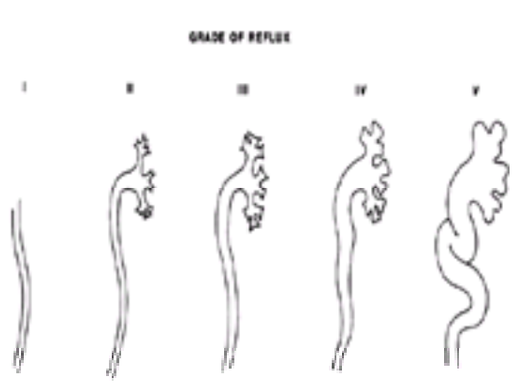

FIGURE 48D.6. International Reflux Classification.

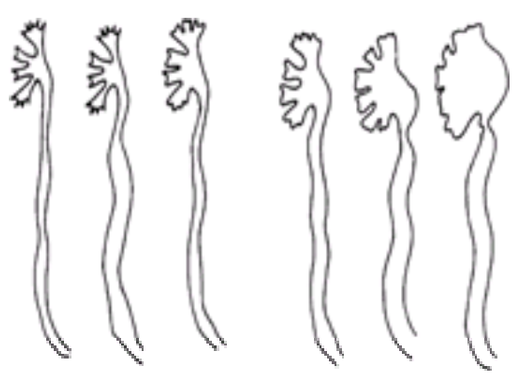

FIGURE 48D.7. Variations with grades III and IV of the International Reflux Classification.

Reflux also can be graded, although less precisely, by nuclear cystogram. Although many radiologists will extrapolate to nuclear cystography the International Grading System, there is no scientific basis for doing so. Indeed, there is no universally accepted grading system for nuclear cystography, with most radiologists simply using the terms *mild, moderate,* and *severe.* Majd and Belman (117) have indicated that the clear advantage of nuclear cystography is the lower radiation dosage, and because of this, it is an excellent tool for screening females and for follow-up studies in both sexes. The disadvantage is the difficulty in recognizing important associated bladder pathology, such as bladder diverticula, or in viewing the male urethra.

Classification of Orifice Shape and Position

The shape and position of the ureteral orifice is primarily of importance in assessing the contralateral ureteral orifice of a refluxing ureter to determine whether it may be incompetent in the future or have refluxed in the past. Paquin (142) has shown that the intramural tunnel is vital to the prevention of reflux. In normal nonrefluxing children, the tunnel length-to-ureteral diameter ratio was 5:1, whereas in refluxing children this same ratio was 1.4:1. It is likely that one needs at least a 3:1 ratio to prevent reflux, although this ratio is not satisfactory with ureters of a large diameter. Cussen (39) has done an exacting study measuring normal submucosal and intravesical ureteral lengths in children of different ages. These data are partially presented and extrapolated in Table 48D.1.

Age (yr)	Intravesical Ureteral Length (mm)	Submucosal Ureteral Length (mm)	Ureteral Diameter at Ureterovesical Junction (mm)
1–3	7	3	1.4
3–6	7	3	1.7
6–9	9	4	2.0
9–12	12	6	1.9

TABLE 48D.1. MEAN URETERAL TUNNEL LENGTHS AND DIAMETERS IN NORMAL CHILDREN

Lyon and associates (115) described four basic orifice shapes: cone, stadium, horseshoe, and golf hole. These four shapes represent increasing levels of orifice incompetency. They believed that orifice shape, rather than tunnel length, determined valvular competency. Mackie and Stephens (116) developed a more complex classification of orifice position that was originally intended for duplex systems but now is generally used for single ureters as well. The system is a complicated one to remember because the authors have related orifice position to the original location of the ureteral bud on the wolffian duct. The three zones of urethral orifice position are depicted in Fig. 48D.8. These classifications are primarily of historical rather than clinical importance because studies have shown poor correlation with cystoscopic findings and reflux resolution (41).

Classification of Renal Scarring

Renal scarring can take a variety of forms (187), as shown in Fig. 48D.9. This classification has less validity today because it was based on IVU interpretation. Attempts to quantify the amount and character of renal scarring are important. Only if precise definitions of scarring and parenchymal thickness are made can one tell if the disease has progressed. This progression is important not only in investigatorial studies that compare treatments but, indeed, in the individual patient who is being followed with medical management. Equally important as the measurement of renal scarring is the measurement of renal growth. Some refluxing patients may exhibit only growth failure as an effect of their reflux. Renal growth is best measured by renal US (166), although Mesrobian and co-workers (128) have shown significant reader error in taking measurements. The results of the International Reflux Study in Children (IRSC) showed that there was another type of injury related to reflux—parenchymal thinning (139). Parenchymal thinning often preceded scar formation but, in some instances, was also reversible.

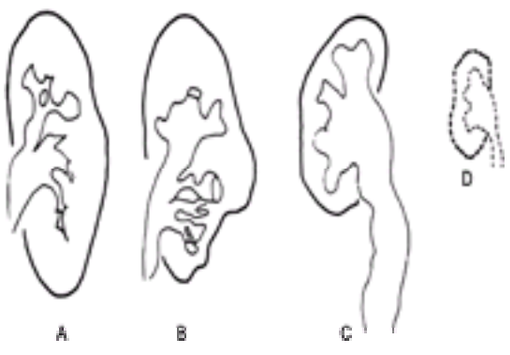

FIGURE 48D.9. A–D: Classification of renal scarring. [From Smellie JM, Edwards D, Hunter N, et al. Vesicoureteral reflux and renal scarring. *Kidney Int* 1975;8(Suppl 4)65, with permission.]

Recent evidence has indicated that DMSA scintigraphy is more sensitive than IVU in detecting renal scarring. ^{99m}CDMSA is an excellent isotope for visualizing the renal cortex. Elison and co-workers (49) evaluated a large number of patients with both IVU and DMSA renal scanning and found a significantly larger number of scars detected by the latter method. In a related study, Rushton and Majd (168) evaluated children with DMSA scanning after an episode of acute pyelonephritis and found that subsequent scarring occurred at the site of renal infection. These authors (168) reviewed an extensive array of studies and concluded that DMSA renal scanning is the most sensitive method of detecting renal scarring. It not only detects scars earlier than IVU but also detects smaller scars. Whether it will detect parenchymal thinning is as yet unclear, but studies in the piglet have suggested that it will (55). The disadvantages of DMSA scintigraphy are its cost and its current lack of availability worldwide and in many areas of the United States.

NATURAL HISTORY

Etiology

Primary VUR results from a congenital anomaly of the ureterovesical junction, wherein an inadequate valvular mechanism allows the retrograde flow of urine from the bladder to the upper urinary tract. Secondary reflux may be the result of several etiologies within the broad categories of anatomic or functional bladder outlet obstruction. However, both of these physiologies may be linked by embryology.

The inadequate valve in primary reflux is the shortened submucosal tunnel. When the intramural and submucosal ureter have an adequate tunnel, the submucosal roof of the tunnel will compress as the bladder fills and will act as a flap valve. The mechanism can be more passive than active, as demonstrated by the success of the cross-trigonal reimplants. The role that the trigone plays is unclear; however, there is an apparent contraction of Waldeyer's sheath and trigone with detrusor contraction, which preserves tunnel length and increases distal ureteral luminal pressure with bladder filling and voiding. Therefore the intrinsic antireflux mechanism is much more dynamic than that achieved by surgery.

The role that infection plays in reflux can be summarized by a review of both experimental and clinical data. Schoenberg and co-workers (178) produced reflux in apparently normal puppies by infecting them with *Proteus.* Roberts and Riopelle (162) observed that reflux resolved spontaneously in infected monkeys as often as in uninfected ones, but it took longer to do so. Their conclusion was that infection delayed maturation. Furthermore, in adult monkeys, infection caused reflux only in damaged orifices, a finding that supported similar observations in humans. Shopfner (181) and Blank and Girdany (27) have stated that most nonobstructed reflux in humans was secondary to infection, but most observers have disagreed with such a sweeping statement. Gross and Lebowitz (61) could find no data in their large series of patients to suggest that infection causes reflux. Their conclusion was that both reflux and infection were independent variables that often coexisted and that the association was seen so often simply because the principal reason for doing a VCUG is UTI. Kaplan (91) has indicated that some children will reflux only if the cystogram is done during an acute infection and that these children remain an unstudied population that may have a worsened prognosis. One can conclude from these data that infection does not cause reflux of the normal mature orifice and would be a factor only for those orifices that are immature or damaged.

As previously defined, secondary reflux occurs in association with obstruction or neurogenic bladder. Virtually all of the reflux that occurs secondary to obstruction occurs in males. Reflux associated with bladder neck obstruction in females is of historical interest only, and that which occurs with urethral obstruction is hard to define because of the controversial nature of the latter. Despite the best efforts of many to deemphasize the role of urethral stenosis in the female, it is nonetheless a diagnosis commonly made by the urologist. The data regarding reflux in obstructed males are likewise unclear. The incidence of reflux in infants with posterior urethral valves is 50%. Much of it is associated with abnormal ureteral orifices (67). If obstruction causes reflux, a much higher percentage of valve patients should reflux. Several clinical investigators, including Hendren (66) and Kurth and associates (101), have tried to classify milder forms of urethral valves on the basis of degrees of reflux. The degree of reflux may alter the severity of bladder changes by offering a pop-off mechanism and reducing the pressure work done by the bladder.

Secondary reflux is common in both occult and true neurogenic bladders. Treatment is much more difficult and has a decreased success rate. Minimal voiding and urodynamic abnormalities are fairly common in primary reflux, and in some instances, the spectrum is such that it may be difficult to differentiate between the patient with nonneurogenic/neurogenic bladder (Hinman syndrome) and the patient with urodynamic abnormalities secondary to reflux. The incidence of dysfunctional voiding is certainly more prevalent and more of a factor than has been appreciated previously. Unfortunately, the true incidence is not known and varies widely between

investigators. Sillen and colleagues (182) found elevated intravesical pressure in 17 of 18 infants with bilateral reflux of high grade as determined by urodynamic studies. On the other hand, the data from the IRSC showed evidence of dysfunctional voiding in 18% of children with reflux whose parents responded to a questionnaire regarding voiding patterns (212). Koff (97) indicated that these children with bladder instability had a different urodynamic pattern from those with nonneurogenic/neurogenic bladder in that the former had a pattern of high end-filling pressures, whereas the latter had high voiding pressures. Thus reflux in this situation should not be considered either primary or secondary, but rather is a combination of two factors—the high intravesical end-filling pressures and the immature ureteral orifice. The disappearance rate of this type of reflux is probably similar to that in children with normal bladder dynamics, but it may be delayed. Treatment with anticholinergics may be effective in decreasing uninhibited contractions and end-filling pressures while allowing the reflux to resolve spontaneously.

Renal Scarring

Hodson (74) was the first to recognize the relationship of renal scars in children with recurrent UTIs, and 97% of these children had VUR. This close relationship caused Bailey (14) to use the term *reflux nephropathy* to describe the radiologic changes, which included (a) focal thinning of the renal parenchyma overlying a clubbed, distorted calyx; (b) generalized calyceal dilation with parenchymal atrophy; and (c) impaired renal growth, either associated with focal scarring or global atrophy (76). The sequelae of such findings, including proteinuria, hypertension, eclampsia in pregnancy, and renal failure, can be devastating, although most scars never pose a health threat to the affected patient.

A number of questions have been raised over the years: Why are children more susceptible to scarring than adults? Is it the reflux or the infection that causes renal scarring? The development of scars is an age-related phenomenon. Just as the highest incidence of reflux is found in younger children, the risk of scarring is greatest in children younger than 1 year of age (223). Patients who experience their first febrile UTI before age 4 have a much greater likelihood of developing a scar than children whose first episode of pyelonephritis occurs at a later age (189). Reflux nephropathy occurs uncommonly after 5 years of age (164). Postinfectious scarring can develop in children of any age who are not properly treated (20). In the European arm of the IRSC, new scars developed in approximately 24% of children younger than 2 years of age, in 10% of those between the ages of 2 and 4, and in only 5% of those older than 5 (139). The clinical studies of Berg and Johannson (21) also suggest that the infant kidney is more vulnerable to damage by infection during the first 3 years of life. Immaturity of the immune system and a lessened ability to fight renal parenchymal infection may play a role.

The “big bang” theory of Ransley and Risdon (151) underscores the susceptibility of young children with reflux to UTIs and proposes that the most severe degrees of renal parenchymal injury occur with the first infection. Because all susceptible segments of the kidney are simultaneously affected, sequential scar formation is unusual, although “little bangs” do occur (152). The theory supports two clinical observations. Most renal scarring in young children is as severe on initial imaging as is likely to develop in follow-up, unless severe episodes of pyelonephritis occur. In addition, the incidence of scarring is not significantly greater in children evaluated after their first infection than in those who present after multiple infections. There is evidence that the renal dysmorphism seen may represent both congenital and acquired lesions. Some renal dysmorphism presumably evolves on a congenital basis, although the pathophysiology undoubtedly differs from that of the more common acquired etiology of pyelonephritis. Such an etiology is likely in newborns with antenatally diagnosed disease. Despite being infection free, 30% to 35% of patients have kidneys that are diminutive and/or dysmorphic and scarred, especially with higher grades of reflux (30,124,133). Male infants are particularly prone to this occurrence because of their tendency to have high grades of reflux (72) and because they are much less likely to acquire scarring because they rarely have recurrent UTIs. One recent study reported primary (congenital) scarring in 86% of boys but only 30% of girls, who were more likely to acquire scars from repeated infections (220).

The histology differs between congenital and acquired lesions, although their radiologic appearance can be indistinguishable. In theory, the interplay between the ureteral bud and renal blastema during the first few weeks of gestation determines the development of the kidney as well as that of the ureterovesical junction. As Mackie and Stephens (116) have suggested, a ureteral bud that is medially (caudally) positioned from a normal takeoff from the mesonephric duct offers an embryologic explanation for primary reflux, whereas those laterally (cephalad) positioned are often obstructed (Fig. 48D.8). Variable degrees of renal dysplasia and caliectasis follow (193,194,198).

In addition to dysplasia, hypoplasia is commonly found in nephrectomy specimens of patients with reflux. Acquired cortical loss is often typically interspersed as a consequence of infection (69), although progressive renal scarring can be avoided if infections are prevented (11). Dysplasia has also been noted in patients with duplex collecting systems and upper ureteral ectopia (116), prune-belly syndrome (120), and posterior urethral valves, where the effects of high-grade obstruction early in embryogenesis may also contribute to renal dysmorphism. In fact, in one series, as many as 50% of infants with urethral valves and reflux had clinically significant renal insufficiency at a time too early in infancy to be caused by infection (80).

Countering the aforementioned information is the evidence that renal scarring is acquired. Hodson and associates' (75) early work implicated sterile reflux and a high-pressure “water-hammer” effect as a significant cause of renal scarring. Surgically creating reflux and occluding the bladder outlet allowed reflux nephropathy to be induced in miniature pigs, even in the absence of infection. High intravesical pressures caused intrarenal reflux, usually in the polar areas, and interstitial fibrosis, whose radiologic appearance was similar to that seen in children with postinfectious reflux nephropathy. Other work has also supported the concept of elevated bladder pressures causing reflux nephropathy (125). The proximal projection of pressure causes a decrease in postglomerular blood flow to the medulla and cortex that results in ischemic damage (158). This cause of nephropathy must be considered in the face of elevated bladder pressures and a high incidence of reflux associated with bladder dysfunction (97), urethral valves, or the high voiding pressures of newborns with antenatally diagnosed reflux (47).

Although abnormal bladder pressures may contribute to renal scarring in some children, the pathophysiology of most renal scarring was better defined by Ransley and Risdon (152), who were unable to create scars in a model similar to Hodson's by keeping the bladder unobstructed and the urine sterile. These findings were recently confirmed using magnetic resonance imaging (MRI), DMSA scans, and histopathologic analyses.

Clinical verification of the importance of infection is documented by a number of reports that cite new scars only in patients with reflux who have recurrent infections. In the combined series of Smellie and colleagues (185) and Huland and Busch (79), new scars developed in only 17 (4%) of 446 patients, all of whom had interval UTIs. The bulk of clinical and experimental studies underscore the importance of infection in the evolution of most renal scars.

Although pyelonephritis can commonly occur in the absence of VUR, reflux predisposes the kidney to ascending infections and may amplify the invasive effects of pathogens. For example, in one series, acute pyelonephritis was documented twice as often in patients with high-grade reflux than in those with low-grade reflux (119). In addition, most studies show a linear relationship between the grade of reflux and frequency of scarring (219,224). Primary renal dysgenesis could also contribute to the latter.

Papillary configuration also plays a role in protecting the renal parenchyma from urinary pathogens. Compound or concave papillae, which are flattened and whose ducts open at right angles to the calyx, are more likely to allow intrarenal reflux than simple or convex papillae. The convex papillae, which project into the renal pelvis and have ducts that exit obliquely into the calyx, provide a valvular action against the retrograde flow of urine into the collecting tubules of the renal medulla. The configuration and action are very similar to the flap-valve created by the ureter itself. Compound papillae are mostly localized in the polar regions of the kidney, where reflux nephropathy is much more likely to occur initially (75,151).

Further deleterious distortion of normal papillae architecture can result from adjacent scarring, hydronephrosis, and high-pressure voiding and eventually involve the entire collecting system. Early studies focused on intrarenal reflux (Fig. 48D.10), which is observed in 5% to 15% of neonates and infants with reflux (164,165). When scarring occurred, it was always in the parenchyma overlying the segment with intrarenal reflux. Autopsy studies in newborns younger than 1 month of age demonstrate intrarenal reflux at pressures as low as 2 mm Hg. Later in development, greater amounts of pressure become necessary to produce the same effect (e.g., 20 mm Hg in a 1-year-old) (54). Intrarenal reflux, like new scarring, is rarely seen radiographically after the age of 5. Ransley and Risdon (150) demonstrated the crucial interplay of intrarenal reflux and urinary infection in piglets, whose renal papillary morphology is similar to that of humans. Scarring occurred only in areas exposed to both infected urine and intrarenal reflux. However, the presence of intrarenal reflux does not alter the likelihood of spontaneous resolution or management strategy if infections can be avoided.

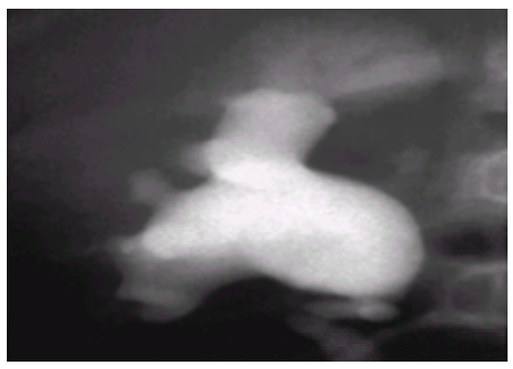

FIGURE 48D.10. Cystogram shows the presence of intrarenal reflux in the upper pole.

Renal Growth

Small kidneys associated with reflux may have that morphology for a variety of reasons, including the congenital dysmorphism often associated with, but not caused by, reflux (30%); the number and type of urinary infections and their resultant nephropathy; the quality of the contralateral kidney and its implications for compensatory hypertrophy; and the grade of reflux in the affected kidney. Studies that could be used to evaluate this parameter do so unreliably. In addition to the variability in interpretation that occurs with excretory urography or US (77,153), the response of the kidney to scarring, with its polar contracture and intermediate hypertrophy, makes interpretation of renal length alone unreliable. Other methods used to measure growth have included parenchymal thickness, renal area and length, and bipolar thickness (64,95,114). Claesson and associates (35) used planimetry to measure urograms and formulate a nomogram that allows determination of renal mass in relation to somatic size.

With the exception of those kidneys that are developmentally arrested, most studies implicate infection as the cause for altered renal growth. Ambrose and colleagues (5) reviewed the pathologic findings from kidney specimens of 63 patients with reflux and found a histologic pattern consistent with pyelonephritis in 51 (81%). In their study, patients with long-term reflux had kidneys that did not grow as well as normal. It was subsequently shown that acceptable growth occurred if urinary infections could be controlled. Elder and colleagues (48), for the Pediatric Vesicoureteral Reflux Guidelines Panel, found no evidence that renal growth is impaired in *unscarred* kidneys exposed to *sterile reflux* of any grade or that surgical correction of reflux facilitates renal growth postoperatively.

In a study of 111 patients with reflux who were managed medically, Smellie and co-workers (190) found slow growth in 11, 10 of whom had documented UTIs. Successful antireflux surgery can accelerate renal growth but may not allow affected kidneys to return to normal size (130,221). In one study of 22 kidneys with reflux nephropathy, significant growth after reimplantation occurred in 15 (68%), 7 of which grew proportionally to its mate (33). The potential for renal growth was less optimistically portrayed by the studies of Hagberg and associates (63) and Shimada and co-workers (180), in which 75% of kidneys with significant nephropathy remained stunted despite reimplantation. In contrast, kidneys without radiographic evidence of scarring usually show rebound growth with the surgical correction of reflux or its spontaneous resolution. In addition, the results from the Birmingham Study Group (24) and International Reflux Study (139,218,219) show no significant difference in rates of growth or parenchymal scarring between patients who were managed medically or surgically.

Renal Function

Renal failure that develops with reflux and renal scarring occurs in a significant number of patients. Bailey (15) indicated that as many as 30% of children may have end-stage renal failure because of reflux. In the Children's Transplant Program at the University of Florida, between 7% and 10% of 110 children had scarred kidneys in which reflux may have been a factor. However, there were some who had reflux unrelated to their renal failure, presenting with diseases such as nail-patella syndrome or asphyxiating thoracic dystrophy. A review and update of infants with severe VUR followed for a long period indicates that 80% have either unilateral or bilateral renal scarring, with 29% of these having either renal insufficiency, proteinuria, or hypertension (16). It is likely that recurrent pyelonephritis associated with reflux may be responsible for the majority of patients with reflux who develop renal failure.

Chronic pyelonephritis was reported as the cause of end-stage renal disease in 15% to 25% of children and young adults in earlier studies (81,175,192), although the presence of active reflux is probably less common at an estimated 10% (170). In many of these patients, prior infection went unrecognized or became evident only with the diagnosis of end-stage renal disease. In a study by Jacobson and associates (84), every adult who had their first infection during infancy had decreased renal function; hypertension was found in approximately 33% and end-stage renal disease in 10%. Increased awareness has had a positive effect on this complication. For example, chronic pyelonephritis accounted for less than 2.2% of end-stage renal disease in a report from the North American Renal Transplant Cooperative (138). In addition, a better understanding and medical management of the renal nephropathy that accompanies scarring should further lessen the progressive nature of the disease.

The mechanism for renal insufficiency or failure might be focal glomerular sclerosis brought on by renal hyperfiltration (70). Preventive treatment may further retard the onset of disease. For example, the effects of therapy with an angiotensin-converting enzyme inhibitor (captopril) were studied in 16 patients with severe reflux nephropathy and microalbuminuria. After 2-year follow-up, proteinuria was decreased and blood pressure and serum creatinine were stabilized in each case (102).

Lesser degrees of renal impairment can also occur with reflux in a progression that has been likened to that with partial ureteral obstruction in that tubular function is affected earlier than glomerular function. Renal damage from reflux occurs in a retrograde fashion, and the increased pressure is felt first by the most distal nephron. The effect of reflux is difficult to distinguish from that of associated UTIs. Defects in concentrating ability have been demonstrated in refluxing children with sterile urine, although almost all have had histories of UTI (215). In experimental animals, the effect of infection on concentrating ability is felt no longer than 6 weeks after the infection is eradicated (92). The defects in concentrating ability in refluxing children are persistent even while the urine is sterile for long periods. Furthermore, the concentrating defect is inversely proportional to the grade of reflux (Table 48D.2). In many refluxing patients, concentrating ability improves after the reflux disappears. Impairment of concentration ability may be related to the anti-antidiuretic hormone (ADH) effect of increased medullary prostaglandin E (PGE) levels in patients with severe VUR (214). Other parameters of tubular function, such as fractional excretion of sodium and magnesium, also may be affected (93). Renal tubular acidosis was identified in 9 (50%) of 18 children with primary reflux, 16 of whom had scars. Four of the affected children also had short stature (62).

Grade of Reflux*	Fasting Concentration (mOsm/kg)	Creatinine Clearance (ml/min)
Control	1,001 ± 104	130 ± 28
Grades I–II	864 ± 135	136 ± 43
Grade III	808 ± 119	127 ± 16
Grade IV	744 ± 129	108 ± 15
All grades with significant parenchymal scarring	543 ± 126	102 ± 41

*International Classification.

TABLE 48D.2. TUBULAR AND GLOMERULAR FUNCTION RELATED TO GRADE OF REFLUX

Glomerular function is usually not affected unless there has been parenchymal damage, and decreases in glomerular function are proportional to the amount of parenchymal loss. In the International Reflux Study, there was no deterioration in glomerular function as measured by serum creatinine nor was there any decrease in glomerular filtration rate when measured by chromium-labeled ethylenediaminetetraacetic acid. Berg (22) measured glomerular filtration rate and renal plasma flow in

a large number of children with renal scarring and VUR. He found that decreases in renal function correlated with the degree of renal scarring, with decreased renal function being the most significant in those with bilateral, small, scarred kidneys. Surgical correction of reflux stabilizes the glomerular filtration rate, but it has not been shown to lead to long-term improvement (48).

Proteinuria accompanies significant renal insufficiency and scarring (209). Genetic markers, including HLA-B12 in females, B8 with A9or BW15 in males, and BW15 in both sexes, have been found with end-stage reflux nephropathy and may represent a genetic link to a susceptibility to renal damage (208).

Physical Growth

Dwoskin and Perlmutter (43) and Polito and colleagues (145) noticed in their series that children with reflux, especially those with a history of recurrent UTIs, tended to be in the lower-weight percentile groups. Eliminating infections with prophylactic antibiotics maintained normal somatic growth for 51 girls with known reflux (191). Surgically correcting reflux has also been shown to positively affect somatic growth (126). Sutton and Atwell (201) compared physical growth while children with reflux received medical therapy and also found that growth improved after subsequent reimplantation. It remains unclear whether one form of treatment offers preferential benefit to this aspect of development because a comparative prospective study in a large series of children with extended follow-up is lacking. The Pediatric Vesicoureteral Reflux Guidelines Panel (48) found no evidence to substantiate an effect of reflux treatment on somatic growth.

Hypertension

Refluxing patients with scarred kidneys are at greater risk for developing hypertension (48). Although the actual incidence of hypertension secondary to reflux nephropathy has been reported to be as high as 38% (195,216,229), methodologic flaws can be found in many study designs (179). Patients without renal scarring are probably not at any greater risk of becoming hypertensive than the normal population. Arterial damage in the area of renal scarring presumably leads to segmental ischemia and renin-driven hypertension.

Abnormalities of Na^+-K^+-ATPase activity have also been described (59). Despite this, renin profiles have been measured in children with a history of reflux and many, but not all, were elevated (46,173). Elevated renins may be related to eventual hypertension for some patients, but others with high renins remain normotensive; a small group of patients, however, revert to normal with extended follow-up (172). In a 15-year follow-up of renin and blood pressure in a cohort of patients with reflux nephropathy, plasma renin levels were significantly higher than those in controls, but they were not predictive of the development of hypertension (58). Most patients who develop hypertension have nearly normal renal function, and the appearance of hypertension is rarely related to renal failure. In most series, hypertension is related to the grade of reflux and the severity of scarring, especially with bilateral involvement (69,209,224). However, in the study by Wolfish and associates (229), primary reflux was not associated with hypertension or the severity of scarring unless there was preexisting dysplasia. The implications of scarring can be subtle. In one provocative study, normotensive children with renal scars demonstrated similar renal function and levels of renin and aldosterone to controls. They also demonstrated the same expected drops in nocturnal blood pressure but significantly greater heart rates, a possible risk factor for future cardiovascular morbidity (148).

The elimination of reflux or its spontaneous resolution does not reverse the predisposition to hypertension once scarring is present (48). Wallace and associates (216), for example, reported hypertension despite successful ureteral reimplantation in 18.5% of children with bilateral scarring and 11.3% with unilateral scarring after more than 10 years of follow-up. Hypertension did not develop without scars. This type of data emphasizes the need for periodic checks of the blood pressure in any child with a history of reflux and scars. Removal of the offending renal parenchyma with partial or total nephrectomy can improve or correct hypertension in some patients (40). Patients with one small, scarred, poorly functioning kidney may be reasonable candidates. Confirmation with selective renal vein renins (ratio greater than 1.5) is instrumental to selection but may still not ensure success with ablative surgery. Global changes in vascular resistance may contribute to persistent hypertension. Those with diffuse bilateral scarring are less-than-ideal candidates because localization is difficult and sparing renal parenchyma assumes primary importance.

MANAGEMENT OF REFLUX

The appropriate management of VUR requires integration of multiple and often complex variables with the individualization of treatment for each patient and clinical scenario. Initially, any patient suspected of having VUR is placed on a prophylactic antibiotic regimen either immediately or after an appropriate course of antibiotic therapy if the latter is warranted by presentation. After therapy, if necessary, antibiotic prophylaxis is continued through diagnostic evaluation, which usually requires urethral catheterization for radiographic or scintigraphic study. If the suspicion of VUR is confirmed and the diagnosis established, a management plan is formulated based on many factors. These factors include but the etiology of reflux (primary versus secondary); mode of presentation; grade of VUR; and age, gender, and general health of the patient.

Surgical and endoscopic intervention, when indicated, are also part of the armamentarium of management options for VUR. More commonly, antibiotic prophylaxis is continued, and serial examinations are performed with knowledge of spontaneous resolution rates and anticipation of such. Medical or expectant management is not a treatment per se, but rather a concerted effort by the patient, the patient's family, and the clinician to protect a patient with VUR from initial or further complication of reflux during the period between its diagnosis and potential spontaneous resolution.

General Observations

One of the most difficult decisions regarding the child with VUR is deciding between medical and surgical management. Despite the many unanswered questions about the natural history of reflux, there are some reasonable observations, that if considered, allow the clinician to make a rational decision:

1. *Reflux will disappear spontaneously in many children.* VUR commonly resolves spontaneously, especially in patients who are young at presentation and when reflux is of low grade. Elongation of the submucosal ureteral tunnel and improved bladder characteristics, including increased compliance and capacity, are mechanisms believed to contribute to the resolution of reflux over time (196).

   Spontaneous resolution of reflux is more likely when the diagnosis is made in the younger the child, regardless of grade of reflux. Burge and colleagues (30) reported a 54% resolution rate at 3 years of follow-up in patients with perinatally diagnosed VUR. This rate of resolution is approximately twofold greater than that observed at 5-year follow-up in the International Reflux Study of patients younger than 10 years of age (202,219). Skoog and associates (183) noted a significantly shorter time to resolution for reflux presenting before the age of 12 months compared with that presenting later (1.44 versus 1.85 years; $p < .02$). Others have reported no difference in time to resolution of grade III and IV VUR for patients younger than 1 year versus those older than 1 year at presentation (129).

   Spontaneous resolution of VUR usually occurs within the first few years following its diagnosis, if it is to occur at all. With variation according to grade of reflux, the mean duration of reflux in those in whom it resolved was 1.69 years, with 30% to 35% resolving each year (183). If serial cystograms do not show an improvement in the degree of reflux, it is unlikely that reflux will resolve spontaneously. The appropriate duration of observation is poorly defined. McLorie and co-workers (129) noted that patients with grade III VUR who resolved, 92% did so within 4 years from the time of diagnosis. Spontaneous resolution of reflux beyond 5 years following diagnosis or with puberty is uncommon, especially if associated with little or no interval improvement in reflux degree (48).

   Most cases of grade I and II VUR resolve spontaneously. Rates of 85% and 80% have been reported by Edwards and colleagues (45), and Smellie and Normand (187), respectively. During 5 years of medical management, the Southwest Pediatric Nephrology Study Group (9) reported reflux resolution rates of 82% and 80% for grades I and II, respectively. Duckett (41) reported a resolution rate of 63% for grade II reflux, and according to Skoog and co-workers (183), 90% of children with grade I to III VUR experienced resolution after 5. Several authors report resolution of grade III VUR in approximately 50% of patients followed for 5 years (9,41,129).

   In general, higher-grade VUR is much less likely to resolve spontaneously. Patients with grades III and IV reflux were followed for 5 years in the International Reflux Study (218). Of patients randomized to medical management in the European arm, reflux resolved in 61% and 10% of patients with unilateral and bilateral VUR, respectively (202). In the American arm, resolution of reflux occurred in 25% overall in the 41 medically managed patients (219). Scholtmeijer (177) studied 93 children with 135 refluxing ureters of varying grades for at least 5 years. Spontaneous resolution was noted in 27 (57%) of 47 cases of grade III and IV VUR. VUR of grades III to V resolved spontaneously in 41% of patients according to Smellie and Normand (187). Skoog and associates (183) reported 9% resolution in grade IV reflux, and McLorie and co-workers (129) noted resolution in 30% of patients with grade IV and 12% of patients with grade V reflux.

2. *Sterile reflux is unlikely to cause renal damage.* Persistent reflux of infected urine causes renal damage. Despite the experiments in swine by Hodson and colleagues (77), renal scarring rarely occurs in refluxing children if a sterile urine is maintained. Recent studies in pigs showed that sterile reflux did not lead to renal scarring. The development of renal scarring in closely followed patients is almost always associated with breakthrough infections. Those incidents in which sterile reflux is implicated in children are almost always anecdotal and retrospective. The only exception may be in grade V reflux, and in this situation, the refluxing megaureter is more analogous physiologically and pathologically to obstructive uropathy.
3. *Long-term antibacterial therapy is usually safe and well tolerated by children.* This fact does not imply that there is no risk, but simply that the risk is small. The physician who implements long-term therapy must monitor the patient to see whether side effects occur. Nitrofurantoin often causes gastrointestinal distress in children and may be better tolerated in the macrocrystal form. Rare reactions include interstitial pneumonitis or pulmonary fibrosis, exfoliative dermatitis, hemolytic anemia, and peripheral neuropathies. Sulfa and trimethoprim-sulfamethoxazole combinations have been associated with blood dyscrasias, Stevens-Johnson syndrome, gastrointestinal symptoms, and central nervous system abnormalities. Both drugs may cause allergic reactions. Monitoring requires alerting the patient and family to possible side effects and promptly ceasing therapy should severe side effects occur. Despite the rare side effect in isolated patients, most patients tolerate long-term antibacterial therapy for years with no problem. This minimal risk of medical therapy must be compared with the real and demonstrated risk of renal scarring and sepsis if antibacterials are not instituted.

   Prophylactic antibiotics may be stopped in a highly select older population with low-grade reflux when the risk of developing a UTI may be small, although very careful follow-up would be necessary (38). In younger children with significant reflux, continuous antibacterial therapy will most likely provide protection against the development of renal scarring. Unfortunately, there is a high rate of noncompliance and being lost to follow-up in medically managed patients (218,219).
4. *Most associated bladder abnormalities do not preclude the possibility that reflux may disappear spontaneously.* Such abnormalities include bladder diverticula, duplex ureter, cystitis cystica (cystitis follicularis), urethral obstruction, and uninhibited bladder. Although any of these abnormalities may lessen the chance for spontaneous disappearance, they do so in an unpredictable fashion and are not contraindications to medical management (2,143). *Ureteral reimplantation surgery has a high success rate.* One should expect surgical success rates of 95% to 98% in patients with normal-caliber ureters and normal bladders. Coleman and McGovern (37) have indicated that success rates decline as the ureter and bladder become more abnormal. In their large series, the success rate in females was 98% when both the bladder and ureter were normal, 54% when the ureter was markedly dilated, and only 40% when both the bladder and ureter were abnormal. The success rate for the American arm of the IRSC was 99% (42).
5. *Reflux that persists in adolescence or adulthood is unlikely to disappear spontaneously.* Reflux in male adults may or may not be associated with significant morbidity. Reflux in adult females may carry a significant morbidity, particularly during pregnancy. The implications of reimplantation surgery were studied by Austenfeld and Snow (12), who found an increased risk of urinary infections and fetal loss in 31 women who had undergone ureteral reimplantation as children, despite correction of the anomaly. In a follow-up study compared with a new cohort of historical controls, women with UTIs and reflux who underwent reimplantation (suggesting an initially higher degree of reflux and increased renal scarring) were still at significant risk of UTI during pregnancy (123). However, they were not at a higher risk of miscarriage than the general population. In a larger study of 77 pregnancies in 41 women whose ureters had been reimplanted, Bukowski and associates reported that the incidence of pyelonephritis during pregnancy was slightly higher than in the general population but that the fetus and mother were a significant risk when renal scarring or hypertension was present (29a).

Based on this information, one can reach an assessment of the individual patient in deciding the course of management. Certainly, for lower grades of reflux in infants and younger children, every opportunity should be given for the reflux to disappear spontaneously. In those in whom it has not disappeared by late childhood or adolescence, consideration should be given to surgical therapy, depending on the sex, likelihood of future infections, patient reliability for follow-up, and patient interest in a resolution to the problem. Patients with severe reflux that represents the more severe varieties of grade IV or V usually require surgical management as the initial form of management. An exception to this is in the neonate in whom dramatic improvement can occasionally occur in what appears to be severe reflux. This may be related to the increased compliance of the newborn collecting system. Patients with breakthrough UTIs, particularly when associated with fever and regardless of the grade of reflux, probably should have ureteral reimplantation. Patients with high-grade III and grade IV reflux who can be maintained with sterile urine can be followed for a time, but the failure of resolution in those with bilateral reflux is a strong factor in favor of earlier rather than later reimplantation.

Specific management decisions can also be made based on the American Urological Association Pediatric Vesicoureteral Reflux Guidelines Panel. The Guidelines Panel reviewed the reflux literature extensively and developed practice policy recommendations on the basis of evidence-based outcomes and panel opinion, reflecting its clinical experience. The Reflux Guidelines Panel made treatment recommendations based on the presence or absence of renal scarring and the child's age during the initial diagnosis (Table 48D.3).

TABLE 48D.3. TREATMENT RECOMMENDATIONS

Prospective, Nonrandomized Reflux Studies

In 1984, the Southwest Pediatric Nephrology Study Group (9) initiated a closely monitored prospective study of the medical management of primary VUR. Entry criteria were age younger than 5 years, primary reflux of grades I to III/V, and radiographically normal kidneys after presentation with the first recognized UTI. Patients received medical therapy, including daily antibiotic prophylaxis, meticulous screening, and prolonged counseling, at each follow-up after the diagnosis of VUR was made. A total of 113 patients with 161 refluxing ureters were entered in the study. Preliminary results were published in 1992. Fifty-nine patients with 84 refluxing units had completed the protocol and were evaluable for analysis after 5-year follow-up.

Resolution of VUR was defined as no reflux on two consecutive voiding cystourethrograms performed annually during the 5-year study. VUR resolved in 82% of the 11 ureters with grade I, in 80% of the 40 ureters with grade II, and in 46% of the 33 ureters with grade III reflux. Bilateral VUR of all grades resolved in 54% of patients compared with 66% with unilateral reflux. Urine cultures were obtained every 3 months as well as if urinary symptoms and/or fever developed. Breakthrough UTIs occurred in 20 (34%) of the 59 evaluable patients over the 5 years of study. Standardized excretory urography was performed at 1, 3, and 5 years following diagnosis to assess renal growth, expressed as planimetric surface area, and to detect renal scarring.

Renal growth assessed at 5 years determined that 20 kidneys (9 with scar), associated with all grades of mild or moderate VUR, were more than 2 standard deviations smaller than the mean normal size. Each of these kidneys became progressively smaller during the study.

Several conclusions have been reached from the Southwest Pediatric Nephrology Study Group report. Renal scarring and impaired renal growth in infants and young children can be associated with any grade of VUR, with or without recurrent infection. Resolution of grade III VUR is much slower than that with grades I and II, and the consequences of grade III reflux on the kidney are worse than those of grades I and II. There is a significant incidence of renal scarring associated with mild VUR (9).

Goldraich and Goldraich (57) have reported a prospective study of 202 children with 314 refluxing units and a mean follow-up of 68.7 months. Mean age at entry following investigation of UTI was 31.5 months. Data regarding spontaneous resolution of VUR were presented according to chronologic age, not the interval between diagnosis and resolution of reflux. Resolution of reflux was the patient's age at the time of the first of two consecutive radionuclide cystograms without reflux.

The diagnosis of VUR was made significantly earlier in males than in females. At entry, 44% of the 314 refluxing units had evidence of reflux nephropathy. At age 5 years, low-grade (grades I and II) VUR had resolved spontaneously in 55% and 60% of ureters in boys and girls, respectively. Resolution of reflux at 5 years was

noted in 42% and 48% of ureters in boys and girls, respectively, with high-grade (grades III and IV) VUR. For patients followed for 10 years, spontaneous resolution was noted in 81% and 90% (low grade) and in 50% and 65% (high grade) of ureters in boys and girls, respectively. Although reflux lasted longer in boys than in girls, this difference did not reach statistical significance.

During follow-up, new renal scars developed in 7 (3.5%) of the 202 patients. All scars appeared in patients following a febrile breakthrough UTI and during the first 18 months of follow-up. Of note, in 3 of the 7 patients with new scars, reflux was of low grade. There was no significant gender predilection for prevalence of reflux nephropathy either at entry or during follow-up (57).

Rates of spontaneous resolution have also been studied in patients with high-grade (grades III, IV, and V) VUR (129). Between 1981 and 1987, 300 patients with high grade VUR were to be observed on prophylactic antibiotics. During the period of follow-up, 132 patients received observational therapy alone, and for specific indications, 168 required surgical correction after varying periods of observation.

Spontaneous resolution of reflux occurred in 3 of 26 patients with grade V VUR, but 23 required surgery. For patients with grade IV reflux, 17% and 30% resolved spontaneously by 2 and 5 years of follow-up, respectively. Rates of resolution for patients in the observation group with grade III VUR were 17% and 50% at 2 and 5 years, respectively. New renal scars developed in 8% of patients during the period of observation. Based on their data, the authors recommend surgical correction of high-grade VUR if it has not spontaneously resolved during 4 years of uncomplicated observational therapy (129).

Prospective, Randomized Studies

Controversy persists regarding what constitutes the best treatment for moderate degrees of VUR. Three prospective, randomized studies comparing medical versus surgical management of patients with moderate to moderately severe reflux have reported results after 5 years of follow-up.

The International Reflux Study was a prospective, randomized investigation comparing the results of medical and surgical treatment of infants and children with grades III and IV (International classification) VUR. Patient recruitment began in 1980 and was completed in 1985. A total of 452 patients entered the randomized trial, 321 and 131 in European and United States arms, respectively. Radiographic requirements at entry included excretory urography and VCUG. Excretory urography was used to evaluate renal scar(s). Blood pressure was recorded, and glomerular filtration rate was estimated using creatinine clearance for all patients. After random allocation, the children were treated with either prompt antireflux surgery or managed medically with antibiotic prophylaxis until spontaneous resolution of reflux (218).

Patients randomized to medical management had similar rates of spontaneous resolution of VUR whether enrolled in the American or European arm of the study (202,219). One-hundred and fifty-five patients were randomized to medical management in the European arm. During the 5 years of the International Reflux Study, reflux resolved in 61% and 10% of patients with unilateral and bilateral VUR, respectively (202). Resolution of reflux occurred in 25% of the 41 patients randomized to medical management in the American arm of the study and followed for 5 years. Results of unilateral versus bilateral reflux were not designated (219).

Randomization to surgery was the fate of 151 patients with 237 refluxing units in the European arm of the International Reflux Study (73). Successful ureteral reimplantation, defined as the correction of VUR and absence of ureteral obstruction, was documented postoperatively in 92% of the refluxing units. Persistent reflux and obstruction was noted postoperatively in 9 and 10 ureters, respectively. Eighty-seven patients with 154 refluxing ureters were randomized to surgical management in the American arm (42). Of the 154 reimplanted ureters, a successful result was obtained in 99.4%. Persistent VUR was present in only one ureter postoperatively.

In the European arm of the International Reflux Study, breakthrough UTIs occurred in 38% of patients during the 5 years of medical management (88). UTIs developed in 39% of patients after ureteral reimplantation. However, the incidence of pyelonephritis was 10% and 21% during follow-up for the surgical and medical groups, respectively. In the United States, there was a threefold and statistically significant higher incidence of pyelonephritis in the medically versus the surgically managed patients (219).

Upon entry to the study, approximately 50% of patients in both the American and European arms had scarred kidneys and the patients were evenly distributed between the medical and surgical treatment groups (218). Over the 5 years of follow-up, no statistically significant difference was noted in the incidence of new renal scarring and parenchymal thinning between the American and European or medical and surgical arms (139,219). In addition, there was no significant difference with regard to renal growth for medical versus surgical management.

The principal conclusions of this study were as follows:

1. Bilateral grade IV reflux was unlikely to resolve within 5 years.
2. There was no difference in renal scarring between patients randomized to surgery or medical therapy at 5 years. There was a difference, however, in the pattern of scarring in that the scars in the surgical group occurred early, whereas those in the medical group were evenly distributed throughout the study. Also, the incidence of clinical pyelonephritis was much higher in the medical group. Thus, because a number of medically followed patients still had reflux, it might be expected that scarring would be higher in two similarly constructed groups followed for another 5 years.
3. The surgical success rate, particularly when done by an experienced surgeon, was quite high.

The Birmingham Reflux Study Group randomized children with severe VUR to receive medical or surgical therapy. Reflux was categorized as grade I, reflux into the ureter; grade II, nondilating reflux into the renal pelvis; and grade III, reflux causing dilated calices. Entry included all patients with grade III reflux and grade II reflux with renal scarring (23,24).

A total of 104 patients were recruited for this prospective study. Fifty-one and fifty-three patients were randomized to surgical and medical management, respectively. Resolution of VUR occurred in approximately 20% to 50% of patients treated medically during the 5-year follow-up period. A 98% success rate was achieved in those patients undergoing ureteral reimplantation. No statistically significant difference was noted between the medically and surgically treated groups with regard to development of new renal scars or renal growth. Their report showed no clear advantage to either surgical or medical therapy in patients with reflux.

In a third prospective study, patients with grade IV VUR were randomized to medical versus surgical management (177). Ninety-three children with 135 refluxing ureters were studied for at least 5 years. Of the 135 refluxing ureters, 35 had grade IV VUR; 24 underwent surgery, and 11 were treated with antibiotics alone. During 5 years of follow-up, VUR resolved in 6 (55%) of the 11 ureters managed medically. Reflux was cured in all ureters treated by reimplantation.

Medical Management

Choice of Antibacterial

Appropriate antibiotic prophylaxis for the purpose of maintaining sterile urine in the face of VUR is the cornerstone of medical management. Several different medications achieve high urinary concentrations and effectively control a broad range of uropathogens. Medications are usually given at half the standard therapeutic dose. Nighttime administration in toilet-trained individuals precedes the longest period of urinary retention and is most effective in prophylaxis.

The antibacterial agent chosen should be one that combines the following: is the least risk to the patient, has high urine concentrations, minimally alters vaginal-perineal flora, has a broad spectrum of action against most Gram-negative bacteria, is available and well tolerated in liquid forms, and is available at minimal cost to the patient. No one antibacterial agent satisfies all of these criteria.

Amoxicillin and ampicillin are well tolerated and are the recommended formulations for children up to 6 weeks of age. These medications have the fewest side effects in the newborn but do favor the development of resistant fecal flora. After 6 weeks of age, sufficient maturation of the biliary system makes trimethoprim-sulfamethoxazole preparations a viable alternative. This usually becomes the antibiotic of choice. However, awareness of side effects, including gastrointestinal symptoms, allergies, Stevens-Johnson syndrome, and leukopenia, is necessary. A complete blood count may be necessary before any surgery in patients using a trimethoprim-sulfamethoxazole preparation. After 2 months of age, nitrofurantoin becomes another acceptable alternative for the purpose of UTI prophylaxis. As an elixir or tablet (crushed, divided, and added to food), this is the best medication for minimizing resistance of and/or altering fecal flora. Rare, but well-recognized, complications of Macrodantin use include pulmonary fibrosis and interstitial pneumonia. Side effects, including nausea and vomiting, hemolytic anemia, peripheral neuropathies, and exfoliative dermatitis, have also been described. A written, summarized description of well-recognized antibiotic side effects

should be available and given to the respective caretaker(s).

All antibacterial agents should be continued as long as the patient is refluxing. *Intermittent* treatment of infections is *ineffective.* With the practice of intermittent antibiotics, Lenaghan and associates (104) noted a 21% incidence of new renal scarring versus a report by Smellie and colleagues (185) of a 1% incidence with the use of continuous antibiotic prophylaxis. Progressive nephropathy is the course for patients who are treated only during symptomatic episodes.

Once the reflux has resolved, the antibacterial agents can be stopped. The patients will continue to require monitoring to make sure that infection does not recur. Recurrent infections are common after reflux resolves (60), although most will now be associated with lower tract symptoms rather than clinical pyelonephritis.

Clinic Visits

Children with reflux should probably be seen at no more than 6-month intervals. Clinic visits should establish any history consistent with intercurrent infection or of reaction to the antibacterial. Physical examination should record parameters of physical growth and blood pressure. Laboratory studies should include urinalysis and culture at each visit, and hemogram, white blood cell count, and serum creatinine clearance should be obtained as needed. These tests represent only the minimum studies and must be altered depending on the child's condition.

Frequency of Radiologic Studies

US or IVU should be performed initially in the infection-free patient and repeated at intervals of 18 to 24 months, but sooner if repeated infections occur. Contrast VCUG is used as the initial study to grade the reflux and ascertain any associated bladder pathology. Subsequent studies should be done at about 12- to 18-month intervals. After the initial study is used for grading, subsequent studies may be done with a radionuclide cystogram. Barthold and co-workers (17) have recommended two normal studies before the assumption that reflux is resolved; however, one study may be adequate unless the patient continues to have febrile infections.

DMSA scintigraphy is probably the most sensitive indicator of renal scarring and gives excellent assessment of differential renal function. It is indicated as both a baseline and for follow-up in patients with higher grades of reflux, after a febrile UTI, and when renal scarring is suspected on IVU or renal US.

Chapter References

The urinary bladder has two major functions: (1) storage and (2) socially acceptable efficient emptying (55). A number of urologic diseases that affect both adults and children, males and females, are characterized by abnormal noncompliant bladders. For example, patients with interstitial cystitis, spinal cord injuries, myelomeningocele, tuberculosis, bladder exstrophy, and posterior urethral valves may all require treatment to normalize bladder function. When pharmacologic manipulation fails, the next step is surgical bladder rehabilitation, which typically requires enlargement with intestinal segments.

For the bladder to be a safe and effective storage chamber, the ideal cellular lining is urothelium. Epithelial cells from the gastrointestinal tract are not optimal for this purpose because they either secrete or absorb electrolytes (38,44). This can lead to chronic electrolyte abnormalities such as metabolic acidosis, which occurs with ileal augmentation cystoplasties. In the case of gastric augmentations, the stomach segment continues to act as a gastric secreting organ, which may predispose to hypochloremic hypokalemic metabolic alkalosis (12,31). Chronic electrolyte imbalance also may lead to abnormalities in calcium homeostasis, resulting in bone demineralization. The risk of tumors in bladder augmentation also is increased based on sporadic case reports and experimental studies (2,14). Intestinal segments also secrete mucus, changing the quality of urine in these patients. The use of bowel in the urinary tract also increases the chance of urolithiasis through unknown lithogenic properties (8).

A number of strategies have been devised to avoid the use of bowel in the urinary tract. Autoaugmentation, as described by Cartwright and Snow, has had success in a select group of patients whose compliance is poor based on abnormal pressures (16). This procedure is technically difficult in patients who have poor volumes secondary to small contracted bladders. The concept of creating a large bladder diverticulum composed of urothelium and lamina propria has been extended by attempting to support the inherently weak autoaugment with deepithelized bowel segments from the stomach or the sigmoid colon (15,45). The well vascularized deepithelized bowel segments can theoretically provide a vascularized stromal support to the urothelial diverticulum. What type of cellular interactions occur at this foreign interface between bladder urothelial cells and intestinal stroma? Before we can answer this question, we first need to define what we mean by “normal” urothelium and “normal” stroma or mesenchyme.

Definition: Note that *mesenchyme* refers to the nonepithelial cellular elements (i.e., connective tissue, fibroblasts smooth muscle). Mesenchyme refers to the embryonic time period and stroma refers to the same non-epithelial elements postnatally.

DEFINING UROTHELIUM

As previously stated, the ideal goal of bladder augmentation is to have a urothelial cell–lined bladder. To accomplish this goal, we need to carefully define the phenotype of the urothelial cell. Presently, urothelium can be defined by morphology, protein expression, turnover, and function. Histologically, bladder urothelium is a stratified transitional epithelium consisting of basal, intermediate, and superficial cells. Functionally, these cells must accommodate rapid changes in volume and pressure (5). During bladder cycling, the urothelial cells function as an impermeable barrier to most solutes. The superficial urothelial cells have a highly specialized apical membrane consisting of thickened plaques of asymmetric unit membrane (AUM), which can be internalized to decrease the luminal surface area of the bladder during emptying. The AUM is composed of urothelial-specific proteins: the uroplakins I, II, and III (56).

It is possible to culture urothelial cells *in vitro* (3,25,28,36,51). Depending on the *in vitro* environment, the urothelial cells can form a monolayer or can be induced to stratify and mimic the *in vivo* phenotype. Southgate and colleagues have been able to show that long-term organ cultures of urothelium retain the same basic phenotype as normal urinary tract tissue *in situ.* The “normal” phenotype is based on the addition of exogenous calcium to the *in vitro* cultures as well as presence of the proper stroma (28,51).

Therefore it is possible to develop a table of antigen expression for urothelium *in situ* and compare the phenotype with urothelium during cell culture and with urothelium that has been placed in the environment of a different stroma such as is occurring in bladder reconstruction (Table 49A.1). Presently, the antigen expression of cytokeratins, uroplakins, integrins, and E-cadherin have been well described (9,36,57).

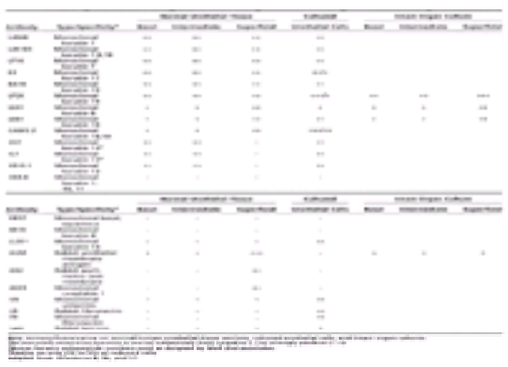

TABLE 49A.1. DEFINING UROTHELIUM

For example, cytokeratin expression in the rat bladder varied as a function of development and cell position (basal versus luminal) (9). Cytokeratin 5 was first detected at 19 days' gestation, whereas cytokeratin 14 was first detected in the newborn rat bladder (day 0). Cytokeratins 7, 8, 18, and 19 were detected in 15-day embryonic bladders, the earliest day studied. Cytokeratins 8 and 18 were localized to the luminal aspect of the epithelium, whereas cytokeratins 5, 7, 14, and 19 localized predominantly to the basal layer of the epithelium. Cytokeratins usually are expressed in pairs (5, 14 or 8, 18) (46,47). Interestingly, in the rat bladder, cytokeratin 5 appears before cytokeratin 14, an exception to the pairs rule. In the corneal epithelia, the expression of the basic cytokeratin 3 also has been found to be discordant with its acidic pair cytokeratin 12. In this case, neutrality is maintained by the simultaneous expression of cytokeratin 19 along with cytokeratin 3 (46). In the bladder, it may be that the discordant expression of the cytokeratin 5/14 pair is compensated by the earlier expression of another cytokeratin as occurs in the corneal epithelium (47). The localization of specific cytokeratins to either the basal or luminal layer of the urothelium suggests that the basal cells and luminal cells perform different functions. The pattern of expression of cytokeratins in the bladder epithelium is unique and can be used as a fingerprint to differentiate urothelium from other epithelium.

The uroplakins (I, II, and III) are known to be specific biochemical markers for urothelial differentiation (56). The uroplakins consist of three major proteins (15, 27, and

47 kDa), which form an asymmetric unit membrane in the superficial umbrella cells of the urothelium. These molecular markers are thought to represent an advanced stage of urothelial differentiation. These unique proteins are not expressed in any other epithelial cells. Uroplakins are thought to play a role in the impressive folding that occurs when the bladder lumen collapses during emptying. The uroplakins are unique markers for urothelium.

STROMA AND SMOOTH MUSCLE CELLS

Using the rat as an experimental model, the ontogeny of both epithelial and smooth muscle differentiation was defined using a panel of antibodies to smooth muscle and epithelial proteins (9). The smooth muscle proteins, a smooth muscle actin, myosin, vinculin, desmin, and laminin are sequentially expressed as a function of developmental stage. At 14 days' gestation, the rat bladder mesenchyme does not have any smooth muscle based on histologic criteria of smooth muscle cells such as a centrally located nucleus, spindle shape, and relatively small nucleus-to-cytoplasmic ratio. Based on immunohistochemical staining, the 14-day embryonic bladder mesenchyme does not express any of the smooth muscle proteins (Fig. 49A.1). The fact that the 14-day bladder of the fetal rat did not express any of the smooth muscle markers provided the opportunity to establish the required bioassay to test the hypothesis that cell–cell interactions between the epithelium and mesenchyme regulate smooth muscle cell differentiation (9).

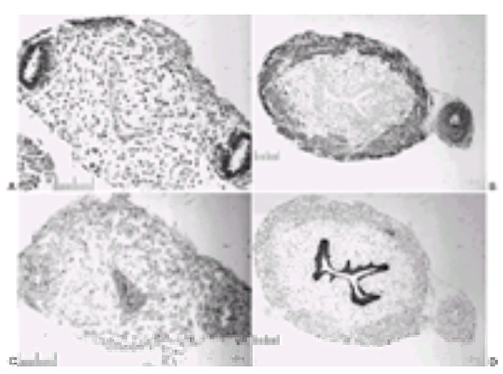

FIGURE 49A.1. Embryonic bladder development: smooth muscle and urothelium. Smooth muscle and epithelial development in the rat bladder. **A:** Embryonic bladder at 14 days' gestation showing a-actin smooth muscle immunostaining. Note the lack of localization in the bladder mesenchyme in contrast to the positive staining of the adjacent umbilical vessels. **B:** In contrast, at 17 days' gestation, well-defined smooth muscle bundles are localized in the outer layer of the bladder by a-actin smooth muscle. **C:** Cytokeratin epithelial immunohistochemistry at 14 days' gestation. Note the sparse localization to the epithelial cells. **D:** In contrast, there is intense localization to the urothelium in the 17-day gestation bladder.

The first mesenchymal marker to be detected during bladder development was vimentin at 15 days' gestation. With time, vimentin expression became localized exclusively to the fibroblasts of the lamina propria and connective tissue between the smooth muscle bundles. A similar pattern of expression has been reported in the developing stroma of the rat prostate and seminal vesicle, where vimentin is initially widely expressed in the mesenchyme, but with time, it localizes to the interductal connective tissue and lamina propria (34). In the developing rabbit bladder, Chiavegato and associates have shown that vimentin and a nonmuscle isoform of myosin are initially expressed in the smooth muscle cells of the young rabbit bladder. With normal aging, these differentiation markers cease to be expressed in the smooth muscle cells of the young rabbit bladder but can reappear following experimental partial bladder outlet obstruction (18). Further work by Buoro and co-workers with the same experimental obstruction model showed that fibroblastic cells adjacent to the bladder serosa may transform into myofibroblasts and subsequently into fetal type smooth muscle cells based on the reexpression of smooth muscle markers (13). At 16 days' gestation, when smooth muscle is first noted by the previously defined histologic criteria, a-smooth muscle actin staining cells are detected in the periphery of the bladder. Subsequently, these actin-positive cells sequentially acquire the remaining smooth muscle markers, vinculin, laminin, myosin, and desmin. Smooth muscle protein expression is consistent with the temporal expression of the message for smooth muscle a-actin (43).

EPITHELIAL-MESENCHYMAL INTERACTIONS

Epithelial-mesenchymal signaling may be required for the smooth muscle differentiation to occur (8). To test this hypothesis, 14-day embryonic rat bladders (before the differentiation of smooth muscle) were isolated, and the epithelium was separated from the mesenchyme following tryptic digestion, which degrades the epithelial basement membrane. The isolated bladder mesenchyme, bladder mesenchyme recombined with urothelium, and intact 14-day embryonic bladders were then grown underneath the kidney capsule of syngeneic hosts. The intact 14-day embryonic bladders underwent normal differentiation, defined by the expression of smooth muscle proteins. In contrast, when isolated bladder mesenchyme was grown alone underneath the kidney capsule, the tissue survived, but the mesenchyme did not differentiate into smooth muscle. However, when bladder mesenchyme was recombined with bladder epithelium, smooth muscle differentiation occurred, although this was less organized than if the epithelium was left intact in its natural state (Fig. 49A.2) (8).

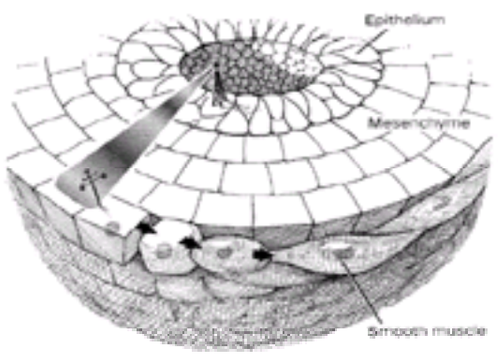

FIGURE 49A.2. Cellular signaling in the bladder. Epithelium is required for bladder mesenchyme to differentiate into bladder smooth muscle. Signaling occurs via an unknown mechanism, possibly diffusable growth factors. (From Baskin LS, Hayward S, Young P, et al. Role of mesenchymal-epithelial interactions in bladder development. *J Urol* 1996;156:1820, with permission.)

The same experiments were repeated *in vitro,* where intact embryonic bladders before smooth muscle differentiation were grown on top of filter paper nourished by standard tissue culture medium. Compared with bladder mesenchyme cultured alone, there was impressive growth of the intact organs. When epithelium was recombined with bladder mesenchyme, again the growth was greatly improved compared with the mesenchyme alone. Labeling of the organ culture with 3H-thymidine showed extensive cellular proliferation in the tissue recombinants composed of bladder mesenchyme plus bladder epithelium and in intact bladders, whereas in the mesenchyme alone, little DNA synthesis occurred. Histologically, tissue recombinants of bladder mesenchyme plus epithelium structures revealed healthy cellular histology, whereas the bladder mesenchyme alone showed evidence of cellular degeneration.

A final experiment determined whether urothelium from a different species could induce bladder smooth muscle differentiation. This hypothesis was tested by performing a unilateral nephrectomy in nude mice (8). Undifferentiated, 14-day rat bladder mesenchyme with the epithelium removed was then surgically attached to the severed mouse ureter. The bladder mesenchyme and mouse ureter were allowed to grow for 1 month *in situ,* with the idea that the ureteral epithelium would induce smooth muscle differentiation of the rat bladder mesenchyme. As expected, the mouse urothelium induced smooth muscle differentiation in the rat bladder mesenchyme, resulting in the expression of smooth muscle differentiation markers. Species-specific probes confirmed that the epithelium was of mouse origin and the smooth muscle was from the rat. These experiments strongly support the concept that cellular signaling between the bladder epithelium and undifferentiated bladder mesenchyme is required for the induction of bladder smooth muscle.

What happens if abnormal signaling occurs? (See Fig. 49A.3.) For example, during bladder augmentation with bowel segments at the anastomotic site, the urothelium is receiving signals from the intestinal stroma and the intestinal epithelium is receiving signals from the bladder stroma. Might this abnormal signaling lead to cellular changes such as atypia and even cancer? Although relatively rare when cancer does occur in augmented bladders, the site is always at the junction between the native bladder and the intestinal segment.

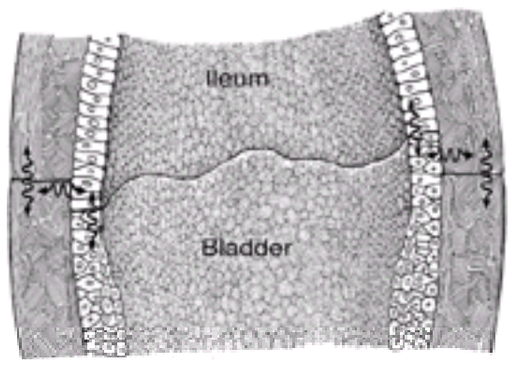

FIGURE 49A.3. Augmentation cystoplasty. Schematic of the heterotypic stromal-epithelial interactions that are created at the anastomotic site of intestinal bladder augmentations. [From Li YW, Liu WH, Hayward SW, et al. Plasticity of the urothelial phenotype: effects of gastro-intestinal mesenchyme/stroma and implications for urinary tract reconstruction. *Differentiation* 2000;66(2 and 3):126, with permission.]

GROWTH FACTORS

If diffusable growth factors play a role in bladder differentiation, one would expect to see differences in their expression during development. RNase protection assays were performed against a panel of growth factors at strategic times during bladder development and smooth muscle differentiation (10). Specifically, rat bladders were examined at the embryonic stage before smooth muscle development (14 days' gestation), at the time of first smooth muscle differentiation (16 days' gestation), and then at subsequent time points (18 days' gestation, newborn, 20 days postnatally, and adulthood). Transcripts for keratinocyte growth factor (KGF) and the KGF receptor, transforming growth factor-a (TGF-a) and epidermal growth factor (EGF) receptor, and the TGF-b family were assessed. TGF-b2 and TGF-b3 were regulated as a function of development, being expressed at a high level in early gestation and then decreasing as a function of time. TGF-a and KGF were expressed in opposite fashion, being minimally expressed in the embryonic period with a greater expression in the mature bladder (10).

A model of bladder outlet obstruction was created in the rodent to study the effect of obstruction on smooth muscle remodeling (52). This resulted in a sixfold increase in bladder volume and a fivefold increase in bladder weight, as well as a doubling of smooth muscle cell diameter. The mRNA for the growth factor TGF-b2 increased twofold, TGF-b3 increased fivefold. The mRNA for TGF-a was elevated tenfold. In contrast, the transcripts for KGF and the receptors for KGF and EGF did not exhibit any changes. TGF-bs are known to affect extracellular matrix synthesis, and it may be that the changes in the bladder wall and increased matrix deposition resulted from the upregulation of these growth factors. Other investigators have shown acute changes in growth factors during bladder outlet obstruction. For example, in an acute model of partial bladder outlet obstruction in the rabbit, transcripts for basic fibroblast growth factor (bFGF), c-myc, c-fos, and Ha-ras and Ki-ras oncogenes are elevated, whereas mRNA encoding TGF-b1 is decreased (17,40).

EXTRACELLULAR MATRIX

The bladder also undergoes significant tissue remodeling as it increases in size and matures in function. In addition to maturation of smooth muscle and urothelium, much of the change in the bladder wall occurs within the extracellular matrix (ECM), which serves both structural and regulatory functions. The changes occurring in the ECM of the bladder during both normal development and in response to obstruction reflect a balance of synthesis and degradation of the fibrous (mainly collagen and elastin) and nonfibrous (proteoglycans and glycosaminoglycans) constituents. Both collagen types I and III are regulated as a function of development and bladder outlet obstruction (4,5,7). The expression and activation of type IV collagenases (MMP-2 and MMP-9) are developmentally regulated and play a role in bladder remodeling during obstruction (53).

BLADDER WOUND HEALING

Further evidence for cellular signaling via growth factors has been shown with a model of bladder wound healing (6). Using the rodent as a model, an incisional wound was created in the bladder and then sutured with primary closure. Histologic analysis revealed that the bladder epithelium regrew over the defect within 24 to 48 hours. RNase protection assays of growth factors showed an eightfold increase in the expression of KGF as compared with sham-operated and control animals. Interestingly, this increased expression occurred in the first 12 to 24 hours corresponding to the period of intense epithelial proliferation noted histologically. At 5 and 7 days, when the epithelium had completely regrown, the expression of KGF returned to baseline.

Another interesting finding is that when the bladder wall was sampled at a distance from the injury, there was still an upregulation compared with sham and nonoperated animals, suggesting that global signaling occurs throughout the bladder in response to injury, which facilitates epithelial repair (Fig. 49A.4) (6). The proliferative activity of the urothelial cell is impressive as it is normally quiescent with turnover every 6 months to a year (35). However, following bladder epithelial injury, KGF released by the stroma binds to receptors on the epithelial surface to cause the urothelium to proliferate (1). Further support for the direct effect of KGF in the bladder was tested by injecting human recombinant KGF subcutaneously into neonatal mice. In comparison with saline controls, urothelial proliferation was greatly enhanced as judged by 3H thymidine labeling (6). A similar finding has been reported for the monkey bladder by Yi and colleagues (58).

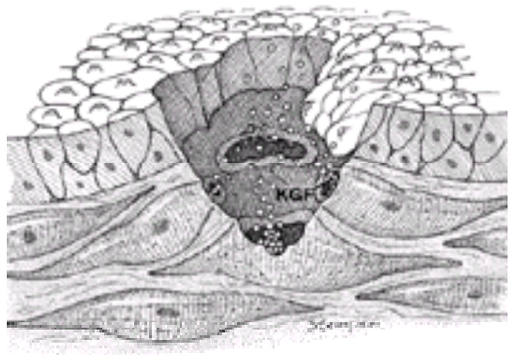

FIGURE 49A.4. Bladder wound healing schematic. Keratinocyte growth factor *(KGF)* is released from bladder stroma cells during bladder injury and directly acts through its urothelial located receptor to cause proliferation and regrowth of urothelial cells mending the bladder injury. (From Baskin L, Sutherland R, Thomson A, et al. Growth factors in bladder wound healing. *J Urol* 1997;157:2388, with permission.)

BLADDER REPLACEMENT

One of the most exciting areas of bladder research is development of new methods of bladder augmentation that avoid the use of intestinal segments. One model of bladder augmentation uses an acellular tissue matrix to elicit regeneration of bladder tissue (Fig. 49A.5) (54). In this model, the dome of the bladder is excised (again, this was first performed in the rodent model) and acellular tissue matrix made from either the bladder or the stomach is sutured to the surgical defect. The acellular matrix is prepared by incubating the bladders or stomachs of adult rats in distilled water for 1 hour to lyse the cells and to release intracellular contents. Tissues are then suspended in 40 mL of 40% sodium deoxycholate (Sigma Chemical Company, St. Louis, Missouri), for 2 to 4 hours, followed by treatment with 2,000 Kunitz units of deoxyribonuclease I (Sigma Chemical Company) in 1 M of sodium chloride solution for 1 to 2 hours. This process is repeated one to three times to extract all

cellular material. Histologic confirmation shows an absence of cells. The preparation of the acellular matrix is designed to avoid complete removal of potentially important growth factors, as well as other extracellular matrix ligands. After suturing the acellular matrix patch in place, animals were sacrificed at serial time points to specifically study the interface between the native bladder and the acellular matrix tissue. Complete reepithelization with urothelial cells occurred by 4 days, and smooth muscle regenerated into the acellular matrix by 2 weeks after grafting. Interestingly, the smooth muscle grew in juxtaposition to the epithelial surface, which over time, matured into normal size bundles by 26 weeks after grafting.

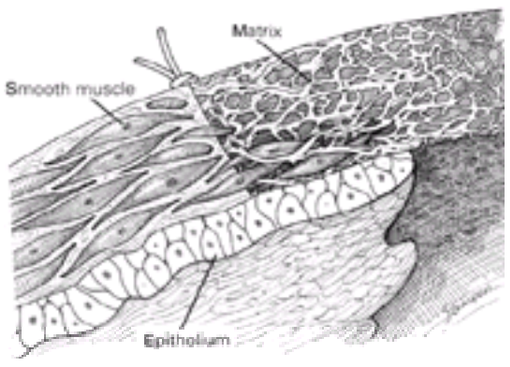

FIGURE 49A.5. Matrix experiment for bladder replacement. A model of bladder regeneration with an acellular tissue matrix shows that urothelium, smooth muscle, and nerves can grow into the tissue matrix, most likely under the influence of stromal-epithelial cellular communication. (From Sutherland RS, Baskin LB, Hayward SW, et al. Regeneration of bladder urothelium, smooth muscle, blood vessels and nerves into an acellular tissue matrix. *J Urol* 1996;156:571, with permission.)

Neovascularization was seen by 2 weeks, and neural elements from the native bladder formed around the developing bundles of smooth muscle as early as 4 weeks. These animals were able to void and function normally. Careful histologic analysis showed that the acellular tissue matrix did not regenerate into completely normal bladder, but over time, smooth muscle bundles did organize into their appropriate position in the periphery of the bladder, and the urothelium itself covered this matrix, presumably under the influence of KGF from tissue injury (6).

ABNORMAL CELLULAR SIGNALING

Normally, the urinary bladder consists of three well-defined layers: (a) an inner layer of transitional epithelium approximately three to five cell layers thick, (b) an underlying connective tissue layer intimately associated with the epithelium, and (c) a surrounding thick layer of organized smooth muscle. The development and maintenance of the bladder, like other organs, depends on positive and negative feedback between these interacting groups of cells (8,20). In certain clinical situations, such as with augmentation cystoplasty, the interacting groups of cells are iatrogenically altered (Fig. 49A.3). In augmented bladders, for instance, foreign epithelia and/or stroma from organs such as the intestine and stomach are permanently placed in contact with bladder tissue. A plausible explanation for the higher incidence of intestinal cancers in the augmented bladder (29,49,50) is that the interactions of the foreign epithelium and/or stroma with the existing bladder epithelium and/or stroma result in abnormal cell–cell interactions that perturb regulation of epithelial growth.

There is a definite cause-and-effect relationship between augmentation and the development of malignancy because the incidence of primary adenocarcinoma of the small bowel in the general population is only 0.1% (42), yet most of the reported malignancies in augmented bladders are in ileal augments (48). Thus the risk of developing a “small bowel” malignancy in a patient with an augmentation cystoplasty is significantly increased (approximately tenfold) compared with the general population.

The pathogenesis of this benign to malignant transformation is not understood but may be secondary to a perturbation in cell–cell signaling caused by the introduction of nonbladder cells into the bladder. Three major arguments support this theory. First, of the 12 reported cases in the literature of primary malignancies in bladder augmentation in which the location of the tumor could easily be defined, 8 were noted at the junction of the bladder and bowel and 2 were located near this junction (48,49). Also, in animal models, it has been shown that when tumors do develop, they almost always occur at the site of the enterovesical junction (42). If cell–cell interactions are important, the malignancy would be expected to occur at the site of the anastomosis. Second, it has recently been shown that the presence of feces or urine is not necessary for tumor development (42,48). Finally, abnormal cell–cell interactions have been implicated in carcinogenesis in general. Both colon (39) and prostate (21) adenocarcinomas are thought to result from perturbed stromal-epithelial cell–cell interactions.

Currently, there is no clear understanding of the cell–cell interactions that occur at the anastomotic site of an augmented bladder. We know that in normal bladder development, epithelium is necessary for the differentiation of embryonic mesenchyme into smooth muscle (8). Epithelium is also essential for the differentiation of mesenchyme into smooth muscle in other organs such as intestine and uterus (19,23,37). Thus a signal must be transmitted from the epithelium to the mesenchyme, which instructs the mesenchyme to differentiate into smooth muscle.

During normal bladder development, signaling from the epithelium is required for smooth muscle development (Fig. 49A.2) (8). Epithelium is also necessary for the differentiation of mesenchyme into smooth muscle in other organs such as the uterus and intestine (50). Recent studies have shown that the inducing signal for smooth muscle differentiation is not specific to the age of the urothelium or in fact dependent on the origin of the epithelium (26). For example, embryonic, newborn, and adult urothelium all have the capability to induce bladder mesenchyme to form smooth muscle. Furthermore, heterotypic epithelia such as ureteral, gastric, uterine, colonic, corneal, and ileal will induce the same effect, although the amount of smooth muscle induction varies according to the type of epithelia Fig. 49A.6 (26). In general, the ability of heterotypic epithelia to induce smooth muscle differentiation in bladder mesenchyme was linked to the amount of smooth muscle with which the epithelium is normally associated. This was the case for gastric, ureteral, myometrial, and bladder epithelium, which all had the ability to induce extensive smooth muscle development in tissue recombination experiments (Fig. 49A.6). In contrast, epithelium not typically associated with smooth muscle such as corneal epithelium and epidermis showed little inducing capability.

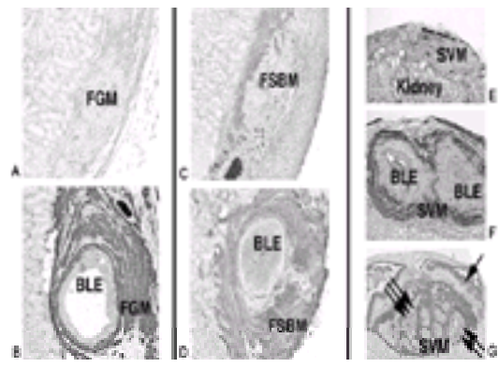

FIGURE 49A.6. Tissue recombination experiments illustrating stroma/mesenchymal-epithelial interactions. Three tissue recombinants using heterotypic fetal (gastric, ileal) and newborn (seminal vesicle) mesenchyme + adult bladder epithelium *(BLE).* When the fetal mesenchyme [gastric *(FGM)* and ileal *(FSBM)*] was grown alone (without epithelium, **A** and **C**), there was little evidence of smooth muscle differentiation (lack of a-actin smooth muscle immunostaining). However, when recombined with bladder epithelium, both gastric **(B)** and ileal **(D)** mesenchyme showed excellent smooth muscle differentiation [immunostaining (a-actin)]. Immunostaining for cytokeratin specific for transitional epithelium reveals a well-developed urothelial layer three to four cell layers thick in **B** and **D.** The entire morphology of the recombinant in **B** and **D** resembles that of bladder. When newborn seminal vesicle *(SVM)* is grown alone, there is evidence of smooth muscle differentiation **(E)** (which is to be expected because seminal vesicle mesenchyme has differentiated into smooth muscle by the time of birth). However, the smooth muscle is disorganized, and a-actin staining is scant **(E).** In contrast, when SVM is recombined with BLE in a female host **(F),** there is maximal smooth muscle differentiation and organization. Interestingly, when SVM is recombined with BLE in a male host **(G),** extensive smooth muscle organization is seen. Also, the epithelium in this tissue recombinant is transitional in some places (cytokeratin staining specific to transitional cells, *single arrow*), and prostatic in others (no pink staining, secretory morphology, *triple arrow*). There are some areas where the epithelium exhibits both transitional and prostatic morphology (*double arrow*). (From DiSandro M, Li Y,

Baskin L, et al. Mesenchymal-epithelial interactionsin bladder smooth muscle development: epithelial specificity. *J Uro*l 1998;160:1040, with permission.)

A large body of scientific evidence exists to support the concept that abnormal cellular signaling can lead to cellular changes. When embryonic or, even more surprising, adult bladder epithelium is placed in direct contact with urogenital sinus mesenchyme, the bladder epithelium is induced to differentiate into glandular epithelium that resembles prostatic epithelium histologically and ultrastructurally, expresses androgen receptors, and secretes prostate-specific proteins (Fig. 49A.6) (22,24,26). For example, both colon and prostate adenocarcinomas also are thought to arise from perturbed epithelial-stromal cell–cell interaction (21,32).

Changes in the stromal environment can profoundly influence adult epithelial morphology and function. This possibility has been tested by transplanting neonatal rat seminal vesicle mesenchyme *in situ* to the cut end of the mouse adult ureter. The adult urothelium was induced by the seminal vesicle mesenchyme to undergo seminal vesicle morphogenesis, to express seminal vesicle cytodifferentiation, and to produce the complete spectrum of major seminal vesicle proteins characteristic of the mouse. The induced seminal vesicle epithelium also expressed androgen receptors that are not seen in urothelial tissue. Staining with Hoechst dye 33258, which can distinguish cells of mouse and rat origin, further demonstrated that the induced seminal vesicle epithelium was indeed of mouse origin and not a contaminant of the inducing rat seminal vesicle mesenchyme. In addition, neonatal prostate-inducing mesenchyme grafted *in situ* beneath the bladder mucosa of adult male mice induced prostatelike acini, indicating that the aforementioned reprogramming of adult organs *in situ* is not an isolated occurrence. Thus it is clear that reciprocal epithelial-stromal interactions are important both in organogenesis and in adulthood in the homeostatic maintenance of normal tissue architecture and function and that adult epithelia retain a capacity to respond to stromal signaling. Further evidence that the stroma influences the epithelial phenotype is illustrated by recombination experiments in which urothelium is placed in an abnormal environment of rectal mesenchyme/stroma. In this case, the stroma causes the urothelium to change phenotype to a glandular mucous epithelium (Fig. 49A.7). Immunostaining of the tissue recombination experiments revealed a loss of uroplakin expression in the bladder cells, further evidence that the cellular phenotype of the urothelium had been changed. These data clearly support the concept of cellular signaling between the epithelium and stroma of the bladder (41). Theses data also illustrate the importance of normal signaling to maintain the normal phenotype of bladder cells.

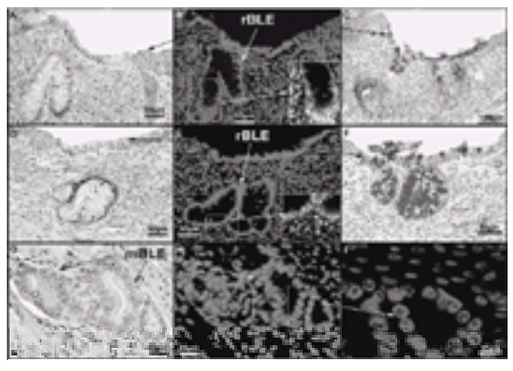

FIGURE 49A.7. Glandular epithelium induced from urothelium. Tissue separation and recombination experiment. **A:** Rat bladder epithelium combined with mouse rectal mesenchyme. Note that the epithelium has changed phenotype to glandular structures. **B:** Confirms that the epithelium is of rat origin. (Hoescht dye 33258 shows that the rat nuclei do not have speckles in contrast to the mouse nuclei in the stroma that have speckles.) The species-specific stain is useful to confirm that tissue contamination did not occur during separation of the epithelium and the mesenchyme. **C:** PAS stain showing mucin in the epithelial glandular structures. Note that some of the urothelium retains its histologic characteristics *(upper left).* **D:** Another example of rat urothelium changed to the glandular phenotype. **E:** Hoescht dye confirming the origin of the epithelium and mesenchyme. **F:** Note the positive mucin staining confirming glandular epithelium. **G:** The reverse tissue recombination experiment with mouse bladder epithelium and rat mesenchyme revealing that the mouse urothelium changed phenotype to a glandular epithelium. **H, I:** Hoescht dye showing origin of the epithelium and mesenchyme. *Arrows* relate area of magnification. [From Li YW, Liu WH, Hayward SW, et al. Plasticity of the urothelial phenotype: effects of gastro-intestinal mesenchyme/stroma and implications for urinary tract reconstruction. *Differentiation* 2000;66(2 and 3):126, with permission.]

It has been postulated that alterations of these interactions may play a role in the genesis of diseases such as benign prostatic hyperplasia and prostate cancer (21). It is also recognized that stromal changes occur in the genesis of many tumors. We have recently hypothesized that the reciprocal communication between incipient prostatic cancer cells and their surrounding stroma can promote of prostatic carcinogenesis (21). A similar scenario also may occur in the promotion of bladder tumors toward an invasive phenotype.

Epithelial-mesenchymal interactions during development continue as epithelia stromal interactions after birth. In numerous experimental systems, we have shown that the stroma regulates the epithelium, and the interactions are likely to be reciprocal (19,20,24). For example, it has been suggested that both normal prostatic development and prostate carcinogenesis are mediated by stromal-epithelial interactions. Recent evidence supporting this model comes from experiments in which the stroma surrounding prostatic tumors was analyzed by immunohistochemistry and shown to be dedifferentiated when compared with normal prostatic stroma. In another experiment, epithelial cells from the rat prostatic Dunning tumor were placed in contact with inductive mesenchymal environments (specifically with urogenital sinus and seminal vesicle mesenchyme). This resulted in a dramatic reduction in growth rate of the Dunning tumor cells and a loss of tumorigenicity (33). These findings demonstrate that the connective tissue environment can have profound regulative effects on neoplastic epithelial cells.

As previously noted, tumors in patients with bladder augmentations are primarily adenocarcinomas that originate at the anastomotic junction between the bladder and the intestine. It is known that nitrosamines are elevated in the urine of patients who have undergone enterocystoplasty. The nitrosamines in turn can cause mutagenic changes to the DNA. This hypothesis that nitrosamines are acting as carcinogens is supported by the increased incidence of cancer at the anastomotic site of patients who have had ureterosigmoidostomies (27).

We propose an alternative hypothesis that abnormal stromal-epithelial interactions at the site of bladder intestinal anastomosis lead to perturbations in reciprocal cell–cell signaling between the intestinal stroma and the urothelium. *In vitro* studies on bladder cancer cell lines support this hypothesis. Gordon and associates showed that altered extracellular matrices influence human bladder cancer cell lines possibly through regulation of the nuclear matrix (30). The authors conclude that the extracellular matrices derived from transformed stroma-producing cells may influence the proliferation, genetic regulation, and maintenance of the overlying urothelial tumor cells.

CONCLUSION

In conclusion, the bladder develops via coordinated signaling between the mesenchyme and the epithelium. Reciprocal cell–cell interactions maintain bladder function throughout life. Growth factors are likely mechanistic candidates that mediate the interactions between cells. Bladder wound healing, which is mediated by KGF, is a specific example of stroma-epithelial cellular signaling. Smooth muscle development, which is dependent on signaling from the epithelium, is another example of cell–cell interactions, although the specific causative growth factors remain to be elucidated. Abnormal cellular signaling may account for pathologic changes such as fibrosis secondary to bladder outlet obstruction or nerve abnormalities. Finally, abnormal stroma-epithelial signaling such as occurs at the anastomotic site of intestinal bladder augmentations may account for the increased risk of cancer documented in these patients.

Exstrophy and epispadias remain one of the most striking and challenging birth defects confronting physicians who specialize in the urologic care of children. With these anomalies, the anterior portion of the bladder and/or urethra and abdominal wall structures are deficient and the pubis symphysis is widely separated from the midline. The deformity has been described as “if one blade of a pair of scissors were passed through the urethra of a normal person; the other blade were used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened” (17). Interestingly, this defect often occurs in isolation so that other organ systems are affected only infrequently. Exstrophy is also a nonlethal defect; its natural history is known and has been described by various authors.

Formal descriptions of exstrophy date back to at least 1597 with Sherk von Grafenberg's description of this congenital defect. Probable depictions of exstrophy also exist on Assyrian tablets from 2000 B.C. Chaussier first coined the term “exstrophie” to describe this defect in 1780 following detailed descriptions of it by Mowat in 1748. Treatment of exstrophy was doubtlessly difficult during these earlier times and it remains challenging today.

Since the nineteenth century, various methods to treat exstrophy have been described. Because exstrophic conditions are rare, these early approaches were empiric and often unsuccessful. More focused efforts in this century have led to a better understanding and improved treatment of exstrophy. Currently, the exstrophic diseases are considered a spectrum of disease processes related by certain principle anatomic features. These diseases are referred to as the exstrophy–epispadias complex (60), which includes the following:

- Epispadias
- Classic bladder exstrophy
- Cloacal exstrophy
- Exstrophy variants

EMBRYOLOGY/PATHOGENESIS

Embryologically, components of the urinary system such as the ureteral buds first appear during the fourth week of fetal development and before the bladder has completely formed from the anterior urogenital sinus. Before this, the cloacal membrane separates the coelomic cavity from the amniotic space during the third week of development. By the fourth week of gestation, the cloacal membrane forms the ventral wall of the urogenital sinus at the root of the allantois. Before the bladder is completely formed, mesenchyme grows inward toward the midline between the bilaminar (ectoderm and endoderm) layers of the cloacal membrane. This ingrowth of mesenchyme later differentiates into the abdominal wall musculature and fascia of the bladder. Following this, the urorectal septum separates the bladder and rectum by growing downward between them to join the cloacal membrane in the primitive perineum. This occurs when Tourneaux's folds migrate craniocaudally to meet Rathke's plicae that merge together in a lateral-to-medial direction. The urinary bladder arises during the eighth week of fetal development when the ventral portion of

the urogenital sinus begins to expand (126).

With bladder filling, the mesenchymal tissue surrounding this structure differentiates into smooth muscle, which eventually becomes the detrusor muscle. Ingrowth of neuronal tissue into this smooth muscle to form motor units is critical to the development of a functional bladder (100). Embryogenesis of the pelvic floor is also important in normal fetal bladder development and function; the pelvic floor acts as a dynamic support for the bladder, which aids in both continence and volitional voiding (56).

Genital development occurs simultaneously. The primordia of the genital tubercles develop cephalad and lateral to the cloacal membrane. These paired structures fuse in the midline above the cloacal membrane to create a single genital tubercle at the same time that mesenchymal ingrowth occurs into the cloacal membrane. The area between the body stalk and cloacal membrane subsequently lengthens to create an infraumbilical body wall.

Pathogenesis of Exstrophy

Early theories implicated trauma to the unborn child or ulceration of the abdominal wall and bladder between the second and third months of life as the underlying cause of exstrophy. In the nineteenth century, syphilis infection was believed to be a possible cause of exstrophy (222). Later, at the turn of the century, bladder outlet obstruction with rupture of the abdominal wall was implicated as the cause of exstrophy. This hypothesis explained the lack of fusion of the bony pelvis and abdominal wall but failed to adequately explain the pathophysiology of exstrophy. As our understanding of embryogenesis has improved, this idea subsequently has been abandoned (33).

Modern theories all implicate an error in embryogenesis rather than an event of arrested development as the cause of exstrophy because the developing human embryo does not normally pass through a stage that corresponds to an exstrophic state (163). Specifically, abnormalities in the appearance, timing, and function of the cloacal membrane are believed to be involved in the creation of exstrophy. Animal models suggest that exstrophy results from pathologic events involving the cloacal membrane. As described earlier, this membrane serves to separate the coelomic cavity from the amniotic space in early development and can first be identified during development at 2 to 3 weeks of gestation (216).

In 1962, Marshall proposed that exstrophy was caused by persistence of this cloacal membrane during fetal development based on autopsy studies of fetuses with bladder exstrophy done earlier in the century (144). Persistence of the membrane would create a wedge effect that would keep the medially encroaching mesoderm from fusing in the midline. The persistent cloacal membrane would then later rupture because of its inherent instability to produce an exstrophic condition (163). To further study this hypothesis, Muecke subsequently created an animal model of cloacal exstrophy using the developing chick embryo. By placing a plastic graft in the region of the tail bud, he created cloacal exstrophy in these animals and concluded that exstrophy was due to persistence of the cloacal membrane as Marshall had originally postulated (163).

Other experimental models have implicated premature disappearance of the cloacal membrane in the pathophysiology of exstrophy instead. Johnston first proposed this mechanism for the development of exstrophy. However, it was not until Thomalla and Mitchell developed a model of cloacal exstrophy in the developing chick embryo by using a CO_2 laser to create an early dehiscence in the tail bud caudal to the omphalomesenteric vessels that the hypothesis was shown to have a valid animal model (118). Their results demonstrated that exstrophy may be caused by failure of the mesoderm to ingrow between the ectoderm and endoderm as the result of an absence of the cloacal membrane that also produces exstrophy. Simplistically, a hole in the anterior abdominal wall results in the herniation of the developing bladder, causing the structure to move anteriorly and to fail to close ventrally (Fig. 49B.1). Such an event could be caused by early hypoxemic infarction in the region of the tail bud with subsequent cellular loss of the mesoderm and herniation of the developing bladder or cloaca (212). This type of ischemic injury has been implicated as the cause of gastroschisis and can explain the spectrum of exstrophy–epispadias complex (211).

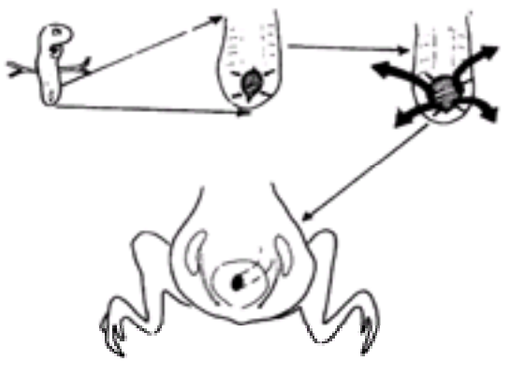

FIGURE 49B.1. Diagrammatic representation of cloacal exstrophy chick model. Defect in cloacal membrane induced by CO_2 laser. (From Thomalla V. Induction of cloacal exstrophy in the chick embryo using the CO_2 laser. *J Urol* 1987;134:991, with permission.)

Other proposed theories for exstrophy include caudal displacement of the paired primordia of the genital tubercles (“caudal displacement theory”). This hypothesis implicates caudal fusion of the primordia of the genital tubercles from their usual location relative to where the urorectal fold divides the cloaca into the urogenital sinus and rectum (172). This theory readily explains the spectrum of variation seen in the exstrophy–epispadias complex. Minimal caudal displacement of the primordia would produce epispadias; more significant caudal displacement would result in exstrophy. However, it fails to explain the higher incidence of exstrophy compared with epispadias; this hypothesis would predict a higher incidence of epispadias if caudal displacement were the underlying cause of exstrophy/epispadias because it represents the most trivial example of this phenomena (216).

Ultimately, the specific underlying cause of exstrophy remains unanswered because it is a rare birth defect and no naturally occurring animal models exist to facilitate research. The chick model to study bladder exstrophy has inherent limitations because chicks normally possess a cloaca so that only cloacal exstrophy can be created with this model. Other animal models to study bladder exstrophy have proven more difficult to create. Slaughenhoupt and colleagues have created an exstrophy model using sheep but have not published any data using this model to study the underlying mechanisms of exstrophy and its effects on bladder development (197).

ANATOMIC PATHOLOGY

The anatomic features of patients with exstrophy or epispadias can vary. The primary organ system—the genitourinary system—is always affected to a variable extent. Other organ systems also may be involved. The various anatomic features for all the exstrophic anomalies are discussed in the following sections (Table 49B.1).

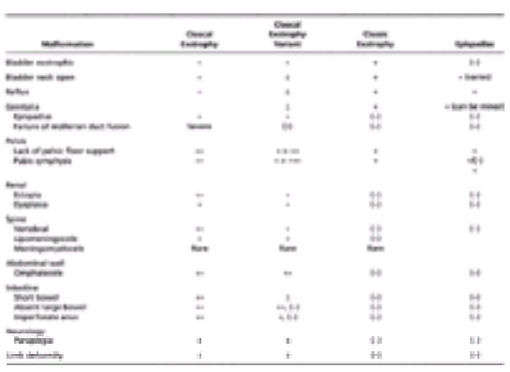

TABLE 49B.1. AFFECTED ORGAN SYSTEMS IN THE EXSTROPHY-EPISPADIAS ANOMALIES

Bladder Exstrophy

The primary features of exstrophy involve an absence of the anterior bladder wall and dorsal urethra with an associated absence of the anterior abdominal wall overlying it (Fig. 49B.2). The urothelium of the bladder and urethra is thus exposed to the environment. Considerable variation exists in the size and compliance of the bladder plate at birth; some bladders are quite small and inelastic, whereas others appear large and compliant. At birth, the urothelium is usually normal in appearance. However, ectopic bowel mucosa or polypoid lesions consistent with cystitis cystica and/or glandularis may be present. If left untreated and if not meticulously protected after birth, the exposed urothelium will undergo squamous metaplasia in response to acute and chronic inflammation. Other inflammatory changes such as cystitis cystica and/or glandularis also will be seen. When left chronically exposed to the environment, the areas of squamous metaplasia often undergo malignant degeneration to adenocarcinoma or squamous cell carcinoma (85,168).

FIGURE 49B.2. Newborn male with classic bladder exstrophy.

Associated Anomalies

Classic exstrophy and epispadias share a low incidence of anomalies affecting organ systems other than the genitourinary tract and bony pelvis. In contrast, patients with cloacal exstrophy have associated anomalies more often than not (12,44). These anomalies can affect the upper urinary tract, intestines, skeletal system, and neurologic system. A possible reason for this is that the cloacal exstrophy defect occurs much earlier in development, affecting subsequent development of related structures including the spine, kidneys, and hindgut.

Kidneys and Upper Urinary Tract

Renal anomalies are not characteristic with bladder exstrophy. Associated renal abnormalities can include cystic dysplasia, ureteropelvic junction obstruction, pelvic kidney, megaureter, renal hypoplasia, and horseshoe kidney (166). In contrast, vesicoureteral reflux occurs almost universally after exstrophy closure. This likely occurs because the ureteric migration into the bladder plate occurs after the anterior herniation of the bladder plate, resulting in an altered anatomy of the ureteric path such that its course is posterior and caudal, “J hooking” (Fig. 49B.3).

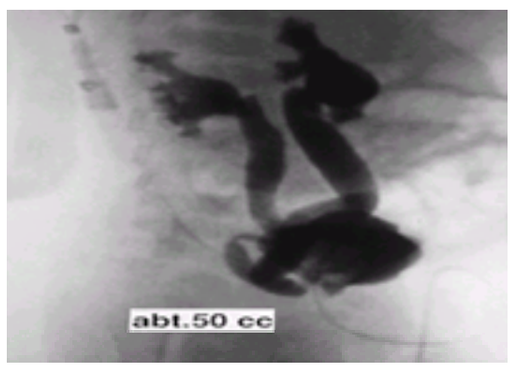

FIGURE 49B.3. Voiding cystourethrogram in 6-month-old boy with bladder exstrophy after closure demonstrating vesicoureteral reflux. The ureters approach the bladder inferiorly and laterally.

Genitalia

The male exstrophy patient has a broad and shortened penis. The penis is deflected dorsally and may have true intrinsic dorsal chordee. The corpora cavernosa are splayed laterally because of their attachment to the separated pubic bones. Because of the pubic diastasis associated with exstrophy, the penis appears variably foreshortened. Magnetic resonance imaging (MRI) evaluation of the penile length of adult male exstrophy and epispadias patients also reveals that the total corporal length is significantly shorter than in a control population. This corporal shortening apparently results from a foreshortened anterior segment (distal to the pelvic attachment). The posterior corporal segment is unaffected (195) (Fig. 49B.4).

FIGURE 49B.4. The phallus of the exstrophic male. The proximal corpora splay laterally from their normal anatomic position and demonstrate dorsal chordee. *White arrow* points to the urethral plate.

The combination of the short urethral plate and dorsal chordee also creates the appearance of the glans penis lying in close approximation to the prostatic utricle. The ejaculatory ducts empty at the verumontanum exposed on the urethral plate. The vas and ejaculatory ducts are typically unaffected in classic exstrophy unless iatrogenically damaged (90). Innervation to the penis is preserved but the anatomic location of the nerves is affected. This has obvious implications for later surgical procedures. In the normal male, these nerves can be found on the dorsal aspect of the penis after they traverse the posterolateral aspects of the prostate and the membranous urethra (225). However, in the exstrophic male, the cavernosal nerves are located on the lateral aspects of the corporal bodies. The prostate is also incompletely formed (71,88). The scrotum usually is not affected, although most exstrophy patients have an increased distance between the base of the penile shaft and the scrotum and a broadening of the scrotum dependent on the degree of diastasis (Fig. 49B.2). The testes may be undescended with exstrophy. Because of the underlying bladder neck anomalies, exstrophic patients may have impaired fertility. A particular problem is retrograde ejaculation if the bladder neck does not close completely during emission following bladder reconstruction (9,15,134).

The exstrophic female has unique anatomic features affecting the genitalia as well (Fig. 49B.5). The mons pubis is absent. In association with a bifid clitoris, the anterior labia are laterally displaced although they fuse in the midline posteriorly. The vagina and introitus also are displaced anteriorly from their usual position and the introitus is tilted upward. The vaginal opening may be stenotic in these patients, but we have not found this to be a characteristic *de novo* feature. However, vaginal stenosis can result as a complication of surgical intervention. Internal genital structures (uterus, cervix, fallopian tubes, and ovaries) usually are unaffected in classic exstrophy although the cervical os often enters the superior wall of the vagina. Uterine prolapse due to deficient pelvic floor support can occur in the older exstrophy patient and poses particular problems with pregnancy (170). Early primary bladder reconstruction may decrease this risk. Uterine suspension procedures such as sacrocolpopexy can be used in these situations as well.

FIGURE 49B.5. Newborn female with classic bladder exstrophy.

Anorectal and Intestinal Abnormalities

The anus is often displaced anteriorly in the exstrophy complex. Some exstrophic patients have insufficient anal continence because of the underlying abnormalities of the pelvic floor support structures including the levator ani and puborectalis muscles. Anal sphincter weakness not only affects fecal continence but also may limit the use of ureterosigmoidostomy and its variants, that is, rectal bladder, ileocecal ureterosigmoidostomy, and so on. In untreated patients, rectal prolapse also can occur because of insufficient pelvic floor support. This can be treated with formal exstrophy repair that corrects the lack of anterior pelvic support. In the interim, most rectal prolapse is intermittent and reducible (60).

Skeletal Abnormalities

Diastasis of the pubic symphysis occurs as part of the exstrophy complex. The pelvis is open anteriorly and flattened in the anterior posterior dimension. This results from outward rotation of the innominate bones along both sacroiliac joints. Outward rotation of the pubic rami at the iliac and ischial junctions is seen as well. Sponseller has noted other differences in the pelvic anatomy of patients with exstrophy, including (a) increased distance between the triradiate cartilage, (b) external rotation and shortening (by 30%) of the anterior segment of the iliac bone, (c) external rotation of the posterior segment of ileum, and (d) retroversion of the acetabula (113,202) (Fig. 49B.6). These pelvic bone abnormalities contribute to splaying of the penis noted with exstrophy and epispadias and cause the penis to appear foreshortened. Gait abnormalities in these children arise as a consequence of these bone abnormalities. Many of these children initially learn to ambulate with a wide waddling gait that resolves as the children grow. Orthopedic procedures to reapproximate the pubis symphysis at the time of primary closure do not appear to offer any long-term benefits to these patients from an orthopedic viewpoint. Long-term follow-up of these patients clearly demonstrates that the pubic diastasis reoccurs over time despite osteotomies (190). Osteotomies to reapproximate the pubis symphysis do, however, increase the chance of successful primary bladder closure in selected patients and may have a significant role in securing continence and support of the pelvic diaphragm (1,14).

FIGURE 49B.6. The bony pelvis in exstrophy. Note wide pubic diastasis seen on this radiograph.

Fascial Abnormalities

Fascial abnormalities with exstrophy involve several factors in addition to the rectus fascial defect associated with the exposed bladder. Inferiorly, the pelvic floor support structures are compromised. In fact, the anterior portion of the pelvic diaphragm is actually thickened in the exstrophic patient. This thickened segment provides anterior support in the absence of the pubis symphysis and is often referred to as the intersymphyseal band or ligament. The remaining portion of the pelvic diaphragm lies completely posterior to the exstrophic bladder and urethra (Fig. 49B.7). The rectus muscles diverge laterally with the widened pubis symphysis. This abdominal defect is most severe in cloacal exstrophy.

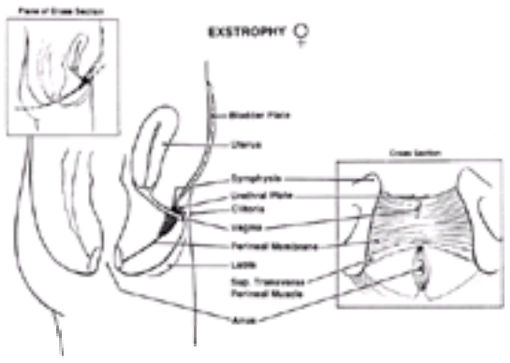

FIGURE 49B.7. Fascial anomalies. The pelvic support structures are compromised anterior to the bladder and urethra. This schematic diagram of a girl with bladder exstrophy illustrates the lack of anterior support.

Inguinal hernias commonly are associated with exstrophy in both male and female patients (34,207) (Fig. 49B.8). The majority of these hernias occur indirectly. They arise as a consequence of enlarged internal and external inguinal rings combined with compromised fascial support and lack of obliquity of the inguinal canal (104). In a review of patients from Toronto Sick Children's Hospital, 56% of classic male exstrophy patients and 15% of classic female exstrophy patients developed inguinal hernias over a 10-year period. The authors recommended these hernias be repaired at the time of primary bladder closure to prevent incarcerated hernias that could affect up to 50% of these patients in the first 2 years of life (30). Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the incidence of later direct inguinal hernias. Umbilical hernias, as a contiguous defect with the bladder plate, also uniformly occur with exstrophy and are repaired at the time of the primary repair.

FIGURE 49B.8. Evidence of an inguinal hernia in this newborn male with bladder exstrophy as demonstrated by the inguinal bulge *(arrow).*

Omphaloceles also can be found in association with bladder exstrophy, although this rarely occurs in classic exstrophy (232). These are surgically corrected at the time of primary closure if they are small. However, cloacal exstrophy is typically associated with an omphalocele defect.

Neurologic System

Spinal cord abnormalities are the exception rather than the rule in bladder exstrophy. Occult spina bifida and even myelomeningocele can occur in combination with bladder exstrophy but this is a rare occurrence, especially in contrast to patients with cloacal exstrophy (20).

Epispadias

Epispadias is considered the least severe defect of exstrophy–epispadias complex and presents as a spectrum of severity as well. It does not involve the body of the bladder or the hindgut. Bladder function may be affected because of low urethral resistance during early development. This is the basis of the argument for early repair of epispadias with bladder neck involvement.

The defect in epispadias involves an absence of the dorsal aspect of the urethra and overlying skin extending to the bladder neck in the most severely affected proximal cases (Fig. 49B.9). The external genital anomalies described for the patient with exstrophy are noted with epispadias as well. These include lateral splaying of the penis and dorsal chordee in boys. In affected girls, the clitoris is bifid, the perineal body is broadened, and the vagina is anterior to its orthotopic position (Fig. 49B.10). Widening of the pubic diastasis occurs in epispadias as well although it is usually not as severe as that seen in classic exstrophy. Importantly, the bladder neck frequently is involved and is often wide and incompetent. This directly affects the continence mechanism of these children and their ability to achieve urinary continence. In untreated boys with epispadias, continence is possible if the epispadias is located distally and the bladder neck is not involved. In girls, however, continence invariably is affected to some degree because of the urethral and bladder neck ectasia invariably involved in female epispadias. This is the basis of the argument for early repair of all girls with epispadias in an effort to maximize bladder function. Because of the shared features with bladder exstrophy, clinicians consider epispadias as part of a spectrum of exstrophy–epispadias complex.

FIGURE 49B.9. Penopubic epispadias in 3-month-old boy. Skin demarcation is due to chronic urine contact dermatitis in this patient.

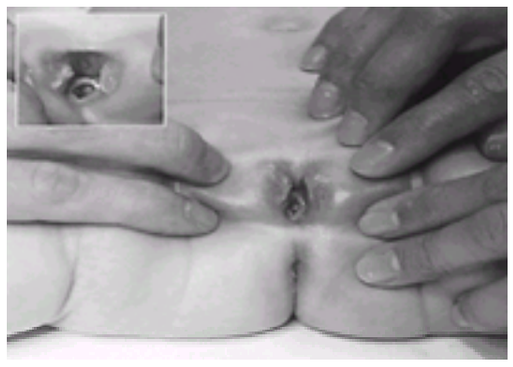

FIGURE 49B.10. Epispadias in 4-month-old girl. The anomaly affects the bladder neck and urethra. The clitoris is bifid.

Exstrophy Variants

Patients with atypical physical findings are categorized as exstrophy variant patients. These patients have some but not all of the typical features of bladder or cloacal exstrophy as well as other features not typically associated with classic bladder exstrophy or cloacal exstrophy. These include covered exstrophy and superior vesical fissure. Patients with exstrophy variants may have anatomically normal genitalia despite their bladder and colon anomalies (Fig. 49B.11).

FIGURE 49B.11. Conjoined twins connected by membranous omphalocele sac containing a shared segment of distal ileum, cecum, and colon draining to a common exstrophic cloaca—an example of an exstrophy variant.

Bladder exstrophy variants include patients whose anatomic features resemble classic exstrophy in regard to the fascial and/or symphyseal defects but who do not have any significant anomaly associated with the urinary tract. These patients are considered to have pseudoexstrophy (125,144, 159,208). Some patients have an isolated ectopic bowel segment or anterior bladder wall defect in association with the previously mentioned findings; they are referred to as *covered exstrophy variants* (29). The sequestration phenomenon that occurs with these patients is not well understood embryologically. Other covered exstrophy variants include patients with overlying skin coverage of a bladder that possesses no anterior wall. These patients generally exhibit characteristics consistent with classic or cloacal exstrophy but initial evaluation is very deceiving. Therefore these patients invariably are incontinent of urine because the defect also involves their bladder neck.

Patients with superior vesical fissure also have the muscular and skeletal defects associated with bladder exstrophy, but only the upper portion of the bladder is affected so that the urethra may be intact and the genitalia are less affected than with classic exstrophy (125). In these patients, incontinence often is not a major problem.

A condition noted as duplicate exstrophy also has been described. Patients with this condition present with a duplicated lower urinary tract. However, one of the urinary tracts appears exstrophic. This duplication may not be recognized until the time of surgical exploration (194). Over nine cases of duplicate exstrophy have been reported in the literature since Marshall and Muecke's first description. Because the duplication anomaly can allow for a normal genitourinary system in one of the paired set of organs, treatment can be quite successful. However, these patients can have genital anomalies consistent with classic exstrophy as well; this association is variable. A subset population of this uncommon anomaly has been recognized and is more severely affected and more difficult to treat (3,164,176,194).

Possible etiologies for exstrophy variants include conjoined twinning or aborted conjoined twinning. Evidence of conjoined twins with exstrophy variants has been described and would explain the duplication phenomena seen in some of these patients (78,81).

Incidence

Bladder exstrophy occurs at a rate of 1 per 10,000 live births to 1 per 50,000 live births (48,133). This anomaly has long been recognized to occur more commonly in males than females with a ratio of 2.3 to 4:1 reported in the literature (111,49). Cloacal exstrophy occurs even more rarely with an incidence of 1 in 200,000 to 1 in 400,000 live births (235).

Genetic factors involved in exstrophy remain incompletely defined. To date, eighteen familial cases of bladder exstrophy have been reported, the most recent of which describes a mother and son with bladder exstrophy (152). In 1984, a survey of pediatric urologists and surgeons, reported 9 cases related to 2,500 index cases of bladder exstrophy; this same series also reported on cases of twins and noted discordance in both fraternal and identical twinships (192). Furthermore, in a study population of more than 6 million births with 208 reported cases of exstrophy, no case had a family history for this anomaly (115). Current recommendations on counseling about risk of recurrence in a sibling of a patient with exstrophy cite an estimate of approximately 1% and a 1:70 chance of transmission to the progeny of an affected parent (152). Based on these findings, bladder exstrophy appears likely to be multifactorial rather than genetically based; environmental factors may play a significant role in the cause of the exstrophy–epispadias complex.

Antenatal Diagnosis

Prenatal identification of exstrophy is possible. The bladder may be visualized at 11 to 12 weeks of gestation and the kidneys at 14 to 15 weeks; both become more obvious with advanced gestational age so that ultrasonography can reliably detect exstrophy before the twentieth week of gestation (8,18,19,70,132,148,154,171,177). Absence of the bladder is a hallmark of exstrophy but several findings also suggest the diagnosis. These include the presence of normal kidneys in association with a low-set umbilical cord. Sonographic examination also may reveal a semisolid mass protruding from the abdominal wall in addition to the above findings (10,112) (Fig. 49B.12). Gearhart and co-workers reviewed the antenatal ultrasonographic studies of 25 women who delivered live infants with exstrophy. They noted the following:

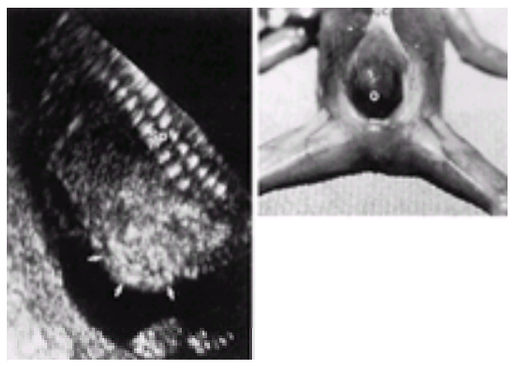

FIGURE 49B.12. Antenatal sonogram of fetus with exstrophy and photograph of fetus with confirmed exstrophy at autopsy. (Adapted from Mirk P, Calisti A, Fileni, A. Prenatal sonographic diagnosis of bladder exstrophy. *J Ultrasound Med* 1986;5:291, with permission.)

- An absent bladder in 71% of the studies
- A lower abdominal protrusion in 47% of the studies
- An anteriorly displaced scrotum with a small phallus in 57% of the male fetuses
- A low-set umbilical cord in 29% of the studies
- An abnormal iliac crest widening in 18% (70)

Because urine production is normal for these fetuses, amniotic fluid levels should be normal. Prenatal diagnosis allows optimal perinatal management of these infants, including delivery near a pediatric center equipped to treat babies with this unusual anomaly. Unfortunately, many affected fetuses are still not detected antenatally (196). In Gearhart's review of 29 antenatal studies of 17 children born with exstrophy, only 3 were identified before delivery despite the presence of findings to suggest the diagnosis (70). Subtle findings such as low umbilical cord insertion and the location of the genitalia will only be seen if the fetus is examined in a sagittal alignment with the spine (189). Because of the abnormal genitalia findings, the diagnosis is easier to make in males than females. Iliac crest widening also can be seen during the routine prenatal evaluation of the lumbosacral spine that is performed to evaluate for myelomeningocele. The iliac angle will be approximately 110 degrees rather than the 90 degrees normally seen (189).

Antenatal diagnosis allows the parents the opportunity to discuss early management of the patient. The early counseling should include the expertise of a pediatric urologist experienced in the treatment of bladder exstrophy. The overall prognosis of these children is excellent, if initial treatment is at medical centers with physicians experienced in the treatment of this disorder. Unfortunately, because of the rarity of bladder exstrophy, health care providers who lack insight and knowledge of this disorder often counsel prospective parents of these patients. The resultant counseling of these families by health care providers who are unaware of the true potential of patients with bladder exstrophy has led to an increase in the abortion rate of these fetuses. This is unfortunate in view of the very satisfactory long-term outcome and life expectancy that are possible with appropriate management (19).

THE NATURAL HISTORY OF EXSTROPHY

> Exstrophy of the bladder, unless the patient is willing to assume the (often mortal) risk of an autoplastic operation, is utterly irremediable; all that can be done is to palliate the patient's suffering by attention to cleanliness, and by the use of a closely-fitting flexible gutta-percha shield, furnished with a gum-elastic bottle for receiving urine... When this cannot be obtained, the part must be kept constantly covered with a thick, soft compress, renewed as often as it becomes wet and disagreeable. The skin around may be protected, if necessary, with pomatum, simple cerate, or zinc treatment” (84).
> —Samuel Gross, 1876

Because the bladder exstrophy–epispadias complex is not a lethal condition, children with bladder exstrophy or exstrophy can survive untreated. Before the modern era of surgery and anesthesia, some patients with bladder exstrophy survived untreated into adulthood. Reports exist of such patients with classic bladder exstrophy living into their eighth decade (169). In contrast, until recently, patients born with cloacal exstrophy died shortly after birth from electrolyte abnormalities and malnutrition. However, the morbidity bladder exstrophy patients experienced was often severe as a result of bladder and kidney infection, skin breakdown, and tumor formation in the bladder plate. Patients left untreated often covered the exposed bladder with various undergarments, including liniment soaked rags, cotton, and wool bolsters, resulting in chronic bladder plate irritation. The surrounding skin around the exstrophic bladder was often inflamed secondary to urine contact dermatitis, loss of skin integrity from constant wetness, and secondary infection. D.I. Williams noted in the 1960s that “inevitably, most untreated exstrophy children are very irritable and bad-tempered and their crying only serves to accentuate their umbilical hernia, their inguinal herniae, and their rectal prolapse”(220). These patients are often social pariahs because of associated odor and hygiene problems. This sad state of affairs prompted these patients to seek treatment and physicians who used heroic measures to help these patients.

Surgical Reconstruction—Early Efforts

The morbidity of exstrophy led surgeons to begin empiric approaches to the operative correction of this anomaly. Surgeons in the nineteenth century attempted urinary reconstructive or diversion procedures to treat these patients. Initial efforts were directed at partial reconstruction of the abdominal wall to allow the application of a urinary receptacle to collect urine. The first successful record of this form of repair is attributed to Dr. Pancoast in 1859. He used skin flaps from the abdominal wall:

> In the treatment of exstrophy of the bladder the principal objects aimed at are either to establish a channel for the conveyance of the urine to the rectum or perineum, or to cover its exposed and sensitive mucus membrane with flaps of skin, thereby protecting it from contact of the clothing, and preventing excoriation of the surrounding parts, as well as facilitating the adjustment of an apparatus for receiving the urine (84).
> A flap is taken from one side of the abdomen or groin, dissected up, and turned over like the leaf of a book so that the epidermis comes into contact with the mucous membrane. A second flap is then taken from the groin on the opposite side and its raw surface applied to the raw surface of the former flap...thus a thick bridge is formed over the cleft (36).

Dr. John Wood and F.F. Maury also described variations on the use of skin flaps to reconstruct the abdominal wall (84,221). Wood used a full thickness skin graft from the abdominal wall followed by a lateral, pyriform flap from each groin held in place with hare-lip pins, wire sutures, and broad straps of adhesive plaster, which were removed 6 to 8 days after surgery (Fig. 49B.13). In contrast, Maury created perineal and scrotal skin flaps to repair bladder exstrophy. These procedures represented early attempts at anatomic closure but did not address the functional reconstruction of these bladders—namely to achieve satisfactory storage and emptying of urine. V.H. Van Buren aptly stated the common sentiment of the time:

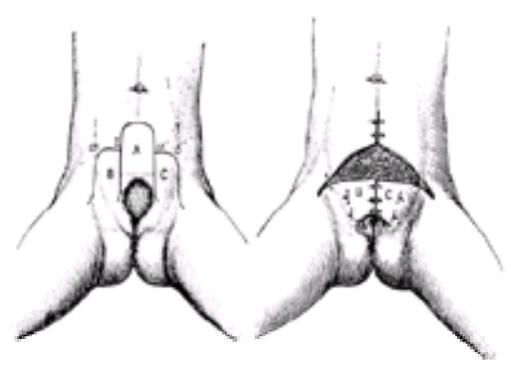

FIGURE 49B.13. Early operation for bladder exstrophy as proposed by Maury in the midnineteenth century. This operation was designed to create skin flaps to

narrow the urinary outlet so that an appliance could be applied to collect urine.

> The most that can be promised by operative interference is to leave behind a fistula, more or less large, over which a urinal must be constantly worn. The patient's virility is not returned to him, nor is his condition very materially bettered. A less dangerous and equally efficacious mode of treatment seems to be to adapt a suitable urinal to the parts as they are left by Nature, such a one as shall shield them from injury, and keep the patient dry and clean (214).

Others, such as Simon, approached the surgical treatment by attempting urinary diversion in these patients through the creation of a ureteral sigmoid fistula. Results were poor: one patient died of peritonitis in the immediate postoperative period, and the other died of renal failure secondary to chronic pyelonephritis (84).

These early efforts suffered from lack of understanding of the physiology of the urinary tract and bladder and subsequently how these operations would affect urine storage and emptying, kidney function, electrolyte homeostasis, the propensity for urinary tract infection (UTI) or calculus formation, fertility, and sexual function. Complications from these operations were often life threatening. That patients were willing to assume this risk in the treatment of this anomaly demonstrates the impact it had on their lives.

SURGICAL RECONSTRUCTION OF EXSTROPHY/EPISPADIAS—THE MODERN ERA

Modern objectives for reconstruction in the treatment of exstrophy can be placed broadly in the categories in Table 49B.2.

Primary Goals	Secondary Goals
Preservation of kidney function	Minimization of urinary tract infections
Urinary continence	Adequate pelvic floor support
Low pressure urine storage reservoir	Minimization of the risk for malignancy associated with the urinary tract
Volitional voiding	Minimization of the risk for urinary calculi
Functionally and cosmetically acceptable external genitalia	Adequate abdominal wall fascia

TABLE 49B.2. MODERN OBJECTIVES FOR RECONSTRUCTION IN THE TREATMENT OF EXSTROPHY

Although these goals are straightforward and interconnected, successful achievement of them often remains elusive. In fact, many of the secondary goals address complications that can arise as a result or complication of surgical procedures used to treat exstrophy. Numerous operations have been devised for the treatment of bladder exstrophy testing the ingenuity of the physicians involved in the care of these patients as well as the resilience of the patients themselves. The objectives underlying these operations have expanded since the first operations were proposed and attempted beginning in the 1800s. These objectives address the primary pathology and problems associated with exstrophy and its management (Table 49B.3).

Primary Pathophysiology (Untreated)	Complications (Associated with Management of Exstrophy)
Urinary incontinence Bladder malignancy	Malignancy (related to the use of intestine in bladder reconstruction), hydronephrosis
Urinary tract infection, reflux	Pyelonephritis, stones
Chronic bladder irritation	
Pelvic floor insufficiency	Cystocele, uterine prolapse
Symphyseal diastasis, pelvic flattening	Abnormal hip dynamics, back pain
Abdominal wall defect	
Severe penile shortening with dorsal chordee Ventral and inguinal hernias	Inadequate phallus in males with subsequent social and psychologic sequelae

TABLE 49B.3. PRIMARY PATHOLOGIES AND PROBLEMS ASSOCIATED WITH EXSTROPHY AND ITS MANAGEMENT

Modern Operative Approaches to Exstrophy

Despite the innumerable operations that have been applied to the treatment of exstrophy, operations for exstrophy currently fall largely into two strategies. The first includes operations designed to remove the exstrophic bladder and replace it with a form of urinary diversion. The second includes reconstructive procedures designed to reconstruct the bladder either in multiple stages or in a single stage. Surgeon preference, patient anatomy, previous surgical procedures, availability of tertiary care facilities, and access to medical care all play a role in which operative procedures are chosen. No standard of care exists for this patient population. However, because of the complexity of exstrophy, specialists with an interest in the exstrophy–epispadias complex best manage these patients by tailoring their care to each patient's situation.

Perioperative Care

Preoperative Care

To prevent trauma to the exposed bladder plate after delivery, the umbilical cord should be ligated with silk suture rather than a plastic or metal clamp. The exstrophic bladder should be protected against the elements by whatever means are available. We prefer a hydrated gel dressing such as Vigilon. This type of dressing protects the bladder plate and stays in place to allow handling of the infant with minimal risk of trauma to the bladder. We have used this dressing for over 2 months for infants who could not undergo immediate repair because of severe prematurity; we noted minimal inflammation of the bladder at the time of total primary repair. The exposed bladder may be covered with plastic wrap as an acceptable alternative. Either dressing should be replaced daily. The bladder should be irrigated with normal saline with each diaper change. Other authors have advocated the use of a humidified air incubator with no dressing at all to minimize bladder trauma (30).

Routine use of intravenous antibiotic therapy in the preoperative and postoperative periods decreases the chance for infection. We also routinely perform ultrasonography to assess the kidneys preoperatively and to establish a baseline examination for later ultrasonographic studies. A spinal sonographic examination also should be obtained if sacral dimpling or other signs of spina bifida occulta are noted on physical examination.

Operative Considerations—Initial Closure

In the newborn period, we perform primary exstrophy closure using general inhalation anesthesia. We advise against the use of nitrous oxide during primary closure because it may cause bowel distention, which decreases surgical exposure during the operation and increases the risk of wound dehiscence. Some authors advocate the use of nasogastric tube drainage to decrease abdominal distention in the postoperative period (59). We do not use nasogastric suction in most patients, but

routinely use a one-time caudal block to reduce the inhaled anesthetic requirement during the procedure.

For patients older than 3 days or newborns with a wide pubic diastasis, pelvic osteotomy will facilitate closure and strengthen the anterior pelvic support that may potentiate later urinary continence (1,14).

Several groups of investigators have reviewed their patient series in an effort to identify factors that increase the success of the initial reconstruction. These include several factors that are important in the operative period:

- Use of osteotomies in selected cases and for newborn closures more than 24 to 48 hours after birth
- Ureteral stenting catheters placed intraoperatively for use in the postoperative period to divert urine
- Avoidance of abdominal distention
- Use of intraoperative antibiotics (107,140)

Postoperative Considerations

After a primary reconstructive procedure for exstrophy, the patient must be immobilized to decrease lateral stresses on the closure. Use of a spica cast for 3 weeks to prevent external hip rotation and optimize pubic apposition can facilitate early discharge and home care (Fig. 49B.14). Modified Buck's traction has been used by many groups for a period of 3 to 4 weeks. A posterior lightweight splint can be used in newborns when the child is out of traction to facilitate home care and early removal of traction. Over the years, we have tended not to use Buck's traction to facilitate earlier discharge and ease of care. External fixation devices also have been advocated by several centers. Fixator pins for these devices should be cleaned several times a day to reduce the chance for infection. Internal fixation may be necessary in older patients. “Mummy wrapping” should *not* be used to immobilize the pelvis because it is unreliable (59).

FIGURE 49B.14. Use of Spica cast following complete primary repair for exstrophy to reduce tension on the closure by preventing hip abduction in the postoperative period.

Because of the high incidence of vesicoureteral reflux, we prescribe low-dose suppressive antibiotic therapy for all newborns after bladder closure. This is continued until vesicoureteral reflux is corrected or is proven to resolve spontaneously. Postoperative factors that appear to directly affect the success of initial closure include the following:

- Postoperative immobilization
- Use of postoperative antibiotics
- Ureteral stenting catheters
- Adequate postoperative pain management
- Avoidance of abdominal distention
- Adequate nutritional support
- Secure fixation of urinary drainage catheters (107,140)

APPROACHES TO FUNCTIONAL RECONSTRUCTION

Reconstruction of the exstrophic bladder to achieve normal function and anatomy remains the primary goal in treatment. This end point defines the current surgical challenge of exstrophy. Canning and colleagues stated it well: “Both the surgeon and the parent feel tremendous excitement when a child voids to completion following a successful reconstruction”(23).

The first efforts at anatomic reconstruction of the exstrophic bladder usually are attributed to Trendelenburg who described his efforts to reconstruct a boy with exstrophy at the turn of the century (213). He emphasized the importance of pubic reapproximation in front of the reconstructed bladder to achieve continence and prevent dehiscence. Unfortunately, his patient ultimately did not achieve urinary continence despite initial urinary control following his operation. Discouraging results such as this led most surgeons in the first part of this century to abandon functional reconstruction of exstrophy. Instead, most surgeons advocated cystectomy and urinary diversion. Ureterosigmoidostomy became the preferred approach to the treatment of exstrophy with no attempt made to salvage the exstrophic bladder. Ureterosigmoidostomy remains the first treatment choice in some areas of the world and offers a reliable means to achieve urinary continence for patients who may not have reliable access to health care facilities or who have not achieved urinary continence despite attempts at functional reconstruction (205).

Despite the common use of urinary diversion to manage bladder exstrophy in the early twentieth century, some surgeons still attempted functional reconstruction for these children. However, successful results were not achieved reproducibly. H.H. Young reported a successful primary bladder closure in 1942, when he achieved urinary continence after reconstructing the exstrophic bladder of a young girl (233). Since Young's report in 1942, other investigators have intermittently achieved a satisfactory result with a one-stage reconstructive effort to repair the exstrophied bladder. Ansell, an early advocate for primary reconstruction of the newborn with exstrophy reported on a one-stage closure in 1971 with a successful outcome in a newborn female (4). He eventually reported 28 cases closed in this fashion (5). Montagnani also described a one-stage functional bladder reconstruction in two female babies, aged 8 and 13 months. His bladder reconstruction procedure included innominate osteotomy, bladder closure, an antireflux procedure, and narrowing of the bladder outlet followed by pubic reapproximation. Continence was achieved in one of the two patients. The second patient required further bladder neck reconstruction (BNR) to achieve continence (162). Fuchs achieved urinary continence in 8 of 15 patients who also were repaired in a single-stage effort (55). However, several large series of patients who underwent single-stage reconstruction in the 1960s and 1970s reported continence rates of only 10% to 30%. Specifically, continence rates ranged from 0% to 45%, with an average of 17% for single-stage reconstruction (28,47,51,149,119,124,145,219). Renal damage was as high as 90% in these series, generally because of bladder outlet obstruction (124) (Fig. 49B.15).

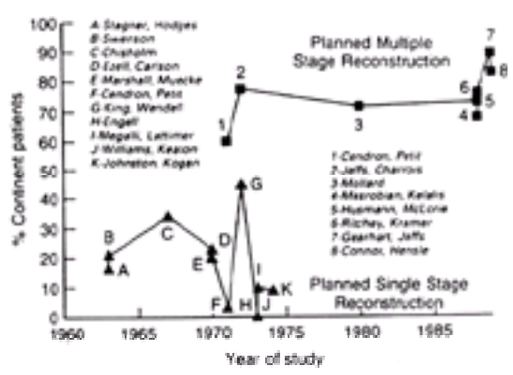

FIGURE 49B.15. Historical data on continence rates in planned multiple-stage versus planned single-stage reconstruction. (Adapted from Churchill B, Merguerian PA, Khoury AE, et al. Bladder exstrophy and epispadias. In: O'Donnell BA, Koff S, eds. *Pediatric urology,* 3rd ed, vol 1. Oxford: Reed Elsevier, 1997:495, with permission.)

Because of these complications and the low rate of urinary continence, reconstructive surgical efforts subsequently were directed toward staged bladder reconstruction, an approach pioneered and advocated by Dr. Robert Jeffs and others (116,188). More recently, Mitchell, Fuchs, Kelly, and others have advocated new techniques of single-stage reconstruction for exstrophy that appear to be safer than techniques used in the past. Continence rates in these series approach or equal those reported in series using a staged surgical reconstruction approach (55,82).

Staged Reconstruction

In contrast to the high rate of renal damage reported by multiple centers using a single-stage reconstructive effort to bladder exstrophy in the 1970s, the complication rate from a staged reconstruction approach appeared significantly better at that time. Jeffs and colleagues reviewed their results with staged reconstruction at Toronto Sick Children's Hospital and noted normal upper urinary tracts in 87% (42). Later series from Johns Hopkins also achieved low rates of renal damage (12% and 17%, respectively) (136,167).

Continence rates for the patients treated with a staged reconstructive approach at selected medical centers have been reported as high as 88% (volitional voiding with 2- to 3-hour continence intervals). In particular, initial and subsequent reports of staged reconstruction, most notably by Jeffs and co-workers, demonstrated continence rates of 60% to 88% (61,107,117,151,160,186). These results prompted a shift from single-stage reconstruction to planned multiple stage reconstruction in the reconstructive approach to bladder exstrophy. Planned staged reconstruction (the Jeffs approach) subsequently became the gold standard to reconstruction of the exstrophic bladder.

Unfortunately, the success using the staged approach to functional reconstruction has not been reproducible at other centers, even centers experienced in the care of children with exstrophy. Rates of urinary continence are as low as 9% with the need for CIC to achieve urinary dryness in as many as 60% of these patients (23,97,120,226). These series reflect the variable success of staged reconstruction. Conversion rates to urinary diversion for patients with a failed repair after staged reconstruction range from 7.4% to 59.4% (151,161,226). Nonetheless, the staged approach to exstrophy reconstruction currently remains the most common method used to treat bladder exstrophy in North America and many other parts of the world.

As currently described, the staged approach to bladder exstrophy reconstruction includes the following steps:

1. *Initial bladder closure*—ideally in the newborn period.
2. *Epispadias repair*—usually performed at 12 to 18 months of age but may be combined with initial bladder closure, especially if initial bladder closure is delayed beyond 6 months of age.
3. *BNR*—usually performed at 4 to 5 years of age or when age appropriate for toilet training and bladder capacity is adequate.

Single-stage Reconstruction

Mitchell, Kelley, and others have recently repopularized a single-stage approach to the functional reconstruction of exstrophy. The goals of this approach include bladder closure, optimization of urinary continence, and correction of epispadias in a single operative procedure. Single-stage reconstruction of the exstrophied bladder is best done in the newborn period for several reasons. The procedure is technically easier in the newborn period than when done in an older child. It also offers theoretic advantages because it may maximize the opportunity for normal bladder development and the potential for urinary continence. The delayed use of the total disassembly technique with primary reconstruction (Mitchell technique) in older children with untreated exstrophy has been shown to be less successful than when used in the newborn period (86). The bony pelvis also remains pliable in the newborn period so that osteotomies may be avoided in some cases, usually if closure can be performed within the first 72 hours of life. While single-stage reconstruction currently remains the surgical approach of a minority of surgeons, several centers have reported the successful use of the total disassembly approach with primary reconstruction for exstrophy (82,87,129).

We favor the total disassembly technique with complete primary exstrophy repair (CPER) for single-stage reconstruction of exstrophy, which is the single-stage technique described in this chapter (82,83). This technique corrects a problem inherent in a primary closure using a staged technique. The principle defect in exstrophy is the anterior position of the bladder plate, bladder neck, and urethra. Closure of only the bladder without moving the urethra posteriorly into the pelvic diaphragm results in a compromise in the restoration of normal anatomy. CPER moves the bladder, bladder neck, and urethra posterior in the pelvis. This positions the proximal urethra within the pelvic diaphragm in an anatomically normal location to maximize the effect of the pelvic muscles and support structures in the achievement of urinary continence. Posterior movement of the bladder neck and urethra also facilitates approximation of the pubic symphysis that, in turn, helps prevent anterior migration of the urethra and bladder neck and provides a more anatomically normal muscular pelvic diaphragm.

In the male, total penile disassembly as part of the exstrophy closure reduces anterior tension on the urethra because the urethra is separated from its attachments to the underlying corporal bodies. These attachments otherwise pull the urethral plate anterior, preventing posterior placement of the proximal urethra and bladder neck in the pelvis. Tension reduction decreases the risk of bladder dehiscence and also reduces the dorsal tension on the corporal bodies that may contribute to dorsal chordee in males. Combining the epispadias repair with primary closure allows for the most important aspect of primary closure—deep incision of the intersymphyseal ligament or band located posterior to the urethra in these patients. To incise this ligament, the urethra must be separated from the corpora cavernosa, tubularized, and relocated within the pelvic diaphragm.

Neonatal closure using this technique seems to optimize the chance for early bladder cycling and consequent normal bladder development. It also may obviate the need for a multistaged repair of the exstrophied bladder, including further BNR, bladder augmentation, and penile reconstructive surgery.

INITIAL BLADDER CLOSURE

Initial bladder closure may be performed using either a staged approach or a single-stage reconstructive effort, such as the total disassembly technique described by Mitchell or the technique described by Kelly. The operative techniques for each are different. The goals of initial bladder closure using a staged approach include a secure closure with a patent bladder outlet to allow drainage of urine from the bladder at low pressures. In the staged approach, no attempt is made to address lack of bladder neck continence or epispadias. In contrast, a single-stage reconstruction intentionally addresses every anatomic component affected by exstrophy. Certain principles remain constant. The use of osteotomies, if indicated; effective urinary drainage; use of antibiotics; and postoperative immobilization appear important to the success of both approaches (67,82).

Primary Bladder Closure—Staged (Jeffs) Approach

For any reconstructive surgical procedure, careful planning and attention to technique are important. To begin the initial bladder closure, ureteral catheters are placed to aid in ureteral visualization before making the initial incision. These may be secured with 5-0 or 6-0 chromic suture. Initial dissection begins with a circumferential incision around the bladder plate. This can be initiated at the umbilicus. The underlying detrusor muscle is mobilized from the rectus sheath to expose the peritoneum. Extraperitoneal dissection lateral to the bladder exposes the retroperitoneal space and identifies the intersymphyseal band. This band should be incised on each side of the prostatic urethra to allow the bladder and bladder neck to be placed deep into the pelvis (Fig. 49B.16). The inferior portion of the dissection is carried distally to the level of the verumontanum in boys and to the vaginal orifice in girls. After a suprapubic tube has been placed, the bladder is closed in the midline in layers with a running 3-0 absorbable suture (Fig. 49B.17). The posterior urethra also is closed onto the base of the penis over a 14-Fr catheter. The urinary outlet should be located at the base of the penis in boys or above the vaginal orifice in girls (Fig. 49B.18). To reapproximate the pubis symphysis, 0 PDS or no. 2 nylon suture also has been used; a figure-of-eight suture with the knot placed anteriorly decreases the chance for suture erosion into the bladder. The umbilicus may be used as the site to bring the urinary drainage catheters out to the skin. Paraexstrophy flaps and division of the urethra should be avoided during primary closure because of the high rate of complications associated with their use (68). Some surgeons also discourage the use of urethral catheters during the postoperative period. Instead, ureteral catheters are used to divert urine and avoid postoperative urinary retention (63).

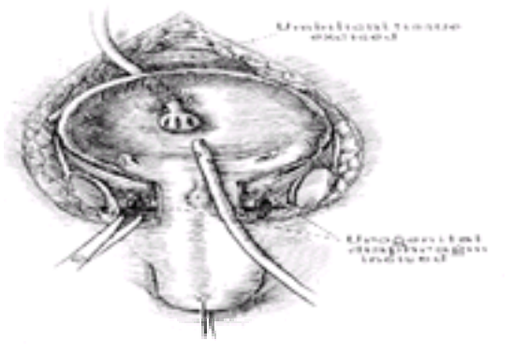

FIGURE 49B.16. In the staged closure of bladder exstrophy, the bladder is mobilized from adjacent structures. The urogenital diaphragm (intersymphyseal band) must be incised to allow the bladder to be positioned posteriorly. However, the proximal penile dissection is incomplete. (Adapted from Gearhart J, Jeffs R. Surgical repair of exstrophy/epispadias. In: Marshall F, Peters C, eds. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:900, with permission.)

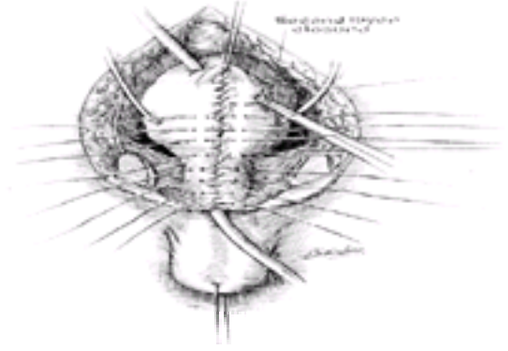

FIGURE 49B.17. The bladder and proximal urethra are closed in continuity over a urethral catheter that will be removed at the end of the operation. (Adapted from Gearhart J, Jeffs R. Surgical repair of exstrophy/epispadias. In: Marshall F, Peters C, eds. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:900, with permission.)

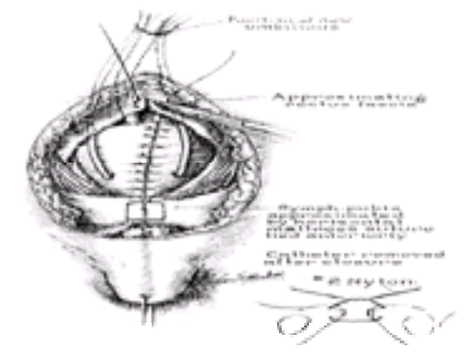

FIGURE 49B.18. After bladder and urethral closure, the pubis symphysis is reapproximated. The urethral opening is left at the base of the dorsum of the penis. (Adapted from Gearhart J, Jeffs R. Surgical repair of exstrophy/epispadias. In: Marshall F, Peters C, eds. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:900, with permission.)

Bladder Closure—Total Disassembly Technique with Complete Primary Exstrophy Repair (CPER or Mitchell Repair)

The basic concept of this repair is that the bladder, bladder neck, and urethra (entire urethra) should be considered as a unit. Therefore the bladder neck and bladder cannot be effectively moved posterior without also mobilizing the *entire* urethra. Care in performing this technique is paramount to success. Before initiating the dissection, we place 3.5-Fr umbilical artery catheters into both ureters and suture them in place with 5.0 chromic suture. To aid in dissection, traction sutures are placed into each hemiglans of the penis (Fig. 49B.19). These sutures are initially oriented transversely in the hemiglans. They will rotate to a parallel vertical orientation as the corporal bodies rotate medially after dissection of the corporal bodies and urethral wedge (urethral plate plus underlying corpora spongiosa) from each other. Initial dissection is directed at separating the bladder plate from the adjacent skin. This dissection is then carried inferiorly (Fig. 49B.20). Fine-tip (tungsten) electrocautery (Colorado tip) is used in performing this dissection. Because the bladder and urethra including spongiosa are moved posteriorly in the pelvis as a unit, the urethra cannot be divided. However, in some cases, the urethra may be too short in the male patient; therefore he would be left with a hypospadias that will require later urethroplasty. The use of paraexstrophy flaps are never necessary or appropriate in this repair (68).

FIGURE 49B.19. Colored markings indicate lines of initial dissection for total disassembly technique with complete primary exstrophy repair (Mitchell repair). A 3.5-Fr umbilical artery catheter is secured in each ureter. The incision will be carried above the umbilicus to allow the umbilicus to move to a more anatomically normal position. The highlighted region represents the area of dissection.

FIGURE 49B.20. The dissection begins at the superior aspect of the bladder plate *(white arrow)* and continues toward the bladder neck. The bladder is dissected from the attachments to the fascia laterally. The bladder neck is then dissected from its lateral attachments and the intersymphyseal band is divided to allow the bladder, bladder neck, and urethra to move posteriorly.

We begin the penile dissection along the ventral aspect of the penis as a circumcising incision (Fig. 49B.21). This should precede dissection of the urethral wedge from the corporal bodies because it is easier to identify Buck's fascia ventrally. The plane of dissection is between Buck's fascia and the overlying tissue on the lateral and ventral aspect of the penis. Staining the dorsal urethral plate with methylene blue or brilliant green facilitates dissection of the urethral wedge. Injection of the surrounding tissues with 0.25% lidocaine and 1:200,000 U/mL epinephrine also improves hemostasis, which assists the dissection. The plane of dissection is on the medial aspect of the corpora cavernosa on the tunica albuginea. There is no Buck's fascia on the medial aspect. One should take care not to narrow the urethral plate because this will be tubularized later. The urethral plate is actually a wedge of spongiosa tissue that extends between the corpora cavernosa. Urethral wedge dissection is carried proximally to the bladder neck. Careful lateral dissection of the penile shaft skin and dartos fascia from Buck's fascia on the corporal bodies is very important because the neurovascular bundles usually are located in this lateral position on the corpora (225) (Fig. 49B.22).

FIGURE 49B.21. During the initial dissection, performing a circumcising incision degloves the penis. The ventral approach seen here (retractor pulling tissue back) is the most efficient way to identify a plane between the corporal bodies and the urethral wedge. The highlighted area represents the ventral aspect of the corporal bodies.

FIGURE 49B.22. Separation of the corporal bodies from each other and the urethral wedge. The highlighted area represents the urethral wedge as it is dissected away from the corporal body. Care must be taken with lateral dissection to avoid damage to the neurovascular bundles.

As described by Mitchell and Bagli (157), the penis is ultimately disassembled into three components—the right and left corporal bodies with their respective hemiglans and the urethral wedge (urothelium with underlying corpora spongiosa) (157). This dissection is easiest to initiate proximally and ventrally. The plane of dissection should be at the level of the tunica albuginea on the corpora. Once a plane is created between the urethral wedge and the corporal bodies, the dissection is extended distally to separate the three components from each other. The hemiglans may be completely separated from each other because they depend on a separate blood supply based on the paired neurovascular bundles. It is important to keep the underlying corpora spongiosa with the urethral plate: The blood supply to the urethral plate is based on this corporal tissue, which should appear wedge-shaped after its dissection from the adjacent corpora cavernosa (Fig. 49B.23). This urethral/corporal spongiosal component later will be tubularized and placed ventral to the corporal bodies.

FIGURE 49B.23. This dissection is then carried proximally to separate the proximal corpora from the bulbar urethra. The phallus and urethra can then be separated into three components—the corpora with hemiglans and the urethral wedge. The bladder and a portion of the urethra have been reapproximated here. They have been highlighted in this photograph. The corporal bodies remain separate.

Proximal dissection of the urethral wedge from the corporal bodies is critical to the posterior placement of the bladder neck and proximal urethra. Bilateral deep

incisions of the intersymphyseal band lateral and poster to the distal prostatic urethra are absolutely necessary to allow the bladder, the bladder neck, and proximal urethra to achieve a posterior position in the pelvis. Failure to adequately dissect the bladder and urethral wedge from these surrounding structures creates anterior tension along the urethral plate and prevents posterior movement of the bladder in the pelvis.

Once the bladder and urethral wedge are adequately dissected from the surrounding tissues, they can be closed (usually the peritoneum is not entered in this process). Before reapproximating the bladder, a suprapubic tube is placed and brought out through the umbilicus, which is usually moved cephalad to a more anatomic position. The bladder is closed using three layers of monofilament absorbable suture. The urethra is tubularized using a two-layer running closure with monofilament suture as well. We have not performed ureteral reimplantation at this time, although this may be considered. However, the bladder is not normal at this point, and antireflux surgery may negatively affect the potential for development (i.e., scarring rather than transition to normal detrusor).

At this point, the bladder, bladder neck, and urethra can be moved posteriorly deep into the pelvis and incised pelvic diaphragm. The symphysis can be closed *without* pressure on the urethra or bladder neck because these structures are moved posterior within the pelvis (Fig. 49B.24 and Fig. 49B.25). It is critical that the symphyseal sutures (usually 2 to 3 figure-of-eight 1-0 PDS) be placed firmly into the symphyseal tissues and tied anterior to the symphysis. Once the symphysis is reapproximated, the blood supply to the corpora cavernosa of the penis should be carefully assessed. If there is any question of reduced corporal perfusion, either the symphysis sutures need to be replaced and/or osteotomies considered. This occurs rarely in newborn classic exstrophy closures, but can happen in a larger patient with wide symphyseal diastasis and is particularly common in cloacal exstrophy patients. Do not try to do too much because staging the initial closure can be effective in these patients. Rectus fascia is reapproximated using a running 2.0 polydioxanone suture. The tubularized urethra is located ventral to the corporal bodies following pubic reapproximation. The corporal bodies tend to rotate medially; this rotation assists in correcting the dorsal chordee and can be readily appreciated by observing the vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion. However, this is rarely needed in newborns. The corpora are reapproximated with fine interrupted sutures along their dorsal aspect.

FIGURE 49B.24. Schematic drawing of bladder and urethral closure demonstrating continuity of these structures. The bladder and urethra are reapproximated using running absorbable suture material before the pubis symphysis is reapproximated.

FIGURE 49B.25. Reapproximation of pubis symphysis occurs before penile reconstruction. The corpora cavernosa are still separated at this point. Penile reassembly takes place after the symphysis closure. PDS is used to approximate the pubis symphysis *(arrow).*

The urethra can then be brought up to each hemiglans ventrally to create an orthotopic meatus. The glans is reconfigured using interrupted mattress sutures of polydioxanone suture (PDS) followed by horizontal mattress sutures of 7.0 braided polyglactin suture (Vicryl) to reapproximate the glans epithelium. The neourethra meatus is matured as in a standard hypospadias repair. Some glans tissue is usually excised from the dorsum of the glans to create a conical appearance. Occasionally, the urethra lacks enough length to reach the glans. In this situation, the urethra may be matured along the ventral aspect of the penis to produce a hypospadias. This can be corrected at a later date as a second-stage procedure. We often leave redundant shaft skin ventrally in these patients to assist in later penile reconstructive procedures.

The penile shaft skin is reconfigured using either a primary dorsal closure or reversed Byars flaps if needed to provide dorsal skin coverage. Skin covering the abdominal wall is reapproximated using a two-layer running closure of absorbable monofilament suture.

Osteotomies

Regardless of whether one approaches the functional reconstruction of the exstrophic bladder in a staged or complete primary approach, use of osteotomies is an important component to achieve a successful result in many cases. Trendelenburg first recognized the importance of osteotomies in exstrophy closure at the turn of the century (213). In 1958, Schultz described a successful functional exstrophy reconstruction that used bilateral posterior iliac osteotomies (191). Osteotomies optimize pubic symphysis apposition and anatomic placement of the bladder, bladder neck, and urethra in the pelvis. They also improve the approximation of the corporal and clitoral bodies. Finally, osteotomies may decrease the chance for later uterine prolapse because the anterior closure brings the pelvic diaphragm into a more normal anatomic position to offer more support.

The need for osteotomy is best determined before closure, but sometimes the decision is made at surgery (see previous discussion). Candidates for osteotomy include those more than 72 hours old, newborns with a wide pubic diastasis, newborns with cloacal exstrophy, and patients who have had a previously failed closure. Osteotomies usually are performed at the same setting as bladder closure to help secure the closure. Although staging osteotomies and closure has been advocated at some centers in the past, this seems to be rarely necessary.

Osteotomies may be performed by an anterior or posterior approach or a combination of approaches (Fig. 49B.26). Posterior iliac osteotomies are performed with the patient in a prone position. The patient is then repositioned for the bladder closure. Anterior iliac osteotomies offer the advantage of a single position and sterile field preparation. Compared with posterior iliac osteotomies, an anterior approach also has been shown to result in less blood loss and better apposition and mobility of the pubic rami (53,54). The group at Johns Hopkins uses combined anterior innominate and vertical iliac osteotomies because of superior initial and long-term results compared with anterior iliac osteotomies alone (203). Both osteotomies may be performed through the same anterior skin incision. McKenna also has described the use of a diagonal midiliac osteotomy performed through the same incision as the exstrophy closure (147). Division of the superior pubic ramus also has been described; although not as effective as the other methods described, it may be used in the newborn period (153,190). Others advocate the use of bilateral anterior pubic osteotomy because it does not require any particular orthopedic skills and therefore can be performed readily by a pediatric surgeon or pediatric urologist. Frey reported on 16 patients using this technique. Preliminary results appear satisfactory although one patient in this series experienced an obturator nerve injury directly related to this technique (53,54). However, it has been our experience that pubic and pubic ramus osteotomies do not serve to correct the real pelvic deformity and

create more problems than they solve by weakening rather than strengthening anterior pelvic support.

FIGURE 49B.26. Use of anterior iliac osteotomies as part of the initial bladder closure.

Complications associated with the use of iliac osteotomies include transient femoral nerve palsy, abductor atrophy, transient perineal nerve palsy, and osteomyelitis (201). Transient nerve palsies appear to occur less commonly with the combined anterior and posterior approach. The pubic diastasis generally recurs when these children are followed over the long term. However, older children may maintain better correction over time, especially when managed in the postoperative period with external fixation. More recently, the reseparation of the symphysis has been reduced by aggressive posterior mobilization of the urethra by deep incision of the intersymphyseal ligament.

EPISPADIAS REPAIR

Since Jeffs' initial description of the staged reconstructive approach to exstrophy, the timing of the epispadias repair has undergone change. Originally, Jeffs advocated epispadias repair as the last stage of reconstruction. However, he later recognized that earlier epispadias repair increased the success of later continence procedures by stimulating bladder growth and increasing bladder capacity (66). Epispadias repair is now typically performed at 12 to 18 months of age as a second-stage procedure when a staged approach to exstrophy repair is used. Various methods can be used. These include Cantwell-Ransley techniques and their modifications or CPER (Mitchell technique) or its variants. These procedures are discussed in more detail later. Both use dissection of the corporal bodies and transposition of the urethral plate to the ventral aspect of the penis. Lack of length of the urethra may result in hypospadias with either of these techniques. This can be corrected later in various ways using operations described for hypospadias repair.

More recently, Gearhart and colleagues (62) have accepted a nonstaged approach and reported on combining bladder closure and epispadias repair in 15 boys. They performed this combined approach as the initial procedure for one boy and used it as a salvage procedure for 14 boys who had previous closure failures. They found that combining a repeat bladder closure with epispadias repair optimized the use of osteotomies and was as successful as staging these operations. Furthermore, two boys who underwent combined repair became continent without further BNR, which has been observed by many groups using a complete primary repair technique. They now recommend combined bladder closure and epispadias repair as the preferred management of patients who have had previously failed bladder closure. Of note, some surgeons advocate the use of topical or intramuscular testosterone to increase the size of the phallus before performing the epispadias repair (74,175).

The approach to epispadias repair should consider the following goals:

- Correction of dorsal chordee
- Creation of a straight urethra to allow easy negotiation during catheterization or cystoscopy
- Satisfactory cosmesis
- Minimal complications, especially regarding urethrocutaneous fistulae
- Maintenance of normal erectile function

Reported rates of success for epispadias repair vary. The degree of epispadias, the age of the patient, surgeon experience, and the presence of previously operated tissues all affect the successful outcome of epispadias repair. Furthermore, penile cosmesis is a subjective measurement. A satisfactory appearance to the surgeon may not equal that of the patient's expectations and vice versa. So, success rates of reported series are difficult to validate and compare for this repair.

Complications involved in epispadias repair, independent of the specific repair used, include the development of urethrocutaneous fistulae. These typically occur dorsally at the base of the penis, where tissue coverage is most tenuous. The corporal bodies do not yet cover the reconstructed urethra. Fistula rates for the Cantwell-Ransley repair range from 5% to 15% (43,64). Fistula rates using the total penile disassembly technique are 10% to 20% (157,175). Other complications include persistent chordee, difficulty with urethral catheterization, and erectile dysfunction.

A recent review of the Cantwell-Ransley technique in 40 patients revealed a successful anatomic and functional result in 90% of the patients at a mean follow-up period of 3 years. These authors also reported complications requiring further procedures in 45% of the patients in their series. Complications were more common in those patients who underwent this procedure as part of a staged exstrophy closure versus isolated epispadias (138). The high rate of reoperation reflects the technical difficulty involved in epispadias repair even in experienced hands.

Zaontz and colleagues (234) reported on a multicenter experience using the total penile disassembly technique and found that 16 of 17 boys had straight erections following repair. Three patients developed pinpoint fistulae of which two closed spontaneously. Perovic (174) has described variants of this technique for epispadias that may be used in selected circumstances as well.

Although both the Cantwell-Ransley and total penile disassembly techniques can be used as salvage procedures for the older child, these children also may require dorsal dermal grafts to achieve a straight penis. The neurovascular bundles may require mobilization to allow graft placement in this situation. Otherwise, it is more prudent to avoid excessive mobilization and handling of these nerve bundles.

Finally, the popularization of the Mitrofanoff principle has significantly improved the management of those patients with tortuous neourethras following urethral reconstruction. Creation of a Mitrofanoff channel allows patients who require CIC (CIC) of their bladders to do so easily. Most patients with bladder exstrophy that require CIC prefer to do so through a Mitrofanoff rather than per urethra even if urethral catheterization is technically straightforward.

OPERATIVE APPROACH TO EPISPADIAS

Various surgical procedures have been devised to correct this anomaly and achieve the goals of epispadias repair including a straight penis and urethra, easy urethral catheterization, normal erectile function, and a cosmetically satisfactory phallus. These goals allow the patient to stand while voiding and to have intromission during intercourse. Epispadias repair can prove challenging. Two of the more successful and popular procedures are described subsequently. Both types of repair can be used as salvage procedures for patients who have undergone previous operations for epispadias.

Modified Cantwell-Ransley Repair

Cantwell first described mobilization and ventral movement of the urethra for epispadias repair at the turn of the century (25). Ransley subsequently successfully modified this technique (179). The modified Cantwell-Ransley repair has been widely used since then by various surgeons (Fig. 49B.27).

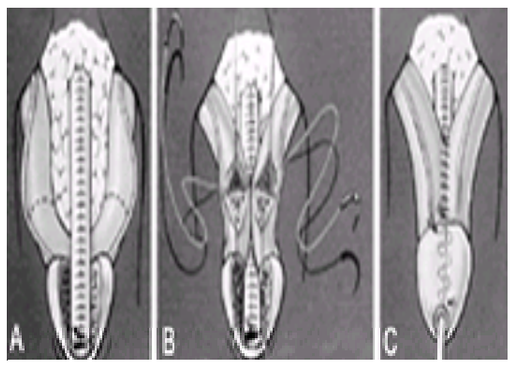

FIGURE 49B.27. Line drawing illustrating the steps for the Cantwell-Ransley repair for epispadias. **A:** The tubularized urethral plate is placed in a dorsal groove incision in the glans penis. The *dotted lines* indicate the site of incision for the cavernosa-cavernostomies. **B:** Approximation of the corpora cavernosa and performance of cavernosal anastomosis. **C:** Glans closure over urethra and skin closure. (Adapted from Brock J III, O'Neill J Jr. Bladder exstrophy. In: O'Neill JA Jr, Rowe MI, Grosfeld JL, et al. *Pediatric surgery,* 5th ed, vol 2. St. Louis, Mosby, 1998:1709, with permission.)

Initially, a traction suture is placed into the glans penis. A marking pen is then used to outline the incisions for a reverse meatal advancement glanuloplasty (MAGPI) or IPGAM procedure at the distal urethral plate. This advances the urethral meatus onto the glans. Skin incisions are then made on the lateral edges of the urethral plate and around the epispadiac meatus. This plate is dissected from the corporal bodies up to the level of the glans distally and to the prostatic urethra proximally. Lateral flaps or wings should be developed in the glans penis as well. The corporal bodies are then separated from each other to allow them to rotate medially. The urethra is then tubularized over a 6- or 8-Fr urethral catheter, typically using running absorbable suture. The corporal bodies are rotated over the urethra and reapproximated using absorbable suture in an interrupted fashion. Cavernostomies may be performed before reapproximating the corporal bodies to help correct persistent chordee. These are performed at the point of maximal angulation. The neurovascular bundles may require mobilization to avoid injuring them if cavernostomies are performed. The glans wings are then closed over the urethra dorsally using interrupted absorbable suture. Penile shaft skin can be trimmed and tailored to cover the penis. Z-plasties at the level of the pubis may decrease the chance of a dorsal retractile scar at the base of the penis.

Complete Penile Disassembly Technique

We have exclusively used the complete penile disassembly or Mitchell technique for epispadias repair since 1989. Bagli and Mitchell reported their results in 1996 (157). Complete penile disassembly offers several advantages compared with the modified Cantwell-Ransley technique. The planes of dissection extend anatomically to the bladder neck (Fig. 49B.28). This facilitates its use with BNR. Complete mobilization of the urethral wedge from the corporal bodies by disassembly also creates a more normal appearance of the penis by allowing ventral placement of the urethra. This technique is based on the unique anatomy of the epispadias. The blood supply of each hemiglans depends on the paired unique dorsal complex found on the lateral aspect of the corpora. Because the corpora are separated, there is no crossed blood supply and the primary circulation of each corpora cavernosa is based on the central artery. Similarly, the urethral plate and spongiosa have their unique blood supply and innervation from the proximal urethra (versus the distal urethra). Therefore the corpora cavernosa with hemiglans can be separated completely from each other and from the spongiosa and urethra complex without potential to damage ultimate function (Fig. 49B.29). This disassembly maximizes potential for anatomic reconstruction. It is important to note the dorsal complex is *not* dissected from the corpora cavernosal bodies. A detailed description of the surgical technique is included in the section on CPER (total disassembly technique for bladder exstrophy).

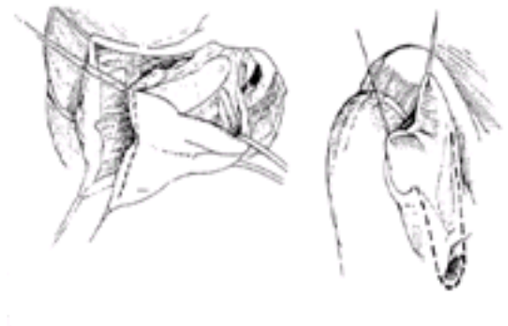

FIGURE 49B.28. Complete penile disassembly technique. On left, lines of initial dissection circumscribing the urethral plate and bladder neck. On right, careful dissection of the urethra from the underlying corporal bodies. *Dotted line* indicates site of distal incision to free the urethra entirely from the glans. FIGURE 49B.29. Complete penile disassembly technique. **A:** Corporal bodies and two hemiglans are separated by a longitudinal midline incision. **B:** The urethra is tubularized and brought to the ventrum. The corpora are reapproximated dorsally. They will rotate medially when adequately dissected from each other. [Adapted from Mitchell ME, Bagli DJ. Complete penile disassembly for epispadias repair: the Mitchell technique. *J Urol* 1996;155(1):300, with permission.]

BLADDER NECK RECONSTRUCTION

BNR originally arose out of efforts to improve the functional reconstruction of the exstrophic bladder. Often, BNR was performed at the same time as the initial bladder closure and epispadias repair. Surgeons who popularized and championed these techniques include Herbert Johnston, D.I. Williams, J. Lattimer, and T. Chisholm (131). Jeffs arrived at the concept of using BNR as part of a staged approach to exstrophy repair in the early 1970s. At that time, Jeffs was inspired by a report of a series of patients with incontinent epispadias followed by O. Culp who had undergone BNR and later achieved a continence rate of 50% (38). Using a staged approach, Jeffs planned to transform the anatomy of bladder exstrophy into complete epispadias during the first staged reconstruction and use BNR later to achieve urinary continence.

With a staged approach to exstrophy repair, BNR is performed when the child is at an appropriate age for toilet training. This is typically at 4 to 5 years of age. Advocates of staged reconstruction emphasize the importance of achieving adequate bladder capacity before performing BNR. A bladder capacity less than 60 mL under anesthesia or during urodynamic evaluation decreases the success of BNR (117,136). Factors that may increase the potential for the bladder to achieve

adequate capacity before BNR include the following:

- Avoidance of UTIs
- Complete bladder emptying with institution of CIC if bladder emptying is incomplete
- Epispadias repair (through increase in urethral resistance)
- Avoidance of bladder prolapse (30)

To reconstruct the bladder neck for exstrophy most surgeons use a Young-Dees or a Leadbetter approach or a modification of these techniques. These BNR techniques offer the best chance to create volitional voiding with continence. They are described in detail later. Ureteroneocystostomy is usually required at the time of BNR to correct vesicoureteral reflux and to move the ureters from the lower bladder where BNR will occur. The Cohen technique is often used. However, others have described a cephalotrigonal technique that is particularly applicable to exstrophy patients because of the angle of ureteral entry into the bladder in exstrophy (24). The Marshall-Marchetti-Kranz bladder neck suspension or a bladder neck wrap using rectus muscle, bladder muscle, or fascia may be combined with BNR as well. BNR requires adequate bladder capacity because using some of the bladder reduces detrusor volume. It must be emphasized that the primary objective of these procedures is to restore anatomy to achieve continence with voiding (versus continence anticipating CIC).

Bladder Neck Reconstruction Procedures

Preoperative Assessment

Following a careful history and physical examination, we perform cystourethroscopy for all patients before proceeding to open BNR. Cystoscopy provides information regarding bladder capacity and the status of any previous repairs, including correction of epispadias.

Preoperative urodynamic evaluation also should be considered because it allows preoperative detection of detrusor hyperactivity or atony as well as assessment of functional bladder capacity and leak point pressures. However, the urethra of these patients may be difficult to catheterize. In these situations we combine our cystourethroscopic examination with suprapubic placement of a urodynamic catheter to be used later that day for the urodynamic evaluation. Preoperative urodynamic testing is often necessary before surgery. For example, results from urodynamic studies performed on exstrophy patients at Boston Children's Hospital before and after BNR indicate that approximately 60% of patients have relatively normal function before BNR and that most developed a hypertonic or hyperreflexic bladder following BNR (11). Urodynamic studies help guide decisions regarding the need for augmentation cystoplasty and the use of anticholinergic agents.

Mitchell Repair

The Mitchell repair uses a modification of the Leadbetter procedure in a previously described technique (120). We currently use this modification as our preferred method of BNR in patients with bladder exstrophy who require bladder outlet repair because it preserves the chance for volitional voiding. In this modification, the anterior urethra is incised transversely and the incision is extended cephalad (Fig. 49B.30A). The urethral incision is full thickness. After cross-trigonal ureteral reimplantation, the urethral strip is tubularized in two layers using Vicryl or Monocryl suture (4-0 or 5-0) over an 8- to 10-Fr urethral catheter, depending on the size of the patient. The bladder may be closed in continuity with the urethral closure. This procedure effectively narrows and lengthens the urethra (Fig. 49B.30B and C). It also moves fibrotic tissue at the level of the original bladder neck away from the new bladder neck. Dissection around the new bladder neck may be performed if a combined bladder neck wrap or sling is anticipated. Although this procedure has been applied to various clinical situations, it is best used in the exstrophy/epispadias patient.

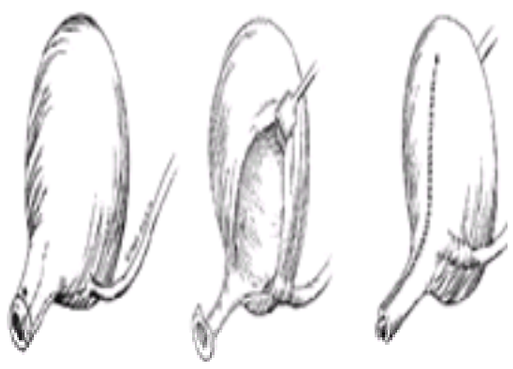

FIGURE 49B.30. Mitchell bladder neck reconstruction. From left to right: *Dotted lines* indicate planned lines of incision. Following this, the urethra is lengthened and narrowed. The urethra and bladder then are closed in continuity with a two-layer closure. [Adapted from Jones JA, Mitchell ME, et al. Improved results using a modification of the Young-Dees-Leadbetter bladder neck repair. *Br J Urol* 1993;71(5):555, with permission.]

Postoperatively, urine is drained through a combination of ureteral stents, a suprapubic tube, and a 6-Fr (Kendall) urethral catheter. The urethral catheter remains for 7 to 10 days after the operation. Ureteral stents are removed at 10 to 14 days after surgery. The suprapubic tube remains for 3 weeks. We routinely clamp the tube before removing it and measure postvoid residual urine volumes to assess for urinary retention before removing the suprapubic tube. As with any BNR procedure (without augmentation), we anticipate that several months of adjustment will be required before the patient develops adequate bladder awareness, capacity, and control to achieve prolonged intervals of urinary continence.

Occasionally, trigonal tubularization must be combined with bladder augmentation because of small bladder capacity; most bladder neck repairs decrease bladder capacity because bladder is used to create the continence mechanism (142). Stomach offers the best potential to preserve spontaneous volitional voiding in this group, but places these children at risk of hematuria-dysuria syndrome, which can be especially troubling in the face of persistent urinary incontinence and normal sensory innervation (57). Other intestinal segments also may be used according to surgeon preference. If augmentation is required, a catheterizable stoma for bladder catheterization (Mitrofanoff operation) also should be strongly considered as urethral catheterization may be difficult.

Young-Dees-Leadbetter Procedure

To perform a Young-Dees-Leadbetter (YDL) procedure, a strip of bladder mucosa approximately 1 to 1.5 cm wide and 3 to 4 cm long is mobilized and constructed into a tube over an 8- or 10-Fr urethral catheter, using interrupted or running polyglycolic acid sutures (4-0 or 5-0) (Fig. 49B.31A). Use of an epinephrine-soaked sponge during this dissection may aid in hemostasis and visualization. Triangular flaps of demucosalized detrusor muscle are developed on either side of the mucosal tube and subsequently wrapped over the mucosal tube in a double-breasted technique using 3-0 polyglycolic acid sutures (30) (Fig. 49B.31B). This reinforces the neobladder, decreases the risk of fistula, and augments the outlet resistance (13).

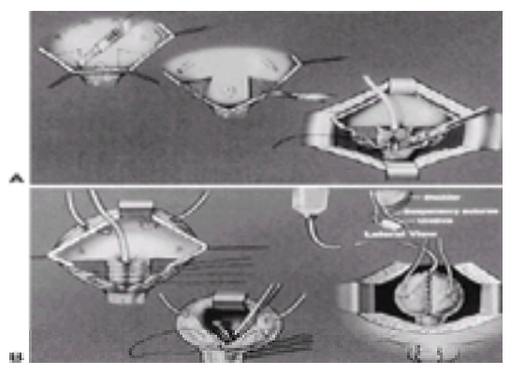

FIGURE 49B.31. The principles of the Young-Dees-Leadbetter procedure. This is performed as the third stage of a staged reconstructive approach to exstrophy. **A:** The ureters are reimplanted as shown here to prevent vesicoureteral reflux and move them out of the area of the bladder neck reconstruction. The base of the bladder is reconstructed to lengthen the urethra and reinforce the bladder neck. **B:** The bladder neck closure is reinforced with a pants-over-vest closure. Drainage catheters are brought out superiorly. (Adapted from Brock J III, O'Neill J Jr. Bladder exstrophy. In: O'Neill JA Jr, Rowe MI, Grosfeld JL, et al. *Pediatric Surgery,* 5th ed, vol 2. St. Louis, Mosby-Year Book, 1998:1709, with permission.)

Gearhart (60) advocates the use of intraoperative urodynamic studies. Retrospective studies have shown that intraoperative closure pressures of 70 to 100 cm H_2O will prevent urinary leakage at 50 cm H_2O intraoperatively (24). Postoperative management is similar to that following the Mitchell repair. Some surgeons recommend avoidance of a urethral catheter in the postoperative period because of concerns that it may adversely affect later urinary continence. Urinary drainage is achieved by the use of ureteral catheters and suprapubic tube drainage (60).

Results

BNR in YDL procedures and its variants has yielded success rates of 30% to more than 80% urinary continence for patients with bladder exstrophy (72,120,160). Many factors influence the outcome of surgery. For instance, an initial failed bladder closure or prior failed BNR reduces the chance to achieve subsequent urinary continence in these patients (73). Use of iliac osteotomies to provide a tension-free anastomosis and patient immobilization through the use of spica casting or Bryant's traction in the postoperative period increases the success of bladder closure and subsequent continence (73,139). Delayed bladder closure increases the likelihood of eventual need for bladder augmentation due to inadequate bladder capacity that, in turn, reduces the chance for volitional voiding.

Woodhouse and Redgrave also have reported that 8 of 13 patients with initially successful bladder closures and BNR required further surgery in their second decade of life because of the gradual development of poorly compliant, low-capacity bladders that caused urinary incontinence (223). Surgeons who care for these patients must be committed to the long-term follow-up of this complex group of patients because late complications such as this may develop.

THE FAILED REPAIR

The results of functional reconstruction for exstrophy can fall short of perfection. As a consequence, surgeons involved in the care of these patients must be well versed in the options available to manage treatment failures. Appropriate clinical perspective is also helpful.

> As in any operation for exstrophy, the results must be viewed in the light of the gruesome condition it is designed to correct.—H.M. Spence, M.D.

Failed Initial Bladder Closure

The following factors can affect the ability to achieve urinary reconstruction via bladder reconstruction in exstrophy patients:

- Primary failure (dehiscence) of the initial bladder closure
- Outlet obstruction
- Bladder prolapse
- Chronic UTI

Failure of the primary closure, the first stage of the staged repair, decreases the chance for eventual continence with volitional voiding (73,140). Gearhart and colleagues (72) reported that only 40% to 60% of patients after a failed primary closure attempt will ultimately achieve a bladder capacity adequate for BNR. If more than two closure attempts are required, chances for continence decrease to 20% (73). With a staged reconstruction, the initial closure is performed to prevent bladder prolapse but avoid outlet obstruction. The use of osteotomies and postoperative immobilization improves the success of initial bladder closure along with the other postoperative factors previously listed. Several investigators have noted the strong relationship between successful primary closure and the appropriate use of osteotomies, an observation also recognized more than 100 years ago by Trendelenburg and later by Schultz (23,69,191,213).

Gearhart and Jeffs (60) have noted that patients who are not initially continent (defined by a 3-hour dry interval) after BNR may achieve urinary continence later. However, such patients rarely improve if they remain wet 1 to 2 years after surgery. Kelalis and Kramer (127) also have observed some male patients who became continent after puberty and postulated that prostatic enlargement may have created enough additional resistance to achieve urinary continence (127). Although this observation appears valid in patients who have undergone epispadias repair, exstrophy patients do not achieve continence with puberty alone. Based on MRI studies in exstrophic patients, prostatic volume is equivalent to age-matched controls, but the configuration of this gland remains abnormal so that it does not surround the urethra (60).

Urinary outlet obstruction is one of the potentially dangerous failed outcomes of bladder closure because it can cause renal deterioration and increase the risk for chronic UTI. It is typically diagnosed when postvoid residuals are greater than half the actual bladder capacity. Outlet obstruction increases the risk of renal damage especially if unrecognized for several months or more because it can raise the maximum typical storage pressure in the bladder to dangerous levels (108). Outlet obstruction also increases the difficulty of clearing a UTI. Outlet obstruction also may decrease the chance to achieve urinary continence. Following the first stage of a staged repair, the bladder outlet following initial bladder closure should be assessed with sounds or bougies 4 to 6 weeks after closure to detect obstruction.

Following total disassembly with complete primary repair technique, the urethra should be assessed at 6 to 8 weeks postoperatively. Routine ultrasonography of the bladder and upper urinary tracts also should be performed frequently after closure to detect hydronephrosis that may indicate outlet obstruction. Evidence of hydronephrosis in combination with high postvoid residual urine volumes requires further evaluation with cystoscopy and urethral dilation or the institution of intermittent catheterization as indicated. In a review of 68 patients at Toronto Sick Children's Hospital, 23% developed hydroureteronephrosis following the initial closure and were then successfully treated with dilation of the bladder outlet or institution of CIC (108). Of note, some children will develop transient hydronephrosis following their initial surgery, which may be related to gradual accommodation of the bladder as it cycles urine. Some of these children may require CIC to assist them in bladder emptying even though there is no evidence of outlet obstruction. Some of these children will show spontaneous improvement, but it is currently not possible to predict this.

Failed Bladder Neck Reconstruction

Patients who fail to achieve continence after BNR should undergo urodynamic evaluation. Some patients will demonstrate bladder hyperreflexivity and/or hypertonicity likely due to increased resistance after BNR. Treatment with anticholinergic agents such as oxybutynin hydrochloride can significantly improve the continence of many of these patients.

If urodynamic evaluation reveals a bladder with adequate capacity but low detrusor leak point pressure, BNR can be performed again. However, this is an unusual occurrence. More commonly, patients demonstrate an inadequate bladder capacity and a low detrusor leak point pressure and usually require bladder augmentation (60).

After failed BNR, several other options are available. Because of the variable success of BNR in the exstrophy population, various treatment options have been explored and reported in the literature. Treatment choice depends on the results of urodynamic studies and other clinical and social factors.

Augmentation Cystoplasty

Indications for bladder augmentation can vary by degree, depending on surgeon preference and commitment to functional reconstruction. However, some patients will not achieve adequate bladder capacity or compliance as a result of postoperative complications and sometimes despite technically successful reconstruction efforts. Lack of adequate capacity and poor compliance can both contribute to urinary incontinence in this patient group. Preservation of the native bladder in these situations

rather than continent urinary diversion offers several advantages. The native bladder offers a convenient substrate for ureteral and Mitrofanoff reimplantation that has a lower complication rate than when intestine or stomach is used for this purpose. Gastrointestinal segments used for bladder augmentation in the exstrophy population include stomach, ileum, cecum, and sigmoid colon (58,114). Stomach has proven to be as equally effective as small or large intestine in this population and offers the possibility of spontaneous voiding (58). The Arap procedure represents an augmentation technique unique to the management of exstrophy. Arap (7) described this novel form of colocystoplasty in 1968. For this procedure, the ureters are implanted into the sigmoid colon, which is then fashioned at the skin as a conduit. Later, the native bladder plate is tubularized to create a neourethra. The sigmoid conduit is then taken down at the skin level and an anastomosis is created to the neourethra to allow CIC per neourethra. Currently, this procedure is infrequently used (7). Augmentation also may be performed with urothelial-lined tissue such as a dilated ureter if this is present. Often, bladder augmentation is combined with a bladder neck procedure to optimize the chance for urinary dryness. Most patients who undergo bladder augmentation will require CIC to empty their bladders of urine following this operation (46).

Artificial Urinary Sphincter

An artificial urinary sphincter (AUS) may be used to achieve urinary continence in patients who have adequate bladder capacity and compliance but an incompetent bladder neck after BNR (40). This device preserves the ability to volitionally void, but because of its current lack of durability and the dexterity required to use it, it is generally not a first choice for younger patients. Others have described its use in combination with bladder augmentation. In one series of 11 patients who underwent sigmoid augmentation with AUS placement, 9 are continent. However, these patients required multiple operative revisions to achieve this degree of continence (137). Sphincter erosion into the bladder neck or bowel segment also can occur (65).

AUS placement may be technically challenging in these patients. The plane of dissection around the bladder neck following BNR may be difficult to establish. A posterior and anterior approach to the bladder neck is useful in these cases. Other surgical options should be available at the time of AUS placement in case of accidental entry into the posterior bladder neck. In this situation, it is also possible to primarily repair the injury and place omentum between it and the AUS cuff. The AUS cuff should not be placed on the bulbar urethra in the exstrophy-epispadias patient. Cuff placement at the bladder neck will be more complicated if there has been previous bladder neck surgery.

Bladder Neck Wrap/Sling

Bladder neck wraps and slings also may be considered. However, series reporting on the use of bladder neck wraps suggest that this procedure does not consistently maintain long-term urinary continence especially in male patients who constitute the gender majority in exstrophy (41,130). Hanna and Stock also have described a bladder neck wrap using a gracilis muscle flap in a “cinch” technique as a procedure for BNR. They reported the achievement of urinary control in 5 of 11 patients with this technique (89).

Submucosal Collagen Therapy

Several authors have used collagen injections at the bladder neck to treat patients with stress incontinence after BNR (16,21). Its use in these situations has been compared with the treatment of intrinsic sphincter deficiency urinary incontinence. Ben-Chaim (16) reported an improvement in continence in 53% of patients after collagen therapy, although most required multiple injections. It can be used as an adjunctive procedure for those patients who demonstrate slight leakage due to stress incontinence after BNR. Submucosal collagen injection also may be used before BNR. Caione (21) advocates use in this situation to increase outlet resistance so that the bladder may increase in capacity.

Patients should undergo collagen skin testing 4 weeks before use to evaluate for possible hypersensitivity reactions. The possibility of multiple treatments with collagen also should be emphasized. Submucosal injections are typically carried out at three different locations at the level of the bladder neck. Collagen should be injected until visual occlusion of the urethra is seen. This usually requires 7.5 mL of collagen per patient (22).

The most significant problem with submucosal therapy at this time is its lack of durability. Volume reduction occurs over time, resulting in coaptation failure and subsequent urinary incontinence. As new endoscopic agents become available, this may become a more popular technique. In general, injection therapy has been disappointing in this patient group.

Bladder Neck Closure

Bladder neck closure in conjunction with appendicovesicostomy is also an option in those patients who have failed multiple attempts at BNR (92). This is a last resort measure because it eliminates the chance to void per urethra and commits the patient to CIC.

URINARY DIVERSION

> The bitter truth is that there is no completely satisfactory substitute for the unique qualities exhibited by a normal bladder and urethra... Patience is required since continence may be slow to develop in even a successful repair but at the same time one must have the wisdom to recognize what McGovern calls 'failure staring you in the face' such that a course of action, no matter how politically correct it may seem, can be abandoned and replaced with an assault from another direction.—Terry D. Allen, M.D.

Approaches to Urinary Diversion

Methods to construct urinary diversions include those listed in Table 49B.4.

External Diversions (Continent Reservoir)	Internal Diversions (Anal Sphincter-based Continence)	Incontinent Diversions
Indiana pouch	Ureterosigmoidostomy	Ileal conduit
Penn pouch	Sigma pouch	Colon conduit
Koch pouch	Ghoneim reservoir	Ileocecal conduit
Miami pouch	Gersuny	Cutaneous ureterostomies
Others	Heitz-Boyer-Hovelacque	
	Rectal bladder with proximal colostomy	
	Ileocecal ureterosigmoidostomy	

TABLE 49B.4. METHODS TO CONSTRUCT URINARY DIVERSIONS

Proponents of urinary diversion for the treatment of exstrophy argue that the varying continence rates achieved with functional reconstruction demonstrate the unreliability of this approach (94). The use of the native bladder often requires later bladder augmentation with intestinal segments to achieve a functional bladder storage capacity. Certainly, some centers report poor rates of continence after primary reconstruction and some urodynamic studies do demonstrate low urine flow rates and poor contractility in patients following primary bladder reconstruction (98,165).

Primary urinary diversion may avoid some of the complications associated with functional reconstruction including urinary retention and subsequent kidney damage, a predisposition to UTI, and later dependence on CIC to empty the bladder with its own possible complications of urethral stricture formation, epididymitis, and UTI (94,96). Advocates of early urinary diversion cite a decreased risk of epididymitis and obstruction of the vas deferens by the creation of a receptacle with a suprapubic window at the level of the prostatic urethra (94). Diversion can be combined with cosmetic operative procedures for the external genitalia.

Urinary diversion is used to provide urinary continence for patients who have failed multiple attempts at functional reconstruction. Some also advocate primary urinary diversion for patients with bladder plates deemed too small to close. However, because we cannot accurately predict which bladder plates will increase significantly in size after primary closure, we do not use this as a criterion for primary diversion and do not divert the urine primarily in exstrophy patients. Arap (7) has described preserving the very small bladder by tubularizing it as the continence mechanism after anastomosing the ureters to a sigmoid conduit in an antireflux manner. Final reconstruction involves attachment of the sigmoid conduit to the neourethra and reconstruction of the abdominal wall (7).

Because of the difficulties encountered with functional bladder reconstruction in exstrophy, advocates of early urinary diversion argue that their approach achieves the primary goals of surgical intervention for bladder exstrophy with fewer operations and higher success rates than those achieved with bladder closure and urethral reconstruction. Ureterosigmoidostomy became the treatment of choice for bladder exstrophy patients as a primary and secondary treatment because of the dismal results associated with primary bladder reconstruction at the turn of the century and well into the 1970s. The long-term complications including hyperchloremic metabolic acidosis, chronic pyelonephritis, and a 250- to 500-fold increased risk of colonic adenocarcinoma formation at the site of anastomosis dampened enthusiasm for this procedure despite the reduction of the metabolic complications after improvements in ureteral reimplantation were developed (102,135,199). Ureterosigmoidostomy subsequently was replaced by incontinent urinary diversions such as the colonic and ileal conduits. In the 1960s ileal urinary diversion was the treatment of choice for bladder exstrophy at many institutions (47). A significant disadvantage to these forms of urinary diversion is the incontinent abdominal stoma associated with conduits. The popularization of CIC allowed the development over the last 15 to 20 years of continent urinary diversions like the Indiana pouch, which was developed for the exstrophy population and is now the preferred method of urinary diversion to the abdomen in the this population.

Rectal Reservoirs

Various investigators have made significant improvements on the use of the rectum as a urinary reservoir including the Mainz II pouch and the Sigma pouch (76,95) (Fig. 49B.32A and Fig. 49B.32B). Use of a rectal reservoir permits urinary continence without reliance on CIC required with other forms of continent urinary diversion. Hohenfellner and Stein report a 92% rate of renal preservation in their series of children treated primarily with a urinary rectal reservoir (Mainz II pouch since 1991). Continence rates of 97% in school-age children are reported in using this technique (96). The Heitz-Boyer-Hovelacque procedure involves isolation of a rectal segment for ureteral implantation followed by posterior sagittal pull-through of the sigmoid colon through the anal sphincter to achieve both urinary and fecal continence. A small series using this procedure reported continence rates of 95% with acceptable complication rates in 1977 (209). This technique, however, is currently not popularly used.

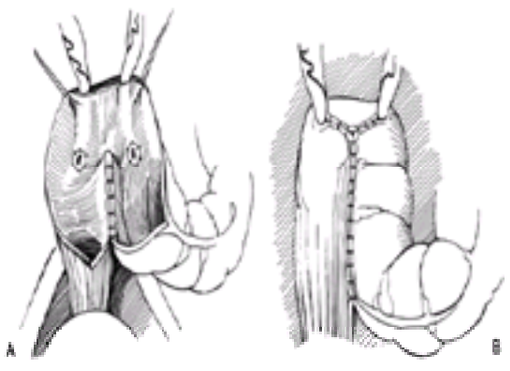

FIGURE 49B.32. Detubularization of the rectosigmoid colon to create a large pouch for urine storage (Sigma rectum pouch). **A:** The ureters are reimplanted in a tunneled fashion in the tenia of the colon. **B:** The pouch is closed to create a large urinary reservoir in continuity with the colon. (Adapted from Hohenfellner R: Sigma rectum pouch. In Hinman F, ed. *Atlas of pediatric urologic surgery.* Philadelphia: WB Saunders, 1994:427, with permission.)

Complications of this form of diversion continue to include fecal-urinary incontinence in patients with impaired anorectal sphincter control (60). Metabolic electrolyte imbalances can be treated with complete frequent emptying of the rectal reservoir, which reduces the contact time between urine and the absorptive rectal mucosa along with oral bicarbonate replacement. Oral bicarbonate replacement is recommended for all patients who have a base deficit of 2.5 mmol/L or greater (94). The risk of malignant degeneration also still remains with this use of a rectal urinary reservoir. Various modifications of the rectal reservoir to prevent admixture of feces and urine may theoretically decrease the incidence of adenocarcinoma formation if it is due to conversion of urinary nitrates into carcinogenic nitrites by fecal bacteria (37). Long-term results are not yet available.

LONG-TERM CONCERNS IN EXSTROPHY

Psychosocial Concerns

Children with exstrophy face significant challenges in the development of their psychosocial identity. Reiner and co-workers have noted that delays in psychosocial and psychosexual development are commonplace (182). Unfortunately, this area of development has been poorly studied to date. A detailed sexual and social history is rarely part of the routine evaluation of these children as they become adults (184). Other studies have shown that adolescent males with exstrophy were psychosexually delayed 2 to 4 years compared with their peers and delayed 4 to 6 years in their activity. Data on teenage girls with exstrophy are incomplete, but Reiner (182) has noted that these girls struggle with sexual self-esteem issues such as body image, genital perception, and genital appearance.

Current recommendations include early psychiatric intervention at birth so parents of these children may be educated about the typical concerns these children will have and how to effectively approach these issues. Serial assessment at 12 to 18 months of age, late preschool period, in the third or fourth grade, at the beginning of middle school, during early, mid-, and late adolescence, and before any surgical interventions should be considered to help the child cope with his or her psychosexual and psychosocial concerns at these times. With early and routine education for parents and patients, exstrophy patients will likely better cope with sexual and social issues that profoundly affect their quality of life. Reiner (184) has found that anxiety and psychosexual disorders are universal in the patients he has evaluated to date. Routine patient and parental education is critical (184).

Woodhouse (231) noted in his series of adult patients with exstrophy that many of them do develop stable partnerships. He found 33 of 43 patients married or living with a partner. However, sexual counseling in these patients is paramount because of the difficulties they face in this regard. A strong network of support groups made up of families with exstrophy is a resource for new parents of children with exstrophy. Later support groups can provide very important cohort support structure for children with exstrophy. The World Wide Web has a number of websites that can prove very helpful to parents and patients. These include the following sites:

1. Seattle Children's Hospital and Regional Medical Center
   www.seattlechildrens.org/surgery/exstroph_new/exsuppgrp.htm
   www.seattlechildrens.org/surgery/exstroph_new/exstrophy.htm

   www.bladderexstrophy.com/support.htm

Andrology, Gynecology, and Fertility

As exstrophy patients age, sexual function becomes a major concern along with urinary continence and physical appearance. Libido for patients with exstrophy is characteristically present with or without surgical correction. For male patients, erectile function is usually intact (228,230). However, variable degrees of chordee can create difficulty in achieving intercourse for some patients (230). In these situations, a female superior position provides closer apposition of the genitalia for

intercourse. For female patients, sexual function is usually intact (228). In Woodhouse's series, 14 of 23 patients had normal intercourse (227).

For men with exstrophy, ejaculation is often present as well despite the extensive reconstructive procedures done for these patients. Fertility varies for men with exstrophy. The seminal emission may be slow and continue several hours after orgasm. Further, sperm quality and quantity is often impaired (134). This may be due to partial obstruction or recurrent UTIs. Transrectal ultrasound (TRUS) findings in a small group of adult male exstrophy patients revealed an abnormally distal insertion of the seminal vesical/ejaculatory duct complexes into the prostate. Semen analysis of these same patients revealed abnormally high seminal fluid pH (91). Despite this, some male patients are fertile and do not require assisted reproductive techniques (ART) to father children (151). However, with improvements in ART, even patients with impaired fertility can successfully achieve fatherhood.

Fertility is unimpaired in female patients with exstrophy, but maintenance of a pregnancy is significantly more difficult (110,193). These pregnancies are more often complicated by uterine or vaginal prolapse, recurrent UTIs, preterm labor, malpresentation, and hydronephrosis. In a 1958 literature review of pregnancies carried by women with exstrophy, Clemston noted 49 live births from 64 pregnancies. Complications in this series included two maternal deaths as well (31). More recent series have demonstrated significantly better outcomes with only one obstetric complication out of 32 pregnancies (231).

Prolapse occurs more commonly because of the lack of pelvic floor support structures and failure of pubic symphysis fusion (128). Often, this results from posterior incision of the pelvis diaphragm without anterior closure (symphyseal approximation); widely opens the pelvic outlet; and reduces support leading to potential for severe uterine, bladder, and rectal prolapse. This can be debilitating for a young, active woman. Unfortunately, because the vaginal introitus is above the pelvic diaphragm (intersymphyseal band) there is a tendency to incise posteriorly to “open the vagina.” This is often done by gynecologists who are inexperienced with the anatomy of the exstrophic pelvis in young adult women. Sling procedures using nonresorbable mesh can be used to correct the prolapse. Bed rest is necessary in the later stages of pregnancy for most of these patients (229). Urinary incontinence and prolapse may develop after pregnancy as well. Elective cesarean section should be performed for any patient with a functioning bladder or with an AUS. Cesarean section may help avoid some of the later problems with prolapse as well. Prolapse, in particular, can be a difficult problem to treat because of the technical challenge involved in correcting the prolapse. Sacrocolpopexy has been successfully used to correct prolapse in these patients (187). Hysterectomy is not advised in this situation because the uterus is acting as the only solid organ supporting the pelvic floor in these patients (224).

Risk for Malignancy

The exstrophic bladder possesses an increased potential to undergo malignant transformation (123,169,173) (Fig. 49B.33). Patients with untreated bladder exstrophy are at greater risk for this than patients treated early in life. However, early reconstruction does not eliminate the risk of malignancy. Justrabo and co-workers (122) estimated that the untreated exstrophic patient is 235 times more likely to develop bladder cancer than someone in the general population. Latency periods range from 40 to 50 years on average. More men than women are affected by a ratio of 2.5:1. The underlying mechanism of tumor development is not known. Hypotheses include chronic inflammation. This may induce a precarcinogenic metaplastic response. Others have suggested that ectopic glandular epithelial tissue in the bladder plate may later serve as the focus of tumor formation. Interestingly, of 53 exstrophic patients with intestinal metaplasia followed for an average of 12 years, none developed adenocarcinoma in their bladders (35). Histopathologically, most bladder tumors in this population are adenocarcinomas. Some have elements of squamous cell or transitional cell carcinoma. The adenocarcinomas resemble adenocarcinomas of the colon. These tumors elaborate sialomucin type mucins and express antigens KL1, ACE, and EMA. Notably, they do not possess the normal urothelial cytokeratins 8, 18, and 19. Adjacent glandular metaplasia is common (122).

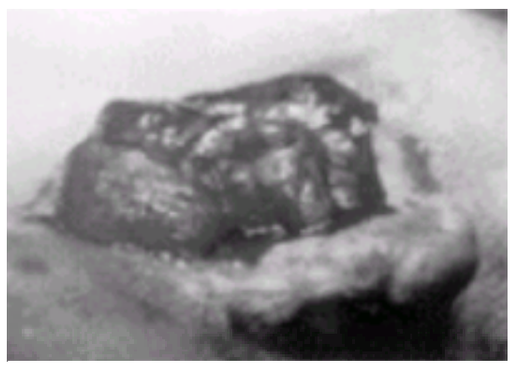

FIGURE 49B.33. Photograph of gross lesion that was identified as adenocarcinoma associated with an exstrophic bladder. [Reprinted from Paulhac P, et al. Adenocarcinoma in the exstrophic bladder. *Urology* (online) 1999;54(4):744, with permission.]

Patients who have undergone urinary diversion with ureterosigmoidostomy are also at risk for developing adenocarcinomas at the ureterosigmoid anastomosis (50,77). Latency periods range from 40 to 50 years on average. More men than women are affected by a ratio of 2.5:1. Routine surveillance by sigmoidoscopy is mandatory because the risk for tumor formation is several hundred times greater than in the general population. Latency periods for tumor development are on the order of decades (217). The risk of tumor development for those patients who have undergone augmentation cystoplasty using intestinal segments is not known, but case reports of tumors developing in the augmented segment following augmentation cystoplasty have been described in the literature (26,79,206). Theoretically, these patients should be at increased risk for malignant degeneration in these segments as well as in the native exstrophic bladder plate and should be followed routinely.

All patients with bladder exstrophy should undergo surveillance throughout their lives. The mortality rate from malignancy of the exstrophic bladder plate was reported as high as 67% in 1926 (215). With modern endoscopic techniques and close follow-up, this rate should be significantly lower. Some investigators also suggest the use of periodic acid–schiff (PAS) staining to screen for digestive tract cells in the urine as a screen for adenocarcinoma or glandular metaplasia (32). Treatment options include radical cystectomy with urinary diversion. Radiation and chemotherapy play a limited role in the treatment of adenocarcinoma of the bladder (173).

MANAGEMENT OF CLOACAL EXSTROPHY

Of the disease entities in this chapter, cloacal exstrophy represents the most challenging condition to manage (Fig. 49B.34A and Fig. 49B.34B). Cloacal exstrophy is rare. It occurs in 1 in 200,000 to 1 in 400,000 births. Although cloacal exstrophy has been recognized as a disease entity for at least several hundred years, Spencer became the first surgeon to report the successful repair and survival of an infant with this anomaly in 1965 (200). Mortality rates of infants with cloacal exstrophy remained high for years following this initial success. These affected infants routinely died of malnutrition and sepsis. In 1979, the mortality rate from this anomaly stood at 50% (218). The popularization of intravenous hyperalimentation in the 1970s significantly changed the survival rate of patients with cloacal exstrophy (103). Because of continued improvement in total parenteral nutrition and neonatal management, mortality rates currently are less than 10% (39). Issues of quality of life are now paramount in this patient group.

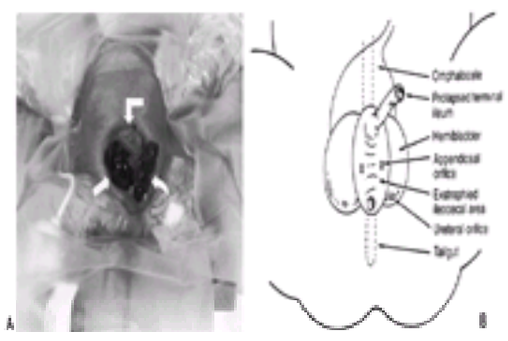

FIGURE 49B.34. Newborn male with cloacal exstrophy. **A:** The right lateral hemibladder plate can be seen here *(short arrow)* along with the central hindgut plate

(curved arrow) and omphalocele *(right angle arrow)*. **B:** Schematic diagram of patient with cloacal exstrophy. [From Hurwitz RS, et al. Cloacal exstrophy: a report of 34 cases. *J Urol* 1987;138(4 Pt 2):1060, with permission.]

Antenatal diagnosis of cloacal exstrophy is possible. Austin (8) reported the typical findings associated with cloacal exstrophy *in utero* (Fig. 49B.35A and Fig. 49B.35B). These include the following:

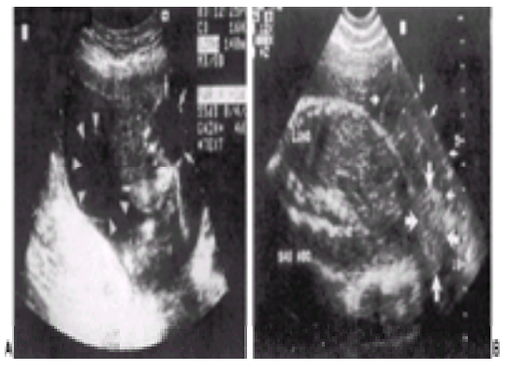

FIGURE 49B.35. Antenatal ultrasonogram of fetus with cloacal exstrophy. **A:** At 22 weeks of gestation, this transverse image reveals a cloacal membrane anteriorly *(arrowheads)* and lumbar myelomeningocele posteriorly *(arrows).* **B:** At 30 weeks of gestation, an omphalocele may be seen *(small arrows)* along with an exstrophic bladder and bowel inferiorly *(large arrows).* (Reprinted from Austin P, Homsey YL, Gearhart JP, et al. The prenatal diagnosis of cloacal exstrophy. *J Urol* 1998;160:1180, with permission.)

- Nonvisualization of the bladder
- A large midline infraumbilical anterior wall defect
- Omphalocele
- Myelomeningocele
- Widened pubic arches
- Lower-extremity defects
- Renal anomalies

In a review of 22 patients with cloacal exstrophy, all or some of these findings could be identified antenatally for 19 patients. As with classic exstrophy, antenatal diagnosis allows expectant parents to anticipate and plan for a child who will have significant anomalies at birth. Discussions regarding treatment options including therapeutic abortion should include pediatric surgeons and urologists familiar with the care of these children. Antenatal identification also permits parents to have these children delivered at a tertiary medical center equipped to provide multidisciplinary consultation and services.

Anatomic Issues

Patients with cloacal exstrophy routinely have multiple organ systems affected. As a result, cloacal exstrophy also is referred to as the OIES complex (*o*mphalocele, *e*xstrophy, *i*mperforate anus, and *s*pinal defects). Other organ systems may be affected as well, including the extremities; the upper urinary tract; and the cardiovascular, pulmonary, and craniofacial systems (103) (Table 49B.1). Because of the broad extent of organ involvement in cloacal exstrophy, a thorough physical examination should be preformed for all these children, and appropriate imaging studies should be obtained before proceeding with reconstructive surgery.

Cloacal exstrophy variants do occur. The anatomic findings for these patients vary from those typically found in the OIES complex. Some cloacal exstrophy variants have anatomically normal genitalia, whereas other authors have reported variants with aphallia (27). Erlich proposed a classification system for cloacal exstrophy and its variants (143).

Lower Urinary System

The hindgut plate separates the hemibladder plates found in cloacal exstrophy; the hindgut plate represents the deformation in the development of the colon that occurs with cloacal exstrophy. Ileum enters and intussuscepts into the middle of the hindgut creating the “trunk of an elephant's face” appearance with appendiceal appendages located laterally to give the impression of “tusks on the face of the elephant”(216) (Fig. 49B.34A).

With cloacal exstrophy, the bladder neck (internal urethral sphincter) and external urethral sphincter are not fully developed because of the failed development of the bladder and urethral remnant located on the anterior and dorsal surfaces of the body wall and penis respectively. Because the innervation to these structures may not be intact because of associated central nervous system defects in many of these patients, the possibility of achieving urinary continence after functional reconstruction is less predictable than with bladder exstrophy (106). The urethral plate is characteristically short as well.

In contrast to classic exstrophy, the herniation defect (deformation) occurs earlier in development during the cloacal stage of the embryo. This results in multisystem involvement. It may be that the early herniation of the cloaca anteriorly prevents the curving of the tail bud ventrally, which ultimately prevents normal spine, renal, and intestinal development.

Kidneys and Upper Urinary Tract

Husmann and Vandersteen reviewed the available series of patients with cloacal exstrophy. They found a 67% incidence of renal anomalies in these patients, including anomalies of location such as pelvic kidney or crossed fused ectopia. Complete ureteral duplication, renal agenesis, and location anomalies represent the most common anatomic problems seen in patients with cloacal exstrophy. Horseshoe kidneys, single system ureteral ectopia, and ureteropelvic junction obstruction may occur as well (103,170).

Genitalia

For male patients with cloacal exstrophy, the penis is often separated into two hemiphalli because of the wide pubic diastasis (Fig. 49B.36). Furthermore, the phallus may be compromised by complete absence or absence of one of the corporal bodies. In many of these cases, the tissue available for penile reconstruction is significantly less than that found in a normal male infant This can make subsequent reconstructive efforts technically more challenging if a male phenotype is preserved (109). Historically, because of the difficulty in reconstructing the phallus in these patients, the prevailing opinion has been to perform gender reassignment for these male patients (210). However, gender conversion is now more controversial in this population because of recent information that suggests that patients who have been virilized *in utero* continue to gender identify as males even after gonadectomy. The lack of outcome data in this patient population and the lack of consensus among physicians that currently care for these patients continue to fuel this debate (103,182). The majority of these patients have a bifid or rudimentary scrotum, and cryptorchidism is the rule with cloacal exstrophy (103).

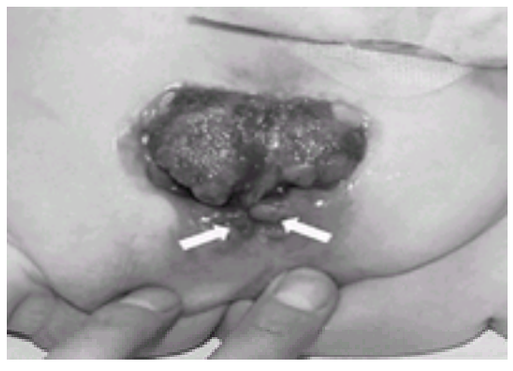

FIGURE 49B.36. Newborn male with cloacal exstrophy. The bifid phallus *(arrows)* in the male patient in association with the bifid scrotum below.

For genotypic girls with cloacal exstrophy, one typically notes a bifid clitoris, wide separation of the labia majora, and anterior displacement of the vaginal vault. These findings are shared with girls who have bladder exstrophy. Gynecologic abnormalities are common as well. These include uterus didelphys (94%), vaginal duplication (54%), and other fusion anomalies of the müllerian duct structures. Vaginal (20%) and clitoral agenesis (17%) are also common (103). Outcome data regarding sexual function and satisfaction toward body appearance for these patients are lacking at this time.

Anorectal and Intestinal Abnormalities

Associated intestinal abnormalities specific to cloacal exstrophy include imperforate anus, foreshortening of the midgut, bowel duplication, malrotation, intestinal atresia, inguinal hernias, and Meckel's diverticulum (103,170). These are in addition to the exstrophy of hindgut, omphalocele, ileal intussusception and exposed appendices that are considered part of the primary pathology of cloacal exstrophy.

Skeletal Abnormalities

In addition to the pubic diastasis associated with exstrophic conditions, patients with cloacal exstrophy can have other skeletal abnormalities. Skeletal anomalies are seen in as many as half of patients with cloacal exstrophy. Anomalies include congenital hip dislocation, talipes equinovarus, and a variety of limb deficiencies (202) (Fig. 49B.37).

FIGURE 49B.37. Skeletal and limb anomalies associated with cloacal exstrophy. This patient has an underlying limb anomaly of his left lower extremity along with a myelocystocele not pictured here.

Fascial Abnormalities

The fascial anomalies associated with cloacal exstrophy include those previously described for bladder exstrophy. Further, omphaloceles almost always are present with cloacal exstrophy (93,141). If the omphalocele is small, it can be closed during the initial bladder closure. If the omphalocele is large, it may require closure as a primary procedure with the reapproximated bladder halves acting as a silo to decompress intraabdominal pressure. Alternatively, the omphalocele may be treated with antiseptic paint to promote skin overgrowth. We prefer to correct the omphalocele surgically if the infant is a surgical candidate. We remove the hindgut and reconstruct it during the initial operation if possible and then proceed with primary reconstruction of the bladder at that time or at a later date, depending on whether the patient can tolerate a complete reconstructive procedure in one setting. In our experience, intraabdominal pressure following omphalocele closure determines whether we may proceed with primary bladder closure at the same time as the omphalocele repair or whether these operations must be staged. Aggressive one-stage closure of a cloacal exstrophy can lead to organ ischemia from increased intraabdominal pressure. Rupture of an omphalocele clearly requires immediate attention in these patients and would take precedence over other considerations. Fortunately, this occurs rarely.

Neurologic Abnormalities

Neurologic involvement of the lower spinal cord in the cloacal exstrophy population is reported between 50% to 100% (99,101,141). Most of these patients have lumbar or sacral cord involvement, but thoracic level myelodysplasia has been reported (141). In a review of the literature, 70% of patients with cloacal exstrophy had myelodysplasia, and 33% developed symptomatic tethering of the spinal cord (103). Because of the high incidence of neurologic abnormalities, management of patients with cloacal exstrophy must include neurosurgical input.

The high incidence of neurologic abnormalities in this patient population also affects the potential for these patients to achieve urinary continence (6,106). This factor also must be considered when counseling patients' families and when choosing the reconstructive technique to use to provide these children with a functional and safe urinary tract.

Perioperative Management

Because the care of patients with cloacal exstrophy involves multiple organ systems, these patients are optimally cared for at a tertiary medical center. As a result of the advances in neonatal care and intravenous nutrition, the survival of neonates with cloacal exstrophy is quite high. Mortality in this time period is usually due to concomitant anomalies affecting the cardiovascular or pulmonary systems in these patients rather than as a direct result of the cloacal exstrophy. In the past, mortality was high because of the poor nutritional and fluid support. With hyperalimentation and surgical sparing of the hindgut to preserve salt and water, the cloacal exstrophy patient has a good prognosis. The length of stay for the initial hospitalization may be significant, however.

In the neonatal period, the bladder and hindgut plate should be covered with a hydrophilic gel (e.g., Vigilon) dressing to protect these structures. The umbilical cord should be ligated with a silk suture because an umbilical clamp will abrade the bladder or hindgut plate. We also routinely administer antibiotic prophylaxis to these patients.

Preoperative studies include ultrasonography and karyotyping. Sonographic examination allows the evaluation of the upper urinary tracts, internal genital structures, and spinal cord. MRI may also evaluate spinal abnormalities. MRI of the pelvis is also useful to characterize the anatomy in the pelvis (150). Because the genital anomalies associated with cloacal exstrophy may cause confusion in accurately identifying the sex of the baby, karyotyping is indicated to define the chromosomal sex. The decision to gender reassign usually is based on the assessment of reconstruction potential. This should only be done by a team very experienced in the care of the cloacal exstrophy patient. However, antenatal imprinting may result in behavioral patterns that follow the genetic sex. This has resulted in sex conversion to the

genetic sex in later years for some of these children who previously had been sex reassigned.

Management Strategies

Management of the genitourinary system for patients with cloacal exstrophy remains challenging. Many factors affect the surgical approach to these patients, including the severity of the underlying anatomic anomalies, availability of tertiary care facilities, surgeon experience with cloacal exstrophy, and the effects of previous surgical procedures. A specific standard of care does not exist for this patient population. Because of the complexity of exstrophy, specialists with an interest in the exstrophy–epispadias complex should manage these patients so that their care may be optimized.

As with the management of classic bladder exstrophy, physicians caring for these patients approach the surgical management of the lower urinary tract of these patients with a strategy of functional reconstruction or urinary diversion. Urinary diversion involves excision of the exstrophic bladder plates and creation of a urinary reservoir from the gastrointestinal system. Functional reconstruction of the urinary tract may proceed in a staged or single-stage approach, depending on the physician team responsible for care and patient anatomy.

The goals of urinary reconstruction or urinary diversion include those listed in Table 49B.5.

Primary Goals	Secondary Goals
Urinary continence	Minimization of the risk for urinary calculi
Volitional voiding (functional reconstruction only)	Minimization of the risk for malignancy associated with the urinary tract
Low-pressure urine storage reservoir	Adequate pelvic floor support
Preservation of kidney function	
Minimize infection	
Abdominal wall closure	
Functionally and cosmetically acceptable external genitalia	

TABLE 49B.5. GOALS OF URINARY RECONSTRUCTION/URINARY DIVERSION

Initial Closure

Closure of a cloacal exstrophy should involve a team of pediatric surgeons and pediatric urologists experienced in the care of cloacal exstrophy. If the baby is medically stable, we prefer to perform the initial reconstructive procedures within the first 48 hours of life. This allows us to take advantage of the pliable bony pelvis if closure of the entire exstrophy is possible. The size of the omphalocele and the size of the hindgut plate and bladder plates largely dictate the extent of the initial closure. A large omphalocele containing liver will preclude any attempt at complete closure (170). In this situation, the omphalocele and plates should be appropriately protected until reconstructive procedures can be undertaken. Usually, the omphalocele is first closed and a colostomy constructed. The bladder plate will function as a silo (all hindgut should be used in the gastrointestinal tract).

Before beginning the dissection, we place ureteral catheters in the ureteral orifices and secure them in place with 5.0 chromic suture. We first approach the omphalocele associated with the cloacal exstrophy. The omphalocele should be repaired first. The initial dissection is begun superiorly (Fig. 49B.38). The umbilical vessels are ligated and the bladder plates are separated from the adjacent skin using sharp dissection. We use Colorado tip electrocautery to do this. We then separate the medial hindgut plate from the paired, separated bladder plates during this stage of the closure (Fig. 49B.39). The ileum should be detached from the hindgut plate. The hindgut is then tubularized and reattached to the ileum to form a large intestinal segment (Fig. 49B.41). The distal end of this segment will be used as a colostomy at the end of the procedure.

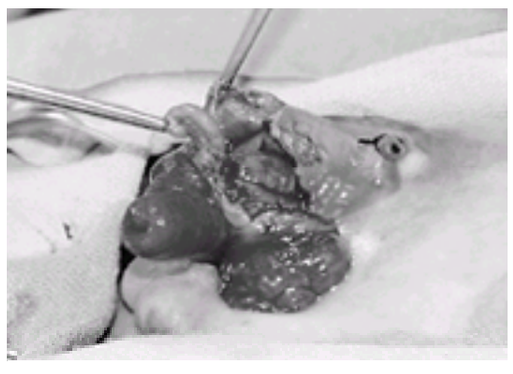

FIGURE 49B.38. Initial dissection used for repair of cloacal exstrophy. The dissection is begun superiorly. The omphalocele should be addressed first before deciding to proceed with hindgut separation from the bladder plate.

FIGURE 49B.39. The bladder halves *(curved arrows)* are separated from the hindgut *(straight arrow).*

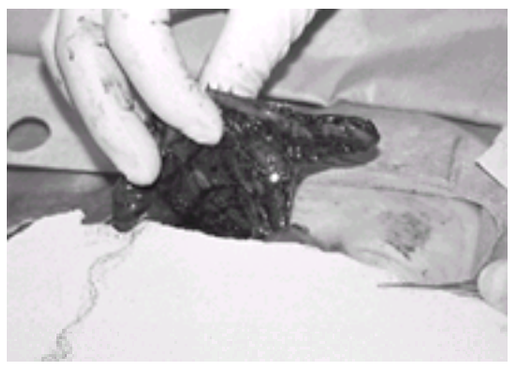

FIGURE 49B.41. The hindgut is separated from the lateral bladder plates and tubularized to allow it to remain in continuity with the rest of the gastrointestinal system.

After the hindgut has been separated from the bladder plates, these plates are reapproximated. Primary bladder closure may be performed at this time if the intraabdominal pressure remains low after omphalocele closure. This can be determined clinically by assessing ventilatory effort following the omphalocele closure. Increased abdominal pressure also may result in organ ischemia following closure.

Single-stage Reconstruction with Total Disassembly Technique and Complete Primary Repair

When possible, we perform a one-stage closure using the complete primary repair technique described for classic exstrophy. The decision to proceed with one-stage closure versus staged reconstruction must be weighed carefully. The importance of including surgeons experienced in the care of these patients cannot be overemphasized. Factors that effect a decision to proceed with a single-stage reconstruction include the size of the omphalocele, the extent of the pubic diastasis, and coexisting medical conditions. In most cloacal exstrophy patients, the bladder and genital repair can be performed several weeks to months after the omphalocele repair without apparent compromise to the primary closure. The bladder, however, must be carefully protected during this period.

When it is not possible to perform a single-stage reconstructive approach for these babies, we prefer to remove the hindgut in its entirety from the exstrophic bladder and then reapproximate the bladder plates (Fig. 49B.42). This, in essence, recreates the anatomy of classic bladder exstrophy. Once the baby has recovered sufficiently to tolerate another surgical procedure, we proceed with functional reconstruction of the bladder, bladder neck, and genitalia using the total disassembly technique previously described in this chapter (178). We have reported on this approach in six patients with cloacal exstrophy. Two patients void volitionally with urinary continence, two patients have dry intervals, and two patients are incontinent of urine and await further reconstructive procedures (82).

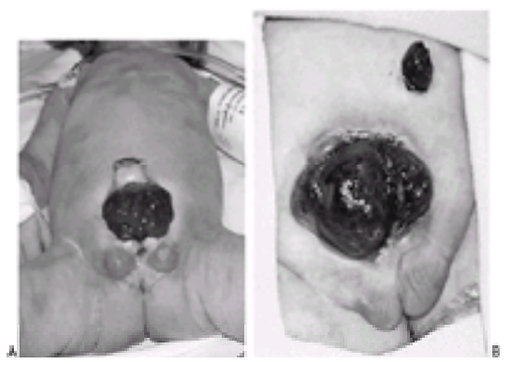

FIGURE 49B.42.A: Photograph before hindgut removal from cloacal exstrophy in a newborn male. **B:** Photograph after removal of hindgut from the bladder halves. The anomaly now appears similar to classic bladder exstrophy in gross appearance. A colostomy is present in the left upper quadrant.

Because of the wide pubic diastasis in cloacal exstrophy, pubic reapproximation often requires iliac osteotomies even if the closure is performed within the first 48 hours of life. We determine the need for osteotomies by assessing the lower extremities and external genitalia for ischemia during pubic reapproximation before osteotomies are performed. We have used osteotomies to assist in the reconstruction of the majority of these patients. Other authors prefer to avoid the use of osteotomies because they believe that osteotomies make the abdominal closure more difficult (103). This has not been our experience.

Staged Reconstruction

A staged reconstructive approach as popularized by Jeffs also has been used to reconstruct the lower urinary system of patients with cloacal exstrophy. Matthews and Gearhart (146) reported on a series of 37 patients managed with a staged approach: 1 patient is continent, 16 patients are dry with CIC, 3 patients have undergone urinary diversion, and 12 patients remain incontinent (146). The results of this series are similar to that reported by Husmann (106) and reflect the difficulty in achieving true urinary continence in this patient population.

The *staged approach* to cloacal exstrophy reconstruction involves the following stages:

1. *Initial bladder closure* ideally is performed in the newborn period. Patients with a wide pubic diastasis may require a staged pelvic closure.
2. *Epispadias repair* is usually performed at 12 to 18 months of age but may be combined with initial bladder closure, especially if initial bladder closure is delayed beyond 6 months of age.
3. *BNR* usually is performed at 4 to 5 years of age or when age appropriate for toilet training and bladder capacity is adequate.

Postoperative Considerations

To increase the success of functional reconstructive procedures, patients must be immobilized adequately following surgery either with a spica cast, external fixators, or Bryant's traction.

Other factors that may affect the success of functional reconstruction include the following:

- Use of postoperative antibiotics
- Ureteral stenting catheters
- Adequate postoperative pain management
- Avoidance of abdominal distention
- Adequate nutritional support
- Secure fixation of urinary drainage catheters (107,140)
- The severity of underlying neurologic anomalies (6,106)

Urinary Reconstruction and Diversion

Because patients with cloacal exstrophy lack a normal functioning anal sphincter, the option of a rectal reservoir is not available. Other forms of urinary diversion may be used including both incontinent and continent forms of urinary diversion. Many of these patients lack adequate intestinal length, especially large intestine. This

may preclude the use of colon in urinary reconstruction for diversion or augmentation. Use of stomach for augmentation in these patients is often appropriate; stomach usually is not affected in cloacal exstrophy and its use will not compromise the remaining intestinal system unlike other forms of gastrointestinal urinary reconstruction (2,156,158). Other innovative procedures to avoid the use of intestine for reconstruction in this patient population include ureterocystoplasty and the double tunnel ureteral technique. In this latter procedure, the ureter is reimplanted in the bladder and then used to create a catheterizable channel to the perineum or umbilicus (121) (Fig. 49B.40).

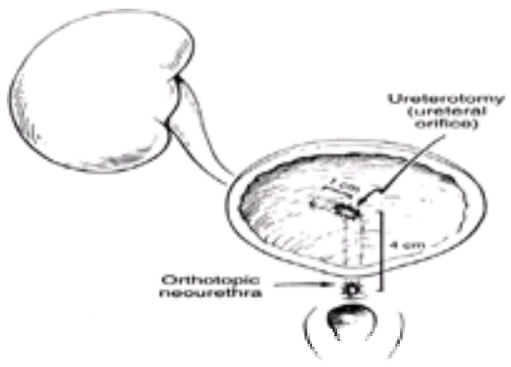

FIGURE 49B.40. Double tunnel ureteral reimplantation and continent catheterizable channel technique. Line drawing of technique. [From Joyner B, et al. A continence procedure using a single ureter as a nonrefluxing ureter and catheterizable neourethra . *J Urol* 1997;157(3):968, with permission.]

Genitourinary Reconstruction/Gender Issues

Currently, the gender issues involved with cloacal exstrophy remain one of the greatest challenges facing physicians who care for these patients. The genitalia of patients with cloacal exstrophy are severely affected. Reconstruction of male patients, in particular, can be quite challenging. Anecdotal accounts of early attempts to reconstruct the genitalia of these patients have been described to result in “the creation of an impotent, psychologically disturbed infertile male.” So, genotypic male patients with cloacal exstrophy have undergone sex conversion in infancy because of these concerns that the small, paired male phalluses in these patients were inadequate for reconstruction. This approach was supported by anecdotal data of unsatisfied patients following reconstruction of the male phallus (141). Furthermore, medical authorities have traditionally recommended a female sex assignment for male patients when reconstruction of the genitalia appears impossible. This strategy is referred to as an “optimal gender policy” (180).

However, sex assignment for patients with cloacal exstrophy is currently under scrutiny both by the medical profession and by the lay public. Woodhouse and coinvestigators (181) have shown that postpubertal males with microphallus can have normal sexual function. Previous notions that humans were gender neutral at birth and therefore could undergo sex conversion safely in infancy have recently come into question (45). Recent evidence suggests that gender imprinting may occur during fetal development (80). Gender identity now appears to be a much more complex issue than previously thought. Questions about gender identity development in these patients currently fuel a debate about the best policy for sex of rearing of male patients. Beyond this, because patients with cloacal exstrophy are rare and have routinely survived only over the last two decades, little is known about their psychosexual development.

Recent support to preserve a male sexual identity for 46XY cloacal exstrophy patients comes from various sources. Because males with cloacal exstrophy have normal gonads, they experience prenatal androgenization, including the putative effects of this on the central nervous system. Some male-to-female sex-assigned patients also appear to maintain male gender activity and identity. Reiner reported on a cohort of genotypic males who underwent gonadectomy at birth for reasons including cloacal exstrophy and were raised as females. One-third of them still identified themselves as male or engaged in male gender role play (183). Others have found that some of these patients have marked shifts in gender role behavior as well (204). In contrast, Meyer-Bahlberg and co-workers have reported that although these patients may show girlhood masculinity, they do not experience any gross gender dysphoria (153). Husmann reported on a series of 15 postpubertal genetic male patients raised as males. Four of these patients were married and engaged in vaginal intercourse successfully. Nine patients had attempted vaginal intercourse but were unsuccessful as a result of inadequate phallus size, and two patients reported erectile dysfunction but refused evaluation (103).

Because of the lack of data and standardized assessment of these patients, current recommendations are influenced largely by anecdotal evidence. Many questions remain to be answered about this psychologically and emotionally sensitive topic. The consequences of growing up with a cosmetically and functional suboptimal penis are not well understood. Self-esteem issues are evident as noted by Reiner's studies of male exstrophy patients (182). However, patients assigned to a female sex role also appear to struggle with sexual and gender identity. Clearly, standardized evaluation of these patients with rigorous psychosexual assessment and improved support networks will improve our understanding and the care of gender development in these patients. At the present time, most institutions perform selective gender assignment of genotypically male patients with cloacal exstrophy. Importantly, routine assignment of these patients in a female sex role should no longer be considered the standard of care.

Our institutional experience with external genital reconstruction in this patient population covers a period of time when patients were gender converted and later when male gender was maintained. We now reconstruct these patients as males whenever technically possible. Our comparison of these two groups suggests that many gender reassigned individuals will later identify themselves in a male gender role in adolescence and adulthood (155). Technically, however, reconstruction of external male genitalia in the cloacal exstrophy population can be quite difficult. The wide pubic diastasis and small phallic size contribute to the technical complexity; these findings make it more difficult to bring the two phallic halves together in the midline.

Gastrointestinal Reconstruction

Short-gut syndrome usually is present in patients with cloacal exstrophy at birth. The effects of malabsorption and fluid loss from this entity appear to be clinically most significant early in life (105). Many such children require parenteral nutritional support in early infancy (52,75). Because of this, we share the belief that the hindgut should be constructed and placed in continuity with the intestine during initial reconstruction. This will perhaps improve nutrition and also preserve intestinal tissue that may be used in later reconstruction of the urinary tract or to form a vagina, if this is eventually needed. It is interesting to note that Rickham noted the importance of preservation of the hindgut in the intestine in his report of the first surviving neonate with cloacal exstrophy (185). Although hindgut can be preserved with the bladder to augment bladder capacity, we prefer to reconstruct these patients with the goal to provide maximal bowel length.

Preservation and incorporation of the hindgut into the gastrointestinal system also decreases the morbidity of malabsorption, dehydration, and nutritional deficits in patients with cloacal exstrophy. Advances in intravenous hyperalimentation have significantly decreased mortality due to short-gut syndrome in the cloacal exstrophy population. Before the era of hyperalimentation, patients who underwent excision of the hindgut and creation of a terminal ileostomy had a mortality rate of 68% compared with a mortality of 24% for patients who had the hindgut incorporated and brought out as a terminal colostomy. Currently, the mortality rates between patients managed with a terminal ileostomy compared with a colostomy are similar at 5% to 10%. However, the morbidity of patients with a terminal ileostomy remains higher, especially in the first 3 years of life. These patients are admitted more frequently with dehydration and are dependent on intravenous hyperalimentation for longer periods (39,105).

For the reasons cited above, we rarely leave the hindgut with the exstrophic bladder. Instead, at the time of the initial procedure, we separate the bladder plates from the hindgut segment. The hindgut is then tubularized with the terminal portion of the ileum and exteriorized as a colostomy. In the event of colonic duplication, we attempt to preserve all intestinal segments and place them in series. We also try to preserve appendiceal segments in these patients for possible use in later reconstruction of the urinary tract as for a Mitrofanoff procedure.

Most patients with cloacal exstrophy are managed throughout their lives with a colostomy. Anecdotal experiences with pull-through procedures in this population have led to the belief that this procedure has an unacceptably low success rate. However, Soffer and co-workers recommend the use of a pull-through procedure for those patients with cloacal exstrophy who can achieve solid stool formation and who respond favorably to an enema program. Using this approach he reported complete fecal continence in 3 of 25 patients and 11 patients who were clean with occasional soiling. Success with this approach appears to depend on preservation of as much hindgut as possible in the gastrointestinal system and the ability to form solid stool. Neurologic impairment does not appear to affect the success of this

approach (198).

Exstrophy represents a complex problem because of its severity and dimension. Although results of therapy are far from perfect, they reflect remarkable accomplishments from many physicians. There is great potential for further improvement such that one day children born with exstrophy will be treated early and completely and never know that they had a major problem. It is appalling that in the face of the many current successes in the treatment of exstrophy, it is the uninformed who are often making the decision to terminate a pregnancy based on information relating to treatments two or three decades old. The result is unfortunately unborn patients who will never benefit from treatments that can result in healthy, happy, and productive individuals.

The Potential For Bladder Healing: Can The Valve Bladder Be Prevented?
Chapter References

> “The primary lesion of posterior urethral valves is a simple one which might be expected to respond readily to simple transurethral resection. Nevertheless, the total care of the boy with urethral valves can be a complicated undertaking.”
>
> D.I. Williams (35)

Obstructive uropathy caused by posterior urethral valves is a complex disease process with the potential for life-threatening consequences. In the 30 years since Williams made his comments, there have been remarkable advances in the diagnosis, treatment, and survival of boys with urethral valves. With the increasing incidence of prenatal diagnosis by obstetric ultrasound, early postnatal intervention is available for most infants in the developed countries. Modern pediatric endoscopic equipment combined with high-resolution video imaging makes primary valve ablation safe and effective in almost all neonates with posterior urethral valves. There is growing evidence that with relief of urethral obstruction in early infancy the normal anatomy and function of the bladder, ureters, and urethra can be restored and that in many patients the steady degradation of the urinary tract can be avoided (4).

In 1982, Mitchell (23) introduced the concept of the valve bladder syndrome with his description of a recognizable complex of physiologic and anatomic changes in certain patients with valves. In a series of 70 boys with a history of severe posterior urethral valves, 16 patients demonstrated polydipsia and polyuria, incontinence and constipation, hydroureteronephrosis without vesicoureteral reflux, and poorly sensate bladders with high pressures at low urine volumes. These patients all had in common a delayed diagnosis of valves made after infancy or a history of treatment by urinary diversion with subsequent undiversion.

A number of significant disorders relating to the urinary tract are found in the valve bladder syndrome (Table 49C.1). At the renal level, there is significant renal tubular dysfunction secondary to congenitally abnormal parenchyma and damage from ongoing high bladder pressures transmitted to the upper tracts. Even with fluid restriction, these patients demonstrate a concentrating defect that results in a high obligate urine output. Urinary volumes as high as 3 L per day are typical even in young boys. Because polyuria from end-stage renal disease can cause bladder decompensation and incontinence even in patients with normal bladders, it is not surprising that valve patients with poorly compliant bladders often are incontinent (29). The concentrating defect also results in chronic dehydration that contributes to constipation in these patients.

Renal	Dysplasia, renal tubular dysfunction	High urine output
	Urine concentrating defect	Increased volume work for ureters and bladder
Ureters	Dilated with poor peristalsis	Large dead space
	Scar and fibrosis secondary to infections or previous surgery	Poor emptying
		Possible obstruction after reimplant
Bladder	Poor compliance, small volume, reduced sensation to high pressure	High bladder pressure most of time
	Myogenic failure in end stage	Progressive renal damage Progressive bladder damage
Urethra	Voiding dysfunction: functional bladder outlet obstruction	Difficulty with bladder emptying
		Magnified bladder pressure effect

TABLE 49C.1. ANATOMIC CHANGES AND CLINICAL CONSEQUENCES IN THE VALVE BLADDER SYNDROME

The second component of the valve bladder syndrome is ureteral dysfunction. Normal ureteral peristalsis is impaired because of ureteral dilation and ureteral wall scarring secondary to previous diversion surgeries and infection. Many of these ureters have no potential for peristalsis because the muscularis of ureteral wall is replaced with collagen. Furthermore, with urinary retention, which is common in these patients, the upper tracts and bladder pressures equalize and the normal falling pressure gradient from renal pelvis to bladder is lost. Therefore the full bladder acts as an impediment to ureteral drainage and, if noncompliant, exerts pressure on the upper tracts. This is because the only way there can be flow from the kidney to the bladder is from a higher pressure point to a point of lower pressure. Therefore the energy for flow from the upper tracts is generated entirely by the kidney. Once the bladder pressure exceeds renal perfusion pressure, there will be no flow. If there is reflux, the situation is worse as the bladder and kidney equilibrate at the bladder pressure, which can be very high (16). After the patient voids, the bladder rapidly fills from the drainage of the upper tracts. This results in rapid return of the functional obstruction of the upper tracts. Inefficient upper tract drainage can be even more pronounced after ureteral reimplantation, which increases distal ureteral resistance.

The bladder is the third major component of the valve bladder syndrome and is the focus for both preventing and treating valve disease. Although it is often described as a small bladder, it is the high pressure and poor compliance of the valve bladder that are fundamental to the syndrome. These patients learn to tolerate high intravesical pressures without discomfort. As a result, they tend to delay voiding and suffer incontinence as well as continuing renal damage secondary to the high, transmitted back-pressures. Furthermore, polyuria causes volume stress and contributes to chronic overdistention of the bladder.

Complete bladder emptying is difficult to accomplish because of poor detrusor function, abnormal urethral dynamics, and rapid refilling of the bladder from the dilated upper tracts. Double or triple voids are necessary to empty the bladder and upper tracts. Understandably, patient compliance to such a voiding chore typically is poor, so complete bladder emptying rarely occurs. Of all components of the valve bladder syndrome, the bladder is the most amenable to intervention. Anticholinergic therapy combined with timed voids or clean intermittent catheterization can decrease bladder pressures and facilitate upper tract drainage by routine bladder emptying. Interestingly, anticholinergics also appear to increase sensation in the valve bladder. Mitchell (22) demonstrated a lower pressure threshold for pain from bladder distention in patients treated with anticholinergics and noted that a sensation of bladder fullness at a lower pressure correlates with effective therapy as the patient becomes aware of minor increases in bladder pressure (Fig. 49C.1).

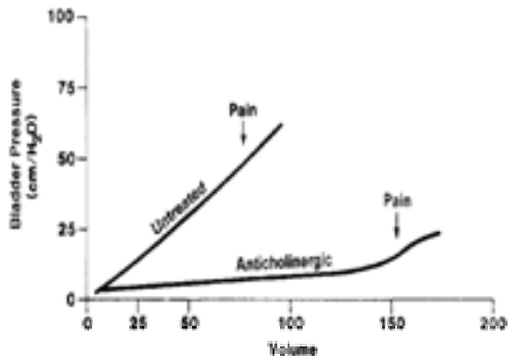

FIGURE 49C.1. Cystometrogram on patient with valve bladder without and with anticholinergic treatment. Without anticholinergic therapy, the filling curve demonstrates low bladder compliance (volume/pressure) and poor sensation to high intravesical pressure. Anticholinergic therapy improves compliance and sensation.

Although the patients originally described by Mitchell represent the severe end of the spectrum of valve disease, there is recognizable dysfunction in the urinary tracts of countless adolescents and young adults with a history of valves. The question remains as posed by Duckett (9) in 1997: “Are valve bladders congenital or iatrogenic?” Two types of variables in valve patients affect the outcome of bladder function: those that are inherent to the bladder's development and those that result from postnatal management. Can the valve bladder syndrome be avoided by changing our approach to the care of these children in infancy?

URETHRAL OBSTRUCTION: A SPECTRUM DISEASE

There is general agreement that posterior urethral valves result in a spectrum of changes in infants' urinary tracts. Variability is in part secondary to the degree of obstruction. Some valves are severely obstructing, leaving only a pinhole opening in the posterior aspect of the urethra, whereas other valves leave a more generous urethral lumen (7). In a postmortem study Stephens and associates (31) reported the urethral lumen at the level of the valves to measure from 3 mm to more than 1 cm in the anterior–posterior dimension (31). In addition to the degree of obstruction, the gestational timing of the abnormality also affects the urinary tract morphology. Very early obstruction of the urethra occurs in prune-belly syndrome and results in urinary tract distention with irreversible dysmorphic development of the bladder, upper tracts, and abdominal wall (7). The obstruction from posterior urethral valves is known to occur later in gestation and results in bladder wall hypertrophy that may be reversible. Severe upper tract and bladder wall changes seen in patients with mild-appearing valves suggests that in some fetuses the obstructive lesions may partially resolve.

Clinical studies support the protean nature of posterior urethral valves. In 1971, Hendren (11) reported the incidence of secondary anatomic problems in 182 boys with posterior urethral valves. High-grade urethral obstruction occurred in 30% of patients and presented early in life with urinary sepsis, renal insufficiency, and pulmonary hypoplasia. About half of these patients demonstrated severe hydronephrosis, megaureter, and renal insufficiency. Mild obstructive disease was diagnosed in older children who presented with incontinence and urinary tract infections. Controversy still surrounds the classification of patients with apparent urethral valves and minimal or no upper tract changes. Hendren reported normal upper tracts with or without associated low-grade vesicoureteral reflux or paraureteral diverticula in 70% of the patients. Some believe that this end of the spectrum may represent normal urethral variation or the functional obstruction of voiding dyssynergia. Pieretti (25) reported mild valves in 41% of 87 boys studied. These patients had no upper tract dilation, vesicoureteral reflux, or paraureteral diverticula. Diurnal or nocturnal enuresis, urinary tract infection, and urinary frequency were the most common symptoms reported. The resolution of symptoms in 34 of the 36 boys after valve ablation seems to validate the significance of these minor lesions.

Mild cases of valves have also been described in boys who do not demonstrate the expected radiographic signs of obstructive changes in the posterior urethra and bladder on voiding cystourethrography (2). These patients demonstrate abnormal urodynamic findings suggestive of obstructive damage to the bladder, including high filling and voiding pressures and detrusor instability. The authors found minor valve leaflets on cystoscopy and reported improvement in symptoms after valve ablation. Because timed voiding and efforts toward complete bladder emptying often parallel surgical intervention in these patients, it is unclear whether these minor urethral lesions exist because of functional urethral obstruction from dysfunctional voiding or from true anatomic obstruction.

PRESSURE POP-OFF MECHANISMS AND VALVES

The anatomy of the trigone and upper tracts also affects the outcome of bladder function and renal function in patients with valves. In 1986, Duckett and colleagues introduced the concept of pressure pop-off mechanisms in valve patients. Contralateral renal function is preserved in patients with high-grade unilateral reflux into a nonfunctioning kidney. This phenomenon, known as the VURD syndrome (posterior urethral valves, unilateral reflux, and renal dysplasia), suggests that mechanisms that relieve bladder pressures may have a protective effect on renal function. Other pressure pop-off mechanisms include large bladder diverticula, bladder rupture with urinary ascites, and renal urinary extravasation. There is some evidence that decompressive mechanisms may protect bladder development and ultimate function. Rather than the typical thick-walled trabeculated bladder, patients with upper tract pop-off mechanisms may demonstrate a smooth-walled bladder on voiding cystourethrogram. In a series of 85 valve patients, Kaefer and co-workers (17) found 63 boys (67%) with a pressure pop-off. Most patients were not diagnosed prenatally but rather presented with urinary tract infection or voiding symptoms. Almost half of the patients without pop-off mechanisms had poor bladder function with mean end bladder filling pressures greater than 40 cm H_2O and small bladder capacities. Because this was a retrospective review, these data also reflect the effects of late diagnosis and prolonged postnatal pressure work by the bladder. Half the patients without pressure pop-off mechanisms had good bladder function, possibly reflecting other favorable parameters, including less severe obstruction or early treatment. Bladder function has not been reported for valve patients with pressure pop-off mechanisms and a history of early valve ablation.

PRIMARY TREATMENT OF POSTERIOR URETHRAL VALVES

To appreciate the potential effect of postnatal management on development of the valve bladder, it is necessary to understand the wide range of treatments used for patients with posterior urethral valves. Throughout the twentieth century, issues of patient survival and limitations in pediatric endoscopic instrumentation have compelled urologists to use a variety of surgical techniques to treat the congenitally obstructed bladder. It is important to appreciate the swings in treatment philosophies relative to the clinical challenges and the available technologies of the past to understand the change in thinking that has occurred with valve treatment.

Hugh Hampton Young (36), who provided the widely used, albeit challenged, classification of posterior urethral valves, should be credited with recommending primary valve ablation (6). After endoscopic ablation of the valve leaflets, Young and McKay (37) advocated bladder drainage via a urethral catheter to allow decompression of the distended urinary tract. The duration of bladder drainage depended on the improvement in renal function. Although this treatment often was feasible, many patients were treated by complete bladder decompression through a suprapubic catheter, resulting in urinary tract infections and poor survival (28). Chronic catheter drainage with total decompression of the bladder also raised concern about a functional ureteral obstruction caused by compression by the thickened bladder wall. In an attempt to avoid these difficulties, in 1963, Johnson (14) popularized supravesical urinary tract diversion by temporary cutaneous ureterostomy. Without indwelling tubes to cause infection, Johnson argued that upper tract stasis would be relieved and bladder function preserved by the high diversion procedure. A decade later, however, there was evidence in the literature that urinary diversion in valve patients is detrimental to the bladder. Lome and associates (20) studied the bladders of children undergoing upper tract diversion by ureterostomy. Unlike normal bladders or bladders with acquired obstruction, congenitally obstructed bladders develop severe, irreversible hypertonicity when defunctionalized. All of his patients showed normal bladder capacity before the diversion. After diversion, all but one patient with valves showed reduced bladder capacity with poor bladder distention and compliance. Likewise, Tanagho (32) demonstrated permanent contraction of bladders in valve patients defunctionalized for 10 to 48 months. Two infants who underwent undiversion after 2 and 3 months had return of normal bladder capacity, although bladder compliance and subsequent function were not reported.

In response to the growing concern over bladder function in diverted patients, Duckett (9a) argued that if urinary diversion was necessary, creating a vesicostomy was preferable because it allowed upper tract decompression while preserving bladder function. He believed that the vesicostomy drainage occurred intermittently, thereby permitting normal bladder distention at low pressure volumes (9a). Hendren (10) addressed the bladder's role in the valve patient and suggested a bold shift away from any urinary diversion for severe valve obstruction. For mild valve cases, he believed that primary valve ablation was sufficient treatment. For cases with more severe obstructive changes such as massive vesicoureteral reflux, hydroureter, and bladder neck hypertrophy, Hendren (10) advocated complete early

reconstruction of the megaureter and bladder neck in addition to endoscopic valve ablation. With or without upper tract reconstruction, Hendren's practice of early definitive valve treatment allowed the bladder to fill and empty normally in the newborn period.

Despite the surgical advances in valve treatment advocated by Duckett and Hendren, the belief that upper tract diversion preserves or improves renal function continued to drive the practice of performing routine pyelostomies or ureterostomies in infants with even mild, early postnatal creatinine elevation. In 1990, high diversion was once again recommended for newborns with valves and a nadir creatinine of more than 0.8 mg/dL after 5 days of bladder drainage by urethral catheter (3). It can be argued that such a sweeping recommendation for diversion fails to recognize the inherent difficulties in assessing renal function reliably in newborns and that many infants with valves have concomitant primary renal dysplasia and will suffer chronic renal failure regardless of bladder treatment. Serum creatinine, urea nitrogen, and electrolyte values that are routinely used to evaluate older patients are not dependable in newborns because of the normal delay in renal maturation. Even at 4 weeks of age, the renal function of a normal term baby is only 40% of normal (34).

Supravesical urinary diversion is still driven by concern about hydroureteronephrosis persisting after bladder decompression. Although other models of upper tract dilation such as primary megaureter or persistent pelvocaliectasis after pyeloplasty persist without obstruction, it is commonly held that hydroureteronephrosis after valve ablation indicates obstruction at the ureterovesical junction. Tietjen and colleagues (33) used the Whitaker test to challenge this concept and demonstrated fixed ureterovesical junction obstruction in only 4% of renal units in valve patients who had undergone proximal urinary diversion for newborn renal insufficiency. In support of proximal diversion, Aliabadi and associates (1) reported renal biopsy evidence of obstruction in 60%, dysplasia in 25%, interstitial fibrosis in 25%, and infectious change in 15% of valve patients studied. However, because biopsies were performed in these patients after the newborn period, these findings may reflect secondary or postdevelopmental influences and not the basic histology of *in utero* obstruction. Histopathologic data from newborns with ureteral obstruction are limited. Tietjen and colleagues (33) reported renal dysplasia in 85% of renal units from babies treated by proximal diversion for renal insufficiency at birth. In an autopsy study of fetuses surviving to 14 to 37 weeks of gestation with bilateral renal obstruction, Diakha-Dalmane and co-workers (8) found that all fetuses at more than 20 weeks of gestation showed renal dysplasia with blastema cells, interstitial fibrosis, and an arrest of nephrogenesis. These findings support the irreversibility of obstructive change that occurs early in gestation.

The impression that high urinary diversion can restore renal function in valve patients with newborn renal insufficiency is not supported by the recent data. In a review of the long-term outcome of patients treated by primary valve ablation, vesicostomy, or high diversion, Smith and associates (30) found no evidence that urinary diversion delayed the onset of end-stage renal failure. Thirteen percent of patients overall progressed to end-stage renal failure by age 15 years. Likewise, a multicenter study of 178 infants treated for valves in the first year of life found no long-term renal benefit with proximal urinary diversion (27). Addressing the same question, we evaluated newborns with posterior urethral valves and renal insufficiency, defined as postbladder drainage nadir creatinine levels greater than 1.2 mg/dL. The patients were treated with primary valve ablation or upper tract diversion, depending on the surgeon's preference. Progression to end-stage failure occurred with either treatment when renal insufficiency was present after creatinine stabilization at birth. Three of six children in each treatment group needed dialysis before age 3 (4). If there is no hope of reversing the primary renal dysplasia and *in utero* damage already suffered by these kidneys, diversion can be avoided and treatment can focus instead on bladder function preservation.

BLADDER FUNCTION AND POSTERIOR URETHRAL VALVES

To date, bladder function in boys with valves has been studied only through historical reviews. The conclusions reached by these authors must be examined carefully because confounding factors including severity of obstruction, age at treatment, and posttreatment bladder management may affect bladder function. The common patterns of bladder dysfunction associated with valves are those reported by Peters and co-workers (24) in 1990. In a urodynamic evaluation of 41 valve patients, the authors found myogenic failure, hyperreflexia, and small, poorly compliant bladders. Furthermore, some of the patients had more than one of these abnormalities. These data add to our understanding of the range of voiding dysfunction in valve patients, but because all patients were referred for voiding abnormalities (35 of 41 patients referred for incontinence), little can be concluded about the incidence of normal bladders in valve patients. Using serial urodynamic evaluations, De Gennaro and associates (5) found similar types of bladder dysfunction with an apparent progression from hypercontractility in infancy to hypocontractility or even myogenic failure in adolescence. Because the authors do not specify the age or type of initial treatment, these data may reflect the influence of a variety of primary valve treatments and the effect of years of dysfunctional voiding and ongoing pressure and volume work by the bladder.

The data presented by Kim and associates often are cited as evidence that urinary diversion in valve patients is not deleterious to ultimate bladder function even though only 4 of 36 patients were treated with proximal diversion, and statistical significance could not be determined because of the small sample size (18). These authors state that patients undergoing diversion by vesicostomy or pyelostomy demonstrated better compliance than those treated with primary valve ablation, although there was no difference in the number of patients with normal compliance in the different treatment groups. The demographics of the treatment groups are dissimilar, with urinary diversion being performed in newborns and valve ablation being delayed to a median age of 7 months. The age at the time of initial valve ablation in patients demonstrating poor compliance is not reported. Furthermore, the valve ablation group includes boys treated as adolescents. The effect of years of probable dysfunctional voiding in the older patients may well contribute to loss of compliance, as would persistent urethral obstruction in infants with treatment delayed beyond several months of life. In our review of patients treated in the first year of life with primary valve ablation, the only patient with poor compliance was the patient whose treatment was delayed until 5 months of age because of a missed diagnosis (4).

Reports of urodynamic findings in valve patients can be misleading if actual bladder pressures and volumes are not presented. High bladder compliance usually is interpreted as a normal bladder with good storage potential and therefore a good prognosis for continence and preservation of the upper tract function. A very large bladder volume can result in a normal volume-to-pressure ratio (good compliance) but still have high end filling pressures that could be detrimental to preservation of upper tract function. This would be magnified in a patient who tended to be inefficient in bladder emptying. In the older valve patient, in whom bladder volumes of 1 L are possible, bladder compliance can be “normal” (greater than 20 mL/cm H_2O) even though bladder pressures are greater than 30 cm H_2O (Fig. 49C.2).

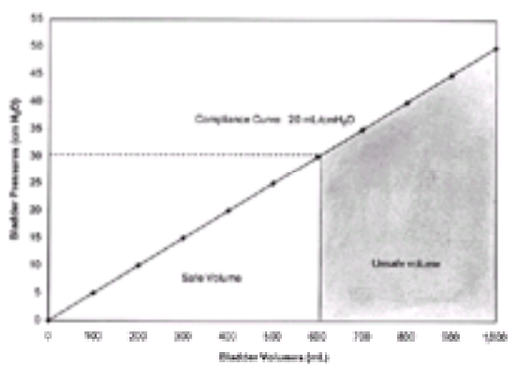

FIGURE 49C.2. Cystometrogram on valve bladder patient with bladder compliance calculated at 20 mL/cm H_2O. Note that because of high urine volume, dangerous intravesical pressures can develop at the high end of bladder volumes even with apparent normal compliance.

Several authors have published retrospective urodynamic evaluations of valve patients treated during infancy. Holmdahl and associates (12) evaluated boys with serial urodynamic studies performed over several years. Although these patients were diagnosed early (mean of 1.3 months), 75% of the patients had prolonged bladder decompression by a suprapubic tube before valve ablation. The authors reported initial hypercontractility and small-capacity bladders that improved slowly over time. Interestingly, the patients with the history of the longest diversions ultimately needed clean intermittent catheterization.

Podesta and colleagues (26) reported urodynamic findings on infants and toddlers treated by valve ablation or vesicostomy in comparison to age-matched controls. Again, this is a historical review, with all patients diagnosed after presentation with urinary tract infection or retention. Valve ablation was performed later than was urinary diversion, with only one primary valve ablation being performed in the first month of life. Three years after treatment, patients treated with valve ablation demonstrated bladder capacities larger than those in age-matched controls but with safe end filling pressures. Decreased compliance and bladder capacity were noted in patients treated by vesicostomy. Dangerously high end filling pressures developed in two of these patients, necessitating bladder augmentation in one patient.

Jaureguizar and colleagues (13) compared urodynamic outcomes for patients treated with high urinary diversion or primary valve ablation. They reported poor compliance in 4 of 30 patients treated with primary valve ablation, with one-third of this treatment group treated after 2 months of life. Poor compliance was similarly found in 5 of 29 patients managed with high diversion, with all patients treated before 2 months of age. Unfortunately, there are no longitudinal studies of bladder function in valve patients treated as newborns and followed closely with appropriate bladder management and evaluation.

THE POTENTIAL FOR BLADDER HEALING: CAN THE VALVE BLADDER BE PREVENTED?

In the fifth month of gestation, the human fetal bladder begins to cyclically fill, with a minimal increase in intravesical pressure. The filling and emptying *in utero* provides stretch forces on the components of the developing bladder wall to produce a compliant organ that can store urine at low pressures and empty effectively. Normal bladder function depends on smooth muscle cells, in addition to elastin and collagen, integrated as the active and passive components of the bladder wall.

With fetal bladder outlet obstruction by posterior urethral valves, the developing bladder carries out pressure work to empty. To overcome outflow resistance, the muscle mass of the bladder expands with an increase in contractile proteins and a significant alteration in the composition and distribution of collagen in the bladder wall. In unobstructed animal models, compliance improves with gestational age as the ratio of type III to type I collagen decreases. In bladder tissue from pediatric patients with anatomic or functional obstruction and poor bladder compliance, the type III-to-type I ratio is increased, with type III collagen infiltrating the detrusor muscle bundles. These aberrations in normal bladder wall architecture appear to be reversible only if the obstruction is relieved before the fibrotic process is too advanced (21). The chronically obstructed bladder in patients with a history of late diagnosis and treatment of valves cannot be rehabilitated and is therefore the focus of long-term management. In contrast, in developed countries obstetric ultrasound and modern pediatric endoscopic equipment are readily available, so early valve ablation should be possible. This would restore normal cycling to the postnatal developing bladder and maximize the potential for bladder healing.

Clinical data support the premise of bladder healing in the newborn. In babies treated with valve ablation alone in the first days of life, normal bladder morphology in previously trabeculated bladders is evident on cystourethrograms performed at age 1 year (Fig. 49C.3). Improvement in bladder function is further implied by the resolution of vesicoureteral reflux in infants after early valve resection (4,15). This is well documented in multiple studies and is consistent with other data showing reflux resolution with improving bladder function in children without valves (19). We found improvement in reflux grade in 18 of 19 refluxing renal units in infants 1 year after primary valve ablation (Fig. 49C.4). Complete resolution of reflux occurred within 2 years of valve ablation in 12 of 14 patients (86%) (4). Urodynamic findings of good compliance and successful potty training in patients treated with early valve resection also attest to bladder healing after immediate postnatal bladder cycling. Urodynamic evaluation comparing children treated with newborn valve ablation and newborn urinary diversion demonstrated better bladder volumes and compliance in the valve ablation group. Furthermore, by age 4 more than 90% of patients treated by valve ablation were potty trained, whereas only 17% of the diverted patients had achieved day and nighttime continence. However, this was not a prospective randomized study, and doubt still exists as to the actual potential for bladder healing. It should be noted that in other models, in infant neurogenic bladder, and in exstrophy, normal bladder cycling seems to stimulate normal bladder development. Abnormal bladder cycling results in an abnormal bladder. Obstruction or diversion may significantly reduce the potential for normal development.

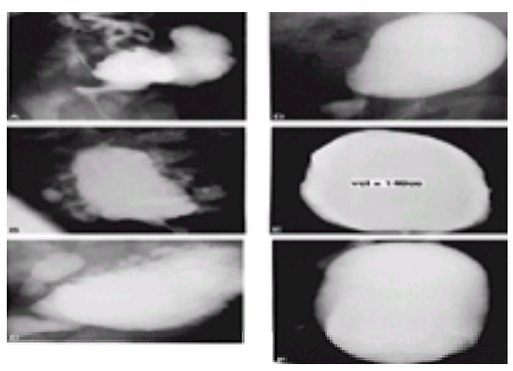

FIGURE 49C.3. A–C: Voiding cystourethrogram in three newborn infants with posterior urethral valves. Note bladder wall trabeculation and diverticula before valve ablation. **D–F:** Voiding cystourethrogram of same patients 1 year after newborn valve ablation, demonstrating healed bladder with smooth wall and normal capacity.

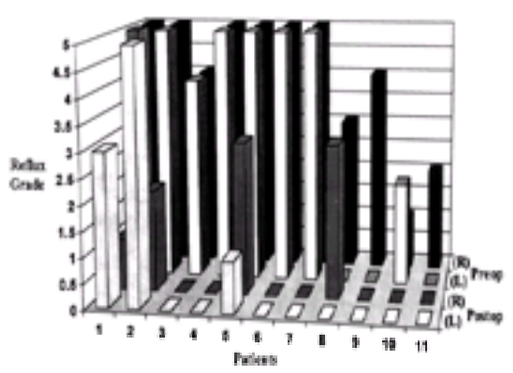

FIGURE 49C.4. Spontaneous resolution of vesicoureteral reflux 1 year early valve ablation alone. Results from 19 refluxing units in 11 patients are depicted. Persistence of reflux is associated with a nonfunctioning renal unit in two patients and upper tract duplication in one patient. L, left; Postop, 1 year postoperatively; Preop, before valve ablation; R, right.

Today, most infants with posterior urethral valves are diagnosed *in utero,* allowing ablation of the urethral obstruction in the first days of life and in some circumstances temporary diversion *in utero.* Although underlying primary renal dysplasia cannot be altered by postnatal intervention, bladder function often can be preserved, thereby avoiding the cascading effects of the valve bladder syndrome. Careful follow-up of these boys is necessary to assess and manage elimination dysfunctions that may contribute to functional bladder outlet obstruction after potty training. Serial ultrasounds, urodynamic studies, and electrolyte evaluations should continue through adolescence. With this careful management after newborn valve ablation, there is a significant chance of preventing the valve bladder syndrome.

Normal function of the lower urinary tract is the result of coordination of many interrelated neural and muscular structures. Balanced reflex activity of the detrusor and periurethral striated musculature is essential to allow the bladder to achieve low-pressure storage, voluntary micturition, and complete emptying. Sensation of bladder fullness acts as both a trigger for voluntary micturition and a protective mechanism against vesical overdistention. Neurologic, infectious, structural, and psychologic processes that alter normal bladder activity may both jeopardize renal function and become a source of incontinence, urinary tract infection (UTI), and renal injury. In addition, unique congenital and developmental problems frequently are associated with neurovesical dysfunction in children. These all challenge the physician caring for such patients to preserve kidney function and secure urinary continence.

DEVELOPMENT OF NORMAL BLADDER CONTROL IN CHILDREN

The normal lower urinary tract provides low-pressure storage and voluntary elimination of urine, functions regulated by somatic, sacral parasympathetic, and thoracolumbar sympathetic nerves (62). Coordinated neuromuscular activity normally results in urethral pressure that is greater than vesical pressure at all times and during all forms of activity that increase vesical pressure. Bladder filling normally results in a negligible rise in intravesical pressure. The sequence that initiates micturition involves total relaxation of the striated sphincter, a decrease in urethral pressure, detrusor contraction, and opening of the bladder neck and urethra.

In the infant, neural pathways involved in micturition remain incompletely developed, and micturition is the end result of an involuntary spinal reflex. Detrusor and sphincter act in a coordinated fashion, voiding occurs frequently, and the bladder is completely emptied (136). This phase of bladder development has been termed detrusor micturition (184). Gradual maturation of the central and peripheral nervous systems brings the act of micturition under voluntary control, the first conscious awareness of bladder function usually occurring between 1 and 2 years of age (136). During the second year of life, normal development enables most children to sense bladder fullness, to communicate recognition of the need to urinate, and to hold increasingly larger volumes of urine for longer periods of time. Micturition therefore occurs less frequently. Between 15 and 24 months of age, most infants become fully aware of voiding, and toileting habits begin to develop with parental encouragement. During this first phase of maturation, reflex micturition ceases as the child begins to exert conscious control, first evident as a voluntary tightening of the bladder outlet in response to the sensation of bladder fullness. In most children, this brief phase of discoordinated micturition rapidly gives way to the normal adult mechanism of suppressing detrusor activity to maintain continence. However, pathologic persistence of the earlier stage may be seen in dysfunctional voiding of minor degrees and is most severe in the Hinman-Allen syndrome (nonneurogenic neurogenic bladder) (106). Further development of neuromuscular coordination between the pelvic floor, abdominal muscles, and diaphragm allows the voluntary initiation or interruption of micturition to be initiated at any stage of bladder filling. This final phase of development usually occurs between 3 and 4.5 years of age. During this period, nocturnal dryness is achieved in most children, although persistent enuresis is common (99,164). Bloom and co-workers (23) retrospectively surveyed the development of bladder control in 1192 children. They found that toilet training was achieved at ages ranging from 9 months to 5.25 years (mean 2.4 ± 0.6 years) in this group. Hellstrom and others (99) performed a similar survey in 7-year-old children. They found nocturnal enuresis in 7.1% of girls and 11.9% of boys, diurnal incontinence in 6% of girls and 3.8% of boys, and urgency in 21% of girls and 18% of boys, underscoring the spectrum of bladder control development in this age group.

Bladder capacity increases gradually with age, playing an important role in the development of urinary continence. Rather than being a primary cause of bladder development, however, increased capacity likely is both a reflection of maturation of the nervous system and behavioral adaptation. During childhood, bladder capacity increases approximately 30 mL per year (136). Muellner (184) documented a rapid increase in voided volume from age 2 to 4.5 years, with a gradual increase through childhood. Several authors have offered guidelines for estimation of appropriate bladder capacity in children. Berger and others (20) estimated bladder capacity in childhood as “age in years plus 2 equals bladder capacity in ounces.” Houle and associates (111) reviewed 923 urodynamic studies in children, using as an end point for bladder filling one of the following: desire to void, sensation of fullness, discomfort, or leak. They defined the minimal acceptable bladder

capacity for age as “16 (age in years) + 70 mL” (Fig. 49D.1).

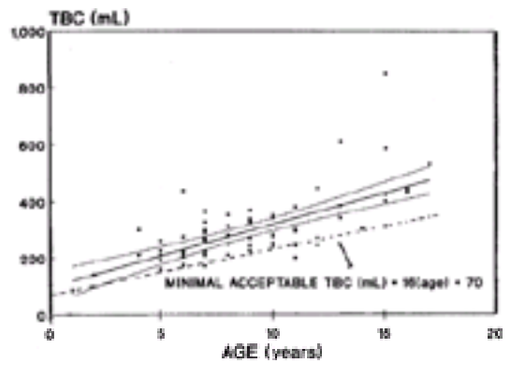

FIGURE 49D.1. Linear regression between age (years) and total bladder capacity [TBC (mL)] with 95% confidence interval for regression. *Dashed line* represents minimal acceptable total bladder capacity (mL) equals 16(age) + 70. (From Houle A, Gilmour RF, Churchill BM, et al. What volume can a child normally store in the bladder at a safe pressure? *J Urol* 1993:149:561, with permission.)

The development of normal continence is a complex process involving neurologic, developmental, and social factors. It also has been shown that emotional factors may influence the development of normal bladder control (65). As a result, many factors must be considered when evaluating a child with abnormal bladder function. This is especially critical during the period of transition from a functionally “reflex” infant bladder to conscious control of urination, a time when the assessment of bladder function is most difficult. The urologist must be prepared to consider all available historical data and to use multiple methods of clinical assessment to determine whether bladder function is normal or abnormal in this age group.

CLASSIFICATION OF NEUROVESICAL DYSFUNCTION

Dysfunction of the lower urinary tract may result from congenital or acquired lesions and may be expressed clinically as urinary retention, frequency, urgency, interrupted urination, incontinence, or UTI. Lower tract dysfunction may alter ureterovesical dynamics and impair ureteral motility. Hydronephrosis or vesicoureteric reflux (VUR) may result. The complexity and heterogeneity of neurovesical dysfunction has lead to the description of several clinically useful classification schemes, several of which are described in the following text.

In 1971, Bors and Comarr (26) classified neurologic lesions that affect bladder function into sensory or motor, complete or incomplete, and according to location above or below the level of the sacral reflex arc. Lapides (154) built upon this foundation to outline a classic description of neuropathic bladder dysfunction, which included five categories: sensory paralytic bladder, motor paralytic bladder, autonomous bladder, reflex bladder, and uninhibited bladder. Many other systems of categorization have replaced this simplistic classification scheme that is outmoded by newer nomenclature that is based on functional derangement and is familiar to most urologists. The *sensory paralytic bladder* describes intact motor function without normal sensation. The absence of sensation may allow chronic overdistention to the point of detrusor decompensation. Bladder rehabilitation by timed voiding may prevent overdistention and preserve normal detrusor function. This type of neuropathic dysfunction is uncommon in childhood. A *motor paralytic bladder* results from loss of motor function, while sensation remains intact. Causes are trauma, poliomyelitis, and lumbar disc disease. *Autonomous bladder* dysfunction results from loss of both sensory and motor innervation leading to a large-capacity bladder with no detrusor contraction. Causes are spinal trauma below the cauda equina, radical pelvic surgery, and meningomyelocele or sacral agenesis. A *reflex bladder* results from complete injury above the level of the sacral reflex arc, commonly from spinal cord injury, tumor, or transverse myelitis. Unchecked sacral reflex activity results in a hyperreflexic bladder. Sensation is absent. *Uninhibited neuropathic bladder* dysfunction reflects incomplete inhibition of reflex activity by suprasacral inhibitory centers, and may be caused by central nervous system lesions (vascular, tumor, degenerative, traumatic). Sensation is present, extreme urgency is seen, and urgeincontinence may result from uninhibited detrusor contractions. Although the Lapides classification is descriptive, few patients fall into a single category, and in clinical practice, most demonstrate mixed lesions with various degrees of severity. For these reasons, urodynamic classification systems as described by Krane and Siroky (146) (detrusor: hyperreflexic, normoreflexic or hyporeflexic; sphincter: coordinated, dyssynergic, or nonrelaxing) and the International Continence Society (115) (detrusor: normal, overactive, underactive; urethra: normal, overactive, incompetent; sensation: normal, hypersensitive, hyposensitive) have appeal. For practical purposes, the end result of neurovesical dysfunction may be classified as either *failure to store* or *failure to empty* (69).

CLINICAL PRESENTATION OF NEUROVESICAL DYSFUNCTION IN CHILDHOOD

Dysfunction of the lower urinary tract may result from both congenital and acquired lesions, and may be expressed clinically as incontinence or retention, interrupted urinary stream, hesitancy, frequency, urgency, UTI, renal failure or a combination of symptoms. Many children with congenital causes of neurovesical dysfunction simply never gain normal urinary control. UTI, typically recurrent, is a common reason for urologic consultation. Constipation and/or fecal soiling are common. Hydronephrosis and/or VUR are common radiologic findings.

EVALUATION OF THE CHILD WITH SUSPECTED NEUROVESICAL DYSFUNCTION

History

Urologists are frequently called upon to evaluate children with known, suspected, or unrecognized neurovesical dysfunction. When neurovesical dysfunction is suspected, it is extremely important to review the child's medical and developmental history to determine whether the dysfunctional pattern is acute or chronic, stable or progressive, and primary or secondary to a period of normal urinary control. It should be noted whether other symptoms that frequently accompany neurovesical dysfunction are present, such as changes in bowel habit or gait, back or leg pain, seizures or neurologic complaints, and erectile dysfunction in the older child. It is important to review the history of prior management of urinary symptoms, including medical and surgical interventions. *Incontinence* is a common presentation of urologic disease in childhood, and an accurate history is perhaps the most important aspect of its differential diagnosis. Incontinence should be categorized as primary or secondary, continuous dribbling or occasional leakage (large or small volume), stress or urge, prevoid or postvoid, and nocturnal or diurnal. Is the urinary stream weak or strong? Is there sensation of fullness or any sensation of voiding, or is the wetness noticed only after it occurs? Is voiding spontaneous, or merely associated with Valsalva maneuver? Hinman (104), Allen (5), Galdston and Perlmutter (81), and others have documented that psychologic, psychosocial, and behavioral disturbances can seriously alter voiding dynamics. A brief review of social history should therefore assess family dynamics, stress, school performance, and peer relationships. This assessment usually can be accomplished superficially with a few probing but nonthreatening questions, and is particularly important in cases of secondary incontinence or in the face of what appears clinically to be neurovesical dysfunction but without signs of an obvious neurologic cause. It is important to assess parent–child interaction during the interview and examination. Strained relationships and affective disorders may suggest social problems in the home, a possible additional factor in the development of dysfunctional voiding. The possibility of sexual abuse as the basis of significant bladder dysfunction should be considered in every patient.

Physical Examination

Physical examination may either confirm or refute the suspicion of neurovesical disease. A complete physical examination should include an assessment of gait, balance, muscular symmetry, and general neurologic status. Reflexes should be tested for symmetry and the presence of either hyperreflexia or hyporeflexia. The back should be examined for the presence of skin tags, dimples, hemangiomas, overlying hair patches, or other signs of dysraphism (4,97) (Fig. 49D.2) Examination of the abdomen is performed to detect bladder distention or a colon filled with stool. The ability to either stimulate bladder emptying by gentle bladder “massage” or to express urine by suprapubic compression or Credé's maneuver should be noted. The genitalia are examined to note the presence of skin excoriation (as a result of incontinence); hypospadias or meatal stenosis; cryptorchidism; and labial, introital, perineal, or anal anomalies. Rectal examination should assess perianal sensation and tone, the presence of hard stool (indicating possible bowel dysfunction), and the presence of a normal sacrum. The bulbocavernosus reflex can be elicited by squeezing the glans penis or clitoris and evaluating the anal wink, indication of an intact sacral reflex arc.

FIGURE 49D.2. Lumbar cutaneous hemangiomas associated with tethered spinal cords. *Arrows* point to transparent membranes. (From Albright AL, Gartner JC, Wiener ES. Lumbar cutaneous hemangiomas as indicators of tethered spinal cords. *Pediatrics* 1989;83:977, with permission.)

Laboratory Examination

Urinalysis is an important part of the initial examination of all children with suspected urinary tract disease. In the infant, urine can be obtained by a bag technique and occasionally by stimulating the voiding reflex by gentle suprapubic massage, in which case a midstream specimen may be obtained in both boys and girls. In older children, clean-catch specimens are generally reliable for culture when proper instruction is provided to the child and parents. When contamination is a concern, urine may be obtained by urethral catheterization or by suprapubic aspiration. All urines with abnormal sediment suggestive of infection should be plated for culture and sensitivity.

Once neurovesical dysfunction has been diagnosed, serum creatinine should be measured. If either elevated serum creatinine or renal scarring is present, glomerular filtration rate (GFR) may be determined by measurement of creatinine clearance. Infants and children who are incontinent may have GFR determination by radionuclide clearance techniques that do not require urine collection (234), or they may be estimated using the method described by Schwartz and associates (218). If significant proteinuria is documented, urinary protein excretion should be quantified.

Radiologic Examination

Radiologic examination of the urinary tract is an integral part of the evaluation of children with neurovesical dysfunction because disordered bladder function may be associated with renal injury secondary to either hydronephrosis or VUR (245). The plain abdominal film should be examined for bony abnormalities (spina bifida occulta, sacral agenesis, and widened interpedicular distance). In addition, the degree of constipation can be assessed and the presence or absence of urinary calculi noted, especially in patients with longstanding neurovesical dysfunction and relative immobility (Fig. 49D.3).

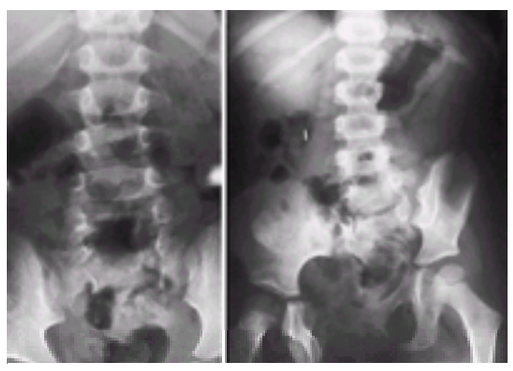

FIGURE 49D.3. Lumbosacral anomalies associated with neurovesical dysfunction.

The upper urinary tract may be imaged by ultrasound, intravenous pyelography (IVP), or radionuclide scan, depending on the age of the child, a knowledge of preexisting renal pathology, and the information desired. Most children are screened adequately with diagnostic ultrasound, which may assess renal size, upper tract dilation, gross renal scarring, bladder capacity, bladder wall thickness, and postvoid residual urine volume (76). When abnormal findings are documented by ultrasound, follow-up urography or radionuclide studies may be indicated. Although the IVP is used less commonly for routine imaging in children with neurovesical dysfunction since the advent of diagnostic ultrasound, it may be particularly useful in specific instances. Common indications for the use of intravenous urography include evaluation of children with severe kyphoscoliosis in whom ultrasound imaging of the kidney is technically difficult, anatomic delineation of ureteral and calyceal anatomy in the patient with calculus disease, evaluation of the patient with urinary diversion, and delineation of the renal anatomy in children with rotational or fusion anomalies of the kidneys. Intravenous urography should be tailored to answer particular questions asked by the urologist while minimizing radiation exposure to the patient.

Radionuclide renal imaging has assumed an ever-increasing role in the evaluation of children with neurovesical dysfunction. Because a multitude of radionuclides are currently in use, the urologist who orders or interprets radionuclide images must understand something about both the characteristics of the radionuclide and the important technical aspects of patient preparation and handling during the imaging process (239). Each study should thus be tailored to answer the clinical questions being asked.

Diuresis renography is usually performed to confirm or exclude the diagnosis of supravesical obstructive uropathy and is most helpful in the assessment of chronic hydronephrosis or hydroureteronephrosis when the question of dilation versus true obstruction arises (Fig. 49D.4) (53). Technetium-99m-diethylenetriamine pentaacetic acid (DTPA) (193) or technetium-99m-mercaptoacetlytriglycine (MAG3) (55) is used most frequently for these studies because they offer rapid renal clearance and tubular excretion. The renogram is performed after oral hydration, and frequently after a period of intravenous hydration as well. This aspect of the study is critical because furosemide acts on the ascending limb of the loop of Henle to promote diuresis, and the results may be invalid if the patient is dehydrated or renal function is poor. An indwelling bladder catheter should continuously drain the bladder during the study. This is extremely important in patients with neurovesical dysfunction, VUR, and other causes of poor bladder compliance (i.e., posterior urethral valves) because a poorly compliant bladder, when even partially full, may generate high enough intravesical pressure to hinder upper tract drainage (167). Diuresis renography is one of the most technically demanding imaging studies both to perform and analyze, and many pitfalls exist (53). The Society for Fetal Urology and the Pediatric Nuclear Medicine Council have described a “well-tempered” renogram that attempts to standardize the many aspects of this study (54).

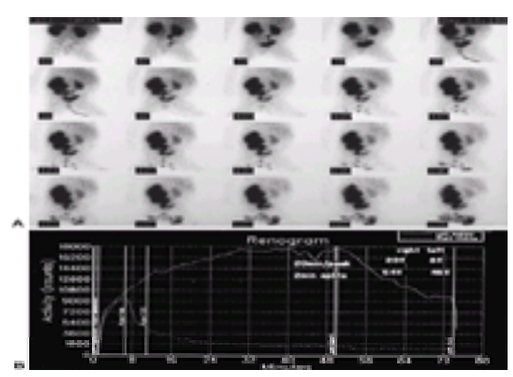

FIGURE 49D.4. A: Diuresis renogram images. Right kidney drains well, left kidney slowly. **B:** Washout curves from diuresis renogram of same patient. Right kidney drains readily, while left kidney takes longer to accumulate radionuclide and drains slowly after furosemide administration.

Static renal imaging using technetium-99m dimercaptosuccinic acid (DMSA) has played an increasingly important role in several clinical scenarios. DMSA images may provide information about differential renal function in children with disordered renal anatomy and renal parenchymal scarring (213) (Fig 49D.5B). DMSA imaging also has proven helpful in the delineation of acute parenchymal inflammation (pyelonephritis) (Fig 49D.5A) (117). This diagnosis is not always easy to make on clinical grounds alone, especially when a child who is managed by intermittent catheterization and who has chronic bacteriuria presents with a fever and lack of other localizing symptoms. In this clinical setting, UTI is frequently considered the source of fever, even though the differential diagnosis may include a viral syndrome. A positive DMSA scan, confirming pyelonephritis, allows the physician to begin appropriate treatment, while a negative scan may prevent unnecessary treatment and even hospitalization. A high degree of interobserver agreement has been found in the reliability of interpretation of DMSA imaging (197).

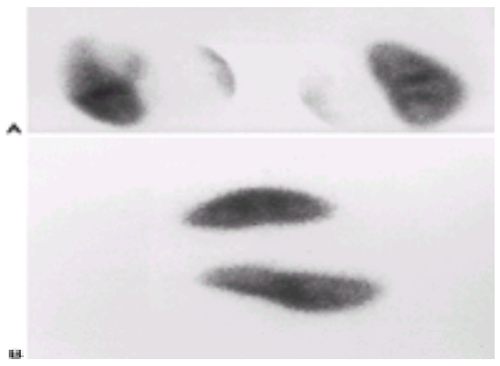

FIGURE 49D.5. A: DMSA scan showing acute pyelonephritis of upper pole of left kidney. Right kidney appears normal. **B:** DMSA scan 6 months later showing scar in upper pole of left kidney.

The voiding cystourethrogram (VCU) plays an important role in the evaluation of children with neurovesical dysfunction and should always be performed in infants, in patients with newly diagnosed neurovesical dysfunction, and when upper tract imaging documents the new onset of hydronephrosis or renal scarring. Likewise, pyelonephritis in a child without known VUR demands that a VCU be performed, preferably after infection has been eradicated and the child has been given suppressive antibacterial therapy for several weeks. Voiding cystourethrography is easily performed with a small catheter (8-Fr feeding tube in most infants). The bladder is filled with room-temperature contrast until voiding occurs. Bladder capacity and configuration, bladder neck and external sphincter competence, and urethral anatomy should be documented in addition to documenting the presence and grade of VUR. VUR should be graded using the standard criteria of the International Reflux Study in Children (115). A carefully performed VCU may offer, in addition to anatomic detail, a gross assessment of bladder capacity, an assessment of postvoid residual urine (assessment of the completeness of bladder emptying), voiding dynamics, and detrusor-sphincter coordination. Although the radionuclide VCU is preferred as a follow-up study for the assessment of VUR (157), the fluoroscopic VCU offers a great deal of anatomic, structural, and functional information not seen in nuclear cystography. Routine fluoroscopic voiding cystourethrography is thus preferred in most cases even for follow-up study in children with neurovesical dysfunction. The VCU and urodynamic evaluation may be combined in a videourodynamic evaluation.

Urodynamic Evaluation

Urodynamic evaluation of children must be tailored to fit both the ability of the individual patient to understand and cooperate with testing, and the information desired by the urologist (10). Although a complete urodynamic assessment might potentially assess bladder capacity and compliance, detrusor function, bladder neck and urethral dynamics, detrusor/pelvic floor coordination and voiding dynamics, these complex urodynamic studies are invasive and require extraordinary cooperation that may be achieved only by adults and a few very cooperative children. However, limited studies designed to elicit specific information may be successful in children. It is extremely important that, before testing, the urologist have in mind specific questions to be answered. Success also necessitates that both parents and child understand the reason for the study, the nature of the testing, and the fact that all possible attempts will be made to minimize discomfort and anxiety. In this context, it is important to realize that not all children with either presumed or documented neurovesical dysfunction require urodynamic evaluation. It is also important to realize that not every urodynamic study will yield useful data.

Although urodynamic studies frequently are performed on infants with neurovesical dysfunction who have limited bladder and urethral sensation, many children presenting for evaluation are grossly neurologically intact. These children require even more intense preparation for the discomfort that may be caused by urethral catheterization. Children must be approached gradually, in a friendly and nonthreatening manner, as an atmosphere of trust is created. Meaningful urodynamic data rarely can be obtained until several visits with the child have taken place. These examinations will allow the physician to make an assessment of patient cooperation and a realistic determination of which urodynamic studies may be best suited for the individual problem in question. Because many children referred for urodynamic study will have had previous radiologic, endoscopic, or surgical procedures, the physician should try to assess the child's reaction to and cooperation with this testing. Pediatric urodynamic studies are best performed and interpreted by the physician or an extremely well-trained and experienced observer who is able to assess the child's response to testing in order to separate fact from artifact and to modify the procedure to suit the cooperation of the child and the needs of the examiner (10). Although children may be sedated for urodynamic evaluation, little more than basic cystometry can be achieved in a deeply sedated child. In many cases, urodynamic testing is best abandoned if the child is unable to cooperate. When formal urodynamic study is deemed infeasible, the state of bladder function must be inferred from other available data (voiding cystourethrography, postvoid residual volume determination, and voiding or catheterization diary).

Noninvasive urodynamic tests include uroflowmetry and electromyographic (EMG)/uroflow studies (49). Uroflow studies are the least invasive and most limited urodynamic studies that can be performed. Uroflow allows the examiner to assess (a) the flow rate (a balance between detrusor contraction and outlet resistance) and, using an electronic flowmeter, (b) the character of the urinary stream. An adequate volume of urine must be voided to allow an accurate assessment of urinary flow rate. Uroflow can be used to assess voided volume, time to maximum flow, peak flow rate, flow time, mean flow rate, and flow pattern. In children with voiding dysfunction, assessment of the pattern of flow may prove revealing, although uroflow by itself may not allow an accurate judgment of the nature of the abnormal voiding mechanics. This is because a low flow rate may be a reflection of either outlet obstruction or impaired detrusor function. We have used a simple flowmeter designed by Drake (66) in some clinical situations to evaluate voided volume, peak urinary flow rate, and a visual assessment of the character of the voided urinary stream in boys.

Micturition studies (uroflow combined with pelvic floor electromyography) are aimed at assessing the function and coordination of the periurethral striated musculature during voiding (78). Anal plug and urethral catheter electrodes may be used, but are liable to introduce artifact because of patient discomfort. Direct measurement of periurethral striated muscle activity can be achieved by the insertion of small needle or wire electrodes into the periurethral area in girls and into the prostatic apex in boys. Bauer (12) has demonstrated the usefulness of the oscilloscope in recording action potentials from the sphincter musculature, thus aiding optimal electrode positioning. Electrodes may be inserted under anesthesia and testing performed later, or may be inserted at the time of testing using local or topical anesthesia in a cooperative child. Insertion of a small trocar cystostomy catheter may facilitate bladder refilling for repetitive urodynamic study, especially if biofeedback training is desired. However, even small cystostomy catheters may introduce a considerable amount of discomfort and artifact in children. In an effort to achieve noninvasive monitoring of pelvic floor activity, Maizels and Firlit (166) described the use of perineal skin patch electrodes. These nonspecific electrodes require skin preparation with alcohol or acetone and tincture of benzoin adhesive to achieve good contact and prevent dislodgment. Because surface electrodes are less specific than electrodes placed directly into the paraurethral musculature, they may be associated with more artifact than is seen when needle electrodes are used. In children, however, the trade-off in gaining patient cooperation may make the noninvasive technique preferable.

During normal micturition, the internal sphincter, pelvic floor, and external urethral musculature relax to allow complete bladder emptying. Detrusor/pelvic floor dyssynergia (discoordination) is documented when pelvic floor musculature fails to relax and EMG activity persists during detrusor contraction (166). Such activity may be particularly difficult to separate from artifact generated by abdominal straining. The use of abdominal EMG patch electrodes to detect abdominal straining

(140) or a rectal balloon to subtract abdominal pressure is especially important in children so that the diagnosis of dyssynergia is not made inappropriately (138).

The performance of cystometry in children requires patience, understanding, and adequate preparation of both the patient and his or her parents. Patient assessment is important, since a child who balks at catheterization is unlikely to be cooperative enough to provide meaningful cystometric data. Sedation is usually not beneficial. However, lidocaine jelly instilled into the urethra before catheterization may diminish discomfort and allow improved cooperation. When cystometry is to be performed, catheterization is best performed immediately after voiding so that a determination of postvoid residual volume can be made. A small 7- or 8-Fr double- or triple-lumen urodynamic catheter or microtip transducer catheter is appropriate for most studies. A balloon catheter placed into the rectum is used to subtract abdominal pressure and negate artifact produced by straining. It is important to avoid latex catheters and balloons in all patients with spina bifida, even those with unproven latex allergy (216). If pelvic floor electromyography is to be performed, catheterization should take place after the micturition urodynamic study is completed. Cystometry may be performed using water or gas. Gas cystometry, although quicker and more convenient, is less physiologic and perhaps less accurate than studies using water (86). Slow-fill cystometry using body temperature water is preferred for most pediatric studies. Bladder filling should be approximately 10% to15% of expected bladder capacity per minute or approximately 3 (age + 2) = mL per minute (bladder capacity in ounces = age in years + 2) (20). During bladder filling, EMG activity may be monitored. In cooperative children, documentation of bladder capacity, sensation, and uninhibited bladder activity can be measured. The pressure (leak-point pressure) and volume at which urine leaks around the catheter during filling should be noted. If the child is capable of spontaneous voiding, the pressure generated in the bladder (voiding pressure) is measured. Cystometry and voiding cystourethrography may be combined in videourodynamic studies because it has been shown that contrast medium does not adversely influence urodynamic findings (125).

Static urethral pressure profilometry measures the passive resistance of the urethra along its length. The side-hole catheter may be positioned at any location in the urethra that requires study, but the measurement has little practical use in children with neurovesical dysfunction unless the efficacy of an artificial urinary sphincter cuff, bladder neck sling, or reconstructed bladder neck is being evaluated. Urethral pressure may vary at the same position in the urethra and is affected by bladder volume, the characteristics of the catheter itself, and infusion parameters (12).

Pediatric urodynamic data are extremely valuable when thoughtfully and carefully obtained. The data are useful in diagnosis, for estimation of the probability that upper tract deterioration may occur in the future, and for biofeedback training, particularly in children with nonneuropathic voiding dysfunction (162). In many cases, a repeat study is helpful, either to confirm suspected findings or to determine whether a change in bladder management programs or pharmacologic manipulation has resulted in a measurable change in measurable neurovesical parameters.

CONGENITAL NEUROSPINAL DYSRAPHISMS

Spina Bifida (Myelodysplasia)

The term *spina bifida* includes a group of developmental anomalies that result from defects in neural tube closure (231). Lesions vary in severity: spina bifida occulta, a generally incidental finding in which only a bony defect is present; meningocele, with a meningeal sac but intact neural elements; spina bifida cystica (myelomeningocele), with an intact skin-covered sac containing neural elements; and spina bifida aperta, in which the sac is open. Myelomeningocele is by far the most common defect seen and the most devastating. Spina bifida is a disease of variable prevalence, ranging from 4.5 in 1,000 births in Belfast to 0.12 in 1,000 births in Singapore (232). In the United States, the prevalence is estimated at 1 in 1,000 births but varies geographically, being more common in the eastern states. Stein (228) reported a steady decline in incidence in all ethnic groups in the northeastern United States from 1930 to 1980 and a progressive decrease in incidence in the United States as a whole from 1970 to 1980, while a significant decline was noted in Liverpool, England, between 1974 and 1979 (194).

The incidence of neural tube defects in England and Wales has, in fact, decreased from 3.2 per 1,000 births in the early 1970s to 0.1 per 1,000 births in 1999. More specifically, data documented a 96% drop in the incidence of neural tube defects between 1970 and 1997. Morris and Wald (182) analyzed this data and concluded that the decline in incidence should be apportioned as follows: 40% decreased incidence was due to antenatal diagnosis and elective termination of pregnancy, and 56% was due to a decline in incidence, perhaps in part because of an increase in dietary folate.

The etiology of neural tube defects appears to be multifactoral (231,232). Epidemiologic data incriminate environmental factors because the birth prevalence has varied over time and by geographic location and because epidemics of neural defects appear to have taken place at different times and in different locations worldwide (182). Genetic factors are incriminated by studies showing female preponderance, ethnic variability, and increased familial tendencies. Sibling incidence has varied from 1.4% to 6.0%, and when two siblings are affected, the risk rises from 4.8% to 12% (238). Neural tube defects likewise are associated with Meckel's syndrome (autosomal recessive), trisomies 13 and 18, and cloacal exstrophy (possibly on a local developmental basis) (238).

Growing evidence over the past several decades that periconceptional supplementation with multivitamins (190) might diminish the risk of neural tube defects correlates with the higher incidence of these anomalies found in areas with lower socioeconomic levels (183). A decade of debate has been resolved by two multicenter randomized controlled studies. The first found a 72% reduction in the recurrence of neural tube defects among women who received a 4-mg daily supplement of folic acid in the periconceptional period (183) This study lead the United States Public Health Service to recommend in 1992 that all women of childbearing age consume 0.4 mg of folic acid daily. These data were given further significance by a second randomized controlled trial, which found the risk of the occurrence of first-time neural tube defects to be reduced by 60% by the use of periconceptional folic acid supplementation (249). A Canadian study, carried out to determine the efficacy of information dispersion concerning the importance of folic acid in preventing neural tube defects, found that most women studied were unaware of the importance of folic acid and were ingesting an amount far below the protective level recommended (79). The U.S. Food and Drug Administration is reportedly considering the fortification of a food staple with folic acid to further diminish risk to the general population (184).

Spina bifida is a disease that has dramatic impact on the involved child and family. Lessons learned from management of the urologic consequences of spina bifida have provided urologists with a significantly expanded armamentarium with which to treat neuropathic bladder dysfunction of all causes. Goals of management for the patient with neurovesical dysfunction are to preserve, or at least stabilize, renal function; to prevent complications of UTI; and to provide socially acceptable continence. The perception of what constitutes acceptable continence may vary among parent, child, caretakers, and peers. The child's age, mental and physical abilities, and socioeconomic status also influence this perception. In addition, normal developmental processes, schooling, and peer pressure may gradually alter his or her personal concept of what represents an acceptable bladder regimen. When continence and social acceptance (rather than medical concerns) become the main goals of urologic therapy in the child with neurovesical dysfunction, particular care must be taken to individualize treatment to fit the needs of the child and not to treat merely for treatment's sake. It is imperative that the urologist have an appreciation for other related problems—orthopedic, neurosurgical, neurologic, psychologic, social, developmental, endocrinologic, and sexual—that may occur as a result of spina bifida because these may influence or be altered by urologic management (186).

Perinatal Evaluation

Spinal dysraphism is usually found unexpectedly at birth but may be detected during prenatal ultrasound examination (109). A detailed examination of the entire spine by an experienced ultrasonographer is necessary to rule out neural tube defects, and even in ideal situations errors may be made (246). The presence of a neural tube defect is suggested when amniocentesis reveals an elevated level of a-fetoprotein (30). Controversy, however, surrounds the use of maternal serum screening for a-fetoprotein because both false-positive and false-negative determinations have been reported and the distribution of normal values of maternal serum a-fetoprotein overlaps values seen in the presence of neural tube defects (249).

The optimal perinatal management of the fetus with myelomeningocele remains the subject of debate. Elective caesarian section has been thought to be beneficial in diminishing trauma to neural elements (48). This conclusion, however, was based on the review of older series of deliveries and has been called into question. Benson and associates (19) reviewed the route of delivery and outcome of 75 babies and concluded there was no difference in outcome, independent of which route of delivery was chosen. These data also have been called into question, and the final answer awaits a more controlled study (110). Recent experience with prenatal surgical correction of myelomeningocele awaits long-term outcome analysis.

Neonate

The initial examination of a neonate with spina bifida should proceed along guidelines noted earlier for the child with suspected neurovesical dysfunction. Because back closure and ventriculoperitoneal shunt placement may have been performed before initial urologic evaluation, the child's general neurologic status should be documented. Abdominal wall tone, lower-extremity function, anal sphincter tone, and function of the sacral reflex arc (bulbocavernosus reflex) should be assessed. It is important to note that the level of the bony defect will not determine the functional cord level, which may be altered by the degree of involvement of the spinal cord

and nerve roots, intracranial anomalies (hydrocephalus, Arnold-Chiari malformation), and perhaps the surgical trauma of sac closure (149). Each child represents a unique neurologic status, and each therefore requires a complete urologic evaluation. Observations of spontaneous voiding, continuous dribbling, or a forceful stream may provide valuable information about bladder capacity and function that, when added to information provided by the radiographic appearance of the bladder, may provide data similar to that provided by the cystometrogram. Abdominal examination is performed to assess renal size, detect bladder distention and assess the efficacy of bladder massage or the Credé maneuver to induce bladder emptying. The Credé maneuver, which is commonly taught to parents of children with spina bifida, is extremely limited in both effectiveness and applicability and, in fact, should be avoided in most cases because the majority of infants spontaneously void enough to provide adequate bladder emptying. Barbalias and associates (8) documented that the Credé maneuver actually produced increased urethral resistance in 98% of patients studied. This maneuver thus may elevate intravesical pressure significantly and is particularly contraindicated when outlet resistance is high or VUR is present because the increased hydrostatic pressure will be transmitted directly to the renal parenchyma. When spontaneous voiding does not occur or is ineffective, intermittent catheterization should be instituted. However, urethral dilation and/or medications to reduce urethral resistance (phenoxybenzamine) have been used effectively in this patient group to limit the need for catheterization in the very young patient.

All neonates with spina bifida should have a complete urologic evaluation performed during the neonatal period. Urinary tract ultrasonography is performed to document the state of the upper tracts and assess bladder wall thickness. Postvoid sonography also can assess the completeness of spontaneous voiding. Although fewer than 10% of neonates with spina bifida exhibit hydronephrosis, Stafford (226) studied ten consecutive neonates of whom six had hydronephrosis. Using IV urography, Gaum (83) studied 68 neonates and found abnormal upper tracts in 13 (19%), bilateral hydronephrosis in 7, ureterectasis in 3, pyelectasis in 1, dysplastic kidney in 1, and horseshoe kidney in 1. Of the group with normal urography, 69% had an abnormal VCU, and of the group with abnormal urography, 92.3% had an abnormal VCU. Cystographic abnormalities included reflux (16%), bladder diverticula (23.5%), and subjective abnormalities of bladder wall thickness or bladder shape seen in the majority of patients. Given these data, it is mandatory that voiding cystourethrography and urodynamic evaluation be performed as part of the initial evaluation of all infants. Both studies should be repeated whenever new-onset hydronephrosis is detected by sonography or when there is a significant change in bladder function or continence. Once a complete urologic evaluation has been performed, an appropriate bladder regimen is designed for each individual patient. For many infants, spontaneous voiding into diapers represents optimal care. The Credé maneuver should generally be avoided. Transient urinary retention or elevated residual urine volumes immediately after back closure may require at least temporary management by intermittent catheterization. If prolonged catheterization is necessary, cystourethrography should be performed to determine the presence or absence of VUR. All neonates started on intermittent catheterization should be placed on prophylactic antibiotics at least until the absence of VUR is documented.

Urodynamic Assessment of the Neonate

Traditionally, urodynamic evaluation of children with spina bifida has been carried out in the late preschool or early school-age years in conjunction with the initiation of a bladder-training program, with the studies serving as a guide to bladder management and pharmacologic manipulation (206). McGuire (173) evaluated urodynamic findings in 42 children studied over a 7-year period and found urodynamic testing to be of prognostic value in determining which patients were at risk for upper tract deterioration. In the low intravesical pressure group (intravesical pressure 40 cm H_2O or less at the time of urethral leakage), no patient had VUR, and only 2 of 22 had ureteral dilation. In the high intravesical pressure group, however, 68% showed VUR, and 81% had ureteral dilation. More recently, Bauer (13) studied 36 neonates with spina bifida soon after sac closure and in follow-up for 18 to 48 months. In the group demonstrating detrusor-external sphincter dyssynergy, 72% had or developed hydronephrosis during the period of study; whereas only 22% with synergy and 11% with absent sphincter activity showed upper tract deterioration. In a subsequent study, hydronephrosis developed in less than 10% of infants considered to be at risk for upper tract deterioration who were placed on a program of prophylactic intermittent catheterization and anticholinergic therapy. These data confirm that early urodynamic evaluation is helpful for both guiding therapy and determining which infants are in need of more closely spaced follow-up studies or aggressive bladder management regimens such as intermittent catheterization, urethral dilation, or cutaneous vesicostomy.

Urodynamic findings also are helpful when counseling parents about the long-term prognosis for both upper tract preservation and the management of urinary continence. Landau and co-workers (153) more specifically analyzed urodynamic data in a group of children with neurovesical dysfunction. They commented on the fact that many of their patients achieved a normal total bladder capacity at the expense of elevated storage pressures. This experience underscores the significance that a catheterization diary can play in children with marginal bladder compliance. By comparing the record of urine volumes obtained at catheterization with the urodynamic data obtained from the same patient, it is possible to assess whether the bladder management program is effective in achieving reasonable bladder pressures during both day and night. If catheterized volumes are in the high-pressure range, a change must be made to the patient's bladder management regimen.

It is important to remember that a great deal of artifact can be introduced into urodynamic studies when performed in infants and children, and that voiding cystourethrography and a voiding or catheterization diary can provide a great deal of information about bladder function. This adjunctive information should not be overlooked in any patient and may prove to be particularly important when urodynamic testing is not available. Adjunctive data should be compared with urodynamic studies when both are available so that any discrepancy between the two can be reconciled when a plan for bladder management is formulated.

GENERAL PRINCIPLES OF MANAGEMENT

One of the most important aspects of the urologic care of patients with neurovesical dysfunction is periodic reevaluation. A well-designed lifelong plan for follow-up should begin in infancy. If neonatal sonography demonstrates normal upper tracts, urodynamic studies are favorable, and urine is sterile and bladder emptying adequate, the infant may be discharged to be managed in diapers by spontaneous voiding. Parents must be counseled that close urologic follow-up is necessary both to prevent renal damage and to provide for periodic reassessment of the efficacy of the child's bladder program. When initial urodynamic and radiographic findings are favorable (good bladder compliance, absence of reflux and hydronephrosis), appropriate follow-up may only necessitate sonography in 3 to 4 months, at 1 year, and at yearly intervals thereafter. If hydronephrosis or urinary infection is documented, a VCU and urodynamic evaluation should be performed as soon as infection is cleared, as a part of the evaluation of the efficacy of the current bladder management regimen. When hydronephrosis, urinary retention, VUR, poor bladder compliance, or detrusor-sphincter dyssynergia is documented in infancy, a plan of action other than spontaneous voiding must be formulated. Intermittent catheterization with or without pharmacotherapy, urethral dilation (22,245), or temporary cutaneous vesicostomy (67) may be appropriate in specific settings for any of the previously noted urodynamic indications.

In children with low leak-point pressure, stable bladder function, and normal upper urinary tracts, close urologic surveillance also is necessary until a formal bladder management program is instituted. This group of children (with favorable bladder dynamics) will eventually have bladder manipulation performed for social indications only. Therefore the determination of what is the most appropriate time for the initiation of a formal bladder management program must be made, based not on chronologic age, but on factors such as the child's desire for continence; his or her manual dexterity; and family dynamics, support, and resources. Not all children or families share the same concept of dryness, and motivation may play a crucial role in determining the success or failure of any proposed regimen of bladder management.

For practical purposes, therapy for incontinence may be aimed at correction of either failure of the bladder to store urine or failure of the bladder to empty effectively, most patients demonstrating a deficit in both functions. Failure of adequate urine storage may result from detrusor hyperactivity or diminished detrusor compliance, inadequate outlet resistance, detrusor-outlet dyssynergy, or, in most cases, a combination of factors. In some instances, these causes of incontinence also may result in UTI secondary to inadequate bladder emptying. However, incontinence secondary to either diminished vesical compliance with elevated intravesical pressure at small bladder volumes or to detrusor hypertrophy secondary to detrusor-sphincter dyssynergy also may be associated with upper tract deterioration from either hydroureteronephrosis or VUR (172).

The management of inadequate urine storage must be aimed to correct or compensate for the source of dysfunction. Detrusor hyperactivity may be managed with anticholinergic agents or by diminishing smooth muscle tone (Table 49D.1). Combination therapy may prove beneficial. Transurethral electrical stimulation has demonstrated some promise for increasing bladder capacity, but the effect is only transient in many cases (130). Failure of pharmacologic therapy may necessitate a consideration of sacral rhizotomy (230) or bladder denervation (227) therapy, both of which have been performed rarely in children with spina bifida. Augmentation cystoplasty (179) may be required in severe cases with significantly diminished bladder capacity or compliance. Augmented bladders thus will be converted to the failure-to-empty category and managed as such. Pharmacologic agents that stimulate a-sympathetic receptors in the bladder neck and posterior urethra may modify insufficient bladder outlet resistance (Table 49D.1). Surgical reconstruction or compression of the bladder neck may be necessary in severe cases. The newest approach to intrinsic sphincter deficiency involves transurethral or periurethral injection of bulking materials (polytetrafluoroethylene, collagen) (127,243). Limited success should be expected in children with bladder neck incompetence due to neurovesical dysfunction.

Action	Drug	Maximum Dosage	Frequency
Cholinergic	Bethanechol	0.6 mg/kg/day	3-4 times daily
Anticholinergic	Propantheline	1.5 mg/kg/day	3-4 times daily
	Oxybutynin	0.2 mg/kg/dose	2-4 times daily
	Dicyclomine	5–10 mg/dose	3-4 times daily
	Hyoscyamine	0.0625-0.125 mg/dose	6 times daily
	Tolterodine	0.5 mg/kg/dose	2 times daily
Sympathomimetic	Ephedrine sulfate	1 mg/kg/dose	3-4 times daily
	Phenylpropanolamine (in combination drugs)	2.5 mg/kg/dose	2-3 times daily
Miscellaneous	Imipramine	0.7 mg/kg/dose	2-3 times daily

TABLE 49D.1. COMMON PHARMACOTHERAPY OF PEDIATRIC NEUROVESICAL DYSFUNCTION

Failure of bladder emptying may result from ineffective detrusor function. Since it is generally considered that bethanechol is ineffective on a long-term basis, pharmacologic agents are rarely useful in clinical practice to improve detrusor function (248). Electrical stimulation (bladder pacemaker) has proved to be of very limited usefulness, particularly in the pediatric population (250). Transurethral electrostimulation has appeared to be beneficial in some children, although conflicting data have been reported (25,59,130,163). Myogenic failure may result from chronic overdistention, and in this scenario, intermittent catheterization may improve detrusor contractility.

Outlet resistance (bladder neck and proximal urethra) may be diminished pharmacologically by a-sympatholytic agents. Striated muscle relaxants may lower outlet resistance at the level of the pelvic floor (dantrolene, baclofen), but side effects related to generalized striated muscle relaxation (generalized weakness, dizziness, drowsiness) are common and have severely limited the usefulness of these agents when used systemically (250). Pharmacologic interruption of nerves responsible for increased outlet resistance (pudendal block) has been used infrequently in children (206,208,237). Johnston and Kathel (122) and Shochat and Perlmutter (219) described overdilation of the bladder outlet in females, therapy that has been reintroduced by Bloom (22,244). Surgical destruction of outlet resistance may be accomplished by transurethral incision of the bladder neck or external sphincter, Y-V–plasty of the bladder neck, or bladder flap urethroplasty. These procedures result in incontinence that is reversible only by surgical means (Table 49D.2).

Failure to Store	Failure to Empty
Detrusor	Detrusor
Pharmacologic therapy	Pharmacologic therapy
Anticholinergic	Cholinergic
Smooth-muscle relaxant	Electrical stimulation
Imipramine	Intermittent catheterization
Neurologic therapy	Bladder outlet
Sacral rhizotomy	Pharmacologic therapy
Bladder denervation	α-Sympatholytic
Bladder augmentation	Smooth-muscle relaxant
Bladder outlet	Neurologic therapy
Pharmacologic therapy	Dilation
α-Sympathomimetic	Surgical
Imipramine (Urinary diversion)	Y-V-plasty of the bladder neck
	Transurethral incision of bladder neck
	External sphincterotomy
	Mechanical
	Valsalva maneuver
	Credé maneuver
	Intermittent catheterization
	Urinary diversion

TABLE 49D.2. THERAPEUTIC OPTIONS FOR THE MANAGEMENT OF NEUROVESICAL DYSFUNCTION

The Valsalva or Credé maneuvers may produce mechanical bladder emptying. It has been demonstrated that Credé's maneuver may simultaneously increase both outlet resistance and intravesical pressure and may produce harmful effects on the upper urinary tract (7). Intermittent catheterization is of proven benefit in managing incontinence and may be used in conjunction with pharmacotherapy or appropriate surgical intervention. Although temporary diversion (i.e., cutaneous vesicostomy) often has proven beneficial in the management of the child with renal deterioration due to neurovesical dysfunction (225), permanent urinary diversion has been relegated to a position of last resort (40,242). It must be kept in mind that incontinence associated with sterile urine and normal upper tracts may be best managed conservatively in small children, older children unconcerned with wetness, and in social situations where diminished functional capacity or noncompliance to pharmacologic and catheterization regimens is a problem.

SPECIFIC OPTIONS FOR THE MANAGEMENT OF NEUROVESICAL DYSFUNCTION

Clean Intermittent Catheterization

Although indwelling catheterization has been used to manage neurovesical dysfunction, many adverse sequelae of long-term indwelling catheterization have been reported, particularly in boys. In 1966, Guttman and Frankel (95) introduced sterile intermittent catheterization to the care of patients with neurovesical dysfunction. The subsequent popularization of nonsterile clean intermittent catheterization (CIC) by Lapides (154,155) has allowed this technique to become the mainstay of management for neurovesical dysfunction in both children and adults, its popularity aided by the poor experience with bladder management by both the Credé maneuver and long-term indwelling catheterization. Cass (39) documented UTI in 72%, upper tract dilation in 45%, and incontinence in 100% of children managed by Credé maneuver. When managed with long-term indwelling catheterization, 100% of children were infected and 57% showed upper tract dilation. In contrast, Plunkett and Braren (200) described stable upper tracts in 82% and improved upper tracts in 15% on intermittent catheterization, with 6% incidence of pyelonephritis. Cass (39) documented an 87.5% incidence of stable upper tracts, improvement in 12.5%, and stable or improved VUR in 75%, and persistently sterile urine in 90% of patients. Nonsterile self-intermittent catheterization, especially in children who may be less concerned about cleanliness in performance of catheterization, is associated with a significant incidence of bacteriuria. Although Cass (39) achieved a 90% incidence of persistently sterile urine on suppressive antibiotic therapy, Plunkett and Braren (200) documented persistent infection in 80%, yet pyelonephritis occurred in only 6%, each episode occurring in a patient with significant VUR. Crooks and Enrile (57) documented that asymptomatic bacteriuria in children on a CIC program was not a problem unless VUR was present, a finding confirmed by Lewis (161).

Nonsterile intermittent catheterization may be initiated to manage VUR, upper tract deterioration, UTI, or incontinence. The aim of an intermittent catheterization program is to provide periodic, complete bladder emptying. The success of the program depends highly on the compliance and motivation of the parents or caretakers, the child, and the professionals caring for the child. When self-catheterization is instituted, a great deal of responsibility is thrust on the child. This responsibility is best undertaken when he or she displays interest in personal hygiene and self-image, a stage that coincides with the acknowledgment of peer pressure and social interaction. This stage in growth and development cannot be measured in years and may vary tremendously with the child's individual needs and abilities. Nor can it be assumed that all children will be able to quickly master the techniques of catheterization; in fact, some may be physically unable because of motor deficits, incoordination, skeletal deformity, or orthotic appliances. Time invested in bladder training at the outset will prove to be invaluable in helping both parents and child cope with setbacks and occasional or persistent wetness, especially when repeated urodynamic assessments and alterations in pharmacologic therapy are necessary. If self-catheterization proves unsuccessful, interaction with school personnel, caretakers, and other family members may be necessary to devise an adequate catheterization program. Each child successfully enrolled in a self-catheterization program will eventually come to design a personalized program that allows an unobtrusive catheterization schedule and technique. Catheters are carried in a small plastic bag and reused. They are simply rinsed under running water before and after use. Many girls can manipulate short plastic or stainless steel catheters more easily than catheters of standard length. Catheterization can be performed while standing at or sitting on the toilet, and micturition will appear close to normal as far as others are concerned.

The likelihood of achieving total continence using a program of intermittent catheterization and pharmacologic therapy greatly depends on bladder storage characteristics and patient compliance and motivation. Wolraich and co-workers (252) achieved 49% total daytime continence with CIC and pharmacotherapy. Cass (39) documented 17% slight dampness but dryness in only 34%, while Purcell and Gregory (201) reported 24% total dryness, 33% wet primarily because of poor patient compliance, and 30% wetness in spite of total patient compliance. Knoll and Madersbacher (137) found an overall continence rate of 40%, but this was as high

as 55% in the group whose detrusor hyperreflexia was controlled by pharmacotherapy in association with a competent bladder outlet. These data must be taken into consideration when goals of a CIC program are discussed with patients and family. Adjuncts to CIC and pharmacotherapy should be considered when adequate continence is not achieved.

Pharmacologic Therapy of the Child with Neurovesical Dysfunction

Drug therapy may effectively alter bladder or outlet function and provide continence in milder cases of neurovesical dysfunction. More commonly, however, drugs are used as an adjunct to intermittent catheterization to modify the function of the detrusor or bladder outlet in an effort to provide both adequate storage capacity and adequate emptying. In children, the dosage and side effects of pharmacologic agents must be monitored carefully. Medication is best prescribed per kilogram of body weight. It is common practice to begin with a single agent at a low dose. As efficacy is monitored, dosages are increased and drugs combined in a stepwise fashion to achieve a desired clinical effect while minimizing adverse side effects (Table 49D.1).

Urethral Dilation

Johnston and Kathel (122) were the first to report that urethral dilation could both improve bladder emptying and diminish hydronephrosis in patients with myelomeningocele, a finding confirmed in a small series by Schochat and Perlmutter (219). Little attention was paid to this technique until the report by Bloom in 1990 (22), which detailed the urodynamic and radiographic effects of urethral dilation in 18 children with meningomyelocele and high vesical pressures who underwent dilation as an alternative to cutaneous vesicostomy. The urodynamic effect of dilation in this group of patients resulted in a decreased leak-point pressure from an average of 55.75 cm H_2O to 31 cm H_2O soon after dilation and 19.3 cm H_2O at later evaluation. Longitudinal studies demonstrated a persistent improvement in bladder compliance after dilation, and suggest that the ability to diminish adverse compliance at an early age by any technique may have salutary effect on long-term bladder function. Dilation may be performed in girls using urethral dilators and in boys using balloon dilation under fluoroscopic control. General anesthesia is used in most children, but may be unnecessary in girls who have little or no urethral and perineal sensation.

Cutaneous Vesicostomy

CIC is the most widely used intervention for the management of vesical dysfunction (32). Intermittent catheterization may be instituted as part of a bladder management program to treat incontinence or to manage hydronephrosis, VUR, or recurrent UTI resulting from poor bladder compliance or inadequate bladder emptying. Although intermittent catheterization can be performed safely even in infants, Blocksom's technique for cutaneous vesicostomy, popularized by Duckett (67), has become an effective alternative for dealing with the poorly emptying neuropathic bladder and its secondary effects on the urinary tract. The Blocksom technique utilizes a small transverse skin incision placed halfway between the pubic symphysis and umbilicus; exposure and isolation of the bladder dome from peritoneum, urachus, and umbilical vessel remnants; and creation of a small stoma after resection of a button of detrusor. The vesicostomy in effect acts as a pop-off valve, lowering intravesical volume and pressure, while allowing the bladder to maintain some urine storage and in many instances to allow voiding per urethra. The decision as to whether vesicostomy drainage will provide satisfactory bladder and upper tract decompression can be made by visualizing marked improvement of the radiographic appearance of the upper urinary tracts after bladder catheterization (a vesicostomy equivalent) (Fig. 49D.6). The decision to perform a cutaneous vesicostomy in preference to intermittent catheterization or when catheterization fails to effectively decompress the upper urinary tract must be made on clinical grounds and seems most warranted in the infant or small child with moderate or severe hydronephrosis or reflux and worrisome urodynamic parameters. Management is simple with routine diapering, and the demands of a catheterization program are not imposed on caretakers. The vesicostomy can be managed in children with orthoses, even those with scoliosis jackets or braces with pelvic bands, if minor orthotic adjustments are made. Adequate continence may be achieved with a pad and belt combination in older children if urethral leakage does not occur. Routine stomal appliances may be used effectively, although occasional leakage may be problematic because the vesicostomy is located in an area of skin that may crease when the child sits or bends.

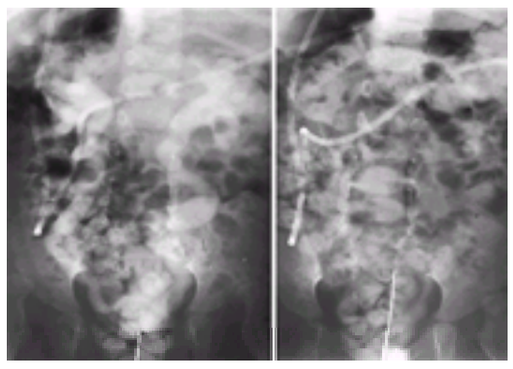

FIGURE 49D.6. Intravenous pyelogram with full bladder and after bladder catheterization.

Cutaneous vesicostomy and intermittent catheterization have been equated in terms of upper tract preservation. Plunkett and Braren (200) described stable upper tracts in 82% and improved upper tracts in 15% of patients managed by intermittent catheterization, with pyelonephritis in only 6%. Cass (39) documented an 87.5% incidence of stable upper tracts, improvement in 12.5%, stable or improved VUR in 75%, and persistently sterile urine in 90% of patients on intermittent catheterization. A report by Duckett (67), however, showed that 54% of patients on a regimen of CIC developed upper tract deterioration (most by 3 years of age), while 85% of patients managed with vesicostomy had complete resolution of hydronephrosis and stabilization in the remainder. No patient with a functioning vesicostomy showed upper tract deterioration. It is likely that the failure of CIC in many cases is failure of the patient, parents, or caretakers to comply with the rigorous catheterization schedule. Finding a caretaker to provide these services in school or when the parents work may be an additional source of stress for a family already struggling with the demands of a handicapped infant.

Complications of vesicostomy are not uncommon but are generally minor and easily managed (112). Snyder and others (225) reported 3 patients with bladder calculi, 6 patients who required reoperation for stenosis or prolapse, and 1 patient requiring stomal catheterization for stenosis among a group of 48. Severe prolapse is extremely rare, but minor mucosal prolapse that does not require surgical revision occurs frequently. Stomal stenosis, even to a severe degree, usually continues to allow adequate urinary tract decompression, with revision being unnecessary. Unless the vesicostomy is created during an acute episode of cystitis, bladder capacity is maintained during the period of diversion (225). Vesicostomy closure combined with ureteral reimplantation and/or bladder augmentation, timed to coincide with institution of a planned self-catheterization program, is the outlook for most patients who undergo cutaneous vesicostomy (51). Long-term vesicostomy drainage has been used in patients unable to perform self- catheterization, usually severely handicapped individuals with poor bowel control who must be managed in diapers. In these individuals, the vesicostomy, although not providing continence, may provide upper tract stability and ease of management.

BLADDER AUGMENTATION

Enterocystoplasty

Children with hydronephrosis, reflux, or incontinence due to diminished vesical compliance and/or capacity may fail to achieve continence or stabilize upper tracts in spite of an optimal trial of intermittent catheterization and pharmacotherapy. Treatment options include bladder augmentation (with or without continent diversion, bladder neck revision, and/or without ureteral reimplantation) or cutaneous urinary diversion (Fig. 49D.7). When bladder augmentation is being considered, several prerequisites are important. Urodynamic studies should confirm diminished capacity and/or compliance. If hydronephrosis or reflux is thought to be secondary to bladder dysfunction, catheter drainage should diminish upper tract fullness. An accurate assessment of the function and adequacy of the bladder outlet should have been completed, and an effective intermittent catheterization program should be in place before surgery.

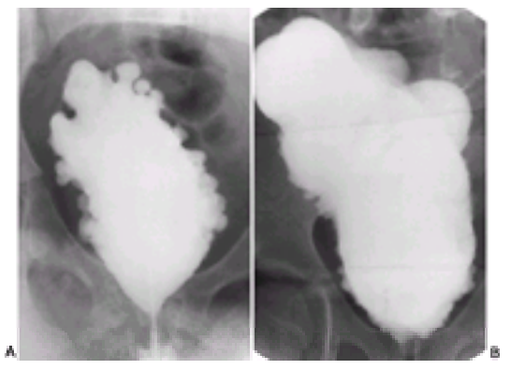

FIGURE 49D.7. A: Cystogram before enterocystoplasty. **B:** Cystogram after enterocystoplasty.

Patients being considered for enterocystoplasty must have adequate bowel length and function to permit exclusion of a segment sufficiently long enough to satisfy the need for increased bladder capacity. Small bowel, colon, and stomach have been the material of choice for bladder augmentation, which gained popularity for the treatment of neurovesical dysfunction after the introduction of intermittent catheterization eliminated concerns about bladder emptying (205,224). Although the choice of bowel segment to be used for augmentation remains controversial, it is imperative that the native bladder be either widely bisected (from just above the bladder neck to trigone), or must be resected to a level just above the trigone. Failure to prepare the bladder base in this manner before augmentation may cause the intestinal segment to act as a diverticulum of the bladder, minimizing the effectiveness of the procedure. Sufficient bowel must be used to provide both adequate capacity and low intravesical pressure. Making optimal use of the shortest bowel segment that will be adequate for the patient's specific needs not only ensures a successful augmentation but also reduces the potential for malabsorption and electrolyte disturbances. Detubularization of bowel segments produces geometric changes, which modify the capacity, accommodation, and compliance of the bladder reservoir in a manner that improves both its storage characteristics and effect on the upper tracts. The geometric advantage of detubularization depends on the geometry of the volume of a cylinder (μpr^2 length) (171) compared with the volume of a sphere (4/3 μpr^3) (138). Koff (139) has tabulated the theoretic increase in bladder volume that can be expected when various lengths of small and large bowel are detubularized before augmentation (Table 49D.3).

TABLE 49D.3. ULTIMATE AUGMENTATION VOLUME OF SMALL BLADDERS ENLARGED WITH BOWEL SEGMENTS OF DIFFERENT DIMENSIONS

Detubularization produces additional beneficial effects on the bladder reservoir. Hinman (105) has shown that accommodation, compliance, and contractility also are altered. Accommodation (increase in bladder volume without a significant increase in pressure) is related to the radius of the reservoir. At any given pressure, a reservoir with a larger radius will accommodate more volume. Compliance (change in pressure/change in volume) is an important facet of bladder augmentation in most cases. Compliance is related to the viscoelastic properties of the reservoir wall, and thus may change over time as the wall stretches and relaxes. Peristaltic activity of intestinal smooth muscle is both phasic and tonic and may be a cause of incontinence after intestinocystoplasty in some patients. Detubularization effectively interrupts the normally coordinated activity of the intestinal musculature. The more complicated the folding process that is carried out, the more disorganized and blunted the bowel contractions become. Sidi and associates (222) compared the clinical and urodynamic results of enterocystoplasty in patients with tubular sigmoid, intact ileocecal, and sigmoid cup-patch augmentations, and found better continence and lower pressures in the cup-patch (detubularized) group, a finding confirmed by others using ileum. Persistent incontinence secondary to peristaltic activity of the bowel segment may be treated with anticholinergic medication or smooth muscle relaxants. In severe cases, enteroplasty, using a second bowel segment as a patch to interrupt the peristaltic activity of the primary bowel reservoir segment, may be considered.

Gastrocystoplasty has been advocated as an alternative form of enterocystoplasty to minimize electrolyte imbalance and urea reabsorption especially in patients with chronic renal failure (1). The net excretion of hydrogen and chloride into the urine from gastric segments is beneficial in the face of metabolic acidosis due to renal failure, which may be worsened by the use of small or large bowel segments that absorb hydrogen and chloride ions. Gastrocystoplasty, however, is not free from complications. Gosalbez (92) reported two patients with severe intractable hypochloremic hypokalemic metabolic alkalosis, one with an intractable seizure disorder and one with respiratory depression and alteration in mental status. Hypergastrinemia has been reported in other patients (236). Nguyen and others (189) described the syndrome of dysuria and hematuria in 36% of 57 patients after gastrocystoplasty. The syndrome is defined as one or more of the following symptoms: bladder spasm or suprapubic, penile, or periurethral pain; coffee-colored or red urine without infection; skin irritation or excoriation and dysuria without infection. Patients particularly at risk are those with diminished renal function and those with incontinence. Treatments have included observation, baking soda, and omeprazole, an inhibitor of the hydrogen-potassium ion adenosine triphosphate (ATP) pump (189).

Mucus production, alteration of bowel function, diarrhea, electrolyte imbalance, the formation of bladder calculi, spontaneous bladder rupture, and malignancy are other reported complications of enterocystoplasty, the incidence varying with the intestinal segment used. Mucous production, generally considered to be a minor nuisance, has been linked to outlet obstruction, calculus formation, and spontaneous bladder perforation (98). Daily irrigation with saline is usually sufficient to prevent complications, although acetylcysteine has been administered orally (700 mg four times daily) and intravesically (30 mL of a 20% solution) (18), and urea has been used (30 mL of a 40% solution left indwelling overnight) with success (34). Diarrhea may be a transient effect of enterocystoplasty, engendered by both the removal of absorptive surface and intense preoperative bowel preparation. In patients with neuropathic bowel dysfunction, the function of the ileocecal valve is particularly important because intractable diarrhea has been reported after ileocecal cystoplasty. The use of the ileocecal segment should be avoided in these patients.

Urinary calculus formation is reported in between 30% and 52.5% of patients after enterocystoplasty, with most stones occurring in the bladder (24). Risk factors appear to be UTI, mucous formation, and the use of both absorbable and nonabsorbable staples (98). Recurrent calculus formation seems to be most problematic in patients after continent urinary diversion, perhaps in part because of the increased likelihood that catheterization from a stoma at the top of the bladder will be less effective in emptying sediment from the bladder floor. Palmer and associates (195) have implicated hypocitraturia as a contributing factor, and in a preliminary statement, believe that oral citrate supplementation has diminished the risk of new and recurrent stone formation. Bladder stones may be managed by both bladder irrigation and transurethral or open surgical techniques. Some authors think that the open surgical technique lessens the risk of recurrent stone formation due to stone fragments remaining in the bladder after crushing or fragmentation by any available technique (24). The surgical treatment of bladder calculi can be particularly vexing for patients with reconstructed bladder necks who are managed by intermittent catheterization via continent stomas. Endoscopic access to these reconstructed bladders for stone manipulation may be severely limited.

Although bladder perforation secondary to intermittent catheterization has been reported, incidents rarely occur in the nonaugmented bladder. However, a growing body of literature has documented delayed “spontaneous” bladder rupture after enterocystoplasty (75). Bauer and others (15) reported 15 spontaneous perforations in 12 of 264 children who underwent enterocystoplasty using small bowel, large bowel, and stomach. All sites of rupture were located in the bowel itself, at or near the junction of the bladder and the enteral patch. Ischemic necrosis is thought to play a role in the mechanism of rupture, and suture granulomas were found in the reservoir wall near the site of rupture. Rosen and Light (212) reported similar findings, and concluded that a common factor was high outlet resistance. Crane and

others (56) postulated that chronic overdistention leads to vascular compromise and ischemia. The lack of sensation of bladder filling, mucous plugs, and failure to comply with routine catheterization schedules may contribute to reservoir rupture. A significant percentage of patients suffering spontaneous rupture have died. Recommendations for prevention include daily bladder irrigation and prevention of overdistention, especially in patients who have a competent bladder outlet or who have undergone a surgical procedure to increase outlet resistance. Spontaneous bladder rupture should be part of the differential diagnosis of the acute abdomen in all patients after enterocystoplasty. Differential diagnosis may be difficult because of abnormal abdominal and visceral sensation. Sonography may demonstrate increased peritoneal fluid. Although cystography should be performed, a normal cystogram, even when the bladder is filled with considerable pressure, does not rule out rupture. If spontaneous rupture is suspected as a cause of an acute abdominal catastrophe, prompt laparotomy is often indicated.

The occurrence of neoplasia at the ureterocolonic anastomosis is a recognized risk of ureterosigmoidostomy (229) Occasional reports of malignancy after bladder augmentation have raised new concern about the long-term outlook for children after enterocystoplasty. Filmer and Spencer (77) tabulated 14 cases of malignancy arising between 5 and 29 years after augmentation. Patient ages were from 42 to 69 years at the time of tumor discovery. Tumor types were transitional cell carcinoma (3), adenocarcinoma (8), signet ring carcinoma (1), sarcoma (1), and oat cell carcinoma (1). The pathogenesis of these lesions is likely multifactorial, and surveillance cystoscopy appears to be warranted, beginning approximately 10 years after augmentation.

Two clinical concerns face the urologist considering bladder augmentation in patients with neurovesical dysfunction: assessment of the bladder outlet and the treatment of VUR. Assessment of the bladder outlet is particularly important in patients with myelodysplasia who commonly display bladder neck incompetence (86). If bladder augmentation is to be performed in these children, preoperative assessment is important to determine whether a simultaneous continence procedure should be carried out at the bladder neck. Appropriate evaluation of bladder neck competence can be made by fluoroscopic examination of the bladder neck during videocystography or videourodynamic evaluation with the patient in the upright or semiupright position (Fig. 49D.8) (147). Valsalva's and Credé's methods should be used as provocative maneuvers if the bladder neck is closed during filling. An open bladder neck indicates the potential need for a simultaneous continence procedure. Cher and Allen (47) prefer to assess the need for bladder neck revision urodynamically and have found that a bladder outlet resistance which exceeds 25 to 30 cm H_2O will be sufficient to prevent postoperative incontinence after enterocystoplasty. VUR that occurs as a result of poor bladder compliance may be refractory to intermittent catheterization and pharmacotherapy and is seen in many patients who become candidates for bladder augmentation. Whether or not to perform simultaneous ureteral reimplantation is an important decision because reimplantation can be technically difficult in abnormal bladders, and yet may resolve spontaneously after bladder augmentation. Historical data are important because reflux, which develops secondary to abnormal bladder function, can be expected to reverse following augmentation (188). Conversely, when historical data document primary reflux; when cystoscopy or operative examination reveals disordered ureterovesical anatomy, parautereric weakness, or nonexistent submucosal tunnels; and when indications for reimplantation are marginal, simultaneous reimplantation should be performed.

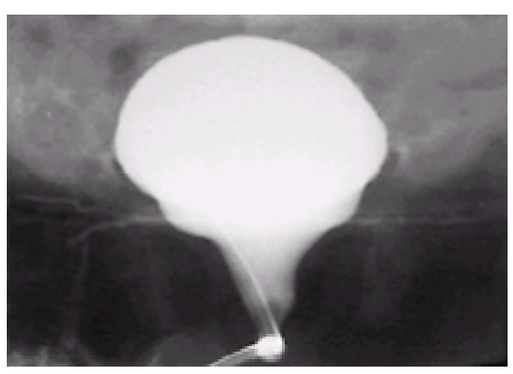

FIGURE 49D.8. Voiding cystourethrogram in a boy with myelomeningocele demonstrates an incompetent bladder neck (intrinsic sphincter deficiency).

When enterocystoplasty has been performed in childhood, long-term follow-up is important. A concern has been the effect of augmentation on the management of pregnancy and delivery. Hill and Kramer (102) surveyed 15 pregnancies after enterocystoplasty. UTI or pyelonephritis occurred in 60%, independent of the presence of reflux. Four patients experienced preterm labor. No incontinence occurred in patients who were delivered vaginally if there had been no prior bladder neck continence procedure. Caesarian section is recommended for patients who have previously undergone bladder neck reconstruction.

Autoaugmentation and Ureterocystoplasty

The reported complications of enterocystoplasty have lead researchers and clinicians to continue to search for viable alternative means of increasing bladder capacity and compliance. Patches of peritoneum, skeletal muscle, de-epithelialized bowel, bowel adventitia, and others have been reported. However, it seems that autoaugmentation (38) and ureterocystoplasty (16,50) have had some reproducible clinical success. Autoaugmentation (detrusor myotomy) is best suited for bladders with reasonable capacity that require a modest improvement in capacity and compliance (Fig. 49D.9). The procedure can be performed extraperitoneally and involves using cautery and sharp and blunt dissection to tease muscle fibers from the mucosa. Surgery is performed with a bladder catheter in place, varying the degree of bladder filling to assist dissection. When one-half to two-thirds of the detrusor has been teased off, the muscle is excised. Although not successful in all cases, autoaugmentation does not interfere with subsequent enterocystoplasty if this procedure becomes necessary. It thus seems to be a reasonable procedure to attempt if there is reasonable consideration that it will improve bladder dynamics. Autoaugmentation has been performed laparoscopically in a small number of patients.

FIGURE 49D.9. Cystogram before autoaugmentation **(A)** and after autoaugmentation **(B).**

Ureterocystoplasty is a procedure that by its very nature is appropriate for only a limited patient population. Prerequisites are either a dilated ureter with a significant volume that is estimated to provide a significant additional increment to bladder capacity or a refluxing megaureter that has already proven its ability to serve as a pop-off mechanism to protect the contralateral kidney from the development of hydronephrosis or reflux (Fig. 49D.10). The technique of ureterocystoplasty may include nephrectomy if the refluxing kidney has poor function, or transureteroureterostomy if function is salvageable. The donor ureter (and renal pelvis if it is large) is mobilized carefully, preserving all adventitial and collateral vessels. The ureter is then divided along its antimesenteric border, the incision taken through the ureteral orifice and continuing to bisect the bladder in the midline or diagonally, as in enterocystoplasty. The detubularized ureter is then folded upon itself and sewn into the bladder defect as in enterocystoplasty. Simultaneous procedures such as contralateral ureteral reimplantation or appendicovesicostomy may be performed. As with autoaugmentation, a significant advantage of ureterocystoplasty is the ability to avoid incorporating extraurinary mucosa into the urinary tract. If, however, the ureter is inelastic because of scarring and fibrosis, the augmented segment may not be as useful as anticipated. Similarly if autoaugmentation results in scar formation rather than regrowth of bladder wall the anticipated results may not be appreciated. The inadequacies of present techniques for bladder augmentation have stimulated efforts to regenerate new bladder tissue that will function as native tissue. The efforts are in early stages of development, but bladder muscle and epithelial cell

cultures on either a synthetic matrix or acellular collagen matrix (SIS) have experimentally resulted in bladder regeneration.

TREATMENT OF DETRUSOR HYPERREFLEXIA

Sacral Rhizotomy

Selective sacral rhizotomy became popular as a treatment for detrusor hyperreflexia after early experience with bilateral rhizotomy demonstrated an unacceptable incidence of impotence and bowel dysfunction. Although selective dorsal rhizotomy has received little attention in the daily management of detrusor hyperreflexia, several centers have developed an expertise and long-term data are now becoming available. Gasparini and others (82) reported follow-up over a mean of 32 months in patients with cervical and thoracic spinal cord injury. They found no adverse effects and a 94% improvement in continence. Storrs (230) combined untethering of the cord with selective posterior rhizotomy in two children with myelomeningocele and reported success in both. The role of sacral rhizotomy in the treatment of detrusor hyperreflexia is still uncertain.

Intrathecal Baclofen

Oral therapy for spasticity resulting from neurologic disease has proven unsuccessful, in large part because the systemic actions of the medications produce generalized weakness but are unable to sufficiently diminish spasticity. Intrethecal baclofen has been used successfully for patients with cerebral palsy or spinal cord injury (3). Investigators have been encouraged by this experience, and some data are available on the effect of intrathecal baclofen on bladder and sphincter function. Nanningia (187) studied seven patients with spasticity secondary to spinal cord injury, and found a decrease in sphincter activity that paralleled a general decrease in spasticity. Six of the seven patients demonstrated an increased bladder capacity, and improved continence was seen in a majority.

INCONTINENCE: INCREASING OUTLET RESISTANCE

Diminished outlet resistance is a common problem for patients with neurovesical dysfunction, especially in cases of myelodysplasia. Appropriate evaluation of bladder neck competence can be made by upright fluoroscopic examination of the bladder neck during cystography or videourodynamic evaluation (91). Valsalva's and Credé's methods should be used as provocative maneuvers if the bladder neck is closed during filling. Electromyographic studies also can be used to assess neuromuscular activity of the pelvic floor and periurethral musculature. An open bladder neck may indicate that intrinsic sphincter weakness is the cause of incontinence, but diminished bladder compliance and capacity also must be taken into consideration as the etiology of or as a contributor to incontinence.

When diminished outlet resistance is a contributor to incontinence, a trial of pharmacotherapy should be initiated before considering surgical intervention (Table 49D.1). Ephedrine, phenylpropanolamine, and imipramine are the most common agents used in the pediatric age group, and they are commonly used in conjunction with anticholinergic agents to achieve continence together with a program of intermittent catheterization. A catheterization trial, even when ineffective in promoting dryness, affords the urologist an interval of observation before surgical intervention to ensure that the child and family are committed to a rigorous program of catheterization that in all likelihood will be a permanent adjunct to surgical therapy. Many surgical options are used to correct an incompetent urethral sphincter. These procedures can be classified as effecting urethral lengthening, urethral suspension, or urethral compression. Several possible alternatives and modifications exist within each category of surgical procedure (Table 49D.3). The sheer number and variety of procedures that have been proposed, each with its proponents and detractors, attest to the fact that a perfect continence mechanism has yet to be described. It is important to recognize that detrusor function may be unfavorably altered after bladder neck reconstruction. This may result in diminished compliance and instability with secondary upper tract deterioration (185). Preoperative urodynamic evaluation of all patients with neurovesical dysfunction who are being considered for bladder neck reconstruction should include a provocative cystometrogram. Woodside and McGuire (254) described the use of a balloon catheter to occlude the vesical neck during the cystometry if urethral leakage occurs around the urodynamic catheter. After performing a routine cystometrogram, the study is repeated using a balloon catheter inflated at the bladder neck to simulate increased outlet resistance. Increased detrusor pressure or instability in the face of bladder neck occlusion is worrisome and raises the question of whether pharmacologic (anticholinergic) or surgical (bladder augmentation) intervention to improve detrusor compliance will be necessary in conjunction with or subsequent to the bladder neck procedure.

Young (255), Dees (61), Leadbetter (156), and Kropp (150) have described commonly used urethral lengthening procedures. The Young-Dees-Leadbetter procedure incorporates proximal reimplantation of the ureters and tubularization of the trigone to afford additional urethral length. A urethral length of 3 to 4 cm should be obtained, the mucosa tubularized over a small 5- or 8-Fr catheter with a pants-over-vest or modified closure of the muscularis. Jones (124) reported a 9% continence failure rate and a 27% reoperation rate after using a modification of this technique. This procedure is rarely applicable to the neurogenic bladder patient but is very useful in the short dilated urethra such as found in epispadias and exstrophy. Normal voiding can be achieved with this procedure. Bladder neck suspension may be performed in conjunction with these urethral lengthening procedures.

Kropp (150) described a novel procedure using a detrusor tube reimplanted into a submucosal trigonal tunnel. He reported continence in 20 of 24 (80%) patients. Belman (17) reported a 78% success rate with this technique. Salle (214) reported improved continence in 70% of patients using another modification that utilizes an anterior bladder flap. The continence mechanism of these procedures is dependent on a flap valve that requires intermittent catheterization to empty the bladder. The procedures are applicable to the neurogenic bladder population and incompatible with normal voiding. The most common postoperative problem in this group has been difficult urethral catheterization.

Urethral suspension for outlet deficiency is commonly performed for incontinence of many types, including neurovesical dysfunction. Common techniques include suprapubic suspension (84,209) and variations of the periurethral and puboprostatic fascial sling. Bauer (14) reported dryness in 72% of girls after a sling procedure and Elder (73) achieved dryness in 9 of 10 girls and 4 of 4 boys after a combined sling and augmentation procedure. Decter (58) found 90% immediate postoperative dryness, but some increased wetness with time. There was no difference in success whether rectus fascia or fascia lata was used. Three patients had difficulty catheterizing postoperatively, and three required bladder augmentation because of postoperative upper tract deterioration.

Urethral compression to achieve incontinence is most often accomplished by artificial sphincter implantation or submucosal injection therapy. The artificial urinary sphincter has proved valuable in achieving continence in a highly select group of children with neurovesical dysfunction. Before sphincter placement is considered, it is mandatory to have a low pressure, compliant bladder. This may be achieved by pharmacologic therapy or may require augmentation cystoplasty (185). Gonzalez and Sheldon (90) implanted sphincters in ten boys and five girls, aged 5 to 17 years. Nine boys achieved continence over an average of 51 months, but only one girl was continent. Erosions occurred in girls whose bladder necks were violated during surgery. Kroovand (148) noted that 37 of 44 (84%) of his patients were dry, 5 of 44 (11%) had stress incontinence, and 3 of 44 (7%) developed erosions. In this group, 20 sphincter replacements were necessary because of mechanical failure, and the 44 patients underwent a total of 99 surgical procedures during the period of study. Bosco and co-workers (28) followed 36 consecutive children for at least 5 years after artificial sphincter implantation and found 75% of the sphincters still functioning. The most common complication requiring reoperation was leakage of fluid from the device. The overall continence rate was 84% at 2 years and 62% at 5 years. The success rate was best with the newest model sphincters. Jumper and others

(126) found no evidence that the artificial sphincter cuff interfered with sexual development or function, or prostate growth and morphology in the growing child with myelodysplasia.

Barrett (9) demonstrated that particle shedding from implanted silicone devices occurs, with foreign body granuloma formation seen in local tissues and regional lymph nodes, Reinberg and co-workers (210) studied six children after artificial sphincter implantation and found silicone particles in the perisphincteric tissue but not in the regional lymph nodes. The clinical significance of this phenomenon is uncertain because no adverse effects have been encountered from migrated silicone particles.

Endoscopically guided submucosal injection therapy can be used to treat intrinsic sphincter deficiency. The purpose of injection therapy is to provide a mechanism for coaptation of the bladder neck and proximal urethra in patients whose open proximal urethra allows increases in intraabdominal pressure to be transmitted directly to the urethra and external sphincter. Polytetrafluoroethylene (Teflon paste), collagen, and autologous fat have been utilized. Teflon is an inert substance that cannot be broken down by the body. Vorstman (240) reported on 11 children who were treated with one or more periurethral or transperineal injections of Teflon paste. Four girls had neurovesical dysfunction, and two became dry on intermittent catheterization after injection therapy. In this series, large volumes of Teflon paste (5 to 21 mL) were used. Other series have found similar results, but the use of Teflon in children has come into disfavor because of the local inflammatory reaction at the injection site and migration of Teflon particles to distant organs. Brown (31) carried out histologic examination of 32 ureters subjected to ureteral reimplantation after submucosal injection of polytef paste to treat VUR. Four ureters were subsequently found to have granulomatous polyps at the site of injection. When the Teflon had been injected into the proper submucosal plane, it remained encapsulated, inciting a minimal foreign body reaction. However, this occurred in only 3 of 27 ureters that had persistence of VUR and were examined histologically at the time of ureteral reimplantation, while the remainder were found to have diffusion of the Teflon and an increased inflammatory reaction. Malizia and others (168) injected polytef paste periurethrally in female dogs and male monkeys. At pathologic examination 10 months later, polytef particles were found at the injection site and in lymph nodes, lungs, kidney, and brain. The pathologic finding at these sites was characterized as a pronounced chronic inflammatory reaction with giant cells. Based on these data, the authors advised against use of this material in children, a point of view held by many urologists in this country.

Glutaraldehyde cross-linked collagen also has been used for the treatment of intrinsic sphincter deficiency. Animal experiments have shown that the collagen becomes integrated with the surrounding tissue and produces no foreign body reaction. Wan (243) reported on eight children treated with collagen, six of whom had neurovesical dysfunction. A total of 17 injections were required (average of 2.1 injections per patient) at an average volume per treatment of 10.9 mL. Continence was produced in 63% of patients, and another 25% improved. Shortliffe and others (220) saw similar improvement. Collagen seems to be a safer material in terms of migration, but sensitivity to the material is reported, and all patients must undergo skin testing 1 month before injection therapy. If the skin test is reactive, implant placement is contraindicated. Collagen seems to be less durable than Teflon and many patients have noted a gradual decline in urethral resistance with time.

Santarosa and Blaivas (215) reported on the use of autologous fat for injection in adults with intrinsic sphincter deficiency. No data are yet available on long-term results or the use of this procedure in children.

CONTINENCE ALTERNATIVES

Although intermittent catheterization has become the primary mode of bladder management for many children with neurovesical dysfunction, institution of a bladder catheterization program provides dryness in only 24% to 49% of reported series (41,201,252). Modern urologic management has provided an excellent outlook for renal function in most children, and social acceptance and freedom from odor, wetness, and embarrassment have now become realistic goals for most children and their families, with an overall social continence of 80% (174,186). Lindehall and associates (162) found that, even when complete dryness was not achieved, adolescents and young adults were encouraged by diminished wetness and less likelihood of embarrassing incontinence. Individualized and sometimes innovative continence alternatives have now become part of the urologic armamentarium, and it is extremely important that the urologist separate medical from social indications for bladder manipulation, particularly when major surgical procedures will be involved.

Diapering is standard management for infants, and may be appropriate for older children who are severely handicapped and unable to provide self-care, especially if effective bowel control is lacking. Institutionalized children frequently are managed in this way. An older child who is incontinent in spite of an adequate intermittent catheterization program may prefer changing diapers to either catheterizing and still being wet, or to dryness if being dry entails surgical intervention and long-term intermittent catheterization. As long as normal upper tracts are maintained, spontaneous voiding into diapers may be a reasonable alternative if wetness can be managed to the satisfaction of the child and caretakers. The only contraindication to this management scheme is the child with an elevated leak-point pressure and poor vesical compliance who might be subject to upper tract deterioration if a catheterization regimen was curtailed or discontinued.

Aggressive management of urinary incontinence requires that a satisfactory program for bowel continence be established before or in conjunction with bladder training. The establishment of an effective bowel regimen cannot be an overnight process and should be started in all infants with neurovesical dysfunction. Once established, however, an effective bowel program may provide tremendous impetus for the child to participate in a bladder management program.

The definition of an appropriate program for the management of urinary continence depends on the desires, social awareness, and individual concerns of each patient and his or her caretakers. Children on a catheterization program with minimal dampness between catheterizations should be encouraged to discard diapers. Occasional dampness may be managed by underwear and a sanitary napkin worn in case of accidents, avoiding the use of a bulky diaper. Condom urinary drainage is feasible in boys with adequate penile length and diameter and may provide socially acceptable continence when bladder emptying is adequate and bowels are well managed. Skin irritations and major penile trauma may occur, and the caretaker and child must be admonished against tight application or prolonged application of condom devices without skin examination (118). Ideally, the condom should be changed daily. In small boys with persistent incontinence who do not want immediate surgical intervention, we have devised a modified condom drainage that has been successful using stomal adhesive at the base of the penis. External sphincterotomy has been used in conjunction with condom urinary drainage in boys with spina bifida, but this creates permanent incontinence that can be corrected only surgically. As a result, this procedure is rarely used in children (144). External urinary collection devices have been designed for the female, although satisfactory dryness has been achieved in a small number of adult patients in few clinical series. Data in children are anecdotal.

The creation of a continent vesicostomy using a detrusor tube as a catheterizable stoma has never achieved a significant degree of success in adults or children. The description of appendicovesicostomy by Mitrofanoff (180) and its subsequent popularization by several authors (70,233) however, has made continent urinary diversion immediately applicable to the care of many children with neurovesical dysfunction. The Mitrofanoff “P'principle,” using a small caliber conduit such as the appendix or distal ureter in an antireflux fashion to provide a tiny catheterizable stoma, has been applied to the native bladder and to bladder replacement reservoirs (70,233) The Mitrofanoff technique was originally used in conjunction with surgical closure of the bladder neck. In most cases, however, it is offered as an alternative to urethral catheterization when catheterization is painful or difficult because of urethral stricture, introital anatomy, or physical handicap which makes access to the urethral meatus difficult. Many other applications of continent urinary diversion have been applied to the pediatric population (101,203). When the appendix is unavailable, inadequate, or is to be used for an antegrade continence enema (ACE) procedure, creation of a small-caliber ileovesicostomy by the technique described by Monti may provide a satisfactory catheterizable continent stoma (36). Laparoscopic techniques have been utilized for the creation of continent stomas in children (35). Paradoxically creation of a continent catheterizable channel to the bladder facilitates bladder neck reconstruction in many patients because the need for urethral catheterization is obviated.

Urinary Diversion and Undiversion

Permanent cutaneous urinary diversion has become a therapy of last resort in the management of the child with neurovesical dysfunction. Ileal conduit diversion, once considered a panacea to salvage kidneys from reflux and infection, has proved hazardous over time. Schwarz and Jeffs (217) followed 96 patients 2 to 16 years after diversion, finding that radiographic evidence of deterioration correlated with the interval of diversion and that stomal stenosis, excessive conduit length, and ureteroileal obstruction contributed to accelerated deterioration. Cass (39) found upper tract deterioration in 16.5% of 50 children followed longer than 10 years. Crooks and Enrile (57) found transient upper tract improvement after ileal diversion with subsequent deterioration in 80% of patients. This was contrasted with stabilization or improvement in the upper tracts of children managed by intermittent catheterization. Nonrefluxing colon conduit diversion has been advocated to prevent the long-term effects associated with ileal conduits (6). Hill and Ransley (103) reported stomal stenosis in 34%, upper tract dilation in 36%, and an overall complication rate of 81% in 47 children with colon conduit diversion. Husman found an acceptable rate of upper tract preservation, but voiced concern about the long-term effects of chronic bacteriuria (113). Clearly, permanent cutaneous diversion should be considered a therapy of last resort in children with neurovesical dysfunction.

Urinary undiversion was initially made feasible by the application of bladder augmentation and innovative reconstructive principles to urinary tracts previously

subjected to either temporary or permanent urinary diversion. These innovative and often extremely complex procedures have become less commonplace as the primary management for neurovesical dysfunction has become more effective and obviated the need for urinary diversion (100). The evaluation of a child for undiversion may include urography and/or radionuclide renal imaging, cystography, retrograde conduit (loopogram) studies, determination of creatinine clearance, and urodynamic evaluation (176). However, the single most important aspect of evaluation, above and beyond that of the assessment of bladder function, is the evaluation of the child's and his or her family's expectations for continence, and their motivation to undergo major surgery and pursue long-term intermittent catheterization (120).

Bladder storage capacity may be assessed before undiversion by intermittent bladder filling (cycling) via suprapubic or urethral catheter. An intermittent catheterization trial carried out at home for several weeks or months allows the urologist to assess not only the child's technical ability to perform catheterization but also his or her motivation to persist with lifelong bladder management. To proceed with undiversion without commitment from the patient and caretakers may risk lifelong incontinence or rediversion. The unique psychosocial stresses that bring children to consider undiversion and the expectations they hold for continence also must be weighed strongly before proceeding with undiversion. Urinary undiversion or reconstruction may be carried out in carefully selected patients as preparation for renal transplantation (89).

Transurethral Electrical Bladder Stimulation

In 1958, Katona and Berenyi (132) first used transurethral electrical bladder stimulation (TEBS) for the treatment of neurovesical dysfunction secondary to spinal cord injury. In 1975, he reported on a group of 100 children with myelodysplasia of whom 71% had attained day and night continence. Kaplan and Richards (130) have popularized TEBS in the United States for neurovesical dysfunction in children with myelomeningocele (130). It is postulated that TEBS stimulates mural receptors that have remained dormant because of a lack of afferent innervation to the bladder. Activation of the receptors triggers small detrusor contractions. Vegetative afferentation progresses, efferent pathways are facilitated, and both motor and sensory function improves. Biofeedback training is then used to link sensation to detrusor contraction as micturition is learned. Reported beneficial effects have included improvement of bladder sensation, stimulation of detrusor contraction, increased bladder capacity, and the establishment of urinary continence. Ebner (71) and associates have studied TEBS in a neurologically intact animal model and found that stimulation involved direct activation of mechanoreceptor afferents, which in turn elicited detrusor contractions.

TEBS therapy is time-consuming, necessitating daily 90-minute sessions. At least 30 sessions are needed to determine whether the patient might respond to therapy, and many patients require more than 100 stimulation sessions to achieve maximal results. Therapy is initiated after performing a baseline urodynamic evaluation and an initial test stimulation. Stimulation is performed after filling the bladder to half capacity with saline via a special electrode catheter. Electrical impulses are passed through the saline. Frequency, intensity, duration, and waveform of the impulse are varied over multiple sessions to produce an optimal result (detrusor contraction) (Fig. 49D.11).

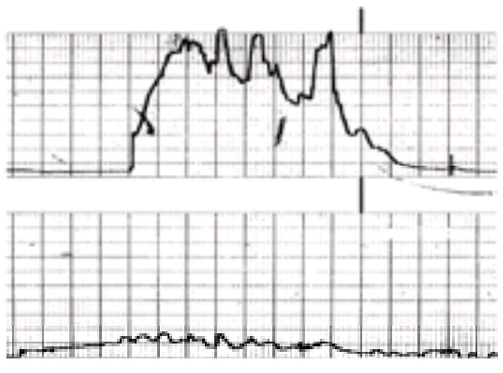

FIGURE 49D.11. Bladder pressure tracing demonstrating a detrusor contraction in response to transurethral intravesical bladder stimulation (upper tracing). Lower tracing reflects intraabdominal (rectal) pressure.

Clinical experience with TEBS has been limited to a small group of patients at a few centers, and the results of therapy were initially encouraging. Lyne and Bellinger (163) reported on a series of 17 patients who had undergone a total of 618 sessions of TEBS. All patients demonstrated detrusor contraction and 88% had some degree of sensation of the contractions. Six patients showed a significant (14% to 158%) increase in bladder capacity during therapy, but in half of these a return to near baseline capacity was noted after therapy was completed. No patient achieved voluntary micturition after therapy, 29% experienced some improvement in bladder parameters, and one patient has had continued improvement in fecal continence. Decter (60) reported a similar experience in 21 patients with neurovesical dysfunction, with initially encouraging results, but in a later report has abandoned offering this therapy to patients because of a lack of significant improvement in bladder function (59). Boone (25) carried out a prospective randomized clinical trial in 36 children over a 3-week period. He found no statistically significant increase in bladder capacity, detrusor activity, or bladder sensation during this short trial period. Further clinical experience with TEBS is in progress in a limited number of centers. Cheng and others (46) reported on a multiinstitutional trial. Of 335 evaluable patients, 53% demonstrated increased bladder capacity of 20% or greater over a period of 1.9 years after the initiation of treatment.

MANAGEMENT OF VESICOURETERIC REFLUX

VUR is found in 3% to 5% of neonates with myelomeningocele and may develop in as many as 30% to 40% by 5 years of age secondary to high intravesical pressures and detrusor-sphincter dyssynergia. Bauer (11) has shown that reflux is rarely seen in neonates unless abnormal bladder dynamics are found. Although Levitt and Sandler (160) failed to find VUR in infants less than 6 weeks of age, Stafford (226) found reflux in 3 of 10 neonates studied. Gaum and others (83) studied 68 consecutive neonates. Of 55 patients with normal urograms, 14.5% had VUR, and when urography was abnormal, 23% were found to have VUR. These data support the view that both urography and sonography are insufficient to screen for VUR in the neonate with neurovesical dysfunction. Cass (39) followed 210 children over 15 years. Although 21% initially had reflux, 38% eventually were found to reflux in subsequent studies, pointing out the importance of periodic reevaluation. Reflux always should be suspected when new-onset hydronephrosis is found on ultrasound examination in a child with abnormal bladder function.

Nuclear cystography is commonly used for the follow-up evaluation of VUR in children with primary VUR and normal bladder function. However, the anatomic detail offered by a routine contrast VCU makes it more applicable to patients with neurovesical dysfunction, for both the initial and follow-up examinations. The ability to assess detrusor trabeculation, bladder neck incompetence, posterior urethral dilation, and function of the external sphincter and bladder outlet during voiding are only a few of the effects of discoordinated voiding dynamics that would not be evaluable by nuclear cystography. These radiographic findings, however, might be important pieces of information for the urologist caring for a child with neurovesical dysfunction. The VCU may be combined with urodynamic assessment in a fluorourodynamic study (videocystometrogram).

The management of VUR in neurologically intact children includes antimicrobial prophylaxis; repeated urine cultures; periodic reevaluation; and, in many cases, surgical intervention when breakthrough urinary infection occurs or when the child fails to outgrow reflux within a reasonable period (116). Management of VUR in children with neurovesical dysfunction also must include meticulous attention to abnormal bladder and urethral dynamics, which, if uncorrected, may cause or promote secondary reflux (2).

Although elevated pressures generated in the neuropathic bladder may be transmitted to the kidney in the presence of VUR, infection remains the primary mediator of renal damage in patients with moderate VUR (207). All children with VUR must be maintained on long-term suppressive antibiotic therapy (72,158). In the young child with minimal reflux, adequate spontaneous bladder emptying, and persistently sterile urine, only antibiotic prophylaxis and close surveillance are necessary. Moderate VUR (grades 3 and 4, International System) (115) in children with neurovesical dysfunction demands aggressive evaluation and management. Urodynamic evaluation should be performed to detect the presence of detrusor hyperreflexia or noncompliance and to assess whether anticholinergic pharmacotherapy may be needed in an effort to improve detrusor compliance. In most cases, intermittent catheterization is begun. If the social situation prohibits an effective catheterization program or if intermittent catheterization in combination with anticholinergic therapy fails to effectively alter bladder dynamics, cutaneous vesicostomy is performed. Kass (131) documented spontaneous resolution of VUR in 31% of ureters once CIC was instituted (100% in nondilated ureters and 0% in dilated ureters), and Kaplan and Firlit (128) found resolution of VUR in 62% of 200 children when CIC was instituted. Close bacteriologic surveillance and periodic radiologic follow-up are necessary in this

group because intermittent catheterization adds an increased risk of UTI. If VUR does not resolve in patients after the institution of a catheterization regimen with or without pharmacotherapy, surgical intervention is warranted.

The surgical management of VUR in the child with neurovesical dysfunction demands an in-depth assessment of bladder capacity, compliance, and emptying. The poor results of reimplantation in many early series (108,119,126) have improved dramatically once bladder rehabilitation with antibiotics; pharmacologic therapy; intermittent catheterization; and bladder augmentation, if necessary, have been achieved. In the severe case with massive reflux, temporary cutaneous vesicostomy may prove extremely valuable. Subsequent vesicostomy closure combined with ureteral reimplantation may be necessary if VUR persists. In many cases, bladder augmentation is necessary to provide adequate bladder capacity and compliance. In general, indications for reimplantation are alike in normal and neuropathic bladders: persistent VUR in spite of adequate pharmacotherapy and intermittent catheterization, recurrent infection (which may be a significant problem for the child on CIC), and upper tract deterioration. Technically, any reimplantation technique may be used, but the technique of Cohen (52) has been advocated because a long cross-trigonal tunnel can be achieved. However, postoperative obstruction may be difficult to deal with if the Cohen technique is used. Suprapubic diversion and ureteral stents are used routinely when one is reimplanting in thickened neurogenic bladders. Using careful bladder management, Jeffs (119) corrected reflux in 33 of 37 children (89%) using the Paquin or Cohen technique. Kaplan and Firlit (128) achieved 96% success in 40 ureters, and Woodard (253) accomplished successful reimplantation in 76% (83% in nontapered ureters and 33% in tapered ureters). Clearly, optimal bladder management is an important contributor to success in reimplantation.

Submucosal injection therapy for VUR was introduced by O'Donnell and Puri in 1986 (192), and subsequently was applied to children with neurovesical dysfunction by Puri (202). Kaplan (127) reported a success rate of 84% after one injection and 87% after two injections. Although Kaplan found no evidence of microscopic migration of Teflon particles to lymph nodes sampled at open surgery after Teflon injection (127), concern has been raised in animal studies (168) (see Incontinence), and many authors have abandoned the use of this material for injection in children (33). Cendren and others (44) reported an overall success rate at 1 year of 65% using cross-linked bovine dermal collagen injection for reflux. Although this material is currently available for the treatment of intrinsic sphincter deficiency, it has not been released for the treatment of VUR. The long-term efficacy of collagen in treating VUR is still to be determined. Tissue reaction is much less than seen with Teflon.

URINARY TRACT INFECTION

Although close surveillance of UTIs is an important part of the management of children with VUR, data conflict regarding the utility of chronic antibacterial prophylaxis in children without VUR who are maintained on a program of nonsterile intermittent catheterization. Bakke and Vollset (7) studied 262 patients on intermittent catheterization and found persistently sterile urine in 28%, occasional bacteriuria in 44%, and chronic bacteriuria in 28%. Among those using chronic antibacterial prophylaxis, fewer episodes of bacteriuria but a greater number of clinical UTIs were noted. Factors related to the presence of bacteriuria included high catheterization volumes and a low frequency of catheterization. Johnson and associates (121) studied the efficacy of short-term nitrofurantoin prophylaxis in 56 children during a 24-week double-blinded placebo-controlled crossover study. They found a diminished incidence of UTI in the treated group, but only a 76.9% compliance with medication usage and a 0.62% incidence of symptomatic UTI. It appears that routine antimicrobial prophylaxis is not indicated in patients managed with intermittent catheterization in the absence of VUR.

ASSOCIATED CONCERNS

Bowel Incontinence

Bowel and urinary incontinence together present a tremendous handicap to normal social interaction for the child with spina bifida. Although a great deal of effort is commonly expended to provide adequate urinary control, failure to provide a good bowel program may leave the child diaper dependent. The purpose of establishing a bowel routine is to provide a method of periodic, effective bowel evacuation while preventing accidental soiling. An effective program must combine diet, controlled evacuation, and a well-regimented schedule (45).

Diet is extremely important for management of fecal incontinence. Although infants generally have loose or soft stools, the addition of table foods to the diet commonly results in hard stool. In general, a high-fiber diet is successful in preventing hard stools, and this diet should be started in early childhood to encourage a lifetime dietary regimen. When necessary, medications may be added to provide increased stool water.

Manual stimulation, reflex stimulation by suppositories, or mechanical stimulation by enemas may be necessary to trigger evacuation of the colon. As with bladder management programs, each child is an individual, and trial and error may be necessary to design an effective bowel program. For many children, saline or soapsuds expansion enemas given via a rubber ear syringe are remarkably effective, simple, and inexpensive (45). Independent of which program is chosen for bowel management, it is important to begin a regimented schedule early in childhood when the child can sit on a potty chair. Successful evacuation may be timed to occur after a meal at the same time each day, in an unhurried atmosphere.

Anorectal manometry has been described as a method of assessing the effect of neuromuscular dysfunction on the lower bowel and sphincters, and biofeedback training has been used with some success in myelodysplastic children (174,241,247). Malone (169) reported on an innovative modification of the Mitrofanoff principle to provide a nonrefluxing catheterizable stoma for ACE. Many reports have confirmed the efficacy of this procedure in providing optimal bowel management for patients with neuropathic bowel dysfunction (21,37,74,145,181).

Sexuality

The normal timetable of sexual development may be altered in children with hydrocephalus. The recognition that precocious puberty may occur in both male and female patients has been made by Meyer and Landau (177) using hormonal data to document true isosexual precocity, although the endocrinologic mechanisms involved are incompletely understood. Because of the potential for the early development of secondary sex characteristics, all children with spina bifida and their parents and caretakers will benefit from early discussion of normal adolescent development and menarche. Data on sexual function in spina bifida are poorly documented, much having been inferred from the spinal cord injury literature (204). Shurtleff (221) described 80% erectile ability and 40% ejaculation in a survey of older spina bifida males. Eighty percent of women were sexually active, all describing satisfactory orgasms. In Cass' series, 12 of 17 women having intercourse had become pregnant (42). Sexual counseling for the preadolescent and adolescent is a valuable part of any total rehabilitation program, and children should be encouraged to attend regular sex education courses in school, from which they may otherwise be excluded because of the mistaken impression that all handicapped children are nonfunctional or sterile. Girls in particular must realize that their fertility is normal and that normal sexual function is possible. Thus, knowledge of effective birth control is essential. Routine gynecologic examination should be encouraged in all girls beginning at puberty.

MISCELLANEOUS UROLOGIC CONCERNS

Circumcision offers two significant advantages for many boys with neurovesical dysfunction: diminished risk of UTI and increased ease of performing catheterization. Human foreskin is known to show a propensity for adherence and colonization by pathogenic bacteria. Wiswell confirmed the significance of bacterial adherence in boys, finding a tenfold increased incidence of UTIs in uncircumcised boys in a group of 209,399 infants. He also reviewed the findings of other authors who showed an increased risk of UTIs in uncircumcised boys, ranging from 5 to 89 times greater than seen in circumcised boys (251). Removal of the foreskin thus not only exposes the meatus for technically easier catheterization but also removes a contiguous source of periurethral skin colonization.

Cryptorchidism in spina bifida males is not uncommon (151). The management of these children should not differ from treatment plans for other boys.

Inguinal hernias (communicating hydroceles) may appear or worsen soon after ventriculoperitoneal shunting in infants. Kaufman and Carmel (133) noted hydroceles in 7% of girls and 23% of boys younger than 1 year of age with shunts. They postulated that a combination of increased abdominal fluid and pressure, an alteration in peritoneal membrane characteristics, and proximity of the shunt tubing to the inguinal canal influenced hydrocele formation. In some instances, the shunt tubing may migrate into the scrotum (Fig. 49D.12). Surgical repair is indicated in these children, and bilateral exploration should always be carried out in young children. Rarely, spinal fluid pseudocysts may present as abdominal masses and may cause urinary tract obstruction (199).

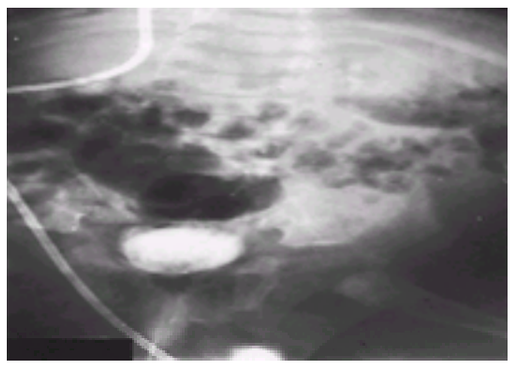

FIGURE 49D.12. Three-month-old boy with large communication hydroceles. At surgery, shunt tubing was found in processus vaginalis.

Tethered Spinal Cord

In children with spina bifida, the spinal cord, fixed abnormally by deformity and postsurgical scarring, may be placed on stretch with growth as the trunk elongates, causing neurologic changes (Fig. 49D.13). Normal somatic growth may thus produce alterations in gait, lower-extremity strength and function, and bowel and bladder control and may result in orthopedic deformities (scoliosis) as a result of neuromuscular imbalance. This "tethered cord syndrome" may progress silently (211). Tethering of the cord also may be seen with diastematomyelia, intraspinal lipomas, and dermoid tumors. Changes in bowel pattern, incontinence between catheterization, or unexpected changes in urinary control or bladder function should raise concern about development of a tethered cord. Urodynamic studies should be performed to document change in bladder dynamics, and neurosurgical consultation should be requested to assess other neurologic changes and to obtain consultation as to whether imaging of the spinal cord and surgical repair are indicated (152). Several series have shown that surgical correction of a tethered spinal cord may result in an increased bladder capacity in some patients, while others may show no change in bladder function, and some may continue to show deterioration in spite of untethering. In many cases, transient postoperative urodynamic changes may be seen (129).

Latex Allergy

IgE-mediated immediate hypersensitivity to latex is now a well-documented phenomenon that has been reported most often in children with myelodysplasia during surgery or other exposures to latex. Although delayed (type IV) hypersensitivity may be manifest as an eczematous contact dermatitis, immediate hypersensitivity to a yet undefined component of furosemide has ranged in severity from rhinitis and conjunctivitis to bronchospasm, anaphylaxis, and cardiovascular collapse (88). The almost epidemic reporting of latex reactions in children with myelomeningocele is not readily explained. [Schneck and Bellinger (216) found 45% of patients tested to have hypersensitivity.] It appears likely that previous allergic or cardiovascular episodes were attributed to other allergens or unknown causes. Because physicians are now attuned to the probability of latex hypersensitivity, many children undergo prophylactic skin testing. It is assumed that recurrent exposure to latex-containing gloves, catheters, and other medical devices (Table 49D.4) during multiple medical and surgical procedures sensitizes children at an early age, although many nonmyelomeningocele children are exposed to latex via baby bottle nipples and pacifiers and have an apparently much lower incidence of hypersensitivity. It is speculated those exposures of peritoneal and mucosal surfaces as well as direct tissue exposure during surgery may heighten the development of hypersensitivity.

Electrocardiogram pads	Tourniquets
Tape	Face masks
Foley catheter	Ventilators, hoses, and bellows
Dilating catheters	Injection ports of IV tubing and IV bags
Surgical drains	Stoppers in medication vials and syringes
Nasogastric tubes	Floating disc valves on some IV burette chambers
Surgical/examination gloves	
Reservoir bags	
Blood pressure cuffs	

IV, intravenous.

TABLE 49D.4. COMMON LATEX-CONTAINING MEDICAL DEVICES

In the absence of a confirmed negative latex allergy test, all patients with myelomeningocele or other forms of spina bifida should be considered to have the potential for latex hypersensitivity. A high index of suspicion is important, and the identification of patients at risk begins with the medical history, including a history of urticarial reactions to common latex-containing products, such as crib pads, rubber balls, and balloons. Patients at risk should undergo further definitive testing. Skin testing using colloidal suspensions of rubber particles is sensitive, but severe anaphylactic reactions may result. RAST (radioallergosorbent) testing, which measures the binding of IgE antibodies has been used in many series. RAST testing has sensitivity ranging from 53% to 86%, with specificity of 76% (223). Schneck and Bellinger (216) found reactivity to 3-antigen radioimmunoassay (RIA) latex-specific IgE to be a more sensitive test.

The identification of patients at risk, prophylactic avoidance of latex-containing products, and prompt treatment of hypersensitivity reactions are important to avoid life-threatening complications of latex allergy. When possible, children with spina bifida or other congenital anomalies who will be required to undergo multiple surgical procedures should be placed on a protocol of latex avoidance from birth. When latex hypersensitivity is documented, avoidance of latex-containing material should be practiced and special precautions taken during medical and surgical procedures. If early signs of latex allergy are detected, removal of the latex device should occur immediately and systemic treatment of anaphylaxis should be begun (143).

Team Approach to Spina Bifida

The consequences of spina bifida may be medical, social, psychologic, economic, and educational in scope (64,159). The medical consequences concern

growth—developmental, general pediatric, neurologic, orthopedic, and urologic—to name only the most basic. With such major concerns, the interdisciplinary approach to the child and family has advantages, the most practical being that one area will not be neglected inadvertently by the patient or family, resulting in a major handicap for the child. Although the interdisciplinary concept has detractors (198), it offers the urologist the nursing skills necessary to initiate and manage a bowel and bladder program and to integrate this program with care of the child's other neurologic and orthopedic disabilities both at home and in school. Institutions committed to the care of children with significant birth defects will develop multidisciplinary clinics to provide the coordinated expertise of urologists, orthopedic surgeons, neurosurgeons, rehabilitation medicine, pediatricians, nursing, and social services. These facilitate and orchestrate the complex care and attention demanded by these young patients and their families.

Sacral Agenesis

Complete or partial sacral agenesis is a rare anomaly that may occur as an isolated lesion or in conjunction with imperforate anus, cloacal anomalies, and the syndromes of caudal regression (29,196). Maternal diabetes mellitus is found in 12% to 18% of cases of sacral agenesis, and 1% of diabetic mothers have infants with sacral agenesis. Although affected children are usually evident as neonates, Guzman (96) found only 50% in the newborn period. It is not unusual for children to present at later ages with a lifelong history of urinary incontinence and encopresis.

Physical findings may include an absent gluteal cleft and abnormal contour to the buttocks. Sacral agenesis may be confirmed by anteroposterior and lateral spine films (Fig. 49D.14), but the neurologic deficit may not correlate well with the bony defects noted. Many patients with isolated sacral agenesis have symptoms related only to bladder and bowel control. The high incidence of hydronephrosis or reflux in cases presenting late in childhood demands an early and complete uroradiologic and urodynamic evaluation of all children with documented sacral deformity (29). Urodynamic findings are extremely variable. Guzman (96) studied 16 patients, finding detrusor areflexia in 7 and hyperreflexia in 9, whereas sphincter EMG showed considerable variation in activity and variable dyssynergia. Therapy is based on clinical and urodynamic findings.

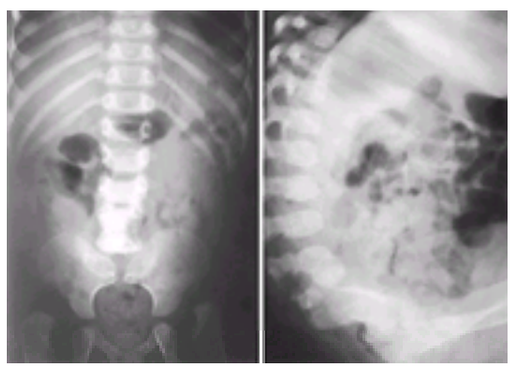

FIGURE 49D.14. Sacral agenesis.

Occult Spinal Dysraphism

Anterior meningocele, lipoma, lipomeningocele, diastematomyelia, ligamentous bands, dermoid cysts, and congenital anomalies of the spinal cord itself may produce variable neurologic deficits, many primarily of neurovesical dysfunction (27). Such lesions should be considered when plain films display abnormal lumbosacral anatomy. Conversely, it is mandatory that the spine be examined carefully on radiographs of all children studied for incontinence or UTI. The physical examination of all children with urinary disorders should include a search of the lower back for skin tags, abnormal tufts of hair, lipomas, dermal sinuses, or pigmented lesions that may be associated with underlying pathologic conditions (4,97). Urodynamic studies may be necessary to document neurovesical dysfunction, because other neurologic tests may be completely normal. MRI of the spine may be helpful in evaluating a lesion of the cord. Foster (80) found abnormal urodynamic findings to be the only sign of spinal cord tethering in 42% of 31 patients with lipomeningocele. If surgery is performed, postoperative urodynamic follow-up is important to document functional improvement or deterioration from the neurosurgical procedure itself. Gross and others (94) found an increase in bladder capacity in 10 of 17 patients, overall improvement in bladder function in 13, no change in 5, and deterioration in 3. In Rigel's series, after release of cord tethering, 3 patients originally thought to have permanent neurologic deficit improved, 5 of 9 with recent loss of bladder function recovered, and 17% lost bladder function (211). Khoury (134) reported on a controversial group of 31 patients with secondary urinary incontinence who had resection of a thickened filum terminale. Incontinence resolved in 72%, urodynamic evidence of detrusor hyperreflexia improved in 59%, and bladder compliance improved in 66% after surgery, but theindications for surgical intervention were unclear. Clearly, appropriate urologic and urodynamic evaluation is extremely important in children with incontinence, and neurosurgical evaluation may be appropriate if urologic findings indicate the possibility of neurovesical dysfunction.

Spinal Cord Injury/Transverse Myelitis

Transverse myelitis and traumatic spinal cord injuries are causes of neurovesical dysfunction that are uncommon in infants and small children, but not rare in adolescents. Infants may suffer spinal cord injury during traumatic delivery, and most other spinal cord injuries are secondary to automobile accidents, gunshot wounds, and diving accidents.

The child with an acute spinal cord injury commonly displays urinary retention, which may be a transient phenomenon, may persist for weeks or months, or may be permanent. Because most spinal cord trauma occurs above the level of the sacral reflex arc, however, urinary retention is usually temporary. An indwelling bladder catheter is placed in most patients with spinal cord injury soon after the injury. This should be replaced by intermittent catheterization as soon as the patient has been medically and surgically stabilized. Catheterization should be performed frequently enough to prevent bladder overdistention, which ultimately may result in myogenic failure. McGuire and Savastano (172) have shown that long-term intermittent catheterization in patients with spinal cord injury is effective in preservation of the upper urinary tract and prevention of pyelonephritis, while allowing both spontaneous voiding to occur and an ongoing assessment of the efficacy of spontaneous detrusor. Because detrusor hyperreflexia and detrusor-sphincter dyssynergia are common findings after spinal cord injury, urodynamic and radiographic studies should be carried out as a baseline and in follow-up of all patients. Evaluation and management of these children parallels that of children with spina bifida and other causes of neurovesical dysfunction.

Head Trauma

Trauma to the spinal cord is a leading cause of neurovesical dysfunction and morbidity (247). Head trauma may result in minor degrees of neurovesical dysfunction that may be an added aggravation during the rehabilitation process. Incontinence and urinary frequency and urgency are common symptoms in this group of patients. UTI, urethral stricture from prolonged catheterization during the acute phase of management, and bladder calculi from indwelling catheters should be considered as possible etiologies for bladder dysfunction and appropriately evaluated. Uninhibited bladder contractions may be discovered on urodynamic evaluation. Treatment must be individualized to meet both the needs and functional abilities of the child.

Cerebral Palsy and Miscellaneous Neurologic Diseases

Cerebral palsy and many stable or progressive neurologic disorders may be causes of bladder dysfunction and urinary incontinence (114,175). In many cases, generalized spasticity is a common finding. The child may be incapable of communicating much useful information about the level of sensation or type of incontinence present. History and physical examination are extremely important in these cases, and one frequently must seek information from the child's caretakers about frequency of urination, force of the urinary stream, bowel habits, and other aspects of history that may be important in terms of differential diagnosis and aspects of management.

Evaluation should begin with history and physical examination and include whatever testing seems appropriate for the level of concern that has arisen. If UTI is a concern, renal sonography, VCUG, and urodynamic evaluation are appropriate. If incontinence is the sole issue, evaluation should begin with a renal and postvoid ultrasound to determine the efficacy of bladder emptying. Urodynamic studies are indicated in many children with incontinence, and in many cases, detrusor

hyperreflexia will be found. Anticholinergic therapy may prove beneficial in many cases, but intermittent catheterization may be required if a large postvoid residual urine volume secondary to incomplete bladder emptying is the cause of incontinence. Although many children with cerebral palsy are challenged with urinary control issues, it is rare that the upper tracts are jeopardized.

Nonneuropathic Voiding Dysfunction and the Hinman-Allen Syndrome

Voiding dysfunction in the neurologically intact child may be seen in a group of children with a wide spectrum of abnormal voiding patterns ranging from frequency to enuresis to severe incontinence and with radiographic and urodynamic findings from mild detrusor hyperreflexia to severely disordered bladder function, reflux, hydronephrosis, and renal failure. Many of the more severely afflicted children share many clinical, radiologic, urodynamic, and psychosocial characteristics that have been variously termed nonneurogenic neurogenic bladder, occult neurologic bladder, subclinical neurogenic bladder, or the Hinman-Allen syndrome (5,63,104,106,107) Although originally thought to represent true neurovesical dysfunction related to occult spinal dysraphism, it has been accepted that acquired behavioral and psychosocial disorders may be reflected in bladder and bowel dysfunction, mimicking neurologic disease.

The symptom complex associated with dysfunctional voiding varies from mild dampness to severe daytime frequency (the frequency syndrome of childhood) (256) to day and nighttime enuresis, encopresis, and constipation, recurrent UTI, hydronephrosis, reflux, and renal failure. Bladder and bowel dysfunction usually are preceded by the development of continence and a recognized period of normal bladder and bowel control, as opposed to primary neurovesical dysfunction in which urinary continence may have never developed. When seen by the urologist, many of the most severely dysfunctional children have a history of recurrent UTI and may have undergone endoscopy or failed urologic surgery for reflux or hydronephrosis.

The initial consideration of dysfunctional voiding is usually raised by the past medical, urologic, and social developmental history. A history of UTIs should be noted, as dysfunctional voiding may trigger or be triggered by acute and chronic cystitis. A thorough evaluation of the child's voiding pattern and social history, both present and during the period of toilet training, must then be obtained. Geist and Antolak (85) noted a high incidence of emotional problems in children with symptoms of interstitial cystitis. Galdston and Perlmutter (81) have shown that anxiety in children may be manifested by alterations in urinary frequency and voiding characteristics. Hinman and Baumann (107) likewise noted shyness, timidity, and an attitude of failure, with some children displaying hyperactivity and general anxiety. Family and social histories frequently reveal strained relationships, separation, or divorce. The child who wets may have been punished repeatedly or ridiculed both at home and at school. Peer interaction is often strained, and many children dislike school, performing poorly. Parent–child interaction during the interview and examination may provide important clues to social problems in the home. Physical examination is generally normal, although a distended bladder may be palpable, and impacted stool may be noted on rectal and abdominal examination. Postvoid bladder ultrasound studies may reveal a large postvoid residual urine volume. Neurologic examination is normal. Many children with severe dysfunctional voiding are withdrawn and uncooperative to examination.

The level of concern raised by dysfunctional voiding and the intensity of evaluation it deserves should be related less to the severity of symptoms than to the clinical, radiographic and urodynamic findings that result. Likewise, the intensity of therapy should be related to the degree of dysfunction and the severity of bladder and upper tract dysfunction that results.

Daytime urinary frequency (the frequency syndrome of childhood) is an increasingly common complaint that brings children to urologic evaluation. The typical symptoms of this disorder are daytime frequency out of proportion to what may be perfect nocturnal dryness; occasional nocturia; and rarely, an episode of enuresis. Children rarely complain of symptoms, but parents, teachers, and caretakers are commonly distressed by the voiding pattern. UTI is not found, and radiographic findings are normal. Zoubek and Bloom (256) found that the average length of symptoms in this group was 7 months; that pharmacologic therapy did not improve symptoms in most cases; and that observation, lack of intervention, and benign neglect were the most effective means of assuring resolution. Screening sonography in the urologist's office will rule out significant bladder wall thickness or hydronephrosis, and reassurance can be given that resolution will occur in the majority of cases. In many cases, this reassurance and visual evidence of normal renal and bladder anatomy is all that is necessary to instill parents with the confidence that they need to deal with the annoyance of urinary frequency.

Moderate dysfunctional voiding is frequently associated with UTI in either a cause or effect relationship. Moderate voiding dysfunction is frequently classified clinically as either the small-capacity bladder, hyperreflexic bladder, or lazy bladder syndromes. Urinary frequency, incontinence, UTI, and constipation are seen in varying degrees in these syndromes, which have fittingly been termed *dysfunctional elimination syndromes.* Renal ultrasonography; voiding cystourethrography; and occasionally, urodynamic evaluation are important to characterize the nature of voiding dysfunction and document whether or not VUR or hydronephrosis is present. Reflux, in particular, may be a worrisome finding and requires close observation. Koff (141) first related abnormal vesical function to VUR in 1979. They studied 53 neurologically intact children with UTIs, urinary frequency, urgency, and/or nocturnal enuresis. All children demonstrated uninhibited detrusor contractions, and 50% were found to have VUR. Taylor (235) confirmed the correlation between the unstable bladder and VUR. Koff and Murtagh (142), in a later prospective study, documented that anticholinergic therapy, when added to a complete program of nonsurgical management of VUR, resulted in a tripled rate of spontaneous resolution of VUR when compared with controls. Treating UTI and antibiotic prophylaxis in some cases results in resolution of both the dysfunctional voiding and reflux, while improvement in the dysfunctional pattern of voiding may conversely diminish the risk of UTI. This appears to be the result of improving the typical pattern of stop-and-start micturition seen with bladder hyperreflexia that allows milk-back of urethral contents into the bladder. Anticholinergic therapy is beneficial in many cases, and timed voiding regimens, treatment of constipation, and attention to stress-related factors are important aspects of therapy. Overall, the treatment of constipation, usually a relatively silent problem, will pay the biggest of dividends in improving bladder function.

The Hinman-Allen syndrome (nonneurogenic neurogenic bladder) represents the most severe end of the spectrum of voiding dysfunction. Uroradiographic studies are generally abnormal. Hydronephrosis (generally bilateral) is found in 66% to 70%, with significant VUR in 50% to 57%. VUR may have been absent in prior studies, and there may be evidence that VUR was acquired secondary to abnormal voiding mechanics (5,104). The bladder may appear large in capacity and may be smooth or trabeculated. A significant postvoid residual may be seen (Fig. 49D.15 and Fig. 49D.16). Voiding films may demonstrate persistent narrowing at the level of the external sphincter, mimicking posterior urethral valvular obstruction. The urinary stream may be intermittent, associated with intermittent closure of the external sphincter during voiding. Voiding may be produced by abdominal straining. Ochoa has described a distinctive urofacial syndrome (the Ochoa syndrome), which is seen in children with nonneurogenic vesical dysfunction who display a unique facial inversion or grimace during the act of smiling (191). He postulates the existence of a lesion somewhere in the reticular formation of the brainstem to account for both aspects of neurologic dysfunction.

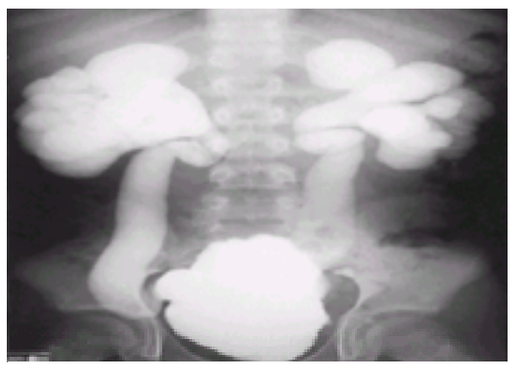

FIGURE 49D.15. Cystogram of 13-year-old boy with Hinman-Allen syndrome.

FIGURE 49D.16. A: Intravenous pyelogram (IVP) of 10-year-old boy with Hinman-Allen syndrome. **B:** Voiding cystourethrogram of same boy mimics posterior urethral valves. **C:** IVP of same boy after cutaneous vesicostomy, psychotherapy, family counseling, and vesicostomy closure 3 years later.

Both VCU and urodynamic evaluation may be extremely difficult to carry out in children with nonneuropathic voiding dysfunction because of a lack of patient cooperation. In some instances, insertion of a small trocar cystostomy and external sphincter electrodes or patches must be carried out under anesthesia, with urodynamic study after recovery. This technique is especially helpful when repeated study or biofeedback training is anticipated, although some children tolerate even small urodynamic catheters poorly and a great deal of artifact may result. Urodynamic findings may reveal increased bladder capacity and resting pressure, occasionally with uninhibited detrusor activity during filling (172). It is imperative to detect straining to void with abdominal EMG or intraabdominal pressure monitors. During voiding, the external urethral sphincter fails to relax and may show increased activity (detrusor-sphincter dyssynergy). These abnormal urodynamic findings appear to represent learned disorders of micturition, either as persistence of habits acquired during transition from the infantile bladder to normal continence or as a response to social or psychologic stress. Once wetness occurs, the child may further strain to tighten pelvic floor muscles and prevent leakage, a habit that may be difficult to unlearn.

Treatment of the child with dysfunctional voiding must be highly individualized. As in any functional disorder, therapy must be aimed not only at the bladder dysfunction and improved bladder emptying but also at constipation and the psychosocial stresses contributing to the dysfunction. In this context, psychotherapy, behavior modification, and biofeedback training may be extremely important, and the urologist must work closely with a child psychologist or psychiatrist who fully understands the nature and significance of nonneuropathic voiding dysfunction. In some cases, hypnosis has been used successfully. Biofeedback training can be extremely rewarding if the child will cooperate, and learned responses may significantly diminish external sphincter contraction during voiding (165). Double and triple voiding may help reduce residual bladder urine. The child with severe hydronephrosis or reflux may benefit from intermittent catheterization to provide bladder drainage while psychotherapy is in process, but many children are so uncooperative that catheterization is impossible. In such severe circumstances, temporary urinary diversion (cutaneous vesicostomy) may be necessary to prevent further renal damage. In severe cases with end-stage bladder dysfunction and fibrosis, bladder augmentation and even continent urinary diversion may be necessary. Whatever treatment plan is chosen, family counseling and stress reduction are of paramount importance. Long-term follow-up and periodic reassessment are mandatory (106).

Knowledge of the normal development of the urethra and adjacent structures in the female fetus is important to a thorough understanding of the various anomalies recognized in the female urethra. The urinary and genital systems in the female are closely interrelated in regard to their embryologic origin and their final anatomic location. To appreciate the great diversity of congenital urogenital malformations, knowledge of the normal embryogenesis of this area is essential.

EMBRYOLOGY OF THE LOWER UROGENITAL TRACT

Classical Theories on the Development of the Cloaca and the Urogenital Sinus

Our understanding of the embryology of lower genitourinary tract and the structures of the posterior perineum is based on embryonic theories that date from more than a century ago. In the traditional teaching, the caudal end of the embryo is partitioned by the fusion of the lateral walls of the cloaca (61) and cranio-caudal descent of the urorectal septum (75). Together, these embryologic events subdivide the cloaca into the urogenital canal anteriorly and the anorectal canal posteriorly. This process occurs between the fourth and sixth weeks of embryogenesis.

In the past, it has been assumed that the distal aspect of the cloaca fused with the urogenital canal and the anorectal canal and formed openings for these systems to the exterior (71). The urorectal septum was believed to fuse with the cloaca during the sixth week, forming the ventral urogenital membrane and a dorsal anal membrane. The area where the urorectal septum and lateral mesodermal folds fused with the cloacal membrane became the perineal body, which represented the partition between the digestive and urogenital systems (5). The anterior portion of the cloaca eventually developed into the bladder and urethra.

New Theories on the Development of the Cloaca and the Urogenital Sinus

Recently, there has been growing evidence that our previously accepted theories about the development of the caudal end of the embryo may be incorrect. Animal models (39,78) and human studies (49,52), along with technological advances, are providing detailed information about the changes occurring in early embryogenesis. With the use of computer-assisted three-dimensional reconstruction of human embryos (49,52) in combination with an image-processing technique called *morphing* (2,52), novel approaches have become available for analysis of the embryologic processes occurring in the caudal region.

The concept of a dynamic movement or change of configuration of cloacal structures better explains the observed changes in the embryo. The growth of the caudal region of the human embryo is accompanied by dramatic shifts in the morphology; positioning; and relative sizes of the primitive urogenital sinus, anorectum, and cloaca. Contrary to the traditional embryologic theories, the “descent” of the urorectal septum occurs as a passive process as a result of the rotation of the embryo. By a process called *transformation,* the structures of the caudal region elongate from the axial growth of the neural tube and the expansion of the embryo. The entire external and internal contour of the embryo is transformed, producing a total rotation of approximately 150 degrees during of the entire embryogenesis (Fig. 50A.1).

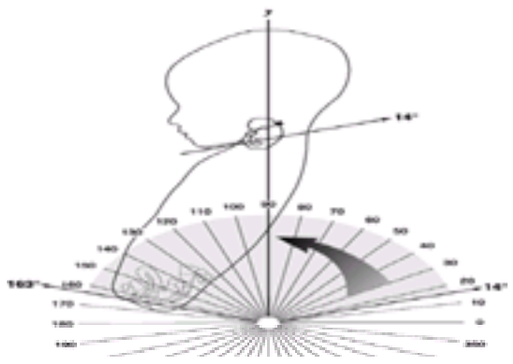

FIGURE 50A.1. Counterclockwise rotation of the embryo as shown through the morphing process. A line through the upper cervical vertebrae (C-1 to C-4; *arrow*) forms the y-axis. An axis during the developing stages was defined by passing from the anus to the urogenital sinus and its angle was measured from the established x-y coordinate system. Starting with the embryo at 29 days of age (angle of 14 degrees), the counterclockwise rotation is completed to an angle of 163 degrees in a term fetus. Total counterclockwise (dorsal) rotation was approximately 150 degrees. (Modified from Paidas CN, Morreale RF, Holoski KM, et al. Septation and differentiation of the embryonic human cloaca. *J Pediatr Surg* 1999;34:877, with permission.)

The urorectal septum thus passively subdivides the cloaca during rotation. Interestingly, the position of the septum with respect to the primitive urogenital sinus and anorectum does not change; it remains static. The apparent decrease in the distance between the tip of the urorectal septum and the cloacal membrane is due to the unfolding process of the embryo, which changes the spatial relationship between the involved structures. Because the urorectal septum does not grow in the direction of the cloacal membrane, the fusion of the septum with the cloacal membrane is never observed. Instead, the cloaca remains until the cloacal membrane ruptures by apoptotic cell death. Eventually, the ventral part of the cloaca will be incorporated into the definitive urogenital sinus (i.e., the vaginal vestibule in the female) (80).

Development of the Genital System, Urethra, and Vagina

The development of the female urethra is closely related to vaginal development. However, our understanding of the embryology of the vagina remains controversial. There are theories that suggest that the vagina is derived from the müllerian ducts (76), whereas others suggest it is derived from the wolffian ducts, the urogenital sinus, or a combination of these structures (45,83). The most generally accepted theory suggests that the superior part of the vagina derives from the fusion of the müllerian ducts and that the inferior part arises from the urogenital sinus; however, this theory assumes the inductor function of the wolffian ducts stimulates adequate müllerian development (6,11,51).

Below the caudal tip of the uterine primordium and above the dorsal wall of the urogenital sinus, a collection of müllerian duct cells forms the müllerian tubercle (1). At this point, the sinovaginal bulb forms as a solid mass between the caudal aspect of the fused müllerian ducts and the dorsal wall of the urogenital sinus to later envelop the müllerian tubercle (Fig. 50A.2A). These cells proliferate to produce a vaginal plate, which elongates to increase the distance between the uterus and the urogenital sinus. The urogenital sinus remains open as the vestibule, into which both the urethra and vagina open. The female urethra, which develops from the more cranial part of the urogenital sinus, is equivalent to the prostatic urethra in the male. The apparent downward growth of the sinovaginal bulb in the direction of the fetal perineum occurs between the tenth and twentieth weeks and has the effect of separating the vagina from the urethra. Later, the central cells of the vaginal plate break down, forming the lumen of the vagina (Fig. 50A.2B).

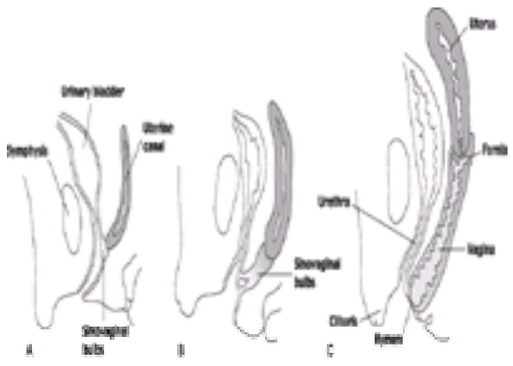

FIGURE 50A.2. A–C: Schematic sagittal sections showing the formation of the distal urethra and vagina at various stages of development. (Modified from Sanders RC, Blakemore K. Lethal fetal anomalies: sonographic demonstration. *Radiology* 1989;172:1, with permission.)

Until late in fetal life, the lumen of the vagina is separated from the cavity of the urogenital sinus by a membrane called the *hymen.* The hymen is formed by invagination of the posterior wall of the urogenital sinus, resulting from expansion of the caudal end of the vagina (Fig. 50A.2C). The hymen usually ruptures during the perinatal period and remains as a thin fold of mucous membrane just within the introitus of the vagina (46). Outbuddings of the most cranial portion of the urethra form the paraurethral (or Skene's) glands in females, whereas homologous buds in the male lead to formation of the prostate. The labial swellings grow posterior and lateral to the vestibule to form the posterior commissure and the labia minora. Bartholin's glands (homologous to Cowper's glands in the male) grow into the labia majora as invaginations of the vestibular endoderm.

The association between the wolffian duct and the müllerian duct is so close that müllerian duct development cannot proceed in the absence of the wolffian duct. However, besides the inductor role of the wolffian ducts on the müllerian ducts, studies have also demonstrated the participation of the wolffian ducts in the formation of the vagina. Bok and Drews (3), using explants of the genital tract of mouse embryos in organ culture at the undifferentiated stage of development, have demonstrated that the sinovaginal bulb observed during the development of the vagina are in fact the caudal segments of the wolffian ducts. This work demonstrates the direct participation of the wolffian duct in the formation of the vagina.

Molecular Approaches to the Mechanisms of the Embryologic Processes of the Caudal Region

The elucidation of the molecular events in the embryologic process of the caudal region in the human embryo is unknown. Differentiation of the caudal region is induced in animals by growth factors, including fibroblast growth factor and transforming growth factor. The Wnt gene family of signaling molecules is also involved in the process (74).

The homeobox gene complex is a phylogenetically well-conserved set of instructions for the longitudinal development of higher animals. There is spatial cephalocaudal organization of the expression of these genes. In humans, the hand-foot-genital (HFG) hereditary syndrome was shown to result from disruption of *Hoxa-13* gene (47). HFG syndrome, which is considered genetically dominant, includes subtle digit abnormalities as well as genital tract malformations of variable expressivity. The most severe defects are found in females and consist of uterine duplication anomalies, abnormal urethra development, and ureteral ectopia (21,73).

Evidence from the mouse indicates that homeobox genes play a role in the mesenchymal development of the genitourinary system (7,82). Using gene targeting experiments, Warot and associates (82) have shown the effects of murine *Hoxa-13* and *Hoxd-13* mutations on morphogenesis of the hindgut and the urogenital tract. Various mutation combinations of *Hoxa-13* and *Hoxd-13* fetuses showed severely impaired development of the urogenital sinus, failure of the distal fusion of the müllerian ducts to form the upper vagina, poor separation of the cloacal cavity into urogenital sinus and rectum, and poor development of the genitalia. These defects exhibited by *Hoxa-13/Hoxd-13* mutant mice presumably result from developmental abnormalities similar to those occurring in HFG patients (82).

ABNORMAL DEVELOPMENT OF THE UROGENITAL TRACT

Numerous theories have been put forth to attempt to explain the various developmental anomalies. Recent observations of the normal embryologic development of the caudal region are in the process of modifying the understanding of the traditional concepts of normal development.

The presentations of the varied urorectal septal defects (i.e., persistent urogenital sinus, persistent cloaca and their associated urinary, reproductive and lower gastrointestinal tract anomalies and communications) reflect the varied degrees of abnormal development and growth of the urorectal septum between the fifth and eighth week of development. The cause or causes of these urorectal septal defects are not known. *In utero* cocaine exposure has been associated with a variety of urogenital anomalies (34). Spinal cord and column anomalies have been associated with urorectal septal defects. These may represent different manifestations of a broader, regional defect in embryologic development. Hartwig and co-workers (23) hypothesized that malformations of the cloaca, abdominal wall, and spinal cord result from a disturbance of the cell deposition process in the caudal end of the fetus.

Cloacal Malformation

A cloacal malformation occurs when there is a common canal into which the bladder, uterus, and rectum empty. Any variation in the arrest of development of the urorectal septum probably reflects the spectrum of anomalies ranging from urogenital sinus to complete persistent cloaca. There is a high incidence of other urologic defects, including vesicoureteral reflux, ureterocele, ectopic ureter, renal agenesis, and uterine and vaginal septations. There may also be associated anomalies of the gastrointestinal tract, the cardiovascular system, and the spinal cord.

Urogenital Sinus

A common drainage outlet of the uterovaginal secretion and urine is present. This condition may be associated with other abnormalities of the urinary tract, such as absence or duplication of the ureters, renal agenesis, or renal ectopia. A urogenital sinus abnormality may also be the result of female pseudohermaphroditism due to congenital adrenal hyperplasia. The abnormality in the role of the urorectal septum and the differentiation of the vesicourethral canal from the true urogenital sinus has yet to be discovered.

In general, any child with anomalous-appearing genitalia, impalpable gonads, and an absent or anteriorly dislocated anus should be suspected of being a female with a urorectal septal defect. It is impossible to predict the internal anatomy from the external examination alone. These patients must be approached as an unknown in whom the spine, urinary, genital, and lower intestinal tracts should be thoroughly and individually assessed. Because these children are at great risk for major complications, this should be done as quickly and expeditiously as possible.

Urethral Anomalies

Congenital anomalies of the urethra are rare in females. Hypospadias may occur but is generally asymptomatic, with only occasional complaints of a sprayed voiding pattern. The urethra and vaginal introitus are common sites of ectopic ureteral orifices. Urethral diverticula are usually acquired phenomena, occurring most commonly with local abscess formation in Skene's glands. They may also occur congenitally in association with blind ending ureters.

Urethral Diverticula

There is no agreement about the nature of urethral diverticula. They have been considered orifices of ectopic ureters or portions of Gartner's duct. Many appear to be infected paraurethral glands or mucosal crypts. Traumatic origin following parturition has been suggested, but about 33% occur in nulliparous women. They are rare in infants and children (17,53).

Developmental Anomalies of the Müllerian Duct System

Various types of uterine duplication and vaginal anomalies result from arrest of development of the uterovaginal primordium during the eighth week: (a) incomplete fusion of the müllerian ducts, (b) incomplete development of the müllerian ducts, (c) failure of parts of one or both müllerian ducts to develop, and (d) incomplete canalization of the vaginal plate (46).

Wolffian Duct Remnants

By the seventh week of gestation, the wolffian ducts begin to degenerate in the female fetus. The degeneration is never complete, however, and a number of structures persist to various degrees. The remnant may persist in females as a thin cuboidally lined nonsecretory system parallel to the fallopian tube in the broad ligament. Tubules in the lateral portion of the broad ligament are referred to as the *epoophoron,* and those more medially are known as the *paroophoron.* Benign cysts occasionally arise from these structures but usually are of no clinical significance. The caudal extent of the regressing wolffian duct lies within the muscular wall of the cervix and vagina. Cystic lesions of varying size may form in these sites in up to 1% of the women and are referred to as *Gartner's duct cysts.* These cysts are typically asymptomatic and benign, although they may cause symptoms such as dyspareunia or irritative voiding symptoms.

Anatomy

The female urethra in the adult averages about 4 cm from the bladder neck to the vaginal vestibule. The epithelial lining changes from transitional to nonkeratinized stratified squamous epithelium as the urethra extends from the bladder neck to the urethral orifice. A series of small mucous glands opens into the urethra. Distally, these glands group together on either side of the urethra as Skene's glands and empty through two small ducts to the urethral meatus. The layers of the submucosa of the distal urethra form a cushion that contributes significantly to urethral closure pressure. These layers are estrogen dependent. A thick layer of inner longitudinal smooth muscle continues from the bladder to the external meatus to insert into periurethral fatty and fibrous tissue. There is no circular smooth muscle sphincter within the female urethra. A rather thin circular smooth muscle envelops the longitudinal fibers throughout the length of the urethra. The striated urethral sphincter in the female invests the distal two-thirds of the female urethra (4,50). Contraction of these fibers (the compressor urethra) closes the urethra against the fixed interior vaginal wall. Near the vaginal vestibule, the fibers completely surround the urethra and vagina to form a urethral vaginal sphincter. Contraction of this muscle group, along with bulbospongiosus, tightens the urogenital hiatus.

The suspensory ligament of the clitoris (anterior urethral ligament) and the pubourethral ligaments (posterior urethral ligament) form a sling that suspends the urethra beneath the pubis. There is apparently little sympathetic innervation in the neourethra. Parasympathetic cholinergic fibers are found throughout the smooth muscle. It is thought that the longitudinal smooth muscle of the urethra contracts coordinately with the detrusor during micturition to shorten and widen and therefore open the urethra (4,16).

The perineum lies between the pubis, thighs, and buttocks and is limited superiorly by the levator ani. Seen inferiorly, the symphysis pubis, the ischial tuburosities, and coccyx line the diamond shape of the perineum. The inferior ischiopubic rami and sacrotuberous ligaments form its bony ligamentous walls. A line drawn from the ischiotuberosities divides the perineum into an anal and a urogenital triangle. In the female, the vestibule of the vagina runs vertically throughout the length of the urogenital triangle (Fig. 50A.3).

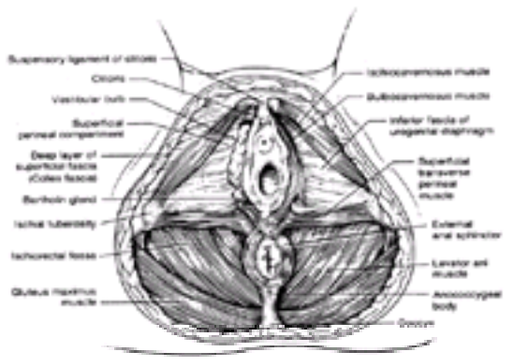

FIGURE 50A.3. The female perineum. Note the ischiocavernosus and bulbospongiosus and their relationship to the vagina and urethra. (From Danforth DN, et al, eds. *Danforth's obstetrics & gynecology.* Philadelphia: Lippincott Williams & Wilkins, 1999, with permission.)

The structure of the superficial pouch in the female is similar to that in the male. The crura of the clitoris attach to the inferior ischiopubic rami. They are surrounded by the ischiocavernosus muscles and converge to form the body of the clitoris. The vestibular bulbs lie to either side of the vaginal vestibule covered by the bulbospongiosus muscles. As homologues of the corpora cavernosus, they are composed of erectile tissue that meets anteriorly at the glans of the clitoris. The vestibular glands are deep to the vestibular bulbs and, unlike the bulbourethral glands in the male, are superficial to the perineal membrane. Their ducts travel to open in the vaginal vestibule on the either side of the labia minor.

History in the Female with a Urethral Anomaly

A large number of the children are referred with voiding complaints. The ability to place children in categories based on the voiding history will help focus the rest of the evaluation and guide further therapy. The time and duration of the voiding disorder must be identified early in the interview. Did symptoms begin before or after toilet training? Is wetting associated with pain, urgency, or frequency? What is the character of the voiding? Is the urinary stream steady from beginning to end, or is it a “staccato” or stop-and-start pattern suggestive of dysfunctional voiding? Are the symptoms worse at a particular time of the day? Does the child void frequently during the day yet sleep through the night without wetting? Is wetting confined to the nighttime, which is suggestive of primary nocturnal enuresis?

The voiding history is incomplete without a record of the child's eating and drinking pattern. Does the child consume small amounts of water during the day and large amounts of alternative liquids such as soft drinks and juices, which tend to be laden with salt and sugar and low on free water? What is the stooling pattern? Does the child have firm, chunky, or pebblelike bowel movements, which are suggestive of a retentive pattern of stooling or does the child have soft, well-formed bowel movements more suggestive of a normal stooling pattern? Very few children hold the urine and not the stool. Conversely, children who retain stool nearly always retain urine. All of these are indicators of a dysfunctional voiding pattern, which may lead to urinary tract infection.

Occasionally, children are referred with symptoms with history of “urethral discharge or vaginal discharge.” Perineal pain or urethral discomfort may be associated with constipation, bladder holding, or vaginal irritation associated with leakage of urine into the vagina with secondary inflammation. A careful history will help elucidate these symptoms and separate urinary from vaginal abnormalities.

Examination of the Female Perineum

The perineal examination in the female is similar to that in the male. In a teenaged girl, the examination should be performed in the absence of the father but may be performed with the mother present, as long as the adolescent agrees. In general, bimanual examination in an adolescent is best performed in the operating room. The girl is placed in a frog-leg position or in a knee–chest position. The clitoris is examined for evidence of hypertrophy, which may be suggestive of an intersex condition. Gently spreading the labia majora in an inferior direction will allow inspection of the clitoral area and usually the introitus. The vestibule is assessed for any evidence of discharge. An easy way to examine the perineum is to gently grasp the labia majora and pull inferiorly. This maneuver tends to better define the various perineal folds and provide for a consistent examination in nearly all cases. The hymen and introitus should be inspected. An imperforate hymen may result in hydrometrocolpos and a lower abdominal mass. In older girls, a small speculum may be used to evaluate the cervix and interior of the vagina. Palpation of the vaginal walls and cervix and bimanual examination of the uterus complete the examination. Having the child perform the Valsalva maneuver may allow adequate assessment of the introital vaginal area. Vaginal discharge is often associated with vaginal voiding and is particularly common in children who hold the urine and subsequently dribble urine into the vagina. Treatment of dysfunctional voiding results in reduced vaginal drainage. Vaginal bleeding in the preadolescent may result from foreign bodies such as wadded toilet paper trapped in the vagina. Occasionally, other foreign bodies may have been inserted intentionally or accidentally.

Blunt injury to the perineum may result in hematoma beneath the perineal skin. The presence of hematoma or contusion alone does not usually require treatment. Penetrating injuries of the vaginal area warrant further careful evaluation, including radiologic evaluation of the urethra and bladder. Benign and malignant tumors of the vaginal area should be considered when vaginal bleeding occurs in young girls. A broad spectrum of entities, including from capillary hemangioma, rhabdomyosarcoma, neuroblastoma, or carcinoma, may be associated with vaginal bleeding. Labial masses may be associated with hernia or hydrocele of the canal of Nuck (37). Adhesions of the labia minora are common. In most cases, they are not symptomatic. Occasionally, a girl with labial adhesions will complain of vaginal irritation from pooled urine. If not separated, the irritation may progress to irregular voiding, which may exacerbate the problem. In some girls, a short course of estrogen creme applied to the labia may be effective. In many, however, separation of the adhesions in the office with local anesthetic creme may be required. Following separation, the child or her mother must apply a barrier ointment within the labia minora to prevent recurrence until the inflammation of the labial membranes has resolved. Labial fusion may be associated with congenital adrenal hyperplasia, gonadal dysgenesis, or cloaca. A genitosinogram is indicated when the urethra cannot be distinguished from the vaginal orifice.

It is absolutely critical to visualize the urethral meatus during the female examination. Incomplete visualization of the urethra, particularly in a small child, may result in inadvertent catheterization of the cervical os (64).

CONGENITAL ANOMALIES OF THE FEMALE URETHRA

Periurethral Masses

Two different types of periurethral masses can be commonly seen in the infant girl. The paraurethral or Skene's duct cysts may be present just lateral to the urethral meatus. In most cases, these present as a white or yellowish swelling of the orifice of Skene's duct that usually displaces the urethral meatal wall medially (Fig. 50A.4). These may resolve on their own over the first few months following birth. In some cases, needle aspiration of the cyst with incision of the superficial membrane may be therapeutic (40).

FIGURE 50A.4. Paraurethral (Skene's duct) cyst in a 1-year-old girl. (Photo courtesy of Dr. Terry Hensle.)

As the wolffian ducts begin to degenerate in the female by the seventh week of gestation, a number of structures may persist to various degrees. A “Gartner's duct cyst” may develop if the wolffian duct persists as a blind-ending limb, usually ending along the lateral margin of the anterior wall of the vagina. The cysts are usually asymptomatic but may result in dysuria. In most cases, a Gartner's duct cyst is found in prepubertal girls in association with an ectopic ureter that is blind ending and is proximal or one that is connected to a rudimentary dysplastic kidney (27). These have been identified prenatally with sonography (70) and with magnetic resonance imaging and can achieve considerable size (20). Although Gartner's duct cysts may displace the bladder neck and result in bladder outlet obstruction (48), most are small and rarely affect voiding. The diagnosis of the cyst is deduced from the location of the cyst on the inferior lateral wall of the vagina, usually near the upper end. No treatment is required for small asymptomatic cysts. Large cysts, however, may protrude through the introitus and may cause local discomfort or difficulty with voiding. Transvaginal marsupialization or perineal marsupialization may be performed for large symptomatic cysts. Rarely, a large Gartner's duct cyst may displace the distal ureter upward over the cyst wall. This may occur in cases of a duplex ureter where the upper pole is dysplastic or absent. In these cases, obstruction of the lower-pole moiety may occur. Occasionally, these systems may require removal. This can be performed through a paravesical or intravesical procedure with or without reimplantation of the associated ureter.

Ureteroceles are covered in more detail in Chapter 48; however, a brief discussion in this chapter is warranted because a ureterocele that prolapses through the bladder neck may present as a mass at the introitus in an infant girl (Fig. 50A.5). Treatment includes incision and drainage in the newborn period and subsequent reconstruction or removal of the ureterocele and the associated upper-pole ureter and kidney. In many cases, however, particularly if the ureterocele is thin walled, the incision may provide a definitive therapeutic result (19). Single-system ureteroceles that prolapse are extremely rare in girls. A prolapsing uterocele that extends through the bladder neck and the urethra and presents as a vaginal mass in girls is also relatively uncommon. In most cases, this mass can be distinguished from other intralabial masses (e.g., rhabdomyosarcoma, urethral prolapse, hydrometrocolpos, periurethral cysts) by its location at the lateral wall of the introitus or along the posterior lateral wall of the urethra (30).

FIGURE 50A.5. Prolapsed ureterocele in a 3-year-old girl. (Photo courtesy of Dr. Terry Hensle.)

Urethral Duplication

Complete duplication of the bladder and urethra is rare and particularly rare in females. In most cases, duplication of the bladder involves two bladder halves, each with a full-thickness muscular wall and each with its own associated urethra. An accessory urethra in the female is also rarely found communicating with the urachus (41). The cause of the condition is unknown, and the malformation varies so widely from case to case that it is unlikely that the same embryologic explanation can apply to all cases (61). In one report of three girls with complete duplication of bladder, urethra, vagina, and uterus, the associated anomalies were different in each child. The first had a symphysis diastasis creating an abdominal hernia, with two bladders dislocated into this space. The second had an anal atresia with colon duplication, and the third had cloacal exstrophy with one open bladder and a second closed with persistent urogenital sinus. Treatment is individualized but generally involves preservation of the ureterovesical attachments with anastomosis of the bladder or urethra as appropriate with excision of redundant tissue (12).

Urethral Atresia

An association between urethral atresia and prune-belly syndrome in females has been recognized, but few reports discuss the outcome of treatment in these gravely ill infants (65). Of 34 patients with prune-belly syndrome noted at the University of Minnesota, 6 had urethral atresia, 3 of these were female. Half of these patients died in the newborn period. Of the three surviving infants, all had vesicocutaneous fistula. As neonates, two suffered from pulmonary insufficiency due to oligohydramnios. Most of these children will come to renal transplant due to severe renal damage that occurred in the neonatal period. However, in at least one case, normal renal function followed decompression of the urinary tract. In males, progressive catheter dilation has been used with reasonable success and would be similarly affective in males (66).

Urethral Stricture

Urethral stricture or stenosis in the female was considered much more common in the past than currently. The “spinning top” urethra (Fig. 50A.6) was initially believed to be an indication of distal urethral narrowing or stenosis is probably more the result of bladder instability and discoordinate voiding than a true stenosis. In the past, when a voiding cystourethrogram (VCUG) demonstrated urethral narrowing distal to the bladder neck during voiding, it was assumed that bladder neck obstruction was the cause (9). It was believed that the urethra was wide because of poststenotic dilation or that habitual voluntary contraction of the striated sphincter resulted in dilation of the segment of the urethra between the urethral meatus and the bladder neck. Following Y-V advancement of the posterior bladder neck, or urethral dilation, as many as 50% of patients were improved. Subsequently, Kaplan and associates (35) compared urethral dilation, internal urethrotomy, and antibiotic prophylaxis in girls with urinary tract infections and found no significant differences in treatment results. The spinning top urethra probably results from a tendency for the female to hold the urine from time to time during development and normal toilet training. The most recent studies suggest that the spinning top urethra may indicate bladder instability in some girls, but bladder instability in “staccato” or intermittent voiding with dysfunction cannot be identified in all girls with an apparent dilation of the proximal urethra. The finding of a spinning top urethra on the VCUG should alert the examiner to functional disorders of the lower urinary tract. However, if no instability can be found with a thorough physical examination and appropriate testing, spinning top urethra should probably be considered a normal variant (24). From a practical standpoint, when we are evaluating girls with urinary tract infections or voiding disorders, we look for the spinning top urethra, and if that is combined with incomplete voiding or significant symptoms, we will enroll these children in biofeedback treatment. It is not known whether urethral dilation is any more effective than training for dysfunctional voiding and may in fact be harmful (22). There is rare indication for urethral dilation in the female child today.

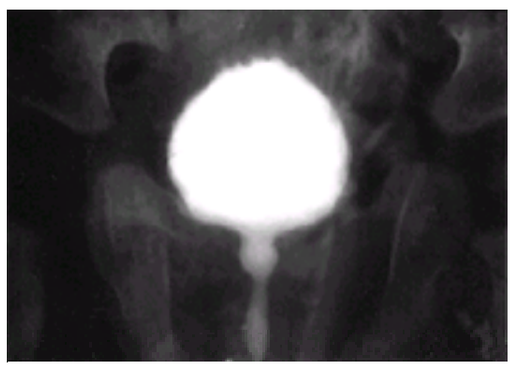

FIGURE 50A.6. “Spinning top” urethra in a 6-year-old girl with recurrent urinary tract infections and wetting. Note dilation of the proximal urethra during voiding.

Urogenital Sinus

A *urogenital sinus* is a common channel into which both the urethra and genital tracts open. There is a wide spectrum of urogenital anomalies caused by lack of development of the urogenital sinus derivatives. The common urogenital sinus is a normal stage of embryonic development in both sexes. Although many of these cases are associated with intersex, others are more characteristic of anorectal anomalies following agenesis of Rathkes plicae and failure of migration of müllerian ducts to the vestibule (72). With ambiguous genitalia, masculinization of the perineum results in closure of the urethral folds distal to the introitus, resulting in an abnormal development of the urethra in the female. Conversely, a urogenital sinus in the absence of ambiguous genitalia occurs as a result of defective caudal migration of Muller's ducts and failure of the distal sinus to evert. In the normal female, an arrest in the development of the müllerian ducts at 9 weeks of gestation after they have been fused with the urogenital sinus can manifest as a urogenital confluence or common urogenital sinus. The variations of the common urogenital sinus as a normal stage of embryonic development occur as a result of arrest and development of the müllerian ducts at 9 weeks of gestation after they have fused with the urogenital sinus. Early arrest may lead to a long urogenital sinus with a short vagina and a high urethral opening. A low or short urogenital sinus occurs with an almost normal vaginal vestibule and low urethral orifice if the arrest occurs late in development (Fig. 50A.7). Early, more severe defects are often associated with anterior placement of the rectum along the continued spectrum toward the cloaca (26).

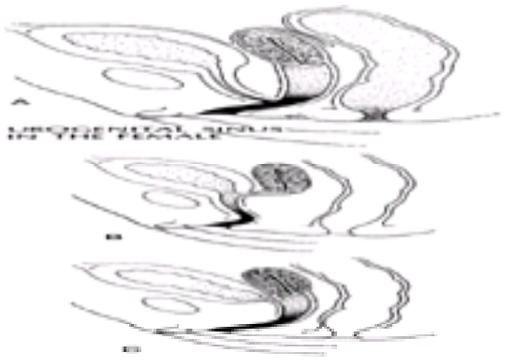

FIGURE 50A.7. A: Urogenital sinus anomaly. **B:** High or early arrest of the müllerian ducts results in short vagina with high confluence of the urogenital sinus. **C:** Low or late arrest of the müllerian ducts results in longer vagina with low confluence.

Ultrasonic suspicion of hydrometrocolpos in the fetus may represent indirect evidence of a persistent urogenital sinus or cloaca. On physical examination, the persistence of a urogenital sinus is usually obvious in that the vaginal opening and urethral opening are not distinct. Anterior displacement of the anus may also be present. Absence of the anus in cases of persistence of the cloaca or enlarged clitoris and rugated labial folds in cases of intersex is characteristic findings. Excluding the intersex cases that are covered in Chapter 52, the goals in the evaluation of the child with a urogenital sinus include assessment of the anatomy and detection of associated anomalies within the wolffian and müllerian systems (15).

In the newborn, a thorough abdominal examination with particular attention to palpation of the kidneys, bladder, and uterus may yield clues suggestive of the internal anatomy. A mass superior to the bladder or a palpable uterus may suggest hydrocolpos. A genitourinary sinogram to identify the point of confluence between the urethra and vagina will be important for surgical planning (Fig. 50A.8). It also often provides information about the internal müllerian anatomy. Laparoscopy and exploratory laparotomy with or without biopsy of the gonads may also be important. Ultrasonography should be an initial study to identify the presence or absence of significant hydrometrocolpos. Stabilization of the infant may require temporary tube drainage of the dilated bladder or vagina while awaiting definitive repair. If the urogenital sinus is short but stenotic, dilation alone may be effective as an adjunct to tube drainage of the uterus and vagina. This may be required regularly. Careful monitoring with ultrasound and frequent examinations are required to ensure effective drainage to prevent urinary tract infection and sepsis.

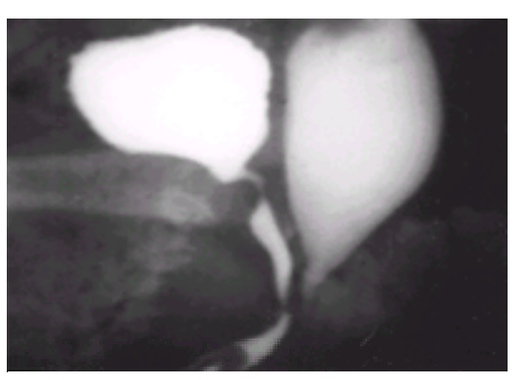

FIGURE 50A.8. Genitourinary sinogram in a newborn girl with 21-hydroxylase deficiency and a low confluence of the urogenital sinus. The urethra meets the vagina at a point only 2 cm from the perineum. This child underwent posterior flap reconstruction. In a child with a more anteriorly placed anus, anterior sagittal transrectal advancement of the urogenital sinus would be more appropriate.

Surgical Management

The surgical management of urogenital sinus and cloacal anomalies has been simplified considerably thanks to the work of innovative specialists who have focussed on anorectal disorders and their application to the urogenital sinus (25,32,54,57,59,60). If a simple urogenital sinus is shorter than 3 cm (Fig. 50A.9), the entire urogenital sinus may be mobilized and advanced as a unit to the perineum. If the urogenital sinus is extremely short, a simple U-flap vaginoplasty will be effective. However, in most cases, the perineal body is shortened because of the anterior placement of the anus that tends to minimize the available tissue with which to support a posteriorly based flap.

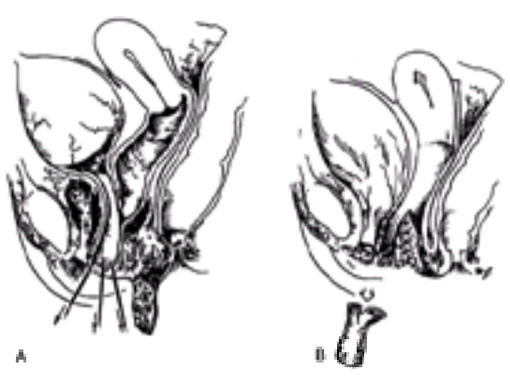

FIGURE 50A.9. When the urogenital sinus is less than 3 cm, the urethra and vagina may be mobilized as a unit through a posterior approach. **A:** A posterior inverted U-flap with the apex at the level of the opening of the sinus is outlined. Alternatively, a midline incision from the anal verge to the sinus may be used. The incision is continued around the orifice of the urogenital sinus, and the dissection is carried superiorly to the prevesical space anteriorly and to the peritoneal reflection posteriorly. **B:** The sinus is pulled down and excised. The posterior vaginal wall is incised to accommodate the flap. Alternatively, the posterior sinus may be incorporated into the repair as augmentations of the labia minora. Separate vaginal and urethral openings are created in the vestibule. (From Gonzalez R, Barthold JS. Urogenital sinus and cloaca. In: Gonzales ET, Bauer SB, eds. *Pediatric urologic practice.* Philadelphia: Lippincott Williams & Wilkins, 1999:676, with permission.)

If the urogenital sinus is between 1 and 3 cm in length, either mobilization via a perineal flap may be made or the anterior sagittal transrectal approach (ASTRA) may be used (8).

The patient is placed in the prone position with the pelvis elevated (Fig. 50A.10). The incision extends from the middle portion of the sacrum through the anus and the perineum and down to the urogenital sinus opening. The entire sphincter mechanism of the rectum and anus may be divided, or alternatively, only the anterior rectal wall is opened along with the perineum from a point from the anterior anal verge to the posterior margin of the labia majora (8). An electrical stimulator helps determine where the midline is by checking the magnitude of the muscle contraction on both sides. The perineal fat also is divided; the posterior wall of the urogenital sinus is identified and opened. Rather than mobilizing the vagina from the urethra, as had been done in the past, because the urethra and vagina share a common wall, in a urogenital sinus shorter than 3 to 4 cm, the vagina and urethra are advanced as a unit to the perineum.

FIGURE 50A.10. Anterior sagittal transrectal approach to the urogenital sinus. **A:** An incision is made from the anal verge to the posterior margin of the labia. **B:** Incision is deepened on the midline through the perineum (and if necessary through the anterior wall of the rectum) to expose the urogenital sinus. **C:** Holding sutures are placed along the site of anastomosis. **D:** Margins are exposed and closed **(E, F)** in two layers of anterior vaginal (urogenital sinus) wall. Posterior wall of vagina **(G)** and rectum **(H)** are closed. (From Domini M, et al. Recurrent posttraumatic urethro-vaginal fistula: a new application for ASTRA. *J Pediatr Surg* 1999;34[12]:1865, with permission.)

This procedure may be done in infants as young as 4 months of age, and in our experience, it may be easier in the younger child because the distance for mobilization is shorter before the child has grown significantly linearly. In this technique, the goal of the treatment of the urogenital sinus is to create a urethral opening separate from the vaginal opening (56). Multiple sutures are placed in both edges of the open urogenital sinus in the vagina and along the vaginal edges. These sutures are used to exert traction and to allow dissection and mobilization of the entire urogenital sinus. There is a natural plane of separation between the urogenital sinus and the posterior aspect of the pubis. After dissecting the urogenital sinus away from the pubis, the suspensory ligaments are divided and an average of 3 cm of length is gained with this advancement. The dissection is carried circumferentially, and the urogenital sinus tissue is sutured back on itself to provide and extend the labial minoral folds. Considerable operative time is saved if the urethra is allowed to remain intact as a unit with the vagina. In addition, the risk of urethral stenosis or vaginal stenosis as a result of ischemic loss of the tissue is minimized.

If there is a long common channel, additional techniques must be used to complete the separation of the vagina from the urinary tract. The vagina must be separated from the urethra. In many cases, however, this maneuver is facilitated after mobilization of the urethra and vagina. Separation after total mobilization will allow the vagina to be brought down as a unit to the perineum following closure of the posterior urethra.

When the urogenital sinus is longer than 4 cm, after the initial posterior approach, the posterior sagittal wound is packed and the patient is turned to perform a midline laparotomy. The bladder is opened in the midline, and feeding catheters are placed into the ureters to protect them during the separation from the vagina and the bladder. Because the ureters pass through the junction between vagina and bladder, there is significant risk of injuring the ureters during the separation of the vagina from the bladder, hence the need for the catheters. The bladder is then mobilized anteriorly as the vagina and uterus are separated from the bladder base posteriorly. In many cases, there are two hemiuteri and hemivaginas. If one is particularly small, it may be removed at this point. If the presence of hydrocolpos required vaginal or uterine drainage early in the baby's life, significant scarring may be present, which may further impede an easy dissection. With a combined inferior and superior dissection, the vagina may then be mobilized and brought to the perineum in most cases. If the vagina is particularly small or high, vaginal replacement with intestine may be indicated. In these cases, sigmoid colon may be used, but a segment of small bowel that has been reconfigured may also be appropriate (55,59).

In practice, the urogenital sinus is usually short enough to allow for an ASTRA or an anterior approach that does not open the anterior rectal wall. When the rectum must be opened and in nearly all cases when a combined anterior and posterior approach must be used, a protective colostomy is used. Following mobilization of the vagina from above, the perineal orifices are then brought to the perineum and sutured in place with absorbable suture. If a bowel interposition is used, it is important not to bring the colon all the way to the skin's surface but to use perineal flaps to prevent an unsightly appearance (15).

Cloacal Anomalies

A cloaca exists when the rectum, vagina, and urinary tract meet and fuse into a single common channel. This group of defects appears in the female as a separate spectrum of malformations of anorectal anomalies.

The length of the common channel varies from 1 to 12 cm. If a short channel is present (less than 3 cm), a well-developed sacrum and favorable neurologic and muscular function to the levator ani complex will likely be present. A longer channel, however, indicates a more complex defect with a poor sphincter mechanism and an abnormal sacrum. The rectum and vagina share a common wall, as do the vagina and urethra (Fig. 50A.11). In more than 50% of these cases, the vagina is partially obstructed and filled with mucous secretions (hydrocolpos). As in the case of urogenital sinus, variations exist, which may suggest severity of the defect and fetal age at failure of the müllerian ducts and urorectal septum to complete (Fig. 50A.11). Approximately 50% of the time a duplicated vagina and uterus are present. This may be manifest by just a septum between the two vaginas or two completely separated structures. A distended vagina will often compress the trigone and lead to hydroureteronephrosis (57).

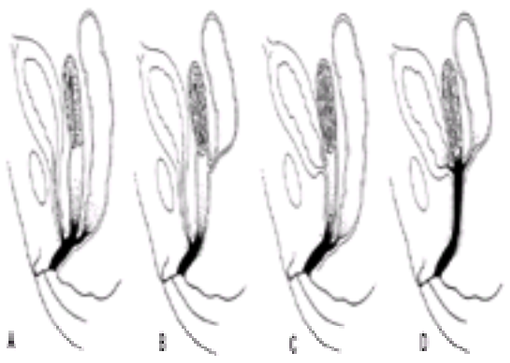

FIGURE 50A.11. A–D: Various forms of cloacal anomaly. Longer cloacal segments (higher confluence of urethra, vagina, and rectum) are associated with higher risk of urinary and rectal incontinence. (From Hensle TW. Genital anomalies. In: Gillenwater JG, et al, eds. *Adult and pediatric urology.* St. Louis, Mosby, 1996, with permission.)

Associated Defects

In persistent cloaca, there is a 90% frequency of associated urogenital defects (67). Hydronephrosis, urosepsis, and metabolic acidosis with poor renal function represent the main sources of mortality in neonates with anorectal malformations. Other malformations include esophageal atresia, duodenal atresia, and cardiovascular defects, especially tetralogy of Fallot. The sacral anomalies correlate with the degree of functional prognosis. More than two absent sacral vertebra represent a poor prognostic sign.

The presence of a single perineal orifice is pathognomic of a cloaca. These patients have a typically phallic-looking structure with flattened labioscrotal folds. The proboscis of tissue has no erectile bodies present. The single opening of the cloaca may be at the base of the phallus or can be channeled to the tip. There may be some rudimentary glans tissue. Rarely, these children inappropriately are designated males at birth. A feminizing genitoplasty is required later.

Once the diagnosis is made, abdominal ultrasound is carried out. This often shows hydroureteronephrosis. At this point, a catheter with a coude tip may be passed into the bladder and a cystogram performed. The catheter often will be directed into one of the dilated hydrocolpos and give a false impression of a bladder. Double-contrast studies, such as iodinated contrast in the bladder with air in the vagina, will often delineate the two chambers.

SURGICAL CORRECTION

Colostomy

A colostomy must be performed after the genitourinary evaluation. When significant urologic problems are present, a divided colostomy is more appropriate than a loop colostomy (Fig. 50A.12). This prevents contamination into the urinary tract with feces spilling into the distal limb of the colon.

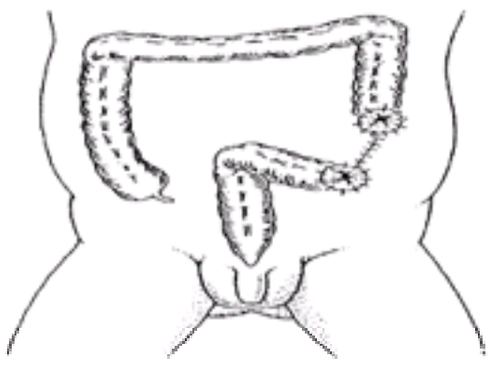

FIGURE 50A.12. The colostomy: The proximal stoma is placed at the supero **l** ateral margin of the wound. The mucous fistula is opened minimally to prevent prolapse and taken to the inferomedial margin of the wound. (From Pena A. Anorectal anomalies. In: Spitz L, Coran A, eds. *Rob and Smith's operative surgery.* London: Chapman and Hall Medical, 1995, with permission.)

Cystoscopic evaluation of the urogenital sinus with dilation of the vaginal openings into the urogenital sinus may provide adequate drainage of the mucus in the hydrocolpos if the vaginal introitus is low and the stenotic segment is short. Urine may be voided from the bladder into the vagina with stasis, which often leads to urinary infection and sepsis. A urethral sound passed posteriorly often will dilate the membrane that deflects the urine into the vaginas. It may be appropriate to perform a vesicostomy at the time of the colostomy to drain the urinary tract effectively.

Recovery after colostomy and appropriate urinary diversion is usually uneventful. The final repair of this defect is a posterior sagittal anorectovaginourethroplasty, which is usually performed at 4 to 6 months of age.

Before the definitive repair, a distal colostography is carried out with water-soluble contrast. This identifies the precise site of the rectourinary fistula located in the most distal part of the rectum. Sometimes, considerable hydrostatic pressure will be required to fill out the distal colon and locate the fistula. This may be done with a Foley catheter, inflating the balloon and applying distal pressure. This will overcome the muscle tone of the striated muscles surrounding the rectum (58).

Posterior Sagittal Anorectal Plasty

In posterior sagittal anorectal plasty (PSARP), the patient is placed in the prone position with the pelvis elevated (Fig. 50A.13A). Electric stimulation elicits muscle contractions throughout the operation so that no paralysis is used with anesthesia. A long incision starting at the middle of the sacrum extends anteriorly to the single perineal orifice. The anatomic relationship of the rectum to the genitourinary structures is complex. When all muscle structures have been divided in the midline, the rectum can be seen, as can the sphincter fibers of the external anal sphincter.

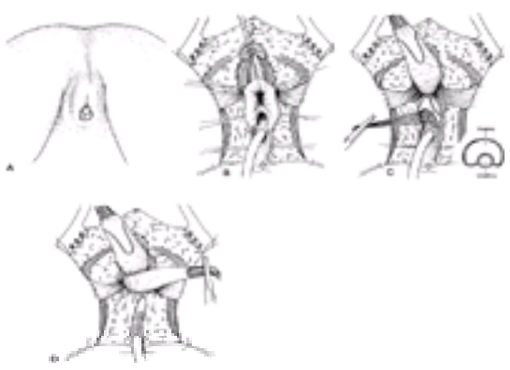

FIGURE 50A.13. A: Usual positioning for posterior sagittal anorectal plasty. **B:** Muscles have been separated carefully at the midline using electrostimulation to identify the appropriate incision line. Carefully placed sutures help separate the opened rectum from the sinus. The plane must be initially made in the common wall between the rectum and vagina; there is no definite line of dissection at this level. Catheter is in the urethra. **C:** The vagina surrounds the urethra for a variable distance. If the vagina is high and the channel is longer than 3 cm, vaginal elongation will be necessary to prevent injury to the vagina or urethra from overzealous dissection. **D:** In cases of common channels of less than 3 cm, the urethra is reconstructed using the whole common channel. (From Pena A. Anorectal anomalies. In: Spitz L, Coran A, eds. *Rob and Smith's operative surgery.* London: Chapman and Hall Medical, 1995, with permission.)

The urogenital sinus is incised posteriorly up to the confluence of rectum/vagina. Traction sutures are carefully placed on the rectal wall and lifted superiorly so that the three openings can be identified. A catheter is in the bladder (Fig. 50A.13B). The rectal wall is separated from the vagina, and the vagina is separated from the bladder neck area and urethra (Fig. 50A.13C). The urethra can be extended out to the perineum by rolling a tube of the urogenital sinus (Fig. 50A.13D).

The vagina surrounds the urethra and the bladder neck for approximately 2 to 3 cm of the dissection (Fig. 50A.13C, inset). This dissection must be carried cranial enough to mobilize the vagina to reach the perineum without injury to the blood supply of the bladder neck and vagina.

If the length of the cloaca is less than 3 cm, a similar technique to that used in the medium-sized urogenital sinus may be used to repair the cloaca (56). In these cases, following separation of the rectal wall from the vagina, no attempt is made to separate the vagina from the urinary tract; rather, the entire urogenital sinus is dissected and mobilized as a unit. A well-defined fat-containing space anterior to the urogenital sinus separates the sinus from the pubic symphysis. A dissection can be made along this space to reach the retropubic space. Traction is then exerted on the vaginal edges as the dissection continues in a circumferential manner to include the vagina and urethra. In this way, the two structures are separated from the rectum and advanced together. The common channel of the urethra and vagina is then mobilized, and the dissection continues circumferentially around the lateral and posterior walls of the vagina and the anterior wall of the bladder and urethra until enough length has been gained to connect the vaginal edges to the perineum. Thus a urethral and vaginal opening of near-normal appearance is accomplished. The vaginal and urethral edges are sutured to the skin and become a urogenital sinus channel that may be used to augment the labia minoral tissue.

For a urogenital sinus longer than 3 cm, some form of vaginal elongation or replacement should be chosen; otherwise, overzealous dissection may result in devascularization and urethral injury. Vaginal replacement can be done with a segment of small intestine with preservation of its mesentery. After the end-to-end anastomosis of the small intestines, the upper segment of a small bowel segment is connected to the upper vagina while the lower part comes to the perineal skin (Fig. 50A.14).

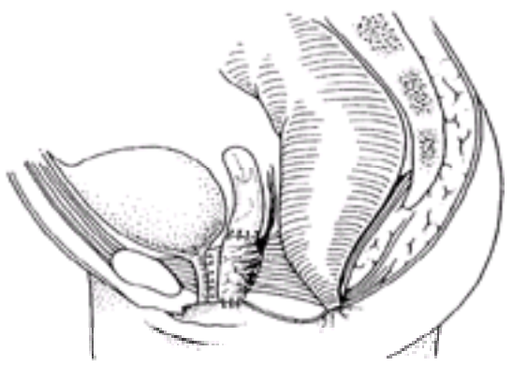

FIGURE 50A.14. When a long channel exists, a segment of intestine is used to bridge the defect from the high vagina and the perineum. (From Pena A. Anorectal anomalies. In: Spitz L, Coran A, eds. *Rob and Smith's operative surgery.* London: Chapman and Hall Medical, 1995, with permission.)

Two large hemivaginas divided by a midline septum may provide enough vaginal wall to reach the perineum. This can be done by removing the rudimentary uterus on one side and rotating the vagina from that side down into the perineum, dividing the septum in between (55). The perineum is reconstructed in such a way that there is a perineal body between the vagina and the new anus. The rectum is tapered so as to locate it into the internal and external sphincter complexes, which can be readily seen from the careful posterior sagittal dissection. The incision is closed carefully to reapproximate the sphincter muscles.

Postoperative Bowel Management

Two weeks after the procedure, anal dilations are started twice daily by the parents. Once the desired rectal size is reached, the colostomy is closed. For a period of time, frequent bowel movements are a problem, but this pattern usually improves by 6 months after closure of the colostomy. If the baby has one to three bowel movements each day and remains clean between bowel movements, this indicates that there is feeling during the defecation process and, in general, a good functional prognosis. On the other hand, if stool is passed constantly, colonic irrigations must be instituted for cleansing purposes. Constipation may become the major postoperative problem. Some patients will benefit from the antegrade colonic enema program (ACE). A cecal attachment to the skin, either through the appendix or through a tubularized portion of cecum, permits the patient to catheterize the stoma and irrigate the colon. This situation is usually preferred by the patient to a high rectal colonic irrigation (18,44)

Neurogenic Bladder

If sacral anomalies occur or if the urogenital sinus is greater than 3 cm in length, it is likely that bladder function may be impaired. A plastic catheter can be used for intermittent catheterization in the postoperative period to manage urinary drainage intermittently. A coude tip may be helpful. In a more inclusive report of 1,192 patients from a single series with anorectal malformations, 75% of all have voluntary bowel movements yet urinary incontinence is relatively common after the repair of cloacae (60). Most patients will require intermittent catheterization to empty the bladder completely, and many will require augmentation cystoplasty to provide for adequate compliance of the bladder to preserve low-pressure storage.

ACQUIRED LESIONS OF THE FEMALE URETHRA

Urethral Prolapse

Urethral prolapse is relatively common, particularly in African-American females. The prolapse is through the meatus, forming a hemorrhagic, often sensitive mass that bleeds with palpation or with contact of the undergarments (Fig. 50A.15). Girls may have difficulty with urination, depending on the size of the prolapse and whether it includes the urethral meatus. Urethral prolapse may respond to topical application of estrogen and may be managed expectantly as long as voiding is normal (64).

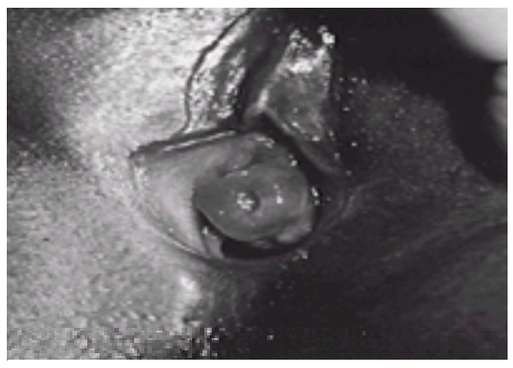

FIGURE 50A.15. Urethral prolapse in a 7-year-old African-American girl. (Photo courtesy of Arnold Colodny, M.D.; from Smith GHH, Duckett JW. Urethral lesions in infants and children. In: Gillenwater JG, et al, eds. *Adult and pediatric urology.* St. Louis: Mosby, 1996, with permission.)

Multiple etiologies have been proposed to describe urethral prolapse. It may be due to excessive urethral mobility, excessive mucosal redundancy, increased abdominal pressure, infection, neuromuscular deficiency, or poor attachment between the muscle layers of the urethra (42). Vaginal bleeding is normally the first symptom, but vaginal discharge or perineal discomfort may also be prominent symptoms. On physical examination, there is characteristic circumferential prolapse of the mucosa. The differential diagnosis includes urethral caruncle or papilloma, urethral polyps, prolapsed ureterocele, sarcoma, botryoides (rhabdomyosarcoma), and periurethral abscess.

An ultrasound of the bladder and upper tracts is needed if there is question about the presence of ureterocele or sarcoma (69). Conservative treatments with estrogen cream can be successful in as many as half of the patients. The rest require excision of the prolapsed lesion. Before excision, cystoscopy is performed, and infiltration of the lesion with 1% lidocaine and 1 to 100,000 epinephrine reduces bleeding during the excision (10,68,77).

Urethral Polyps

Urethral polyps in girls are rare but do occur. The most common presenting symptom is hematuria. Occasionally, a urethral polyp is identified at the urethral meatal orifice in a female, but most often it is identified as a filling defect of the urethra or bladder neck on VCUG or during cystourethroscopy. Urethral polyps may be managed with transurethral resection, with nearly universal success. The biologic activity of these polyps is uniformly benign, and there have been no recurrences following complete excision (13,38).

Urethral Caruncles

Urethral caruncles are most commonly found in the postmenopausal period but have been reported in children. They characteristically present as a red and tender mass protruding from the inferior portion of the urethral meatus. Symptoms may be nonspecific but usually include dysuria or urinary frequency or hematuria. On histologic examination, a caruncle is composed of a highly vascularized fibroplastic connective tissue stalk heavily infiltrated with leukocytes. Overlying the mass is an epithelium that is either transitional or squamous (28). A few have had colonic mucosal-like intestinal heterotopia, suggesting that a few of these caruncles may be congenital (29). These small tumors are readily incised, and the treatment is similar to that of a urethral polyp.

Malignancy

Virtually the only malignant tumor that occurs in the female urethra in children is rhabdomyosarcoma. These tumors may occur at any age but are most common in young children. Embryonal rhabdomyosarcomas characteristically produce polypoid lesions at the base of the bladder that have given rise to the descriptive term *sarcoma botryoides.* These “grapelike clusters” may grow out through the lumen of the urethra, forming a mass that may be identified at the urethral meatus in the female (Fig. 50A.16). This appearance occurs only in hollow organs such as the bladder or vagina, which allows unimpeded growth of the tumor into the lumen. The treatment of this tumor is discussed in more detail in Chapter 54. Current therapy, however, includes chemotherapy with excisional biopsy only if the tumor can be excised without crippling surgery; otherwise, chemotherapy follows a diagnosis made through incisional biopsy and surgery is confined to resection of the residual tumor (33).

FIGURE 50A.16. Mass protruding from the vaginal introitus in a young girl with rhabdomyosarcoma. (From Ritchey ML, Andrassy RJ, Kelalis PP. Pediatric urologic oncology. In: Gillenwater JG, et al, eds. *Adult and pediatric urology.* St. Louis: Mosby, 1996, with permission.)

Trauma

Traumatic injury to the female urethra in children is unusual. In the vast majority of cases, treatment is the same as outlined in Chapter 12 for the adult woman. However, a few specifics to the female urethra in children and trauma should be mentioned. First, because the urethra in the female is short, pelvic fracture of urethral injuries occur less commonly in females than in males. Second, the female urethra, because it is relatively less well attached to the pelvic diaphragm, requires a more severe injury before significant damage is suffered, compared with the male. The most severe injuries seem to be associated with complete rupture of the urethra and a distraction defect suggesting an avulsion type of injury. These injuries, although rare, may be difficult to reconstruct with preservation of continence (79).

The urologist needs to have a high index of suspicion for urethral and vaginal injury following blunt traumatic injury to the urogenital region, particularly in the prepubescent girl. The emergency room evaluation, both by emergency physicians and pediatric urologists, of young girls who have suffered blunt urogenital trauma seems to grossly underestimate the severity of injuries that would be apparent if an examination under anesthesia was performed. Most girls will have findings in the operating room under anesthesia that are more extensive than those perceived during routine physical examination in the emergency room (43).

Pelvic fracture following an automobile accident is the most common source of major trauma to the urethra in females, as in males. After stabilization of the pelvic fracture and resuscitation, in most cases, attempts should be made to surgically reconstruct the urethra and the associated vaginal laceration. Appropriate urinary drainage for 10 to 14 days following repair usually results in reconstructive success (14). Unfortunately, sexual assault and other penetrating injuries are also relatively common sources of injury in children. Because urethral and bladder injuries as well as renal injuries are also present in many cases, nearly all girls with significant external genital trauma should be evaluated for possible coexisting renal or ureteral injury. In severe injury, the child should be stabilized with urinary diversion via suprapubic catheterization with later reconstruction. If a urethral vaginal fistula occurs after trauma, it can be repaired using the anterior sagittal transrectal approach (Fig. 50A.10) (8).

Sexual Abuse

Sexual abuse includes any activity with a child before the age of legal consent that is for sexual gratification of an adult or a significantly older child. Sexual abuse includes oral–genital, genital–genital, genital–rectal, hand–genital, hand–rectal, and hand–breast contact; exposure of sexual anatomy; forced viewing of sexual anatomy; and the showing of pornography to a child or use of a child in the production of pornography. Sexual intercourse includes vaginal, oral, or rectal penetration. Penetration is entry into an orifice with or without tissue injury. Younger perpetrators tend to have younger victims but are more likely to have intercourse with older victims. Sex acts perpetrated by young children are learned behaviors and are associated with experiencing sexual abuse or exposure to adult sex or pornography. Without detection and intervention, sexual abuse may progress from touching to intercourse. Sexual play, on the other hand, may be defined as viewing or touching of the genitals, buttocks, or chest by preadolescent children separated by not more than 4 years in age in which there has been no force or coercion. Sexual abuse is surprisingly common. From 12% to 38% of adult women were sexually abused by age 18. The incidence of sexual abuse of males ranges from 3% to 9% of the population; males account for up to 20% of the reports. About one-third of sexual abuse victims are younger than 6 years of age, one-third are 6 to 12 years of age, and one-third are 12 to 18 years of age. Reported offenders are 97% male (31).

The abuse of daughters by fathers and stepfathers is the most common form of reported incest, although brother–sister incest is considered the most common type. Pedophiles have indicated that they seek positions and opportunities where they can be in contact with potential victims. The vulnerable children they describe include those with mental and physical handicaps, unloved and unwanted children, previously abused children, and children in single-parent families. Children of drug abusers and children with low self-esteem and poor achievement are also at risk. A father's desire for sexual gratification and a daughter's need for affection and nurturing may lead to incest when the mother is unavailable and there is longing to maintain the family unit. Violence is not common in sexual abuse; however, its incidence increases with the age and size of the victim.

The possibility of sexual abuse should be considered as a result of associated physical symptoms, including (a) vaginal, penile, or rectal pain, discharge, or bleeding, or (b) chronic dysuria, enuresis, constipation, or encopresis. Behaviors likely to be associated with sexual abuse include sexualized activity with peers, animals, or objects; seductive behavior; and age-inappropriate sexual knowledge and curiosity. Investigating the possibility of sexual abuse requires supportive, sensitive, and detailed history taking. Many hospitals have a sexual abuse team that can be readily consulted if sexual abuse is suspected. The key is to be aware of the possibilities when they might exist and to invite the team in early. The pediatric urologist will likely be asked to evaluate the abdomen and perineum (31). Examination of the female genitalia with the patient in the frog-leg position for young children or the knee–chest position for older children expedites the examination with minimal touching. Sexual abuse should be considered when the vaginal mucosa is bruised or injected, the vaginal opening is dilated, or the hymen is damaged, showing a V notch or cleft (81). Despite these guidelines, the diagnosis of sexual abuse is made by the history and not by the physical examination. In one review of 157 children referred to a sexual abuse clinic with only a physical complaint without a history of abuse, only 16% had examination findings suggestive of sexual abuse (36). If abuse is suspected, it must be reported to the police. If the perpetrator is a caregiver of the child or a parent, the state child welfare team must be contacted as well.

Chapter References

Abnormalities of the male urethra are varied and may be both acquired and congenital. The most common congenital problem, hypospadias, is covered in Chapter 52B. Posterior urethral valves is the most common anomaly associated with significant obstruction of the bladder. Anterior urethral valves and urethral atresia may have just as much effect on the bladder and upper tracts. Urethral polyps and congenital strictures may also cause obstruction. Urethral stricture disease in children is usually acquired, secondary to previous hypospadias surgery or trauma.

Over the past decades, many advances have occurred in the management of boys with congenital urethral problems. Urologists are better aware of their presentation and natural history, and radiographic evaluation is improved and generally definitive. More sophisticated instrumentation allows safer and more effective treatment of many of the lesions. However, despite those advances, progression to renal failure remains a potential problem for those patients with significant obstruction.

The symptoms of urethral lesions remain nonspecific; most children have frequency, urgency, incontinence, or terminal hematuria. When questioned, few parents and children denote a decrease in force or an abnormal stream. This is probably because most have never had a normal void with which to compare. The diagnosis of urethral anomalies is usually made with a properly performed voiding cystourethrogram. Retrograde studies of the urethra are sometimes helpful, with endoscopy occasionally required for diagnosis. Ultrasound has assumed a major role in assessing the upper urinary system in such patients and may also be helpful in evaluating bladder function by examining residual urine or bladder wall thickness.

EMBRYOLOGY OF THE MALE URETHRA

The embryology of the urethra is not completely understood, particularly as it pertains to pathologic anomalies. The proximal or posterior urethra is formed by differentiation of the urogenital sinus, and the anterior urethra results from tubularization of the urethral plate. The urethra is usually divided into four sections:

1. The prostatic urethra, which is defined from the bladder neck to the proximal portion of the urogenital diaphragm
2. The membranous urethra, or that portion that traverses the diaphragm
3. The bulbar urethra, that segment from the membranous urethra to the penoscrotal junction
4. The penile urethra, which traverses the penile shaft and glans

Between the fourth and seventh week of gestation, the cloaca subdivides into a posterior portion (anorectal canal) and an anterior portion (primitive urogenital sinus) (Fig. 50B.1). The urogenital sinus then develops into a cranial portion that dilates to form the urinary bladder and pelvic portion that forms the proximal prostatic urethra and the membranous urethra. The anterior urethra is formed from the urethral folds on the genital tubercle. That portion of the urethra, unlike the posterior urethra, is dependent on 5a-reductase. The persistence of posterior urethral valves was first described by Tolmatschew (146) in 1870 as a simple enlargement of the folds and ridges seen in the posterior urethra. Bazy (9) in 1903 recognized them as incompletely resorbed membranes in that area. Lowsley (105) followed in 1914 with a description of a valvular formation related to abnormal development of the wolffian and müllerian ducts. It was 1919 when Young and colleagues (157) gave a clear description of valves. In their original essay, they recognized three variations of congenital urethral obstruction. They classified those as types 1, 2, and 3 (Fig. 50B.2). The classic type 1 valve is a membrane that billows with voiding and creates obstruction. The membrane begins on each side at the posterior base of the verumontanum and inserts anteriorly at the level of the membranous urethra. This in effect creates two leaflets of tissue with an aperture of varying size located posteriorly. With voiding, the leaflets billow like a sail and create various degrees of obstruction (Fig. 50B.3).

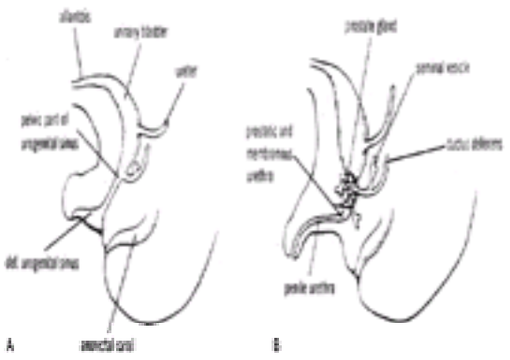

FIGURE 50B.1. A: Development of the urogenital sinus into the urinary bladder, the pelvic part of the urogenital sinus, and the definitive urogenital sinus. **B:** In the male, the urogenital sinus develops into the prostatic, membranous, and penile portions of the urethra. The prostate gland is formed by outbuddings of the urethra, and the seminal vesicles are formed by an outbudding of the ductus deferens. (From Langman J. *Medical embryology,* ed 2. Baltimore: Williams & Wilkins, 1969:157, with permission.)

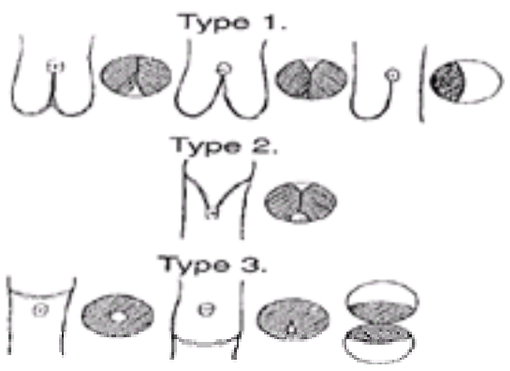

FIGURE 50B.2. Original diagram of Young and colleagues' (157) classification of posterior urethral valves. (From Young HH, Frontz WA, Baldwin JC. Congenital obstruction of the posterior urethra. *J Urol* 1919;3:289, with permission.)

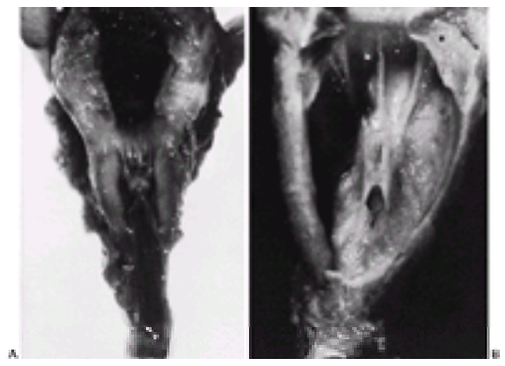

FIGURE 50B.3. Photographs of two type 1 posterior urethral valves. **A:** Posterior urethra opened in the midline; it give the impression of leaflets. **B:** Posterior urethra unroofed; it gives the impression of a membrane. However, it is attached to the veru. (From Robertson WB, Hayes JA. Congenital diaphragmatic obstruction of the male posterior urethra. *Br J Urol* 1969;41:592, with permission.)

Several different theories have been generated in regard to the development of posterior urethral valves. In the normal male, the mesonephric ducts insert laterally into the cloaca. As the cloaca folds inward in its midportion to separate the anorectal canal from the urogenital sinus, the ostium of each mesonephric duct migrates posterolaterally and cranially to assume a final position at the verumontanum. In a normal male, this pathway of migration appears to persist as plicae colliculi. Type 1 valves have been thought to result when the mesonephric ducts enter the cloaca in a more anterior portion than normal. As a result, when the cloaca undergoes separation and infolding, the mesonephric duct migration is impeded in midline fusion. Of note is that children with type 1 valves typically do not have plicae colliculi (Fig. 50B.4).

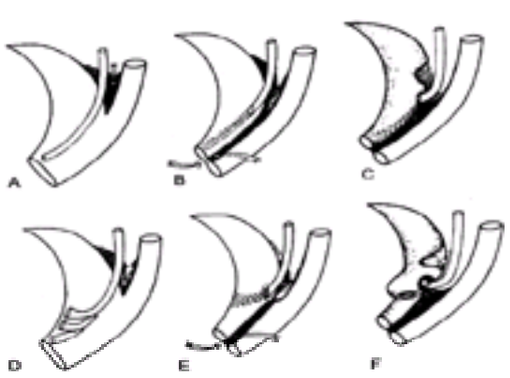

FIGURE 50B.4. Development of type 1 valves. **A–C:** Development of the normal urethral crest. Migration of the orifice of the wolffian duct from its anterolateral position in the cloaca to the site of the Müller tubercle on the posterior wall of the anorectal septum occurs synchronously with cloacal division. (Dots denote pathway of migration.) This wolffian remnant is more lateral and posterior and remains as the normal inferior crest and the plicae colliculi. **D:** Abnormal anterior positions of the wolffian duct orifices. **E:** Abnormal migration of the terminal ends of the ducts. **F:** Circumferential obliquely oriented ridges that compose the valve. (From Kelalis PP, King LR, eds. *Clinical pediatric urology.* Philadelphia: Saunders, 1976, with permission.)

Type 2 valves were initially described as folds radiating proximally in the urethra from the veru to the posterolateral bladder neck. It is now generally accepted that such valves are not obstructive and do not exist. Young and colleagues' classification system, however, remains imprinted on most urologists.

Type 3 valves are thought to represent an incomplete dissolution of the urogenital membrane. The resulting membrane is typically found distal to the veru at the level of the membranous urethra with a central aperture. Depending on its elasticity, it may create various appearances on fluoroscopy, including the wind-sock variety described by Field and Stephens (54a). Their embryonic explanation for such valves includes abnormal canalization of the urogenital membrane with subsequent slight constriction at the level of the perineal membrane. This causes varying degrees of obstruction (Fig. 50B.5).

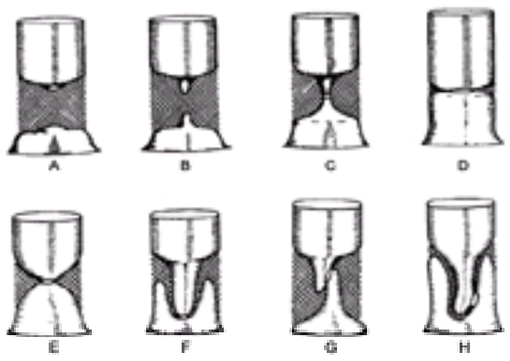

FIGURE 50B.5. Development of congenital urethral membranes (type 3 valves). **A–D:** Normal canalization of the urogenital membrane. **D:** Normal slight constriction at the level of the perineal membrane. **E:** Stricture formation. **F:** Canalization by central downgrowth and circumferential ingrowth resulting in building membrane with a central stenotic orifice. **G, H:** Side openings creating valvular wind-sock membranes. (Drawings and descriptions supplied through the courtesy of Dr. F.D. Stephens. From Kelalis PP, King LR, eds. *Clinical pediatric urology.* Philadelphia: Saunders, 1976, with permission.)

Field and Stephens (54a) also suggested the existence of an additional type of proximal urethral obstruction, which they called type 4 valves. This is an obstruction most often seen in boys with the prune-belly syndrome where the poorly supported prostatic folds telescope into the urethra, creating relative outlet obstruction.

Type 1 valves make up 95% of the valves noted in newborns. Despite potential differences in embryologic derivation, there is no difference in the clinical presentation among children with type 1 and 3 valves. Both may have significant obstruction and effects on the kidneys and bladder. Rosenfeld and colleagues (129) suggested that type 3 valves may be associated with a worse prognosis.

The classification system described by Young and colleagues (157) has recently been challenged by Dewan and colleagues (35). In their description titled "Congenital Obstructing Posterior Urethral Membrane," they noted that if endoscopy was performed before any instrumentation, a membrane was seen in all cases. They postulated that a membrane could be converted to a type 1 appearance by passing a catheter through the membrane or disrupting it with a hook. Debate continues because Young and colleagues (157) did not describe any attachment of the type 3 posterior urethral valve to the verumontanum as is seen with virtually all type 1 valves.

POSTERIOR URETHRAL VALVES

Historical Perspective

Review of the diagnosis and treatment of posterior urethral valves in boys reflects an interesting evolution in pediatric urology. Langenbeck in 1802 is credited with the first description of valves. However, it was not until Young and colleagues (157) described 36 cases that it was identified as a true entity. Treatment originally focused not only on the valves themselves but also on the bladder neck. That concern initially led to unnecessary bladder neck surgery. Severely ill infants were sometimes treated with cystostomy tubes, which were associated with infection, severe bladder spasms, and contracture of the bladder (89). Those children often succumbed to overwhelming sepsis. Treatment options then included many different types of supravesical diversions. Attempts at improving upper tract drainage and recovery began with low loop ureterostomy diversions and gradually were followed by high loop ureterostomy (87). Proximal loop ureterostomies were often done in the face of sepsis or when small bladders and markedly tortuous ureters were found. They did often lead to a difficult course of reconstruction because the bladder was defunctionalized and sometimes contracted further.

Supraurethral diversion in the form of vesicostomy was promoted by Duckett (42) at the Children's Hospital of Philadelphia in the 1970s. Primary valve ablation at the time was limited by the instrumentation for newborns. The caliber of the sheaths was too large for many neonatal urethras, and options were poor. If primary valve ablation was undertaken, it was often done by open valve resection through a perineal urethrostomy as described by Johnston in 1966 (88). He used an otoscope to visualize and resect the valves. At about the same time, Hendren (69) described immediate and total reconstruction of the urinary tract in young patients with posterior urethral valves. He included not only valve ablation but ureteral tapering and reimplantation.

In the 1970s, a major advance in the treatment of these patients occurred with the introduction of a new Hopkins-Storz lens system. Primary valve ablation for newborns by endoscopic means became a viable option and treatment. It rapidly became evident that it was not necessary to reconstruct all children completely and that renal function, as well as the pyelographic appearance, improved in many children after primary valve ablation alone. Effective treatment of the obstruction immediately after diagnosis would seem to be the end of the story; however, patients continued to develop renal failure, and some surgeons suggested that better drainage of the kidneys might be ensured by upper tract diversion.

The Philadelphia group reviewed 100 patients followed for a median of 11.2 years after valve ablation. Thirteen percent had end-stage renal disease by 15 years of age. They also reported ten patients who underwent initial high diversion, only one of whom appeared to have improvement in renal function related to the diversion. At the same time, Krueger and Churchill (98) in 1980 reported that high diversion seemed to decrease renal failure and improve somatic growth in their patients. Controversy remains over the role and effectiveness of high diversion in patients with valves, primarily because numerous studies have not noted similar improvement. In 1997, Tietjen and colleagues (145) confirmed suspicions that segmental renal dysplasia could be found in many patients at the time of high diversion and often resulted in little improvement in renal function despite the diversion. The authors stated that they thought that fixed ureterovesical junction obstruction was rare, as was the need for supravesical diversion.

The widespread use of prenatal ultrasound has now provided the opportunity to identify many patients with valves well before birth. It makes intuitive sense that such diagnosis might allow earlier relief of obstruction and greater recovery or protection of renal function. The exact role of fetal intervention remains to be determined, although thus far it has not been possible to prevent early dysplasia.

Much early interest centered on the association of valves and the function of the kidneys. It has become clear that bladder outlet obstruction also affects the development and function of the urinary bladder. Persistent bladder dysfunction can then clearly cause secondary effects on the upper tracts. The urologist caring for patients with valves typically cannot change developmental renal dysplasia. It is imperative, however, that the urologist recognize bladder dysfunction and avoid secondary insult to the kidneys. Such bladder dysfunction can affect the native kidneys or a transplanted one. Marshall and colleagues (109) did not think that the valve bladder after relief of the obstruction affected a transplanted kidney. Churchill and colleagues (27) and Reinberg and colleagues (126) did suggest that the valve bladder significantly compromised renal transplantation. The Philadelphia group, evaluating their 100 patients managed with primary valve ablation, thought that bladder function was preserved in most. This was confirmed in a study of transplant patients in Birmingham (84). With 10-year follow-up, the study's authors noted no statistically significant difference in graft survival in posterior urethral valve patients with the native bladder intact.

Incidence

Posterior urethral valves are the most common cause of infravesical obstruction in the male child. It is also the most common cause of obstructive uropathy leading to childhood renal failure (148). The incidence ranges from 1:8,000 (21) to 1:25,000 (6) live male births. Valves may be associated with up to 10% of severe prenatally diagnosed hydronephrosis (16).

Developmental Renal Physiology

To better understand and evaluate renal functional outcomes and the role of urologic intervention in patients with valves, it is imperative that developmental renal physiology be well understood. Many babies are presently delivered prematurely either because of problems or recommendations for early relief of obstruction. To understand the fall of serum creatinine, particularly in respect to treatment, one must know the limitations for a specific child at a given age or gestational period.

Wilkens (150) confirmed that the glomerular filtration rate (GFR) quadruples from 26 to 40 weeks of gestational age. At 40 weeks of gestation, the GFR is typically 20

to 30 mL per minute. The GFR increases to approximately 50 mL per minute by 2 weeks of age and to 100 mL per minute by 1 year. Normal adult GFR is usually reached at approximately 2 years of age (Fig. 50B.6). From 80% to 90% of nephrons, however, are formed by 26 weeks of gestational age. Subsequent improvements in GFR may be due to changes in renal vascular resistance with redistribution of renal blood flow in the kidney (Fig. 50B.7). There is also a marked increase in capillary surface area with a resultant increase in total surface area for filtration. Changes in the permeability constant that lead to a change in the basement membrane permeability also improve function (154).

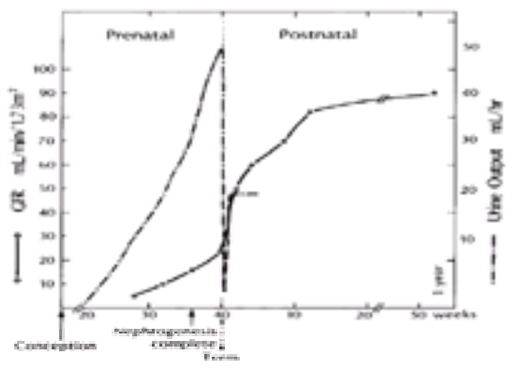

FIGURE 50B.6. Changes in glomerular filtration rate *(GFR)* and urine output during fetal development and infancy. A report by Rabinowitz and colleagues (122a) suggests that urine output at term may be 50 mL per hour.

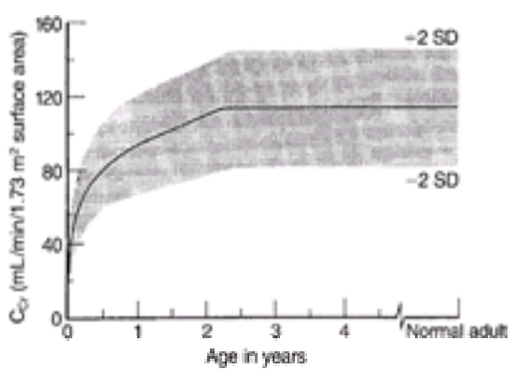

FIGURE 50B.7. The change in glomerular filtration rate with age. (From McCory WW. Regulation of renal functional development. *Urol Clin North Am* 1980;7:243, with permission.)

In addition to GFR, the tubular function of the kidney changes rapidly in the fetus and neonate. At birth, the normal neonate can concentrate the urine to 400 to 600 mOsm/L. The concentrating ability of the kidney gradually achieves adult status by 3 to 6 months of age.

The inability of the newborn to concentrate urine is related to an inefficient countercurrent mechanism, with decreased urea in the medulla, increased medullary blood flow, decreased tubular responsiveness to antidiuretic hormone, and a relatively short loop of Henle (155). Premature infants are likewise unable to acidify their urine as well as full-term infants (140). This results not only from an inability to excrete hydrogen ions well but also from a lower renal threshold for bicarbonate reabsorption.

With the knowledge of the normal fetal to neonatal progression of renal function, one must take into consideration the ability of the previously obstructed urinary tract to respond to being unobstructed. Standard treatment protocols have been based in the past on drainage of the bladder with achievement of certain renal parameters necessary to identify the next proper step in management. Historically, we believe that the rapid leap to upper tract diversion resulted from an approach that did not fully take into consideration the developing anatomy and the time required for an abnormal immature system to respond to treatment. It has become increasingly clear that upper tract diversion is not helpful in most cases due to the fact that lower tract treatment has provided adequate drainage if given time for the renal system to recover and mature. Furthermore, those who have not improved with high diversion did not because dysplasia plays a significant role (145).

Pathophysiology of Congenital Obstruction and Posterior Urethral Valves

The early obstruction of the urinary tract is associated with a variety of abnormalities. This includes ascending problems related to bladder storage and function and ureteral motility and drainage. It also has a great impact on proper renal development with resultant dysplasia, which impairs glomerular and tubular function. Unfortunately, depending on the timing and the severity of the obstruction, with the resultant increase in intraluminal pressure, the embryologic maldevelopment is so severe that even with prompt relief of obstruction, function does not return to acceptable levels. This leads to long-term clinical and pathologic problems. We will discuss the impact that posterior urethral valves and obstruction have on the development of glomerular and tubular function, vesicoureteral reflux, and bladder function.

Glomerular Function with Valves

The treatment of boys with posterior urethral valves is focused on preserving renal function. Unfortunately, there are many potential insults to renal function with a wide spectrum of etiologies. Clearly, problems can occur at the embryologic level and result from abnormal ureteral bud inducement of metanephric blastema (71). Mackie and Stephens' study (106a) suggested that abnormal position of the initial ureteral bud and eventual ureteral orifice is associated with resultant renal dysplasia or hypoplasias and that this same phenomenon exists in patients with valves. Their concept fits nicely with later recognition of the VURD syndrome (valves, unilateral reflux, and dysplasia); the refluxing kidney has profound dysplasia and the contralateral one is relatively spared or normal (78) (Fig. 50B.8).

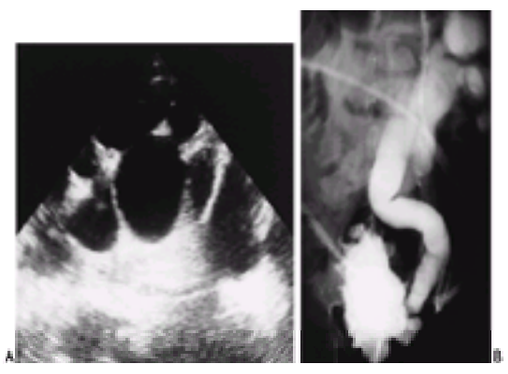

FIGURE 50B.8. Vesicoureteral reflux and dysplasia (VURD) syndrome demonstrated on ultrasound **(A)** and VCUG **(B).**

One cannot ignore, however, the potential pressure effect of obstruction on the primitive developing kidney. Beck (10) thought that dysplasia could result from high

intrapelvic pressure during nephrogenesis. Controversy arose when *in utero* ligation of animal ureters resulted in severe hydronephrosis but not consistent dysplasia (3,61,62,63). Maizels and Simpson (107) noted that the timing of ligation of the ureter in chick embryos was important in inducing dysplasia, as was the amount of metanephric blastema associated with the ureteral bud.

It is clear that the development of renal dysplasia is the single most influential factor with respect to the ultimate outcome of renal function in boys with valves. Despite early diagnosis and in some cases even early appropriate treatment, it does not appear that urologists at this point are capable of preventing its development. However, there are numerous secondary insults to renal function in patients with valves or any obstruction that can be affected by aggressive medical and surgical management. The first of these is obstruction, which must be relieved. Obstruction not only results from the valves themselves, but also potentially high intravesical bladder pressure resulting from either bladder noncompliance or uninhibited contractions. There is some evidence that satisfactory relief of obstruction may lead to an increase in parenchymal mass and GFR in the newborn or very young infant (110).

Recurrent urinary tract infections may cause decreased renal function. These children are at greater risk for infection secondary to increased intravesical pressure, nonemptying, diverticula, vesicoureteral reflux, and urinary stasis. They have the same risk of renal scarring with urinary tract infection as patients with primary reflux; however, their risk may be even more pronounced secondary to the association with increased intravesical pressure in many patients. Aggressive prevention of urinary tract infection by promoting emptying, decreasing the intravesical pressure in those patients with poor compliance or uninhibited contraction, and chemoprophylaxis can significantly lower the ongoing renal damage secondary to urinary tract infection. Selected use of surgery for those with reflux and poor bladder compliance also plays a role in protecting the upper tracts in some patients.

It is interesting to note that renal function seems to be better preserved in select valve patients with a pop-off mechanism. These vents include large diverticula, urinary ascites secondary to bladder or forniceal rupture *in utero,* and massive unilateral reflux with preservation of the contralateral renal mass (30,115,127). The pressure pop-offs are thought to dissipate the increased intraluminal pressure and allow renal development (Fig. 50B.9).

FIGURE 50B.9. A: Perirenal urinoma.

CHRONIC RENAL FAILURE

Chronic renal failure remains a final endpoint for a number of these patients. Unfortunately, the definition of chronic renal failure varies. Parkhouse and colleagues (116) defined *chronic renal failure* as a plasma creatinine concentration of 150 µmmol/L. *End-stage renal disease* is easily defined as a requirement for dialysis, renal transplantation, or death from renal failure.

The cause of progression to renal failure is multifactorial (40). On the one hand, there is the predetermined child with severe renal dysplasia at birth. A significant number of these babies either are stillborn or die soon after birth unless heroic measures with dialysis are instituted. The next group includes those with progressive renal damage secondary to ongoing obstruction, infection, or delayed diagnosis (13). Finally, there is the group who has adequate GFR and renal function to allow growth until puberty. At that time, however, the acceleration of somatic growth outstrips the ability of the kidneys to keep up and the renal reserve is overloaded. The hyperfiltration theory proposed by Brenner and colleagues (14) may play a role in these patients.

End-stage renal disease occurs in 25% to 40% of patients with posterior urethral valves. This also appears to occur with a bimodal age distribution with one-third manifesting end-stage renal disease after birth and two-thirds after puberty irrespective of surgical treatment (133,137) (Fig. 50B.10).

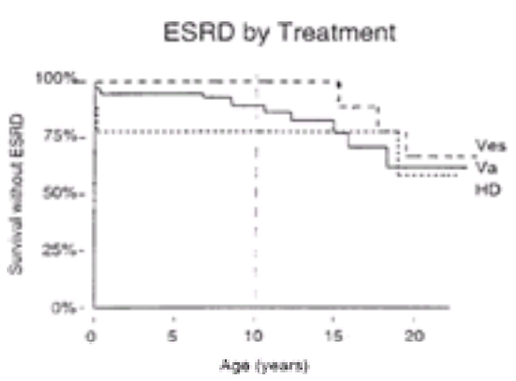

FIGURE 50B.10. Survival curve of the timing of renal failure in posterior urethral valves. Note that end-stage renal disease *(ESRD)* occurs in two peaks: the first few months of life and during the late teenage years.

TUBULAR FUNCTION

Experimentally, obstruction of the urinary system primarily affects the medullary portion of the tubule first. Clearly, there is washout of the medullary gradient necessary for resorption of water from the distal tubule, thus leading to an inability to concentrate urine (37). Work by Parkhouse and Woodhouse (117) suggested that renal tubular injury occurs before glomerular injury and that the tubule is more easily affected. Of 11 patients with a GFR less than 80 mL/ 1.73 m^2, all had evidence of tubular injury, whereas only 6 of 13 patients with a GFR greater than 80 mL/1.73 m^2 had abnormal concentrating ability.

This type of injury is potentially quite significant in the neonate. In spite of a reasonable glomerular filtration rate, the child must drink vigorously to keep up with urinary output. The child is very susceptible to severe dehydration with other minor illnesses associated with vomiting and diarrhea. The increased urine output also affects the lower urinary tract. The ureters and bladder must handle the volume, and resultant dilation may be physiologic. Increased volume can eventually result in increased pressures in the abnormal bladder that can then secondarily harm the kidneys. Unfortunately, this nephrogenic diabetes insipidus is usually not responsive to hormonal therapy. Changes in diet and careful fluid balance may be helpful in some.

Other tubular functions such as acidification of the urine and resorption of filtered loads of protein and sodium may also be affected before changes in glomerular filtration rate. Those proximal tubular functions may be better preserved than distal tubular concentrating ability. Even in the absence of frank metabolic acidosis, unrecognized problems in acid–base balance may affect the growth and general health of some patients with valves.

Bladder Function

The congenital obstruction produced by posterior urethral valves often results in significant collagen deposition within the bladder (49). This, in addition to muscular hypertrophy, may lead to uninhibited contractions and noncompliance that can persist after relief of the obstruction. Other patients may exhibit myogenic failure. Typical urodynamic findings of posterior urethral valves in patients with persistent dysfunction are demonstrated in Fig. 50B.11 (8,18). These patterns are thought to persist in up to 25% of patients in spite of adequate relief of the obstruction. Boys with valves typically have very little sensation of fullness even at extreme pressures. This may be due to exposure of the bladder to such pressures all throughout development. Bladder emptying may play an important role in bladder function after valve ablation. Failure to empty well may expose the bladder and kidneys to consistently higher pressure and promote urinary tract infection.

FIGURE 50B.11. Urodynamic tracings showing the three common types of detrusor dysfunction seen in posterior urethral valves. (From Peters CA, Bolkier M, Bauer SB, et al. The urodynamic consequences of posterior urethral valves. *J Urol* 1990;144:122, with permission.)

Debate has developed concerning the effect of bladder defunctionalization on ultimate bladder function. Leome and associates (104), followed by Tanagho (142) and Close and Mitchell (28), have suggested that the bladder must cycle with filling and emptying to develop normally. Others have noted that relief from pressure and obstruction, even with defunctionalization, can result in normal function. It is clear that bladder function can change over time in patients with valves. Before valve ablation, Holmdahl and colleagues (76) found small, hypercontractile bladders in all children. After valve ablation, the bladder capacity increased, although some boys demonstrated uninhibited contractions and poor emptying.

Bladder dysfunction may cause urinary incontinence in boys after valve ablation but may have far worse ramifications. Increased intravesical pressure may contribute to vesicoureteral reflux, hydronephrosis, and even secondary renal deterioration (75). Parkhouse and colleagues (116) showed that adolescents who had incontinence in childhood had a more severe degree of renal insufficiency. Even though much of the incontinence in the group improved at puberty with growth of the prostate, the authors suggested that bladder dysfunction and increased intravesical pressure created an unfavorable environment for the kidneys.

Management of bladder dysfunction is based on urodynamic findings (95,96,100). Treatment consists of providing a low-pressure environment with adequate bladder emptying. Timed voiding with double voiding techniques may be sufficient to empty with intravesical pressures below a critical level. In those who do not respond to this, anticholinergic therapy or clean intermittent catheterization may be required. Because boys with valves have normal sensation, clean intermittent catheterization is often poorly tolerated. In the worst-case scenario, bladder augmentation may be necessary. This can be accomplished with many different substances, including small and large bowel, stomach, and urothelium with the use of dilated ureter (1,11,20,24,102).

VESICOURETERAL REFLUX

Vesicoureteral reflux is found in one-third to one-half of patients with posterior urethral valves. This usually is reflux secondary to increased intravesical pressure and loss of ureterovesical junction competence, but the study of Henneberry and Stephens (71) suggests that primary reflux may also be present in some. They demonstrated a significant incidence of lateral ectopia in their study of fetuses and newborn infants.

Because reflux is common in posterior urethral valves, it should not influence the overall management (90). At least one-third of the reflux resolves with treatment of the primary outlet obstruction. Surgical intervention is usually reserved for patients with breakthrough urinary infections or those with massive reflux that interferes with bladder function.

Whether reflux affects prognosis is controversial. Johnston and Kulatilake (91) in 1971 found that those patients with bilateral reflux at diagnosis had a mortality rate of 57%, those with unilateral reflux had a mortality rate of 17.4%, and those with no reflux had a mortality rate of 9.1%. Johnston (90) also reported a higher incidence of end-stage renal disease in patients with reflux. The etiology of this is unclear. Hulbert and Duckett (79), however, did not show a correlation between reflux and renal function in 120 patients followed for an average of 5 years. Williams (151) also published the same results as early as 1973.

Prenatal Diagnosis

Most boys with posterior urethral valves are now diagnosed antenatally because of the improved sensitivity and specificity of ultrasonography and its widespread use in pregnant women. Unfortunately, antenatal ultrasonography is usually not performed until 20 weeks of gestational age, which is too late to change the outcome of renal and pulmonary development for some patients (65,68).

Hutton and colleagues (82) reported 17 cases of antenatally detected valves at a mean of 18 weeks of gestation. The ultrasound appearance was characterized with respect to dilation, cystic change or echogenicity of the renal cortex, and the amount of amniotic fluid. With median follow-up of 5.7 years, 10 of the 17 boys had a poor outcome, with death in 4 and chronic renal failure in 6. Eight of nine boys with marked prenatal hydroureteronephrosis at an early gestational age did poorly, in contrast to only two of eight with milder upper tract changes. The authors concluded that the worrisome findings provided important information for parental counseling. Others have noted that early detection of severe upper tract changes secondary to posterior urethral valves does not change the outcome but does identify patients more at risk for renal failure (85).

Beyond the ultrasonic appearance of the kidneys and bladder *in utero,* the quality of the fetal urine, obtained by ultrasonically guided aspiration, may provide additional information about the risk of renal failure. The fetal kidney usually produces hypotonic urine with various parameters used to predict eventual renal function. Normal ranges of fetal urinary concentration of various urine markers and electrolytes have been proposed based on the gestational age of the fetus (Table 50B.1). However, there have been clear cases in which the eventual outcome for the patient did not match that predicted by antenatal determination of fetal urine quality (51). It has been suggested that serial urine measurements may be of greater benefit than a single evaluation alone (86). Furthermore, urinary b_2-microglobulin and *N*-acetyl-b-D-glucosaminidase may be helpful in identifying severe forms of obstruction, as may amino acid concentration in the urine (53,143).

TABLE 50B.1. NORMAL FETAL URINE VALUES

The ultimate goal in caring for any patient besides identifying a problem is to intervene when necessary and improve the ultimate outcome. Initially, therefore, there was enthusiasm for prenatal intervention for posterior urethral valves in hopes of improving ultimate renal and pulmonary function. The benefit of such intervention, even when effective from a mechanical standpoint, remains controversial. Effectiveness must be evaluated in terms of both pulmonary and renal function (103). Once the natural history of severe hydronephrosis and oligohydramnios is reasonably well defined and understood, it should be relatively easy to determine whether prenatal intervention in certain circumstances may benefit the fetus from a pulmonary standpoint (67). On the other hand, many variables affect the ultimate outcome for renal function in boys with posterior urethral valves, and not all can be determined antenatally. When so many variables potentially play a role in outcome, it is much more difficult to predict the natural history early in gestation. Even if antenatal intervention does not change the ultimate number of boys progressing to renal failure with posterior urethral valves, it will be difficult to determine whether it does or does not affect the timing of such progression. In any event, with appropriate criteria less than 1% of boys with antenatally detected hydronephrosis should undergo any consideration of antenatal intervention.

Freedman and colleagues (56) evaluated 55 consecutive patients who underwent prenatal intervention, including 13 patients with posterior urethral valves. Unfortunately, they concluded that prenatal intervention resulted in no difference in outcome from those detected postnatally. In a later report, however, Freedman and colleagues (57) noted that fetal intervention may help those fetuses with the most severe forms of obstructive uropathy generally associated with a fatal outcome. They suggested that intervention might allow some boys to progress along a course similar to less severe cases. Holmes and Baskin (77) reviewed the outcome of 33 fetuses undergoing antenatal intervention for valves over a 17-year period. All patients had favorable urinary parameters and a mean gestational age of 21.8 weeks at intervention. They found that intervention carried a rate of immediate fetal demise of 40%. They also concluded that intervention may not change the progression of renal function despite the finding of favorable urinary electrolytes. They therefore concluded that parental counseling should focus on the fact that intervention may assist in bringing the fetus to term and then surviving from a pulmonary standpoint but that the sequela of the valves may not be preventable. El-Ghoneimi and colleagues (52) also concluded that the ultimate outcome of children with valves from a renal standpoint has not been affected by prenatal diagnosis. The exact role of fetoscopy and valve ablation or vesicoamniotic shunting remains to be determined and probably will require a long and well-organized multicenter trial (122).

Multiple factors may influence the outcome of posterior urethral valves. Embryologic dysfunction associated with them may have a profound role in prognosis. Stephens' ureteral bud theory suggested that renal dysplasia in valves is not solely a function of increased pressure secondary to obstruction but also depends on the position of the ureteral bud. The lateral ectopia of the ureteral bud in valve patients led to renal dysplasia or hypoplasia much as it could in patients without a lower tract problem. Abnormalities in signaling and control between the ureteral bud and metanephric blastema may contribute to abnormal inducements that are just beginning to become understood. Other genetic determinants may influence such interactions and then affect the response of a given kidney to an insult such as obstruction (73,74,156).

Postnatal Evaluation

The typical radiographic evaluation of children with posterior urethral valves has evolved. Intravenous pyelography was the study of choice for the upper urinary system 20 years ago but has largely been replaced by ultrasonography and nuclear renography. Lower tract evaluation is done using voiding cystourethrography, which is diagnostic. Urodynamic evaluation of the bladder may ultimately be necessary to evaluate and treat persistent bladder dysfunction.

Ultrasound

Ultrasound was a significant advance in diagnosis. Not only does it tell us the degree of hydronephrosis, but it also can assist in predicting renal functional outcome through many other parameters. The determination of renal parenchymal thickness and renal size can be important. Renal echogenicity can predict the degree of dysplasia. However, the most important radiographic finding appears to be that of corticomedullary differentiation. Hulbert and colleagues (81) showed that patients with a lack of corticomedullary differentiation appear to have a higher percentage of renal insufficiency.

Ultrasound also has been used to evaluate the bladder in children with posterior urethral valves. Dilated ureters posterior to the bladder in addition to abnormal bladder thickness are highly suggestive of posterior urethral valves. There have been attempts to correlate bladder wall thickness ultrasonographically with a diagnosis of posterior urethral valves. This, however, remains somewhat problematic in that the state of bladder filling clearly influences the bladder wall thickness.

Renography

The MAG-3 Lasix renogram has become the standard for determining upper tract function and drainage. This has replaced the need for invasive upper tract urodynamics studies (Whitaker test) in most children. Prognostically, serial studies not only assess degree of response to specific treatments, but also can predict further renal reserve and long-term outcome.

Voiding Cystourethrogram

The ultimate diagnosis of posterior urethral valves is made by a well-performed voiding cystourethrogram VCUG. This requires a voiding phase within the study. The hallmarks of posterior urethral valves include a dilated posterior urethra, elevated bladder neck, and trabeculated bladder. One may also see a filling defect at the prostatomembranous junction or an enlarged bladder. Vesicoureteral reflux is present in 50% of the patients. Findings such as these make endoscopy mandatory to complete diagnosis and allow for treatment.

MANAGEMENT

The vast majority of boys with posterior urethral valves are now diagnosed *in utero.* This affords initial management from a team approach including pediatric urologists, pediatric nephrologists, the maternal–fetal medicine physician, neonatologists, and pediatricians. Depending on the severity of the renal impairment and the gestational age at birth, different problems may arise.

The initial management after birth must include drainage of the bladder. This is usually done per urethra with a small, soft feeding tube. One must be sure that the catheter is in the bladder to achieve adequate drainage. At times, the catheter may coil in the dilated posterior urethra due to difficulty passing the elevated bladder neck. Urine may drain, despite inadequate bladder decompression. If necessary, radiographs should be obtained to ensure proper placement in the urinary bladder. In some rare cases, the urethra cannot be traversed and access to the bladder must to obtained suprapubically. Once bladder access is obtained, aggressive management of any fluid and electrolyte problems is required. Patients often have voluminous urine output secondary to loss of concentrating ability and may lose a significant amount of solute in the urine in the form of sodium and potassium (37). Prudent intravenous fluid management includes aggressive fluid and electrolyte replacement (43,44).

Children with valves may also have potentially severe acidosis depending, again, on the severity of the renal dysfunction. Careful assessment of urine and serum bicarbonate concentration may aid in adjusting intravenous fluid replacement and bicarbonate therapy in such patients (23).

The renal function, as measured by serum creatinine, should be monitored closely after bladder drainage. The measured creatinine in the first several days of life reflects that of the mother. Subsequently, the creatinine measures the clearance of the child. In the presence of an elevated serum creatinine, the time required to see a decrease may be highly variable and may depend on the gestational age at birth. Some authors have suggested that the creatinine level after approximately 5 days of drainage would be useful in determining appropriate intervention. Without a satisfactory decrease in creatinine, an upper tract diversion was often considered in the past. Gonzales (64) has reported that nadir creatinine of 1.8 mg/dL or greater after several days of transurethral drainage should prompt consideration of upper tract diversion. He considered patients with a creatinine level between 1.5 and 1.8 mg/dL to be an intermediate group in which endoscopic management or diversion might be appropriate. He reported that primary valve ablation should be performed in those patients whose creatinines fell to below 1.5 mg/dL. For patients without such a decrease, repeat ultrasounds may be useful to demonstrate decreased hydronephrosis and help avoid unnecessary upper tract diversion. Even with a persistently

elevated serum creatinine, there has been a trend away from immediate upper tract diversion.

Transurethral Resection of Valves

Treatment of the valves has included open dissection by perineal urethrostomy, fluoroscopic rupture using a Whitaker hook, and antegrade passage of a balloon catheter (22,36,97,149). The primary treatment of choice is now direct endoscopic visualization and ablation (32) (Fig. 50B.12). Major improvements in technology have made transurethral valve ablation a viable option in virtually all cases. The availability of the 7-Fr scope with a working channel of 2 to 3 Fr allows access to the posterior urethra in most babies, even if premature. Improved fiberoptic lens systems in such small scopes have made adequate visualization a reality. Proper ablation of valves should accomplish destruction of the valves while sparing the urethra from injury. Transurethral “resection” is clearly a misnomer because aggressive attempts at complete resection may lead to significant posterior urethral injury and resultant stricture (25,101). This complication produces a very significant reconstructive challenge.

FIGURE 50B.12. Whitaker hook.

The goal of the transurethral technique is to ablate the valves so that they are nonobstructive. This can be accomplished in a retrograde fashion using small instruments and a Bugby electrode. Ablation is accomplished using cutting current and incisions at the 5, 7, and 12 o'clock positions. In older children, incision can be easily accomplished using a resectoscope and a wire hook electrode to engage and incise the valve (Fig. 50B.13).

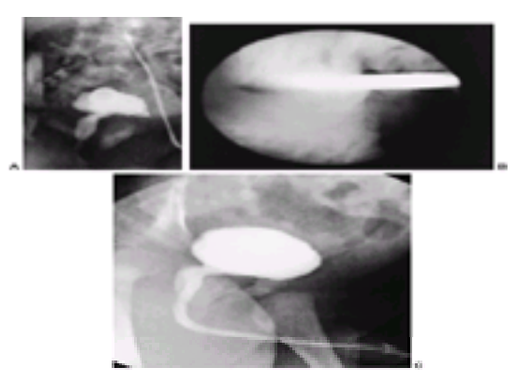

FIGURE 50B.13. A: Preoperative valves. **B:** Endoscopic view of valves. **C:** Postoperative valves.

Zaontz and Firlit (158) described an antegrade technique for ablation of valves. Access to the bladder is gained percutaneously, and a flexible cystoscope is passed through the bladder neck (Fig. 50B.14). The valves are ablated in a similar position using a Bugby electrode or the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (12,47,48). This approach offers the advantage of avoidance of instrumentation to the small male distal urethra, although reported strictures after neonatal valve ablation have been rare. It may allow endoscopic access to the valves of premature boys who previously might not have accepted available cystoscopes in a retrograde fashion.

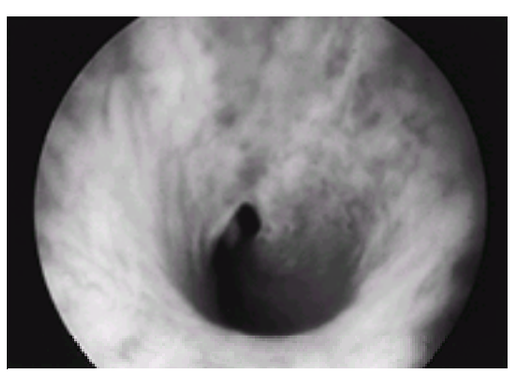

FIGURE 50B.14. Antegrade endoscopic view of posterior urethral valves.

Primary valve ablation reliably relieves the urethral obstruction and allows the bladder to cycle regularly (112). Some authors have suggested that such cycling is important to decrease collagen deposition and prevent noncompliance. When treated with primary valve ablation, many patients demonstrate a resolution of initial reflux, and most have remarkable improvement in upper tract hydronephrosis. Concern may remain for the adequacy of upper tract drainage in an occasional child with persistent hydronephrosis and renal insufficiency. In that setting, patience and close follow-up are necessary to gain confidence that the kidneys are recovering as much as possible and that upper tract diversion is not warranted.

Vesicostomy

In children whose valves cannot be primarily ablated, usually for technical reasons, vesicostomy remains a viable option of treatment. The functioning vesicostomy provides good drainage of the lower tract with a minimally invasive, easily reversible technique. Duckett (41,42) was an early proponent of vesicostomy, as were Walker and Padron (147). They noted that the cutaneous vesicostomy was safe and ensured adequate drainage, although their review did not show any overall improvement in renal function when compared with primary valve ablation.

We believe that vesicostomy is an excellent choice for drainage in select cases of posterior urethral valves. We have primarily used it in very premature infants in whom safe visualization or incision of the valves was not possible. Vesicostomy can be performed through a small, 2-cm transverse incision made below the umbilicus. After the anterior bladder is exposed, it should be mobilized to the urachus, which may be divided. Although the valve bladder is generally quite thick and less prone to prolapse, the vesicostomy should be performed posterior to the urachus to make sure that the posterior wall of the bladder is not redundant and prone to prolapse. When done in this fashion, the cystostomy into the thick valve bladder may be made large (24 Fr) to avoid stenosis. The bladder wall adjacent to the

cystostomy is then attached with suture at the level of the fascia and skin. Importantly, a vesicostomy allows cycling of the bladder to take place at low pressures (94).

High Diversion

The decision to proceed with high diversion is difficult, as discussed previously. Several reports from Toronto have supported upper tract diversion to maximize renal function (26,99). Krueger and colleagues (99) compared two groups of children treated for valves with renal insufficiency. They thought that patients demonstrated improved renal function and better somatic growth when treated with upper tract diversion compared with those undergoing primary valve ablation. Their conclusions, however, have been challenged by several authors concerned about selection bias in that study. Duckett and Norris (45) and Reinberg and colleagues (124,125) in separate reports evaluated similar patients undergoing upper tract diversion and did not find a benefit in terms of renal function.

If high diversion was not without specific disadvantages, one could argue that the surgeon and patient risk little by proceeding with this to maximize renal function. However, such diversions make it cumbersome to keep the child dry as he grows, and it commits the child to major upper tract reconstructive procedures. Recent concerns have suggested that complete diversion of urine from the bladder may ultimately compromise bladder function. If upper tract diversion is to be done, we prefer a cutaneous pyelostomy when possible, although a proximal loop cutaneous ureterostomy may often be easier to get to the skin without tension. A small incision is made at the level of the twelfth rib. The retroperitoneum is entered, and the ureter is identified. Care is taken not to injure the ureteral blood supply during dissection. If a proximal loop of ureter is brought to the skin, the ureteral adventitia and longitudinal blood supply are swept away from the area of incision and preserved. Proximal diversion provides excellent drainage of the kidneys and relatively simple closure. We often perform a renal biopsy at the same setting for prognostic purposes.

Total Reconstruction

Hendren (69,70) demonstrated that total reconstruction of the urinary system in patients born with valves could be accomplished when hydronephrosis persisted after primary valve ablation. Total ureteral tapering and reimplantation was often necessary. Hendren thought that such reconstruction eliminated potential ureterovesical junction obstruction, decreased stasis, and allowed more effective peristalsis. All of this was done to improve drainage and renal function. Hendren clearly showed that such reconstruction could be done with good results. Better understanding of the natural history of hydronephrosis associated with posterior urethral valves has demonstrated that true, persistent ureterovesical junction obstruction is rare. As much as one-third of vesicoureteral reflux will resolve with ablation of the valves alone. When significant hydronephrosis or reflux persists, bladder function must be carefully evaluated and managed. Thus most early upper tract reconstruction can be avoided in patients doing well.

Prognosis

The infant mortality rate related to valves has fallen from the 50% reported by Johnston and Kulatilake (92) in 1972 to the 1% to 3% reported by Churchill and colleagues (26) in 1990. Better urologic care, aggressive management with fluid and electrolyte replacement, antibiotics, and dialysis or transplantation have allowed these children an opportunity for life. Unfortunately, the outcome for patients with valves in terms of renal failure has not changed despite antenatal diagnosis and good urologic care (17,116,144). The incidence of renal failure continues to be 25% to 40% among patients with severe posterior urethral valves. Because of better survival, many of those patients have become candidates for renal transplantation. Results of transplantation have improved over the past several decades as well, primarily due to improved immunosuppressive therapy (7,83). More urologic interest in bladder dysfunction among valve patients and better resultant care may avoid renal failure and the need for transplantation in an occasional patient. It may also lengthen the time until transplantation is necessary (114). Besides protecting the native kidneys, recognizing and treating bladder function may also improve graft survival with transplantation. Reports have shown that transplantation can be safely performed in patients after valve ablation, although they must be followed closely to ensure no deterioration in the function of the bladder or renograph (84,136,141).

Fertility

It has been noted that most patients with treated valves were fertile as adults (117,152). However, occasional patients experienced anejaculation or retrograde ejaculation. The etiology of the problems appears to be multifactorial and is potentially related to an abnormal posterior urethra, obstructed ejaculatory duct, changes in bladder neck dynamics, or complications of valve ablation.

Minimalist Posterior Urethral Valves

Posterior urethral valves, as much as any congenital anomaly, occur in a wide spectrum of severity. This discussion has primarily concentrated on severe valves because they are the most typical. However, patients may be found with minimal valves, various voiding complaints, and no upper tract changes (121). They typically manifest after toilet training with a wide variety of complaints ranging from urgency, frequency, and incontinence to hematuria and urinary tract infection. The diagnosis of such valves is made by voiding cystourethrography (Fig. 50B.15), and treatment remains transurethral ablation. Despite relief of the obstruction, they may require significant voiding modification in the form of timed and double voiding techniques. They also sometimes require anticholinergic medications to store urine normally. If voiding complaints continue well after relief of obstruction, urodynamics are necessary to elucidate the problem and affect treatment.

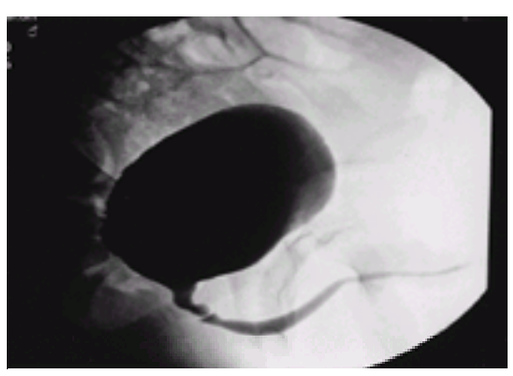

FIGURE 50B.15. VCUG of mini-valve.

ANTERIOR URETHRAL VALVES

Anterior urethral valves are a much less common cause of infravesical obstruction, with as much potential morbidity as posterior urethral valves. Because anterior urethral valves are occasionally found at the distal end of a diverticulum, it is unknown whether the anomaly developed primarily as a diverticulum with undermining of the distal urethra and secondary development of valvular obstruction or early valvular obstruction that resulted in proximal maldevelopment of the urethra and spongiosum.

The embryologic origin of anterior urethral valves is somewhat controversial. It has been suggested that they may be the result of an aborted attempt of a urethral duplication, failure of alignment between the proximal and distal urethra resulting in a tissue remnant that may act as a valve, or congenital cystic dilation of periurethral glands resulting in a flaplike valve. These valves may be located anywhere in the anterior urethra. Forty percent have been found in the bulbous urethra, 30% at the penoscrotal junction, and the remaining 30% in the pendulous urethra. They have rarely been reported in the fossa navicularis (132).

Anterior urethral valves manifest with a wide spectrum of severity based on the degree of urethral dilation, presence of an associated diverticulum, and the grade of upper tract dilation. These patients commonly have dribbling of urination, difficulty in voiding, incontinence, poor urinary stream, and recurrent urinary tract infections. In the neonatal period, the obstruction may result in megacystis, bladder rupture, severe hydroureteronephrosis, azotemia, or urinary ascites (59). Older children may also have enuresis, postvoid dribbling, or failure to thrive.

VCUG is the diagnostic study of choice (Fig. 50B.16). Interestingly, the urethra often appears narrow distal to the valves and dilated proximally. The valve itself may

be visualized as a linear defect along the ventral wall but also may only be noted as an abrupt change in the caliber of the urethra. Vesicoureteral reflux has been noted in approximately one-third of patients, and upper tract dilation noted in one-half.

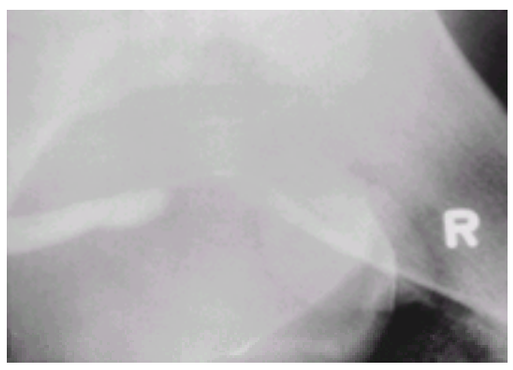

FIGURE 50B.16. VCUG of anterior urethral valves.

Endoscopically, the valve appears as a filmy, ventrally located cusp or flap of tissue (Fig. 50B.17). It occasionally has been described as an irislike membrane. One must examine the urethra carefully at the distal end of any urethral diverticulum because retrograde flow of irrigant may flatten the valve mechanism against the urethral wall. Suprapubic pressure with the bladder full and irrigation ports on the scope open may demonstrate the valve mechanism more readily. Furthermore, elevation of the valve with an endoscopic loop is invaluable in the identification of the lesion. Transurethral incision of the valve is effective for most patients, but one must be careful to aggressively incise to avoid any distal obstructing lip. Endoscopic treatment does leave the patient with a urethral diverticulum in most cases. An occasional patient with a huge diverticulum and a defect in the spongiosum may benefit from open repair, which allows reconstruction of the valve, diverticulum, and investing tissues (Fig. 50B.18). In a rare patient with severe renal disease associated with obstruction, a temporary cutaneous vesicostomy may be used to allow drainage and improvement in renal function (130).

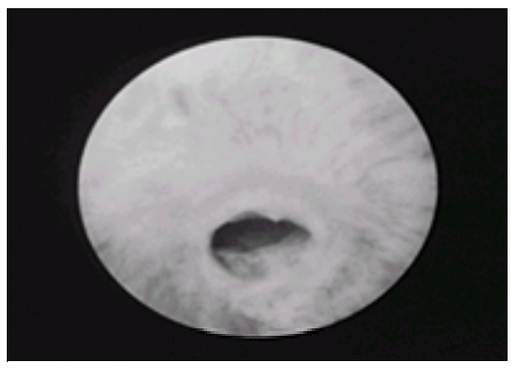

FIGURE 50B.17. Retrograde endoscopic view of anterior urethral valves.

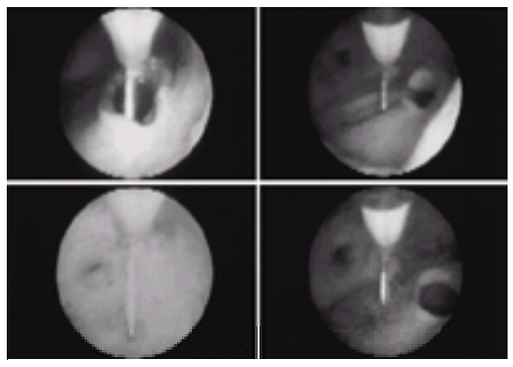

FIGURE 50B.18. Transurethral incision of anterior urethral valves.

URETHRAL ATRESIA AND AGENESIS

Urethral atresia and agenesis must be included in the differential diagnosis of renal anomalies and bilateral hydronephrosis diagnosed *in utero.* Unfortunately, unless there is some other egress for the urine to escape the bladder, such as a patent urachus or a urorectal communication, these lesions are not compatible with renal development. Management will depend on the specific anomaly and the amount of renal function salvaged by alternative urinary drainage.

URETHRAL STRICTURE

Urethral strictures in children are the result of three etiologic possibilities: congenital, infectious, or traumatic (iatrogenic or noniatrogenic).

Congenital

The question as to whether congenital strictures truly exist has been previously debated. Having cared for children who have had no previous trauma or instrumentation of the urethra and finding a stricture has convinced us that these do exist. However, the distinction between a congenital and a type 3 valve can be quite difficult, with the first being just distal to the veru and the latter found in the membranous urethra. The true incidence of congenital stricture is not known. However, if one defines a stricture as being congenital when there is no known trauma or instrumentation, Kaplan and Brock (93) found that 14% of the strictures they encountered in children fit this classification.

Infectious

Infectious etiology is a rare cause of strictures in children due to the generation time for strictures to develop, often being decades. Inflammatory etiology should be considered different than infectious, and indwelling catheters play a role in development.

Traumatic

A traumatic event is the single most important etiologic factor in the development of stricture in children. A straddle injury or iatrogenic trauma following endoscopy, traumatic urethral catheterization, and surgery accounts for most events leading to stricture. Previous series have shown posthypospadias surgery patients to

represent the largest group of patients with iatrogenic stricture (93). Treatment for these is presented in Chapter 52B.

MEGALOURETHRA

Megalourethra is a rare congenital anomaly characterized by abnormal dilation of the pendulous urethra. It shares some of the characteristics of a urethral diverticulum but includes more extensive and uniform involvement of the urethra. The anomalies were originally described by Nesbitt (113) in 1955 and then classified by Dorairajan (38) in 1963. The classification of fusiforme and scaphoid types reflects the severity of the defect and the resultant effect on the corpus spongiosum and corpora cavernosum. The scaphoid form results from deficiency or absence of the ventral corpora spongiosum. A fusiforme megalourethra also affects the dorsal sponge and corpora cavernosa. More recently, Adamson and Burge (2) have described a third type with all corpora intact.

The cause of megalourethra remains somewhat controversial. Stephens and Fortune (139) postulated that a delay in cannulization of the distal epithelial core might lead to obstruction and proximal dilation. Others have suggested that embryologic arrest of the mesoderm investing the urethral folds influences the development of the corpora and erectile tissue (38).

Megalourethra is often associated not only with other urorectal anomalies such as imperforate anus, prune-belly syndrome, and urethral valves, but also with varying degrees of uropathy (54,55,66,98,131,135). Diagnosis is often suspected on physical examination, particularly if the child is seen to void (Fig. 50B.19). The urethral meatus may be normally placed but patulous. The rare and more severe fusiforme type is often characterized by a soft, elongated phallus with palpably inadequate corpora. Ventral ballooning with voiding is typical of scaphoid megalourethra. Voiding cystourethrography and renal ultrasonography are performed to establish the diagnosis and evaluate the upper tracts (Fig. 50B.20).

FIGURE 50B.19. Megalourethra suggested by physical examination.

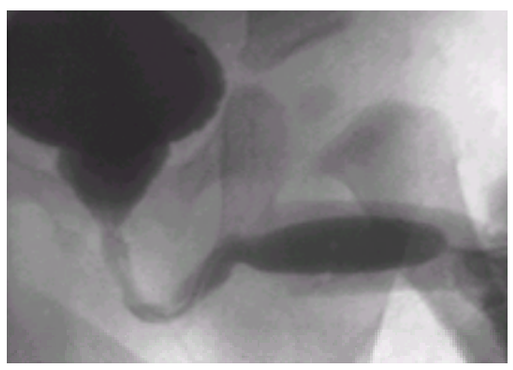

FIGURE 50B.20. VCUG of scaphoid megalourethra.

Treatment centers on reconstruction of the urethra and spongiosum using common principles of hypospadias repair. The scaphoid urethra can be opened longitudinally using the better dorsal and lateral tissue (Fig. 50B.21). The fusiforme variety presents a much more difficult challenge depending on the amount of corporal tissue present. Some may be impossible to completely repair from a functional standpoint and benefit from corporal reconstruction with placement of penile prostheses as adults. Uropathy remains a significant problem. Appel and colleagues (4) noted that 19 of 31 patients with scaphoid megalourethra ultimately developed azotemia or had died from renal failure, as did 7 of 10 with fusiforme megalourethra.

FIGURE 50B.21. Operative view of scaphoid megalourethra. **A:** Before opening urethra. **B:** With urethra laid open.

URETHRAL DUPLICATION

Another rare set of urethral anomalies is duplication. Johnson (86) suggested that faulty fusion of the genital ridge and urethral fold could result in two separate channels, and Lowsley (106) proposed persistence of the urogenital plate during infolding of the genital ridge as an explanation. Considering the many different anatomic variants, there is probably no common embryologic pathway to explain all findings of urethral duplication. Equally confusing have been classification schemes that have come forth for these anomalies. The wide variety of anatomic variations prohibits simple classification and easy division into specific categories (31,153). Simple, unique descriptions of each lesion as used by Effmann and colleagues (46) based on the plane of duplication, the dominant urethra, and the position of the meatus are useful (Fig. 50B.22).

FIGURE 50B.22. A–J: Variations of presentation for urethral duplication in the sagittal plane. Note in each of these drawings that the ventrally positioned channel is depicted in the central region of the prostate, indicating that it is the more normal urethra. (From Colodny A. Urethral lesions in infants and children. In: Gillenwater JY, Grayhack JT, Howards SS, et al, eds. *Adult and pediatric urology,* ed 2. St. Louis: Mosby, 1991, with permission.)

Urethral duplication can occur with complete duplication of the phallus or urinary bladder as a more severe abnormality. Most duplications occur in the sagittal plane with a single phallus. When one is found above the other in this setting, the ventral one is virtually always the dominant urethra. Woodhouse and Williams (153) described sagittal duplication with the dominant, ventral urethra opening in an orthotopic position on the glans beneath a secondary epispadiac urethra. Sagittal duplication can also occur with the dominant urethra exiting in a hypospadiac position and the accessory urethra in the orthotopic position. Many of the nondominant dorsal urethras end blindly short of the bladder. If, however, they do reach the bladder, the child is often incontinent from the accessory channel. The dominant, ventral urethra typically has a normal path through the sphincter mechanisms and remains continent. In those cases associated with an epispadiac meatus, a widened symphysis pubis may be found, suggesting a relationship to the exstrophy–epispadias complex (19,134).

In those patients with sagittal duplication and the dominant urethra in an abnormally ventral location, the anomaly can be complete or partial, in which case the urethra bifurcates distal to the bladder neck. The dominant, ventral meatus may be found anywhere along the penile shaft with the most severe position being that of a meatus located at the anterior anal verge (Fig. 50B.23). Despite that very abnormal location, the dominant urethra for urinary flow again is usually the ventral one, and the dorsal urethra is usually narrowed and inelastic (Fig. 50B.24).

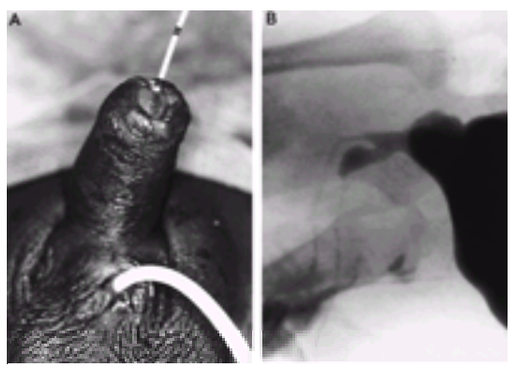

FIGURE 50B.23. Duplicated urethra. **B:** VCUG of complete duplication. (Courtesy of John Wiener, M.D., Duke University Medical Center.)

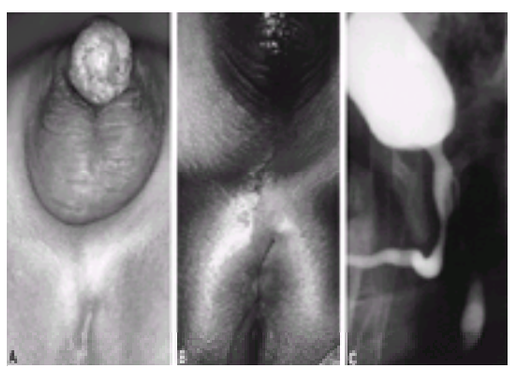

FIGURE 50B.24. A: Duplicated urethra. **B:** Anterior and margin. **C:** Urethrogram of duplicated urethra with unusual dominant dorsal urethra. (Courtesy of John Wiener, M.D., Duke University Medical Center.)

Management of the urethral duplication depends on the anatomy of each particular anomaly. The anatomy can usually be well defined on voiding cystourethrography, which allows preoperative planning for correction. Endoscopy at the time of reconstruction may occasionally be necessary to completely understand the lesion. If the problem is noted because of minor splitting of the urinary stream during voiding, repair rarely may not be necessary (72). Such consideration is typically only appropriate for those patients with both meatuses immediately adjacent to each other, and even those patients may benefit from a simple meatoplasty to combine both openings as one. Complexity of the repair increases as the two openings diverge, especially if the dominant ventral meatus is very proximal. In that situation, the ventral perineal urethra usually must be mobilized away from the rectum to a more orthotopic position and the remainder of the urethra reconstructed with a variety of urethroplasty techniques. A complete prepuce is useful when present. Obviously, patients should not undergo neonatal circumcision if the anomaly is noted. Mucosal grafts may be necessary in some patients having undergone prior circumcision or surgery. They also may be necessary for some patients in whom the prepucial skin is not adequate in length. With the aggressive dissection needed for reconstruction of the ventral urethra, exposure for excision of the accessory, dorsal urethra is usually good. That structure may also be anastomosed to the ventral urethra proximally. Passerine-Glazel and colleagues (118) have described gradual serial dilation of the dorsal urethra to render it useful for voiding. We would prefer mobilization and reconstruction of the dominant urethra in most cases.

URETHRAL POLYPS

Urethral polyps are another unusual anomaly of the male urethra. They may be congenital in nature but have also been reported in adults, suggesting that they can be acquired or that they may slowly grow until large enough to cause symptoms (119) (Fig. 50B.25). Polyps most commonly arise from the verumontanum and are typically covered with transitional epithelium over a fibromuscular core. Arteaga and associates (5) in 1993 reported on 339 cases. The presenting symptoms for most patients included urinary retention, straining to void, urgency, stranguria, and hematuria (123). Voiding cystourethrography often shows a filling defect in the urethra that may vary in location (39). The diagnosis is then confirmed by cystoscopy, at which time treatment consists of transurethral excision (60).

FIGURE 50B.25. Urethral polyp.

ABNORMALITIES OF COWPER'S GLANDS AND DUCTS

Cowper's glands are paired structures found along the posterolateral aspect of the proximal urethra. The main glands lie within the urogenital diaphragm, and accessory glands are located more distally along the bulbous urethra. The ducts from these paired organs travel medially and posteriorly from the gland to empty side-by-side in the bulbar urethra (Fig. 50B.26). Cysts, possibly developing due to obstruction of the orifices, may be seen as a filling defect along the floor of the bulbar urethra on voiding cystourethrography. These cysts were termed *syringoceles* by Maizels and colleagues (108) (Fig. 50B.27). Spontaneous rupture of these cysts may occur, resulting in a diverticular structure in that area or retrograde filling of a prominent duct. Many of the abnormalities of Cowper's glands and ducts may cause terminal hematuria, bloody spotting at the meatus, postvoid dribbling, or obstructive symptoms. Most Cowper's duct anomalies are discovered as minor findings on voiding cystourethrography done for urinary tract infection or other reasons and are probably asymptomatic.

FIGURE 50B.26. VCUG of Cowper's duct.

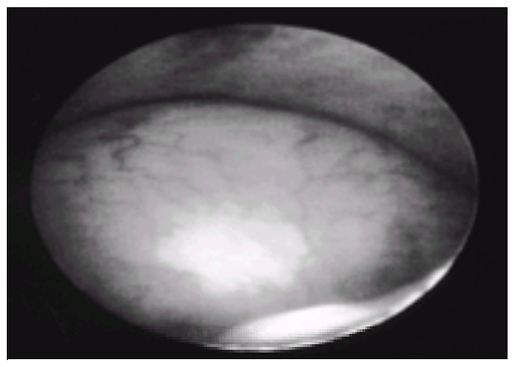

FIGURE 50B.27. Endoscopic view of Cowper's cyst.

Surgical treatment is reserved for those patients who are symptomatic. Transurethral unroofing of a cyst typically is adequate, although one should take care not to leave a distal obstructing lip, which may act as a valve. Open resection by a perineal approach has been occasionally performed for a massively enlarged cyst producing obstruction (15).

VALVE OF GUÉRIN (LACUNA MAGNA)

This very distal anomaly was first described by Guérin in 1864. It is a diverticulum of the dorsal urethra (lacuna magna) that is partially separated from the glanular urethra by a septum. Embryologically, it is thought to result from abnormal fusion of the very distal urethra formed from canalization of ectodermal ingrowth in the proximal urethra developing from urethral folds. Sommer and Stephens (138) discovered the anomaly in 10 of 20 routine postmortem examinations, suggesting that mild forms may be asymptomatic or a variant of normal. Symptomatic presentation is rare; Friedman and King (58) noted 10 symptomatic cases over a 7-year period. The most common presenting complaints in their experience were blood spotting in the underwear, hematospermia, and hematuria.

The diagnosis of such an anomaly is elusive unless one is looking carefully for it. The valve of Guérin may be noted on a VCUG if careful examination of the distal urethra is performed. The lacuna magna may mimic a small drop of contrast at the meatus (Fig. 50B.28). Even at endoscopy, the cystoscope will pass the lesion immediately with insertion without careful placement. Gentle probing of the dorsal aspect of the meatus may be useful in patients suspected of the anomaly. Once identified, the valve can be easily crushed and incised with the scissors.

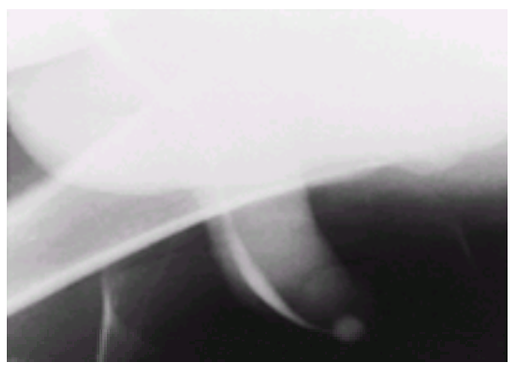

FIGURE 50B.28. VCUG of a valve of Guérin. This appearance can be mimicked by a drop of contrast at the meatus.

MEATAL STENOSIS

Meatal stenosis is a common, usually acquired, abnormality of the male urethra. It is most often found in boys after newborn circumcision. Irritation of the meatus in the months or years following that procedure may eventually lead to narrowing of the meatus. The lesion is usually identified after toilet training when the urinary stream is easier to observe. The classic sign of meatal stenosis is a very narrow urinary stream that is upwardly deflected. In routine cases, not enough obstruction is created to cause renal or bladder effects or urinary tract infection. We have seen rare boys with meatal stenosis and a history of bloody spotting or intermittent dysuria who have responded well to meatotomy. Anecdotally, occasional boys have had resolution of enuresis with meatotomy as well.

One should be careful not to overdiagnose meatal stenosis based on the visual appearance of the meatus. Although appearing nearly pinpoint, the meatus may sometimes be very elastic at voiding. Meatal calibration or simple observation of voiding is typically diagnostic. By 18 years of age, 90% of boys have a meatal caliber of 12 Fr or larger. Treatment consists of a meatotomy. This historically required a brief anesthetic procedure. It is now well tolerated as an office procedure with the use of anesthetic creams. Acquired meatal stenosis after surgical reconstruction of the urethra, particularly following hypospadias repair, can result in much more significant obstruction and sequelae.

Complex Reconstructions
Chapter References

The child with significant anatomic and/or functional abnormality of the urinary tract can present a major challenge. The spectrum of potential abnormalities can be broad and can encompass many anatomic and physiologic variations. Furthermore, it rapidly becomes obvious to one involved in treating such patients that not only does the understanding of these complex problems change with time but so do the available modalities for therapy. A century and a half ago, ureterosigmoidostomy was performed in a young boy with exstrophy, initiating the concept of a surgical approach to a problem that had been believed to be nonapproachable. Fifty years ago, urinary diversion was the most appropriate treatment for children with exstrophy, severe urethral valves, and myelodysplasia; however, it now is rarely used as a primary treatment for these conditions. The early part of the twentieth century ushered in more aggressive surgical approaches to a variety of urologic malformations in children. At that time, the primary therapy, urinary diversion, certainly salvaged renal function and the lives of many children. However, it was Hendren (16), among others, who initiated the next phase of treatment. He applied recently developed techniques of reimplantation of the ureter to prevent reflux (35), developed techniques for megaureter repair, and used newer endoscopic technology with fiberoptics primarily to destroy urethral valves (13,14). The result was what he termed *undiversion* (15). In fact, with his reconstruction of the urinary tract, he actually was correcting the primary problem such that the urinary diversion could be reversed and the previously nonfunctional urinary tract could function more appropriately. The net result of undiversion was that it became obvious that primary diversion could be and should be avoided. Care should focus on primary repair rather than diversion and undiversion. Hence, undiversion really paved the way for primary reconstruction. The real proof of the success of undiversion is that it rarely is necessary anymore. These facts lead us to the questions, where are we in this progression of understanding and technology, and what are some of the important lessons learned?

Lessons Learned

Patient Assessment

Although a certain patient may carry a well-recognized diagnosis (e.g., cloaca, cloacal exstrophy, exstrophy, epispadias, spina bifida, urethral valves, caudal regression, bilateral ectopia), each patient must be considered as unique and in the total context. Management and care must be tailored according to individual needs. How can the needs of a particular patient best be met to achieve an endpoint of “good health” and to maximize social acceptability? The following are the general goals of reconstruction:

- Protect renal function.
- Minimize infection.
- Maximize social acceptability (dependable urine and bowel control).

For some patients, normal voiding may be a real possibility. However, when not possible, intermittent catheterization may be the next best alternative and may result in a dry patient. However, this requires manual dexterity and commitment on the part of the patient and patient support systems. The limitations of the patient, family, and support systems must be clearly understood before reconstruction can be considered. For example, an orthotopic catheterizable stoma is ideal in the young female with good dexterity and mobility who is dedicated to making it work and is concerned about her body image. Unfortunately, the same form of continent diversion is a potential disaster in an obese, wheelchair-bound female patient with poor upper extremity dexterity. However, a catheterizable, continent channel constructed between the bladder and umbilicus may work ideally in such a patient. An extreme example is a teenager with myelodysplasia who refuses to actively participate in self-care. Urinary reconstruction that depends on frequent self-catheterization could result in significant risk of bladder rupture in such a patient. This patient may be best treated with pads or urinary diversion into an appliance.

A clear, individualized plan for reconstruction and care must be formulated to fit the particular clinical situation. Before any surgery, this plan is presented to the patient and family. All involved in the patient's care must make a clear commitment to the anticipated postreconstruction course of therapy. Without such a commitment, reconstruction should not be considered. The “technically best reconstruction in the world” is a failure if the patient and/or support systems cannot or will not comply with therapeutic plans.

The concept of support systems goes far beyond the immediate family. It includes school systems, local physicians, friends, institutional personnel, and the like. If a patient is either very young or incapable of self-care, a care support system must be in place to ensure maintenance of an adequate treatment plan. A complex patient with little or no dependable support system may be best treated with a passive form of therapy (i.e., diversion or pads) rather than risk loss of renal function or sepsis because someone “forgot” to catheterize or administer medications. As the surgeon, one should know the home environment of the patient considered for reconstruction. Unfortunately, this is all too often ignored in a busy clinical setting. A good surgeon knows and understands the surgery, a great surgeon also knows the patient.

Age and Development

The age of the patient can be a significant consideration. In very young children, major reconstruction as described by Hendren (15) may not always be appropriate. For example, it is now clear that it is not necessary to reconstruct dilated ureters in infants with valves or significant reflux. Many of these patients will improve significantly in the first year or two of life (4). Furthermore, megaureter repair in the very young child can result in obstruction (34). Similarly, ureteropelvic junction obstruction may improve with time in some patients (44). On the other hand, it progresses in some young patients. It may be impossible to perform intermittent catheterization frequently enough in the infant with myelodysplasia to protect the upper tracts, but in the older patient this is no problem. A primary difference between children and adults is that children, particularly the very young, are continually and rapidly changing. For example, it is well known that, in the urinary tract, the kidney does its major growth and maturational development in the first few years of life (see Chapter 47). It is becoming more apparent that the bladder also changes from its structure and physiology *in utero* to a completely different structure and physiology after potty training. Therefore strategy of treatment and follow-up must be adjusted to accommodate this potential change. This is true of both prereconstruction and postreconstruction patients. Stability in follow-up may be defined in terms of weeks and months, not years. The value of following the growth curves of these patients cannot be overemphasized. In many cases, a flattening in the patient's growth curve offers the first clue to difficulties in the young child. In fact, considering the many expensive tests used in the chronic care of children with significant urologic problems, the simple monitoring of height and weight often is the most useful in assessing the general status of the patient.

Children and young adults present an emotional and developmental “moving target” for the physician. Very young children heal faster than older children but may have a greater tendency to have urinary obstruction from edema. Therefore double-J stents may be useful in reimplantation of the ureter or pyeloplasty in neonates but may be used rarely in teenagers. It is possible to perform a pyeloplasty as a 24-hour admission in a 6-month-old, but not in a 10-year-old.

Emotional development and maturity of the patient significantly affect management planning. For example, it rarely is appropriate to anticipate that a 4-year-old child will actively participate in self-catheterization. However, most 8-year-old children will perform self-catheterization. Even so, there are many 8-year-old patients who can self-catheterize but who need to be continually reminded (this may go for teenagers as well), and there are some 8-year-old children who cannot catheterize

themselves. Many young children and teenagers are capable of self-care but choose not to follow treatment plans. Caregivers often overlook this simple formulation in trying to understand why a patient is not doing as well as anticipated. Sometimes, what a patient says is happening is actually what the patient wants to be happening. Unfortunately, this may not be what is really going on. A patient may inform a physician that all is going well, when actually this is not the case at all (this is why surgeons have difficulty getting accurate follow-up data from their patients).

Management of urinary and bowel incontinence seems to be particularly sensitive to these patient variables. It is a general rule of thumb that if a patient, regardless of chronologic age and maturity, does not care if he or she is wet (or soiled), treatment for incontinence will fail despite the wishes of family and physicians. Surgery for incontinence is based firmly on the maturity and commitment of the patient. This clearly changes with patient age, depending on school, cohort, and sibling pressures. Simply stated, the same procedure for incontinence may fail in a 6-year-old but be successful in an 8-year-old, with patient maturity being the main variable. Unfortunately, the failure at age 6 may jeopardize the treatment at age 8. Patient maturity and commitment go a long way toward securing a successful outcome in reconstruction surgery, particularly for urinary continence. These issues are as important as any preoperative study and can result in failure in the face of “perfect” surgery. Unfortunately, the assessment of maturity and commitment are difficult and presently not precise. Emotional testing instruments are available, but these are used in only the more complex and obvious situations (e.g., autism, developmental delay, severe illness) (24,40). Usually, however, the judgment on appropriate timing and type of procedure is left to the surgeon's assessment of the information available, such as direct observations in the preoperative period, interviews with parents and patients, and input from other professionals involved in the patient's care. The key questions to be answered are listed in Table 51A.1.

Information	Key Questions to Be Answered
History	
Support systems	Are support systems in place? Are they committed to therapy as outlined?
Patient age and maturity	Will the patient be committed to and capable of following therapeutic plans?
Physical	
General growth and development	What is the general health of patient? Is there evidence of significant metabolic disease? What is the potential for change?
Neurologic and physical examination	Will patient be able to care for himself or herself? Can patient get to the toilet? Can patient do CIC?
	What are the specific needs of this patient?

CIC, clean intermittent catheterization.

TABLE 51A.1. ASSESSING THE CHILD FOR URINARY RECONSTRUCTION OR CONTINENCE SURGERY

History and physical examination of the patient should be thorough, with particular attention to findings that may have specific bearing on potential therapeutic options. Because of the broad spectrum of possible anatomic and physiologic abnormalities, only general concepts will be covered here. Broken down into the simplest terms, only a few questions need to be clearly answered.

1. What is the health of the patient and is there evidence of significant metabolic disease? What is the potential for change?

   Patient height, weight, vital signs, and general appearance often are the most direct method of answering this question. A history of polydipsia and polyuria may give early indication of significant renal impairment with concentrating defect. Polyuria complicates any reconstruction because the urine volume load must be accounted for in planning any continent reconstruction. This is particularly important in previously diverted patients who can produce large urine volumes. This can be overlooked because, usually, little attention is directed to urine volumes collected in external collection devices. Because children are in a constant state of change, correction of a pathology can have a major long-term positive effect; for example, when a chronic infection in the urinary tract is corrected. Another example would be urinary undiversion or reconstruction in a renal failure patient planned in preparation for renal transplant. Native renal nephrectomy may be considered if a significant renal concentrating defect would potentially contribute to patient dehydration after transplantation.
2. Will the patient be able to care for himself or herself? Can the patient get to the toilet? Can the patient possibly perform self-catheterization?

   Commitment to care has been mentioned previously; however, regardless of desire, realistic assessment of the patient's physical ability to perform self-care should be clearly and accurately assessed. It does not make sense to create a catheterizable stoma if the patient cannot perform self-catheterization and no support system is available to provide this aspect of care.
3. What are the specific needs of the patient?

   Every patient is different and unique, and the specific potential needs of the individual patient need to be clearly delineated. What is good for one patient may be totally inappropriate for the next. The caring physician must demonstrate diagnostic acumen to define these unique needs, and the flexibility and ingenuity to respond appropriately. These skills need to go far beyond the successful planning and execution of the surgical procedure.

   Broken down to the simplest denominator, a physician needs to know whether the patient has the mental capacity to comprehend, the physical ability to enact, and the will to carry out therapeutic plans.

STUDIES

The broad spectrum of potential pathologies makes required studies somewhat unique to the individual patient. In general, the studies required for urinary reconstruction need to define the anatomy and physiology of the entire genitourinary tract and other systems that may affect the success of the reconstruction. Most of these are outlined in Table 51A.2 and have been specifically mentioned elsewhere in this text.

Area of Interest	Useful Studies
1. Anatomy	PE, KUB, ultrasound with contrast (IVP, VCUG, retrograde, antegrade, fluoroscopy, CT), MRI, cystoscopy
2. Physiology	
a. Kidney	Chemistries (CBC, electrolytes, BUN, creatinine, calcium, phosphorus), DMSA, MAG-3 with furosemide, 24-hour urine for creatinine clearance and volume
b. Ureter, bladder, urethra	Contrast (antegrade perfusion study, IVP, urodynamics with fluoroscopy)
3. Other	
a. Pelvis	KUB, CT pelvis
b. Spine/neurology	Ultrasound (newborns), KUB, MRI
c. Gastrointestinal	Chemistries (vitamin B_{12}, folate, electrolytes), contrast (upper GI study)
d. Genital (internal)	Ultrasound, MRI, CT contrast (CT, gentiogram), endoscopy

BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; DMSA, dimercaptosuccinic acid (scintigraphy); GI, gastrointestinal; IVP, intravenous pyelogram; KUB, abdominal radiograph; MAG-3, mercaptoacetyltriglycine; MRI, magnetic resonance imaging; PE, physical examination; VCUG, voiding cystourethrogram.

TABLE 51A.2. STUDIES OFTEN REQUIRED FOR URINARY RECONSTRUCTION IN CHILDREN

Evaluation of the Anatomy of the Urinary Tract

The anatomy of the urinary tract can be assessed with a number of studies as outlined in Table 51A.2. However, a detailed and accurate surgical history often provides more information than many expensive studies. Knowledge of what was previously done (surgeries and other therapies) and why may be critical to the ultimate success or failure of a planned complex procedure. Physical examination can be of great help as well. For example, observation of an abdominal mass may indicate ureteral or bladder outlet obstruction or possibly a problem with bowel elimination. Abdominal scars and stomas should correlate with the patient's history. Absence of abdominal muscles may indicate prune-belly syndrome and inherent problem with the structure of the ureters, bladder, and urethra. Imperforate anus may be associated with reflux and other urinary abnormalities. A single or absent perineal opening is consistent with a urogenital sinus or cloaca malformation and

indicates a broad spectrum of potential malformation of the bladder, urethra, genitalia, rectum, and spine. Components of the vertebral, anal, cardiac, tracheal, esophageal, renal, and limb (VACTERL) association may implicate urinary abnormality. Epispadias may indicate significant bladder neck malfunction. Spinal malformation, sacral dimple, or hair patch may indicate potential for neurogenic bladder dysfunction.

Radiologic evaluation minimally includes a plain radiograph of the abdomen (KUB); renal; and bladder ultrasound and contrast studies to clearly define the entire urinary tract. For patients with previous surgery, diversion, infection history, or ureteral dilation, it often is helpful to study the ureters with fluoroscopy to define the exact anatomy of the ureters and the presence or absence of peristalsis. A voiding cystourethrogram (VCUG) will define the presence and grade of vesicoureteral reflux, reveal the nature of the bladder wall and bladder neck, and may help define the presence or absence of bladder outflow obstruction. In children, magnetic resonance imaging (MRI) or computed tomography (CT) rarely are necessary. However, they may be indicated in cases of poor renal function, question of calculus, or ureteral or renal ectopia.

Cystoscopy with anesthesia remains the gold standard for defining the anatomy of the pelvic structures that open to the perineum (16). Complex cases often require cystoscopy as an isolated diagnostic procedure before the definitive surgery. At the time of this initial diagnostic study, a suprapubic tube may be placed to facilitate urodynamic evaluation. It should never be presumed that radiology alone can totally define the anatomy despite the skill of the radiologist and the use of advanced technology.

Physiology of the upper and lower urinary tracts also should be evaluated carefully before reconstruction surgery. Kidney function is evaluated by standard chemistries. Debate exists in consideration of the timing of reconstruction or undiversion in the face of marginal renal function. It is now generally held that it is better to perform reconstruction before renal transplant to facilitate normalization of the urinary tract before transplantation and immunosuppression (11,26). Many children with obstructive uropathy (e.g., ureterocele, urethral valves, cloaca, ureteral ectopia) will have normal or only slightly elevated serum creatinine in the face of a significant concentrating defect. This may be suspected with slightly elevated serum blood urea nitrogen (BUN), resulting from dehydration. This is important to realize before reconstruction, because the volume of urinary output in such patients can be quite prodigious and must be included in the calculations of functional bladder capacity. Twenty-four-hour urine collection for volume and clearance and urinary specific gravity will help define renal function and inability to concentrate urine.

The physiology of the ureters, bladder, and urethra can be defined with urodynamic evaluation. In the case of the ureters, antegrade perfusion with pressure monitoring (Whitaker test, or fixed pressure perfusion) and fluoroscopy can define peristaltic potential and possible obstruction (45,46,48). Mercaptotriglycylglycine (MAG-III) scan with furosemide (Lasix) washout also can be used. The specifics of these studies are covered elsewhere; however, observation of the presence or absence of ureteral peristalsis is crucial in planning ureteral repair. A peristaltic ureter usually can be tapered with realistic anticipation that it will ultimately function as a normal ureter. Conversely, an aperistaltic ureter usually indicates significant ureteral pathology that probably will *not* change with reconstruction; such a ureter must be considered to be a “lead pipe.” It will function as a fixed tube only, with the energy for flow coming from the pressure differential of each end of the ureter (the kidney). Any distal ureteral resistance (i.e., reimplantation or poor bladder dynamics) will result in relative obstruction of the kidney. This is why reflux megaureters with history of infection and previous surgery (aperistaltic) seem to be more difficult to successfully reconstruct than obstructed megaureters (37).

The dynamic assessment of the lower urinary tract is the foundation of a successful reconstruction/undiversion. The problem is that the studies are difficult to perform in many patients because of patient factors (age and poor cooperation) and physiology (massive reflux or diverted urinary tract). The needs of each patient are determined by all information available; usually, the projected bladder capacity and need for construction of a catheterizable stoma are based on history as well as physical and urodynamic study. Hourly urine output is calculated based on the 24-hour collection. Functional bladder capacity can be estimated by assuming bladder emptying every 4 hours (catheterization more often than every 4 hours usually is inconvenient and not realistic). Therefore the approximate projected need for bladder volume is as follows:

24-hour urine volume ÷ 6 = Anticipated bladder capacity

For example, if a patient has a 24-hour urine volume of 2,400 mL, his or her 4-hour capacity is 400 mL. If the patient does not get up at night, he or she needs an 800-mL bladder to make it through. Furthermore, if from urodynamics, the bladder pressures are calculated to be more than 30 cm H_2O for a significant proportion of the time (based on anticipated urine volume), the patient is at risk to develop hydronephrosis (2,18).

As shown in the hypothetic study in Fig. 51A.1, if the calculated 4-hour volume is A, the patient has appropriate bladder volume and capacity, and reconstruction does not need to include bladder augmentation. However, with the same pressure–volume relationship, if the 4-hour urine volume is B, there may be inadequate volume/compliance to properly protect the upper tracts, particularly if the patient is not waking to empty the bladder at night. In such a patient, if reconstruction were anticipated without accommodation for this physiology, the upper tracts may be put at risk and urinary continence may be a problem.

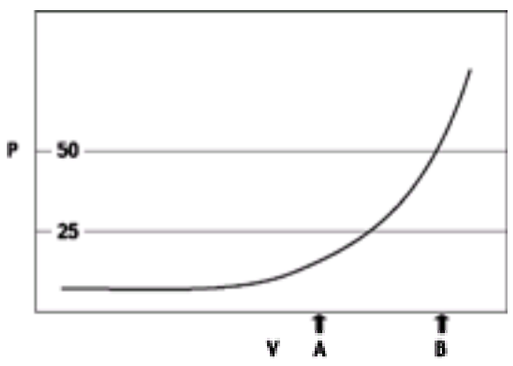

FIGURE 51A.1. Bladder pressure volume relationship. **A:** Average predicted 4-hour urine volume for patient A. **B:** Average predicted 4-hour urine volume for patient B. P, pressure; V, volume.

Other studies may relate to defining the anatomy and physiology of the pelvis, spine, gastrointestinal (GI) tract, and genital system, any or all of which could have direct or indirect impact on urinary reconstruction. However, because of the broad spectrum of pathology possible, the evaluation of a given patient must be individualized.

For patients with exstrophy complex, caudal regression, cloaca, and pelvic tumors, detailed evaluation of the pelvis may be necessary, including three-dimensional (3D) CT scan. The size of the pelvis may be relevant in considering physical space for a bladder or continent reservoir. This may be particularly important in the young patient after radiation therapy, or severe pelvic flattening in the patient with cloacal exstrophy. A wide symphyseal diastasis may indicate the need for pelvic osteotomy, particularly if reconstruction for continence is contemplated (5,23,27,33,39).

Many patients with significant urinary malformation also are at risk for spinal malformation. This is seen with ectopia of the kidneys, imperforate anus, cloacal malformations, and VACTERL complex (8,17,25,41,43). The spine can be evaluated with a variety of studies, including ultrasound in newborns, spine films, and MRI. MRI is useful in the evaluation of patients for cord tethering when clinical symptoms suggest this diagnosis.

Many urinary reconstructions require an intraabdominal approach and use of bowel; therefore assessment of the GI tract is very important. Minimally, a KUB should be obtained with an abdominal ultrasound. Upper and lower GI series may be indicated, particularly in the patient with previous surgeries or history of intestinal malabsorption. A nutritional evaluation also may be considered in some patients, particularly if poor growth and development is observed, which may relate to chronic illness, renal or hepatic failure, chronic diarrhea, or ileostomy and short gut syndrome. This information may be critical in planning the surgical procedure and postoperative management of the patient. For example, small bowel resection may be contraindicated in a patient with cloacal exstrophy and an ileostomy, but gastrocystoplasty may be appropriate.

Evaluation of genital malformations beyond careful physical examination includes contrast studies of every available orifice (cystogram; vaginal and rectal study; or urogenital sinus study or cloacal study). MRI or CT can be used to augment the pelvic ultrasound to better define ureteral and müllerian duct structures. Endoscopy

under anesthesia usually is the most dependable method for elucidating the potentially complex anatomy of some of these patients.

Preparation of the Patient and the Surgeon

With the current efforts to reduce hospitalization time, early hospitalization for bowel preparation and final assessment is a luxury that few medical systems can afford. This is unfortunate, because day-of-surgery admission for procedures that may take 12 to 14 hours sometimes is associated with increased risk from inadequate bowel preparation, superficial evaluation by anesthesia, and even inadequate information availability for the surgical team (patients forget to bring the outside studies). Therefore most institutions now will accept admission the day before a major procedure. However, in many cases, we see the patient the day before, in clinic, for reevaluation by the surgical team and anesthesiologist. Outpatient bowel preparations are inconsistent and seem to depend totally on patient and support systems. Patients in whom bowel preparation is critical should be admitted early. The type of bowel preparation is the surgeon's preference. The authors use a mechanical preparation only.

The Surgeon and the Operative Team

Other than the surgeon and his or her operative assistant(s), the team is completed by the following persons:

1. *Anesthesiologists* with extensive experience with children and prolonged operative procedures are the keystone to the operative team. Without excellence in anesthesia support, even the most skillful surgeon cannot and should not attempt a major urinary reconstruction in children.
2. A *scrub nurse* and a *circulator* who have extensive experience with pediatric urologic surgical techniques and procedures are important members of the team. To a large degree, the efficiency of the procedure resides with them. In a prolonged case, inexperience in this portion of the team can add hours to the operating time with needless frustration and tension. Ideally, the team should be composed of people with long-term commitment and extensive experience with these procedures.
3. A *hospital facility* that is equipped to handle complex surgeries and postoperative care and that is staffed with a full complement of pediatric specialties including pediatric neurosurgery, pediatric surgery, pediatric plastic surgery, pediatric orthopedic surgery, pediatric intensive care, infectious disease, pulmonology, gastroenterology, and rehabilitation medicine is necessary for a successful surgery.

The surgeon, who is in charge of this team, must approach challenging cases with as much information as possible (see previous discussion) and with a surgical plan that includes options for dealing with almost every anticipated complexity. The key is to always have an alternative plan—just in case. Still, the need for ingenuity and inventiveness at the time of the surgical procedure is always present.

COMPLEX RECONSTRUCTIONS

Urinary reconstructions, such as urinary undiversion, in the child can be complex in evaluation of the patient, in planning, and in execution (16). Each procedure is unique and depends on multiple variables, some of which are not very predictable (30,31 and 32,38). It sometimes is easier to consider the previously mentioned *clinical objectives:*

1. Protect renal function.
2. Minimize infection.
3. Maximize social acceptability.

With these in mind, the *surgical objectives* would be to achieve the following:

1. Unidirectional low-pressure flow of urine from the kidney to the bladder
2. A large, compliant bladder
3. Dependable urinary continence (Fig. 51A.2).

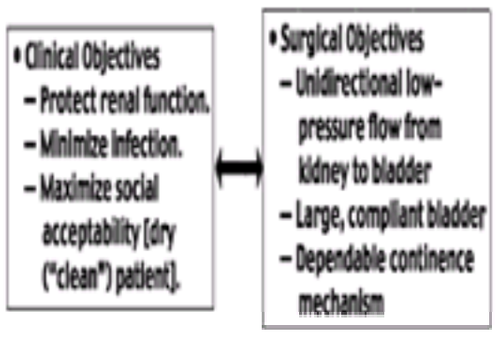

FIGURE 51A.2. Clinical and surgical objectives in urinary reconstruction in children.

Almost every urinary reconstruction can be broken down into multiple associated techniques that focus on achieving the aforementioned surgical objectives. The remainder of this chapter is dedicated to a few of the currently used procedures and techniques believed to maximize potential for success in achieving these objectives. These certainly will change as the concepts and understanding of the physiology and pathophysiology of the developing urinary tract grows.

Unidirectional low-pressure flow from the kidney to the bladder is covered in the section on ureteral reimplantation, megaureter, and ureteroureterostomy. The urodynamic and radiologic evaluation also is covered elsewhere in this text. One important concept is that ureters can vary in potential for peristaltic function and potential for function. Certain ureters, classically those with associated urethral valves and/or reflux with recurrent infection, can have little potential for peristalsis. This seems to result from potentially irreversible change in the ureter with replacement of the ureteral muscularis with collagen. The net effect is that such a megaureter, when tapered and reimplanted, may become functionally obstructed regardless of the surgical procedure employed (7,21,22,28,37,42). Such ureters can be best considered “lead pipes”—conduits for urine whose flow depends on the pressure gradient. However, extensive tapering may improve the flow because wall tension for a given pressure is reduced so that minimal contraction potential is maximized (12). In the patient with prune-belly syndrome, the distal ureter can behave in such a manner while the proximal ureter functions more normally; therefore the tendency to remove as much of the distal ureter as possible. The appropriate timing for ureteral surgery to maximize the potential for healing and function is not known. However, it is the general impression of those with extensive experience in pediatric urinary reconstruction that the earlier the repair with restoration of “normal” physiology, the better the potential to achieve a normal ureter (9,13,47). Often, the repair includes correction of reflux and reduction of bladder pressure (29).

If construction of a large, compliant bladder is the cornerstone of urinary reconstruction, then clean intermittent catheterization (CIC) is the keystone. There are many procedures for the creation of a large, compliant bladder; however, as mentioned previously, the critical issue is not only the characteristics of the constructed bladder (reservoir) but the regularity and completeness of emptying. Unfortunately, this so often is limited by patient factors that are poorly understood before surgery, because the patient (and/or support systems) could not adequately comply with the plan of therapy (i.e., regular bladder emptying). It sometimes is better not to reconstruct, not to undivert, but rather to maintain some patients with passive modes of therapy (in pads or diversion), particularly if preoperative assessment raises questions about commitment or capability of the patient and support systems. In this author's opinion, this is the single, most critical issue of complex urinary reconstruction in children. Failures often come from nontechnical factors; unfortunately, the technical aspects tend to be discussed most often. Many options exist in bladder reconstruction. The current trend seems to be focused on early treatment, permitting the bladder to heal and function normally, thus avoiding the need for augmentation. This seems to be true in exstrophy, in patients with valves, and even in patients with congenital neurogenic bladder dysfunction (1,3,4,6,10,19,20,29,36,47,49). In fact, the need for augmentation may be interpreted, in the near future, as a failure in early treatment of the primary problem.

The cost of urinary continence can be high in terms of risk and heartache to the patient and family. It depends on multiple factors that ultimately determine a delicate balance between bladder function and urethral function (Fig. 51A.3). The surgical procedures described to increase urethral resistance to achieve continence

(dryness) depend on the compliance and capacity of the bladder. However, the foundation of surgery for continence is CIC (Fig. 51A.3). Urinary continence with voiding to completion is certainly an objective of many reconstructions, but often is a difficult endpoint to achieve. In fact, many procedures for dryness totally depend on CIC, the Kropp procedure, the Mitrofanoff procedures, and almost all continent reservoirs, to mention a few. Furthermore, even if voiding is anticipated, as in a Young-Dees-Leadbetter procedure or with placement of an artificial sphincter, the potential for CIC still must be secure (i.e., with either a catheterizable urethra or stoma). CIC represents the single greatest contribution to urinary continence in children, not only as a primary therapy but also by facilitating potential for reconstruction in patients who previously could be treated safely only with pads or urinary diversion. Therefore the commitment to CIC by the patient and family/support system before surgery must be absolute. The only exception to this would be continent diversions based on the rectal sphincter (i.e., ureterosigmoidostomy or the Ghoneim rectal bladder procedure).

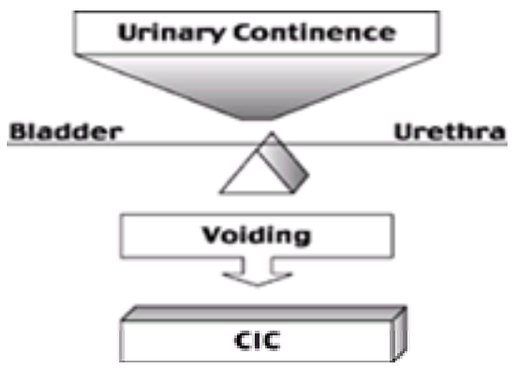

FIGURE 51A.3. Urinary continence, a delicate balance between bladder and urethral factors. Most reconstructions for continence in children are based on the potential need to use clean intermittent catheterization *(CIC).*

The potential for surgical complications from operations that involve a number of different procedures, such as ureteral reimplants with transureteroureterostomy (TUU), bladder augmentation, and bladder neck and Mitrofanoff procedures, increases with every additional procedure. Therefore the potential for complication is as shown in the following equation:

$$0.90 \times 0.95 \times 0.85 \times 0.80 \times 0.85 \approx 0.49$$

Even using favorable outcomes for each component, with each additional procedure the potential for complication is approximately 50%, which may be a somewhat pessimistic projection, but it does make the point that extreme care in planning and execution is necessary to achieve the anticipated results. During surgery, time should not be the critical factor. These procedures can be long and difficult and require complete concentration; therefore they should *not* be performed by a busy surgeon with a million places to go. The surgeon must be precise and meticulous. If there is any question about any aspect of a procedure during surgery, it should be *r*eperformed. An intraoperative assessment of, “that will probably be all right,” often is condemnation for surgical complication or failure. Furthermore, if one is not confident in the way something looks during surgery, there is *no* confidence that the postoperative course will be smooth. Surgical exposure should be more than adequate; the flow of the operation must be orderly according to the preoperative plan. In contrast to the current trends to minimize surgery and surgical incisions, success in these cases often rests on doing more rather than less. Hendren, the father of undiversion and urinary reconstruction in children, maintains that, “The most common error in surgery is not doing enough, rather than doing too much.” This author believes that this is a useful observation.

Complex urologic reconstructions such as undiversion of a previously diverted patient, repair of a cloaca, repair of a cloacal exstrophy, and primary and/or repeat repair of complex urologic malformations can be facilitated by keeping the following four stages of the procedure in mind:

1. Have a plan with multiple prioritized options.
2. Secure a wide exposure and keep all options open (do not throw anything away, do not cut any blood supply).
3. Define the anatomy completely before the repair is initiated.
4. Do a complete repair; cover all bases and satisfy all objectives.

The feeling at the conclusion of the procedure should be that this is absolutely the best job that could have been done.

In summary, complex urinary reconstruction in children is a challenge that encompasses a broad spectrum of procedures and physiology. Every case is unique but usually can be broken down into component procedures that are well established. The patient evaluation, surgical plan, procedure, and follow-up flow naturally and are interdependent (Table 51A.3).

Phases of Urinary Reconstruction in Children	Key Questions
1. Patient evaluation History Physical Studies (e.g., radiograph, urodynamics)	1. What are the patient's special needs? Is clean intermittent catheterization (CIC) possible?
2. Surgical plan development Set goals and objectives Determine and prioritize options	2. What are the objectives? What is the surgical procedure?
3. The procedure Wide exposure, keep options open Define anatomy completely Repair completely, cover all bases	3. How can the potential for success be maximized?
4. Postoperative care Follow-up, anticipated Management of complications	4. Have goals and objectives been successfully achieved?

General Considerations
Technical Considerations
Surgical Correction of Vesicoureteral Reflux
- Intravesical Procedures
- Extravesical Procedures
- Combined Procedure

Laparoscopic and Endoscopic Ureteral Reimplantation
Transvesical Laparoscopic Ureteral Reimplantation
Subureteric Injection for Vesicoureteral Reflux
Surgical Correction of Megaureter
Special Circumstances
- Ureteral Duplication
- Neurogenic Bladders
- Infants
- Complications
- Persistent Reflux

Chapter References

GENERAL CONSIDERATIONS

Indications for surgical correction of reflux may include (a) high-grade reflux unlikely to resolve; (b) persistent urinary infections despite prophylactic antibiotics; (c) poor compliance with prophylactic antibiotics; (d) reflux that persists in girls at puberty; (e) failure of kidney growth, presence of new kidney scars, or deterioration of renal function during observation; (f) parents highly unreliable to keep follow-up appointments; and (g) failure to thrive in young children with high-grade reflux. Indications for reimplantation are shown in Table 51B.1.

MAJOR	MINOR
1. High-grade reflux	1. Reflux after puberty
2. Breakthrough infections	2. Failure to thrive in young child
3. Poor compliance with therapy	3. Unreliable parents
4. Poor renal growth or new scarring	

TABLE 51B.1. INDICATIONS FOR REIMPLANTATION

It probably is more accurate to say that the decision for surgery to correct reflux is based case by case and depends on multiple factors and considerations. Perhaps the most important preoperative consideration is whether reflux is primary or secondary. In the latter case, bladder dysfunction should be managed optimally before any surgical decisions are made (51). Furthermore, it is important that parents and patients are clear that correction of vesicoureteral reflux will not eliminate the potential for urinary tract infection, but that it will diminish the future risk of pyelonephritis. In the International Reflux Study, surgical patients experienced only half as many postoperative episodes of pyelonephritis as did the nonsurgical group (38). However, bacteriuria is relatively common, reported in up to 40% of postreimplant patients, most without pyelonephritis (64,66,68).

TECHNICAL CONSIDERATIONS

The literature regarding surgical correction of vesicoureteral reflux contains descriptions of a remarkable array of procedures. Generally, when a medical condition has many procedures described for its correction, it is because none of those procedures has a predictably successful outcome. However, in the case of ureteroneocystostomy most procedures share equally high success rates of greater than 95%.

In years past, cystoscopy was commonly performed before antireflux surgery to evaluate the bladder wall, ureteral orifice position, and submucosal ureteral tunnel length. Because the location and configuration of the orifice correlates closely with the radiographic grade of vesicoureteral reflux and measurement of tunnel length is poorly reproducible, cystoscopy before or at the time of antireflux surgery seldom provides additional information regarding these variables.

Improvement in surgical technique, instrumentation, and magnification has lessened patient morbidity significantly. As always, good surgical exposure is key. Sponges packed in the bladder dome and retracted superiorly will flatten the posterior wall of the bladder, and vastly improve visualization of the trigone. A self-retaining ring retractor (Denis-Browne, Bookwalter) works nicely for this exposure. Many surgeons use surgical loupes to better visualize the ureter and to facilitate dissection. Delicate handling of the bladder and a “no touch” technique with the ureter have lessened the degree of postoperative ureteral edema, and thus shortened the hospital stay. The use of fine forceps (Gerald forceps) and fine-tipped scissors (tenotomy) are important.

A good understanding of the anatomy of the ureter in the pelvis is crucial in performing extravesical reimplantation. Many times, the ureter is not easily seen adjacent to the bladder and finding the ureter crossing posterior to the obliterated umbilical artery or anterior to the common iliac vessels facilitates surgical progress. It is important to recognize that the most common major complications after antireflux surgery are ureteral obstruction and persistent reflux. Keeping this in mind during the procedure helps the urologist create adequate submucosal tunnels and avoid obstructing sutures, ureteral devascularization, or acute ureteral angulation.

SURGICAL CORRECTION OF VESICOURETERAL REFLUX

Each of the techniques is predicated on creation of a flap valve mechanism at the distal ureterovesical junction. This generally takes the form of creating a submucosal tunnel buttressed beneath with detrusor muscle. A 5:1 ratio of ureteral tunnel length to ureteral diameter is the commonly quoted surgical goal, although documentation of this ratio in the literature is scant (55). The physics of a successful antireflux mechanism would require only that the pressure inside the distal ureter slightly exceed that of the bladder. This requires a servo-mechanism such that the intraluminal ureteral pressure is always slightly higher than that of the bladder and rapidly adjusts to bladder pressure. This requires elasticity of the ureteral wall and a luminal diameter that permits coaptation.

Procedures to correct reflux have been categorized in many ways. This section divides the repairs into intravesical, extravesical, combined, and endoscopic. The most

common repairs and those that differ technically in a significant way are illustrated.

Intravesical Procedures

Politano-Leadbetter

One of the most commonly used reimplant techniques in the United States was described by Politano and Leadbetter in 1958 (57). Success rates of 98% to 99% are reported (12).

Technique

Once the bladder is open, the ureter is cannulated for ease of manipulation and a mucosal incision is made around the orifice (Fig. 51B.1). The ureter is dissected free proximally along Waldeyer's sheath away from its detrusor attachments. Once the ureter is free from the bladder, care is taken to sweep retroperitoneal tissue and peritoneum away from the posterior bladder wall so that a right-angle clamp can be passed into the retroperitoneal space from this original hiatus and directed to a more superior position where a new hiatus is to be created. The tip of the right angle is brought through muscle and mucosa at the intended site for the new hiatus, and a second right-angle clamp is then used to pass in the reverse direction. This allows the second clamp to grasp the traction stitch on the ureter and the ureter is thus drawn into the new hiatus. The original muscular hiatus is closed to reapproximate the floor of the bladder. A submucosal tunnel is created from the new hiatus toward the bladder neck so that the ureter can be reimplanted. Once the ureter has been passed through the submucosal tunnel to the proper position on the trigone, it is sutured in place with absorbable suture and the urothelium over the new and old hiatus are closed.

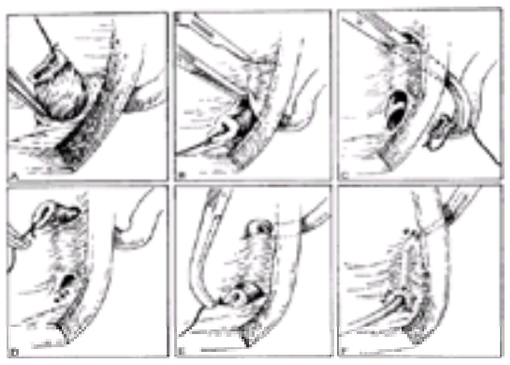

FIGURE 51B.1. Politano-Leadbetter. **A:** A traction stitch aids in dissection of the ureter to free it from bladder attachments. **B:** A new ureteral subepithelial tunnel is made with the right angle and a scalpel incision at the area of the new hiatus. **C:** The ureter is retrieved from its extravesical position. **D:** The ureter is drawn through the new hiatus in the bladder wall. **E:** The ureter is placed in its new subepithelial tunnel. **F:** Ureterovesical anastomosis is completed and the bladder epithelium repaired.

Concerns over the Leadbetter-Politano technique generally revolve around the formation of the new hiatus (15). The Leadbetter-Politano technique has a slightly higher risk of obstruction at the new hiatus as well as occasional problems resulting from inadvertent peritoneal penetration and injury to pelvic organs or intestine.

Glenn-Anderson

The Glenn-Anderson procedure remains one of the more common advancement procedures (procedures using the same ureteral hiatus) in the United States (30). Following modest ureteral mobilization (as per Leadbetter-Politano), a subepithelial tunnel is made from the hiatus down the trigone toward the bladder neck (Fig. 51B.2). The ureter is next passed through the subepithelial tunnel to the new orifice site and matured. For widely spaced ureters on a large trigone, this procedure allows a great deal of promise because the ureter can be advanced significantly onto the trigone creating an adequate tunnel length. In some patients, the trigonal anatomy does not allow for enough advancement and enough new subepithelial tunnel to reliably prevent reflux. For patients with a smaller trigone, Allen (1) modified the technique by dividing detrusor lateral and superior to the original hiatus. This requires that detrusor be repaired after the ureter is “lateralized” to create a new hiatus. This allows the Glenn-Anderson procedure to be used in patients whose ureters do not otherwise allow a significant length of advancement toward the bladder neck from their original hiatus.

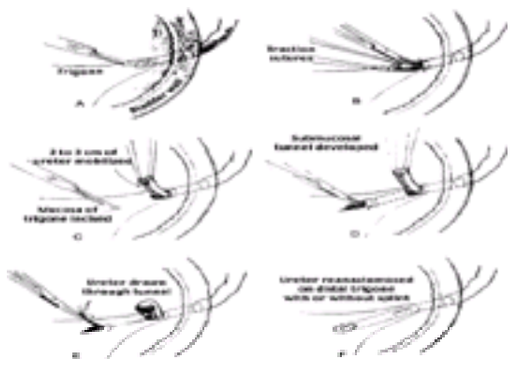

FIGURE 51B.2. Glenn-Anderson. **A:** Incision around the ureteral meatus. **B:** The ureter is freed from its bladder attachments. **C:** Bladder mucosa is incised. **D:** Submucosal tunnel is created. **E:** The ureter is placed in the submucosal tunnel. **F:** Vesicoureteral anastomosis is completed and the original site closed.

Cohen

Cohen (21) described a cross-trigonal reimplant that currently enjoys a great deal of popularity among pediatric urologists (40). A circular incision around the orifice is carried proximally allowing for 4 to 5 cm of ureteral mobilization (Fig. 51B.3). The detrusor hiatus is then partially closed inferiorly. Long subepithelial tunnels are made in a cross-trigonal fashion, placing one ureter cephalad to the other and allowing the ureteral orifice to be sutured in a position on the opposite side of the bladder from which it arises. This operation allows for significant lengthening of subepithelial tunnels without the need for a new hiatus. Therefore postoperative obstruction of the ureter has been reported less commonly with the Cohen technique than with other operations such as the Leadbetter-Politano, which uses a new hiatus. There has been significant concern that as these children grow, attempts at ureteral instrumentation for stones or other urologic disease might be thwarted by the unusual orifice position. However, techniques are available to facilitate instrumentation of the ureter in these patients.

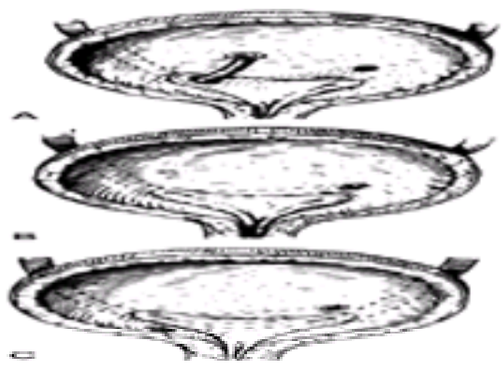

FIGURE 51B.3. Cohen. **A:** The right ureter is freed from its bladder attachments and mobilized with the future reimplant site noted by the *black dot.* **B:** The ureter is placed through the new subepithelial tunnel and anastomosed across the trigone on the opposite side of the bladder. **C:** Both ureters have been reimplanted across the trigone with the right ureter being cephalad to the left.

Hutch I

Hutch (36) contributed significantly to the early enthusiasm for reflux repair by describing a novel technique. This involved splitting mucosa over the ureter, mobilizing the ureter to an intravesical position, and closing the detrusor and mucosa posterior to it. This left the orifice intact, moved the hiatus further laterally, and left a portion of the ureter exposed within the bladder. This procedure seldom is used at present because the intravesical ureteral length gained is not great, and lateral orifices remained in their original lateral position. In 1963, Hutch developed an advancement procedure that, since that time, has gone by the name of Hutch II (35). An incision around the ureteral orifice was made to include a mucosal flap extending toward the bladder neck. The ureter was mobilized modestly. The distal flap was excised, and the ureter was advanced toward the bladder neck into the flap defect. Again, the gain in submucosal tunnel length was modest. This operation, in part, paved the way for the more popular Glenn-Anderson procedure.

Bischoff

In 1957, Bischoff described a U-shaped incision wherein the curve of the U was created over the ureteral orifice and the arms of the U carried toward the bladder neck (11). The edges of the flap were mobilized and then sutured together to extend the ureteral tunnel toward the bladder neck over a ureteral stent. The ureter itself was not mobilized, and the new segment extending from the orifice was simply an epithelial tunnel. The procedure never gained popularity.

Witherington

Witherington described an operation using a mucosal flap based at the ureteral orifice (69). The mucosal flap was mobilized from over the ureteral tunnel and rotated down toward the bladder neck. This flap was anastomosed to two parallel incision lines extending from the orifice toward the bladder neck. This procedure, again, created only an epithelial extension of the ureter, and because of the unusual mucosal flap creation and the minimal extension of the tunnel, it has not been used commonly.

Williams

Williams described a technique wherein a triangular incision distal to the orifice pointing toward the bladder neck was made (67). The ureter was elevated slightly and advanced into the apex of the triangle near the bladder neck. This procedure was not applied widely because it did not significantly mobilize the ureter and thus advancement was minimal.

Gil-Vernet

In 1984, Gil-Vernet touted a very simple technique for vesicoureteral reflux correction (29). This involved an incision made transversely across the interureteric ridge between the ureteral orifices (Fig. 51B.4). A suture was then placed just beneath the orifice and used to draw the ureteral orifices together in the midline. This operation showed initial success and has gained some popularity in Europe. The general feeling among pediatric urologists in the United States is that reflux resolution is not durable, and the technique is uncommonly used in this country.

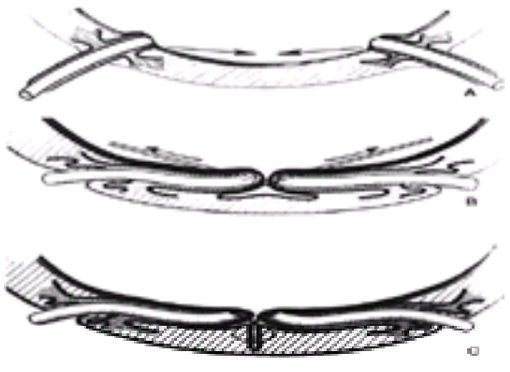

FIGURE 51B.4. Gil-Vernet. **A:** The *arrows* show how the ureters will be drawn together in the middle of the trigone. **B:** A suture is placed at the inferior edge of each ureter and drawn together. **C:** Suture being tied, inverting the trigone, and bringing the two ureteral orifices together near the midline.

Extravesical Procedures

Lich-Gregoir

This extravesical reimplant evolved at similar times in the United States (44) and in Europe (31). This simple technique has subsequently been used more commonly in Europe. It fell out of favor after a 1974 report by Hendren declaring a high reflux recurrence rate (33). As the detrusorrhaphy procedure reintroduced the concept, enthusiasm for the Lich procedure was renewed because of its simplicity and diminished hospital stay.

Technique

This procedure is performed on the posterior lateral bladder wall where the ureter is found and dissected to the bladder hiatus (Fig. 51B.5). In a superior lateral direction from the hiatus, detrusor is divided with electrocautery and the fibers are separated down to the bladder epithelium creating a 3-cm-long epithelial bulge. The ureter is then laid into the trough upon the bladder epithelium, and detrusor muscle is closed over this to create backing for the ureteral tunnel. It is important that the tunnel be created in the same orientation that the ureter naturally courses. When the bladder is retracted, the tendency is to make the tunnel too medial, thereby giving the ureter an opportunity to be kinked. The authors use traction sutures to help flatten the posterior bladder wall and aid in the dissection. Judgment should be used about how cephalad to allow the hiatus to be on the posterior bladder wall with concern that bladder filling may induce ureteral angulation and obstruction.

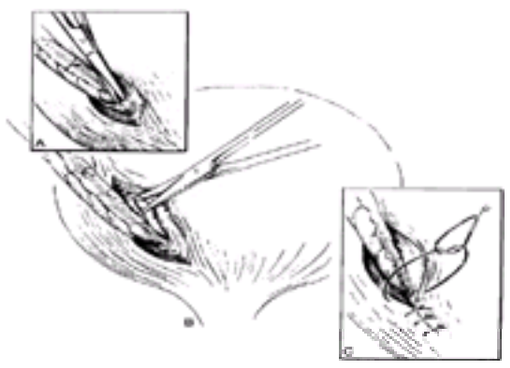

FIGURE 51B.5. Lich-Gregoir. **A:** Extravesical sharp dissection along the ureteral wall to the ureteral hiatus. **B:** The detrusor muscle is separated so that the epithelium can be easily seen. **C:** The detrusor muscle is sewn over the ureter so that the ureter lays against the epithelium and has more detrusor backing.

Detrusorrhaphy

In 1987, Zaontz and colleagues reported a modification of the Daines-Hodgson and Lich-Gregoir extravesical repairs (23,71). The ureter is located extravesically and followed to its insertion into the detrusor. A muscle incision is made around the ureteral insertion, extending 1 cm caudad and further cephalad on the detrusor, allowing muscle fibers to be separated and a bulge of the bladder epithelium to be seen (Fig. 51B.6 and Fig. 51B.7). The orifice is then advanced distally with two sutures placed from ureteral musculature to muscle edge at the distal extent of the detrusor incision; this improves the position of the orifice on the trigone. Once the ureter is advanced approximately 1 cm toward the bladder neck using this method, the ureter is placed within the muscular trough and muscle is closed over it up to a new hiatus. This portion is identical to a Lich-Gregoir repair. Initial success was reported in 93% of cases. Several reports have touted the quick return of bowel function, diminished pain, minimal bladder spasms, and shortened hospital stays using the detrusorrhaphy technique. There also have been reports of postoperative voiding dysfunction and urinary retention (9,45); some have suggested that this technique be limited to unilateral vesicoureteral reflux only caused by high rates of transient voiding dysfunction following bilateral procedures (25). Despite this issue, the procedure remains one of the more popular techniques used in the United States.

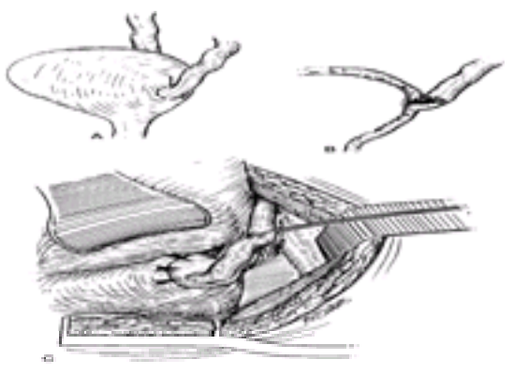

FIGURE 51B.6. Detrusorrhapy. **A, B:** An incision around the extravesical ureter with an extension cephalad on the bladder is made. **C:** The *arrowheads* depict the area around the extravesical ureter that has had the detrusor muscle separated away and the bladder epithelium bulging.

Combined Procedure

Paquin

The Paquin technique combines an extravesical ureteral mobilization with an intravesical reimplant (56). Because of this combined approach, it is not used as often as an exclusive intravesical or extravesical technique. It has been reported to be effective when used with a psoas hitch (49). Success rates have been reported as high as 96% (70).

Technique

The bladder is retracted medially, and the ureter is exposed extravesically, dissected to the bladder hiatus, ligated, and divided (Fig. 51B.8). The bladder is then opened, and a new hiatus superior to and lateral to the old one is chosen. A subepithelial tunnel is created in the direction of the trigone. The ureter is drawn through the subepithelial tunnel, spatulated, and sutured to the selected site on the trigone.

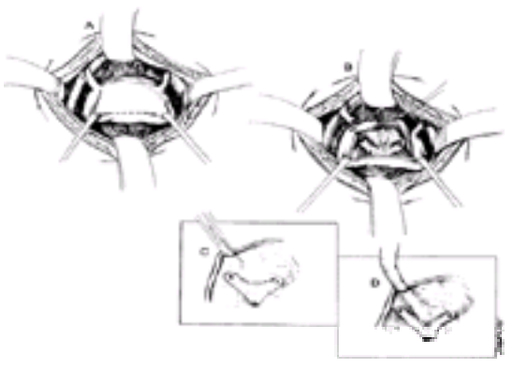

FIGURE 51B.8. Paquen. **A:** The bladder is opened with an L-shaped incision toward the ureter to be reimplanted. **B:** The ureter is divided from the bladder extravesically. **C:** A new subepithelial tunnel is made from a new hiatus toward the trigone. **D:** The ureter is passed through the subepithelial tunnel and reimplanted in the trigone and then the bladder is closed.

LAPAROSCOPIC AND ENDOSCOPIC URETERAL REIMPLANTATION

The past few years have seen a significant interest in developing laparoscopic techniques for achieving ureteral reimplantation. The initial efforts have involved an extravesical reimplant through a transperitoneal approach, essentially a modified Lich-Gregoir reimplant performed laparoscopically (4,5,61). After initial success in a porcine model, a few reports of clinical experience have emerged.

Ehrlich and associates issued an initial report on two patients with “successful outcome” and minimal perioperative discomfort (26). Janetschek and associates described their experience in six children, one of whom required postoperative ureteral stenting for 6 weeks owing to obstruction (37). Although they believed that the procedure was technically achievable, it proved quite complex and offered no significant recovery advantage to the patient. In a more recent and larger series, Larshmanan and colleagues have performed laparoscopic repair in 26 children (37 ureters) ages 4 to 13 years (42,43). The technique requires four ports and gains access to the bladder transperitoneally. Operative time, after an initial learning curve, is approximately 1.5 hours per ureter. With a minimal follow-up (3 months), only 1 of 37 ureters demonstrated vesicoureteral reflux.

Although Larshmanan and colleagues remain enthusiastic, many authors have concluded that the difficulty of the technique puts laparoscopic extravesical reimplant in disfavor compared with open reimplant surgery. Difficult visualization in the deep retrovesical space along with an extended operative time have led to limited application of this approach to date.

TRANSVESICAL LAPAROSCOPIC URETERAL REIMPLANTATION

Shortly after the initial reports of extravesical reimplantation, experience with a combined transvesical and transurethral endoscopic approach to ureteral reimplantation was reported by two groups (16,54). The initial attempt by each group was to use the Gil-Vernet or trigonoplasty concept. The procedure has been termed *endoscopic trigonoplasty* or *percutaneous endoscopic trigonoplasty* (PET).

In this approach, the intravesical space is accessed via two laparoscopic ports placed suprapubically into the bladder. Using CO_2 insufflation of the bladder, a transverse dissection with an endoscopic scissor is carried out between the two ureteral orifices. Mucosa is dissected away from each side of the incision, exposing a muscular trough onto which the orifices may be advanced. Laparoscopic suturing allows a series of sutures to draw the orifices to the midline and thereby elongate the intravesical segment of the ureter (Fig. 51B.9).

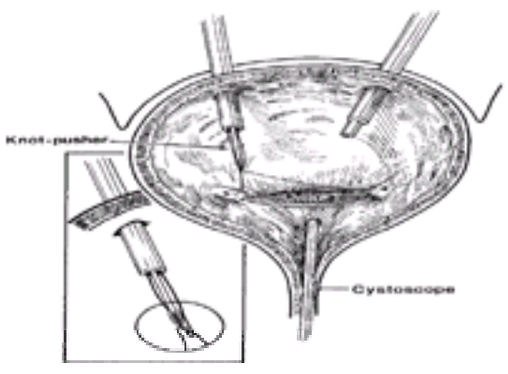

FIGURE 51B.9. Endoscopic trigonoplasty. The suture is tied in the midline drawing the orifices over the muscular trough.

In the most recent series from the two institutions pursuing this approach, success rates are only modest. Cartwright and Snow reported experience in 22 children undergoing percutaneous endoscopic trigonoplasty (16). Reflux was of moderate grade in most and high grade in a few. No ureteral obstruction was created with the procedure, but reflux resolved in only 20 of 32 (62.5%) ureters at a 6-month follow-up. Success was not related to patient age, side of reflux, initial reflux grade, operative sequence, or the presence of preoperative bladder instability. Okamura and associates recently reported a difference in outcomes in children versus adults (53). At 3 months, the resolution rate for adults and children were 96% and 70%, respectively. By 12 months of follow-up, this had decreased to 74% and 59%. As an extension of this technique, there has been a recent small report of seven children undergoing a limited cross-trigonal type of reimplantation following laparoscopic dissection of the ureter and repositioning intravesically (28). This resulted in long-term reflux resolution in 10 of 12 ureters.

Although interesting and technically challenging, these approaches do not seem to warrant clinical application at this point. New equipment and innovations may arise, which will improve the feasibility.

SUBURETERIC INJECTION FOR VESICOURETERAL REFLUX

In the search for a less invasive method to correct vesicoureteral reflux, the concept of subureteric injection was introduced. The basic premise is to supply a buttress beneath the ureteral orifice to compensate for the lack of usual muscular backing to the submucosal tunnel, and thereby cause ureteral mucosa to coapt during bladder filling and prevent reflux.

Matouschek introduced the idea in 1981 using polytetrafluoroethylene (Teflon) paste (47). The procedure was popularized and given the name STING procedure by O'Donnell and Puri shortly thereafter (52). Although the concept has good merit, there has been great discussion about what the ideal substance for injection might be. To date, there have been animal and clinical reports on many substances, both autologous and nonautologous, including the following: Teflon, polyvinyl alcohol, silicone particles (Deflux), bioglass, detachable membrane device, collagen, fat, bladder muscle cells, and chondrocytes (4,6,7,13,14,19,27,48,52,60,65).

The technique for subureteric injection is straightforward. The ureteral orifices are visualized through the cystoscope. A needle-tipped stent (18 to 25 gauge depending on the substance injected) is passed via the working channel and inserted beneath the bladder epithelium at the 6 o'clock position beginning 5 mm distal to the orifice. It is advanced beneath the orifice, and the substance is injected under direct visualization as the bulking material displaces the lumen of the ureter anteriorly (Fig. 51B.10). This is continued until the orifice is pushed anteriorly and obtains an inverted crescent shape; the needle is left in place for 2 minutes so that

extravasation upon withdrawal is minimized.

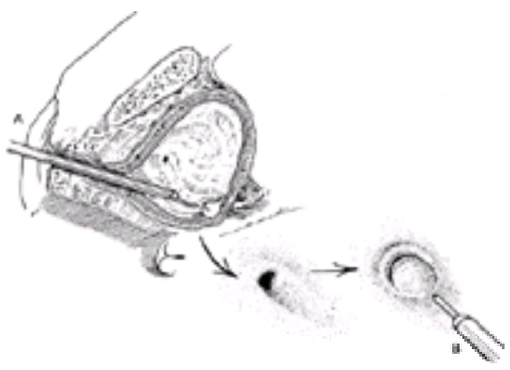

FIGURE 51B.10. Sting. Subureteric injection for reflux. **A:** Normal orifice. **B:** Orifice after subureteric becomes elevated and assumes an inverted crescent configuration.

The results of endoscopic treatment for vesicoureteral reflux are summarized in Table 51B.2. In evaluating these data collectively, it is apparent that reasonable success can be obtained but that the rate of reflux cessation is routinely lower than for standard open reimplantation. In addition, some patients will require more than one injection to obtain the stated results and for all substances there is declining success as patients are followed longer postoperatively. The real attraction to this approach is minimal postoperative discomfort and feasibility to be completed as an outpatient procedure.

Study	Agent	Patient (n)	Ureters (n)	Success Rate (%) —1 Injection
Puri, Wiersby	Teflon	4,234	6,316	75.9
Leonard, Frey, Frankenschmidt	Collagen	483	269	59.8
Stenberg, Lackgren	Deflux	75	101	68.0
Chancellor, Malone	Autologous fat	19	29	22.6
Diamond, Caldamone	Autologous chondrocytes	29	50	60.0

TABLE 51B.2. OUTCOMES IN PATIENTS WITH SUBURETERIC INJECTION FOR REFLUX

Of the nonautologous materials, Teflon is by far the most commonly used (58,59). In addition to data on using Teflon in primary reflux, it has been reported as successful in approximately 90% of patients with persistent reflux after open reimplantation (41). Although its proponents quote a long track record of reasonable success with minimal morbidity, there has been concern about its safety, especially in children. Malizia and associates found, in experimental animals, both granuloma formation around Teflon particles and migration of the particles to lymph nodes, lung, and brain (46). Along with scattered clinical reports of particle migration, this has curtailed the use of the STING procedure in the United States (20,24). The other substances each have drawbacks leading to limited clinical application. Bovine cross-linked collagen has been used with only modest success because of its tendency to break down and lose bulk over time.

Autologous substances may be the source for an eventual acceptable and durable agent due to lack of foreign body reaction and immunogenicity. Fat has proven to be a poor substance due to high bulk loss (18). Autologous collagen has been tried in experimental models and may experience less breakdown than bovine collagen does (17). Quite promising are both autologous bladder muscle cells and chondrocytes harvested and grown on alginate (3,4). Further clinical trials are underway with chondrocyte injection; as always, longer follow-up periods will be needed to see if cessation rates are acceptable. The attractiveness of simple subureteric injection is great enough that the search for an appropriate material, one that is safe, effective, and durable, will continue.

SURGICAL CORRECTION OF MEGAURETER

Regardless of the cause, surgical repair of a megaureter requires the use of one of three techniques: Starr plication, Kalicinski folding, or open tapering.

The most versatile of the techniques is open ureteral tapering, popularized by Hendren in 1969 (32). Careful inspection of the ureteral blood supply is made before deciding on which portion of the ureter to taper. Noncrushing ureteral clamps are placed around the ureter with the ureteral stent in the lumen of the portion to be preserved, and the excess megaureter wall is excised for 6 to 8 cm (Fig. 51B.11). The ureteral wall is then reapproximated side to side with absorbable suture and reimplanted in a subepithelial tunnel by one of the standard methods.

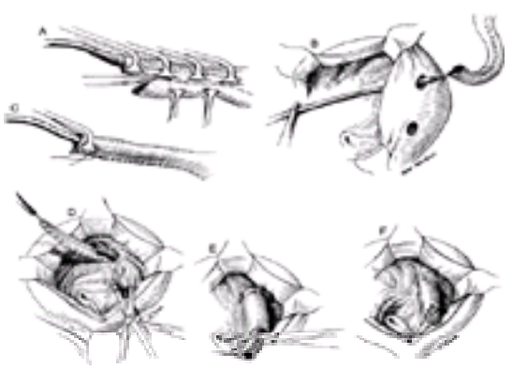

FIGURE 51B.11. Hendren. **A:** Shows megaureter clamps in place and the excessive megaureter tissue being excised. **B:** Shows closure of the megaureter over a ureteral stent. **C:** Extravesical view of the bladder showing the original hiatus and the new hiatus with the tapered megaureter being drawn into the bladder. **D:** A new subepithelial tunnel is made. **E:** The megaureter is drawn through the new tunnel to the trigone. **F:** The megaureter is sutured in place at the trigone with the bladder epithelium being repaired over the new hiatus.

Kalicinski and coauthors described a plication technique in which, over a ureteral stent, a running suture is placed parallel to the stent for the distal 6 to 8 cm (39) (Fig. 51B.12). This excludes a significant portion of the ureter from the urine-containing channel; this excluded portion is folded over the side of the remaining portion and is not excised. This technique is used for small to medium-sized megaureters. Subsequent studies have shown that the excluded ureter lumen obliterates and vascularity is preserved (8).

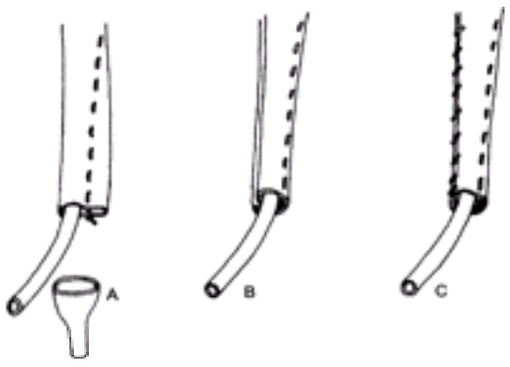

FIGURE 51B.12. Kalicinski. **A:** The distal narrow end of the megaureter is excised, and then a running suture parallel to the ureteral stent excludes a long triangle of the megaureter. **B, C:** The excluded portion of the megaureter is folded around the megaureter and tacked in place with absorbable suture narrowing the entire megaureter for reimplantation.

Starr described an alternative plication technique by placing ureteral sutures in a Lembert fashion along the distal 6 to 8 cm of the ureter, thus enfolding a segment of the ureteral wall over a ureteral stent (63) (Fig. 51B.13). A Starr plication is also chosen when the degree of megaureter is mild to moderate such that the bulk of the plicated ureter is not too great to put into a subepithelial tunnel. It enjoys the advantages of creating no open ureteral suture line and maintaining excellent ureteral blood supply.

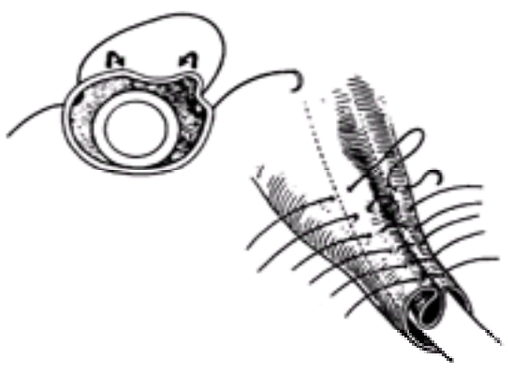

FIGURE 51B.13. Stan. Absorbable sutures are placed in a Lembert fashion to fold in the redundant megaureter making it snug around a ureteral stent.

Reimplantation after the ureter has been narrowed can be by any number of techniques, the most common are the Politano-Leadbetter with a new, more superior hiatus or a cross-trigonal technique (22). The entire tapering and reimplantation also may be accomplished extravesically. Psoas hitches have been employed commonly to lengthen and flatten the posterior bladder wall to allow a longer tunnel length for these more dilated ureters. Postoperative stenting is usually preferred in cases of tapering and in most cases of plication.

SPECIAL CIRCUMSTANCES

Ureteral Duplication

Ureteral duplication commonly is encountered with reflux. Conventional wisdom suggests that the ureters should be reimplanted together, as a common sheath, because distal ureteral blood supply often will be inseparable. Prior reports and personal experience suggest that such ureters may, in fact, be separable in certain cases, and the ureters may be managed individually. A challenging situation arises with duplicated ureters when one ureter is quite large and requires tapering. Tapering generally is carried out on the portion of the larger ureter opposite its attachment to the more normal one to avoid compromising the common blood supply. At other times, it may be best to resect much of the larger ureter, perform a ureteroureterostomy above the bladder, and reimplant the more normal ureter.

Neurogenic Bladders

Neurogenic bladders may function at higher elevated pressures and therefore are commonly associated with reflux that requires surgical repair. The detrusor may be thickened, making reimplantation difficult and not as successful as when performed in a normal bladder. It is crucial to optimize bladder storage parameters using medication, catheterization, or augmentation before or along with reimplantation; this will improve outcomes significantly.

Infants

In the past, surgical repair of reflux has been less successful in young infants when compared with older children. With the improvement of magnification and using loupe magnification and delicate tissue handling, success rates in young infants currently are likely equivalent to those in the older group. It is important to remember that a significant percentage of even high-grade reflux will resolve spontaneously as young infants move through their first year; thus, in most instances, observation is prudent (2,10). This is particularly pertinent in young boys who may initially have high voiding pressures that progressively decrease during the first year of life, making reimplantation unnecessary (62).

Complications

Ureteral obstruction is the most concerning complication after reimplant surgery. Although transient obstruction from edema is relatively common, persistent obstruction, thankfully, is quite unusual. Such obstruction occurs due to stenosis at the orifice, an ischemic distal segment, narrowing or angulation at the muscular hiatus, or kinking around a fibrous band in the retroperitoneum. It is appropriate to obtain ultrasound imaging after reimplant surgery to document that obstruction has not occurred. Imaging too quickly after reimplant surgery may be confusing because residual edema generally will cause modest dilation of the ureter and renal pelvis; imaging at 4 to 6 weeks minimizes this concern. When hydroureteronephrosis is discovered, the severity and clinical circumstances will guide treatment. If the obstruction is mild, observation with repeat imaging may be all that is necessary. If the patient has nausea and vomiting, poor appetite, or pain with worrisome dilation, a percutaneous nephrostomy tube may be needed. Cystoscopic stent insertion may be considered, but often is difficult early after surgery, particularly if cross-trigonal reimplants have been performed. If nephrostomy drainage and contrast imaging reveal continued obstruction, it may be prudent to place an indwelling stent in an antegrade fashion to remain in place for several weeks.

Persistent Reflux

Persistent reflux after reimplantation is a frustrating finding. Persistent reflux is more likely with higher initial grades of reflux. Some authors suggest that if the reflux is mild to moderate (grades I to III) before surgery, cystography after surgery is not required because of predictably high resolution rates. Cystography would only be used if these patients developed future urinary infections.

If cystography is performed and persistent reflux is found, observation on prophylactic antibiotics is almost always the first course of action. Careful voiding history should be obtained and voiding dysfunction should be eliminated, which is often a factor causing persistent reflux. Persistent reflux commonly resolves in the first 6 to 12 months after surgery. In the unusual patient requiring reoperation, standard open reimplant techniques can be performed with a high degree of success.

Preoperative cystoscopy may be helpful to assess tunnel length and to evaluate for the possibility of a ureterovesical fistula (above orifice). Some have used the STING procedure in this circumstance, finding this to be a simple and relatively successful approach for persistent reflux.

Contralateral reflux occurs in 10% to 15% of patients who have undergone a unilateral reimplant. Again, the best course of action is observation (34). Almost all contralateral reflux is low grade and resolves within the first year after surgery (50). Prophylactic antibiotics may be necessary during this time. Again, voiding dysfunction should be suspected and treated if present.

PYELOPLASTY

The approach to the repair of the ureteropelvic junction (UPJ) obstruction has evolved from a ureteral advancement procedure (Foley Y-V–plasty) to incising the ureter and allowing for secondary epithelialization (Davis intubated ureterotomy). In 1949, Anderson and Hynes (2) popularized a dismembered pyeloplasty technique in which the ureter is divided at the renal pelvis, spatulated, and reanastomosed to the opened renal pelvis. Historical approaches that were abandoned are now being revisited due to the popularity of endoscopic and laparoscopic techniques.

Foley Y-V–plasty

The Foley Y-V–plasty is best applied to reconstruction of the UPJ obstruction associated with high ureteral insertion (20). In many respects, it is limited; for example, it is rarely indicated in the patient with an obstructing lower-pole vessel. Furthermore, the technique also does not allow for surgical reduction of the dilated renal pelvis. Therefore use of the Foley Y-V–plasty and other flap techniques has, for the most part, been supplanted by the more versatile dismembered pyeloplasty.

In the approach for a Foley Y-V–plasty, the pelvis and proximal ureter are exposed in the retroperitoneum. A widely based triangular or V-shaped flap is marked on the renal pelvis (Fig. 51C.1). The base of the V is positioned on the dependent medial aspect of the renal pelvis while the apex is brought to the UPJ. The incision is made on the apex of the flap (i.e., the stem of the Y), and this is continued along the lateral aspect of the proximal ureter. The incision in the ureter should completely traverse the area of stenosis and extend well into normal-caliber proximal ureter. The pelvic flap and ureterotomy are then developed. A fine scalpel blade is used to make the initial pelvic incision. Potts or Metzenbaum scissors are used to complete the flap and ureterotomy incisions. An internal stent can be placed and the repair performed over it. The apex of the pelvic flap is first brought to the apex (inferior aspect) of ureterotomy using fine absorbable suture. The posterior walls are then approximated using interrupted or running suture technique. The repair is completed with anastomoses of the anterior walls. Many authors believe that it is preferable to use the interrupted suture technique because it decreases the potential for a purse-string effect on the suture line. An interrupted technique may also minimize ischemia compared with a running suture. However, with finer resorbable sutures, a running vascular technique is faster and equally effective.

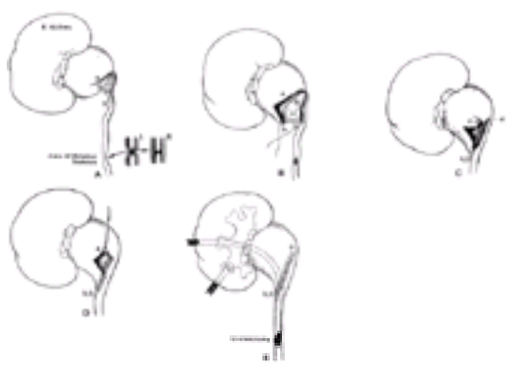

FIGURE 51C.1. Classic Foley Y-plasty. **A:** Anterior and posterior pelvic incisions should be the same length as the ureteral incision. **B:** The tip of the flap and the lower end of the ureterotomy should be approximated first. **C, D:** The closure is started at *(b,b')* and extended upward to *(a,a').* A dog-ear may form at point *a. I* and *II* illustrate the infrequent relative narrowing of the ureter, which is occasionally seen lower in the ureter. **E:** If there is a narrow segment, it can be treated by a ureterotomy or dilation. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH, et al, eds. *Campbell's urology,* ed 4. Philadelphia: WB Saunders, 1979, with permission.)

Intubated Ureterotomy

The Davis intubated ureterotomy, first described in 1943, is rarely used today as an open technique. This procedure, which depends on secondary epithelialization from the incised ureter, can be effective and should be reserved for the rare situation in which it appears to be needed. Its greatest use might be for correcting strictures in the lumbar ureter when the defect is too great to bring the kidney down or the distal ureter up for a primary anastomosis when insufficient upper ureter is present for a direct transureteroureterostomy.

The technical aspects of the intubated ureterotomy remain little changed from the thorough description of Smart (76). The strictured portion of the ureter should be adequately exposed with careful preservation of the ureteric blood supply. A ureterotomy is performed from at least 1 cm above the stricture to 1 cm below, in a meticulous fashion. Proximal diversion must be established with a well-located nephrostomy tube and a stent placed across the ureterotomy. It is critical that the stent not be so large as to induce ischemia and possible stricture formation. Davis (13) recommends stenting for 4 to 6 weeks. A report by Ackerman and Frohmuller (1) achieved a 70% satisfactory result in 68 cases of ureteral intubation. Thus this technique does have sufficient success to maintain it in the reconstructive urologist's armamentarium.

Pelvic Flap Pyeloplasty

The Culp and DeWeerd (12) spiral flap is created from the renal pelvis, which is used to repair the defect at the UPJ (Fig. 51C.2). Such a flap is able to bridge the gap between the pelvis and healthy ureter over a distance of several centimeters. Scardino and Prince (70) described the use of a vertical flap that can be used in the situation of a dependent UPJ with a large, square-shaped extrarenal pelvis (Fig. 51C.3). The rare case of giant hydronephrosis that can be associated with a completely atretic ureter can be dealt with by reconstructing an entire ureter out of redundant pelvic tissue (39). This repair would seem to have a greater likelihood of

success when compared with other autogenous pedicle graft repairs, such as full-thickness abdominal wall skin (38) or appendix (42,84).

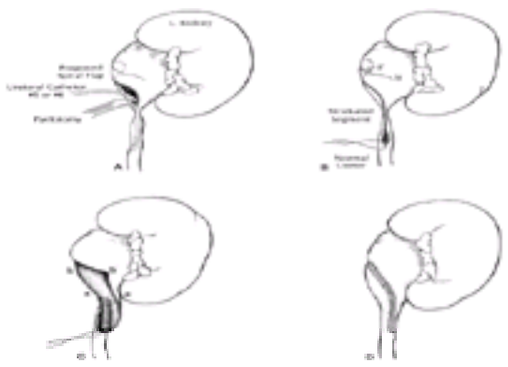

FIGURE 51C.2. Technique of Culp-DeWeerd spiral flap ureteropelvioplasty. **A:** If the ureteropelvic angle is oblique (greater than 90 degrees), a spiral flap will produce an acceptable ureteropelvic funnel. This method also produces a longer flap than the vertical flap operation. **B:** The pyelotomy should be planned and marked with sutures before opening the pelvis. A ratio of length to width of 2:1 or 3:1 should be planned. **C:** Suturing should start at the apex of the flap and the distal ureterostomy. **D:** The edges are closed with 4-0 or 5-0 absorbable sutures. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH, et al, eds. *Campbell's urology,* ed 4. Philadelphia: WB Saunders, 1979, with permission.)

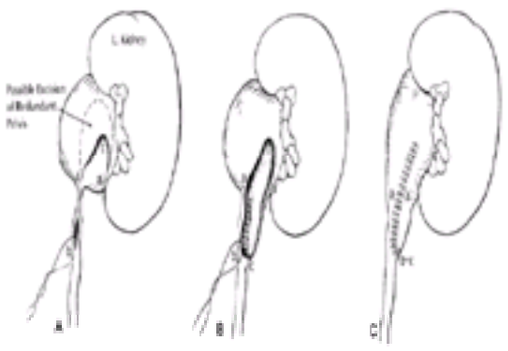

FIGURE 51C.3. Technique of Scardino-Prince vertical flap ureteropelvioplasty. **A:** This technique is best used when the ureteropelvic angle is approximately 90 degrees. The flap should have a 2:1 or 3:1 length-to-width ratio and be the same length as the ureterotomy. **B:** A pyelotomy is made in the lower pelvis and carried down the ureter. **C:** The flap is cut and redundant pelvic tissue excised with sharp plastic surgical scissors. The apex of the flap is sewn to the end of the ureterotomy incision. Absorbable sutures (4-0 or 5-0) are used, starting at the apex so that any dog-ears will be in the renal pelvis. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH, et al, eds. *Campbell's urology,* ed 4. Philadelphia: WB Saunders, 1979, with permission.)

Dismembered Pyeloplasty

Most urologists routinely use a dismembered pyeloplasty because this procedure is almost universally applicable for the repair of a primary UPJ obstruction. The technique may be used for a high or dependent insertion of the ureter on the renal pelvis. It also facilitates reduction of a renal pelvis or straightening of a lengthy, tortuous proximal ureter. Furthermore, anterior or posterior transposition is easily accomplished in cases with aberrant lower-pole vessels. In contrast to a flap technique, the dismembered pyeloplasty allows complete excision of an anatomically or functionally abnormal UPJ. Dismembered pyeloplasty may be inappropriate in patients with a long segment of proximal ureteral obstruction or for patients in whom the UPJ is associated with a small intrarenal pelvis, which would be difficult to access.

With an open repair, the approach to the UPJ is retroperitoneal, using either an anterior abdominal approach with muscle-splitting technique (anterior) or a posterior lumbar approach (posterior lumbar). Exposure of the UPJ is generally obtained with initial identification of the proximal ureter in the retroperitoneum. The ureter is minimally dissected cephalad toward the renal pelvis. Care must be taken to preserve periureteral tissue for ureteral blood supply (Fig. 51C.4). Once the UPJ is identified and the pelvis dissected free of surrounding periureteral tissue, the medial aspect of the proximal ureter is marked with a fine suture placed below the level of the obstruction. This helps maintain proper orientation during repair and prevents twisting of the ureter, a known cause of operative failure, particularly when the repair is done from the posterior (kidney retracted medially and anteriorly). Similarly, the superior, lateral, and medial aspects of the dependent portion of the renal pelvis may be tagged with traction sutures. The UPJ is then transected and the proximal ureter spatulated on its lateral aspect well distal to the area of narrowing to the most dependent point of the anticipated anastomosis. The redundant portion of the renal pelvis is removed (amount depends on the degree of pelviectasis). One must beware of excessive excision in the patient with elongated calyces. The spatulated ureter is then brought along the medial aspect of the open renal pelvis. The anastomosis is initiated at the most dependent portion of the opened renal pelvis and at the most distal apex of the spatulated ureter. A 7-0 Maxon running suture is used to suture the spatulated ureter to the renal pelvis. The posterior suture is completed initially, followed by a second anterior suture. The technique is similar to that of a vascular anastomosis. It is sometimes helpful to leave a 5-Fr pediatric feeding tube in the ureter during the most distal portion of the anastomosis. This is removed before completion. A ureteral stent may be placed in very young patients or in complex cases. Usually, for straightforward pyeloplasty, tube drainage is not necessary. Most surgeons do leave a Penrose drain in the flank.

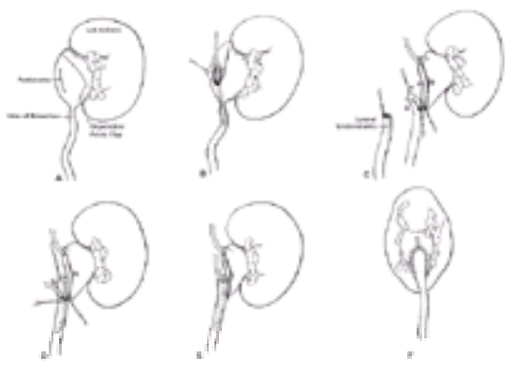

FIGURE 51C.4. Dismembered Foley Y-plasty operation. The obstructing segment is excised and a dependent funneling of the pelvis is achieved. **A:** The pyelotomy and ureterotomy incisions are planned and marked. **B:** The pyelotomy incision is started. **C:** The lateral ureterotomy is done and ureteral stent passed after excising the ureteral segment. **D:** Suturing with 4-0 or 5-0 absorbable sutures is started on the posterior surface at the apex. **E:** Traction sutures are used to approximate the edges. It is important not to crush the tissue with heavy forceps. The tip of the flap is sewn to the ureterotomy. It is important to start at the apex. **F:** The funnel is completed, and any redundant pelvis can be resected. The pelvis is reconstituted. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH, et al, eds. *Campbell's urology,* ed 4. Philadelphia: WB Saunders, 1979, with permission.)

Table 51C.1 outlines the success rate from a contemporary series of predominantly pediatric patients who underwent a dismembered pyeloplasty. Reported success rates range from 83% to 100% in these series. The authors report few complications. Prolonged drainage from the Penrose drain was noted in some instances, but

this did tend to improve over time.

TABLE 51C.1. OPEN PYELOPLASTY

Endopyelotomy

The endoscopic approach to UPJ obstruction has been successful in both an antegrade and retrograde fashion. Balloon dilation was attempted in 13 infants and children (median age of 16 months) (79). Following placement of a guidewire in a retrograde fashion along with dilation of the ureterovesical junction, a 3.8-Fr radial balloon dilator was used to dilate the UPJ, followed by stenting with a 4.8-Fr internal double pigtail catheter for 6 weeks. An overall success rate of 70% was achieved, but the follow-up was brief (3 to 6 months). A similar approach was used in several children using an Acucise device (Applied Medical, ureteral cutting balloon catheter, 5 Fr) (5). Postoperative stenting was required for 6 weeks, with a 100% success rate being achieved. In a much larger series of adult patients, Kim and colleagues (40) reported an overall success rate of 78%. However, two patients required angiographic studies and embolization of lower-pole branching arteries because they developed gross hematuria following Acucise endopyelotomy.

Antegrade endopyelotomy can be readily accomplished in both the adult and preadolescent or adolescent patient. Figenshau and Clayman (19) recommended this procedure for any patient with a reasonably functioning kidney (more than 25% on renal scan), mild to moderate hydronephrosis, and no evidence of a crossing vessel. Computed tomography (CT) or magnetic resonance imaging (MRI) can be used for preoperative assessment of a crossing vessel, or an endoluminal ultrasonography can be used before the procedure. Access to the kidney is usually achieved with the assistance of an interventional radiologist. A midpole posterior calyx provides good access to the UPJ. A percutaneous tract is established, which is dilated to 10 Fr (range of 10 to 18 Fr) if an Acucise balloon is used. An alternative is the use of a 2-Fr fine-tip right-angle electrosurgical probe. Direct visualization of the UPJ obstruction allows for use of a cold knife, electrocautery, and even contact laser fiber to achieve the endopyelotomy (64). Following fluoroscopic documentation of successful incision and/or dilation of the UPJ, a double-pigtail ureteral stent is placed under direct vision in the renal collecting system and fluoroscopically positioned into the bladder.

The issue at hand is whether the need for fluoroscopy with endourologic intervention along with two and sometimes three anesthetics for preoperative stent placement, endopyelotomy, and stent removal are justified when compared with the ease of an open pyeloplasty. Certainly, older pediatric patients may be managed with the less invasive procedures, with good overall results and improved postoperative convalescence.

Laparoscopic Pyeloplasty

The evolution of laparoscopic procedures includes the repair of the UPJ obstruction. Such a procedure is technically demanding because it requires the use of intracorporeal suturing (59). This technique has improved with the use of automatic laparoscopic suturing devices, which allow for much simpler placement of interrupted sutures. To date, most descriptions in the literature have included small series of patients (11,72). The initial descriptions of this technique included an intraabdominal approach with mobilization of the ascending or descending colon, depending on which kidney was affected. Tan described performing the procedure using a 7-mm umbilical trocar and two 6-mm instrument trocars (80). Gerota's fascia is opened with limited mobilization, and the UPJ obstruction is identified by tracing the dilated renal pelvis medially until the gonadal vessels are seen crossing the pelvis. Tan did not find it necessary to insert a ureteral catheter as a preoperative measure for identifying the UPJ. The pelvis is stabilized with a hitch stitch by passing a straight suture through the anterior abdominal wall, suturing the pelvis and passing the suture through the same entry point on the abdominal wall. External traction on the suture stabilizes the pelvis sufficiently to create the anastomosis. The pelvis is dismembered from the proximal ureter. The ureter is spatulated along its lateral margin using the renal pelvis to orient the ureter correctly. Anastomosis is begun by accurate placement of the suture at the apex of the spatulated ureter, taking care not to create a mucosal flap. The ureter is sutured to the most dependent part of the pyelotomy and the two dismembered ends reapproximated with an intracorporeal knot. The posterior anastomosis is completed with a continuous suture locked at the apex. The transanastomotic stent is placed by inserting a Teflon catheter into the anterior abdominal wall and steering it into the proximal ureter. A straight guidewire is passed through the catheter into the bladder. The catheter is withdrawn and a 3.8- or 5-Fr variable-length double-pigtail catheter is passed over this guidewire in an antegrade fashion into the bladder. The proximal end is placed in the renal pelvis. The anastomosis is then completed by closing the pyelotomy and anterior layer with a second continuous suture. The hitch stitch is removed, the UPJ is allowed to drop back into the renal bed, and the proximal ureter and pelvis are inspected to ensure no kinking before the abdominal cavity is desufflated. The entire operation is completed within an average of 90 minutes (range of 70 to 160 minutes).

Table 51C.2 summarizes the published results of laparoscopic pyeloplasty. Even experienced laparoscopists can struggle with such a procedure, though. The patients tolerate surgery well, require reduced narcotics postoperatively, and are discharged home with shorter hospital stays than conventional open pyeloplasties.

TABLE 51C.2. LAPAROSCOPIC PYELOPLASTY

PYELOURETEROSTOMY/URETEROURETEROSTOMY

Pyeloureterostomy or ipsilateral ureteroureterostomy can be used in duplex kidneys to treat upper-pole obstruction or reflux (usually to the lower pole). Significant difference in size does not seem to greatly affect the result. Huisman and colleagues report that significant luminal disparity at the time of ureteroureterostomy resulted in no adverse outcomes (33).

In complete ureteral duplication, the ureters may be treated as completely separate entities as long as care is taken to preserve the unique blood supply to each ureter. Often, when the ureteral orifices are close in the bladder, the distal portion of the duplex ureters will have a common blood supply and very tightly adherent sheath (common sheath). This is important to realize because separation of such ureters distally will result in ischemia of one or both ureters; therefore such ureters

should be treated as a single unit. Proximal ureteroureterostomy or ureteropyelostomy and distal ureterectomy requires very careful dissection to preserve the blood supply of the ureter left in place. This is particularly true of the distal few centimeters of the ureter.

Surgical techniques for ureteroureterostomy and ureteropyelostomy are technically the same. Circumferential suture lines should be avoided; therefore the ureters are spatulated on opposite sides to elongate and oblique the suture line. Although, classically, interrupted 4-0 or 5-0 chromic sutures have been used, many surgeons are now running 6-0 or 7-0 monofilament resorbable sutures. The anastomosis should be absolutely watertight and leakage should *not* be expected. The key to a successful ureteroureterostomy is that it should be tension free, have good blood supply, be watertight, and have a stent going across the anastomosis.

A distal ureteroureterostomy is an excellent alternative for treating a *nondilated* ectopic ureter to an upper-pole segment. The upper-pole ureter is divided as distally as possible and sutured from end to side of the lower-pole ureter. Prestenting of the lower-pole ureter facilitates identification of this ureter and allows for placement of a stent across the anastomosis. The terminal portion of the ectopic ureter can either be left in place, dissected as far distally as possible or simply split widely, and its edges cautiously removed.

An alternative approach in the very young patient or a patient with significant function in the hydronephrotic upper-pole segment is to suture the upper-pole ureter (or pelvis) to the lower-pole pelvis (or ureter). This may be difficult in the patient with an intrarenal pelvis. In such a case, a proximal ureteroureterostomy may be considered. The approach would be like that for a dismembered pyeloplasty (anterior to the kidney but retroperitoneal), and the anastomosis should be free of tension. Table 51C.3 outlines the overall success rates for patients who have undergone either ureteroureterostomy or pyeloureterostomy.

[a]Pyeloureterostomy. [b]Ureteroureterostomy.

TABLE 51C.3. URETEROURETEROSTOMY/PYELOURETEROSTOMY

What then is the risk of a distal ureteral stump causing a problem, and is there a certain anatomy that is more prone to developing an infection? This issue must be decided at the time of pyeloureterostomy or ureteroureterostomy. From the flank approach, the ureter can be dissected well down into the pelvis, particularly in the small child. A small inguinal incision can be made in an infant to remove the majority of the distal ureter, but a Pfannenstiel or Gibson incision may be needed in an older patient. In fact, 10% to 15% of patients can develop a urinary tract infection secondary to the ureteral stump being present (60). Those patients who develop a urinary tract infection were noted to either have reflux into the ectopic ureter preoperatively or developed reflux postoperatively. Thus reflux noted into the ectopic ureter necessitates ureteral stump removal at the time of the renal surgery.

The laparoscopic ureteroureterostomy or pyeloureterostomy has been hindered by intracorporal suturing. Experimental work has been performed using nonperforated titanium vascular closure staples to perform a ureteroureterostomy in a porcine model (43). Short-term histologic analysis shows that when a functionally patent anastomosis is achieved, the technique is fast and effective, without evidence of encrustation, stone formation, or intraluminal clips. Clinical application will undoubtedly be forthcoming.

Ureterocalicostomy

Neuwirt (52) is credited with the first description of the ureterocalicostomy, in which the ureter is sutured to the renal capsule after successful anastomosis to a dependent calyx. This approach led to obstruction of the intrarenal ureteral segment because of fibrosis of the cortex. Jameson and colleagues (34) demonstrated that amputation of enough of the lower-pole cortex to permit the ureter to be safely joined to a tangential opening of the lower-pole calyx was required for success (Fig. 51C.5). Hawthorne and colleagues (24) emphasized this along with spatulation of the ureter to create a maximum diameter patent anastomosis. A stent and nephrostomy tube are usually used. Duckett performed the ureterocaliceal anastomosis over an 8-Fr feeding tube with running fine catgut. A nephrostomy tube (14-Fr Malecot) is also placed through the parenchyma into the renal pelvis or collecting system. Because the caliceal tissue may be inflamed, generous overlapping bites into the fornix and capsule may be of assistance in performing the anastomosis. An omental pedicle graft is brought through a posterior peritoneal window to wrap around the anastomosis. The nephrostomy is clamped, and the stent removed 2 to 3 weeks postoperatively. Such a repair for a previously failed pyeloplasty should be at least 2 months following the initial surgery to allow for resolution of the inflammatory process (15).

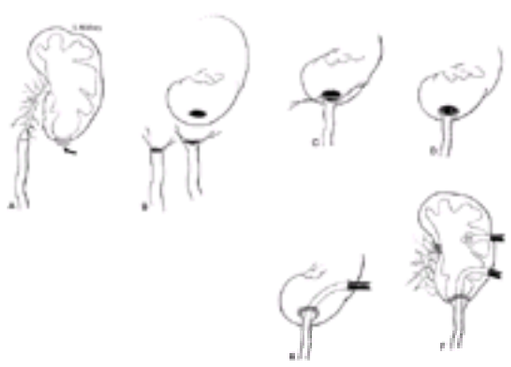

FIGURE 51C.5. Ureterocalyceal anastomosis for difficult situations in which anastomosis to the pelvis is impossible. **A:** The scar tissue is excised. The renal pelvis is closed after placing a stent and nephrostomy tubes. **B:** Ureterotomies are done after orientation sutures are placed in the ureter. The ureteral opening is enlarged, ready for the anastomosis. An elliptic segment of renal parenchyma is excised. The dimensions of the opening should be the same as those of the ureter to be anastomosed. **C:** Ureter is sutured to calyceal mucosa with interrupted 4-0 or 5-0 absorbable sutures. **D:** Ureteral stent is passed after posterior anastomosis is complete. **E:** Anastomosis is completed. **F:** Diagram of funneling. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH, et al, eds. *Campbell's urology,* ed 4. Philadelphia: WB Saunders, 1979, with permission.)

Although not as commonly used as some other techniques for dealing with a short ureter, the ureterocalicostomy can be particularly useful when the pelvis and upper ureter have been rendered unusable secondary to previous surgery or trauma (37). Table 51C.4 outlines several reported series of ureterocalicostomy and their overall success rate. Complications reported have included persistent obstruction of the ureter, renal artery thrombosis, anastomotic urinary leakage, and candidal perinephric abscess.

TABLE 51C.4. URETEROCALICOSTOMY

TRANSURETEROURETEROSTOMY

One of the most useful techniques in urinary tract reconstruction is the transureteroureterostomy (TUU) (Fig. 51C.6). Following an initial description by Hodges and colleagues, the technique gained increasing popularity during the era of urinary undiversion (23,25,28). In both adults and pediatric series, reported success rates have exceeded 90%. This is been tempered by some reports of complications (16,69), but adherence to several principles ensures a uniformly favorable outcome. Wide exposure is essential and usually is achieved transabdominally. Adequate mobilization of the donor ureter is important so that a tension-free anastomosis can be accomplished. Wide ureteral mobilization, including the gonadal vessels in some cases, permits the ureter to be brought to the opposite side without tension. If the ureter is too short to lie comfortably under the inferior mesenteric artery, the ureter should be placed above the vessel. The anastomosis should be placed on the medial wall of the recipient ureter. When possible, the recipient ureter should be left *in situ* without mobilization. This ensures a better blood supply to the area of anastomosis. Spatulation of the donor ureter should ensure a generous anastomosis with the recipient ureter. Size discrepancy between the ureters is not a problem. If the donor ureter is larger than the recipient ureter, it simply is cut at a right angle. The length of incision in the recipient ureter can be varied as needed. Drainage is particularly critical to prevent extravasation of urine and subsequent fibrosis with wound contracture around the TUU. Urine has a remarkable ability to induce the formation of fibrous tissue (55). Accordingly, ureteral wounds from which urine has been diverted have considerably less fibrosis surrounding them. A ureteral stent across the anastomosis is critical. As with any ureteral anastomosis, it should be watertight and well drained to prevent the potential for scar formation. Meticulous attention to technique clearly contributes to the achievement of this goal.

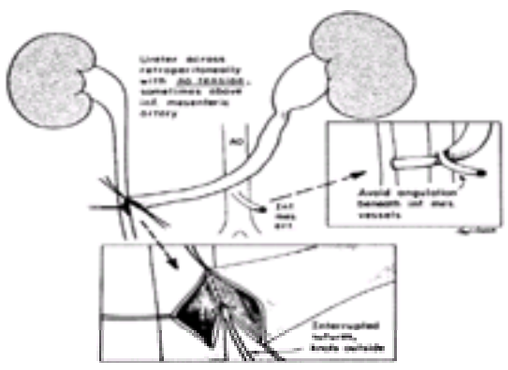

FIGURE 51C.6. Transureteroureterostomy. Meticulous attention to technical detail and avoidance of tension gives a high success rate. (From Hendren WH, Hensle TW. Transureteroureterostomy: experience with 75 cases. *J Urol* 1980;123:826, with permission.)

The usefulness of TUU is primarily in letting one good ureter serve as effective drainage for two renal units. On the other hand, both kidneys are now dependent on drainage from a single ureter. One good long reimplant with a TUU is usually better than two compromised reimplants. The psoas hitch contributes to success in this endeavor. In general, the better ureter with the least dilation is the preferred ureter in which to reimplant into the bladder. Used in this way, TUU can make a major contribution to successful nonrefluxing reconnection of the upper urinary tract to the bladder or urinary reservoir. Table 51C.5 outlines the results of both historical series and contemporary series in which a TUU was used. The overall success rate has been uniformly very good, with successful outcomes reflecting the diverse applications of the TUU (3,7,14). Patients included those with failed ureteroureterostomy, exstrophic bladder, spina bifida, noncontinent diversion, undiversion, and neuropathic bladder. Complications cited were rarely associated with the ureteral anastomosis but included anastomotic leakage, ischemic stenosis of the common ureteral trunk, and progressive deterioration of renal function in one kidney.

TABLE 51C.5. TRANSURETEROURETEROSTOMY

Psoas Hitch and Boari Flap

A large and supple bladder can be used to make up for a deficient ureter. Even when the bladder is small and thick walled, it can often be gently stretched and surgically reshaped to permit a ureteral reimplant to be performed. In general, it is more satisfactory to use up bladder in achieving a nonrefluxing uroepithelial-to-uroepithelial anastomosis than being concerned about the lack of bladder volume that can follow. Augmentation of the bladder effectively deals with the bladder problem, although it too has its own set of problems.

The mobilization of the portion of the bladder by suturing it upward against the psoas muscle above the iliac vessels was popularized in the late 1960s (62,81). This vesicopsoas hitch facilitates reimplantation of the short ureter and permits placement of at least the distal third of the ureter without difficulty (Fig. 51C.7).

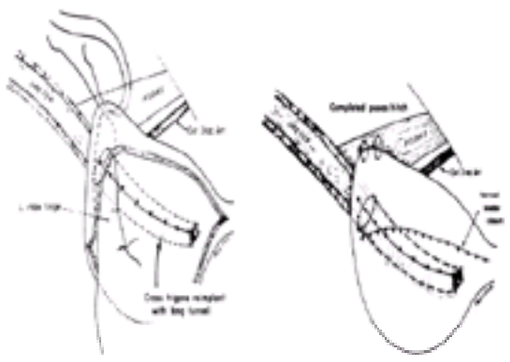

FIGURE 51C.7. Vesicopsoas hitch. Stretch of the bladder and fixation to psoas muscle permits a good reimplant of a short or dilated ureter. The Boari flap is an extension of this technique with a broad flap of detrusor hinged at the bladder dome. (From Hendren WH. Some alternatives to urinary diversion in children. *J Urol* 1978;119:653, with permission.)

The principles as espoused by Hendren (27) in performing such a procedure include opening the bladder on the side away from the proposed hitch to permit more bladder to the stretched up toward the psoas muscle. To facilitate a permanent fixation of the bladder to the muscle, fat is cleared off the psoas and bladder wall to ensure muscle-to-muscle apposition. Either absorbable suture or permanent suture is then placed through the bladder wall but not including the mucosa. It is generally easier to make the hiatus after seeing where the bladder will lie comfortably against the psoas and then creating the submucosal tunnel before fixing the bladder into position. The surgeon can hold the stretched bladder up against the psoas, relieving tension, while the assistant ties down the three to five sutures necessary to anchor the bladder. The sutures directed into the psoas muscle should avoid the genitofemoral nerve. The ureter is then drawn into the submucosal tunnel, taking care that there is no angulation or torsion at the hiatus. Stenting the ureter becomes the surgeon's preference at this point.

The Boari flap is an extension of the concept of the vesicopsoas hitch. Although originally performed successfully by Casati and Boari (10) in experimental dogs, the popularization of the use of a bladder flap for ureteral replacement is the work of Ockerblad (53). In this procedure, a bladder flap is formed from the front wall of the bladder with its hinge at the lateral dome of the bladder, permitting the flap to be rotated upward toward the kidney. By combining this flap with the vesicopsoas hitch, a nearly complete replacement of the ureter can be performed. Essential to the success of this flap is the preservation of a good blood supply to the bladder muscle that constitutes it. The base of the flap should be wider than the apex, and following the principles of plastic surgery, it is best to maintain a length-to-diameter ratio of not greater than 2:3 to 2:1. Boxer and colleagues (6) recommended a base with a width of at least 4 cm and apex of at least 3 cm. It is wise to fix the length of the muscular flap posteriorly against the muscle of the gutter to maintain its position. After the attachment of the ureter, it is tubularized as part of the bladder closure. An antirefluxing, submucosal course for the ureter in the upper portion of the flap can be created as recommended by Gil-Vernet (21).

MEGAURETER

The dilated ureter may contribute to urinary stasis and ineffective peristalsis, which can lead to ongoing damage to the kidney in the form of obstruction and recurrent urinary tract infections. Often diagnosed before birth, the newborn with a megaureter is placed on antibiotic prophylaxis. Voiding cystourethrography (VCUG) and diuretic renography determine the type of megaureter: refluxing, obstructed, both obstructed and refluxing, or neither with or without bladder outflow obstruction. Ureterostomy can stabilize the infected kidney and result in reduction of the ureteral ectasia and reduced ureteral scarring, even potentially making tapering at subsequent reimplantation unnecessary (82). However, ureterostomy may also severely compromise the potential for future ureteral reconstruction.

Hendren's extensive experience with megaureters included performing an upper ureteral repair in nearly 50% of their patients during the 1960s, but only 14% in the 1990s (27a). Successful distal ureteral tapering and reimplantation led to a decrease in the diameter of proximal ureters the majority of the time. The technique of excisional tapering requires careful handling of the periureteral tissues, which provide blood supply to the ureters. The ureter is initially approached intravesically and then extravesically to straighten the ureter maximally. The redundant portion is excised, and formal tailoring performed. The lateral portion of the ureter is preserved and the redundant medial portion excised, with tubularization being performed over a 8- to 12-Fr catheter. The ureter must be gradually tapered to prevent an abrupt transition, which can lead to obstruction. The ureter is closed in a watertight fashion with a running, locking fine absorbable suture, followed by a second layer of absorbable suture. The distal aspect of the ureter is closed with interrupted suture to permit distal resection of the ureter. The ureter is then reimplanted using either a cross-trigonal or Politano-Leadbetter technique.

Carr and Hendren's overall success rate was greater in the obstructed megaureters as opposed to the refluxing megaureters (93% versus 83%). Presumably, this reflects the increased potential for scarring in the refluxing megaureter. The bladder's status also affected the outcome, with “normal” bladders providing for a greater success than those with a history of prior obstruction.

The excisional tapering repair was joined subsequently by two different infolding techniques: the Kalicinski and Starr procedures. These techniques decreased ureteral diameter by imbrication. The Kalicinski ureteral folding technique involves a running suture down the lateral aspect of the ureter to narrow the diameter (35). This free margin of the ureter is then folded back onto the ureter with interrupted sutures. Thus the diameter of the ureter is narrowed, but the bulkiness of the ureter remains. Ehrlich (17) reported an overall success rate of nearly 95% from megaureter surgery using his modification of the Kalicinski repair for megaureters. He simply folded the ureter under the narrowed lumen after placing horizontal mattress sutures to narrow the caliber of the ureter. Starr (78) described a double plication technique to accomplish a reduction in the caliber of the ureter, but this approach of double-folding may have a greater potential for obstruction to occur. Table 51C.6 lists the overall success rate for a number of contemporary series of megaureter repairs.

Author	Year	Technique	Megaureters	Type	Success (%)

TABLE 51C.6. MEGAURETERS

URETERAL RECONSTRUCTION

A number of surgical techniques for ureteral replacement have been described that may become of historical footnote, especially in an era in which tissue engineering holds great promise. The Davis intubated ureterotomy, first described in 1943, depends on secondary epithelialization from an incised ureter. It is no different than the endopyelotomy, in which prolonged stenting facilitates healing of this ureteral segment. An intact blood supply to the segment of the ureter is critical to facilitate appropriate healing. Whereas in the past a 70% satisfactory result was reported by Frohmuller, one wonders whether the use of small intestinal submucosa (SIS) may be beneficial in covering the intact mucosa of the incised ureter (1). Preservation of intact urothelium may be preferable to a small bowel pyelopyelostomy or segmental intestinal interposition (26).

The literature is replete with descriptions of free graft materials in experimental ureteral replacement, such as bladder mucosal graft (31,32), parietal peritoneum (18),

and split-thickness skin graft (29). There are also descriptions of pedicle grafts using appendix (71), full-thickness abdominal wall skin to form a tube (38), and renal pelvis as a successful total ureteral replacement in association with giant hydronephrosis (39). Thus there may be a use for an occasional autogenous pedicle graft repair in clinical practice.

Goodwin and associates (22) popularized the *ileal ureter.* Hendren (26) reported further refinements in the technique. The review of the UCLA experience with children highlighted the importance of bladder emptying in situations of a refluxing ileal ureter (6). The ability of the ileum to resorb urea and electrolytes also can cause complications in patients with significant renal failure, particularly if compounded by poor drainage of the system. Hyperchloremic acidosis was not seen in the UCLA experience if the serum creatinine was less than 2 mg/dL before ileal ureter construction. If intrahepatic disease limits urea metabolism, hyperammonemia can also be a problem. Middleton (46) demonstrated that the absorption of urinary solutes is directly proportional to the surface area of the ileum exposed and transit time. Ileal tapering reduces the surface area significantly, and this theoretically should be advantageous in the creation of ileal ureters in patients in renal failure. Furthermore, tapering of the lower ureters appears to be important in achieving an antirefluxing anastomosis of the ileal ureter to the bladder.

With the construction of a transversely tubularized bowel segment (TTBS) for use as a catheterizable channel, it seems only natural that this principle would be applied for ureteral replacement. Two case reports exist describing ureteral replacement using a reconstructed 2-cm segment of right colon (61) and transverse colon (36). The TTBS has advantages over ileum, tapered or not, for ureteral replacement. The segment used is much smaller, offering less surface to be exposed to urine. A double tube can replace extensive ureteral segments. Additional experience and long-term follow-up will be necessary to determine the ultimate utility of such a procedure, but this technique has rapidly gained favor for the reconstructive surgeon (48).

Augmentation cystoplasty is performed to increase bladder capacity and compliance. The primary use of augmentation cystoplasty in children is to protect renal function, to achieve urinary continence, and often, to facilitate urinary tract reconstruction. The most common problems associated with the need for bladder augmentation in children are neurogenic bladder dysfunction secondary to myelodysplasia, exstrophy of the bladder, and posterior urethral valves. However, many other conditions have resulted in the need for bladder augmentation (Table 51D.1).

Neurogenic Bladder
Myelodysplasia
Sacral agenesis
Caudal regression
Spinal tumors, vascular malformation
Myelitis
Idiopathic
Congenital
Exstrophy (cloacal, classic, epispadias)
Posterior urethral valves
Cloaca
Urogenital sinus
Bilateral single ectopic ureter
Infantile bladder syndrome
Ureterocele
Prune-belly syndrome
Other
Infection (tuberculosis, viral cystitis, bacterial cystitis)
Interstitial cystitis
Iatrogenic (multiple surgeries)
Chemotherapy
Radiation therapy
Tumor (rhabdomyosarcoma, neurofibromatosis)

TABLE 51D.1. CONDITIONS THAT MAY REQUIRE BLADDER AUGMENTATION

Only a small percentage of children undergoing augmentation cystoplasty can completely empty their bladder by voiding spontaneously. Therefore it was the success and widespread acceptance of clean intermittent catheterization in the mid-1970s that made augmentation cystoplasty and continent urinary diversion possible in children (34,35).

Intestinal segments commonly are used in augmentation cystoplasty. Ileum, sigmoid, and stomach all have been used, and studies show all these segments to be reliable (20,39,54). However, viable alternatives for bladder augmentation include the use of a dilated ureter (either naturally dilated or balloon dilated) and autoaugmentation. Autoaugmentation involves excision of the detrusor muscle from the dome of the bladder, allowing the epithelium to form a large diverticulum (6,10,11,14,45). Currently, tissue-engineered substrates such as small intestine submucosa (SIS) and synthetically engineered tissues are being investigated and may be commonly available in the future (24,31,33,44). At this time, gastrointestinal (GI) segments remain the gold standard for increasing bladder capacity and improving compliance. Even so, there are significant potential problems with using intestinal segments in the lower urinary tract. In children, some of these, such as the resorption of ammonium chloride with the use of large and small bowel, result in significant negative consequences such as chronic metabolic acidosis and associated growth retardation.

Therefore augmentation cystoplasty is offered only after medical intervention such as anticholinergic medicines and intermittent catheterization have failed to achieve dryness or to improve bladder compliance sufficiently. Almost all children who undergo augmentation cystoplasty will require intermittent catheterization. The commitment and capacity of both the child and the family to comply with catheterization must be assessed carefully. Any failure with catheterization could result in complication and potential harm to the patient. All potential complications should be discussed in detail with the family.

THE TECHNIQUE OF AUGMENTATION CYSTOPLASTY

General Principles

In augmentation cystoplasty, the two critical aspects of the surgery are the preparation of the bladder and the augmentation segment chosen.

Bladder

In augmentation cystoplasty, the bladder usually is addressed first. Most commonly, a midline incision is used to expose the abdomen and pelvis. If possible, the peritoneum is not entered until the bladder has been prepared for augmentation. Therefore the peritoneum initially is dissected off of the dome and the posterior wall of the bladder. The bladder is then opened in the sagittal plane from the bladder neck anteriorly to the trigone posteriorly, thus forming a “clam-shell” configuration (Fig. 51D.1). This maneuver is extremely important because the bladder must be opened fully to prevent the augmentation segment from acting as a diverticulum with the formation of an “hour-glass” deformity. Supratrigonal cystectomy generally is not recommended because the augmentation segment is anastomosed to the wings of the bisected bladder. The native bladder wings can be used for implantation of a continent catheterizable channel (e.g., Mitrofanoff) or ureteral reimplantation. Concurrent procedures, such as ureteral reimplantation or bladder neck reconstruction, are performed before harvesting the augmentation segment. The exception is when concurrent placement of an artificial urinary sphincter (AUS) is performed. The AUS usually is placed after the augmentation cystoplasty is completed and the abdomen irrigated.

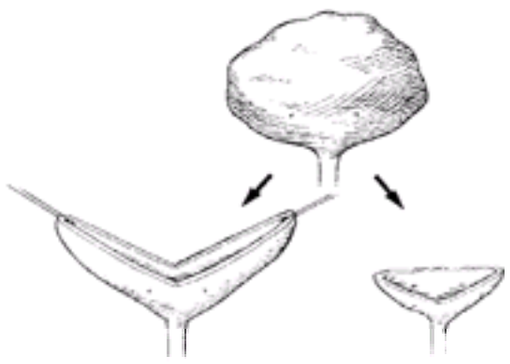

FIGURE 51D.1. The dysfunctional bladder is opened in the sagittal plane from the bladder neck to the trigone.

Augmentation Segment

The size and configuration of the augmentation segment probably are more important than the type of bowel used. To maximize the benefit of a given segment, it must be reconfigured ("detubularized") to maximize the added surface area to the bladder. The end-objective is a spherical bladder that, by geometry, maximizes the volume for a given bladder wall area (Fig. 51D.2). In addition, the spherical configuration also maximizes the radius of curvature, thereby increasing surface tension for a given bladder pressure, which tends to lead to further bladder expansion. This is the relationship of Laplace's law (T = kRP), where *T* is wall tension, *k* is a constant dependent on elasticity and wall characteristics, *R* is the radius of curvature, and *P* is the luminal pressure (Fig. 51D.3). Furthermore, by opening the tubular intestine on its antimesenteric border and reconfiguring the segment, the intrinsic innervation is disrupted and peristalsis is decreased significantly (22,29) (Table 51D.2). In general, the length of segment used depends on the radius of the bowel used; therefore a longer segment of small bowel usually is required. The length of segment used depends on the patient's age, available intestine, the size of the pelvis, and required bladder volume; usually this translates into a segment of 15 to 30 cm. If a segment of stomach is to be used as the augmentation segment, a wedge of at least one-third of the stomach is harvested (3). The gastric wedge requires no reconfiguring because it fits well onto the bivalved bladder (Fig. 51D.8). If the ureter is to be used as an augmentation segment, there must be significant dilation and it should likewise be detubularized before being anastomosed to the bladder (2) (Fig. 51D.9).

Cystoplasty	Mean Age (yr)	Mean FFB (mL)	Mean Cap (mL)	Mean Value At 300 mL cm H_2O	First Contraction Mean Vol (mL)	First Contraction Mean P cm H_2O	Max. Contraction Mean Vol (mL)	Max. Contraction Mean P cm H_2O
Tubular right colon	17.5	9.7	630	18.6	139	37	457	63

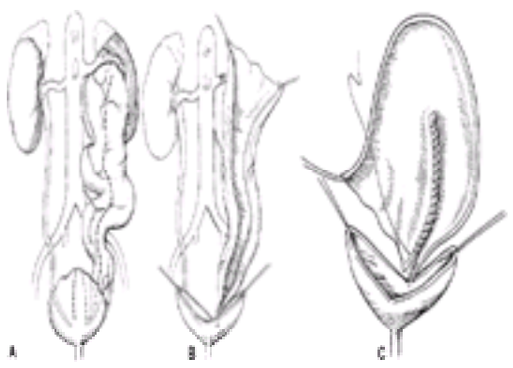

FIGURE 51D.9. A: A megaureter and poorly functioning kidney are required for ureterocystoplasty. **B:** After nephrectomy, the dilated ureter is detubularized, taking care to preserve the blood supply. **C:** The detubularized ureter is reconfigured before being anastomosed to the bladder.

The choice of augmentation segment needs to be tailored individually to each patient. For example, a patient with a short ileal mesentery may require use of the sigmoid to allow for a tension-free anastomosis. Patients with short gut, renal insufficiency, or a history of pelvic radiation may be better served with a gastrocystoplasty (3). Patients with myelomeningocele or imperforate anus theoretically could develop diarrhea if the ileocecal valve is taken from their GI tract (19,28). Other factors to consider include the need for ureteral reimplantation and the need for a continent catheterizable channel. In addition, if the child has a urinary concentrating defect and makes large volumes of urine each day, then a larger segment may be required to provide sufficient capacity. Therefore it is important to consider each patient individually when selecting the appropriate augmentation segment (Table 51D.3).

Bowel Segment	Advantages	Disadvantages
Stomach	1. Previous radiation, short gut 2. Prevents systemic acidosis, salt retention 3. Facilitates tunnels for continence and antireflux 4. Reduces infection 5. May potentiate growth in children	1. Acid secretion salt loss, metabolic alkylosis 2. Hematuria-dysuria syndrome 3. More difficult to use
Jejunum	1. Few, not recommended	1. Salt and water loss, metabolic acidosis
Small Bowel	1. Availability 2. Good compliance 3. Less mucus	1. Metabolic acidosis salt resorption 2. Loss of resorption surface in GI tract (B_{12}, folate) 3. Sometimes difficult to work with (no tunnels)
Cecum	1. Availability 2. Good compliance 3. Potential for tunnels and use of IC valve	1. Metabolic acidosis, salt and water resorption 2. Loss of IC valve may cause diarrhea
Sigmoid	1. Most available 2. Good compliance 3. Potential for tunnels	1. Not available in some patients (radiation, constipation) 2. Metabolic acidosis, salt and water resorption 3. Possible increased potential for rupture

GI, gastrointestinal.

TABLE 51D.3. ADVANTAGES AND DISADVANTAGES OF SPECIFIC BOWEL SEGMENTS IN CHILDREN

Techniques of Augmentations

Ileocystoplasty

Use of ileum as an augmentation segment dates to the nineteenth century. As noted previously, the segment of ileum must be detubularized and reconfigured (Fig. 51D.4). A segment 15 to 30 cm in length with excellent blood supply is selected and folded back onto itself. This will permit assessment of the mesentery to ensure that the segment will reach into the pelvis without tension. Bowel clamps are used to prevent spillage of succus into the abdomen. An ileoileostomy is then performed superior to the isolated segment. The isolated segment is irrigated and opened on its antimesenteric border. The ileal segment is then folded into a U, S, or W shape, and the edges are sutured with a running absorbable suture. Once reconfigured, the reconfigured ileal cap is anastomosed to the bivalved bladder. It is easiest to start the anastomosis at the most posterior apex of the bivalved bladder. A suprapubic tube is brought out through the native bladder wall for drainage. Ileum does not allow for standard reimplantation of the ureters or the creation of a continent catheterizable channel (i.e., Mitrofanoff), but newer techniques such as the seromuscular trough, as described by Abol-Enein and Gonheim (1), do allow the use of ileum should these procedures be required (Fig. 51D.5). However, because of its muscle backing, native bladder (or a gastric flap) is still the primary choice for ureteral reimplantation or construction of a Mitrofanoff valve.

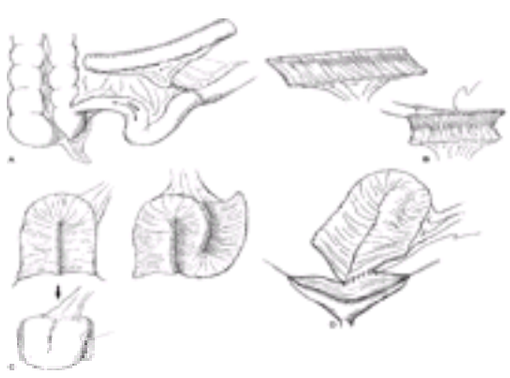

FIGURE 51D.4. A: A 15-cm segment of ileum proximal to the ileocecal valve is isolated and an ileoileostomy is performed. **B:** The isolated segment of ileum is opened along the antimesenteric border. The opened segment is then folded and the edges are sutured together. **C:** The opened segment is reconfigured to increase the surface volume. **D:** The reconfigured ileum is anastomosed to the opened bladder beginning at the posterior apex.

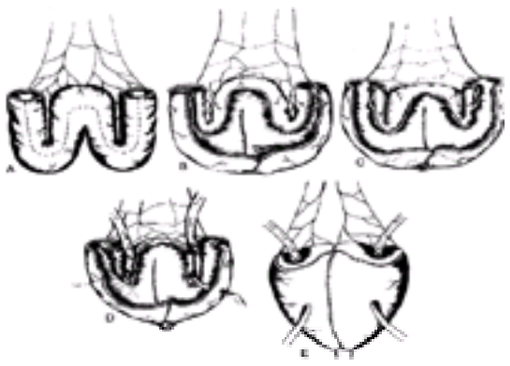

FIGURE 51D.5. A–E: The seromuscular trough formed by anastomosing the edges of the ileum together allows for nonrefluxing ureteral reimplantation into the ileum.

Sigmoid Cystoplasty

Sigmoid colon continues to be a commonly used segment in augmentation cystoplasty (21) (Fig. 51D.6). Native sigmoid produces strong unit contractions in its tubular form; therefore it must be opened and reconfigured. The proximity of the sigmoid colon to the bladder makes it a convenient choice, and mesenteric length is rarely a problem. A segment of sigmoid is isolated and divided along with the mesentery, preserving excellent blood supply. Colocolostomy usually is performed inferior to the isolated segment. Once the isolated segment is irrigated, it is opened along its antimesenteric border. The sigmoid can then be folded into a U shape and the edges anastomosed together before suturing to the bladder. In an alternative method described by Mitchell (40), the ends of the isolated sigmoid segment are closed and the opened antimesenteric edges are anastomosed to the bivalved bladder (Fig. 51D.7).

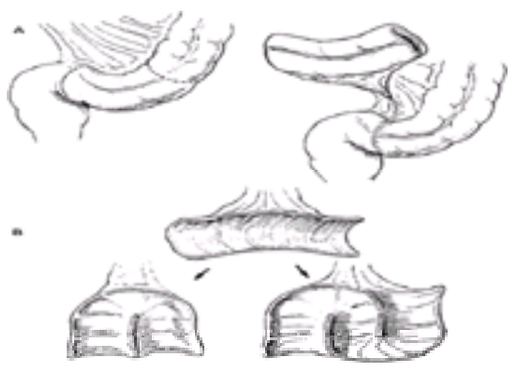

FIGURE 51D.6. A: A segment of the redundant sigmoid is resected and bowel continuity is reestablished. **B:** The isolated segment of sigmoid is opened on its antimesenteric border and then reconfigured before being anastomosed to the bladder.

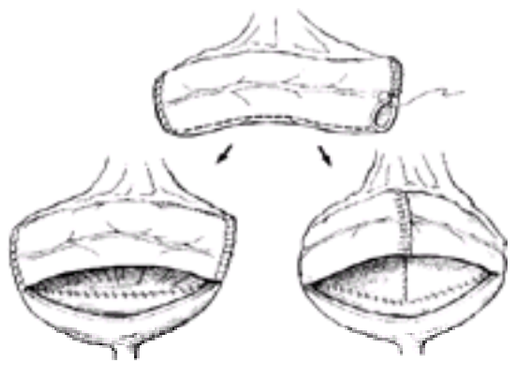

FIGURE 51D.7. The isolated segment of sigmoid is opened along the antimesenteric border. The two ends are then closed and the opened antimesenteric edges are sutured to the bladder.

Gastrocystoplasty

In 1988, Adams and colleagues (3) described the wedge gastrocystoplasty (Fig. 51D.8). This procedure requires an extended abdominal incision from the xiphoid process to the pubic symphysis. A gastric wedge from the midportion of the greater curvature of the stomach is harvested. The right gastroepiploic usually is more robust, but sometimes the segment can be based on the left gastroepiploic (common in the cloacal exstrophy patient). The wedge segment to be harvested includes both the anterior and posterior walls. The omentum is mobilized off of the transverse colon and the stomach is grasped with Babcock clamps and brought into the surgical field. Generally, one-third of the stomach is harvested with the use of an intestinal stapling device. The short gastric branches off the proximal gastroepiploic vessel must be divided, leaving the short gastric branches to the augmentation segment intact. The stomach is closed in layers and a nasogastric tube is placed through the anastomosis. The isolated segment is then brought through both the transverse colon mesentery and the small bowel mesentery so that the pedicle is retroperitoneal. Next, the segment is anastomosed to the bivalved bladder. If a stapling device is used to harvest the stomach, the staple line must be excised before completing the anastomosis. The stomach wall provides an ideal backing for both ureteral reimplantation and the Mitrofanoff procedure.

Cecocystoplasty and Ileocecocystoplasty

The same principles used in other GI segments apply to the use of cecum and ileocecal segments. However, these segments usually are not used in patients with a neurogenic bladder secondary to spina bifida. These patients often rely on the ileocecal valve for fecal continence and may develop diarrhea postoperatively if the ileocecal valve is taken (19,28). However, the segments do provide teniae, which can be used as a flap-valve continence mechanism for reimplantation of ureters or a continent catheterizable channel.

Alternatives to Gastrointestinal Cystoplasty

Alternatives to intestinocystoplasty in children are given in Table 51D.4.

Alternative	Advantages	Disadvantages
Ureter	1. Urinary epithelium, no mucus 2. Good compliance	1. Only applicable if the patient has a dilated ureter 2. Ureter may be scarred (reflux, infection)
Autoaugmentation (Bladder myomectomy)	1. Urinary epithelium, no mucus 2. Relatively easy, no bowel resection	1. Inconsistent results can result in bladder scarring 2. Sometimes difficult bladder scarring or diverticula
Demucosalized intestinal flap or urothelium (colon, DAIMS)	1. Urinary epithelium, decreased mucus 2. More physiologic	1. Difficult procedure 2. Inconsistent results
Bladder regeneration on substrate (SIS)	1. No bowel resection 2. Easily performed	1. Unproven in children 2. Dependent on native bladder potential for regeneration
Tissue engineering	1. Bladder regrowth in laboratory 2. Potentially unlimited capacity, no mucus	1. Unproven in children 2. Dependent on vascular and nerve ingrowth

DAIMS, demucosalized augmentation with gastric segment.

TABLE 51D.4. ALTERNATIVES TO INTESTINOCYSTOPLASTY IN CHILDREN

Ureterocystoplasty

A massively dilated ureter and a nonfunctioning or poorly functioning kidney are the prerequisites to ureterocystoplasty (Fig. 51D.9). As with GI segments, the ureter is detubularized and folded into a U shape to increase the surface area and volume. The ureter may be opened all the way through the ureteral orifice, or a small nondetubularized distal segment may be left intact (2). The ureter then is anastomosed to the bivalved bladder in standard fashion. Great care must be taken to protect the blood supply to the ureter when performing the nephrectomy and mobilization of the ureter. The proximal ureteral blood supply comes from the aorta and is medial to the ureter, whereas the distal ureteral blood supply arises posterolateral. The major drawback to the use of ureter in augmentation cystoplasty is the paucity of patients who have both a megaureter and a nonfunctioning kidney. However, it has been shown in the animal model that it is possible to experimentally dilate a normal ureter and successfully use this for bladder augmentation (25).

Autoaugmentation

In autoaugmentation, the detrusor on the dome of the bladder is excised, leaving the mucosa intact and forming a diverticulum (Fig. 51D.10). The lateral edges of the bladder with intact detrusor can be sutured to the psoas muscle to prevent collapse of the diverticulum. The major drawback to autoaugmentation is limited increase in capacity and long-term scarring or fibrosis of the autoaugmentation segment. Some authors have combined autoaugmentation with demucosalized GI segments such as the stomach and the sigmoid colon (7,13,15,18). The long-term results of this type of augmentation are not consistent (9). Gonzalez and associates continue to use demucosalized sigmoid along with autoaugmentation in certain patients and reported a lower incidence of bladder calculi and mucus production (18).

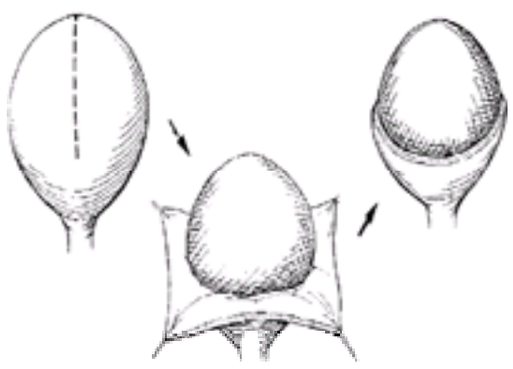

FIGURE 51D.10. In autoaugmentation, the detrusor is excised leaving the urothelium to act as a diverticulum.

CONTINENT URINARY RESERVOIRS

In children, a bladder that can be used in augmentation cystoplasty usually exists. However, if a suitable bladder template does not exist, then a heterotopic or orthotopic continent urinary reservoir may be constructed. Most of the experience with the various types of continent urinary reservoirs relates to the adult population following cystectomy. However, at least two of these continent reservoirs were developed initially for pediatric patients. The Indiana pouch initially was used in patients with exstrophy who had previous cystectomy and the Kock pouch was developed by a pediatric surgeon to create a continent ileostomy. Examples of reservoirs now sometimes employed in the pediatric population include the Indiana pouch, Kock pouch, and gastric pouch (36,49,52). Obviously, many other continent reservoirs can be applied to children. The difficulty with the construction of a continent reservoir in children often is that a major limitation is that of limited useful intestine for construction of a urinary reservoir. For example, in the patient with cloacal exstrophy there is commonly an associated deficiency of large and small bowel such that stomach is the only reasonable tissue that can be used. This limitation is rarely present in the adult patient. The surgeon frequently must have imagination and individualize the reconstruction based on the patient's needs.

Indiana Pouch

The Indiana pouch is a continent urinary reservoir formed from an ileocecal segment of intestine (49) (Fig. 51D.11). Approximately 8 to 10 cm of terminal ileum, along with 20 cm of cecum and ascending colon, is harvested. Bowel continuity is reestablished. The colon segment is then split along its antimesenteric border up to the base of the cecum. The ureters are reimplanted into the tenia of the colon, thus creating a nonrefluxing anastomosis. The ileum is used as the efferent catheterizable channel. However, the ileum requires narrowing and this usually is done with a stapling device to ensure creation of a smooth, uniform caliber channel. The continence mechanism is based on the ileocecal valve, and continence is promoted by plication of the valve with Lembert sutures. The pouch is then closed by folding the distal colon down. The efferent limb is brought out as a stoma in the right lower quadrant. If the appendix is available, it can be used to construct the catheterizable channel (i.e., Penn pouch) and the terminal ileum can be used to augment the cecal reservoir.

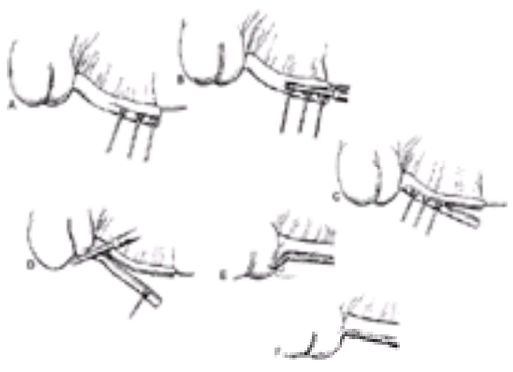

FIGURE 51D.11. The efferent continent catheterizable channel of the Indiana pouch is constructed from the distal ileal segment and ileocecal valve. The ileum is narrowed over a catheter with the use of a stapling device. Lembert sutures over the staples are used to plicate the ileocecal. **A–D:** Stapling technique. **E, F:** Placement of sutures at ileocecal valve.

Kock Pouch

The Kock pouch is a continent ileum-based reservoir originally introduced in 1982. The current Kock pouch has undergone numerous modifications by Skinner's group at the University of Southern California, thus decreasing the complication rate (52,53) (Fig. 51D.12). Continence and antireflux mechanisms of this pouch are based on creating nipple valves by intussuscepting the ileum at both ends of the isolated segment. The central segment, between the two intussuscepted ends, is folded into a U and opened along the antimesenteric border. A spherical reservoir is then formed by folding the bowel segments appropriately. The afferent and efferent nipples are formed by intussuscepting a segment of ileum that has been stripped of a small segment of the mesentery. A stapling device is used to secure the nipple valves to the reservoir. Skinner and co-workers (52,53) also use mesh circumferentially around the intussuscepted segments outside the reservoir to provide additional support. The ureters can be sewn end-to-side into the afferent nipple and the efferent nipple is brought out to the skin as a continent catheterizable stoma.

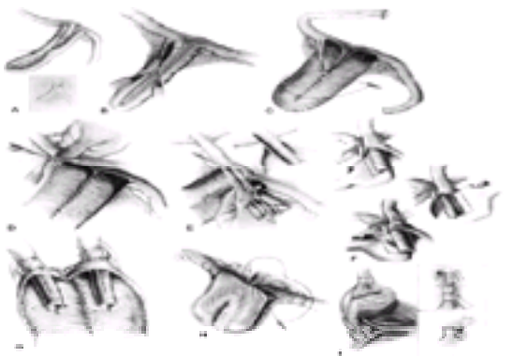

FIGURE 51D.12. A—I: Modifications of the Kock pouch done by Skinner's group at the University of Southern California. Their modifications have decreased the complication rate associated with this pouch.

The majority of the initial problems with this reservoir was the loss of the continence mechanism of the efferent nipple valve. The described modifications lowered the complication rate. In addition, bladder calculi have been known to form on the staple line.

Gastric Reservoir

A continent reservoir may be constructed using the wedge flap technique (36) (Fig. 51D.13). By harvesting a large wedge from the stomach, it may be made into a reservoir by suturing the apex to the urethra, or the wedge may be closed and used as a continent cutaneous reservoir. The muscle backing of the stomach allows for continent mechanisms and ureteral reimplantation to be based on the flap-valve principle. Alternatively, a strip of gastric tissue can be tubularized and nippled into the reservoir to provide a continent catheterizable channel. The problem with this reservoir is that it usually is difficult to resect enough stomach to create a large reservoir without compromising gastric capacity. It often is necessary to augment the gastric reservoir with a segment of bowel to increase capacity and reduce salt losses in the urine.

FIGURE 51D.13. A: The gastric wedge flap may be constructed into a continent urinary reservoir. **B:** The gastric muscle provides ideal backing for creation of continent catheterizable channels or ureteral reimplantation **(C). D:** A strip of the gastric wedge may be formed into a catheterizable channel. Continence may be obtained by creating a nipple valve.

Postoperative

Children remain on intravenous fluids, intravenous antibiotics, and nasogastric tube drainage until the return of bowel function. Suprapubic tubes are left to gravity drainage and are irrigated every 8 hours and as needed to promote continual drainage. H_2 blockers are used in patients after gastric augmentation who are on bladder drainage to prevent ulcer formation. The patient is discharged from the hospital with the suprapubic tube in place. Reservoir cycling is usually started at approximately 1 week postoperatively. The suprapubic tube is removed after 3 weeks. The family or child must demonstrate the ability to perform intermittent catheterization before removing the suprapubic tube.

COMPLICATIONS

Table 51D.5 presents metabolic consequences of bladder reconstruction with bowel.

Problem	Stomach	Ileum	Colon
Segment loss from GI tract	1. Early satiety 2. Decreased stomach acid production 3. Increased gastrin production	1. Decreased absorption of B_{12}, folate, and iron 2. Short-gut syndrome	1. Diarrhea 2. Water loss
Acid-base balance	1. Alkalosis 2. Hematuria/pyuria	1. Chronic metabolic acidosis 2. Ammonium and chloride resorption	1. Acidosis 2. Bicarbonate loss 3. Ammonium chloride resorption
Salt balance	1. Sodium and potassium loss	1. Sodium and chloride resorption	1. Sodium and chloride resorption
Mucus	1. More soluble, less apparent	1. Problem with catheter obstruction, irrigation necessary	1. Problem with catheter obstruction, irrigation necessary
Stone formation	1. Rare problem (low pH)	1. Can be a major problem, irrigations recommended	1. Can be a major problem, irrigations recommended
Infection	1. Moderate	1. Common	1. Common
Tumor	1. None documented but too early to tell	1. Reported	1. Significant in ureterosigmoidostomy
Perforation	1. Reported with potential for ulcer formation in anuric or diverted patient	1. Reported, major problem because of potential for infection	1. Reported, major problem because of potential for infection

TABLE 51D.5. METABOLIC CONSEQUENCES OF BLADDER RECONSTRUCTION WITH BOWEL

Electrolyte Disturbances

Intestinal segments placed in the urinary tract retain their inherent properties of absorption and secretion of water and solutes. As such, different segments of the GI tract will produce different metabolic changes when placed in the urinary tract (37). Gastric segments continue to secrete hydrochloric acid with systemic bicarbonate release, which may result in hypochloremic metabolic alkalosis (3). Ileal and colonic segments absorb ammonia and chloride and secrete bicarbonate and sodium, which may lead to hyperchloremic metabolic acidosis (37). The severity of the metabolic disturbances depends on many factors such as the length of segment used, the amount of time urine is in contact with bowel mucosa, and the patient's metabolic reserve to compensate for electrolyte changes. Electrolyte changes usually are not significant in patients with normal renal function. However, patients who undergo augmentation cystoplasty with GI segments should be monitored periodically for electrolyte changes.

Megaloblastic Anemia

Vitamin B_{12} is absorbed in the distal ileum. Therefore if the distal ileum is removed from the GI tract, megaloblastic anemia may result secondary to B_{12} deficiency (8). B_{12} stores may last for up to 6 years and therefore this is a potentially late complication resulting from the use of distal ileum (38). One report documented B_{12} deficiency in 35% of patients 5 to 11 years after construction of a Kock pouch (4). This complication is prevented by sparing the distal 15 cm of ileum. However, if it is necessary to use the distal ileum in bladder reconstruction, long-term monitoring for megaloblastic anemia is necessary.

Mucous Production

GI segments used in urinary tract reconstruction continue to produce mucus. Mucous production is greatest from colonic segments, followed by ileal segments, with stomach producing the least (32). Mucous production may or may not be a problem for patients (17,27,47). Production of mucus usually increases at the time of a urinary tract infection. Increased mucus may slow or prohibit drainage from the reservoir through a small caliber catheter. Furthermore, mucous production has been implicated as a nidus for stone formation (42). To prevent complications, daily irrigation of mucus from the reservoir with normal saline is encouraged.

Tumor Formation

A long-term concern with placing GI segments in the urinary tract is tumor formation. It is well recognized that patients with ureterosigmoidostomies are at risk for the development of carcinoma and polyps at the ureterocolonic anastomosis (23,55). In the patients with ureterosigmoidostomies who developed tumors, the average time lapse before tumor detection was 26 years after ureterosigmoidostomy (23). In a meta-analysis review by Filmer and Spencer (16), 14 patients with augmentation cystoplasty were found to have developed carcinomas in the augmentation segment (8). Therefore long-term surveillance is important in children. Periodic cystoscopy is recommended 7 to 10 years after GI cystoplasty.

Reservoir Perforation

Delayed perforation of the reservoir is a well-recognized complication of augmentation cystoplasty and can be a catastrophic event (5,12,46,50,51). Several patients with GI continent urinary reservoirs or augmentations have decreased sensation and therefore delay in diagnosis is common. Symptoms may be abdominal discomfort, nausea, vomiting, abdominal distention, and peritonitis. An abdominal computed tomography (CT) scan with a contrast-filled bladder is probably the most accurate diagnostic tool. The exact etiology of delayed spontaneous perforation is unknown. It may be related to overdistention of the reservoir with areas of ischemia or unit contractions of the augmentation segment elevating the reservoir pressure. Therefore it is extremely important in children with high leak-point pressures to be compliant with catheterization schedules. Perforations have been seen in all GI segments. In the largest reported series, Indiana University reported a 8.3% incidence (22 of 264) in children with augmentations, with a slightly larger incidence in the sigmoid colon augmentations (48). Management of a child with a perforation usually includes surgical exploration with closure of the perforation and catheter drainage for several days.

Stone Formation

Most stones that form in GI urinary reservoirs are composed of struvite. Reservoir stones have been reported to form in all GI segments, but are extremely rare in gastric segments (26,30). Kronner and colleagues (30) at Indiana University found stones in 10% of their augmentation population. Likewise, Kaefer and associates (26) at Boston Children's Hospital found stones in 13% of their augmentation population. Stone formation is likely multifactorial in etiology, including the presence of urea-splitting bacteria, stasis of urine, mucus, and foreign bodies. Therefore preventive measures such as regular catheterization, irrigation of mucus, and antibiotic therapy for stone forming bacteriuria should be instituted.

Hematuria-dysuria Syndrome

Hematuria-dysuria syndrome is a complication that is unique to patients in whom gastric tissues are placed in the urinary tract. The syndrome originally was described by Nguyen and coauthors (41) as any of the following symptoms in patients following gastrocystoplasty: bladder spasm; suprapubic, penile, or periurethral pain; coffee-brown or gross hematuria without infection; skin excoriation; and/or dysuria without infection (41). This syndrome is seen more commonly in patients who have intact urethral sensation and are incontinent. Hematuria-dysuria syndrome usually is intermittent in nature and rarely requires continuous therapy (43).

Urinary Tract Infections

Most of the GI urinary reservoirs are emptied by clean intermittent catheterization, and bacteriuria is common (17,20,27). Although most patients will have bacteriuria, a higher percentage of bacteriuria is reported with the use of bowel segments when compared with gastric segments. Asymptomatic bacteriuria is not treated routinely unless the organism is a urea-splitting organism. Symptoms and signs that may require antibiotic therapy include foul-smelling urine, fever, suprapubic discomfort, and urinalysis showing a white blood cell (WBC) count of greater than 50 WBCs per high-power field.

THE MITROFANOFF PRINCIPLE AND CONSTRUCTION OF CONTINENT CATHETERIZABLE CHANNELS

Two decades ago, Paul Mitrofanoff (68) described a procedure using the appendix (or ureter) to construct a continent catheterizable channel to the bladder. This concept has come to be known as the *Mitrofanoff principle.* Although it was originally described for use in children with neurogenic bladders, it has become widely used for many different clinical situations. Channel continence is maintained by creating a flap valve by tunneling the channel into the bladder using techniques similar to ureteral reimplantation. Mitrofanoff initially described use of the appendix or ureter to construct a catheterizable channel combined with closure of the bladder neck. Since the introduction of “the concept,” other tubular structures have been used as the catheterizable channel and its application has been expanded to create a channel for catheterization into the intestine for antegrade enema instillation [antegrade continent enema (ACE) procedure] (59). Surgical experience with the Mitrofanoff principle has increased over the years with high patient satisfaction (38). It has become an extremely important adjunctive technique in pediatric urologic reconstruction.

Mitrofanoff Appendicovesicostomy

Surgical Technique

The patient is given an initial bowel preparation. We use a mechanical bowel preparation using polyethylene glycol–electrolyte solution. As described by Mitrofanoff in 1980, the appendix is mobilized, maintaining its vascular pedicle from the terminal branches of the ileocolic. The appendix is removed form the cecum (Fig. 51E.1A) and is reimplanted into the bladder through a submucosal tunnel in the bladder wall (Fig. 51E.1B and Fig. 51E.1C). Either the anterior or posterior bladder wall can be used (43,86) as long as adequate tunnel length (four times the diameter of the tube) is maintained and the course of the channel is not angulated between the bladder mucosa and stoma (71,87,88). The appendix is best oriented in an antiperistaltic direction, but this is not always possible. A slowly absorbable suture is used to anchor the appendix into the bladder to prevent the appendix from slipping back out of the tunnel. The stoma is created by anastomosis of the opposite end of the appendix to the abdominal wall, either at the umbilicus or in a separate right lower quadrant site (11,23,68,71). It is important to meticulously maintain the appendix blood supply, to spatulate the anastomosis, and to insert a broad-based skin flap to prevent stomal stenosis (Fig. 51E.1D).

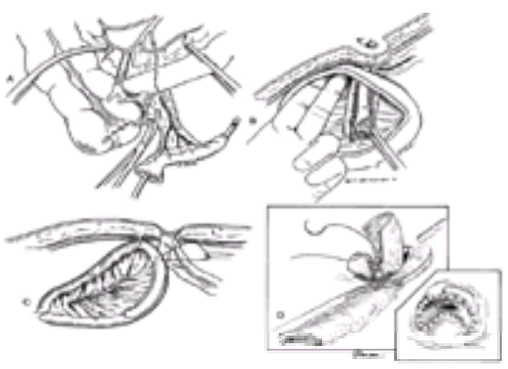

FIGURE 51E.1. Mitrofanoff construction. **A:** The appendix is divided from the cecum and is mobilized carefully, preserving the mesenteric blood supply. **B:** The mobilized appendix is tunneled submucosally into the posterior wall of the bladder. The bladder is secured to the posterior aspect of the abdominal wall to eliminate tension on the anastomosis and to ensure a straight path for catheterization. **C:** Lateral view of completed appendicovesicostomy demonstrating straight posterior submucosal tunnel. Note that the bladder is secured to the abdominal wall. **D:** The stoma is created using an inverted U or V umbilical skin flap, which is inset into the spatulated appendix to prevent stomal stenosis. The appendix mucosa is recessed into the umbilicus, minimizing visible scars and hiding the stoma site. (**A–C** from Keating MA, Rink RC, Adams MC, et al: Appendicovesicostomy: a useful adjunct to continent reconstruction of the bladder. *J Urol* 1993;149:1091, with permission.)

Surgical Results

Using the appendix for a catheterizable channel offers several advantages. The appendix provides a supple uniform channel intrinsically, which can usually be mobilized to reach the bladder and still have the stoma hidden within the umbilicus. The surgical results of appendicovesicostomy are good and predictably reproducible (9,23,36,42,43,86,87 and 88). There is an overall 86% to 98% surgical success rate (dry and catheterizing). To achieve urethral continence, it may be necessary to perform a concurrent bladder neck procedure and/or bladder augmentation if indicated by preoperative urodynamics. Important aspects to consider

when creating a catheterizable channel are outlined in Table 51E.1.

Aspect	Considerations
1. Preoperative bladder assessment	Should preoperative urodynamics be performed? Stomal continence depends on the presence of a sufficient capacity, compliant bladder, with adequate urethral resistance.
2. Bowel preparation	Use a mechanical bowel preparation (polyethylene glycol–electrolyte solution).
3. Appendix	Is there adequate appendix length, lumen, and blood supply? Can the appendix be placed in an antiperistaltic direction? If the appendix is absent or inadequate, consider creation of a transverse tubularized bowel segment channel from ileum or colon.
4. Location of tunnel	Is there adequate tunnel length on the anterior or posterior bladder wall?
5. Secure appendix in tunnel	Secure the appendix in long submucosal tunnel with slowly absorbing anchoring stitch and tacking sutures if necessary. Fix the bladder to the abdominal wall to support tunnel.
6. Ease of catheterization	Make sure path of catheter is direct and straight. Test ease of catheterization before and after closure.
7. Stoma	Use a skin flap and spatulated anastomosis (not circular stoma). Stoma is best situated in umbilicus if possible.

TABLE 51E.1. IMPORTANT ASPECTS OF CREATING A CATHETERIZABLE CHANNEL

Complications

The most common complication is stomal stenosis. Stomal stenosis occurs postoperatively in 7% to 24 % of patients. Reoperation rates have been reported in up to 7% to 26% of patients, mainly for correction of stomal stenosis, difficulty with catheterization, or revision of the flap valve continence mechanism (9,36,87). Stenosis of the stoma may be treated with initial dilation; however, formal surgical revision (V-Y–plasty) is often required to prevent recurrence. Parastomal infection and necrosis of the conduit are rare but can occur. Late complications of stone formation can also occur. Stones may develop in the bladder or reservoir as a result of inadequate drainage or mucus from the catheterizable channel and can be prevented by regular bladder irrigation. Risk of postoperative incontinence through the Mitrofanoff stoma can be reduced by forming an adequately long tunnel at least four times the diameter of the tube being implanted. To protect against loss of the valve mechanism and channel angulation, the bladder should be anchored to the abdominal wall to reduce tension on the tunnel anastomosis (Fig. 51E.1C). The relative length of the appendix can be increased with the use of a tubularized cecal cap (2,16,86) (Fig. 51E.2).

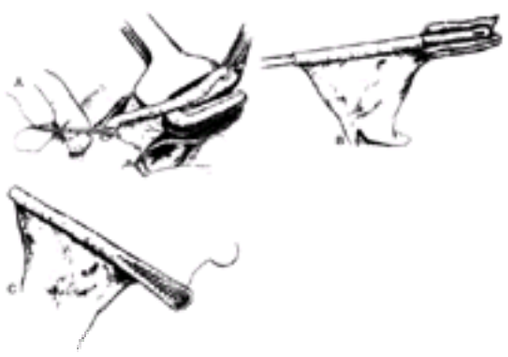

FIGURE 51E.2. Extended appendix with cecal cap. Stapled technique tubularizing contiguous cecum to increase the length of the catheterizable conduit. **A:** A window is made through the appendiceal mesentery. The base of the cecum is stapled, excluding a cecal segment adjacent to the proximal end of the appendix. **B:** The cecum is calibrated for tubularization in line with the appendiceal lumen. **C:** The adjacent cecum is tubularized in two layers over a catheter. [**A–C** from Cromie WJ, Barada JH, Weingarten JL. Cecal tubularization: lengthening technique for creation of catheterizable channel. *Urology* 1991:37(1):41, with permission.]

Alternative Options for Catheterizable Channel Construction

When the appendix is not available, there are other options. The ureter can be used (68,69). However, several disadvantages have been reported when the ureter is used for the channel. There are reports of increased discomfort with catheterization and a higher rate (22%) of stomal incontinence (69). Furthermore, when the ureter is used, the stoma can rarely be brought out through the umbilicus. However, the ureter can be used as a pedicle flap to construct an orthotopic catheterizable stoma in girls (41,67). There have been reports of use of the fallopian tube (92), vas deferens (23), and tubularized prepuce (47) to form catheterizable channels. However, these structures are less proven with long-term experience and therefore not recommended, except as a last resort. Tapered ileum can be used, but the mesentery is bulky, making the tunneling and stoma more difficult. More recently, techniques have been developed to create the channel by transverse tubularization of short segments of small or large intestine.

Transverse Tubularized Bowel Segments (Monti Procedure)

Wen-Horng Yang (94) first described the use of a transversely tubularized bowel segment to create a Mitrofanoff channel in 1993. Unfortunately, the novel catheterizable channel was not the focus of the paper, and the technique did not become widely recognized until after Monti and colleagues published it in 1997 (66). Monti and associates (66) performed animal studies using the catheterizable channel, and later performed these techniques in humans. The beauty of the transverse tubularization technique is that the length of the tubularized channel is now a result of the diameter of the bowel segment used and that the mesentery becomes centralized (Fig. 51E.3). This allows the proximal and distal ends of the formed tube to be easily implanted into the bladder and external stoma without jeopardizing the blood supply. Also, the natural intestinal folds become oriented lengthwise in the channel, facilitating catheter passage. The procedure is versatile; short segments of small or large intestine from anywhere in the abdomen can be selected. Multiple channels can be constructed. Double-length channels can be constructed by attaching two channels in continuity (Fig. 51E.4). Use of transverse tubularized bowel segments has rapidly become popular as a second-line channel (after appendix) among pediatric urologic surgeons (9,12,30,31,34,85).

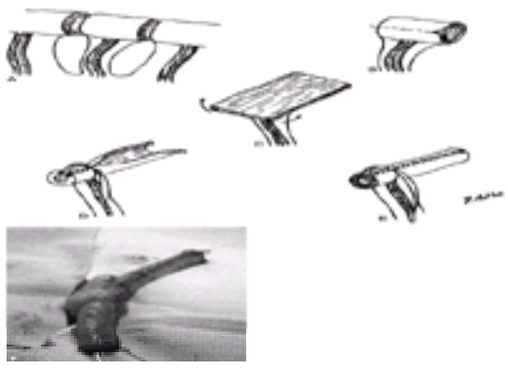

FIGURE 51E.3. Creation of a transverse ileal tube. **A:** A 2.5- to 3-cm intestinal segment is isolated. **B:** The intestinal segment is detubularized through a longitudinal incision made on one side at some distance from the mesentery. **C:** Isolated opened ileal segment, which is now a pedicle flap. **D:** The flap is transversely tubularized using a two-layer closure with absorbable suture. **E:** Completed transverse ileal channel. Note the mesenteric blood supply is now localized to one side of the channel. The side of the tube with the longer nonmesenteric length can be reimplanted. Note that if the initial longitudinal incision were placed directly antimesenteric, the blood supply would have a central location on the channel. **F:** Intraoperative photo of a completed transverse ileal channel. (**A–E** from Monti PR, DeCarvalho JR, Arap S. The Monti procedure: applications and complications. *Urology* 2000;55:617, with permission.)

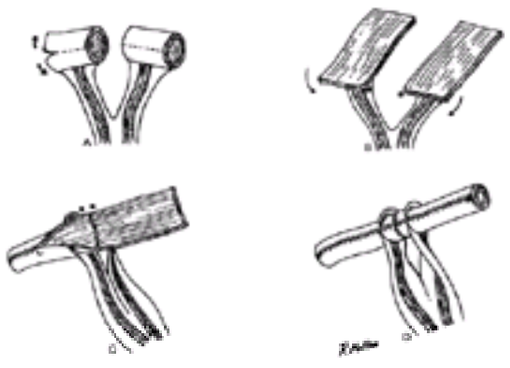

FIGURE 51E.4. Double-length transverse channel. **A:** Another useful technique is to create a double-length channel by selection of two adjacent short bowel segments that are sewn end-to-end to form a continuous channel. It is important to centralize the two mesenteric blood supplies using this technique by completing the transverse intestinal incisions as illustrated, close to the mesentery. **B:** The two adjacent flaps are rotated and joined end-to-end. (It is usually easier to join the two open segments before tubularization.) **C:** A long (double-length) tube is created by lengthwise tubularization. Note that formation of a colon transverse tubularized channel will already naturally be longer in length because the colon is a larger-diameter structure. **D:** Completed double-length channel. (From Monti PR, DeCarvalho JR, Arap S. The Monti procedure: applications and complications. *Urology* 2000;55:617, with permission.)

Surgical Technique

The bowel is cleansed preoperatively with a mechanical bowel preparation. A 2- to 3-cm segment of ileum is usually selected. (However, other segments of small or large intestine can be used.) Ileal anastomosis is performed. The bowel segment is isolated on its mesenteric vessels, and the antimesenteric end is split lengthwise (Fig. 51E.3). The intestine is then closed transversely over a 10- to 14-Fr catheter using a running or interrupted suture line. It is important to place interrupted sutures at either end of the closed channel to allow for subsequent spatulation. A two-layer closure (mucosal and serosal) is usually performed. If necessary, a longer catheterizable channel can be constructed by joining two adjacent intestinal segments together (Fig. 51E.4).

Surgical Results

A recent publication (65a) combined published results from all published series in which transversely tubularized bowel segments were used as continent channels. A total of 54 channels were included. The range of follow-up was from 6 to 14 months. Approximately 97% of the channels catheterized easily. The overall incidence of stomal stenosis was 6%. Continence rates were 91%. In comparison to appendicovesicostomy, the incidence of stomal stenosis was slightly lower and continence was the same. Although long-term results from transversely tubularized bowel segments are not yet available, the initial results are promising. The versatility and availability of using short intestinal segments for the Monti procedure make it an appealing technique.

Continent Vesicostomy

Surgical Technique

Continent vesicostomy formation was first described in the 1970s (77,78). Using Schneider's technique, a bladder tube is created from an anterior flap of full-thickness bladder measuring 9 cm in length and from 5 to 3 cm in width. The distal extent of the flap is tubularized, and the continence mechanism is created by intussusception of the channel within the bladder for a distance of at least 3 to 4 cm to form a valve mechanism (Fig. 51E.5). The distal end forms the stoma, which is brought out to the abdominal wall either at the umbilicus or at a separate lower abdominal wall stoma site. The technique is best suited for patients who have a large bladder capacity and nonthickened bladders. A modified technique to form a continent catheterizable bladder tube in children was described by Casale in 1995 (75a). This technique uses a bladder flap measuring 7 cm in length and 2 cm in width. The full-thickness of the flap is tubularized distally. Proximally, the continence mechanism is formed using a submucosal tunnel. To create the proximal bladder tube and the submucosal tunnel, the proximal bladder incisions are extended for an additional 3 cm. The muscularis and mucosa of the bladder is tubularized proximally, and mucosal flaps are elevated bilaterally and joined to form a submucosal tunnel (9,42) (Fig. 51E.6). Continence and ease of catheterization of the vesicostomy are assessed after construction. The bladder is decompressed by catheter drainage during healing. A catheter is left within the vesicostomy channel for 3 weeks as it heals.

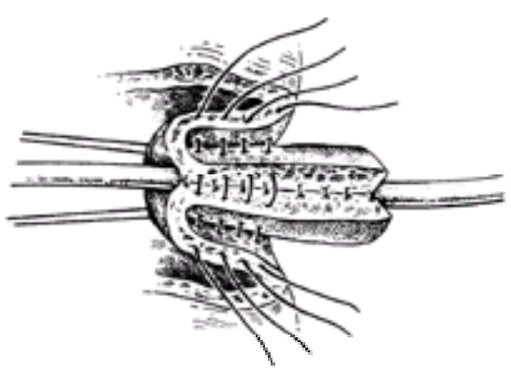

FIGURE 51E.5. Continent vesicostomy techniques. The anterior bladder flap has been intussuscepted to form a nipple valve mechanism for continence. (From Schneider KM, Reid RE, Fructman B, et al. The continent vesicostomy: clinical experiences in the adult. *J Urol* 1977;117:572, with permission.)

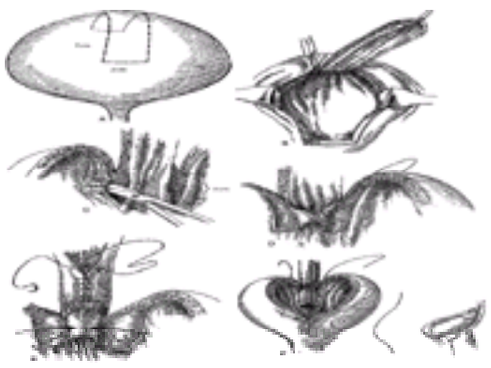

FIGURE 51E.6. Continent vesicostomy. **A:** A full-thickness anterior bladder flap is created measuring 2 cm in width and 7 cm in length. **B:** The bladder flap is rotated cephalad. **C:** The mucosal incisions are extended an additional 3 cm distally through the bladder mucosa at the base of the flap. The lateral adjacent mucosa is elevated in preparation for the submucosal tunnel. **D:** The mucosal and muscularis layers of the distal bladder incision are tubularized, with care to maintain the detrusor flap blood supply. **E:** A continuous tube is created by continuing tubularization of the full-thickness detrusor flap proximally. **F:** The adjacent mucosal flaps at the 3-cm extension of the tube are approximated to one another and closed, forming a submucosal tunnel. The tube is brought out to an abdominal wall stoma. (From Kaefer M, Retik AB. The Mitrofanoff principle in continent urinary reconstruction. *Urol Clin North Am* 1997;24(4):795, with permission.)

Surgical Results

In the largest published study of 17 adult patients who underwent continent vesicostomy using the intussuscepted valve technique (77,78), surgical success was reported in 13 (76%). Continent vesicostomy was not achieved in four patients, and two patients required a second procedure to repair the intussuscepted nipple valve mechanism (attributed to initial use of absorbable sutures). Cain and associates published results of 22 patients (median age of 10) who underwent continent vesicostomy using a modified Casale vesicostomy technique (9) (Fig. 51E.6). Complications occurred in 29% of patients in this series (6 of 21). All of these patients required surgical revision for difficulty with catheterization and stomal stenosis. The modified Casale vesicostomy technique has several advantages. It uses less bladder capacity (a smaller-dimension bladder flap is used), and it has better continence rates when compared with the nippled valve technique.

Antegrade Continence Enema

Surgical Technique

The Mitrofanoff continent catheterizable channel concept has also been applied to the colon to administer antegrade continence enemas (the ACE procedure). This technique was initially described (59) for patients with fecal incontinence refractory to conventional medical treatments. It is particularly well suited for patients who require regular high enema clean out. In the Malone ACE technique, the appendix is used to form a continent channel into the cecum. The initial reports describe reversing the direction of the appendix with tunneled reimplantation (Fig. 51E.7A and Fig. 51E.7B). However, more recent reports describe leaving the appendix *in situ,* with or without intussusception of the appendix into the base of the cecum, with similar continence results (56,89,91) (Fig. 51E.7C). Considerations important to success include patient and family motivation for fecal continence, thorough preoperative bowel preparation, and frequent catheterization postoperatively to prevent stomal stenosis. As with any reconstructive procedure, proper patient selection is critical.

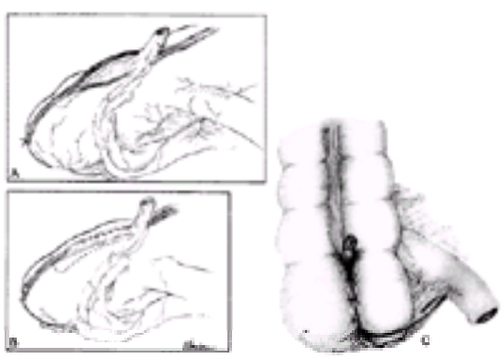

FIGURE 51E.7. Creation of an ACE channel. **A:** Reimplanted appendix ACE channel. The appendix is isolated in a similar fashion as when it is used for appendicovesicostomy. The direction of the appendix is reversed and it is tunneled into the cecum through a submucosal tunnel beneath the colonic taenia. **B:** Completed reimplant of the reversed appendix through a submucosal tunnel into the cecum. **C:** Creation of a channel using *in situ* appendix. The appendix can be imbricated into the cecum to promote continence. (**C** from Walsh RA, Waxman SW, Koyle MD. The Malone ACE procedure for fecal incontinence. *Infect Urol* 2000;July/Aug:102, with permission.)

ACE Irrigation

After ACE channel construction, the channel is intubated for 3 to 4 weeks. The indwelling catheter can be used to begin bowel irrigation when bowel function has returned in the postoperative period. Antegrade enema administration can usually be initiated through the indwelling catheter within the first week after surgery, depending on the extent of concurrent procedures. In this way, patients and their families can become comfortable with performing antegrade enemas before hospital discharge. After the indwelling catheter is removed, daily catheterizations are initiated. Even if daily antegrade enema administration is not necessary, the ACE channel should be catheterized every day to prevent stomal stenosis (35,91).

Several different solutions can be used for ACE irrigation. We prefer to start irrigation with a 1:1 mixture of glycerin and water, 10 to 20 mL of each. Glycerin is a hyperosmolar laxative that stimulates colon contraction. The volumes of glycerin and water can be adjusted for each patient to optimize timely stool evacuation (usually within 30 minutes) while minimizing abdominal cramping. This regimen has been used by others with good results (24). Other antegrade enema regimens include polyethylene glycol–electrolyte solutions, saline alone, docusate, or phosphate enemas followed by saline lavage (13,59). Unfortunately, hyperphosphatemia can result from colonic absorption of phosphate (15,61). To prevent the possible serious complication of phosphate toxicity (hyperphosphatemia, hypocalcemia, hypokalemia, metabolic acidosis, tetany, asystole, and even death), phosphate solutions are not recommended for antegrade enemas, especially in children. Other safer and effective regimens are available. Patient satisfaction with the ACE procedure improves with ongoing consultation with health care professionals familiar with ACE management to ensure an optimal antegrade enema regimen is established.

Malone ACE Complications

The largest reported series of Malone ACE procedures is from the United Kingdom (17). In this series of 300 Malone ACE procedures, the overall success rate was 79%. The main complication was stomal stenosis (30%). Other complications included stomal leakage (7%), adhesion obstruction (2%), gangrenous channel (2%), and phosphate toxicity resulting from retained phosphate enemas. Ultimately, larger, controlled, prospective studies are needed to provide more accurate information about the open ACE procedure as well as percutaneous and laparoscopic ACE techniques.

Alternatives to Use of the Appendix for ACE Construction

If the appendix is unavailable, channels can be created with cecal tubes or transverse tubularized bowel segments (17,91). Percutaneous techniques can be used to secure access to the cecum. There is early experience with cecostomy button placement for antegrade enema administration (13,22,24,80). This technique uses a “button” device similar to those used for percutaneous gastrostomy. Long-term data on this technique are not yet available. A laparoscopic approach has also been advocated (56). In this technique, the appendix remains attached to the cecum. The appendix is mobilized, and the distal end is secured to the fascia and spatulated to a right lower quadrant stoma. The initial published series of patients who underwent laparoscopic ACE procedures showed complication rates were similar to those of open techniques (56). In 30 patients, stomal stenosis occurred in 8 (27%) and troublesome stomal leakage occurred in 2 (6.7%) (56).

Stoma Formation

Formation of the stoma site is an important aspect of catheterizable channel construction, both in terms of prevention of the most common complication (stomal stenosis) and for patient satisfaction. The initial stomas that brought a circumferential cuff of intestinal mucosa to the skin level were often complicated by stomal stenosis and stoma site irritation related to protrusion (35). These stomas were larger, and the cosmetic appearance was less pleasing. Currently, a V- or U-flap of skin is inset into the distal end of the spatulated catheterizable channel (Fig. 51E.8) (35,43,59). These techniques help prevent stomal stenosis and improve the cosmetic appearance. The umbilicus is used as the preferred stoma site for Mitrofanoff channels. There are several advantages to placement of the stoma at the umbilicus: (a) The cosmetic appearance can be excellent; (b) the central abdominal location facilitates easy catheterization while in a sitting position; and (c) the abdominal wall thickness at the umbilicus is thinnest, especially in older patients who have significant subcutaneous adipose elsewhere on their abdominal wall. A broad-based superior or inferior U- or V-flap technique is generally used to construct the umbilical stoma (Fig. 51E.1D and Fig. 51E.8). Given the typically already inverted characteristics of the umbilical skin, the effect is to create a completely hidden channel opening.

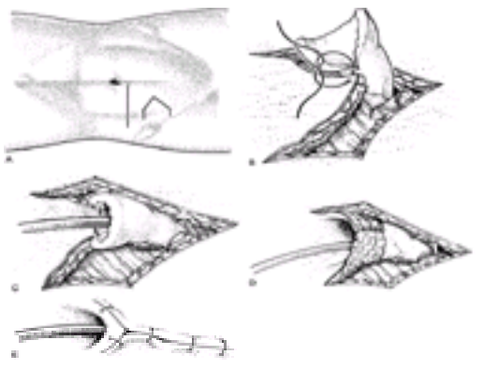

FIGURE 51E.8. Example of abdominal wall catheterizable stoma formation using a right lower quadrant cutaneous V-flap anastomosed to the spatulated appendix. **A:** A right lower quadrant broad-based V-flap is made as shown. **B:** The appendix or Monti catheterizable channel tube is spatulated and the skin flap anastomosis is performed. **C–E:** The skin flap is reconstructed forming a hidden channel stoma. (From Griffiths DM, Malone PS. The Malone antegrade continence enema. *J Pediatr Surg* 1995;30:69, with permission.)

Umbilicoplasty

If the patient does not have an umbilicus (as in cases of bladder or cloacal exstrophy), a neoumbilicus can be fashioned out of adjacent skin flaps. Our technique for umbilicoplasty is demonstrated in Fig. 51E.9. The site for the umbilicus is chosen in the midline at the level of the iliac crests. The umbilicoplasty is generally part of concurrent intraabdominal procedures, and the initial midline abdominal incision is made keeping the umbilicoplasty in mind. The incision is carried to the left at the level of the selected site for the umbilicus, and a U-flap is fashioned from the midline skin. The U-flap is then advanced under the lower abdominal skin to create the central umbilical depression. If a Mitrofanoff is being formed concurrently, the flap is anastomosed to the distal spatulated aspect of the channel using interrupted absorbable sutures (Fig. 51E.9). If there is no need for a concurrent midline incision at the level of the umbilicus, an “M incision” can be used to create skin flaps to anastomose to the catheterizable channel (Fig. 51E.10).

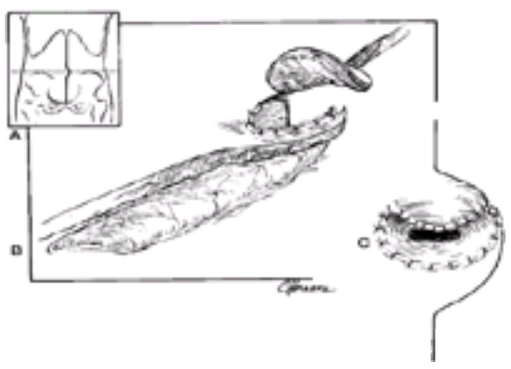

FIGURE 51E.9. Umbilicoplasty with concurrent midline incision. **A:** An initial midline incision is made, curved to the left at the level of the iliac crests. **B:** An adjacent U-flap is marked and inset into spatulated catheterizable channel. **C:** The left lateral aspect of the skin flap is advanced superiorly to create the completed stoma.

Umbilicoplasty without concurrent midline incision. **A:** The “M-flap” incision is marked at the level of the iliac crests. **B:** The inner aspects of the inverted V-flaps are joined with absorbable interrupted sutures. **C:** The superior V-flap and the conjoined inferior skin flaps are anastomosed to the spatulated catheterizable channel. **D, E:** Superior and lateral views of the completed neoumblilicus and catheterizable stoma.

BLADDER NECK RECONSTRUCTION

Urinary continence requires coordination between the bladder and bladder outlet to maintain bladder outlet resistance at a higher pressure than intravesical pressure. Various factors affect this balance, including intrinsic urethral resistance, urinary sphincter function, pelvic floor support, and bladder volume/compliance. Therefore urinary incontinence may result when these mechanisms are abnormally developed or damaged as a result of previous surgery or trauma. When urinary incontinence results from low outlet resistance, operations to increase outlet resistance may be required. Patients with a variety of conditions (Table 51E.2) may require bladder neck operations when they fail conservative management to gain urinary continence.

Exstrophy–epispadias complex
Third stage of staged exstrophy repair (Jeffs approach)
Low outlet resistance following complete primary exstrophy repair (Mitchell approach)
Neurogenic bladder with low outlet resistance
Myelodysplasia
Sacral agenesis
Ureteral anomalies affecting continence
Bilateral ureteral ectopia
Erosive ectopic ureter
Scarring and fibrosis of bladder continence mechanisms producing low outlet resistance
Trauma
Previous surgery (e.g., urethral valves, cecoureterocele)

TABLE 51E.2. INDICATIONS

When considering bladder neck operations, the surgeon can choose between a number of operations (Table 51E.2). Each operation has unique advantages and

disadvantages that must be considered in regard to the individual patient's specific needs (Table 51E.3 and Table 51E.4) and his or her underlying disease state. In general, these operations rely on urethral lengthening, urethral narrowing, urethral compression, and/or bladder neck suspension to create urinary continence (81). Some of these operations preserve patients' ability to void volitionally [i.e., Young-Dees-Leadbetter (YDL), artificial urinary sphincter (AUS)], but other operations do not (i.e., Kropp, Pippi-Salle).

Operation	Advantages	Disadvantages
Young-Dees-Leadbetter (or modifications)	Supports intrinsic sphincteric function; no foreign material	Potentially decreases bladder capacity to produce continence
Bladder neck sling	Technically easy, reversible	? Durability
Endoscopic injection therapy	Technically easy	? Durability; very inconsistent
Artificial urinary sphincter	Dependable, reversible	Limited durability of device; foreign body; expensive; dependent on patient dexterity and commitment
Bladder neck lengthening		Limited applicability
Distal vaginal lengthening	Applicable to girls with a short urethra	Limited applicability

TABLE 51E.3. OPERATIONS THAT POTENTIALLY PRESERVE VOLITIONAL VOIDING

Operation	Advantages	Disadvantages
Kropp	Dependable dryness	Potential for bladder rupture, increased difficulty with catheterization, requires CIC
Pippi-Salle	Potential for "pop-off"	Requires CIC
Bladder neck closure	Dependable dryness	Mitrofanoff stoma required; CIC necessary; not easily reversible

CIC, continuous intermittent catheterization.

TABLE 51E.4. OPERATIONS THAT DO NOT PRESERVE VOLITIONAL VOIDING

Preoperative Evaluation

Before bladder neck surgery, absolute commitment of the patient and family to treatment plans must be appreciated. Regardless of the operation performed, patients must be willing and able to perform clean intermittent catheterization (CIC) after surgery. Patients who undergo a bladder neck reconstruction that does not preserve volitional voiding will always need to perform CIC to empty the bladder. Patients who undergo a bladder neck procedure that preserves volitional voiding may also need to perform CIC after surgery on a temporary or more permanent basis. At times, it can be difficult to predict whether there will be efficient bladder emptying postoperatively, even when the attempt is made to preserve volitional voiding.

Specific assessment of the lower urinary tract should include a urodynamic evaluation and cystoscopy, when indicated. A detailed history of the underlying disease state, including previous operations performed on the lower urinary tract, is also important because the blood supply to the lower urinary tract will likely be altered by these conditions.

Urodynamic Evaluation

Urodynamic evaluation is the cornerstone upon which lower urinary tract management is based. In particular, videourodynamic evaluation offers the best assessment of the lower urinary tract because fluoroscopic images are combined with simultaneous pressure monitoring. During urodynamic evaluation, the investigator should monitor detrusor compliance, the presence of uninhibited contractions, and leak-point pressure (LPP). Sensation with filling, functional bladder capacity, and ability to volitionally empty the bladder are also assessed during urodynamic evaluation. Simultaneous videoscopic monitoring allows evaluation of the bladder neck during filling and offers a sense of bladder shape and the presence of vesicoureteral reflux (VUR).

The urethra of some patients may be difficult to catheterize due to previous trauma or surgical procedures (e.g., exstrophy–epispadias). In these situations, we combine a cystourethroscopic examination with suprapubic placement of a urodynamic catheter to be used later for urodynamic evaluation. A “difficult urethra” strongly implies the need for construction of an alternative catheterization channel (Mitrofanoff) at the time of bladder neck reconstruction.

Cystoscopy

Following a careful history and physical examination, we perform cystourethroscopy for all patients who have a history of previous trauma or surgical procedures involving the lower urinary tract before proceeding to open reconstruction. Cystoscopy provides information regarding bladder capacity and the status of any previous repairs.

Indications for Urinary Outlet Procedures

The two most common conditions requiring urinary outlet procedures are neurogenic bladder with low outlet resistance and the exstrophy–epispadias complex. Important differences exist between these two conditions. Typically, patients with a neurogenic bladder cannot void volitionally, in contrast to patients with exstrophy–epispadias or low outlet resistance due to prior trauma. Furthermore, patients with a neurogenic bladder can have learning disabilities, emotional impairment, and developmental delay that must be taken into account when considering reconstructive procedures that will require them to rely on CIC to effectively empty the bladder. Therefore specific factors must be considered for these patient populations.

Neurogenic Bladder with Low Outlet Resistance

Specific criteria for bladder neck reconstruction can be difficult to determine in this population. Most children with neurogenic bladder dysfunction who remain wet with intermittent catheterization and pharmacotherapy ultimately require surgery to become dry. In patients with myelodysplasia, McGuire and colleagues (62) found the fluoroscopic appearance of the bladder neck predicted continence, as evidenced by the fact that those with an open outlet invariably had leakage despite medical management. Similarly, those with an LPP of less than 55 cm H_2O are more prone to leakage secondary to stress incontinence when they transfer or ambulate (63). These urodynamic criteria help determine who is a potential candidate for a bladder neck operation. Patients with poor detrusor compliance or hyperreflexia refractory to medication will also need bladder augmentation to store urine at safe intravesical pressures.

Surgery for incontinence can be safely performed in young children with a neurogenic bladder. In fact, bladder neck reconstruction is technically easier in this age group because the bladder is still primarily an abdominal organ. Furthermore, there are psychologic benefits for the child to be continent before joining his or her peers in school (3). Therefore we offer surgery to families that have been compliant with intermittent catheterization and routine follow-up when the patient is 4 to 6 years old. However, if concerns exist about the family's or child's commitment to care and CIC, reconstruction should be deferred until these concerns have been adequately addressed. Otherwise, the surgeon risks a “pyhhric victory”—a victory in which the patient is now continent of urine but that damages the upper urinary

tracts and puts his or her life at risk due to inattention to care (7).

Exstrophy–Epispadias Complex

Compared with those with a neurogenic bladder, patients with exstrophy have no bladder neck or anterior bladder wall but are more likely to be continent and able to void after bladder neck reconstruction. As a result, the urologist may consider bladder neck operations that preserve volitional voiding in this patient population. Results of a staged approach to reconstruction as championed by Robert Jeffs have become a popular form of management for bladder exstrophy (26,27). In this approach, the bladder is closed at birth and the epispadias and bladder neck are reconstructed later. Typically, adequate bladder capacity and interest to toilet train are confirmed before bladder neck reconstruction is performed. Gearhart and Jeffs (26) have recommended epispadias repair as a second stage because it produces resistance at the bladder neck, resulting in bladder cycling and increased bladder capacity. Bladder neck reconstruction usually follows as a third stage.

Urinary Outlet Procedures That Do Not Preserve Volitional Voiding

The two most commonly performed outlet operations in this category include the Kropp procedure and its modifications and the Pippi-Salle technique. These operations likely create continence by urethral lengthening and flap-valve compression. Kropp originally described his operation as creating a flap-valve mechanism similar to ureteral reimplantation in which bladder pressure closed the outlet. However, after surgery, these bladders often do not reach pressures comparable to those needed to compress the ureter. Instead, resistance is increased in part by mucosal coaptation within the tube as well as by compression from any rise in intravesical pressure. Kropp has demonstrated tube pressures average 25 cm H_2O at rest, rising to 60 cm H_2O at bladder capacity. The Pippi-Salle repair seems to function by a similar means (90).

Surgical Technique

Kropp Procedure

The Kropp operation begins with a midline retroperitoneal lower abdominal incision to expose the anterior bladder wall (Fig. 51E.11). Then, a 6 × 2 cm detrusor strip based upon the bladder neck is incised by electrocautery. The bladder neck remains attached to the remainder of the bladder. This rectangular strip is next tubularized over an 8-Fr (12- to 14-Fr in adolescents) retention catheter using two layers of absorbable suture. This detrusor tube is then tunneled under the urothelium along the base and posterior wall of the bladder. As a modification, the tunnel may be placed into a shallow trough on the bladder floor made by incising the mucosa longitudinally between the ureteral orifices rather than tunneling it under the urothelium. The meatus and midportion of the tube are sutured to underlying musculature, and the mucosal edges of the trough are sewn to either side of the tube to completely cover its suture line (84) (Fig. 51E.12). When augmentation is required, the bladder is left open and the peritoneum explored to select a bowel segment. In addition, we simultaneously create an appendicovesicostomy (Mitrofanoff principle) in essentially all cases of bladder reconstruction for neuropathic disorders.

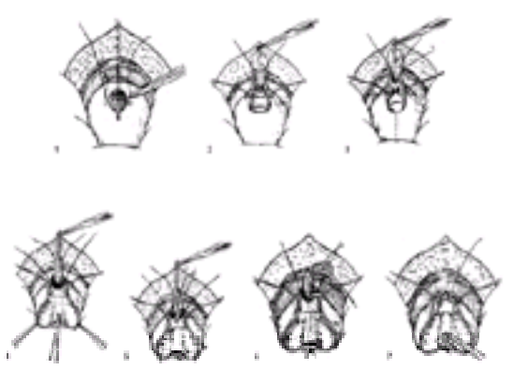

FIGURE 51E.11. Detrusor flap valve. A detrusor tube is created (anterior shown, posterior tube also possible) and tunneled submucosally in bladder to create a competent flap valve. (From Kropp KA, Angwafo FF. Urethral lengthening and reimplantation for neurogenic incontinence in children. *J Urol* 1986;135:534, with permission.)

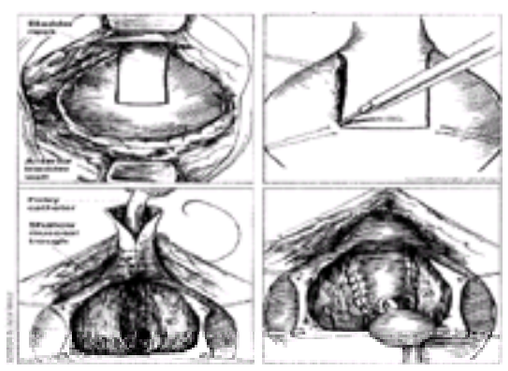

FIGURE 51E.12. Modified Kropp procedure. **Top left:** A rectangular strip is outlined on the anterior bladder wall based upon the bladder neck. **Top right:** The margins of the flap are incised. **Bottom left:** The flap is tubularized around an 8-Fr Foley catheter. **Bottom right:** The detrusor tube is laid into a shallow submucosal trough between the ureteral orifices.

The retention catheter and a suprapubic tube remain in place for 6 weeks. Then, the catheter is removed and the suprapubic (SP) tube occluded. This tube is subsequently removed once it is certain intermittent catheterization can easily be done per urethra or, preferentially, through the Mitrofanoff channel in patients with this means of access.

Pippi-Salle Operation

For the Pippi-Salle operation, a narrower and shorter rectangular flap 5 × 1.5 cm is mobilized, also based upon the bladder neck (Fig. 51E.13). Parallel longitudinal incisions of equal length are made 0.5 cm apart through the mucosa on the floor of the bladder between the ureteral orifices. These anterior and posterior strips are then sewn together in two layers over an 8-Fr catheter. To facilitate the repair, the ureters are usually reimplanted cephalad to the opening of the flap.

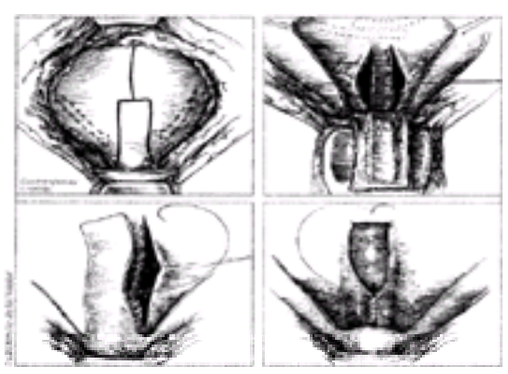

FIGURE 51E.13. Pippi-Salle procedure. **Top left:** A rectangular strip is outlined on the anterior bladder wall extending to the bladder neck. **Top right:** After the ureters are reimplanted cephalad, a rectangular flap is developed on the posterior bladder surface. **Bottom left:** The two flaps are sutured to create a tube lying on the bladder floor. **Bottom right:** The mucosa is closed over the detrusor tube.

Surgical Results

Kropp-type procedures have reported continence rates of 78% to 92% in both males and females (46,84). These results compare favorably to all other continence operations, including the Pippi-Salle, the AUSs, and bladder neck sling.

The main criticism of the repair has been difficulty with intermittent catheterization. Kropp reports 28% of his patients, both male and female, have had at least one episode of difficult catheterization, but only 14% had recurrent problems (90). Simultaneous construction of an accessory channel using the Mitrofanoff principle minimizes this complication.

LPPs following the Kropp procedure can be quite high. The original Kropp operation places most patients into complete urinary retention. This does increase the risk of bladder rupture in patients who have undergone bladder augmentation. The modified Kropp appears to create an outlet with a lower LPP so that patients are more likely to leak if they delay catheterization. This difference likely relates to surgical technique. The Kropp procedure tunnels the detrusor tube, restoring the bladder neck to its original position while placing the whole tube intravesically. In contrast with the Kropp modification, the tube will not reach distally to the original bladder neck; therefore one-third to one-half the tube comes to lie extravesically. Apparently, this small difference makes the continence mechanism less efficient for urinary continence (84).

Both Kropp's and Pippi-Salle's original descriptions of their operations include bilateral ureteral reimplantation to move the ureters away from the site of outlet reconstruction (46,70). Ureteral reimplantation is typically performed for patients who have VUR on preoperative cystography. If ureteral reimplantation is not performed, approximately one-third of ureters will demonstrate VUR postoperatively. Fortunately, this new-onset VUR usually resolves spontaneously within 1 year (84).

Urinary Outlet Operations That Preserve Volitional Voiding

Young-Dees-Leadbetter–Type Bladder Neck Reconstruction

This operation represents an evolution of ideas that began early in the twentieth century and relies on urethral lengthening and narrowing to achieve urinary continence. In 1919, H.H. Young (94) described an operation to correct urinary incontinence by excising the posterior bladder neck and then narrowing the remaining tissue the bladder neck. In 1949, Dees (19) described a modification of this operation that removed more lateral tissue and lengthened the proximal urethra toward the trigone. Leadbetter (50) subsequently extended the degree or urethral lengthening and narrowing to such a degree that ureteral reimplantation was required to move the ureters out of the field of reconstruction. Others have modified this procedure further. Lepor and Jeffs (52) have described concomitant urethral suspension and intraoperative urodynamic evaluation to improve their results. They use a Marshall-Marchetti-Krantz procedure for urethral suspension and attempt to achieve a 3.5-cm continence length with a urethral closure pressure between 60 and 90 cm H_2O with bladder distention. Koff (44) described a further modification of this type of outlet reconstruction—the “cinch” procedure. This procedure involves wrapping the neourethra with a muscular flap and suspending it to the anterior abdominal wall. Jones and colleagues (39) also modified the Leadbetter procedure, called the *Mitchell repair.* In this procedure, the anterior urethra is incised transversely and the incision extended cephalad to narrow the bladder neck and lengthen the urethra.

Occasionally, trigonal tubularization must be combined with bladder augmentation; this type of bladder neck reconstruction decreases bladder capacity because bladder is used to create the continence mechanism (60). Various intestinal segments may also be used according to surgeon preference. The stomach offers the best potential to preserve spontaneous volitional voiding in this group, but it places these children at risk of hematuria-dysuria syndrome, which can be especially troubling in the face of persistent urinary incontinence (25). If augmentation is required, many surgeons will simultaneously perform an appendicovesicostomy for children who have difficult urethras to negotiate because of the possibility that they may require intermittent catheterization to empty the bladder after reconstruction.

Surgical Technique

Young-Dees-Leadbetter Procedure

Before performing the bladder neck reconstruction, ureteral reimplantation is usually required to move the ureteral orifices out of the field of reconstruction. To perform a YDL procedure (Fig. 51E.14), a strip of bladder mucosa (approximately 1 to 1.5 cm wide and 3 to 4 cm long) is mobilized and constructed into a tube over an 8- or 10-Fr urethral catheter using interrupted or running polyglycolic acid sutures (4-0 or 5-0). Use of an epinephrine-soaked sponge during this dissection may aid in hemostasis and visualization. Triangular flaps of demucosalized detrusor muscle are developed on either side of the mucosal tube and subsequently wrapped over the mucosal tube in a double-breasted technique using 3-0 polyglycolic acid sutures (27). This reinforces the neobladder, decreases the risk of fistula formation, and augments the outlet resistance (4).

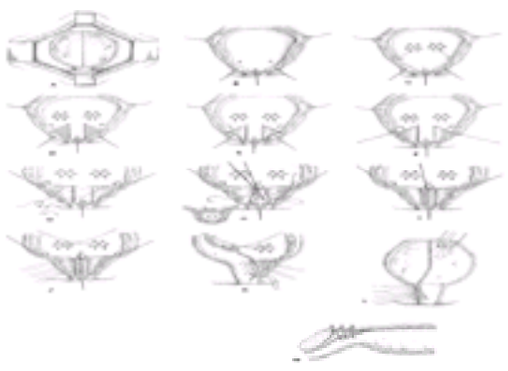

FIGURE 51E.14. Young-Dees-Leadbetter-Jeffs bladder neck reconstruction (BNR). **A:** After mobilization of the bladder neck and proximal urethra, a low transverse incision is extended vertically exposing the ureteral orifices and the entire trigone and proximal urethra. **B:** The bladder muscle lateral to the mucosal strip is denuded by sharp dissection. **C:** Ureteral reimplantation is performed using either a cross-trigonal technique or a cephalotrigonal technique to provide additional trigonal tissue for the repair. **D:** A strip of mucosa approximately 15 to 20 mm in width by 30 mm in length that extends from the midtrigone to the prostatic or posterior urethra is outlined. **E–F**: Multiple small incisions into the bladder muscle in the area of the denuded lateral triangles allow lengthening of the bladder neck area and allow the bladder to retract into a more cephalad position. **G–H:** The bladder neck is closed, beginning with a suture that incorporates detrusor muscle and urothelium. Each suture is placed on traction to draw up more of the strip to allow for easier subsequent placement of the more distal sutures. **I:** The completed mucosal layer of the repair. **J:** Ureteral stents, which will be left for 10 to 14 days, are placed and sutured. The first layer of the double-breasted bladder neck plasty is placed. **K:** The second layer of horizontal mattress sutures is placed. **L:** The bladder is closed after placement of a suprapubic catheter, which will remain in place for 3 weeks. **M:** The outer layer of the vest-over-pants repair is brought anteriorly as a Marshall-Marchetti-Krantz bladder neck suspension. (From Gearhart JP. Bladder neck reconstruction in the incontinent child. In: Frank J, Johnston, JH, eds. *Operative paediatric urology.* Edinburgh: Churchill Livingstone, 1990, with permission.)

Mitchell Repair

In a Mitchell repair (Fig. 51E.15), the anterior urethra should be incised *transversely* and the incision extended cephalad to narrow the bladder neck and lengthen the

urethra. The incision is made full thickness. After cross-trigonal ureteral reimplantation, the urethral strip is tubularized in two layers over an 8- to 10-Fr urethral catheter, depending on the patient's age. The bladder may be closed in continuity with the urethral closure. This procedure effectively narrows and lengthens the urethra. Following the closure, dissection around the new bladder neck may be performed if a combined bladder neck wrap or sling is to be performed.

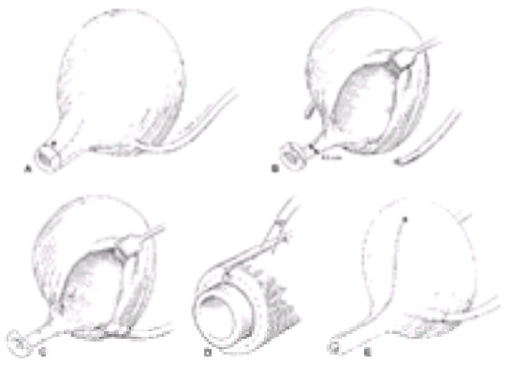

FIGURE 51E.15. Mitchell bladder neck plasty. **A:** A transverse incision is made distal to the original bladder neck area. Note the location of the asterisk relative to the incision. **B:** The incision is extended laterally, posteriorly, and then cephalad toward the ipsilateral ureteric orifice on each side. **C:** The ureters are dissected free from the bladder and reimplanted cephalad in the posterior bladder wall. **D:** The resultant posterior strip of bladder is tubularized in two layers. **E:** The bladder is closed longitudinally as an extension of the bladder neck closure. Note the site of the original bladder neck marked by the asterisk, which is now near the dome. (From Jones J, Mitchell M, Rink R. Improved results using a modification of the Young-Dees-Leadbetter bladder neck repair. *Br J Urol* 1993;71:555, with permission.)

Surgical Results

Bladder neck reconstruction in YDL procedures and its variants has yielded success rates of 30% to 80% or better for urinary continence in patients with bladder exstrophy (28,65). Many factors influence the outcome of surgery. For instance, an initial failed bladder closure or prior failed bladder neck reconstruction reduces the chance to achieve urinary continence later in these patients (28). Use of iliac osteotomies to provide a tension-free anastomosis and patient immobilization through the use of spica casting or Bryant's traction in the postoperative period increases the success of bladder closure and subsequent continence (29,55). Delayed bladder closure increases the likelihood of eventual bladder augmentation due to inadequate bladder capacity, which, in turn, reduces the chance for volitional voiding.

Woodhouse and Redgrave (93) have also reported that 8 of 13 patients with initially successful bladder closures and bladder neck reconstruction required further surgery in their second decade of life because of poorly compliant, low-capacity bladders that caused urinary incontinence.

ARTIFICIAL URINARY SPHINCTER

Indications

The pediatric patient with urinary incontinence secondary to intrinsic sphincter deficiency (ISD) presents a formidable challenge. Surgical options to achieve continence (versus dryness) in these children include procedures such as the YDL, urethral slings, periurethral injection of bulking agents, and the AUS. Of these various options, the AUS reliably allows the patient to spontaneously void postoperatively. From 25% to 30% of children with the AUSs in place have been reported to void spontaneously (32,53). Yet, unlike the other procedures to increase outlet resistance, the pressure exerted to compress the urethra or bladder neck is very dependable and determined by a pressure-regulating reservoir with different potential pressures (51 to 60, 61 to 70, 71 to 80, and 81 to 90 cm H_2O). Thus the AUS provides substantial and reliable outflow resistance for patients with urinary incontinence secondary to intrinsic sphincter deficiency and offers good potential for voiding.

The AUS is a mechanical device engineered to provide continence by circumferential compression of the bladder neck or bulbous urethra. In 1973, Scott and co-workers (79) were the first to report the use of the AUS for patients with incompetent urinary sphincters. The current model, the AS800, has been in use since 1983 and consists of three components: the pump, the reservoir, and the sphincter cuff, which are all interconnected by silicone tubing (Fig. 51E.16). To decrease the mechanical failure rate, several modifications have been made to the original AUS. These include (a) treating the surface of the cuff with silicone, (b) narrowing the back cuff, (c) color-coding kink resistant tubing, and (d) making a seamless reservoir.

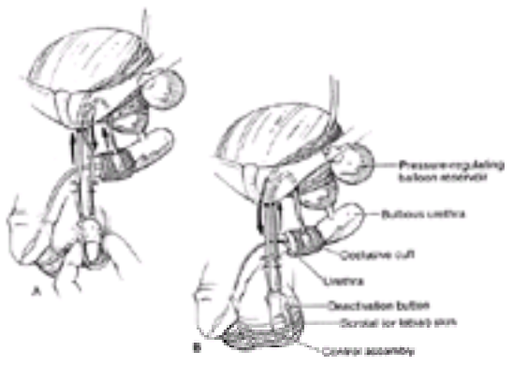

FIGURE 51E.16. Components and cycling of the AS800 AGUS. **A:** Squeezing of the scrotal/labial pump transfers fluid out of the compression cuff and into the reservoir initiating voiding. **B:** A delayed refill resistor slowly allows the cuff to refill automatically over 3 to 5 minutes.

The pump, placed in either the scrotum or labium majora, transfers fluid from an inflated cuff to the reservoir via a one-way valve. The pump has a refill–delay resistor that allows fluid to refill passively into the cuff after the bladder has been emptied. The pump also has a separate deactivation device with a poppet valve that allows the cuff to remain deflated if so desired. A modification of the pump for pediatric patients separates the deactivation device from the pump, thus allowing a smaller pump to be placed in the scrotum or labia of a small child.

The reservoir, placed either intraperitoneal or extraperitoneal, is an expandable silicone sphere and serves as the pressure regulator of the system. The fluid-filled reservoir transmits pressure to the sphincter cuff. The pressure exerted by the cuff is determined by the thickness of the reservoir wall. Currently, obtainable pressures are 51 to 60, 61 to 70, or 71 to 80 cm H_2O, depending on which reservoir is placed. The sphincter cuff (4 to 11 cm in length) is placed around the bladder neck or bulbous urethra and provides circumferential compression when filled with fluid. To empty the bladder, fluid must first be transferred from the cuff to the reservoir by sequential compression of the pump. The cuff then refills as fluid is passively transferred from the reservoir after 1 to 5 minutes.

Preoperative Assessment

The AUS is ideally suited for the patient who can void volitionally and who has a compliant but low-capacity bladder such that urinary outlet reconstruction would necessitate augmentation just to maintain capacity. Incontinent patients with adequate bladder capacity but ischemic or fibrotic tissue at the bladder neck may benefit from an AUS with sphincter placement at the bulbous urethra. However, the bulbous urethra can be used only in the postpubescent male. Children with a neurogenic bladder who can empty their bladders effectively with or without intermittent catheterization may also be good candidates for an AUS. Relative contraindications to AUS placement include patients who have chronic urinary tract infections because of the risk of infection of the AUS and patients with poor manual dexterity because

they will not be able to manipulate the pump. Some investigators advise against using an AUS for patients who require CIC (54), but others do not see this as a contraindication (20). Because of the expectation of eventual revision and the dexterity required to use it, it is generally not the best option for younger patients.

Before implantation of the AUS in children, a complete medical history should detail the nature of incontinence, a summary of previous surgical procedures, expectations of the child and the family, the ability of the child or family to perform intermittent catheterization. Most importantly, the motivation and dedication of the child and family to the success of the procedure should be critically assessed. In general, the child should be at least 7 years of age and demonstrate excellent manual dexterity if he or she is going to be using the pump with commitment to using the device. The mental readiness of the child to accept responsibility is probably more important than age. It is also important that the family and child understand the mechanics of the device. Preoperative teaching of the child and the family before implantation of the AUS is critical to success. The family also must understand that the AUS is a mechanical device that will require revision in the future. Unfortunately, long-term effects of having a silicone device in the body are not known, but unlike with breast implants, difficulties have not been reported (76).

A critical component to the preoperative evaluation of a child anticipating a sphincter placement is videourodynamics. Important information to ascertain includes bladder capacity and compliance, the presence of uninhibited contractions, the presence of VUR, the appearance of the bladder neck, the LPP, the ability of the child to spontaneously void, and the postvoid residual. If the bladder neck is significantly incompetent or wide open, a balloon catheter is used to occlude the bladder neck to assess detrusor function. If decreased capacity, decreased compliance, or uninhibited contractions are detected with urodynamics, consideration should be given to a trial of anticholinergics before surgery. No improvement while taking anticholinergics may indicate the need for simultaneous augmentation at the time of AUS placement with minimal increased morbidity (64).

Operative Technique

At the time of AUS placement, the child should have sterile urine. A 24-hour course of intravenous antibiotics before the procedure may be considered, especially if the child performs CIC. Also, if a concomitant procedure is to be performed, such as a bladder augmentation or antegrade continence enema, a full mechanical and antibiotic bowel preparation should be performed.

Cystourethroscopy is performed before open bladder surgery and allows for a visual inspection of the urethra, the bladder neck, the ureteral orifices, and the bladder wall. High-grade reflux, bladder calculi, and ureteral ectopia close to or into the bladder neck are all relative contraindications to sphincter placement. In the male patient, a sponge is placed in the rectum to help prevent injury to the rectum during placement of the sphincter by facilitating identification of the anterior rectal wall. The vagina is irrigated with an antiseptic solution before surgery. A Foley catheter is placed after the surgical field has been prepared.

In children, the AUS is usually placed around the bladder neck. If concurrent bladder augmentation or a Mitrofanoff procedure is to be performed, a midline incision provides appropriate exposure. Otherwise, a Pfannenstiel incision is indicated. When other procedures are planned, placement of the AUS is usually the final step in the surgery. If the bladder is opened for bladder augmentation, the plane between the bladder neck and vagina in the female and the bladder neck and rectum in the male is developed before completing the augmentation. The plane between the rectum or vagina and posterior bladder neck is more easily identified with the bladder open. If the bladder is not opened, traction on the Foley balloon aids in identifying the posterior and lateral aspects of the bladder neck. If there is any difficulty with development of this plane, the dome of the bladder should be opened to provide visual guidance.

Once the plane is developed around the bladder neck, the sizer is placed around the bladder neck. This sizer determines the appropriate size of the sphincter cuff to be used. The surgeon should place the sizer snugly, but not tightly. Usually, at the bladder neck in children, a cuff between 4 and 6.5 cm is used (Fig. 51E.17).

FIGURE 51E.17. The cuff tubing is passed through the hole in the cuff tab and then snapped into place.

The individual components of the AUS are then primed before being brought to the operative field. We prefer to use a 61- to 70-cm H_2O pressure-regulating balloon in children. The components are flushed with an isotonic contrast solution to remove all bubbles. Twenty-two milliliters of the contrast solution is placed in the reservoir, and the pump control is left full of fluid; the cuff is empty. The individual components are then brought to the surgical field. Antibiotic irrigant is liberally used in the wound throughout the surgery. The sphincter cuff is placed around the bladder neck and snapped to itself. The reservoir is then placed either intraperitoneal or in the preperitoneal space between the abdominal wall and peritoneum. The tubing from the reservoir and the tubing from the sphincter cuff are then brought through the rectus muscle on the side of the body that the pump will be placed. A plane is then developed above the rectus fascia down into the dependent portion of the scrotum or labia to place the pump.

After placement of the pump in the scrotum or labia, the tubes from the pump are connected with the tubing from the cuff and tubing from the reservoir. The tubing is color coded to ensure correct connections. We use the sutureless Quick Connect connectors to connect the tubing as provided by the manufacturer. It is important to not allow blood or debris to get into the system while making these connections. All connections are made above the level of the rectus fascia in the subcutaneous space.

In the older child with a fully developed scrotum or labia, we use the standard pump, which also contains the deactivation device. However, in the younger child without a fully developed scrotum or labia, we have used a modified pump. In this pediatric modification, the deactivation device is separate from the pump. This allows a smaller-sized component (pump without deactivation device) to be placed in the scrotum or labia. In this pediatric modification, the deactivation device is connected between the pump and the tubing from both the cuff and reservoir above the rectus fascia in the suprapubic space. The AUS is left deactivated with no fluid in the sphincter cuff for 6 weeks to allow healing.

Results and Complications

The results of the most recent large series of children with the AUS are characterized in Table 51E.5.

Material	Advantages	Disadvantages
Rectus fascia	Autologous tissue	Morbidity of harvest
Fascia lata	Autologous tissue	Morbidity of harvest
Cadaveric fascia	No morbidity to harvest	?Risk for viral infections (prions)
Gracilis muscle	Well vascularized	Technically more difficult to harvest; bulky
Polypropylene	No morbidity to harvest	Foreign body; increased risk of erosion and infection
Silicon	No morbidity to harvest	Foreign body; increased risk of erosion and infection
Polytetrafluoroethylene (Gore-Tex)	No morbidity to harvest	Foreign body; increased risk for erosion and infection

TABLE 51E.5. BLADDER NECK SLING AND WRAP MATERIALS

Continence

Placement of an AUS is one of the most reliable means to increase bladder outlet resistance and provide continence in both adults and children. The reported continence rate for pediatric patients who have an AUS in place is between 71% and 100% (Table 51E.5).

Mechanical Failure and Revisions

One pitfall of the AUS is that it is a mechanical device; thus revisions will eventually be required. Fortunately, the improvements in design have significantly reduced the need for revisions. Simeoni and co-workers (82) found mechanical failures in 21 of 107 patients at follow-up. These failures included perforation or rupture of the cuff in two patients, perforation or rupture of the reservoir in three, perforation or rupture of the tubing in two, kinking of the tubing in two, pump malfunction in six, fluid leakage in four, and organic material occluding the hydraulic system in two (82). Simmons and colleagues (83) described a mechanical failure rate of 1 per every 12.5 patient years in their 15-year follow-up of 134 patients. Similarly, Kryger and associates (48) reported 0.08 revisions per patient-year in patients who had the AS800 placed. Twelve of their revisions were for fluid leaks and six revisions were for component malfunction. In a meta-analysis of published studies in both adults and children, Hajivassiliou (37) reported a global revision rate of 32%.

Bladder Deterioration

After implantation of an AUS, some patients have demonstrated significant changes in detrusor function. Some of these patients have required subsequent augmentation to protect their renal function and to aid in achieving continence. In 1998, Kronner and colleagues (45) evaluated 38 children who underwent AUS alone. In follow-up, 15 of the 38 patients required subsequent augmentation cystoplasty at a mean of 49 months after initial AUS placement. They found no statistical significance in the preoperative bladder capacity or compliance when comparing those patients who eventually required augmentation with those patients who did not require augmentation (45). Therefore it is important to closely follow children in who an AUS is placed for subsequent change in bladder function. Proposed etiologies of deterioration in bladder function are unrecognized hyperreflexia or decreased compliance preoperatively, tethered chord, progression of myelomeningocele, or the bladder's response to outlet obstruction.

Erosion and Infection

Two potential complications of placing and artificial device into the body are erosion through adjacent tissues and infection. Gonzalez and co-workers (32) reported a 41% removal rate in follow-up, and all devices were removed secondary to either erosion or infection. Although not statistically significant, Gonzalez and associates (32) believed that risk factors for erosion in their patients included previous AUS erosion, previous bladder neck surgery, and a balloon pressure greater than 70 cm H_2O. No erosions were noted in patients with an AUS placed around a previously unoperated upon bladder neck. Therefore they have used the AUS as a first-line treatment for all patients with neurogenic sphincter incontinence (32). We, on the other hand, tend to use the AUS as a secondary procedure, unless the children void spontaneously before surgery.

BLADDER NECK SLINGS AND WRAPS

Sling operations are used to coapt the incompetent bladder neck. Typically, these are wrapped snugly around the bladder outlet. In that regard, they are similar to artificial sphincters. Sphincters, however, provide more effective closure, especially in boys, and have the advantage of reducing the closure pressure for voiding. Bladder neck wraps (and slings to some degree) should be considered to provide a fixed urethral closure. Complications of slings include erosion and difficult intermittent catheterization. Sling procedures also demonstrate less durability and seem to have less effectiveness in boys (49,72). We use them as an adjunct to other procedures.

Bladder neck wraps and slings may also be performed in conjunction with urethral lengthening (YDL) procedures. Series reporting on the use of bladder neck wraps alone suggest that this procedure does not consistently maintain long-term urinary continence, especially in male patients who constitute the gender majority in exstrophy (18,49). Bladder neck wrap and sling procedures have been performed with a variety of substances. These include autologous tissue–like rectus fascia, tensor fascia lata, and gracilis muscle and synthetic products such as silicon elastomers, Vicryl mesh, polytetrafluoroethylene membrane (Gore-Tex), and others. Fascia remains a popular choice for these procedures (6).

Surgical Technique

Bladder neck wrap and sling procedures may be performed transvaginally or transabdominally. The transvaginal approach is best suited for patients who do not require a concomitant transabdominal procedure and who are large enough to provide the surgeon with enough exposure to the anterior vaginal wall. As a result, transvaginal operations for urinary incontinence are rarely used for prepubertal girls.

With use of a transvaginal approach, the patient is first placed in the dorsolithotomy position. After sterile preparation and draping, a urethral catheter is placed to empty the bladder and assist in identifying the location of the urethra. The sling tissue to be used should be ready or harvested before beginning the vaginal dissection. An inverted U-flap or longitudinal incision is then made in the anterior vaginal wall to expose the underlying connective tissue. A low transverse abdominal incision is made. This incision is used to allow an endoscopic suture-passer such as the Stamey needle to transfer suture material from the vaginal incision to the abdominal incision. The bladder should be empty to reduce the chance of entering the bladder during suture passage. The sutures are attached to the sling material prior their passage to the anterior abdominal wall. The sutures can be tied to each other over the abdominal wall fascia or anchored to bone depending on surgeon preference (Fig. 51E.18).

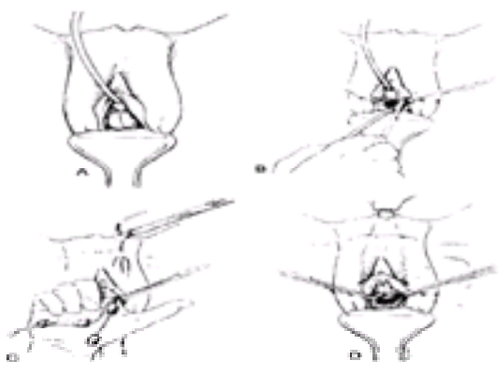

FIGURE 51E.18. A–D: McGuire's modified pubovaginal sling. A 1 × 3 cm rectus fascial strip is pulled up by techniques of a Stamey endoscopic suspension to add a compressive element. (From McGuire EJ, Wang C, Usitalo H, et al. Modified pubovaginal sling in girls with myelodysplasia. *J Urol* 1986;135:94, with permission.)

A transabdominal approach to bladder neck wraps and slings is most commonly used for children and male patients (Fig. 51E.19). It is often combined with other operations such as bladder augmentation. If this operation is performed alone, the surgeon may use a low transverse abdominal incision. Otherwise, it can be performed through a longitudinal midline abdominal incision in combination with another operation.

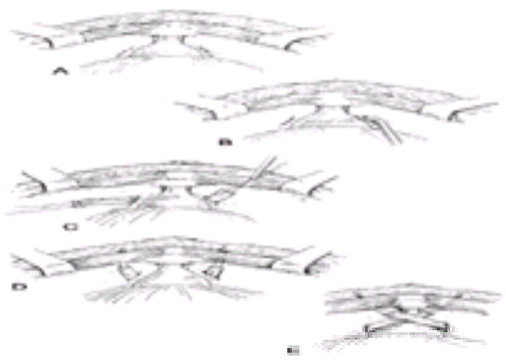

FIGURE 51E.19. A–E: Transabdominal approach for bladder neck wrap.

As in the case of AUS placement, safe circumnavigation of the bladder neck is the most technically difficult portion of this operation. Dissection around the bladder neck can prove technically challenging in these patients due to a patulous bladder neck, previous surgery in this area, and concomitant skeletal abnormalities in some of these patients. A prevesical and retrovesical approach may be necessary to accomplish this dissection without entering the bladder neck. The bladder may also be opened anteriorly to help identify the plane of dissection behind the bladder neck. If the urethra, vagina, or bladder neck are inadvertently entered during attempts to establish a plane of dissection around the bladder neck, the wrap or sling may still be performed if the opening is small, although healthy tissue should be brought between the bladder neck and sling tissue if possible. If the opening is large, the bladder neck procedure should be converted to another operation as appropriate. Bladder neck closure may be performed in this situation as well.

Once the bladder neck dissection has been preformed, the coapting tissue may be passed around the bladder neck. The number of times the tissue is passed around the bladder neck and the amount of tension placed on the wrap depend on surgeon preference and tissue availability. The bladder neck may be suspended from the inferior surface of the pubis symphysis following suture fixation of the fascial tissue to the bladder neck and to itself. Suprapubic urinary drainage following a bladder neck wrap or sling avoids pressure on the repair site. It also provides a mechanism for urinary drainage, if a trial of volitional voiding or CIC is unsuccessful in the initial postoperative period.

URETHRAL BULKING INJECTION

Politano and co-workers (73) introduced the concept of urethral bulking in 1974. At that time, they described the use of polytetrafluoroethylene (Teflon) paste to coapt the urethral wall by injecting it in a submucosal plane. Since then, various other agents have been proposed, including adipose, bovine collagen, carbon-coated beads (Durasphere), and silicon elastomers (Macroplastique) (74). Some investigators are also evaluating the use of myoblasts, chondrocytes, and other autologous agents (14). Each has advantages and disadvantages (Table 51E.6). None of these agents has demonstrated enough long-term success or dependability to replace other procedures. However, endoscopic injection of bulking agents is technically easy and offers minimal patient morbidity. It also preserves the ability of patients to void volitionally in many situations. Of note, before the use of bovine collagen for endoscopic bulking therapy, the patient must be tested for hypersensitivity to this agent. This is assessed by subdermal injection.

Agent	Advantages	Disadvantages
Polytetrafluoroethylene	Durable	Difficult to inject; tissue migration and granuloma formation (51,58)
Bovine collagen	Ease of injection (8)	Not durable (59); hypersensitivity reactions in some patients (1)
Autologous fat	Biocompatible	Not durable; morbid to harvest; difficult to inject (51)
Silicone elastomer (75)	Promising story; durable	Long-term results?
Pyrolytic carbon–coated beads	Promising story; durable	Long-term results?

TABLE 51E.6. PERIURETHRAL BULKING AGENTS

Injectable bulking agents may be used as *de novo* therapy or adjunctively after a bladder outlet operation. Currently, injectable therapy enjoys its broadest application for the treatment of intrinsic sphincter deficiency in women with stress urinary incontinence. Success rates vary widely. In general, success rates are highest immediately after therapy and deteriorate over time. Success rates also appear higher when injectable therapy is used as a first-line agent rather than as adjunctive therapy following bladder neck reconstruction (21).

At present, bovine collagen is the most popular injectable agent available. It is most commonly used for stress urinary incontinence in adult women. Several authors have used bovine collagen injections at the bladder neck to treat patients with stress incontinence after bladder neck reconstruction as well (5,10). Ben-Chaim and colleagues (5) reported an improvement in continence in 53% of patients after collagen therapy, although most required multiple injections.

In children, injectable bulking agents are more commonly used for adjunctive therapy for those patients who demonstrate slight urinary leakage due to stress incontinence after bladder neck reconstruction. These agents are rarely used for primary therapy in children with stress urinary incontinence.

Surgical Technique

Cystoscopic evaluation of the bladder and bladder neck is first performed. A large-bore needle (e.g., 17 gauge) is then inserted submucosally proximal to the bladder neck. The needle is advanced in this plane, and the agent is injected (Fig. 51E.20). Proper needle placement is visually confirmed at this time by watching the submucosal tissue coapt as the agent is injected. The properties of the specific bulking agent and the plane of injection will dictate the ease of injection. Needle placement too deeply into the tissue will make injection difficult and will not result in tissue coaptation. Injections are typically performed at various locations in the urethra, such as the 3, 6, and 9 o'clock positions. The amount of agent injected depends on the particular bulking agent chosen, the ease of injection, and the ease of tissue coaptation.

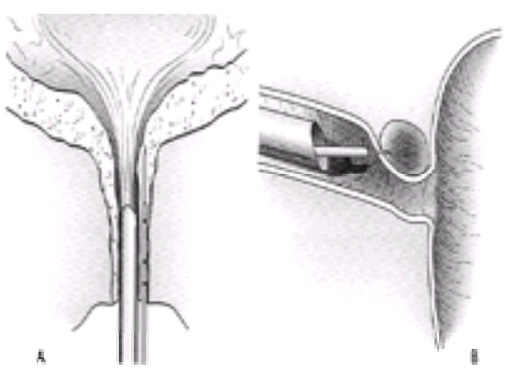

FIGURE 51E.20. A–B: Technique for periurethral injection.

BLADDER NECK CLOSURE

Bladder neck closure in conjunction with appendicovesicostomy is also an option in patients who have failed multiple attempts at bladder neck reconstruction. We reserve this as a final solution because it eliminates the chance to void per the urethra and commits the patient to intermittent catheterization. This procedure should not be taken lightly. It can be technically difficult to perform because it is often required in the patient who has had multiple previous surgeries and extensive scarring at the bladder neck. As with any closure, the dissection of the bladder neck should be complete enough to facilitate a two-layer closure. Both the bladder neck and urethra should be closed and healthy tissue placed between. Often, omentum can serve this purpose. Breakdown of a bladder neck closure can and does happen. This is very disappointing to both the patient and the surgeon.

GENITAL ANOMALIES: MALE

In humans, the Y chromosome induces testis formation and thus male sexual development; in the absence of a Y chromosome, gonads differentiate into ovaries and female development ensues. Molecular genetic studies have identified the Y-located testis-determining gene SRY as well as autosomal and X-linked genes necessary for gonadal development (5,69,94).

Beginning at 8 weeks of gestation, genital development occurs in two distinct areas: internal duct structures and external genitalia (23). Development of internal duct structures in both male and female depends on the presence or absence of a fetal testis (Fig. 52A.1). In the presence of a fetal testis, there will be production of androgen (testosterone) as well as müllerian-inhibiting substance (MIS) (36). Secretion of fetal androgen by Leydig cells stimulates the Wolffian duct to differentiate into the vas deferens, seminal vesicle, and epididymis. At the same time, the Sertoli cells of the fetal testis secrete a nonsteroidal substance (MIS) that prevents development of müllerian duct structures into the fallopian tube, uterus, and upper third of the vagina. The development of the female internal duct system does not depend on hormonal induction and occurs normally in the absence of MIS, whereas the Wolffian duct structures will regress in the absence of high levels of fetal androgen (57).

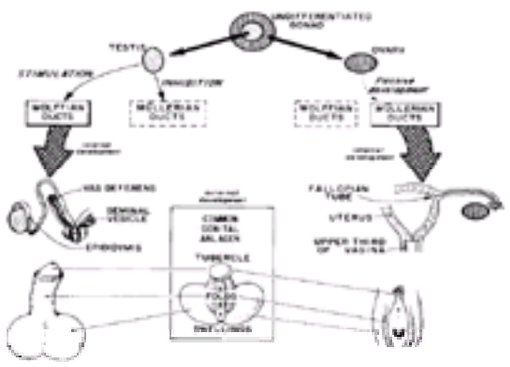

FIGURE 52A.1. Normal sexual development in the male and female. (Adapted from Federman DD. *Abnormal sexual development: a genetic and endocrine approach to differential diagnosis.* Philadelphia: WB Saunders, 1967, with permission.)

Differentiation of the external genitalia occurs somewhat later, probably between 12 and 16 weeks of gestation (Fig. 52A.1). The process in the male requires not only the fetal testis and adequate amounts of fetal androgen but also the ability of the target organ to respond to the circulating androgen. Testosterone exerts its effect on the target organ in several ways, the most important of which is the conversion of testosterone to dihydrotestosterone (DHT) under the enzymatic influence of 5a-reductase (11). This conversion takes place within the tissue of the common genital anlage, where DHT combines with a cytosol receptor that is coded for by one or more X-linked genes (2,75). These androgen receptor complexes are then activated and moved to nuclear acceptors (3). Subsequently, DNA-dependent RNA polymerase activity increases, followed by enhanced production of protein. These serve as the initial steps for differentiation of the common genital anlage (50). Under the influence of DHT, the genital tubercle will differentiate into the glans penis, the genital folds become the shaft of the penis, and genital swellings become the scrotum. If there is a deficiency in production of fetal testosterone, failure of conversion of testosterone to DHT, or insensitivity in the target organ to DHT, the genital tubercle will passively develop into the clitoris, the genital folds will become labia minora, and the genital swellings will become labia majora (36,53).

The clinical and molecular spectrum of the androgen insensitivity syndromes (AIS) has been well defined over the past several years and offers one of the better examples of genetic interactions in the human sex determination pathway. This disorder is caused by mutations of the androgen receptor and is an X-linked recessive trait. Hiort and colleagues (49) studied 47 patients with AIS and characterized the underlying molecular abnormality in the androgen receptor gene. They noted that mutations in the androgen receptor gene may be present throughout the whole coding region, but provided evidence that several mutational hot spots exist. Bevan and associates (6) found milder mutations to be associated with milder clinical phenotypes. There also is clear evidence that phenotype does not solely depend on androgen receptor function. Nonetheless, some mutant receptors are able to respond to high dosages of androgens *in vitro,* suggesting that patients carrying these mutations may be candidates for androgen therapy (52).

There are significant numbers of patients with disorders of sexual differentiation in whom no mutation has yet been characterized. It is likely that further genes involved in sexual differentiation will be identified and shown to be the etiology of a number of these diseases (51,104).

Danso and Tobani (19) have used cytogenetic investigations in confusing states of intersexuality and disorders of sexual differentiation to make sex assignment slightly easier and more sensible. They suggest performing these studies in the very early stages of life. In all 87 patients studied, cytogenetic investigations helped to categorize the ambiguous genitalia patient accurately. They concluded that cytogenetic studies should be a prerequisite, are an advantage, and are imperative in

patients with ambiguous genitalia.

In cases of genital anomalies, parents and sometimes patients themselves must be advised in a meaningful manner (96). The anomalies of sexual development and their etiologies and management are discussed to provide the reader with a foundation when approaching these challenging and fascinating cases.

Penile Agenesis

Endocrine testicular function in patients with penile agenesis (Fig. 52A.2 and Fig. 52A.3) has been shown to be normal as judged by a normal response to gonadotropin stimulation (28,59,102). Recommended treatment should be early gender reassignment and gonadectomy. The urethra should be transposed anteriorly away from the anal verge, and the scrotal skin should be preserved to aid later vaginal construction. Recently, consideration has been given to penile reconstruction utilizing free flaps from the arm or leg to construct a phallus. This is very innovative and demanding surgery, with little long-term follow-up. With normal testes and receptor function, male imprinting may be significant, therefore providing possible justification for such efforts.

FIGURE 52A.2. Penile agenesis.

FIGURE 52A.3. Agenesis of the penis and scrotum.

Penile Duplication

Duplication of the penis is another rare anomaly, probably resulting from incomplete fusion of the genital tubercle. The anomaly appears in two basic forms, the first and more common being the bifid penis, which is often associated with the exstrophy-epispadias complex (Fig. 52A.4) and is present in almost every male with cloacal exstrophy. In these cases, the bifid penis consists of a single corporal body on each side associated with a hemiglans penis (55).

FIGURE 52A.4. Penile duplication in a patient with bladder exstrophy.

The other form of penile duplication is true diphallia. This is an extremely rare condition in which there is a duplication of all or part of the penis (91). The deformity exists in a spectrum that ranges from duplication of glans alone, arising from the single shaft (Fig. 52A.5), to complete duplication with two separate scrotums. With complete duplication, each penis has a complete urethra, which is associated with an independent bladder or at times with a bifid bladder. The urethral opening can be in the normal position or either hypospadiac or epispadiac. When bladder duplication is associated with penile duplication, both erection and urination can occur synchronously or asynchronously.

FIGURE 52A.5. Complete penile duplication.

Treatment of penile duplication varies depending on whether other congenital anomalies are present. If the bifid penis is associated with cloacal exstrophy, penile reconstruction may not be technically possible and gender reassignment is considered. One of the bifid phalluses can be removed, retaining the other to act as a clitoris. In true diphallia, the decision of which penis should be removed and which salvaged should be based on not only the physical appearance of both structures, but also on the size of the bladder associated with each segment, and the erectile function of each unit. Patients with true diphallia should also be thoroughly evaluated for other genitourinary or gastrointestinal (GI) tract anomalies because the association of other anomalies with this defect is abnormally high.

Microphallus

Microphallus can best be defined as a normally formed penis (Fig. 52A.6) whose length is more than 2.5 standard deviations (SDs) below the norm for age (Table 52A.1) (25, 95). In the neonatal period, the penis should measure at least 2 cm from pubis to tip when fully stretched (66). The term *microphallus* by definition excludes hypospadias and ambiguous genitalia.

Age	Mean ± SD cm	Mean −2.5 SD cm
Newborn, 30 wk	2.5 ± 0.4	1.5
Newborn, 34 wk	3.0 ± 0.4	2.0
Newborn, term	3.5 ± 0.4	2.4
0–5 mo	3.9 ± 0.8	1.9
6–12 mo	4.3 ± 0.8	2.3
1–2 yr	4.7 ± 0.8	2.6
2–3 yr	5.1 ± 0.9	2.9
3–4 yr	5.5 ± 0.9	3.3
4–5 yr	5.7 ± 0.9	3.5
5–6 yr	6.0 ± 0.9	3.8
6–7 yr	6.1 ± 0.9	3.9
7–8 yr	6.2 ± 1.0	3.7
8–9 yr	6.3 ± 1.0	3.8
9–10 yr	6.3 ± 1.0	3.8
10–11 yr	6.4 ± 1.1	3.7
Adult	13.3 ± 1.6	9.3

TABLE 52A.1. STRETCHED PENILE LENGTH IN NORMAL MALES

FIGURE 52A.6. True microphallus.

In general, the cause of microphallus can be thought of as either inadequate androgen stimulation of the target organ or an insensitivity of the target organ to available androgen. Inadequate amounts of androgen reaching the target organ can be on the basis of either poor Leydig's cell stimulation, thus suggesting a problem in the hypothalamic-pituitary axis, or a failure of the conversion of testosterone to DHT by 5a-reductase.

The nature of the defect can be determined by the individual's response to gonadotropin stimulation. In most infants with microphallus, the ability to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in response to gonadotropin-releasing hormone (GnRH) is present, and the testis is able to respond to LH by secreting testosterone. In addition, androgen-sensitive target organs such as the penis generally respond to testosterone administered locally or parenterally. Thus it seems that in most infants with microphallus, the hypothalamic–pituitary–end-organ axis distal to the hypothalamus is intact, implicating the hypothalamus as the site of the primary defect (66). Additional evidence for this is seen in several associated disorders, such as Kallmann's syndrome and Prader-Willi syndrome. Other endocrine disturbances, such as abnormal levels of adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and growth hormone, can be seen frequently in patients with microphallus.

The treatment of microphallus should begin early (39). In rare individuals with identifiable AIS and associated microphallus, gonadectomy and gender conversion to female is best done at an early stage. In most patients with true microphallus, male gender assessment can be maintained, and androgen stimulation should begin in the first year of life. Monthly injections of testosterone enanthate are given for 3 months in doses of 25 to 50 mg delivered parenterally (15). Application of 3% testosterone cream locally is also a reasonable way to deliver androgen; however, the absorption is variable, and the dose is not as easily controlled (60). In most instances of true microphallus, an increase of phallic growth of approximately 2 cm in the first year of treatment can be expected. When this early stimulation is stopped, the penis does not usually revert to its previous proportions. Multiple courses of androgen stimulation can be used, and if significant growth does not occur, gender conversion can be considered (77).

The long-term outlook for patients with true microphallus recently has been reviewed by Reilly and Woodhouse (89). In 12 postpubertal patients who had carried the diagnosis since childhood, they found the prospect for long-term sexual activity to be hopeful. Eleven of their patients experienced ejaculation, and nine were sexually active, all reporting vaginal penetration. All of the patients in their series had been stimulated with human chorionic gonadotropin, testosterone, or cortisone during childhood.

Penile Torsion

Rotational defects of the penis, or penile torsion (Fig. 52A.7), can occur in either a clockwise or counterclockwise position, with or without other associated defects such as hypospadias (83). The defect usually has more cosmetic than functional significance. Mild degrees of torsion are not associated with either erectile or voiding dysfunction, and the surgical correction of penile torsion usually is not indicated for children with a rotation of less than 90 degrees from the midline. Surgical correction of mild penile torsion usually involves nothing more than simply degloving the penis and reorienting the median raphe to its normal position (83).

FIGURE 52A.7. Penile torsion. (Courtesy of A. Barry Belman, M.D.)

In cases of more significant penile torsion, there can be a defect in the position of the glans penis on the corporal bodies. In the treatment of patients with extreme torsion, the glans usually must be mobilized to some degree and rotated on the corpora to achieve derotation. This is a significant surgical undertaking and should not be considered in mild forms of penile torsion.

Lateral Curvature of the Penis

Lateral penile curvature rarely is recognized in infancy but certainly can be noted in early childhood and must be differentiated from chordee without hypospadias (Fig. 52A.8). Lateral curvature usually is caused by an overgrowth of one corporal body, or concomitant hypoplasia of the contralateral corpora (26). The defect can be associated with corporal injury, but in most instances, there is no history of trauma.

FIGURE 52A.8. Curvature of the penis secondary to unilateral corporal overgrowth. (Courtesy of John Duckett, M.D.)

Surgical correction of corporal discrepancies should be considered only when the discrepancy significantly interferes with erection. The procedure of choice in most instances was described by Nesbit and involves excising ellipses of the tunica albuginea from the dominant corpora in the area of maximum curvature to reduce the apparent defect (34). When corporal discrepancies are the result of trauma, there is often a scar on the contralateral (shorter) corpora, which can be excised and grafted with either tunica vaginalis or some other form of genitourinary tissue.

Penile Lymphedema

Primary lymphedema (Fig. 52A.9) of the foreskin and penile shaft is a chronic condition seen in children with either abnormal penile lymphatics or a decreased number of lymph channels draining the foreskin (13). The condition occasionally is seen after circumcision; however, it also may be seen in uncircumcised newborn children as well as in adolescents. When it is seen in the uncircumcised newborn, elective circumcision should be avoided because this generally escalates the process of poor lymph drainage, making the situation worse.

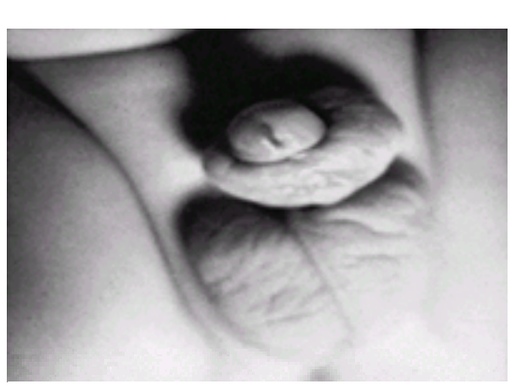

FIGURE 52A.9. Lymphedema of the foreskin following newborn circumcision.

In most instances, a reduction of the excess skin and subcutaneous tissue will give a reasonable cosmetic result. When the problem is extensive, the edema may involve the entire shaft and scrotum. Feins (24) has suggested extensive resection of the subcutaneous and lymphatic tissue to deal with the problem in its more severe form.

Penoscrotal Transposition

Complete transposition of the penis and scrotum (Fig. 52A.10) is a rare anomaly that often is associated with other congenital anomalies, many of which are incompatible with life. The embryologic defect is probably the abnormal positioning of the genital tubercle in relation to the genital swellings; this abnormality also has been referred to as a *prepenile scrotum* (17).

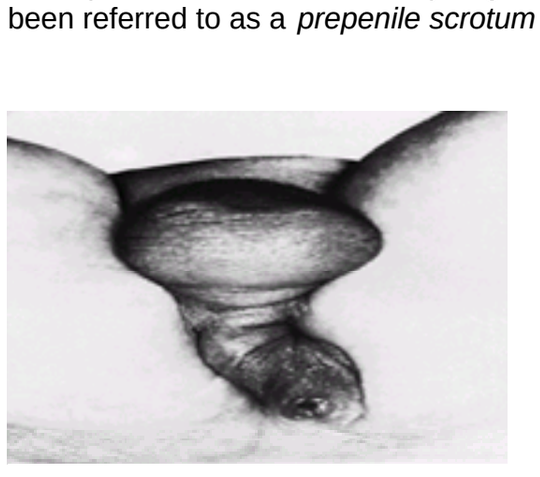

FIGURE 52A.10. Penoscrotal transposition. (Courtesy of A. Barry Belman, M.D.)

Scrotal transposition has been reported with both a normal penis and with bifid scrotum and various penile deformities. Surgical correction of the scrotal transposition

is advocated for cosmetic and psychologic reasons, although urinary and erectile function are not always impeded by this anatomic inversion. There is at least one case report of a patient with complete penile-scrotal transposition who has produced four children (4). Surgical correction can be achieved either by completely dividing the scrotum and transposing the penis upward, or by tunneling the penis to a midline position.

Bifid Scrotum

Bifid scrotum usually is seen in conjunction with severe degrees of hypospadias such as penoscrotal or perineal hypospadias (Fig. 52A.11). It usually is associated with significant skin chordee, where the skin of the lateral surface of the penis is firmly attached to the midline between the two hemiscrotums. Surgical correction of the bifid scrotum involves release of skin anteriorly to be rotated down to the midline, with realignment of the two scrotal halves in the midline. The most severe form of bifid scrotum is scrotal transposition in which the scrotum appears to be transposed above the penis. This is not true penile-scrotal transposition as described earlier.

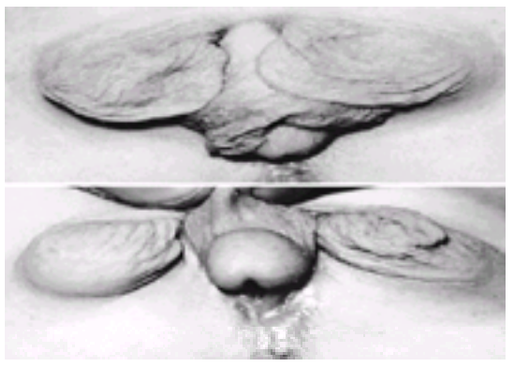

FIGURE 52A.11. Bifid scrotum in a patient with perineal hypospadias.

Scrotal Ectopia

Scrotal ectopia is a rare condition occasionally seen in boys with otherwise normal genitalia (64). The ectopic scrotum usually is found somewhere near the external inguinal ring but can be found anywhere along the inner thigh or buttocks (Fig. 52A.12). The testis on the side of the scrotal ectopia can be normal or dysplastic, and treatment should be based on the amount of ectopic scrotum present and the condition of the testes. If there is a significant amount of scrotum and reasonable testes, an attempt should be made to bring the testes down along with the ectopic scrotal tissue. If there is only a small, rudimentary amount of ectopic scrotal tissue or dysplastic testes, one or both should be removed.

FIGURE 52A.12. Scrotal ectopia.

Scrotal Hypoplasia

Scrotal hypoplasia can be either unilateral or bilateral and usually is associated with the absence of a testis on one or both sides (Fig. 52A.13). If there is monorchia or anorchia, the scrotum is typically flat and nonrugated on the affected side. Usually, the placement of a testicular prosthesis along with the application of local testosterone cream will improve the cosmetic situation to a significant degree.

FIGURE 52A.13. Unilateral scrotal hypoplasia (left hemiscrotum is absent).

Scrotal Hemangioma

Hemangiomas of the scrotum are rare lesions first reported by Robert (90) in 1851. Hemangiomas are common and occur in 10% of all infants younger than 1 year of age. They may involve any area of the body and are not uncommon in the urogenital tract. However, hemangiomas of the external genitalia make up only 1% of all cutaneous hemangiomas and are more common in females than in males. Currently, fewer than 45 cases of scrotal hemangiomas are reported in the literature (86). Hemangiomas of the scrotum generally are seen in the first 20 years of life but may occur at any age; the youngest case reported is a 1-month-old infant. There are no reports of a complete involution of this lesion; rather, a progressive enlargement is commonly noted.

On physical examination, the scrotal hemangioma is a soft, spongy compressible mass that has a “bag of worms” sensation somewhat similar to a variocele of the cord. There is no pulsation or bruit associated with the mass. The overlying skin can have a normal color or a pinkish, bluish, or purplish tinge. Often, the skin is thinned in some areas due to the pressure of the tumor, and thickened in other regions (Fig. 52A.14). The testes, epididymides, and vas deferens are generally normal on palpation. The mass remains distended without visible decrease in size when the patient is supine with the scrotum elevated. The lesion occurs with equal frequency on the right and left sides, unlike a varicocele. Scrotal hemangioma can also occur bilaterally, and cases have been reported in association with bladder

tumors and Klippel-Trenaunay syndrome (68).

FIGURE 52A.14. Scrotal hemangioma.

The scrotal hemangioma usually is painless and nontender, although the mass can be associated with a feeling of heaviness and a dragging sensation. Angiography generally shows a capillary or venous (or both) hemangioma that may be supplied by a number of vessels, including the internal pudendal and the testicular artery among others. Microscopic examination reveals a benign unencapsulated lesion made up of a large number of cavernous vascular spaces supported by the subcutaneous tissue, with reduced cells and intraluminal thrombi present in the vascular spaces.

Complications of scrotal hemangioma include thrombosis, phlebitis, massive hemorrhage, and infertility. Eastridge and colleagues (22) reported that this lesion has no effect on potency or fertility. However, Gotoh and associates (32) reported a case of bilateral testicular damage, with absence of germinal cells in the seminiferous tubules and changes in the Sertoli cells, in a 16-year-old with a largely left-sided lesion. The authors postulated that the azoospermia was related to the high temperature of the hemangioma.

The treatment of choice is wide local excision of the tumor with the overlying skin, if possible. Other modalities that have been used include subcutaneous ligation, electrofulguration, intravenous (IV) prednisolone, solid carbon dioxide, and hemiscrotectomy and orchiectomy. Hemiscrotectomy and orchiectomy appear unnecessary because no testicular involvement or malignant changes within the lesion have been reported. Because of their natural involution, hemangiomas of other areas of the skin normally require no treatment (86).

Splenogonadal Fusion

Splenogonadal fusion is an unusual malformation consisting of an abnormal connection between the spleen and the gonad. The entity was first described in 1883 (8). Since then, 110 cases have been reported to date (37). Most of the cases present as a scrotal mass or scrotal tenderness (Fig. 52A.15). Some are discovered as an incidental finding at the time of herniorrhaphy or orchidopexy, and approximately 25% are found at autopsy. Four cases have been reported in females (40), and the abnormality has been seen from newborn to old age. Approximately half of the cases are reported in children, and only one case of splenogonadal fusion on the right side has been reported (84). The most common preoperative diagnosis is testicular neoplasm, which is reasonable because these splenic nodules are firm and do not transilluminate.

FIGURE 52A.15. Left hemiscrotal mass is consistent with splenogonadal fusion.

Two forms of the malformation have been presented clinically: continuous and discontinuous splenogonadal fusion (100). In continuous splenogonadal fusion, the main spleen remains connected to the left gonad by a strand of tissue. This cord may be completely splenic, fibrous, or beaded with multiple nodules of splenic tissue. With discontinuous splenogonadal fusion, there is no connecting cord between the spleen proper and the left gonad. The ectopic splenic tissue is usually a distinct and encapsulated mass. Approximately 25% of the reported cases of continuous splenogonadal fusion will have other anomalies, including micrognathia, anal atresia, asymmetry of the skull, or abnormal fissures of the lung and liver. None of the reported cases of discontinuous splenogonadal fusion has demonstrated any other malformations.

The evaluation of splenogonadal fusion usually takes place in the operating room. In theory, a technetium-99 colloid liver spleen scan could easily identify splenic tissue in the scrotum (101); however, this usually is not done as a preoperative event. Scrotal ultrasound has not been helpful.

The treatment of splenogonadal fusion usually involves removal of both the testis and the adjoining mass (Fig. 52A.16). If one were able to make a diagnosis of ectopic splenic tissue before surgery, a simple excision of the splenic nodule would suffice in virtually all cases of discontinuous splenogonadal fusion. In cases of continuous splenogonadal fusion, exploratory laparotomy is usually necessary to properly identify any anatomy involved and to deal with the continuous cord that is usually present.

FIGURE 52A.16. Splenic tissue open adjacent to gonad.

GENITAL ANOMALIES: FEMALE

Embryology

The female reproductive system is derived primarily from the müllerian or paramesonephric ducts. In the absence of a fetal testis, there is no elaboration of androgen or MIS; therefore the Wolffian system regresses and the müllerian system is free to differentiate (10). Between the sixth and eighth weeks of gestation, the paired müllerian ducts develop lateral to the Wolffian ducts and then cross medially to fuse in the midline. The fused müllerian ducts then join the urogenital sinus at the müllerian tubercle and, by the tenth week of gestation, form a single tube called the *uterovaginal canal.* The lateral aspect of the müllerian ducts, which remains separate, will ultimately become the fallopian tubes, and the fused portion of the ducts, which thickens, will become the fundus, body, and cervix of the uterus.

The exact embryologic origin of the vagina is somewhat uncertain. Koff (61) suggested that the upper four-fifths of the vagina is formed from the müllerian duct and the lower fifth from the urogenital sinus. The major body of evidence supports the dual nature of the vagina, but the exact contribution from each source is still uncertain. At the twelfth week of gestation, vaginal development begins at the müllerian tubercle, where the uterovaginal canal joins the urogenital sinus. Bilateral endodermal invaginations called *sinovaginal bulbs* form in the area of the müllerian tubercle. As the bulbs grow, the müllerian tubercle regresses and the distance between the uterovaginal lumen and the urogenital sinus increases. The sinovaginal bulb completes its growth by the fifteenth or sixteenth week of gestation and is called the *primitive vaginal plate.* Canalization of this cord of cells beings at the urogenital sinus and progresses cephalad, so by the fifth month of embryonic growth, vaginal development is complete (Fig. 52A.17).

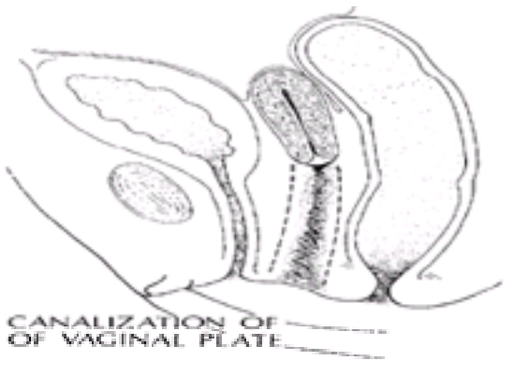

FIGURE 52A.17. Vaginal development.

Differentiation of the external genitalia of the female occurs between 12 and 16 weeks of gestation. In the absence of fetal androgen, particularly DHT, the common genital anlage develops passively into external genitalia of the female. The genital tubercle elongates slightly and becomes the clitoris, the urethral folds do not fuse and form labia minora, and the genital swellings form labia majora. The urogenital groove remains open and forms the vestibule of the vagina (57).

Vaginal Agenesis (Mayer-Rokitansky-Kuster-Hauser Syndrome)

Complete absence or agenesis of the vagina probably results from a disorder of the ureterovaginal canal or the vaginal plate (Fig. 52A.18). Mayer (73) first reported vaginal agenesis in stillborn infants with multiple birth defects. Kuster (63) and Rokitansky (92) described the entity and recognized that there also was usually a rudimentary uterus with normal ovaries and normal external genitalia (Fig. 52A.19). Hauser and colleagues (41) reported the frequent association of renal and skeletal anomalies. Mayer-Rokitansky-Kuster-Hauser syndrome is a failure of müllerian duct fusion with resulting vaginal agenesis. The incidence of this syndrome has been reported to vary from 1 in 4,000 to 1 in 5,000 live female births (12). The ovaries and distal fallopian tubes arise from a distinct embryologic origin and are normal and functional. The patients are typically 46,XX females with normal secondary sex characteristics who most commonly have primary amenorrhea (93). The uterus in these patients may vary from normal to the more characteristic finding of a rudimentary bicornuate structure without a lumen. The association between congenital absence of the vagina and anomalies of the urogenital system is very common, with approximately one-third (34%) of these patients having renal abnormalities (27,35). The most common abnormality is agenesis of one kidney or ectopia of one or both kidneys. Fusion abnormalities such as horseshoe kidney and crossed renal ectopia also are very common.

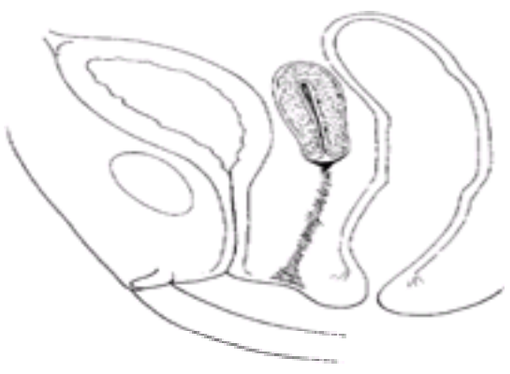

FIGURE 52A.18. Vaginal agenesis resulting from a failure of canalization of the vaginal plate.

FIGURE 52A.19. External genitalia of a 13-year-old girl with vaginal agenesis.

Skeletal anomalies have been reported in 12% of these patients, which would make such anomalies approximately half as common as the renal anomalies seen (35). Two-thirds of the patients with skeletal anomalies have spine, limb, or rib anomalies. Six percent of the skeletal malformations were of the Klippel-Feil type, which reflects an aberration in cervical thoracic somite development (38). Duncan and associates (21) have recognized the frequency of these associated events and suggested that this combination of malformations be termed the *MURCS association,* an acronym for *mü* llerian duct aplasia, *r*enal aplasia, and *c*ervicothoracic *s*omite

association.

The diagnosis of vaginal agenesis is made most commonly at the time of puberty in association with amenorrhea. However, the diagnosis can also be made occasionally in the neonatal period, usually as the cause of a lower abdominal mass. In older patients, pelvic ultrasonography, computed tomography (CT) scanning, and laparoscopy are means of making an accurate diagnosis. Recently, magnetic resonance imaging (MRI) has emerged as a valuable modality in the evaluation and classification of developmental anomalies of the female genitourinary system (79,81). MRI should be analyzed in conjunction with other imaging modalities. Previous surgery makes MRI interpretation more difficult and therefore should be carried out before any surgical intervention, if possible. An accurate MRI examination may be extremely helpful before surgery, and it is essential for the radiologist to have knowledge of how such complex anomalies are managed and what pitfalls to avoid (65).

Treatment of vaginal agenesis is predicated on the anatomy present. If pain is present, radiographic imaging is necessary to define anatomy before surgery, which may be indicated to manage an obstructed uterine horn or subsequent endometriosis before the creation of a vagina. If there is a uterus and the vaginal remnant is too short to reach the perineum, construction of a vagina that will communicate with the uterus should be undertaken before the onset of menses (18). This usually is accomplished using a free split-thickness skin graft as advocated by McIndoe (74), or an isolated intestinal segment (71). If only the distal portion of the vagina is absent, posterior and lateral skin flaps can be mobilized and rotated into the proximal portion of the vagina to provide an introitus; however, in most instances, this is difficult to accomplish and the long-term results vary. If no uterus is present, construction of a vagina should be undertaken just before the initiation of sexual activity. A split-thickness skin graft or an isolated intestinal segment is most often used for vaginal construction. Gosalbez and coauthors (31) reported the use of ureter for vaginal reconstruction. Hensle and Chang (47) recently reviewed the pertinent diagnostic and pretreatment considerations as well as the surgical options, in particular, bowel vaginoplasty, for these patients. An international collaborative study evaluated patients with congenital vaginal agenesis and reported an overall success rate of 68.2% for any primary surgical reconstruction (30).

Vaginal agenesis has been reported in association with a uterus and functional endometrium. These patients often have an obstructive lesion of the reproductive tract with a hematometrocolpos of the existing vagina. Treatment may involve the creation of a functional vagina that can drain the uterine cavity. Letterie (67) reported a case of a two-step approach to management of a patient with both cervical and vaginal agenesis. At the time of this publication, this patient was 2 years postoperative without complications and had regular monthly menses without dysmenorrhea or pelvic pain. However, cases of morbidity and mortality with attempted anastomotic procedures have been reported in the literature (16).

Congenital Vaginal Obstruction (Hydrocolpos and Hydrometrocolpos)

Congenital vaginal occlusions are probably the result of an incomplete canalization of the vagina that occurs during the fifth month of gestation. An imperforate hymen can result in gross distention of the vagina, which is termed *hydrocolpos,* or in distention of both the vagina and uterus, which is called *hydrometrocolpos.* Congenital vaginal obstruction most commonly is caused by a simple imperforate hymen (99) (Fig. 52A.20A), and less commonly by more proximal lesions such as a high transverse vaginal septum (9) (Fig. 52A.20B). A high transverse vaginal septum can also be associated with partial anterior vaginal agenesis, as well as with persistence of a common urogenital sinus.

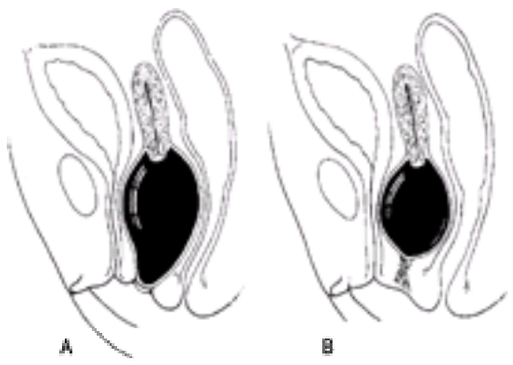

FIGURE 52A.20. Congenital vaginal obstruction. **A:** Imperforate hymen. **B:** High transverse septum.

The newborn with vaginal obstruction will have a lower abdominal mass and often urinary tract obstruction. The abdominal mass is the distended vagina, which results from excessive secretion of the cervical glands in response to maternal estrogen. Abdominal ultrasonography reveals a large midline sonolucent mass displacing the bladder forward and the rectum posteriorly. Percutaneous needle aspiration and injection of contrast material may aid in the diagnosis and can be performed either through the perineum or the anterior abdominal wall (Fig. 52A.21). If no abdominal mass is present at birth, the condition often is not detected until early adolescence, at which time symptoms may include amenorrhea, cyclic abdominal pain, and an abdominal mass secondary to hematocolpos (Fig. 52A.22).

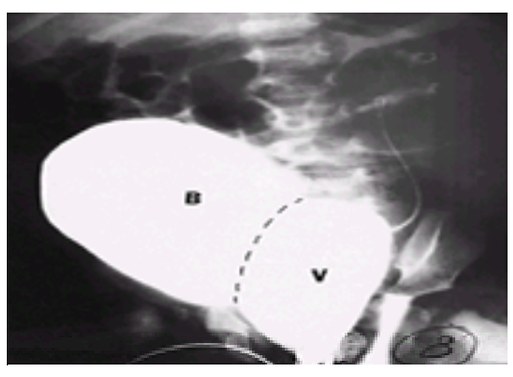

FIGURE 52A.21. Percutaneous injection of obstructed vagina *(V)* in newborn, with simultaneous cystogram *(B)* and retrograde catheterization of solitary left ureter and kidney.

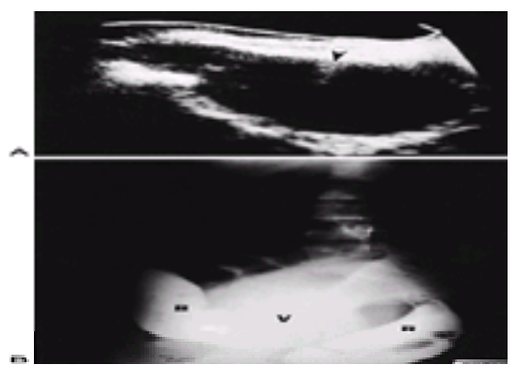

FIGURE 52A.22. A: 13-year-old girl with sonolucent midline mass. Note cervical impression *(arrowhead)*. **B:** Lateral view of same patient with midline mass pushing bladder *(B)* forward and rectum *(R)* posteriorly. V, vagina.

The treatment of vaginal obstruction depends on the anatomy. An imperforate hymen in the newborn that bulges at the introitus can be incised easily without anesthesia. It is important to identify the anatomy at the time of the drainage procedure to be certain that there is neither a common urogenital sinus nor other urinary anomaly associated with the lower vaginal obstruction. Obstruction resulting from a high transverse vaginal septum or a partial agenesis of the anterior portion of the vagina can be more difficult to correct. These children must be investigated thoroughly before treatment. The high transverse vaginal septum with or without a common urogenital sinus probably is best treated by draining the vagina anteriorly with a simultaneous perineal vaginal pull-through. However, if the rectum and anus are displaced anteriorly, it may be difficult to perform a definite vaginoplasty in the infant. In this situation, it may be more appropriate simply to drain the obstructed vagina through the common urogenital sinus and delay the vaginal reconstruction until a later date, when it can be done in conjunction with a posterior anoplasty.

Fusion and Duplication Anomalies

Disorders of embryogenesis that produce duplication anomalies of the vagina and uterus occur at approximately 9 weeks of gestation and involve progression of the uterovaginal septum (1). These anomalies, which are very common, can include two uteri and two cervices fused with a single vagina or two separate vaginas, and two uteri fused with a single cervix and a single vagina (20) (Fig. 52A.23).

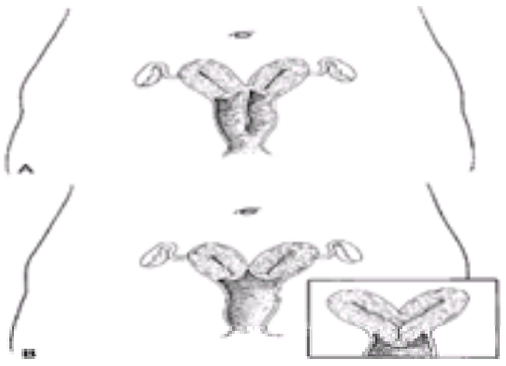

FIGURE 52A.23. A, B: Fusion anomalies of uterus and vagina.

If there is complete vaginal duplication, one vagina can be obstructed and the other patent so that the external genitalia will appear normal (9,99) (Fig. 52A.24). The diagnosis of uterus didelphys and a unilateral obstructed vagina should be entertained as part of the differential diagnosis in a newborn with a sonolucent abdominal mass. Classically, the mass will push the bladder forward and the normal vagina posteriorly (Fig. 52A.25). Vaginoscopy may reveal a bulging mass high in the vaginal sidewall. If technically possible, simple incision of the obstructing septum will provide adequate drainage; however, further division of the septum usually is necessary (14). At times, a formal laparotomy is required to provide adequate drainage and to confirm the diagnosis. Careful attention to the anatomy is essential to avoid an unnecessary ablative procedure. Simple division of the vaginal septum is all that is warranted in most of these patients, because successful term pregnancies have been reported in both uterine horns, suggesting that fertility is not impaired.

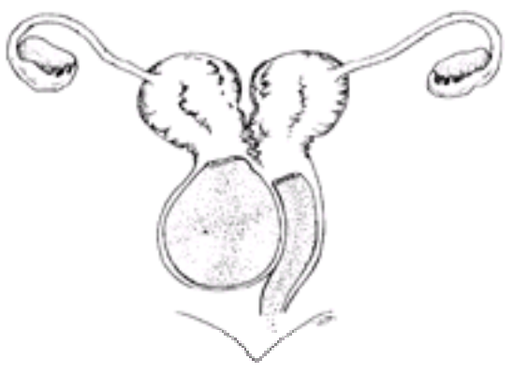

FIGURE 52A.24. Unilateral obstruction of duplex vagina in patient with uterus didelphys.

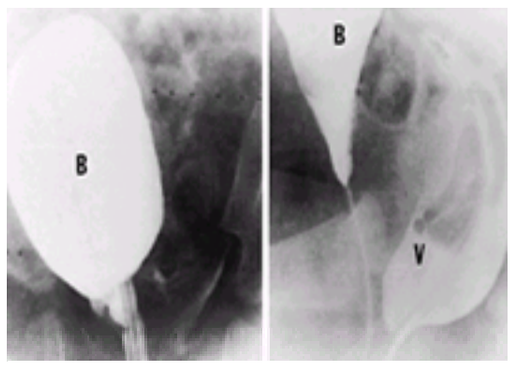

FIGURE 52A.25. Simultaneous cystogram and vaginogram in a patient with uterus didelphys and unilateral obstruction of a duplex vagina, showing separation of the bladder *(B)* and normal vagina *(V).*

This condition should also be considered in pubertal girls who, despite having menses, present with cyclic pelvic discomfort and a mass. By ultrasound, the mass will either be sonolucent or have some scattered internal echoes. A vaginogram will once again show the bladder and normal vagina pushed apart by the mass (Fig. 52A.26). Pelvic MRI will typically show a normal uterine horn above a dilated blood-filled vagina. The blood gives off a very bright signal on the T_1-weighted image (Fig. 52A.27). Treatment of pubertal girls is identical to that for younger patients and can most frequently be done vaginally.

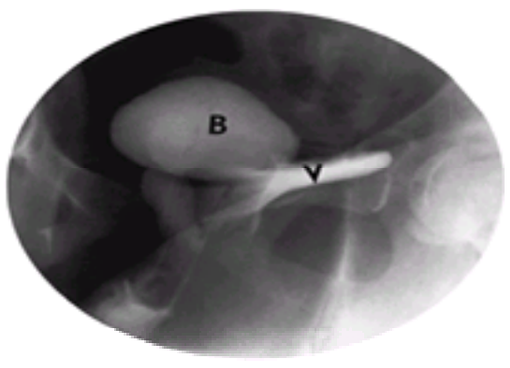

FIGURE 52A.26. Separation of the bladder *(B)* and normal vagina *(V)* by a distended obstructed hemivagina.

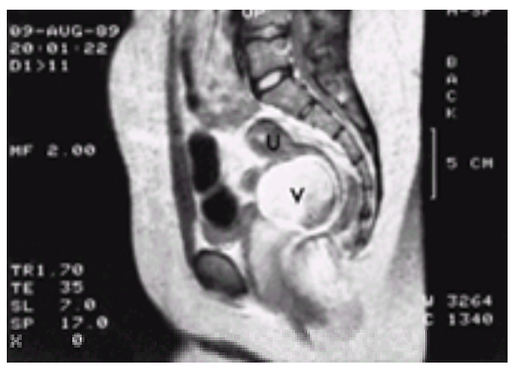

FIGURE 52A.27. Pelvic magnetic resonance image. U, uterus; V, vagina.

Urogenital Sinus Anomalies

Urogenital sinus is a common channel into which both the urinary and genital tracts open. There is a wide spectrum of urogenital anomalies caused by a lack of development of the urogenital sinus and its derivatives. The common urogenital sinus is a normal stage of embryonic development in both sexes. In the normal female, an arrest in development of the müllerian ducts at 9 weeks of gestation, after they have fused with the urogenital sinus, could be manifested as a urovaginal confluence or common urogenital sinus (Fig. 52A.28) (103). An arrest of vaginal differentiation at a slightly later date can lead to the varying degrees of the urogenital sinus anomaly seen clinically (Fig. 52A.29). A long urogenital sinus with a short vagina and a high urethral opening will result if the defect occurs at an early stage. A short urogenital sinus with an almost normal vaginal vestibule and low urethral orifice will occur if the arrest is late in development (72). Early defects with a high insertion of the vagina and urethra into the urogenital sinus are also commonly associated with an anteriorly placed anus. This indicates that there is also poor formation of the urorectal septum in these patients.

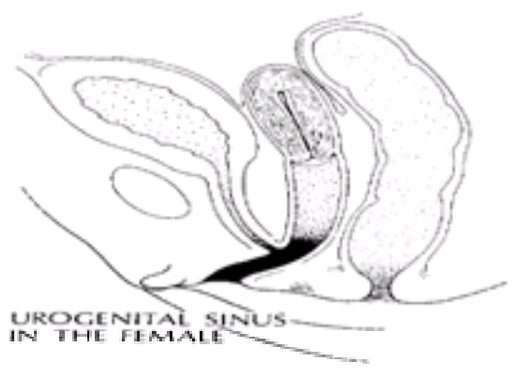

FIGURE 52A.28. Urogenital sinus anomaly.

FIGURE 52A.29. Variations of the urogenital sinus anomaly.

The diagnostic approach to the urogenital sinus is based on adequately defining the anatomy present. Retrograde contrast material injection into the urogenital sinus will help delineate the length of the common channel and identify the anatomic relationship of the vagina and urethra (45) (Fig. 52A.30). Endoscopy of the urogenital sinus can provide important information about the length of the urethra, particularly in cases of high confluence of the vagina and the urethra. In such patients, catheterization of the urethra can be difficult, if not impossible.

FIGURE 52A.30. Sinogram of urogenital sinus showing high confluence of bladder *(B)* and vagina *(V)* into a long urogenital sinus.

Once the anatomy of the defect has been clearly identified, the various treatment options can be considered. If the urogenital sinus is low, with a short common channel, a simple U-flap vaginoplasty will be effective (42). Unfortunately, the urogenital sinus often is associated with an anteriorly placed anus, which may require posterior relocation to accomplish a skin-flap vaginoplasty from the perineum (46). If the vagina enters the urogenital sinus too far proximally, a division of the vaginal

moiety from the urogenital sinus will be necessary in conjunction with a pull-through vaginoplasty. In the most difficult form, there is a confluence of both the bladder and vagina high in the urogenital sinus. This defect requires not only a pull-through vaginoplasty but also often the creation of a neourethra from the anterior vaginal wall (44).

Cloacal Anomalies

The combination of a urogenital sinus and an anorectal anomaly usually is referred to as a *cloacal malformation* (33). In the early embryo, there is a cloacal stage during which there is confluence of the allantois (the early urinary and genital tract) and hindgut (97). At 4 to 6 weeks of gestation, the urorectal septum should descend and divide the allantois from the hindgut; however, if this separation does not take place, a common cloaca will result. A persistent cloaca is the conjunction of the urethra, vagina, and rectum into a single common channel. Expertise in management of this constellation of structural abnormalities is critical to avoid catastrophic consequences.

These infants generally are born with abdominal distention and an abnormal perineum. There is usually no anus and a single perineal opening is usually found, although in some severe cases no perineal opening may be obvious. Frequently there is a hooded appearance to the phalluslike structure, which gives an initial masculinized gender appearance (Fig. 52A.31). Patients with cloacal disorders may initially be thought to represent intersex disorders. The bladder may enter the common urogenital sinus either just inside the perineal opening or very high. The insertion of the bladder may be associated with a relatively normal length of urethra or may occur very close to the bladder neck. The entrance of the rectum into the cloaca can similarly be either high or low, near the perineum (54) (Fig. 52A.32). Vaginal abnormalities are common in patients with a cloacal anomaly, and vaginal duplication is the most common of the abnormalities seen. There also may be significant obstruction at the perineum in these patients, causing both hydrocolpos and obstructive uropathy (Fig. 52A.33).

FIGURE 52A.31. Perineum of a patient with a cloacal anomaly.

FIGURE 52A.32. Various forms of the cloacal anomaly.

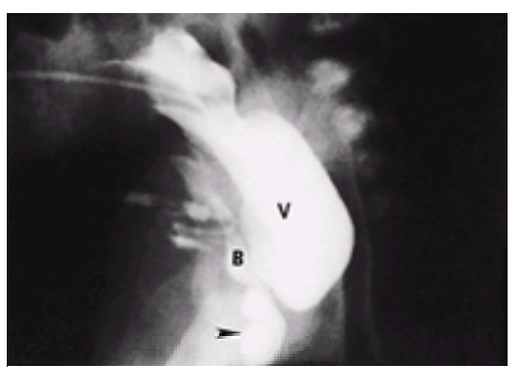

FIGURE 52A.33. Antegrade study of the bladder *(B)* and vagina *(V)* in a patient with a cloacal anomaly, demonstrating a dilated urogenital sinus *(arrowhead)* and relative obstruction at the perineal outlet.

The diagnosis of a cloacal anomaly is confirmed by retrograde contrast studies through the single perineal opening. There is often a confluence of the genitourinary and the GI systems. However, often, all of the components of the anomaly will not fill on a retrograde study; thus it is not until an open procedure is performed that the exact anatomy can be defined.

Treatment of the various forms of cloacal anomalies is complex and presents one of the more difficult problems for pediatric surgeons and pediatric urologists. The first principle of treatment is to completely identify the anatomy involved (58). Reconstruction must be individualized based on the defined anatomy. Clearly, the GI tract must be dealt with initially, and if the opening of the rectum into the urogenital sinus is low, a simple cutback anoplasty in the perineum may be possible (43). More frequently, however, a supralevator opening is present, and a primary colostomy is necessary, followed by a later pull-through procedure. If there is no significant urinary obstruction, specific treatment may not be necessary in the immediate perinatal period. If urinary obstruction exists, a simple cutback of the urogenital sinus may afford adequate egress of urine to relieve obstruction. However, in the young patient with a cloaca and high imperforate anus, there often will be a high confluence (urethra, vaginas, and rectal fistula). In such cases, the patient usually will void into the cloaca and drain poorly, hence these children will have dilated müllerian structures and hydronephrosis. Clean intermittent catheterization of the cloaca usually will provide temporary resolution of the vaginal distention and bladder outflow obstruction, and the patient can be stabilized for months until definitive repair is planned. The obstruction of the distal cloaca is curious and often behaves like a voiding dyssynergia. Stricture or narrowness of the distal cloaca is rarely the actual cause of the obstruction. Simple calibration and dilation will not resolve urinary retention in a cloaca patient.

Complete reconstruction of a cloacal anomaly is technically easier in later infancy and should be delayed until after 1 year of age, if possible (85). If feasible, reconstruction should be performed in one stage. Hendren (46) has stressed the importance of repairing the imperforate anus at the time of vaginal reconstruction. When a cutback anoplasty or pull-through is performed, it is important to be certain that the anus is placed far enough posteriorly to allow enough perineum for an adequate vaginal introitus and urethra. Once detachment of the rectum has been accomplished, the operative approach to the anterior portion of the cloacal anomaly is similar to that of a straightforward urogenital sinus (42). Pena (82) has achieved favorable results using a posterior sagittal anorectovaginoplasty. A percentage of

patients will require laparotomy if the vagina or rectum does not easily reach the perineum without tension.

Masses of the Introitus

A mass at the introitus between the labia is often a diagnostic dilemma. The differential diagnosis includes prolapse of the urethra, prolapsed ectopic ureterocele, or prolapsed rhabdomyosarcoma. It is important to recognize each of these entities and to understand the diagnostic criteria for each.

Prolapse of the urethra (Fig. 52A.34) occurs almost exclusively in African American girls between the ages of 3 and 9 years. The child often has blood spotting on the underwear and a necrotic mass at the introitus, which represents a prolapsed and infarcted portion of the anterior urethra (80). The etiology of this lesion is unclear, although the histology closely resembles the capillary hemangioma pattern of a urethral caruncle in an adult. An accurate diagnosis depends on recognition of the entity. No diagnostic studies are needed, and the treatment usually involves simple excision of the prolapsed segment with suturing of the normal urethra to the meatus (87). Complications are virtually nonexistent except mild degrees of meatal stenosis following excision of the prolapsed segment and primary repair.

FIGURE 52A.34. Prolapsed urethra in a 9-year-old African American girl.

A prolapsed ectopic ureterocele can present as an intralabial introital mass (70) (Fig. 52A.35). This is usually a smooth white or slightly edematous lesion that extrudes from the urethral meatus. The urethral meatus usually can be seen above the lesion. The diagnosis often can be made on IV urography, which will demonstrate a lower pole collecting system, which is pushed laterally and inferiorly (drooping lily sign) with displacement of the ureter away from the midline on the affected side, and a filling defect in the bladder (Fig. 52A.36) (78). Direct injection of the prolapsed segment is possible and may demonstrate the anatomy involved; however, this often is difficult to do, especially in newborns.

FIGURE 52A.35. Prolapsed ureterocele in a 3-year-old girl.

FIGURE 52A.36. Intravenous urogram in a patient with an ectopic ureterocele, demonstrating a right lower pole collecting system being pushed laterally and inferiorly (drooping lily sign) along with a filling defect in the bladder *(arrowhead).*

Sarcoma botryoides, or rhabdomyosarcoma of the bladder or vagina, is the most common malignancy of the lower genitourinary system seen in infancy (48). It commonly presents with blood spotting on the underwear, and the lesion appears as a lobulated, grapelike mass. The diagnosis can be made by direct biopsy, but the extent of the lesion is best determined by pelvic ultrasonography and CT scan (76) (Fig. 52A.37).

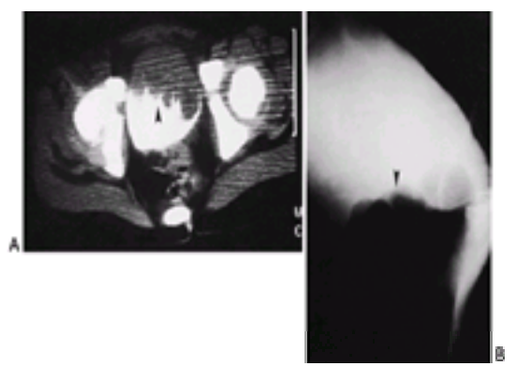

FIGURE 52A.37. Computed tomogrpahy scan **(A)** and cystourethrogram **(B)** in a patient with a bladder rhabdomyosarcoma, demonstrating a filling defect in the anterior portion of the bladder *(arrowheads).*

Other lesions that can appear as intralabial masses include a low simple imperforate hymen, which can present as a bulging intralabial mass in newborn girls (88) (Fig. 52A.38). This is often simply an imperforate hymen with some degree of hydrocolpos resulting from maternal estrogen stimulation. These lesions are easily recognized and need incision and drainage; rarely do they require further therapy.

FIGURE 52A.38. Bulging hymen in a newborn girl.

Paraurethral cysts (7) also present as interlabial masses in female infants. They tend to displace the urethral meatus to one side, and a normal urethra and vaginal introitus usually can be identified (Fig. 52A.39). These cysts seem to be embryologic remnants of Skene's glands or Gartner's duct. Most of these cysts will rupture spontaneously, but they may have to be incised and drained.

FIGURE 52A.39. Paraurethral cyst in a 1-year-old girl.

Cystic lesions of the meatus also can occur in males (Fig. 52A.40). Parameatal urethral cysts were first reported in the English literature in 1956 (98), and scattered reports have appeared since. Most recently, 41 cases were reviewed from Japan (62), and in that review, although the patients ranged in age from 9 months to 43 years, almost 50% presented at younger than 15 years of age. The mass was totally asymptomatic in 75% of the cases, and dysuria was the presentation in the other 25%.

FIGURE 52A.40. Parameatal cyst in a 3-year-old boy.

Although the etiology of these cysts is unclear, we believe that they are most likely related to some obstruction of one of the paired parameatal glands (29). Histologic features include a cyst wall lining that can vary from columnar to transitional to cuboidal epithelial. The most common lining is columnar. Treatment of these parameatal urethral cysts usually consists of simple unroofing. In a minute number of patients, the cyst may recur, and in this situation, total excision of the lining is required.

Conclusion

There is a vast spectrum of symptoms and presentations of female genital anomalies. A careful history and physical examination enhanced with reliable imaging modalities are of utmost importance. A detailed assessment of genetic, gonadal, and phenotypic status is essential. The experienced multispecialty team with an accurate diagnosis and appropriate treatment plan offers the best chance of achieving optimal psychosocial, sexual, and reproductive function.

Hypospadias is a common congenital anomaly of the penis in which the urethra opens proximal to its normal position at the tip of the glans. The term has been credited to Galenus and is derived from the Greek words *hypo*, meaning “under,” and *spadon,* indicating a “rent” (20). Extending distally from the hypospadiac meatus is a strip of epithelium overlying connective tissues, the remnant of the unformed urethra, which in the past decade has been commonly referred to as the “urethral plate.” In addition, the penis with hypospadias typically has an incompletely formed prepuce and may exhibit ventral curvature. Therefore correction of the anomaly includes penile straightening, urethroplasty, glansplasty, and circumcision, with the ultimate goal a functionally and cosmetically normal penis.

Using modern surgical techniques, this ideal can often be realized, usually in a single outpatient procedure. It has not always been so. Carl Beck (20) reviewed the state of the art in 1917 when operations were done in two or more stages and concluded, “It is not absolutely necessary to obtain a cosmetic result with smooth surfaces and a urethra in the center of the glans.” Although he wrote just 30 years after the modern era of hypospadias surgery began, Beck (20) already found that “the surgeon has to choose from a chaos of methods to find the proper one for his case, and without experience he often chooses the wrong method with subsequent failure.” Since Beck's time, operative techniques have continued to proliferate as the field of hypospadias surgery has grown to include not only proximal anomalies that were the original focus of intervention, but also the less severe distal lesions, which are more common. Furthermore, as late as 1981, Mills and colleagues (90) still questioned the need for a meatus at the tip of the glans, having observed that “if the anatomically normal phallus is the goal of the surgeon and family, then they must be aware of the attendant risks of the techniques that accomplish this goal.”

Previous editions of this textbook were published in 1987, 1991, and 1996, and in each the chapter on hypospadias was written by the late John Duckett. In describing this discipline he coined the term *hypospadiology,* and it is no exaggeration to say that Duckett was one of history's greatest hypospadiologists. His MAGPI procedure revolutionized the repair of distal hypospadias and, together with the onlay and tubularized preputial flaps he popularized, made it possible to correct almost any hypospadias anomaly by one of Duckett's methods. Furthermore, he challenged the longstanding view that penile curvature indicates a fibrotic urethral plate, thereby paving the way for greater reliance on surgical techniques that use these tissues.

Yet the field continues to evolve, and procedures that once were standard have fewer proponents today. Instead, new understanding of both penile curvature and the nature of the urethral plate creates new options for repair that bring hypospadias surgery nearer its goal. Consequently, this chapter emphasizes these techniques and presents an updated algorithm for hypospadias repair.

EMBRYOLOGY

The external genitalia of the developing fetus are initially indifferent, capable of developing either the male or female phenotype (Fig. 52B.1). This anlage first appears as the genital tubercle during the sixth week of gestation. Subsequently, endodermal cells from the cloaca extend along the ventral midline surface of the tubercle to form the embryologic urethral plate. Then proliferation of mesoderm on either side of the plate creates urethral folds while the superficial layer of cells within the plate dies, the end result being the urethral groove.

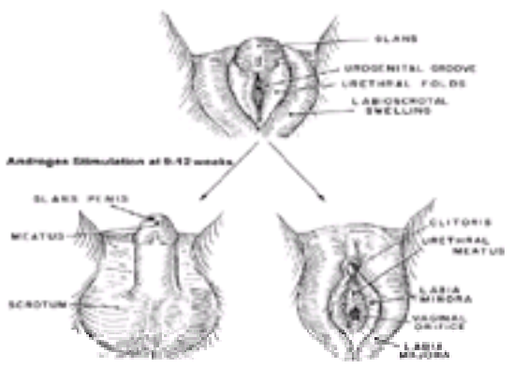

FIGURE 52B.1. Embryology of the external genitalia. The indifferent anlage are programmed to develop the female phenotype unless androgen stimulation occurs between the ninth and twelfth weeks of gestation.

The primordia of the external genitalia inherently feminize unless appropriate androgenic stimulation occurs between the ninth and twelfth weeks of gestation, when fetal Leydig cells within the testes begin producing testosterone. The microsomal enzyme 5a-reductase type 2 in genital tissues converts testosterone to dihydrotestosterone, which interacts with the androgen receptor and results in synthesis of proteins with androgenic effects.

This hormone stimulation causes the tubercle to elongate, prompts fusion of the urethral folds, and tubularizes the urethral groove beginning proximally and continuing to the level of the glans (Fig. 52B.2). The mechanism of glanular formation has been disputed. Prior investigations concluded that its development involved both fusion of glans folds proximally and ectodermal ingrowth distally (9,61,110,133). However, immunohistologic studies by one of us (LSB) suggest instead that the entire male urethra, including the glanular portion, forms by tubularization of the endodermally derived urethral plate from fusion of urethral and glanular folds. The stratified squamous epithelium of the distal glanular urethra arises from cell differentiation rather than ectodermal ingrowth (84).

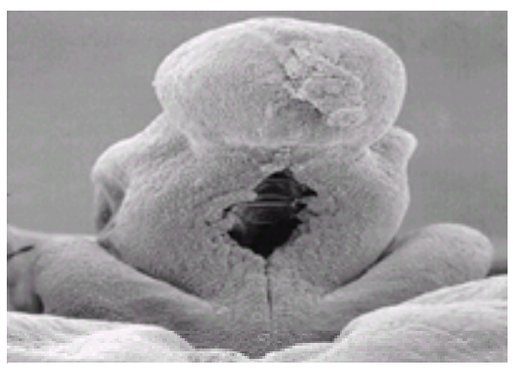

FIGURE 52B.2. Fusion of the urethral folds. A key step in penile development is fusion of the urethral folds, which tubularizes the urethral groove. In females, the urethral folds become labia minora.

Mesenchyme within the urethral folds then differentiates into corpus spongiosum and ultimately fuses with the glans as urethral formation is completed. The corpora cavernosa and preputial skin have different rates of growth on their dorsal and ventral aspects during penile development. Consequently, the fetal penis typically exhibits ventral angulation (61,79) (Fig. 52B.3). Furthermore, the ectodermal tissues of the prepuce on the dorsal surface proliferate at a faster rate than does the mesoderm forming the corpora cavernosa. As a result, folds of skin extend over the glans dorsally, traveling obliquely on either side back to the urethral opening ventrally. As tubularization of the urethra proceeds distally, these ventral preputial extensions fuse in the midline, terminating in the frenulum (73).

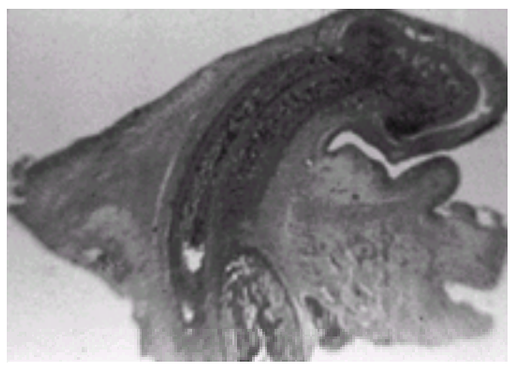

FIGURE 52B.3. Curvature of a normal penis at 22 weeks of gestation. (From Kaplan GW, Lamm DL. Embryogenesis of chordee. *J Urol* 1975;114:769, with permission.)

Sensation of the penile shaft, glans, and anterior urethra is primarily derived from the dorsal penile nerve, with the frenulum also receiving innervation from the perineal nerve (134). Branches of the dorsal nerve extend longitudinally along the surface of the tunica albuginea enclosing the corpora cavernosa, from the 1 to 5 o'clock and 11 to 7 o'clock positions, before terminating in the glans. According to the anatomic studies of Baskin and colleagues (17), no nerve fibers are found at the 12 o'clock location in either normal or hypospadias penises (Fig. 52B.4).

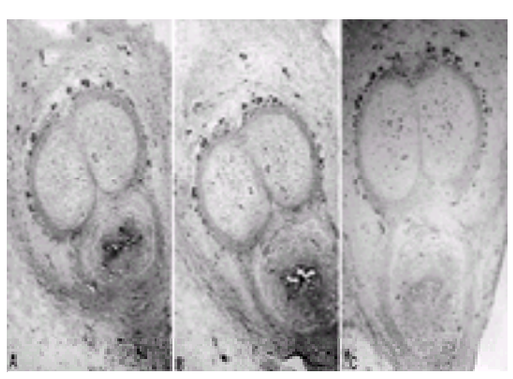

FIGURE 52B.4. Normal human fetal penis, 25 weeks. **A–C:** Transverse sections distal to proximal immunostained with neuromarker 5-100 (25×). Note localization of 5-100 nerve marker in brown completely surrounding the cavernous bodies up to the junction with the urethral spongiosum along the penile shaft except at the 12 o'clock position.

Hypospadias results from an arrest of urethral formation. Based on the sequence of steps in normal penile development, typical findings of the anomaly can therefore be predicted. The urethral opening is found anywhere along the ventral midline from the perineum to the glans depending on the time at which fusion of the urethral folds ceased. The strip of epithelium clinically referred to as the urethral plate extends from the opening distally to the tip of the glans where the meatus would normally be located. This plate exhibits a spectrum from a flat surface to a deep cleft, presumably reflecting the extent of development of the urethral groove.

In the hypospadias penis, the ventral glans does not fuse in the midline, but instead consists of two “wings,” one on each side of the urethral plate. Similarly, corpus spongiosum usually does not cover the ventral aspect of the most distally formed urethra, but rather diverges laterally to join the glans wings. Accordingly, shaft skin often adheres directly to the distal urethra. Furthermore, in most cases there is only a dorsal hood of prepuce, development having stopped before its ventral aspect and frenulum could form. Finally, the penis may demonstrate persistent ventral angulation, which has been commonly referred to as “chordee.”

CLASSIFICATION

The severity of hypospadias is generally determined by the position of the urethral meatus and the extent of ventral penile angulation. However, the location of the

urethral opening may be misleading. For example, a subcoronal meatus can be the terminus of a penile urethra lacking corpus spongiosum envelopment, which therefore consists only of a thin epithelial tube extending from the midshaft or penoscrotal junction (Fig. 52B.5). Similarly, correction of penile angulation may relocate the meatus to a more proximal location. Consequently, preoperative assessment not uncommonly underestimates the true severity of the lesion.

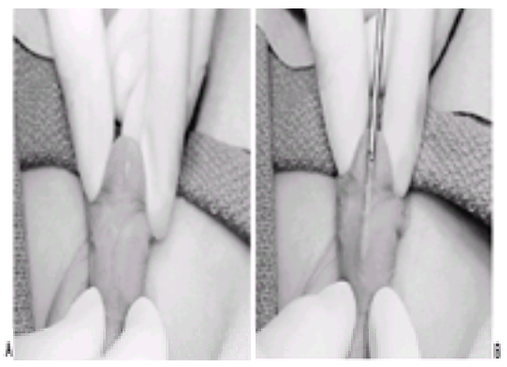

FIGURE 52B.5. A: Proximal glanular hypospadias. **B:** Sound demonstrates the distal aspect of the urethra to be a thin tube, lacking normal investment by the corpus spongiosum.

Historically, hypospadias has been classified in three degrees. *First-degree hypospadias* refers to a glanular meatus. Openings on the penile shaft are termed *second-degree hypospadias,* and penoscrotal to perineal anomalies are *third-degree hypospadias.* The urologic literature identifies glanular, subcoronal, distal shaft, midshaft, penoscrotal, scrotal, and perineal hypospadias, although, again, the shortcomings of any preoperative classification must be recognized.

Most boys with hypospadias have a subcoronal or proximal glanular meatus. This finding is predicted by the fact the last step of urethral formation occurs in this region. Overall, approximately 80% of hypospadiac meatuses are located on the proximal glans or distal shaft, 15% are midshaft to penoscrotal, and the remainder are scrotal to perineal.

One subgroup of distal hypospadias that warrants special mention is the megameatus intact prepuce (MIP) variant (44). Boys with this lesion have an enlarged, “blunderbuss” urethral opening concealed by a completely formed prepuce (Fig. 52B.6). Consequently, the anomaly is often not detected before circumcision and is sometimes misconstrued as a surgical injury. According to Duckett and Baskin (46), 6% of distal hypospadias consists of this variant, which they state is not associated with chordee. However, we have found typical ventral penile angulation in some cases.

FIGURE 52B.6. Megameatus intact prepuce hypospadias variant. Newborn circumcision was performed before the anomaly was recognized.

INCIDENCE

Hypospadias is a common congenital anomaly. In fact, a study of the 18 leading major birth defects in the United States (which notably did not include cryptorchidism) reported that hypospadias was the most common anomaly among whites, second most common among African Americans, and fourth most common among Hispanics (28). In the late 1960s, birth registries in the United States reported its occurrence in 16 per 10,000 live births, from which it has been calculated the defect is found in 1 of 300 boys. This figure corresponds to the results of nineteenth-century surveys (20). However, birth defect monitoring programs subsequently recorded a rising incidence of hypospadias during the 1970s and 1980s in seven European countries. Analysis of recent U.S. data also shows an apparent doubling in the rate of hypospadias between 1968 and 1993 (99). Although it is possible that increased reporting of minor glanular lesions accounts for some of this trend, it is noteworthy that the incidence of penile shaft and more proximal defects rose threefold to fivefold during this time interval.

Although the overall incidence of hypospadias is between 0.3% and 0.6%, there is a significantly greater risk of the anomaly once it has occurred within a family. Bauer and colleagues (19) studied family pedigrees in 307 hypospadiac boys and found that 21% had another family member with the condition. Fathers reported having hypospadias in 7% of cases. The likelihood that a second child would be born with hypospadias was 12%, increasing to 21% if the father was affected. The authors cautioned, however, that their population was skewed toward more severe hypospadias and that the degree influenced their findings. For example, no boy with a coronal defect had a brother with hypospadias, whereas of those with penoscrotal defects, 18% had an affected sibling.

Further evidence of genetic risk factors underlying hypospadias comes from the Birth Defects Monitoring Program referenced previously (28). In their study of congenital malformation distributions among racial and ethnic groups, the comparable rates of hypospadias per 10,000 live births were 33 in whites, 25 in African Americans, and 15 in Hispanics.

ETIOLOGY

Although it is a common birth defect, the cause of hypospadias remains obscure. Observations regarding racial and familial incidences suggest genetic factors inherited in a multifactorial fashion. However, most boys diagnosed with the anomaly do not have a known family history of hypospadias. Furthermore, whether a given case appears to be sporadic or inherited, the presumption has long been that hypospadias results from an endocrinopathy with incomplete masculinization. As mentioned previously, the external genitalia are initially indifferent, and in the absence of androgenic stimuli develop the female phenotype. Therefore disorders of testosterone synthesis, 5a-reduction to dihydrotestosterone, or the structure or function of the androgen receptor, as well as errors in postreceptor activity or the timing of androgen stimulation, all theoretically could result in hypospadias. In that regard, hypospadias may occupy one end of a spectrum, which, at the opposite extreme, includes intersexuality.

Disordered testosterone production is implicated as a cause of hypospadias by the findings of several investigations. For example, elevated basal levels of luteinizing hormone (LH) (94) and blunted testosterone response to luteinizing hormone–releasing hormone (LH-RH) or human chorionic gonadotropin (hCG) stimulation (6,94,114) have been reported, especially in boys with proximal lesions. Similarly Gearhart and colleagues (56) found elevated basal LH levels in 16 adult men with hypospadias. Taken together, these studies may indicate Leydig cell unresponsiveness to stimulation or defective testosterone synthesis. Further evidence of the latter was recently reported by Aaronson and El-Sherbiny (1). They found that 66% of boys with midshaft to coronal, and 40% with penoscrotal, lesions had significantly elevated levels of testosterone precursors.

Assuming normal hormone production, hypospadias could also result from deficient 5a-reductase type 2 conversion of testosterone to dihydrotestosterone. Neither Allen and Griffin (6) nor Gearhart and colleagues (55) found impaired 5a-reductase activity in their evaluations of prepubertal boys with hypospadias, although the

total number of patients studied was small. Recently, DNA sequence analysis in a larger series indicated that 8% of boys had mutations in the genes coding for 5a-reductase type 2 production (115). The authors concluded such mutations could diminish enzyme efficiency, thereby reducing tissue levels of dihydrotestosterone required for normal penile development.

Studies to determine the role of the androgen receptor in hypospadias originally characterized the receptor according to its physicochemical properties, most notably androgen binding. Based on tissue cultures of genital skin, these investigations reported conflicting results, some indicating decreased receptor levels while others yielded normal findings (132). In recent years, molecular biology techniques have improved detection and characterization of the receptor. Point mutations have subsequently been described in association with perineal hypospadias (7,18,67,129). Sutherland and colleagues (129) evaluated 40 boys with penile hypospadias, finding a mutation of the androgen receptor in only one, who had a distal shaft lesion. One difficulty in determining etiologies for hypospadias is that most studies have applied specific tests to groups of patients rather than using an array of tests to establish diagnoses in individual patients (4). Nevertheless, the findings of multiple defects in the processes of masculinization support the conclusion of Allen and Griffin (6) that hypospadias most likely is the nonspecific result of a variety of endocrinopathies.

Increasingly, researchers are examining the role of cellular signals other than testosterone and dihydrotestosterone in normal phallic development and hypospadias. For example, embryogenesis of the urogenital system depends on epithelial-mesenchymal interactions, and it has been hypothesized that aberrant signaling between epithelium and mesenchyme could result in hypospadias (84). In addition, defects in homeobox (Hox) genes might also adversely influence penile development. Hox genes regulate transcription and play an essential role in directing embryogenesis, with Hox A and D clusters expressed in regionalized domains along the axis of the urogenital tract. Transgenetic mice with loss of function in single Hox A or D genes exhibit homeobox transformations and impaired genitourinary morphogenesis (22,39,72,102). Human males with hand-foot-genital syndrome, an autosomal-dominant disorder characterized by a mutation in Hox A13, exhibit hypospadias (40,53,92). Furthermore, embryonic expression of certain Hox genes is regulated by hormonal influences as, for example, estrogen and the synthetic estrogen diethylstilbestrol (DES) inhibit Hox A9, Hox A10, Hox A11, and Hox A13 genes in mice (85).

Another problem is recognized from investigations of possible links between environmental agents and hypospadias. The apparent upward trend of hypospadias reported during the past two decades has raised concerns of increased in utero exposure to progesterones, estrogens, or other antiandrogens. However, despite the increased incidence of the anomaly, epidemiologic studies require evaluation of such large populations of mothers and offspring to reach statistical significance as to be unfeasible (2). Available clinical reports have mixed findings. In one study of 130 boys with hypospadias, 11 mothers gave a history of having ingested progestins, alone or in combination with estrogen, in early pregnancy (2). Offspring of mothers treated with DES have also been noted to have a greater likelihood of hypospadias by some investigators (59,66), but not by others (41). Oral contraceptives, particularly if continued in early pregnancy when the penis is developing, could theoretically cause hypospadias, but case control studies (78) and a meta-analysis of relevant articles (103) have failed to establish any significant association. One recent report found a fivefold increased incidence of hypospadias in boys conceived by *in vitro* fertilization, which might indicate disturbance of the maternal–fetal endocrine milieu by the progesterone therapy that accompanies assisted reproductive technology (86,116). Pesticides, fungicides, and industrial pollutants, which inhibit function of the androgen receptor, have been identified as possible contributors to disordered male sexual development (80).

ASSOCIATED ANOMALIES

Cryptorchidism

Because both hypospadias and cryptorchidism may result from androgen deficiencies, it is not surprising the two conditions may coexist. Studies indicate that approximately 8% of boys with hypospadias also have an undescended testicle. Furthermore, the incidence varies according to the severity of hypospadias, with 5% of distal versus up to 32% of proximal lesions associated with cryptorchidism (27,81).

Prostatic Utricle

This vestigial structure has a mixed origin, arising from the mullerian ducts and urogenital sinus. Enlargement of the utricle has been noted in boys with hypospadias, possibly indicating delayed or inadequate secretion of müllerian inhibiting factor or incomplete masculinization of the urogenital sinus (38). Although an enlarged utricle is sometimes found in distal hypospadias, both the incidence and size increase with increasing severity of hypospadias, occurring in approximately 11% of penoscrotal to perineal cases (38,74,113). Enlarged utricles can result in urinary tract infection, but more commonly cause difficulty with catheterization during hypospadias repair.

Intersexuality

Although hypospadias and intersex disorders may occupy different points along a spectrum, the boy with an isolated urethral opening on the shaft of a normal-size phallus rarely has a dilemma of gender identity. The likelihood of intersexuality increases, however, with a meatus positioned in the scrotum or perineum. Similarly, hypospadias associated with cryptorchidism may indicate an intersex disorder, and if the undescended testis is nonpalpable the risk of intersexuality approaches 50% (77). Possible intersex disorders associated with hypospadias phenotype are listed in Table 52B.1.

Adrenogenital syndrome: A newborn with hypospadias and bilaterally nonpalpable testes must be evaluated for female pseudohermaphroditism.
Mixed gonadal dysgenesis: These patients have unilateral cryptorchidism, representing the dysgenetic streak gonad, and often have a small phallus.
Male pseudohermaphroditism: This diagnosis is usually considered in newborns with scrotal or perineal hypospadias with palpable gonads, or after the adrenogenital syndrome has been ruled out in those with nonpalpable gonads.
True hermaphroditism: Asymmetric gonadal descent and hypospadias sometimes indicate this intersex state.

TABLE 52B.1. INTERSEX DISORDERS ASSOCIATED WITH HYPOSPADIAS

Malformation Syndromes

Hypospadias, often associated with cryptorchidism, occurs in a number of recognized syndromes (13,76). Among these are the Opitz and the Smith-Lemli-Opitz. Hypertelorism and hypospadias are the key features in males with Opitz syndrome, which includes both X-linked and autosomal-dominant forms with similar clinical manifestations. Other findings include mild to moderate mental retardation and swallowing problems resulting in aspiration.

The Smith-Lemli-Opitz syndrome is the first described with multiple congenital anomalies attributed to a single metabolic defect (95). This autosomal-recessive condition occurs in 1:20,000 births, ranking it third in prevalence among whites, behind cystic fibrosis and phenylketonuria. Affected individuals have impaired cholesterol synthesis because of a deficiency of 7-dehydrocholesterol reductase, resulting in mental retardation, facial deformities, syndactyly, and genital anomalies. The spectrum of external genital findings in males ranges from a female phenotype to hypospadias with cryptorchidism.

PRESENTATION AND EVALUATION

Hypospadias is usually recognized during initial physical examination of the newborn. Typically, the abnormal prepuce calls attention to the anomaly and then further evaluation often finds the penile raphe displaced from the midline and the glans tilted downward. The meatus may appear pinhole in size but is not usually obstructive. Ventral curvature of the penile shaft may be noted during erection.

These characteristics, the dorsal hood, altered glans morphology, and penile curvature, also can now be identified prenatally by fetal ultrasonography. Observation of micturition from a ventrally displaced meatus confirms the diagnosis. Initial reports described penoscrotal hypospadias detected between 29 and 34 weeks in association with multiple congenital anomalies (119). More recently, isolated glanular hypospadias has been diagnosed as early as 20 weeks (35).

Although some boys with hypospadias have demonstrable endocrinopathies, intersex evaluations are generally limited to those with scrotal or perineal urethral openings and patients with both hypospadias and cryptorchidism (64,118). In these situations, physical examination and the karyotype guide subsequent evaluation and therapy.

Before 1975, it was routine for boys with hypospadias to undergo intravenous pyelography and voiding cystourethrography. However, given the fact even severe hypospadias is an arrest in development beyond the eighth week of gestation after the ureteral bud has joined the metanephros, the likelihood of detecting upper urinary tract anomalies is small, with clinically significant lesions found in less than 5% (27,112,113). Today, with prenatal ultrasonography done routinely, the yield from screening predictably would be even less. Therefore radiologic studies are obtained only in those few boys with hypospadias who also develop urinary tract infection or whose anomaly is part of a malformation syndrome.

Because proximal hypospadias interferes with both normal voiding and procreation, the need for reconstruction is not questioned. However, parents not infrequently ask whether a subcoronal or proximal glanular defect justifies an operation. The authors are not aware of any study addressing the psychologic impact of such anomalies if left untreated. Fichtner and colleagues (51) implied that they were of little significance based on the response by 10 of 16 men in Germany with distal hypospadias who stated that they and their partners were unaware of any genital deformity. However, these patients lived in a country where circumcision is rarely done, so a partially formed prepuce may have seemed more normal than it might have appeared to men in the United States.

Because the abnormal foreskin often calls attention to hypospadias, it may be reasonable to recommend its removal. In addition, many boys with distal lesions have a transverse web of tissue just distal to the meatus, which may deflect the urinary stream. Furthermore, approximately 10% of these patients have ventral penile curvature. Given the ability of modern operations to create a functionally and cosmetically normal penis, it makes little sense to perform circumcision without simultaneous urethroplasty.

Based on a variety of psychologic, anesthetic, and surgical considerations, the recommended age for hypospadias repair is between 6 and 18 months (8,29). However, the healthy term boy with an adequately sized phallus can safely undergo this procedure as day surgery as early as 3 months of age. Preterm infants initially have a higher risk for postanesthetic apnea, but elective day surgery can probably be accomplished by 5 months of age (30).

Pretreatment with androgen stimulation is sometimes considered, especially in boys with a small phallus and proximal hypospadias. Testosterone cream or injection and hCG injections have been used, but the parenteral route is more reliable. Proponents report that therapy increases penile size, making it possible to harvest longer preputial flaps (54,82), and even decreases severity of hypospadias by moving the meatus distally (82). Others have not found testosterone stimulation beneficial (46). Gearhart and Jeffs (54) recommend that 2 mg/kg of testosterone enanthate be given intramuscularly (IM) 5 and 2 weeks preoperatively, but there are no uniform dosing guidelines, and androgen therapy for microphallus typically involves higher doses, 25 to 50 mg IM once a month for 3 months.

SURGICAL REPAIR

The goal of hypospadias surgery is to create a penis with both normal function and appearance. Because the anomaly includes a wide spectrum of severity, ranging from the glanular to perineal meatus in a penis that may be straight or significantly curved, it is not surprising that well over 200 operative techniques and variations have been described. The fact that the origins of nearly all of these procedures can be traced to the late 1800s, when surgical repair began in earnest, attests to the difficulty of achieving a functional neourethra in a straight penis that appears to have only been circumcised.

In the past decade, new concepts regarding the etiologies of penile curvature and the best means to correct it have gained acceptance. As a result, the urethral plate is now more commonly preserved and incorporated into the urethroplasty. Together these developments have brought hypospadias surgery nearer its ultimate functional and cosmetic goals. The following section presents a brief overview of the history of hypospadiology to explain the evolution of its modern principles.

HISTORICAL BACKGROUND

In 1869, Karl Thiersch first tubularized skin flaps to repair epispadias. Theophile Anger adopted his technique for hypospadias and in 1874 reported successful repair of a penoscrotal lesion, inaugurating the modern era of hypospadias surgery. Soon thereafter, the French surgeons Duplay, Nové-Josserand, and Ombrédanne each described methods that became the foundation on which the work of subsequent generations of hypospadiologists has been based (Fig. 52B.7). Of the three, Duplay's contributions have arguably been the most enduring, earning him the title “father of hypospadias surgery” (12).

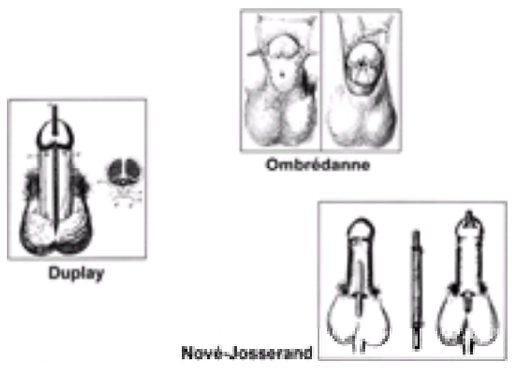

FIGURE 52B.7. The French schools of urethroplasty. Duplay's first method of constructing the neourethra by tubularizing ventral shaft skin. The inset depicts his second method in which a buried dorsal strip of skin was expected to epithelialize ventrally around a catheter. Ombrédanne's flap was centered on the meatus and drawn closed by a single purse-string suture into a pouchlike urethra. Nové-Josserand placed tubularized skin grafts subcutaneously using trocars.

The early pioneers generally limited intervention to boys with proximal defects and significant curvature, meaning the repair of hypospadias began with the most difficult cases. These operations were usually done in multiple stages as recommended by Duplay. First, the penis was straightened. Then the neourethra was fashioned and in the final stage joined to the native urethra. Although today most repairs are accomplished in a single operation, this sequence of steps is still followed. Any penile curvature must first be corrected, because the means used for straightening determines the options available for urethroplasty.

Chordee

Ambroise Pare may have been the first to describe chordee in the medical literature. Writing in the 1500s, he observed that the “bridle” or “ligament” of the penis was occasionally too short, resulting in downward curvature, and he advised that it be cut to achieve straightening. Two hundred years later, Pierre Dionis agreed that transverse incision of a short bridle would remedy penile bending (108). In 1842, Mettauer (89) found that multiple subcutaneous incisions were needed to divide the “contracted structures,” which impaired normal erections. Bouisson further elaborated on this theme, describing in 1861 excision of a “fibrous band” through a transverse incision closed vertically (69). Duplay adopted Bouisson's technique in the first stage of his operation (Fig. 52B.8), and then Edmunds (48) modified it somewhat by formally resecting the “shrunken” urethral groove from the tip of the glans back to the meatus.

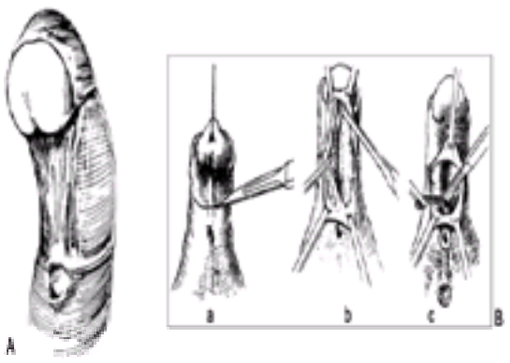

FIGURE 52B.8. A: Traditional concept of chordee tissues representing fibrous remnants of dartos fascia, Buck's fascia, and corpus spongiosum extending in a fan shape from the meatus to the glans. (From Hinman F Jr. *Atlas of pediatric urologic surgery.* Philadelphia: Saunders, 1994:554, with permission.) **B:** Duplay's method to straighten the penis. A transverse skin incision was made across the urethral plate *(a),* fibrous subcutaneous tissues were excised *(b),* and then the skin was closed vertically *(c)*.

Over time, these descriptions of “bridles,” “contracted structures,” and “fibrous bands” were replaced with scientific terms such as “dysgenetic mesenchyme” and “dysplastic corpus spongiosum.” Gradually, the notion became firmly entrenched that the urethral remnant distal to the hypospadiac meatus consisted of epithelium covering dense fibrous tissues of abortive spongiosum (31). Meanwhile, surgical excision of these tissues also became more extensive. For example, in 1955 Byars (25) warned that abnormal fibrous elements had to be removed from the entire ventral half of the penile circumference down to the corpora cavernosa and into the intercorporeal septum.

Devine and Horton wrote extensively on chordee in the 1960s and 1970s, emphasizing the additional contribution of dysgenetic dartos and Buck's fasciae to penile curvature. Like Byars, they believed meticulous dissection to remove all fibrous tissues should leave the corpora cavernosal surface “clean and glistening” (36). Even into the mid-1980s it was the practice of many surgeons to approach proximal hypospadias repairs via a subcoronal circumferential incision with removal of the urethral groove down to the meatus. After Duckett popularized the term *urethral plate,* some have argued that the plate either is comprised of fibrous tissues or it tethers the corpora cavernosa by fibrous attachments to produce penile curvature (16).

However, alternative views regarding the causes of penile bending are also found sporadically in literature dating to the 1800s. For example, although he used Bouisson's method to straighten the penis, van Hook (71) wrote in 1898, “It must not be forgotten that the downward curvature of the penis is largely due to lack of development of the corpora cavernosa.” But not until 1952 was there a serious challenge to the prevailing opinion that chordee results from fibrous spongiosum. Smith and Blackfield (117) argued that they were able to reliably correct bending without resecting any “phantom” midline bowstring by simply releasing ventral skin attachments distal to the meatus. Then Allen and Spence (5) found that a circumferential skin incision proximal to the meatus was also effective, enabling the penis to be straightened without disturbing the meatus in distal hypospadias. Critics described this approach as a “glorified circumcision.”

Artificial erection is required both to accurately diagnose and assess the degree of penile curvature and to demonstrate success of corrective measures. Therefore it is important to emphasize all these concepts developed before Gittes and McLaughlin (60) described corpora cavernosa injection in 1974. Until that time, intraoperative evaluation was largely based on visual inspection and palpation of the ventrum with countertraction on the glans.

Nesbit (93) reported dorsal plication in 1965, presenting three cases of chordee without hypospadias. None had a fibrous bowstring, but instead were each thought to have “rare” corpora cavernosal asymmetry. Although today this means of straightening is commonly called *Nesbit plication,* the technique had already been described by Syng Physick in 1844 (96). But it was Duckett who popularized this approach, insisting that corpora cavernosal disproportion was the most likely cause of persistent bending after the penis was degloved, when he realized that transection of the urethral plate under these circumstances did *not* achieve straightening (15,70). Through the combined force of this observation backed by his strong personality, Duckett was able to convince many hypospadiologists to stop excising the plate and rely instead on dorsal plication.

Urethroplasty

Neourethras were first constructed from local skin flaps. Applying Thiersch's operation to hypospadias, Duplay made parallel longitudinal incisions from the meatus extending distally and rolled the skin into a tube, covering this neourethra with lateral skin flaps. His approach had the disadvantage of overlapping suture lines and often required a relaxing incision through the dorsal shaft skin for sufficient mobility to close skin flaps ventrally. Several years later, Duplay reported a second means of repair. By cutting a narrower skin strip for the neourethra, he found it easier to close the ventral shaft without a relaxing maneuver. However, it was no longer possible to roll a tube, so Duplay simply left a catheter lying on this now buried strip of skin, convinced that epithelialization during healing would complete the neourethra (12). Predictably, both of Duplay's operations commonly resulted in fistulae and eventually fell into disuse until Browne (23) briefly resurrected his second method. Nevertheless, today the name Thiersch-Duplay is evoked when local skin is tubularized.

It was the apparent need for additional tissues to form the neourethra or resurface the ventral penis that gave rise to literally hundreds of operations (Fig. 52B.9). Many surgeons used the adjacent scrotum, with Cecil (26) ultimately refining the technique by creating the urethra from penile skin while using scrotum for ventral shaft covering. This kept hair out of the neourethra, but it meant that hairy skin extended to the corona.

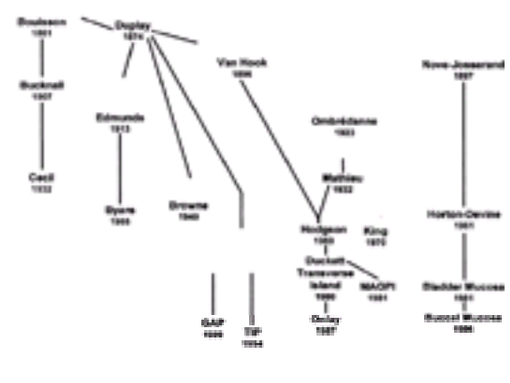

FIGURE 52B.9. Abbreviated genealogy of hypospadias repairs.

Meanwhile, in 1896 van Hook may have been the first to tubularize a pedicle flap of preputial skin (71). Shortly thereafter, Edmunds (48) introduced splitting the prepuce and transposing it ventrally for later tubularization. Byars (25) added a slight modification, and today the term *Byars' flaps* describes the first of a two-stage repair.

Another school of urethroplasty began with Ombrédanne's report of a U-shaped flap, centered on the meatus, which was drawn into a pouchlike neourethra by a single purse-string suture (12). Mathieu (88) added some refinements, replacing the purse-string closure with parallel suture lines. This “flip-flap” repair subsequently became one of the most widely used operations for distal hypospadias.

Hodgson (68) combined elements of the flip-flap and preputial pedicle flap in his various repairs. Furthermore, he supported Devine and Horton's enthusiasm for one-stage repairs, which gradually replaced multistaged operations in the 1960s. Asopa and colleagues (10) and Duckett (42) further modified these techniques to

describe tubularized preputial flaps and, later, the onlay flap (50).

The third school of urethroplasty is credited to Nové-Josserand. Before the late 1800s, trocars had been used to tunnel under the skin and through the glans to create a neourethra. Nové-Josserand placed tubularized skin grafts subcutaneously by this means. Subsequently, homografts of veins and appendix were all tried without much success, primarily because of strictures (12). The preputial grafts described by Devine and Horton and the more recent use of bladder and buccal mucosa all derive from Nové-Josserand's earlier efforts.

One innovation without obvious connection to these French surgeons was the meatoplasty and glansplasty, or MAGPI. Introduced by Duckett in 1981, the operation was primarily intended for the subcoronal meatus (43). Previously such distal hypospadias usually had not been repaired because it rarely caused voiding or procreational difficulties, but this relatively simple procedure with few complications offered the means to improve the appearance of the glans. Soon other techniques to repair more severe hypospadias came under increasing scrutiny, as the standard for measuring success was raised to include not only functional outcomes, but also the cosmetic results.

By the late 1980s, the hypospadiologist could rely on the MAGPI, flip-flap, or onlay and tubularized preputial flap to correct most abnormalities (21). However, one problem with flip-flaps and onlays was the rounded, horizontally oriented meatus that often resulted. Both Johanson and Avellán (75) and Rich and colleagues (107) recognized that urethral plate configuration actually determined the cosmetic outcome, because a flat plate yielded a horizontal meatus while a deeply grooved one produced a more normal, vertically orientated meatus. Consequently, Rich and colleagues (107) described “hinging” the flat plate by incising it distally to improve meatal cosmesis. A few months later, Snodgrass (121) extended this midline incision through the entire urethral plate and realized that the plate could then be tubularized without adding skin flaps.

NEW CONCEPTS

From these trials and errors, four concepts emerged in the 1990s that have revolutionized hypospadias repair. The first is designation of the tissues distal to the hypospadiac meatus as the urethral plate, implying that it is a unique structure. Although the term was coined in reference to epispadias (104), Duckett popularized its use in hypospadias. Previously no distinction had been made between the urethral plate and glans. Instead, the glans was described as being flat or grooved when this appearance actually referred to characteristics of the plate. The developmental arrest that results in hypospadias leaves the ventral glans open with its wings fused to the lateral edges of the urethral plate.

The second concept is that the urethral plate is rarely the cause of penile bending. It is important to emphasize that there have been very few reports concerning histology of the hypospadiac penis, and the authors are aware of only one that purported to demonstrate fibrous tissue comprising an inelastic band stretching under the surface epithelium from the meatus to the glans (98). Conversely, Avellán and Knutsson (11) did not find histologic evidence of a fibrous band within the tissues of the urethral plate in patients with hypospadias and ventral penile curvature. We have also obtained biopsies of the urethral plate, as well as the corpus spongiosum, dartos, and Buck's fasciae in a small number of boys with hypospadias and penile curvature, and have yet to encounter fibrous or dysplastic tissues (127).

A limited number of autopsy studies also challenge the fibrous bowstring theory of chordee. For example, Marshall and colleagues (87) examined one newborn with penoscrotal hypospadias and found no fibrotic tissues within the urethral plate and no abnormal fibrotic attachments of the plate to the underlying corpora cavernosa. Similarly, the fetal specimens evaluated by Kaplan and Lamm (79) demonstrated ventral curvature without fibrous tissues or bands. Their report corroborated the earlier studies of Glenister (61), suggesting that the penis is normally curved during development and may remain so if development is arrested. It is an interesting historical observation that the French word *chordee,* meaning “cord” or “band,” apparently did not come into popular use until the 1950s. Now perhaps it, like the older terms *bridles* and *ligaments,* should be retired.

Third, incorporation of the urethral plate into the neourethra may reduce surgical complications. Hollowell and colleagues (70), Mollard and Castagnola (91), and Wiener and colleagues (132) all reported advantages to onlay versus tubularized preputial island flaps. In these series, reliance on an intact urethral plate as scaffolding to support the neourethra was cited as a benefit of the onlay approach.

The fourth concept is that the urethral plate can be primarily tubularized without additional skin flaps after a dorsal midline relaxing incision is made. This observation was first reported in 1994 in a small series of boys with distal hypospadias (121). Multicenter experiences with the technique for both distal (122) and proximal (123) hypospadias confirmed the findings and led to widespread use of the principle.

DECISION MAKING IN HYPOSPADIAS SURGERY

In the past, the choice of operation was determined by specific meatal and glanular (actually urethral plate) configuration encountered. For example, the MAGPI was best limited to the small, pliable subcoronal or glanular meatus with a flat ventral glans. So-called meatal variants (58) were better managed by other techniques, such as the glans approximation procedure (135) and pyramid repairs (44) for a patulous meatus with a deep glanular groove, or flip-flap and onlay flaps when the glans was flat.

Now it is commonly held that *every* primary operation for hypospadias begin with preservation of the urethral plate. Decision making as to method of repair occurs after degloving the penis and correction of the chordee.

CORRECTION OF PENILE CURVATURE

No study has assessed curvature by artificial erection before degloving the penis, so the relative contribution of ventral shaft skin to penile bending is difficult to determine. However, several features of the skin in hypospadiac penises are obvious. First, there are often relative deficiencies not only of the ventral prepuce but also of the ventral shaft skin. In addition, coverage proximal to the meatus may be quite thin due to deficiencies in the dartos and corpus spongiosum normally interposed between skin and urethra. Furthermore, the median raphe is typically displaced laterally, sometimes in association with torsion of the penis. That these skin anomalies may twist or bend the penis is apparent, and without doubt the ventral glans tilt observed with most hypospadias is usually due to skin tethering, because it resolves when these attachments are released.

A circumscribing incision is made subcoronally and 2 mm proximal to the meatus to begin distal hypospadias repair. If the skin overlaying the distal urethra is thin, however, a U-shaped incision is extended back to healthy skin. Similarly, a U-shaped incision is made along the lateral borders of the urethral plate to the meatus for proximal hypospadias. The penis is then degloved to the scrotal junction in the plane between dartos and Buck's fasciae, and artificial erection subsequently is done in every case, because even a coronal meatus is sometimes associated with penile bending.

In a series of boys with penile hypospadias treated with onlay flaps, 27% still had curvature requiring intervention after the penis was degloved (15). Similarly, the tubularized, incised plate multicenter studies combined found 24% of patients with bending when the skin was released (unpublished data). As expected embryologically, significant curvature is more likely as the severity of the hypospadias increases. Baskin and colleagues (15) attributed this bending to corpora cavernosal disproportion, and in both their and the multicenter reports, dorsal plication was done to achieve straightening.

An algorithm to correct penile curvature is depicted in Fig. 52B.10. When the degree of bending is mild, dorsal plication will reliably straighten the penis (Fig. 52B.11). However, curvature greater than 30 degrees has traditionally next led to transection of the urethral plate, even though this step alone often is not sufficient to accomplish straightening. Because it is preferable to retain the plate, when possible, the authors now follow the suggestion of Mollard and Castagnola (91) and first mobilize the plate from the meatus to the corona, dissecting immediately along the corpora cavernosal surface (Fig. 52B.12). In limited experience, this maneuver has not completely corrected bending, but in some cases has improved it such that dorsal plication was then feasible to achieve straightening without having to transect the plate.

FIGURE 52B.10. Algorithm for penile straightening. After the skin is degloved, most boys with hypospadias have either a straight phallus or mild ventral curvature readily corrected by dorsal plication.

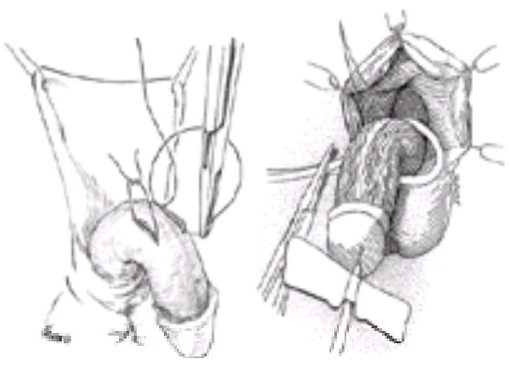

FIGURE 52B.11. Dorsal plication for penile straightening. Parallel incisions are made superficially into the tunica albuginea of the corpora cavernosa adjacent to the neurovascular bundles opposite the point of greatest curvature. It is not necessary to remove an ellipse of tunica or to expose spongy tissues. The 6-0 Prolene sutures are placed as shown, burying the knot. Alternatively, because their studies found no sensory nerves at the 12 o'clock position, Baskin and colleagues (17) recommend dorsal plication in the midline.

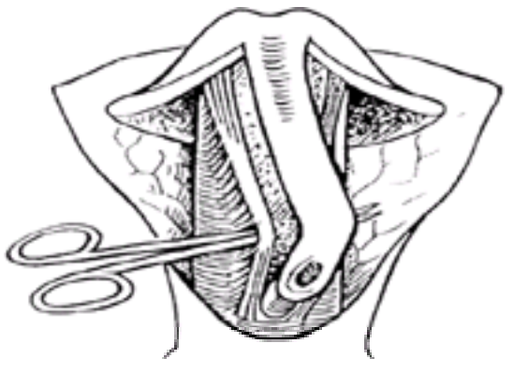

FIGURE 52B.12. Mobilization of the urethral plate from the underlying corpora cavernosa may assist in penile straightening. [From Mollard P, Castagnola C. Hypospadias: the release of chordee without driving the urethral plate and onlay island flap (92 cases). *J Urol* 1994;152:1238, with permission.]

Despite these measures, there remain occasional instances in which penile straightening requires transection of the urethral plate. After transection, bending sometimes resolves or improves to an extent that dorsal plication is then successful. In other patients, however, there is still too much curvature, or the penis is intrinsically so short, that plication may not be adequate or advisable. In these circumstances, ventral grafting to lengthen the corpora cavernosa has been done using dermal (37) or tunica vaginalis (100) grafts. Others dissect ventrally into the intercorporeal septum to separate the corpora cavernosa and then rotate the corpora laterally to straighten the penis (32,34,83). Perovic and colleagues (101) recommend complete penile disassembly when there is severe curvature.

TUBULARIZED, INCISED PLATE URETHROPLASTY

In most hypospadias repairs, penile straightening is achieved without transecting the urethral plate (Fig. 52B.13). Next, 1:100,000 epinephrine is infiltrated into the ventral glans along the visible junction to the plate. Then the plate is separated from the glans wings by parallel longitudinal incisions and the wings are mobilized laterally for subsequent tension-free closure. With the occasional exception of the deeply grooved urethral plate, most often the plate at this stage is too narrow to be tubularized.

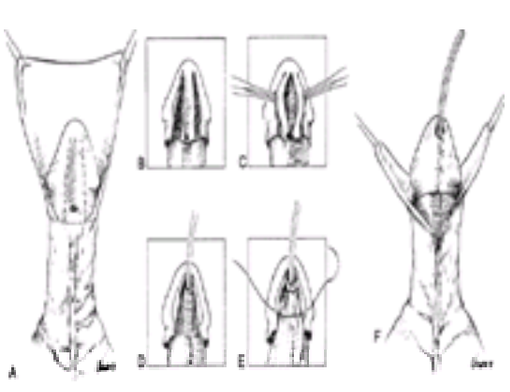

FIGURE 52B.13. Tubularized, incised plate hypospadias repair. **A:** *Horizontal dotted line* indicating circumscribing incision approximately 2 mm proximal to the meatus. *Vertical dotted lines* indicate the junction of the urethral plate to the glans wings. **B:** Urethral plate is separated from the glans wings, which are then mobilized laterally. **C:** The key step of the operation is a deep, midline incision into the urethral plate extending from within the meatus to its distal margin, but not continuing into the glans apex. **D:** The plate is tubularized over a small stent leaving a generous, oval meatus. **E:** The neourethra is covered by a dartos flap, and then glansplasty begins at the coronal margin. **F:** Glans wings, mucosal collar, and ventral shaft skin are closed. (From Snodgrass W. Tubulanized incised plate hypospadias repair: indications, technique, and complications. *Urology* 1999;54:6, with permission.)

The key step in the operation is a midline relaxing incision made from within the meatus to the distal extent of the plate. This incision carries through the epithelial surface of the plate deeply into underlying connective tissues down to the corpora cavernosa. With the surgeon and assistant maintaining countertraction using fine forceps, division of the plate is observed to widen it significantly, and continues until no additional mobility is gained. It is recommended that tenotomy scissors, rather

than a knife, be used so as to gain sufficient depth without injury to the corpora cavernosa.

Plate configuration determines the depth of the relaxing incision (Fig. 52B.14). When the urethral plate is flat, the incision will be made deeper than when it is already naturally grooved. Regardless, plate incision should consistently serve to broaden the plate tissue to the extent that the neourethra will exceed 12 Fr (Fig. 52B.15). If bleeding occurs, 1:1,000 epinephrine is dripped onto the site and then pressure is held for several minutes. A tourniquet can also be applied at the base of the penis, but it is advisable not to use electrocautery either to incise the plate or control bleeding.

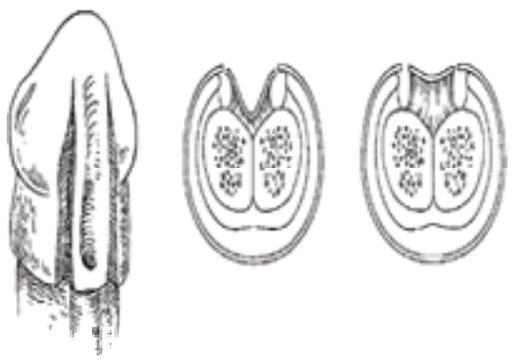

FIGURE 52B.14. The depth of the midline urethral plate incision is determined by the extent of its natural groove. The relatively flatter plate on the far right requires a deeper incision than the more deeply grooved plate in the middle figure.

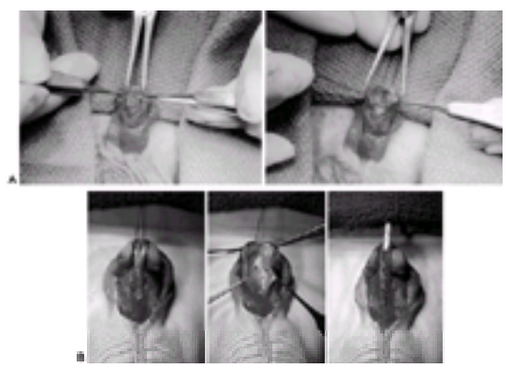

FIGURE 52B.15. Results of urethral plate incision. **A:** Before incision, the plate in this case measured 6 mm in width. After the dorsal relaxing incision, the plate measured 15 mm in width, ensuring a final neourethra greater than 12 Fr. **B:** Midline incision markedly widens the urethral plate in a case of proximal shaft hypospadias.

Before tubularization, a 6-Fr stent is passed into the bladder for postoperative urinary drainage. Closure of the urethral plate always begins at the midglans level, with no more than one, or rarely two, stitches placed further distally. To avoid stenosis, the neomeatus should have a generous oval opening. The plate can be tubularized using a running subepithelial 7-0 chromic catgut suture.

The entire neourethra is covered with a thin dartos pedicle mobilized from the dorsal prepuce and shaft skin. This provides a very important second layer of tissue over the neourethra closure line. Next, the glans wings are closed in the midline using a subepithelial 6-0 suture of the cornea, followed by a 6-0 chromic catgut vertical mattress to approximate the glans surface. One or two additional stitches are placed further distally, again with care to avoid constricting the neomeatus. Simple stitches of 7-0 chromic catgut between glans and meatus at the 4 and 8 o'clock positions may improve the cosmetic results of the meatus.

The mucosal collar is approximated in the midline and the shaft skin is refashioned to simulate the median raphe (120). In obese boys, the skin should be anchored to the base of the penis using absorbable sutures to minimize its distal migration (i.e., formation of a “buried penis”). Subcuticular stitches are advised along all skin edges to avoid suture tracks (126). A Tegaderm dressing is applied at the conclusion of the procedure (Fig. 52B.16), and the child discharged home. The stent drips urine into diapers for 5 to 7 days.

FIGURE 52B.16. Postoperative dressing preferred by the author.

OUTCOMES OF TUBULARIZED, INCISED PLATE URETHROPLASTY

Tubularized, incised plate (TIP) hypospadias repair produces a functional neourethra greater than 10 Fr ending in a vertical, slitlike meatus (Fig. 52B.17). The effectiveness of this repair is thought to relate to the use of healthy urethral plate tissue, which has good potential to regenerate midline epithelium, thus expanding urethral tissue without skin flaps or grafts. After surgery, most boys appear to have only been circumcised. The results to this point have been durable, with low incidence of meatal stenosis, neourethral stricture, and diverticulum formation (124). However, relative to other repairs, follow-up is short. The most frequent complication has been that of fistula formation, which occurs in approximately 2% of the total cases reported to date (125). However, the likelihood of fistulae is minimized by covering the neourethra with a dartos flap (52,121).

FIGURE 52B.17. Postoperative appearance following tubularized, incised plate (TIP) repair.

A significant advantage of hypospadias repair using the TIP urethroplasty is that it can be used to correct essentially all distal and many proximal anomalies. The glans approximation procedure (GAP) and pyramid repair also involve tubularization of the urethral plate. However, the GAP was designed only for cases with a patulous meatus and a deeply grooved plate and has the disadvantage of overlapping suture lines between the urethroplasty and glans closure. Similarly, the pyramid was only described for use in megameatus repair. By definition, boys with this variant have a generous, in fact sometimes too wide, urethral plate, but in some the plate lies flat in a horizontal plane such that midline incision helps recess the neourethra deeper into the glans. Consequently, repair of these specific anomalies follows essentially the same steps described previously.

Both the TIP and MAGPI can be used to correct proximal glanular hypospadias. Both procedures have low complication rates, and the MAGPI has the advantage of being a stentless repair. Drawbacks of MAGPI include its potential distortion of the glans and meatal regression. Unless the meatus is pinhole in size and freely mobile, it will not advance distally. The dorsal sutures may act less to move the urethra than to pull the glans apex proximally, resulting in a flattened rather than conical glans. Early postoperative results of MAGPI may not be durable. Whereas Park and colleagues (97) reported no meatal regression at 3-year follow-up, Hastie and colleagues (65) found partial regression in 26 of 28 cases with similar long-term evaluation.

At the time the MAGPI was introduced, it was unparalleled in its ability to achieve excellent cosmetic results in the repair of distal hypospadias. The TIP repair currently seems to accomplish the same goal without glans distortion and with little risk of meatal regression. Similarly, the TIP concept can be applied to cases that previously would have required either flip-flap or onlay flap techniques to create the neourethra, without many of the difficulties experienced with these repairs. The resulting meatus is usually slitlike and vertically oriented on the glans.

OTHER REPAIRS

The two contraindications to TIP urethroplasty are (a) severe curvature requiring transection of the urethral plate and (b) a plate that appears thin or is insufficiently widened after dorsal incision. Options for repair in these circumstances are found in the algorithm in Fig. 52B.18.

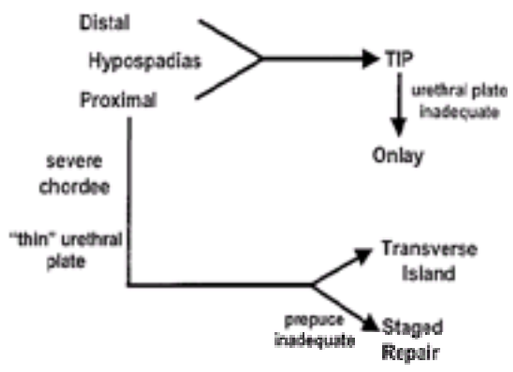

FIGURE 52B.18. Algorithm for primary hypospadias repair. TIP, tubularized, incised plate.

Onlay Flaps

Rarely, the lateral margins of the urethral plate may appear thin due to deficiency of its connective tissues. In this situation (which the authors have encountered in approximately 1% of cases), all unhealthy tissues must be excised. An onlay flap is generally necessary to complete the urethroplasty (Fig. 52B.19). However, the preputial flap should be a minimal width to avoid a diverticulum.

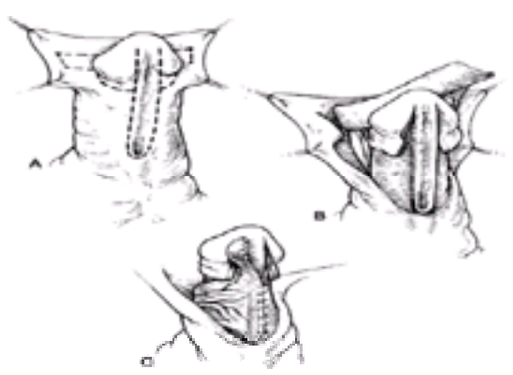

FIGURE 52B.19. Onlay preputial flap. **A, B:** A rectangular flap of appropriate length and a width of approximately 8 to 10 mm is cut from the inner prepuce, maintaining its blood supply. **C:** The flap is rotated ventrally and sutured to the urethral plate. The pedicle of the flap is used to cover the neourethral suture lines.

Tubularized Preputial Flap

Two options remain for urethroplasty when severe penile curvature leads to transection of the urethral plate. One is to complete the repair in one stage using a tubularized preputial flap (Fig. 52B.20). A rectangular flap of sufficient length and a width of approximately 14 mm is developed from the inner prepuce, tubularized, and then rotated ventrally maintaining its blood supply. Although the tubularized preputial flap offers the advantage of a one-stage repair, in some series it has been associated with complication rates of 38% to 50%, including fistulae, meatal stenosis, strictures, and diverticula (49,132).

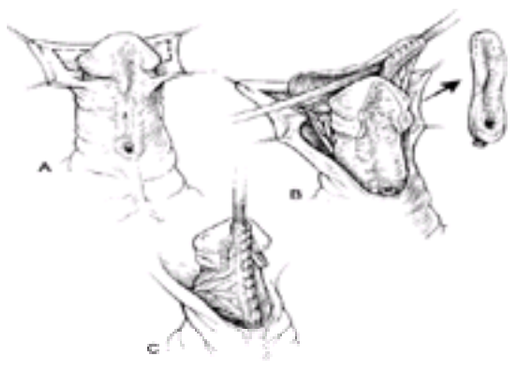

FIGURE 52B.20. Tubularized preputial flap. **A:** A rectangular flap of appropriate length approximately 14 mm wide can be harvested from the inner prepuce. **B:** Following resection of the urethral plate, the flap is mobilized and then tubularized over a stent. **C:** The neourethra is rotated ventrally, placing the suture line against the corpora cavernosa.

Two-stage Repair

When the proximal urethral plate must be transected. it may be preferable to stage the urethroplasty (Fig. 52B.21). The dorsal prepuce is split to the level of the corona and the resultant flaps are advanced ventrally to provide adequate skin for later tubularization. In the past, the distal urethral plate was also excised and the prepuce advanced into the space between the glans wings. However, the prepuce may be rotated to the subcoronal level *without* disturbing the distal plate.

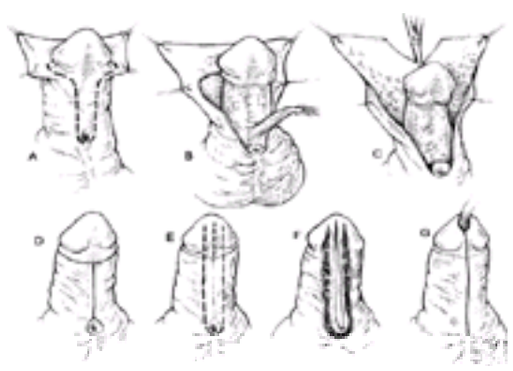

FIGURE 52B.21. Two-stage hypospadias repair. **A:** The initial U-shaped skin incision preserves the urethral plate. **B:** Removal of the shaft portion of the urethral plate is sometimes needed for penile straightening. **C:** Prepuce is incised dorsally to rotate skin to the ventrum. **D:** The first stage is completed using subcuticular stitches. **E:** Lines of incision for the second stage. The glanular incisions are the same as those used in distal TIP urethroplasty, with the outer incisions separating the glans wings from the urethral plate while the midline relaxing incision widens the plate. **F:** The incisions are completed and the neourethra will next be tubularized over a stent. **G:** The completed repair.

The second stage is done 6 months later. Parallel longitudinal incisions 12 to 14 mm apart outline the flap on the penile shaft and continue distally onto the glans wings at their junction with the urethral plate. Then the plate is incised in the midline, and the entire strip of plate and skin is tubularized into the neourethra.

Although the trend since the early 1980s has been toward one-stage repairs using tubularized preputial flaps, there has been a resurgence of support for a two-stage repair for boys with proximal hypospadias and severe penile curvature. This approach permits careful correction of the chordee and maximizes the potential for viable ventral flaps. Reports have emphasized that this approach may yield fewer complications and better cosmetic results than a one-stage approach in this setting (63,105).

COMPLICATIONS

Several general precautions may diminish the risk for complications following hypospadias repair. With reconstruction now recommended in the first few months of life, use of delicate instruments, fine suture materials, and optical magnification is essential. Careful attention to the blood supply of flaps and meticulous wound hemostasis are of obvious importance. Given the choice of vascularized flaps versus free grafts, most surgeons today prefer vascularized tissues. Creating a neourethra of appropriate size that is neither too small nor too large and then interposing a barrier layer between it and the skin will also reduce the likelihood of subsequent problems.

Urethrocutaneous Fistula

Urethrocutaneous fistula is the most common complication of hypospadias repair. Although most are isolated findings, a fistula sometimes indicates meatal stenosis, distal urethral stricture, or the presence of a diverticulum. Historically, fistulae have occurred in up to 50% of patients, but reports of the operations described in this chapter document much lower rates. As discussed previously, fistulae have been noted in 2% of TIP urethroplasties. Onlay and tubularized preputial flaps develop this complication in 6% to 17% of cases (15,57,131), and modern two-stage repairs have a 5% or less incidence of fistulae (63,105).

Meatal Stenosis

Inadequate blood supply to the meatus or iatrogenic constriction of the opening during repair can result in meatal stenosis. Regardless of the operative procedure, at its conclusion the meatus should have a generous oval configuration. In the TIP repair, incising dorsally beyond the plate into the glans apex, suturing the neourethra too far distally, or constricting the meatus during glans closure can all lead to stenosis. Occasionally, the meatus appears small in an asymptomatic patient after surgery, but in our experience, a 10-Fr sound has always passed easily, and routine calibration is not necessary. Meatal stenosis occurs in less than 5% of boys undergoing modern repairs.

Urethral Stricture

A stricture of the neourethra usually indicates a region with poor vascularity (assuming the original diameter was adequate). The proximal anastomosis of tubularized preputial flaps is also an area more prone to strictures (62). Therefore an advantage of both onlay flaps and the two-stage approach is avoidance of such a circumferential anastomosis. However, given the large number of hypospadias operations and the few patients reported with strictures, it appears that this is currently not a complication of major significance (47,111). Neourethral stricture seems to be uncommon following TIP repair. In their study of onlay and tubularized preputial flaps, Wiener and colleagues (131) had a combined 6% rate of strictures and did not find a significant difference in risk between the two types of repair.

Diverticula

Diverticula typically cause visible ballooning of the reconstructed urethra during voiding and postvoid dribbling. They develop secondary to distal obstruction, from creation of too large a neourethra, or as a result of turbulent urinary flow (3). One case has been reported in association with meatal stenosis after TIP repair (123), but otherwise this is an unlikely complication of that procedure because skin flaps are not used. When preputial skin is required, onlay flaps develop diverticulum less often than do tubularized ones, the latter having a reported incidence of approximately 10% (3,131). This finding is cited as an advantage of securing onlay flaps to

the stable urethral plate. Greenfield and colleagues (63) noted a 21% incidence of diverticula in their two-stage repairs and concluded that these resulted from turbulent flow proximal to the comparatively fixed glanular urethra. When skin flaps are needed, it is important to avoid the temptation of creating a larger than normal neourethra.

Recurrent Penile Curvature

Artificial erection should detect penile curvature at the time of repair and then document its correction. Although the etiology of bending and the best means to achieve straightening remain sources of debate, there have been very few reports of recurrent curvature after hypospadias surgery in childhood. Vandersteen and Husmann (130) evaluated 22 men with recurrent curvature more than 10 years after proximal hypospadias repair, all of whom had undergone artificial erection followed by corporoplasty using either dorsal plication or ventral tunica vaginalis patch grafts. Failures of both plications and grafts were noted, but definitive risk factors could not be identified in this small series.

Other Complications

Several other complications occasionally occur following hypospadias repair. Dehiscence may be the result of several factors, including infection, poor vascularity, or tension on the repair. Use of small stents for urinary drainage may reduce pressure on suture lines that can develop from postoperative swelling. Stents size 6 Fr are preferred for repairs in children because they provide adequate urinary drainage with minimal risk.

Suture tracks are a theoretic risk whenever stitches penetrate the skin. We have found these to occur on the ventral penile shaft despite use of 6-0 chromic catgut for wound closure. They may not be apparent until more than 1 year postoperatively, presumably because of the time needed for such small sinuses to fill with keratin (126). Following application of eutectic mixture of local anesthetics (EMLA) cream, these can be opened with a sharp-pointed scissors in the office, but most likely would have been avoided in the first place by subcuticular wound closures.

Scars on the dorsum of the penis and glans should not result from the procedures described in this chapter. A deformed, scarred glans is particularly distressing and often cannot be improved, which emphasizes need for delicate handling of these important tissues. Similarly, we routinely attempt to create a median raphe ventrally as preputial flaps are rotated, avoiding “bear hug” flap closures that once were popular and still are occasionally depicted in textbooks. A functional penis with unsightly scars can, at best, be considered only a partial success of hypospadias repair.

REOPERATION

Reoperative surgery after hypospadias repair ranges from closure of simple fistulae to extensive reconstruction of the entire neourethra. Every boy with a complication should be carefully evaluated to detect other associated problems, because reoperations must be designed to address all comorbid conditions. In addition to office examination, reports of previous operations should be reviewed. In general, reoperations are delayed at least 6 months following the last repair to allow complete healing. Then, at the time of surgery, urethroscopy is done to directly visualize the urethra, facilitating diagnosis of fistulae, strictures, and diverticula. Distending the urethra with methylene blue is also useful to detect small fistulae that might otherwise be overlooked.

The principles of fistula repair include excision of all unhealthy tissues, watertight urethral closure, and interposition of a barrier layer between the urethra and skin (Fig. 52B.22). Small fistulae on the penile shaft can be circumferentially excised down to the urethra with a full-thickness skin flap then advanced to cover the repair. These minor procedures do not require postoperative urinary diversion. However, subcoronal and glanular fistulae require more extensive dissection. The distal urethra is opened from the meatus to the fistula and separated from the glans. After unhealthy tissues are excised, the hypospadias repair is essentially redone, tubularizing the urethra, covering it with dartos tissues from the penile shaft, and then reapproximating the glans wings. Therefore a stent is left indwelling for 5 to 7 days.

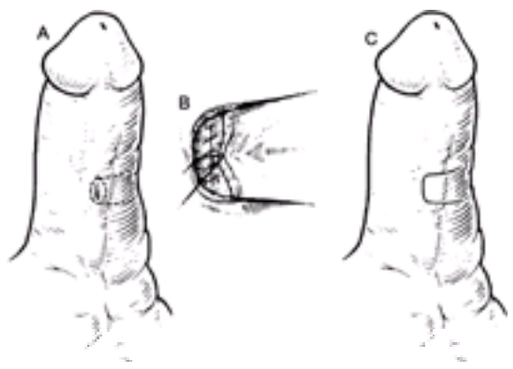

FIGURE 52B.22. Fistula repair. **A:** Proposed lines of incision around the fistula extend laterally to create a skin flap. **B:** After excision of the fistula tract, the urethra is closed and the flap advanced to accomplish wound closure without overlapping suture lines. **C:** The repair is completed using subcuticular stitches.

Short neourethral strictures may respond to a single dilation under anesthesia (14,111), especially if the lesion is detected within the first few postoperative months (111). Alternatively, direct-vision internal urethrotomy may also be considered in this situation. Unfortunately, initial improvement may not prove durable; Duel and colleagues (47) reported long-term success by these methods in only 20% of patients. Because neourethral strictures and meatal stenoses may indicate regions of compromised vascularity, healthy tissues must be incorporated into their repair. This is best accomplished using flip-flaps or onlay flaps derived from local tissues.

Diverticulum repair involves excision of redundant tissues followed by closure of the urethra to an appropriate diameter. Overlapping suture lines are avoided either through use of a degloving skin incision or by interposing dartos tissues. An indwelling stent is used for postoperative urinary diversion.

After a failed hypospadias repair, there is often insufficient penile skin to reconstruct the urethra. One option is incision and tubularization of the urethral plate, which generally remains supple despite the glans approximation procedure, flip-flaps, or onlay flaps (106,109,122). TIP urethroplasty has also been used after MAGPI and even following dehiscence of a prior TIP repair (125). However, reconstruction must be based on healthy tissues; therefore a reoperative urethroplasty cannot depend on incision of an obviously scarred plate. Similarly, should it be apparent from previous operative records or the visual appearance of tissues that the urethral plate has been excised and replaced, for example by tubularized prepuce, a relaxing incision probably cannot be done with the expectation of satisfactory healing.

When neither the TIP method nor vascularized penile flaps are feasible, buccal mucosa grafts are used, preferentially as an onlay rather than tubularized urethroplasty. The technique has been well described (24,33,45) and consists of first preparing the recipient bed of the penis. All scarred tissues are excised, and artificial erection is performed to be certain there is no residual curvature. The proposed graft is then outlined on the inner cheek, avoiding encroachment on either Stenson's duct or the vermilion border (Fig. 52B.23). Buccal mucosa grafts tend not to shrink. The edges of the proposed graft are infiltrated with 1:100,000 epinephrine for hemostasis, and then the graft is harvested by sharp dissection superficial to the buccinator muscle. The wound is sutured using 4-0 chromic catgut.

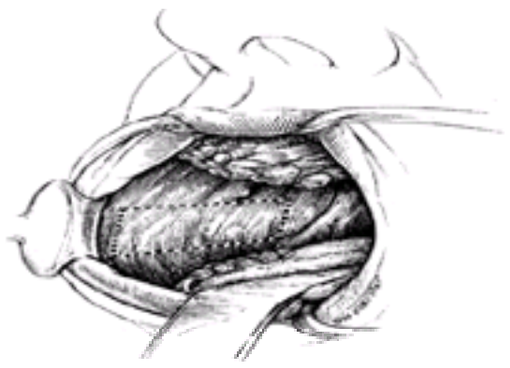

FIGURE 52B.23. Buccal mucosa graft. *Dotted line* indicates region for graft harvest avoiding Stenson's duct and the vermilion border.

All fat and muscle remaining on the graft is excised, and then it is sewn onto the dorsal urethra as an onlay patch. When necessary, tube grafts can be constructed by tubularizing a single wide graft or by combining two narrower strips.

Several considerations may influence the likelihood of graft take. First, it is important to cover grafts with well-vascularized tissues. The vascularity of ventral shaft skin and dartos is unreliable in extensive reoperations, so tunica vaginalis pedicles are used (128). We prefer to obtain these through a small scrotal incision that allows the pedicle to be generously mobilized proximally from the spermatic cord, minimizing the risk of penile tethering when it is tunneled to the surgical site. Second, histology of buccal grafts demonstrates greater intrinsic vascularity than seen with other tissues (45), yet the graft still must survive the initial period of imbibition and revascularization. Consequently, it is also important to immobilize the wound for at least 5 days and to minimize patient activity during this crucial phase of recovery. Urethral stents are used for urinary diversion for 14 days.

CONCLUSIONS AND FUTURE DIRECTIONS

TIP urethroplasty is applicable to nearly all distal and many proximal hypospadias anomalies, and it may also be useful in reoperations. The rare case with a urethral plate that is inadequate for incision and tubularization can readily be converted to another operative technique. The main limitation is severe penile curvature, which occurs in a minority of cases, usually with penoscrotal or more proximal defects. But if curvature limits options for urethroplasty, desire to preserve the urethral plate drives reconsideration of the means used to straighten the penis. For example, influenced by Mollard and Castagnola (91), we have elevated the plate from the corpora cavernosa to assist in penile straightening and then incised and tubularized it. Whether such maneuvers are advisable remains to be seen.

Despite more than 100 years of operative intervention for penile curvature, the cause of “chordee” and therefore the best means to correct it remain sources of controversy. As previously mentioned, we are accumulating specimens of the urethral plate, corpus spongiosum, and dartos and Buck's fasciae from boys with hypospadias, and our preliminary data challenge the concept of fibrous dysplasia of these tissues. This finding might be predicted from the normal development of the urethral folds, which, in the absence of androgen stimulation, differentiate into connective tissues within the labia minora. The practical importance of such observations is further evidence that there are rarely fibrous bands to excise in order to straighten the penis.

The algorithm proposed in this chapter for urethroplasty offers the hypospadiologist an orderly decision-making process using repairs with good functional and cosmetic outcomes and low complication rates. There are additional techniques not included in this review that some use with good results. Any operation that consistently yields good functional and cosmetic results can be a useful part of the surgeon's armamentarium. But if the choices for urethroplasty have recently been simplified, the standard for measuring success has also been raised. Furthermore, there are subtle nuances of technique applied by knowledgeable surgeons according to specific anatomic findings of individual cases, which defy description in a general chapter. Consequently, the occasional operator might best continue to avoid hypospadias repair, leaving it instead within the domain of the experienced hypospadiologist.

Prevailing psychologic theories state that three factors determine how a person will interact with society: sexual identity, personal goals, and lifestyle. Intersex disorders, or the simultaneous expression of female and male characteristics within the same individual, may lead to the patient's inability to define either psychologically or physically his or her sexual identity. The disorientation that results from an ambiguous sexual identity can lead to significant mental confusion, psychologic trauma, and the patient's dissatisfaction with his or her role in society. To successfully understand and manage the patient with an intersex disorder, the physician must be cognizant of the difference between the terms gender role and gender identity. *Gender role* is a person's sex as assigned by the physician, family, and society in general. G *ender identification* is a person's self-assigned sex. In individuals with intersex disorders, the pediatric urologist classically has been cast as the individual to reconstruct the dysfunctional anatomy to match the assigned gender role. Over the past decade, it has become apparent that the assigned gender role of some individuals with intersex disorders eventually will not match their gender identity. This chapter is written with the purpose of helping the physician better understand the relationship between sexual development, sexual identification, and intersex disorders.

SEXUAL DEVELOPMENT

Sexual differentiation follows the classic sequence of chromosomal sex determining the development of the fetal gonad, with the endocrine function of the gonad eventually establishing the sexual phenotype. Each step in the development of the sexual phenotype depends on the appropriate timing and function of the preceding event.

Chromosomal Sex

It is well established that the sexual phenotype of humans is determined by a chromosomal difference between the sexes, with females having two X chromosomes and males having one X and one Y chromosome. Two broad categories of sex ambiguity exist. First, if the genotype and the gonadal sex match but are incongruous with the phenotype, clinical evaluations usually reveal defects in either the synthesis of or lack of the end-organ response to sex steroids. Second, if the chromosomal sex is disparate from the gonadal sex, the etiology of the sexual ambiguity is usually a genetic abnormality. Most of the strides made in understanding how genes determine gonadal differentiation have come from the investigations of these latter individuals.

Genes Determining Development of the Bipotential Gonad

The gonad is believed to be bipotential, capable of forming into either a testis or an ovary until the sixth week of gestation. The initial formation of the bipotential gonad requires the function of at least three different genes: Wilms' tumor gene (WT-1), Fushi-Tarazu factor–1 (Ftz-F1), and LIM-1 (Fig. 52C.1) (123,208,213).

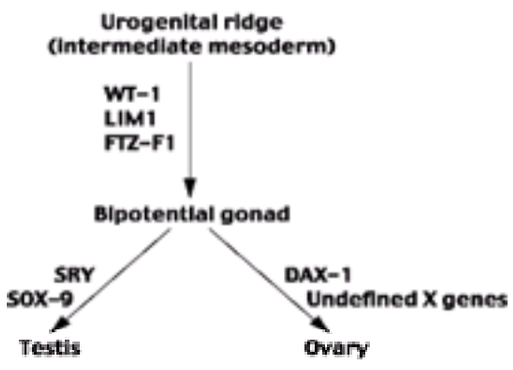

FIGURE 52C.1. Genes involved in gonadal development and gonadal differentiation.

Wilms' Tumor Gene (WT-1)

The best-characterized transcriptional regulatory factor known to be necessary for the development of the bipotential gonad is the Wilms' tumor suppressor gene (WT-1) located at the 11p13 locus. The WT-1 gene is variably expressed during different time points of embryogenesis in various organs. Its expression is mandatory for the development of both the kidney and the gonad. The development of the kidney and the testis arise from two diverse embryonic progenitor tissues: the kidney

arises from the ureteral bud and the metanephric blastema, and the testicle and epididymis arise from the primordial germ cells, the germinal epithelium, and the mesonephric duct. The WT-1 gene plays an integral role in the interaction between the various tissue components in organogenesis. In renal development, WT-1 is first manifested in the metanephric blastema and is mandatory for the induction of the ureteral bud from the mesonephric duct. Delayed or diminished WT-1 function early in the development of the kidney is alleged to be responsible for the development of ureteral bud abnormalities or renal agenesis. Later in renal development, activation of the WT-1 gene again appears to be necessary to organize the renal tubules. It is hypothesized that alterations in the function of the WT-1 gene at the latter point of organogenesis will lead to renal dysplasia or renal dysmorphism or induce abnormal mesenchymal epithelial interactions that will result in the production of a Wilms' tumor.

Within the testicle, WT-1 is first expressed within the germinal epithelium and is believed to coordinate the interaction between the germ cells, germinal epithelium, and mesonephric ducts. The absence of WT-1 function early in testicular development is believed to result in testicular agenesis. Disruption of WT-1 function later in organogenesis leads to the development of streak gonads and/or dysgerminomas.

In essence, abnormal WT-1 expression can affect the normal developmental process of the kidney and testicle along with the tumorigenic potential of the organs. In the clinical arena, WT-1 abnormalities have been found to be associated with sporadic cases of Wilms' tumor, WAGR syndrome (Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation) and Deny-Drash syndrome (congenital nephrotic syndrome, Wilms' tumor, and mixed gonadal dysgenesis) (38,111,123,124,147).

Location Chromosome 11p12-13

Location chromosome 11p12-13 (LIM-1) is a transcriptional regulator factor that serves as an intermediary messenger between the developing germinal epithelium and the mesonephric ducts during the organization of the gonad and between the collecting ducts and the renal tubules in the kidney. Homozygous deletions in mammals have been found to result in both renal and gonadal agenesis (123,181).

Fushi-Tarzu Factor –1 and the Regulation of Steroidogenic Factor–1

The main purpose of the Fushi-Tarzu factor–1 (Ftz-F1) gene in gonadal differentiation is to regulate the nuclear hormone receptor called steroidogenic factor–1 (SF-1). A functional SF-1 gene is necessary for the production of müllerian inhibitory factor (MIF) and several of the enzymes used in producing steroid hormones. Ftz-F1 is originally expressed in the urogenital ridge during gonadal development. As gonadal organogenesis continues Ftz-F1 ceases to be expressed within the developing ovary but continues to be expressed within the Sertoli cells of the developing testicle. FTZ-F1 upregulates the production of SF-1 within the Sertoli cells and is responsible for the transcription of the antimüllerian hormone gene, and subsequently, the production of MIF. Latter in embryogenesis, FTZ-F1 or SF-1 genes become expressed within both the ovary and testis. Inappropriate function of these genes at this time results in the inability of the gonad to maintain gonadal integrity and failure of the gonad to produce the appropriate steroid hormones necessary for sexual differentiation. It is currently hypothesized that a delayed or diminished FTZ-F1 or SF-1 secretion early in organogenesis results in complete gonadal agenesis with the persistence of the müllerian ductal systems. Inadequate secretion of the two transcriptional factors following gonadal development results in the inability of the individual to maintain the gonadal tissue, eventually resulting in the development of streak gonads and inadequate sexual differentiation (123,128,183,208,213).

Genes Affecting Testicular and Ovarian Differentiation

Once the bipotential gonad is formed, the next pivotal occurrence in sexual determination is the presence or absence of a gene located on the short arm of the Y chromosome, termed the *sex-determining region* (SRY). It is the activity of SRY and its interplay with SOX-9 and DAX-1 that determines if the fetus will develop either a testis or an ovary.

Sex-Determining Region of the Y Chromosome—SRY (Testicular Determination)

In the developing fetus, SRY production originates not from the germ cells but rather from the somatic cells of the urogenital ridge. This finding is consistent with the hypothesis that the germ cells are originally bipotential, the sex-specific gonad being determined by the secretion of SRY from the somatic cell lines. Clinically, three important observations have documented that SRY determines whether or not a testicle is formed: (a) The microinjection of the SRY gene into an XX fertilized ovum results in offspring with testes and male external genitalia, (b) 15% to 20% of human XY females have mutations in the SRY gene, and (b) the majority of XX males are found to carry the SRY gene (32,109,123,200).

SOX-9 (Testicular Determination)

The existence of another testicular determining gene in addition to SRY was identified because of the association of congenital skeletal malformations with 46,XY sex reversal. In this syndrome, known as campomelic dysplasia, 46,XY sex reversal is present in three-fourths of the affected males. Genetic evaluations of the sex-reversed males revealed a functional SRY. In an effort to explain how a 46,XY female could develop in the presence of a functional SRY, extensive genetic analyses were performed. The investigations revealed that the affected males have a translocation abnormality involving the SOX-9 gene located on the long arm of chromosome 17 (autosomal sex reversal).

SOX-9 is originally expressed within the urogenital ridge in both sexes before the appearance of SRY. SRY expression upregulates SOX-9 in the male. However, if no SRY is expressed (i.e., a female), SOX-9 is downregulated. It is currently believed that SOX-9 activation plays an integral role in the development of the epididymis and the interaction between the epididymis and the testis. Inadequate or delayed SOX-9 function is alleged to result in testicular dysgenesis. In addition to its role in testicular development, this gene also has been found to play a function in cartilage formation; hence, its diminished or abnormal function results in both skeletal abnormalities (campomelic dysplasia) and 46,XY sex reversal (105,190,205,221).

DAX-1 (Ovarian Determination)

According to classic Jostarian teaching, removal of the testes from a male fetus results in the development of female external and internal genitalia, that is, female phenotype by default. This concept, although true for the phenotypic expression of the individual, is not true for development of the gonads. Indeed, it is currently known that active genetic regulation of at least one gene is required for the development of a fully functional ovary. This finding arose from the investigations of 46,XY females with intact SRY locations. Chromosomal analysis of these patients revealed that duplications of the short (p21) arm of the X chromosome could overwhelm SRY function, resulting in a female gonadal determination and phenotype. The finding that duplicated Xp21 regions resulted in XY sex reversal gave rise to the concept that ovarian development was directly related to the number of copies of this gene, that is, dosage-sensitive sex reversal. Through careful investigation, the short arm of the X chromosome, a gene known as *DAX-1,* was eventually isolated and found to be responsible for ovarian determination. Examinations of the developing gonads reveal that DAX-1 is originally present in the bipotential urogenital ridge and gonads. The products of SRY and DAX-1 competitively compete for a regulatory protein known as the *steroidogenic acute regulatory protein* (StAR), with SRY having a higher affinity for the promoter. (The StAR protein facilitates the movement of cholesterol into the mitochondria for its conversion to pregnenolone—the first step in steroidogenesis.) In the normal male, individual SRY production overpowers the one functional DAX-1 gene, stimulates StAR activity, and subsequently results in testicular organogenesis and increased testosterone production. If two functional DAX-1 genes are present, DAX-1–induced proteins result in StAR downregulation, inhibition of testicular development, and ovarian organogenesis, that is, dosage-sensitive sex reversal (14,19,20,101,141,123,193,195).

Although the DAX-1 gene appears to play the key role in ovarian determination, other downstream X-linked genes appear to be required for complete ovarian development. This discovery arose from investigations of patients with only one functional DAX-1 gene, such as 46,XY males who are missing a functional SRY locus and patients with Turner's syndrome (45,X). The default gonadal pathway within these individuals is for testicular regression (unsuppressed solitary DAX-1 function) and ovary formation. Investigations of embryos with these deformities reveal that they originally form ovarian tissue; however, complete ovarian formation does not occur and a streak gonad eventually develops. These findings strongly suggest that other still-to-be-identified genes located on the X chromosome are necessary for complete ovarian development (22,42,123,214).

Hormonal Secretion and the Establishment of Sexual Phenotype

The sexual phenotype is chiefly determined by the appropriate hormonal function of the testis (Fig. 52C.2) (101).

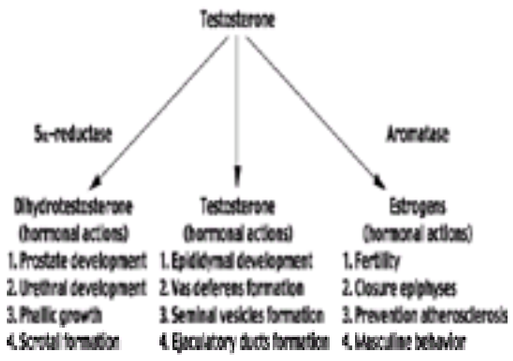

FIGURE 52C.2. Physiologic activities of testosterone in the male. Proper hormonal function determines the sexual phenotype and plays a large role in gender identity.

Müllerian Inhibitory Factor

Sertoli cells secrete MIF in a sexually dimorphic pattern beginning in the seventh week of gestation until puberty. In infants and prepubertal boys, MIF is a highly specific marker of testicular tissue. With puberty, secretion of this hormone by the testis decreases and ovarian production increases, eventually resulting in MIF values that overlap between the two sexes. In males, MIF's downregulation chiefly occurs as a result of androgen secretion. Without appropriate androgen function (e.g., in defects of androgen synthesis or action), postpubertal MIF levels may be elevated persistently because of the increased stimulation of the testicle (Sertoli cells) by elevated levels of gonadotropins [follicle-stimulating hormone (FSH)].

During normal physiologic development, MIF becomes bound to the MIF receptor present on the mesenchymal cells that surround the müllerian ducts. It is believed that MIF causes dissolution of the müllerian ducts by inhibiting the action of various growth factors. The production of MIF and the subsequent activation of its receptor are responsible for the regression of the uterus, fallopian tubes, and upper one-third to two-thirds of the vagina. MIF's secretion and subsequent action is the first hormonal event to occur in the development of the male phenotype. Following its normal activity, the only vestigial müllerian remnants left behind in the male are the appendix testis and the prostatic utricle. The appropriate timing of MIF secretion is critical because the müllerian ducts lose their ability to respond to MIF by the end of the eighth week of gestation.

MIF predominantly acts as a paracrine hormone, that is, a hormone that binds to nearby cells to affect their function. In patients with asymmetric gonadal differentiation (i.e., mixed gonadal dysgenesis) in whom a streak gonad is present on one side or in individuals who have an element of testicular dysgenesis present, the reduced volume of Sertoli cells results in diminished local levels of MIF. Clinically, this becomes manifest with the development of unilateral salpinx or hemiuterus. In essence, the degree of müllerian ductal persistence in intersexual disorders is directly related to the Sertoli cell volume of the ipsilateral testicle and the functional local levels of MIF (23,97,99,114,169,170).

Virilization of the Genital Tract

Virilization of the male fetus results from the activity of testosterone or its 5 a-reduced metabolite dihydrotestosterone. Under most circumstances, testosterone diffuses into the cell via an activity gradient. Inside the cell, it may be bound directly to the androgen receptor reduced by 5a-reductase to the more potent male hormone, dihydrotestosterone, or aromatized to the female hormone, estradiol (Fig. 52C.2).

For a target organ to be virilized, testosterone or dihydrotestosterone must bind to the androgen receptor. Both steroids bind to the same androgen receptor protein; the chief difference between the two is that the receptor's affinity for dihydrotestosterone is four to five times higher than that of testosterone. During embryogenesis, the enzyme 5a-reductase is known to be absent from the proximal wolffian ductal tissues. It is therefore believed that the direct diffusion of testosterone down the lumen of the wolffian ducts is responsible for the stabilization of the epididymis, vas deferens, seminal vesicles, ampullae of the vas deferens, and the ejaculatory ducts. Because of the low levels of testosterone secreted by the fetal testis and its weak affinity for the androgen receptor, testosterone cannot directly virilize the prostatic and penile urethra, prostate, penis, and scrotum. Formation of these latter masculine structures requires the beneficial support of the 5a-reductase enzyme and its more potent metabolite dihydrotestosterone. As can be determined from this discussion, absence of appropriate androgen receptor function results in resolution of the wolffian ducts and feminization of the external genitalia. In turn, absence of 5a-reductase enzyme results in normal formation of the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts; however, feminization of the external genitalia will be present (57,93,120,136,199,207,217).

Initial Testosterone Secretion: Gestational Weeks 7 to 12

The production of testosterone by the Leydig cells in the seventh to twelfth week of gestation is responsible for the masculinization of the penis. Whether a gonadotropin is responsible for this initial testosterone surge is controversial. For certain, we can state that an elevation in fetal luteinizing hormone (LH) is not the cause for testosterone secretion during this time because fetal LH is not produced until the twelfth gestational week. It is currently debatable whether the placental secretion of human chorionic gonadotropin (hCG) or the autonomous secretion of testosterone by the Leydig cell is responsible for the initial androgen surge. This argument is primarily centered upon whether or not the hCG and LH receptors, necessary prerequisites for gonadotrophic hormones to activate the testis, are absent from the fetal testis during this time interval. This controversy is still unanswered, with some laboratories demonstrating the presence of the gonadotropin receptors in the testis during this time, while others contest their findings.

Whether or not gonadotropins are responsible for this surge is important in understanding the pathophysiology of penile malformations. If gonadotropins do not play a major role in the production of the initial testosterone surge, the etiology of hypospadias and other penile malformations is due to either the delayed autonomous secretion of androgens by the Leydig cells and/or end-organ insensitivity. If, however, placental gonadotropins play a major role in the initial surge of testosterone, either gonadotropin malfunction (inadequate secretion of placental hCG), malfunction of the Leydig cell, or end-organ insensitivity may be responsible for these congenital abnormalities (3,31,34,39,90,119,171,194,220).

Testosterone Secretion After Gestational Week 12 and During the Neonatal Time Period

The fetal hypothalamic and pituitary gland initiate their function during the twelfth week of gestation, reaching neonatal peak values in the twenty-second week. Ironically, fetal serum testosterone reaches its peak in the fourteenth week of gestation and subsequently decreases in concentration. This reduction in fetal testosterone levels occurs despite the presence of an elevated fetal LH. The decline in testosterone is believed to be due to the direct suppressive effects of maternal prolactin and estradiol on testicular steroidogenesis. Between the eighteenth week of gestation and birth, no significant differences in serum testosterone levels are found between the male and female fetus. Fetal LH secretions also will be inhibited by elevated maternal estradiol and will nadir during the thirtieth week of gestation.

In the male infant, a vigorous rise in neonatal testosterone secretion occurs within the first 48 hours after birth. This brief postpartal surge in testosterone secretion is due to the loss of the direct inhibitory control of the maternal estrogen and prolactin on the Leydig cells of the testes; it is not correlated with an increased output of fetal LH. As the maternal estrogens and prolactin continue to decrease in the neonate's serum during the first postnatal week, a surge in LH secretion subsequently occurs. This postpartal LH surge is due to the removal of negative inhibitory effects of maternal estradiol and prolactin on the hypothalamus. The hypothalamus, freed from the effects of the negative feedback, increases the release of hypothalamic gonadotropin-releasing hormone (GnRH). Eventually, this translates into an increase in pituitary secretion of LH and an increase in the testicle's production of testosterone. Neonatal testosterone values usually peak during the second to third month of life. By the sixth month of life, testosterone will fall to sexually indifferent levels, where it will remain until puberty (39,44,90,102,103,142,219).

Feminization of the Genital Tract

According to classic Jostarin teaching, feminization of the internal müllerian ducts and external genitalia is an autonomous process. The evidence for this comes from Jost's classic experiments with gonadectomized male and female fetuses developing entirely along female phenotypes. Although this finding suggests that the female phenotype forms by default, it should be remembered that the female embryo is bathed in a “sea” of female hormones throughout embryogenesis. Unlike aberrant androgen receptor function, defects in the physiologic function of the estrogen receptor until recently were believed to be incompatible with life. Over the past decade,

several cases of partial estrogen resistance or aromatase deficiency have been documented to exist. These defects result in normal external male or female phenotypes; however, infertility of both sexes, an increased incidence of coronary atherosclerosis, and increased height are evident among the affected individuals. Although it was once believed that testosterone was responsible for closure of the epiphyses and cessation of skeletal growth, evaluation of patients with estrogen receptor defects have revealed that estrogen both initiates and completes skeletal maturation. Testosterone acts to close the epiphysis only via its aromatization to estradiol (84,101,110,188,191,197).

Androgen Imprinting

The physiologic purposes of the fetal and neonatal androgen surges are not fully understood. However, experimental studies have discovered that both fetal and neonatal testosterone may act to permanently imprint how an androgen- sensitive organ will respond to testosterone at puberty. In essence, lack of fetal or neonatal androgens at key points during embryogenesis results in a diminished capacity of the androgen-dependent organ to respond to testosterone at adulthood. At this time, fetal and neonatal androgen imprinting is believed to have two major effects: one central activity, related to masculine behaviors and one peripheral activity, related to how androgen-sensitive organs such as the prostate and seminal vesicles will grow in response to androgens in adulthood (13,55,90,148,158,163,203).

INTERSEX AND SEXUALITY

An infant who is born with ambiguous genitalia prompts two major concerns: Which gender role should be assigned? Will the patient's gender identity at maturation match the gender assignment? To assign a gender role, the physician must understand how an infant's gender identity is derived. To provide a basis for this knowledge, we review the impact of steroid hormones, genetic determination, and societal or familial nurturing on the establishment of gender identity.

Sexually Dimorphic Brain Structures

Critical to the understanding of sexuality and brain function is the knowledge that significant sexual differences in brain formation exist between the sexes. These sexually dimorphic areas—the preoptic area, the nucleus of the stria terminalis, the medial nucleus of the amygdala, parts of the cerebral cortex, the corpus callosum, and the main fiber tract connecting the cerebral hemispheres—have increased levels of androgen and estrogen receptors. During embryologic development, these regions possess several specific regulatory mechanisms unique to them. Specifically, the androgen receptor protein is generally considered as an autoregulatory receptor. Studies in the brain, however, have revealed that androgens can upregulate the production of the androgen receptor in the sexually dimorphic areas of the brain in both males and females. Upregulation of the androgen receptor in the developing brain results in a masculine brain configuration. In essence, the presence of androgens, not genetic makeup, appears to have a major impact on brain development in sexually dimorphic areas (71,85,86 and 87,126,132,135,175).

Imprinting of the Brain by Steroid Hormones: Effects on Brain Development and Sexuality

The current concept regarding imprinting the brain by steroid hormones is based on the perception that the human brain is bipotential with regard to sex. Brain development in the male or female direction is determined by the influence of the steroid sex hormones. The basic concept of this hypothesis is that the patient's genetic code determines whether or not testes or ovaries will develop. After gonadal determination occurs, it is the hormonal products of the gonads that establish both the sexual differentiation of the genitalia and the brain. In this theory, the same prenatal and neonatal testosterone surges that cause development of the internal masculine ducts and development of the external genitalia also impose masculinity on the brain. The masculine brain develops under direct hormonal influence, whereas the feminine brain forms in default—similar to the Jostarian theory for development of the müllerian ducts and external female genitalia.

Steroidal hormones have two major effects on the brain and behavior: activational and organizational. Activational influences typically occur in mature animals. They are transient and depend on the rise and fall of hormonal levels. A classic example of this is the waxing and waning of sexual interest in females during different phases of their menstrual cycle. The organizational ability of steroids on brain development is critical to the understanding of gender identification and intersexual disorders. Experimental studies have documented that alterations in the levels of fetal steroid hormones can sexually reverse the dimorphic areas of the brain, change the secretion patterns of gonadotropins, and permanently affect the adult's reproductive and nonreproductive behavior (e.g., aggression, ability to interpret geometric designs). It is noteworthy that the fetal hormonal influence on the organization of sexual behavior is not an all-or-none phenomenon. Male and female characteristics exist on a continuum, with the amount, duration, and timing of fetal and neonatal hormone exposure determining their position on the continuum (86,101,157).

Estrogen Hypothesis (Masculinization of Brain by the Aromatization of Testosterone to Estrogen)

Numerous laboratory studies have found that treatment of female fetal and or neonatal laboratory animals with high levels of estrogens enhances masculine behaviors and impairs feminine responses. Similarly, treatment of male rodents with aromatase inhibitors results in increased feminine traits. Although on the surface, the idea of estrogens enhancing masculine traits appears to be paradoxical, we now know that in the fetal central nervous system, testosterone serves as the primary source for estrogen. Within the developing fetus, estrogens are tightly bound by a-fetoprotein, making this steroid hormone relatively unavailable to the developing brain. a-Fetoprotein, the chief serum protein in the fetus has less of an affinity for testosterone, allowing free testosterone to readily enter into the cerebrospinal fluid (CSF). Once in the brain, testosterone has two major effects: (a) inducing production of its own receptor in the sexually dimorphic areas of the brain and (b) activating the androgen receptor, which upregulates the production of brain aromatase. Upregulation of brain aromatase in the sexually dimorphic areas of the brain results in the increased production of estradiol within these regions. The increased levels of estradiol are then responsible for developing the anatomic differences in the sexually dimorphic areas of the brain and establishing masculine traits.

It is interesting to note that in testicular feminized animals, testosterone freely enters into the CSF, but because of faulty androgen receptors, no induction of brain aromatase occurs. Failure of the activated androgen receptor to induce brain aromatase results in feminization of the brain. In partial androgen insensitivity syndromes, the development of masculinity is variable, depending on the activity of the androgen receptor (86,126,132,135,175).

Critical Time Periods for Sexual Organization of the Brain by Steroid Hormones

The ability of steroid hormones to affect the organization of the brain appears to have a significant timing variability among different species. The capability of steroids to organize the brain has been found to occur within three different time periods, depending on the species studied. The brains of most species of monkeys and guinea pigs were affected during the prenatal period only. Rats and mice brains were affected during the prenatal, perinatal, and immediate postnatal periods, and hamsters and songbirds brains were affected in the postnatal period only. The ability of steroid hormones to organize the brain in humans is currently unknown. Two major hypotheses exist; the first states that the critical time period for sexual organization in the human occurs only prenatally during gestational weeks 8 to 24. The alternative hypothesis is that both a prenatal and postnatal steroid organizational affect occurs simultaneously, with the peaks of fetal and neonatal androgen secretion, that is, gestational weeks 8 to 24 and postpartum during the first 6 months of life. This latter hypothesis is based on experimental findings in the rhesus macaque monkeys. Within this species, early exposure of female fetuses to androgens resulted in abnormal-appearing external genitalia and more masculine behavior, whereas exposure to androgens later in development or in the early neonatal time span resulted in normal-appearing external genitalia but variable degrees of masculine behavior. Using this hypothesis, various scenarios have been developed in which the timing of hormonal manipulations can produce masculine traits, feminine traits, bisexuality, or asexuality (40,66,67,69,70,117,156).

Steroid Hormones Organizational Effects on Gonadotropin Release

Exposure of the developing brain to steroid hormones determines the pattern of gonadotropin release established at puberty. Specifically, male and female mammals differ in their patterns of gonadotropin release. In females, gonadotropins are released in a cyclic fashion, producing the fluctuations of ovarian hormones associated with the menstrual cycle. In males, gonadotropin release is secreted in a more constant fashion, with some diurnal variation. This results in the production of high, fairly constant levels of testosterone in adulthood. In experiments carried out in rodents (species in which perinatal organization of the brain occurs), the ability to obtain either a cyclic or tonic secretion pattern of gonadotropins appears to be regulated by the levels of testosterone secreted during perinatal life. Inadequate testosterone secretion in male rat pups in the perinatal time span results in the cyclic secretion of gonadotropins in adulthood, with affected adult males being able to support implanted ovaries. Similarly, treatment of female rat pups with testosterone shortly after birth prevents the cyclic release of gonadotropins (66,86).

Effects of Prenatal, Perinatal, and Postnatal Steroids on Reproductive Behavior

In rodents, testicular hormones have a dramatic influence on the development of reproductive behavior in the male and female. When testosterone is administered to female rodent pups (remember rodents are perinatal in brain organization), their reproductive behavior is permanently altered. For example, if the androgenized

female pups are given estrogens and progesterones as an adult, they will not demonstrate routine female sexual behavior, that is, lordosis (a posture characterized by an arched back showing receptivity to a male); rather, the androgenized females will demonstrate masculine behavior by mounting receptive females. Similarly in nonandrogenized male pups given androgens as an adult, they will not demonstrate routine male sexual behavior; that is, they will not mount sexually receptive females; rather, the nonandrogenized males will show lordosis and be receptive to males. In keeping with the concept that estrogen secretion plays little if any role in sexuality, female rat pups oophorectomized at birth and given activating doses of estradiol and progesterone as adults, will act as females. If given testosterone, they are no more likely than any normal female to show male behavioral patterns. However, there is some controversy regarding whether the neonatal ovarian secretions enhance the quality of feminine behavior. In any event, it appears as if testosterone, not estrogens, predominantly determine sexual behavior (69,70).

Although the behavior of animals in response to prenatal, perinatal, and neonatal steroids may be studied in a regulated fashion and conclusions derived from these investigations, it is far more difficult to evaluate the organizational effects of prenatal and postnatal steroids on sexual behavior in humans. This area of clinical investigation is fraught with hazards regarding interpretation of the data. Investigators often have preconceived concepts, the number of cases are small, and the hormonal defect present may be individualistic. Conclusions from human studies should therefore be interpreted with great caution until numerous studies from various authors can confirm similar findings.

When sexual behavior in intersex disorders is evaluated, two specific sexual traits are usually measured: (a) gender identity, the sense the person has of being either male or female and (b) sexual orientation. When the data regarding intersex are interpreted, it is important to note that abnormalities in gender identity normally occur in approximately 1 in 30,000 men and 1 in 100,000 women. The incidence of homosexuality in both males and females without an associated intersex disorder appears to be approximately 5% (8,96).

Information regarding the ability of prenatal and neonatal hormones to influence sexual orientation in the human has largely come from the studies of patients virilized secondary to congenital adrenal hyperplasia and from diethylstilbestrol (DES)-exposed female fetuses. Regarding the ability of excess androgens to affect sexual orientation in women with congenital adrenal hyperplasia, the data are controversial. Two studies, one from the United States and another from Germany, found that these women were more likely to have bisexual or homosexual interests (47,48,145). In contrast, another key study demonstrated that both homosexual and heterosexual interests were reduced in women with congenital adrenal hyperplasia compared to normal controls (224). Interpretation of these papers and the data regarding sexual orientation of women virilized by congenital adrenal hyperplasia is extremely difficult. The success and type of the genital reconstruction procedures were not taken into consideration. (Could the success of the surgical procedures affect sexual orientation?) In addition, the adequacy of hormonal control of the patient often is not stated. Because sexual interest requires appropriate hormonal activation, it is possible that either inadequately suppressed or oversuppressed adrenal function in patients with congenital adrenal hyperplasia could have resulted in alterations in sexual interest.

In an effort to clarify this issue, sexual orientation studies of DES-exposed women have been performed. It is noteworthy that high levels of DES in rodents and rhesus monkeys does not affect the development of the female external genitalia, but they do masculinize the brain (69,70). Evaluation of DES-exposed women regarding their sexual orientation has confirmed an increase in bisexual and homosexual activity, while physical examinations have revealed normal external female genitalia. The findings that DES-treated females have a higher incidence of homosexuality rules out the possibility that abnormalities of the female sexual organs discouraged heterosexual interests and significantly strengthens the conclusions that hormones influence the brain mechanisms involved with sexual orientation (86,138,140).

Scientific evidence also indicates that hormones contribute to the development of gender identity. This concept is predominately supported by data from three different sources: (a) women with virilizing congenital adrenal hyperplasia, (b) males with 5a-reductase deficiency who were raised as females, and (c) male infants raised as females following neonatal penile ablation. In all three scenarios, the fetuses were exposed to high levels of androgens and their brains should subsequently have been masculinized. When evaluating women with virilizing congenital adrenal hyperplasia, most of the patients have a female gender identity; however, the incidence of gender dysmorphia—the patient choosing to switch from a female to a male gender identity—is significantly higher than normal (138,224,225).

Lending further support to the argument that hormones may establish gender identity is the information regarding 5a-reductase patients. Individuals with this enzymatic deficiency are born with a diminutive phallic structure associated with severe penoscrotal hypospadias and bilateral cryptorchidism. However, the brain should be masculinized because testosterone metabolized to estradiol by the enzyme aromatase is responsible for masculinization of the brain. If the neonate is incompletely evaluated at birth, the appearance of the external genitalia is feminine and the infant may be assigned to a female sex and raised as a girl. At puberty, the external genitalia virilize, and in many cases, the patients will preferentially switch to the male gender identity (95). In final support of this hypothesis are the reports of two different infants who had their penis ablated during a circumcision, one at 2 months of age the other at 7 months of age. Both were reassigned to the female gender and surgically repaired to have female-appearing genitalia. The child who had his penis ablated at 2 months of age is currently 26 years old and has accepted a female gender identity. This patient is predominantly sexually attracted to females but has been sexually active with both men and women. She has characterized her own sexual identity as bisexual. With maturation, the patient whose penis was ablated at 7 months of age became unhappy with his female role and underwent phallic construction at 25 years of age. He is now living as a male (26,46,225).

Regarding the ability of steroids to affect the sexual behavior of humans, we would caution the reader that the degree of virilization of the external genitalia at birth does not necessarily correlate with the sexual behavioral outcome and gender identity. Genital formation occurs between gestational weeks 8 and 12 and is the result of the combined influence of testosterone secretion, 5a-reductase activity, functional androgen receptor, and end-organ responsiveness. In contrast, sexual behavioral outcomes are based on the combination of testosterone secretion, a functional androgen receptor, and brain aromatase activity during gestational weeks 8 to 24, with possible fine tuning of sexual behavior modified by the postpartal androgen surge during the first 6 months of life. Clinical confirmation that external genital size and development are not correlated to sexual behavior can be found in the fact that most genetic females with virilization due to congenital adrenal hyperplasia are assigned to the female gender and reared as girls. When these individuals are evaluated in adulthood, most are pleased with their sexual assignments. Corroborating the fact that genital size and development at birth cannot predict the adult's sexual behavior may be found in genetic males with 5a-reductase deficiency. Individuals with this disorder have hypospadiac micropenis at birth. Even if raised as girls, almost all invariably adopt a male gender role in adulthood as their phallic structure grows in response to testosterone (86,95,225).

Genetic Determination of Sexual Behavior

“We used to think our fate was in our stars. Now we know, in large part our fate is in our genes” (209). The power of new scientific technologies has revolutionized the biologic underpinning of many human traits. Geneticists using linkage studies have reported the location of many genes that can be correlated to human behavior. Locations of genes related to psychiatric illnesses, alcoholism, aggression, and sexual orientation have been published. Indeed, in 1991 Drs. Bailey and Pillard reported on the finding that a substantial genetic component to homosexuality exists. Bolstering this concept was the finding by Dr. Simon LeVay, who noted a relationship between brain structure and homosexuality. Indeed, implicit in these researchers' writings is the argument that homosexuality should be accepted because if an individual's sexual behavior is genetically based, then men or women have little choice over their sexual orientation, a concept called genetic fatalism. Genetic fatalism is the perception that if a behavior is in our biologic codes, it is fixed and unchangeable. This hypothesis is unnerving to some geneticists and physicians because of its similarity to the “eugenics theory” indorsed by the Frankfort Institute of Hereditary and Biology in the 1920s and 1930s. Specifically, at that time, researchers in the United States and Western Europe had discovered that the intelligence quotient (IQ) scores of African Americans and eastern Europeans were lower than standard norms. They subsequently failed to assess the social or educational environment as possible causes for the inferior scores. Instead, they leapt to the conclusion that African Americans and Eastern Europeans were biologically inferior. The Ku Klux Klan and the Nazis used this “scientific finding” as a reason for the persecutions of African Americans in the southern United States and for the termination of the Jews and Eastern Europeans during World War II. Several scientists currently fear that finding a genetic basis for sexual behavior would not lead to an increased acceptance of homosexuality, but rather to the development of a method that could identify and purify the gene pool to prevent its sexual degradation (6,9,10 and 11,72,78,118).

At this time, it is unknown how much of the sexual behavior of an intersex patient could be determined by direct genetic influence. It is hoped that with completion of the human genome project that scientists could establish normal genetic standards for gender identity. If this could be done, comparisons of the genetic code of intersex patients to normal standards for individuals who have accepted a male or female gender could aid the physician in determining sexual assignment. Unfortunately, use of genetic technologies for this purpose strikes at the very heart of scientific fears.

Familial and Societal Impact on Sexuality (the Nurturing Hypothesis)

Psychiatrists have argued for decades whether nature (biologic factors) or nurturing (social factors) will eventually determine an infant's sexuality. How the family and society influence the sexuality of the intersex patient is difficult, if not impossible, to measure. The nurturing hypothesis states that the sexual identity of an individual is largely determined by the parental interpretation of the genitalia's appearance. The parental perception of the child's sexual gender affects how he or she is dressed, hairstyles, and physical activities. Psychosexual development and the establishment of gender identity are therefore based on social contact. Imitation of

same-sex specific activities combined by differential reinforcement by the child's parents, siblings, and peers establishes the individual's gender identity. According to this hypothesis, social imprinting overrules the genetic determinants and the fetal/neonatal hormonal milieu the infant was exposed to. At this time, several scientific reports disprove this theory. Although there is little doubt that nurturing plays a role in sexual determination, it is too simplistic to believe that nurturing alone establishes an individual's sexual identity (26,46,52,139,143).

INTERSEXUAL DISORDERS

Evaluation of the Intersex Child

History and Physical Examination

Clinical evaluation of the infant with an intersex disorder begins with a carefully taken historical evaluation. Particular attention is given regarding maternal medications used just before or during pregnancy. A family history should be obtained with direct inquiry regarding the possible presence of genital defects or infertility in the father, siblings, or other close male relatives.

Physical examination should include observation of the skin for abnormal skin pigmentation. In infants with congenital adrenal hyperplasia, excess adrenocorticotropic hormone (ACTH) secretion may result in increased skin pigmentation of the aureole and external genitalia. Palpation of the abdomen for masses and evaluation of the infant for an imperforate anus or cloacal abnormality are necessary. Indeed, in our experience, approximately 25% of cloacal abnormalities were originally misdiagnosed as an intersex disorder (4). The appearance of the external genitalia should be recorded and, if the parents allow, photographed. Care should be given to note the size and shape of the phallus. A well-developed phallus suggests the presence of circulating high levels of androgens, associated with a functional androgen receptor and 5a-reductase enzyme. The position of the urethral meatus should be recorded. The symmetry of scrotal development is evaluated. Asymmetric scrotal development suggests the presence of functioning testicular tissue on the well-developed side. Palpation for the presence of gonadal tissue is imperative for the initial differential diagnosis. I would caution the reader that appearance of the external genitalia may vary widely in patients with the same condition; therefore, the definitive diagnosis should not be made on physical appearance alone.

Buccal Smear

A buccal smear for the presence of a Barr body (inactive second X chromosome) or fluorescein *in situ* hybridization stains for the presence of a Y chromosome may be performed. We have found these tests to be quick and insightful in the evaluation of infants with suspected congenital adrenal hyperplasia. It is, however, our opinion that the limited results of these tests are insufficient for the complete genetic evaluation of the neonate with an intersex disorder, and in all circumstances, a full karyotype evaluation is necessary.

Karyotype

A karyotype may be available within 24 to 72 hours, depending on the facility. The result of this genetic evaluation along with the physical examination classically is used to classify intersex disorders into its categories (Fig. 52C.3) (5).

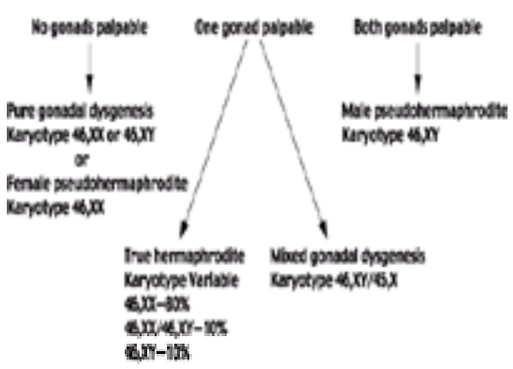

FIGURE 52C.3. Schematic for the initial workup of the infant with an intersex disorder. Schematic for rapid evaluation of an infant with an intersex disorder.

Metabolic Studies

Infants should be evaluated for hypoglycemia, hyponatremia, hyperkalemia, and metabolic acidosis, chemical imbalances that can develop with untreated congenital adrenal hyperplasia. A rapid assay for 17a-hydroxyprogesterone should be performed to rule out 21-hydroxylase deficiency. In addition, a timed urine collection for elevated titers of 17-ketosteroids and pregnanetriol is obtained for completeness. Serum samples from both the infant and the mother for testosterone levels are acquired. The maternal testosterone levels are obtained to rule out exogenous maternal steroid ingestion or the presence of a functional maternal adrenal or ovarian tumor as the cause for virilization of a female infant. The infant's serum testosterone level is evaluated to ascertain testicular function. Male neonatal testosterone levels are rapidly fluctuating during the first 6 months of life; we therefore measure testosterone levels at the time of the initial evaluation and again at 2, 4, and 6 months of age (39,44,90,102,103,142,219).

In 46,XY males with bilateral impalpable gonads, determination of müllerian inhibitory substance (MIS) has been touted to aid in determining if functional testicular tissue is present. Specifically, serum MIS values that are normal (greater than 5 ng/mL) are indicative of testicular function. Low or undetectable levels of MIS suggest either anorchia or the presence of dysgenetic gonads. Unfortunately, low or undetectable levels of MIS alone are not conclusive enough to diagnose anorchia. In these situations, the physician must proceed with either surgical exploration or laparoscopy to confirm the absence of a dysgenetic testis. Because of the continued need to confirm anorchia by surgical means, measurement of MIS values in our experience does not significantly help the diagnostic investigations of the intersex patient (75,98,115).

Human Chorionic Gonadotropin and Pituitary Functional Evaluations

Some experts believe that hCG stimulation tests and pituitary functional investigations are helpful in infants with nonpalpable gonads who fail to demonstrate the appropriate neonatal rise in testosterone. We do not routinely use these evaluations because of two major concerns: (a) A positive test response only determines the presence of functional testicular tissue and does not adequately define the intersex condition, and (b) a negative response to the initial hCG stimulation test is associated with a 15% false-negative rate; that is, although functioning testicular tissue is present, there is little to no increase in testosterone in response to hCG. (Note: Serum testosterone should rise tenfold in response to the hCG stimulation test. Absence of a tenfold rise is indicative of either absent testes or substrate depletion in the chronically understimulated hypogonadotrophic male.)

Although we do not routinely use the hCG stimulation tests to aid in the diagnosis of the intersex child, we do use an hCG trial to confirm the absence of testicular tissue in true hermaphrodites being raised as females. In this circumstance, we perform the test approximately 1 month after all functional testicular tissue has presumably been removed. To perform the hCG stimulation test, baseline FSH, LH, MIS (helps rule out the presence of functioning testicular tissue), and serum testosterone levels are obtained before hCG stimulation. A dose of hCG is administered at 100 IU/kg (maximum of 1,500 units hCG) every 48 hours for three doses, administered over 3 days (i.e., Monday, Wednesday, and Friday). A serum testosterone is again obtained 12 hours after the third injection. The presence of functioning testicular tissue is documented if there is a tenfold rise in testosterone over the baseline value. If a tenfold rise is absent, a chronic hCG stimulation test may be performed at the physician's discretion. Performance of a chronic hCG trial takes 6 weeks to perform, but it significantly enhances the ability of this test to determine the presence of functional testicular tissue. A chronic trial of hCG is administered at a similar dosage as noted before but is given every fifth day for 6 weeks. A repeat serum testosterone level is taken at the end of the sixth week. A serum testosterone value of less than 200 ng/dL is indicative of the absence of testicular tissue (75,90,98,115,121,172).

Radiographic Studies

The mainstay radiographic studies obtained in evaluating the neonate with intersex disorders are the abdominal and pelvic ultrasound, genitogram, and on occasion, the pelvic magnetic resonance image (MRI). Abdominal and pelvic ultrasonography usually demonstrate müllerian structures lying behind the bladder in most cases of female pseudohermaphroditism, true hermaphrodites, and mixed gonadal dysgenesis. The ultrasound also may be used to assess for the location of the gonads. Unfortunately, in our experience, the ability of ultrasound to detect the presence or location of the gonads has been highly variable. The genitogram, a simultaneous voiding cystourethrogram and vaginogram, is extremely useful in determining the presence of a vagina, the vaginal size and configuration, and the level at which the vagina opens into the urogenital sinus. It is also helpful in confirming the ultrasound findings of a uterus by identifying the presence of a cervical impression within the vaginal vault. On occasion, we have found a pelvic MRI study to be of significant help when we have discordant findings between the ultrasound and genitogram evaluations.

Vaginoscopy and Cystoscopy

Examination of the urogenital sinus is imperative before surgical reconstruction. It allows physicians to confirm the location of the vaginal opening and the presence or absence of a cervix. We often use these procedures to place glide wires and, subsequently, Foley catheters into the vaginal vault and the bladder. Placement of catheters into these structures facilitates their proper identification during the subsequent surgical dissection.

Gonadal Biopsy, Laparoscopy, and Exploratory Laparotomy

The intersexual abnormalities of congenital adrenal hyperplasia and some forms of androgen insensitivity are made by metabolic evaluations; all other intersex disorders require a gonadal biopsy and histologic evaluation of the gonadal tissue for appropriate diagnosis. Palpable gonads may be exposed for biopsy by an inguinal incision, whereas impalpable gonads are approached by either a low Pfannenstiel incision or laparoscopy. In either case, the gonad must be fully exposed. When mobilizing the gonad, the physician must pay attention to the adjacent tissues for either wolffian or müllerian ductal structures. Bilobar or elongated gonads are consistent with either a true hermaphrodite or dysgenetic gonads. If the gonad is bilobar, biopsies must be taken from each lobe. If the gonad is ovoid and homogenous, it is recommended that the gonad is deeply bivalved, and biopsies should contain both peripheral and central gonadal tissue. This is imperative because ovarian and testicular tissues may overlie one another, causing superficial biopsies to miss the underlying component. Frozen sections of the tissue are evaluated. If dysgenetic tissue is present, we prefer to remove the gonad at this time. If frozen sections reveal both ovarian and testicular tissue, we usually remove the gonadal tissue that is inconsistent with the assignment of the sex of rearing at this setting (1).

CLASSIFICATION OF INTERSEX DISORDERS

Female Pseudohermaphrodites

Female pseudohermaphrodites are characterized by a 46,XX genotype, nonpalpable gonads, (i.e., normal ovaries), and a variable degree of virilization of the external genitalia. Congenital adrenal hyperplasia is the cause of female pseudohermaphroditism in more than 95% of the cases; the remaining virilized female infants are usually due to excess maternal androgens. Two different enzymatic deficiencies are predominantly responsible for the virilizing sexual ambiguity of congenital adrenal hyperplasia, 21-hydroxylase deficiency and 11b-hydroxylase deficiency. Both are inherited recessive disorders, and genetic counseling of affected families should be obtained (113,212).

Virilizing Congenital Adrenal Hyperplasia: 21-Hydroxylase Deficiency

More than 90% of the cases of congenital adrenal hyperplasia result from 21-hydroxylase deficiency. The enzyme 21-hydroxylase catalyzes the conversion of progesterone and 17a-hydroxyprogesterone to deoxycorticosterone (DOC) and deoxycortisol, respectively (Fig. 52C.4). Enzymatic blockade results in a reduced output of cortisol. Because cortisol negatively feeds back to the pituitary to stop ACTH secretion, loss of cortisol production results in increased ACTH production. In turn, the increased ACTH production drives the adrenal to attempt to make more cortisol. This eventually causes the increase in the concentration of the metabolites above the enzymatic block, particularly, 17-hydroxyprogesterone and 17-hydoxypregnenolone. These latter substances are metabolized to androgens and result in the virilization of the fetus.

FIGURE 52C.4. Pathway for cortisol synthesis: defects in steroid biosynthesis associated with intersex disorders. Both feminizing (defects in the enzymes: 20,22-desmolase, 3b-OH steroid dehydrogenase, 17a-hydroxlyase and 17,20-lyase) and masculinizing forms of congenital adrenal hyperplasia (defects in the enzymes: 21-hydroxylase and 11b-hydroxlyase) are known to exist.

This hereditary disorder is due to a mutation on the short arm of chromosome 6 that encodes for the 21-hydroxylase enzyme. Three forms of 21-hydroxylase deficiency exist: classic, simple virilizing, and nonclassic disorders. The three disorders are due to variable activity levels of the gene. The classic disorder is defined by the combination of salt wasting and virilization, the simple virilizing disorder is manifested by virilization and no salt wasting, and the nonclassic disorder has normal genital differentiation but becomes manifest by postpubertal virilization. The nonclassic 21-hydroxylase deficiency has a rather high incidence of occurrence with approximately 1% of the population manifesting this genetic abnormality (15,113,218).

The diagnosis of 21-hydroxylase deficiency is suspected in a masculinized infant without palpable gonads. In general, the salt-wasting forms of this disorder are manifested by the most severe virilization of the external genitalia. Pelvic ultrasound documents the presence of a uterus. Chromosomal analysis reveals a 46,XX karyotype. Metabolic evaluations reveal significantly elevated levels of 17-hydroxyprogesterone and adrenal androgens (androstenedione). If assessed, 24-hour urine values for 17-ketosteroids and pregnanetriol are elevated (Fig. 52C.4).

If this disorder goes unrecognized, approximately three-fifths of the affected infants will develop vomiting dehydration, hyperkalemia, and circulatory collapse due to the reduction of aldosterone production within the first 2 weeks of life. In children with the salt-wasting form of this disorder, plasma renin levels are significantly elevated. Measuring the plasma renin to urinary aldosterone ratios is therefore frequently used to monitor adequacy of medical therapy. Elevated ratios are indicative of salt loss and poor medical control. If 21-hydroxylase deficiency is left undiagnosed or is poorly treated, the infants grow rapidly, developing a muscular build with precocious growth of pubic hair and increasing phallic enlargement. Bone age becomes advanced and the epiphyses fuse early. Menstruation and breast development are inhibited (113,122,161,218).

Although the diagnosis is almost invariably made on metabolic evaluation and confirmed by karyotype and radiologic findings, if laparoscopy or surgical exploration is performed, it reveals the presence of only müllerian structures. The wolffian ductal structures having already regressed by the time the adrenal androgens reach high concentrations (113,218).

Virilizing Congenital Adrenal Hyperplasia: 11b-Hydroxylase Deficiency

Abnormalities in 11b-hydroxylase activity occur as a result of genetic mutations located on the long arm of chromosome 8. Deficiency in this enzyme accounts for approximately 9% of the individuals with congenital adrenal hyperplasia. Loss of this enzyme's activity results in the accumulation of both 17- hydroxyprogesterone and the salt-retaining metabolites DOC and 11-deoxycortisol. Unlike 21-hydroxylase deficiency, for which the onset of hypovolemic shock is a significant risk, infants affected with 11b-hydroxylase deficiency are often hypertensive because of mineralocorticoid excess. Hypokalemia, however, may be of significant concern because of the increased mineralocorticoid secretion with resultant potassium wasting. The genital ambiguity of the affected infant is highly variable, depending on the activity of the enzyme. Clinically, poor to no correlation can be found between the degree of virilization, the extent of the patient's hypertension, and hypokalemia. Diagnosis of this enzymatic defect is confirmed by finding high levels of 17-hydroxyprogesterone, DOC, and 11-deoxycortisol (Fig. 52C.4). Plasma renin levels are usually very low because of the excess secretion of mineralocorticoids (113,211,212).

Congenital Adrenal Hyperplasia: Prenatal Diagnosis and Maternal Treatment

In families with a history of congenital adrenal hyperplasia, prenatal therapy with dexamethasone, initiated before the tenth week of gestation, can significantly reduce the risk of female virilization. Ideally, once pregnancy has been confirmed in a family with a positive history of congenital adrenal hyperplasia, the mother is started on dexamethasone 20 µmg/kg given twice daily beginning at the fifth week of gestation. Confirmation that the genetic abnormality for congenital adrenal hyperplasia is present may be performed by two different methods. At 9 to 11 weeks of gestation, chorionic villus samples can be obtained for both karyotype analysis and for the presence of the CYP 21 gene, the gene responsible for the most common type of congenital adrenal hyperplasia, 21-hydroxylase deficiency. An alternative to chorionic villus sampling is to wait to 15 to 18 weeks of gestation and analyze the amniotic fluid for the karyotype, CYP 21 expression and 17-hydroxyprogesterone levels. The latter evaluation is useful for the other forms of congenital adrenal hyperplasia. If the fetus is found to be either a male or if no evidence of congenital adrenal hyperplasia is present, the dexamethasone is discontinued (137,180).

Congenital Adrenal Hyperplasia: Postnatal Treatment

Medical therapy involves treatment with hydrocortisone. This medication replaces the corticosteroid deficiency and prevents overstimulation of the adrenal glands by ACTH. In patients with salt-wasting disorders or in individuals who are found to have elevated renin levels, mineralocorticoid therapy with 9a-fluorohydrocortisone (Florinef) is done to prevent salt wasting and/or hypokalemia. Efficacy of pharmacologic therapy is ascertained by intermittent measurements of serum 17-hyroxyprogesterone, serum renin-to-urinary aldosterone ratios, and serum testosterone. Gender assignment should always be female. Most physicians advocate early feminizing surgery, including clitoroplasty, feminizing genitoplasty, and vaginoplasty (15,122).

Maternal Medications and Tumors: Effects on Fetal Phenotype

Progesterone is used to prevent abortions in the first trimester of pregnancy, especially following *in vitro* fertilization. Progesterone can effect the developing fetus in various ways. In high concentrations in the female fetus, it can act as a weak androgen by binding to the androgen receptor. In the male infant, it can impair androgen activity by directly interfering with the synthesis of testosterone by the testis, cross-regulate (downregulate) the androgen receptor and competitively inhibit testosterone activity by acting as a substrate for 5a-reductase. In essence, progesterone can virilize a female infant and feminize a male. In the female infant with virilization or the male infant with hypospadias and cryptorchidism, a careful maternal history for the use of progesterone should be ascertained to rule out this cause as a possible etiology for the abnormal phenotype (27,151,159,184).

Maternal tumors, especially luteomas of the ovary, have been associated with virilization of the female fetus. To rule out excess production of androgen by the mother, we obtain a maternal blood sample at the time we evaluate the neonate with an intersex disorder. If a diagnosis of female pseudohermaphroditism is made, we analyze the maternal blood sample for the presence of androgens (129,204).

Male Pseudohermaphrodites

This category of intersex abnormalities is characterized by a 46,XY genotype, normal testes (bilaterally palpable gonads), with either partial or complete failure of the external genitalia to masculinize. The presence of müllerian ductal structures is variable, depending on the cause of the disorder. Male pseudohermaphroditism may occur as a result of a defect in any of the three events required for virilization: androgen synthesis, androgen action, or müllerian ductal regression.

Defects in Androgen Synthesis via the Adrenal Glands and Testicles

Feminizing Congenital Adrenal Hyperplasias: 3b-Hydroxylase Deficiency, 17a-Hydroxylase/17,20-Lyase Deficiency, and 20,22-Desmolase

Deficiency in any one of the steroidogenic enzymes—3b-hydroxylase, 17a-hydroxylase/17,20-lyase and 20,22-desmolase—results in the insufficient secretion of both adrenal and gonadal steroids. These disorders occur rarely and frequently are fatal. Because of the locations of the enzymatic blockade, the male infant cannot form the more potent androgens, androstenedione and testosterone (Fig. 52C.4). Affected males have either proximal hypospadias (usually perineal in location, with or without associated cryptorchidism) or complete failure to virilize. Females may exhibit mild clitoromegaly. Females are always assigned to the female gender. Male gender assignment is usually based on the ability of the phallus to enlarge in response to androgens (1,25,149,185,222).

Deficient Androgen Synthesis via the Testis

17b-Hydroxysteroid Dehydrogenase Deficiency

The enzyme 17b-hydroxysteroid dehydrogenase is mainly limited to the testis. It serves to catalyze the conversion of androstenedione to the more potent androgen testosterone. Defects in this enzyme are inherited in an autosomal-recessive pattern and are usually seen in Arabs from the Gaza strip. Males with 17b-hydroxysteroid dehydrogenase (17b-HSD) deficiency, also known as *17-ketosteroid deficiency,* have a feminine external genitalia associated with a mild to moderate degree of clitoral hypertrophy. The urethra and a blind ending vaginal pouch have separate ostium. Wolffian ductal derivatives are present suggesting that androstenedione is a potent enough androgen to stabilize these structures. The testes may be located anywhere from an intraabdominal position to the labial folds. Diagnosis is made at puberty, when penile growth and the development of male secondary sexual characteristics occur. The virilization that develops at puberty is due to increased levels of serum androstenedione with the conversion of the androstenedione to testosterone by nonmutant 17a-HSD isoenzymes in nontesticular locations. This virilization also is aided by the pubertal increase in activity of 5a-reductase enzymes. Gynecomastia may simultaneously occur within affected individuals at puberty as a result of the peripheral conversion of high levels of androstenedione to estradiol by aromatase. Gender conversion at puberty from the female sex of rearing to a male gender identity is the norm. It is noteworthy that some subjects have undergone clitoroplasty, gonadectomy, and vaginoplasty to the female gender in infancy. Unfortunately, no long-term results regarding their long-term gender identity have been forthcoming. Diagnosis is based on an increased level of serum androstenedione to testosterone in postpubertal patients and or an increase in this ratio following hCG stimulation in prepubertal patients. If identified in the neonate or prepubertal infant, testosterone therapy to enlarge phallic size, reconstruction of the hypospadias, and assignment of the infant to the male sex of rearing is recommended (15,74,94,177).

Leydig Cell Agenesis

Leydig cell agenesis, a rare disorder, is characterized by a male genotype, female levels of testosterone, no response of the testes to hCG stimulation, and the absence of Leydig cells on testicular biopsy. The clinical appearance of affected individuals is usually that of a feminine external genitalia with mild clitoromegaly with the urethra and a short blind ending vaginal pouch having two separate ostium. On rare occasions, genital ambiguity or micropenis is noted suggesting that Leydig cells once had been present but subsequently disappeared. Testicular position varies from intraabdominal to intralabial in location. Wolffian ductal structures are present and müllerian ductal structures are absent. Most patients present with the complaint of primary amenorrhea in the late teenage years. Diagnosis is made by the combination of karyotype evaluation, endocrine analysis, and testicular biopsy. Patients invariably gender identify as female. Female sex of rearing, orchiectomy, vaginoplasty, and estrogen replacement therapy are standard (142).

Defects in Androgen Action

Complete Androgen Insensitivity

Complete androgen insensitivity (CAIS), also known as *testicular feminization syndrome,* arises either *de novo* in the infant or is inherited in an X-linked recessive pattern. A female phenotype, a male karyotype, and bilateral testes characterize this disorder. The phenotype of individuals with CAIS is so classically feminine that affected individuals are not usually diagnosed at birth. Characteristically, the clinical diagnosis occurs by the finding of a testis within an inguinal hernia, (approximately 2% of all prepubertal females undergoing hernia repair have this disorder) or by the evaluation of amenorrhea at puberty. Physical findings in affected individuals reveal a normal to small clitoris, associated with normal labia and a short, blind-ending vagina. Because various different mutations that may or may not involve the androgen receptor are responsible for this clinical disorder, müllerian and wolffian ductal structures may or may not be present. When completely evaluated, approximately one-third of the affected individuals have either vestigial wolffian or müllerian ductal structures present. Breast development is normal because of the conversion of high plasma testosterone levels to estradiol by the aromatase enzyme. The development of pubic and axillary hair requires androgen activity; subsequently; hair development within these regions is sparse to nonexistent. Testes may be located in the labial, inguinal, or intraabdominal positions. The incidence of malignant tumors developing within the testicles, if left *in situ* after puberty, has been reported to range as high as 10%. Although seminomas predominate as the most common type of tumor within CAIS patients, other nonseminomatous germ cell tumors also have been reported. No prepubertal cases of testicular malignancy in CAIS are known to exist.

The diagnosis of CAIS is based on clinical and family history, endocrinologic evaluation, and characterization of the patient's androgen receptor. In the prepubertal infant with a female phenotype and testis tissue, endocrinologic studies are not very useful and usually reveal normal prepubertal levels of LH, FSH, and testosterone. In this situation, the major concern is misdiagnosing a patient with a 5a-reductase deficiency (male sex of rearing) as having CAIS (female sex of rearing). If the diagnosis is in doubt in the prepubertal patient, genetic sequencing of the patient's 5a-reductase and androgen receptor genes are of significant benefit. Endocrinologic assessment of the untreated postpubertal patient with CAIS classically reveals elevated LH, testosterone, and estradiol levels.

Patients with CAIS characterize their sexual identity as female, apparently because masculinization of the brain requires a functional androgen receptor to upregulate the brain aromatase enzyme. CAIS patients should therefore be raised as female. Gonadectomy is indicated to prevent the development of testicular neoplasia. In the prepubertal patient, we prefer to remove the gonads when the diagnosis is made and initiate estradiol therapy at puberty. This alleviates the concern that the patient could be lost to follow-up and a testicular malignancy could develop before removal of the gonads. Alternatively, one could leave the gonads in place to allow breast development to occur spontaneously with removal of the gonads in the immediate postpuberty time span. In either situation, long-term hormonal therapy is necessary. On occasion, patients may suffer from dyspareunia because of a foreshortened vaginal vault. If this occurs, either an augmentation vaginoplasty using bowel, split-thickness skin grafts (McIndoe procedure), or sequential vaginal dilation may be necessary to enlarge the vagina (1,15,30,59,83,86,88,126,132,135,146,162,175,178).

Partial Androgen Insensitivity

Partial androgen insensitivity presents as a variety of clinical syndromes: Reifenstein, Lub, Gilbert-Dreyfus, and Rosewater. It usually is due to a single base pair mutation in the androgen receptor gene that may arise *de novo* or be inherited as an X-linked or autosomal-recessive trait. Ironically, although the same genetic defect may be present within a family, the phenotypic expression within each affected individual may vary greatly. Indeed, in some families with the same identical gene defect, the phenotypic variability has ranged from complete failure of the fetus to virilize to various degrees of hypospadias. Because of the unpredictability of phenotypic expression with the same point mutation, prenatal and neonatal counseling of affected families is extremely difficult. The clinical spectrum of partial androgen insensitivity can run from mild virilization (mild clitoromegaly, separate urethral and vaginal openings with partial labial fusion) to normal male genitalia, with affected males exhibiting only infertility and gynecomastia at adulthood.

Management of the patient with partial androgen insensitivity syndrome should be tailored to the individual. Because of the wide variability in phenotypic expression, the sex of rearing is frequently chosen based on the individual's ability to respond to testosterone. We usually recommend a trial of testosterone ethanate in a dose of 2 mg/kg given intramuscularly. The response of the penis to testosterone is evaluated in 3 weeks. If an inadequate growth response is noted, we double the dose of testosterone and reassess in another 3 weeks. If no response is noted to the second dose of testosterone, consideration for gender conversion may be given. In some families, siblings with identical point mutations have been raised successfully as females (failure to virilize, i.e., no phallic growth with testosterone) and other siblings with the identical point mutations have been raised successfully as males (virilized with testosterone). Although a trial of neonatal testosterone injections is still the most common method to determine the sex of rearing in these cases, a few words of caution should be given. In the infant with partial androgen insensitivity, whether phallic growth response to testosterone is durable is controversial; some authors report favorable long-term response, whereas others have not. Further complicating this issue is that some affected individuals with perineal hypospadias and micropenis who were raised as males have not successfully identified to the male gender in adulthood. Hypothetically, the inability of the affected individual to gender identify with males could reflect the fact that partial androgen insensitivity resulted in both the failure of androgens to imprint the brain and in inadequate virilization of the external genitalia (15,19,54,68,73,90,91,116,144,160,168,189,210,216).

5a-Reductase Type 2 Deficiency

5a-Reductase is the enzyme responsible for catalyzing the conversion of testosterone to its fourfold to fivefold more potent metabolite, dihydrotestosterone. Two forms of 5a-reductase exist in humans: type 1 predominates in skin and nongenital tissues, and type 2 predominates in the sexual organs. The type 2 enzyme is responsible for masculinization of the external genitalia and prostate. Defective action of the type 2 enzyme is inherited as an autosomal-recessive disorder and results in a syndrome called pseudovaginal perineal hypospadias. At this time, more than 35 different mutations in the type 2 gene have been identified. The percentage of residual enzyme activity of the mutant gene results in the variations of phenotypic male expression found in this disorder. Classically, affected males have a small penis with severe hypospadias, variable degrees of scrotal development, a urogenital sinus, and separate openings for the urethra and a small, blind-ending vaginal pouch. Testes are usually inguinal or labial in location. In untreated patients, marked virilization occurs at puberty. Postpubertal virilization occurs because of the increasing levels of testosterone and conversion of the elevated testosterone levels to dihydrotestosterone by the nonmutant type 1 gene. Masculinization of the brain appears to be intact with individuals who were misdiagnosed at birth and raised as girls, subsequently changing the gender identity from females to males at puberty. Diagnosis is based on metabolic evaluation with the finding of a high serum testosterone to dihydrotestosterone ratio (normal 14 ± 5 to 1) combined with an abnormal genetic sequencing of the 5a-reductase type 2 gene. Recommended treatment is with genital reconstruction as a male. It should be noted that most of these patients have small phallic structures as an adult despite prepubertal androgen therapy. Despite documentation that some affected individuals can produce sperm, no cases of fertility have ever been reported. The risk of testicular neoplasia within this patient population does not appear to be increased (93,95,160,207,215,217).

Persistent Müllerian Duct Syndrome

In the absence of MIF, müllerian ducts develop to form the uterus, salpinx, and upper one-third to two-thirds of the vagina. Persistent müllerian duct syndrome is usually diagnosed at the time of laparoscopy/orchiopexy for either unilateral or bilateral cryptorchidism. The cryptorchid testicle is typically associated with an inguinal hernia, with the uterus or fallopian tubes found within the hernia sac; consequently, the other clinical name for this syndrome is hernia uterine inguinalis. Besides the presence of hernia uterine inguinale, transverse testicular ectopia is another commonly encountered entity with this disorder. Indeed, when transverse testicular ectopy is found on physical examination, strong consideration for the possible diagnosis of persistent müllerian duct syndrome should be given. Appropriate screening examinations, with a pelvic ultrasound and serum MIF levels, subsequently should be obtained.

In the persistent müllerian duct syndrome, testosterone secretion and response of the gonads to gonadotropins (hCG stimulation test) is within normal limits. This syndrome is therefore never found to be associated with hypospadias. Consequently, the constellation of persistent müllerian ducts and associated hypospadias should rule out this clinical etiology and considerations for another diagnosis should be made.

If the patient with persistent müllerian duct syndrome is seen before puberty, the serum measurement of müllerian inhibitory factor is a useful screening test to define the existing congenital abnormality. In approximately half of these patients, MIF is low or undetectable (MIF negative). These patients usually are found to have a mutation in the MIF gene and subsequently cannot secrete MIF. Analyses of these patients have found that the MIF gene is located on chromosome 19, and defects are inherited in an autosomally recessive pattern. In the remaining patients, serum MIF levels are normal or high (MIF positive), and these patients usually have mutations in their MIF receptor. Chromosomal analysis of these patients reveals a defect in the MIF receptor genes located on chromosome 12. This defect is also inherited in an autosomal-recessive pattern. Identification of one patient with either disorder should prompt screening of other male siblings with a physical

examination. Those with cryptorchidism should undergo further workup with a screening pelvic ultrasound to rule out the presence of this syndrome. The likelihood of coexisting male siblings with this disorder is approximately 25% (33,92,125,170).

Orchiopexy in children with persistent müllerian duct syndrome is no small feat and is usually encountered when a surgeon least expects it. Indeed, the surgeon is usually unaware of the diagnosis until the gonad is found attached to a fallopian tube at the time of surgical exploration. When this phenomenon is encountered in the operating room, a blood sample should be obtained for both karyotype analysis and serum MIF levels. The gonad should be biopsied and replaced along with the herniated müllerian ducts into the pelvis and the hernia closed. Full evaluation of the patient for an intersex disorder subsequently should be performed.

Despite normal testosterone secretion in these patients, the spermatogenic function of patients with persistent müllerian ductal syndrome usually is impaired, with infertility being a frequent occurrence. Whether the infertility is due to primary gonadal dysfunction or is a consequence of testicular undescent is controversial. Because fertility occasionally has been reported within affected individuals, every attempt should be made to place the testicles down into the scrotum. After a 46,XY karyotype and a normal testicular histology are confirmed, a second operative procedure is performed. Experience dictates that if the testicle was palpable before the first operation, then the gonadal vessels are usually long enough to allow for a successful orchiopexy using standard techniques. If, however, the testicle was impalpable, the testicle may be unable to reach the pelvis because of either a shortened gonadal artery or, in most circumstances, entanglement of the vas deferens with the uterus and tubes. If the gonadal vessels are limiting the dissection, a Fowler-Stephens orchiopexy, ligating the gonadal vessels and leaving the fallopian tubes and vasal structures intact, is performed. Hypothetically, it is tempting to excise the persistent müllerian structures, because leaving the müllerian structures *in situ* could predispose to endometrial malignancies, hematuria, and voiding dysfunction. Surprisingly, long-term follow-up of patients with müllerian structures left *in situ* reveals these complications to be extremely rare.

If the uterus and fallopian tubes are limiting the dissection, the fimbriae and distal fallopian tube are left intact and severed from the proximal tube. Note the distal fallopian tube intricately shares blood supply with the gonadal vessels. Injury to the gonadal vessels is common if complete salpingectomy is performed. Unfortunately, in most cases, this maneuver is still not enough to allow the gonad to reach the scrotum. Excision of the uterine fundus is then necessary. During this dissection, the surgeon must be aware that an extreme risk of vasal injury exists. Strong consideration should be given to performing a partial hysterectomy, leaving the myometrium behind where it is attached to the vas.

At this time, the true risk of malignancy in testes associated with persistent müllerian duct syndrome is unknown, with reported ranges varying from 2% to 15%. Because of the unknown risk of neoplasia within these gonads, we believe that any testicle that cannot be lowered into a palpable position should be excised (51,56,104,125,173,201).

True Hermaphrodites

True hermaphroditism is characterized by the presence of both ovaries and testicles. The karyotype and the appearance of the external genitalia vary widely, ranging from an apparent normal male to an apparent normal female with mild clitoral hypertrophy. Most affected patients (approximately 60%) tend to be masculinized with a well-developed phallus with perineal hypospadias and a single urogenital sinus opening. The labial scrotal folds show asymmetry, with one side, usually the right, being well developed with a palpable gonad; a poorly formed contralateral hemiscrotum without a palpable gonad usually is noted. Most cases arise from a sporadic mutation; however, an autosomal-recessive inheritance pattern also is know to exist. The genotypic findings of true hermaphroditism vary depending on the race evaluated. Currently, more than 70% of the recorded cases have a karyotype of 46,XX and have been reported in African Americans. Twenty percent of the cases occur in Caucasians, with the most common karyotype finding being a mosaic configuration of either 46,XX/46,XY or 47,XXX/46,XY. Ten percent of the cases arise in people of Asian inheritance; the most common genotype abnormality found within this racial group is 46,XY. Although one would assume that XX/XY mosaicisms, and SRY mutations and or translocations would be the cause of true hermaphroditism, less than 40% of the total cases are found to have these genetic abnormalities. The finding that approximately 60% of true hermaphrodites lack an SRY gene suggests that other non-SRY locations play a role in the development of the testes in this intersex abnormality.

True hermaphroditism is characterized by the presence of both ovarian and testicular tissue. The most common gonadal composition found is the ovotestis/ovary (35%), bilateral ovotestis (25%), ovary and testis (25%), and ovotestis/testis (15%). The testis is much more likely to be present on the right side. The ability to palpate the gonad is directly related to the extent of testicular tissue present within the gonad. Although ovotestes are usually bilobar in configuration, one lobe being testicular the other ovarian, up to 20% may occur in an oval configuration with one cell type or the other confined to the deep hilar region of the gonad. To rule out the presence of an ovotestis, the bilobar gonad should have each lobe biopsied and the ovoid gonad should be bivalved and deep biopsies taken. The internal ductal structures are usually appropriate for the type of gonad found—wolffian structures for testes and müllerian structures for ovaries. Indeed, approximately 80% of true hermaphrodites have a rudimentary or fully formed uterus present. In ovotestis, fallopian tubes are predominant, although both ductal structures may be seen. The ovarian histology and function is normal and several pregnancies have been confirmed in true hermaphrodites that were raised as females. In contrast, the testicular tissue is found to have spermatogonia in infancy and early childhood, but the testis almost invariably undergoes fibrosis with maturation. Fertility in true hermaphrodites raised as males is rare.

The diagnosis of true hermaphroditism is usually suggested by either the genotype (mosaic XX/XY) or the findings of müllerian structures in a predominantly virilized neonate. Confirmation of the diagnosis is found by gonadal biopsy combined with laparotomy or laparoscopy. Gonadectomy of the tissue not consistent with sex of rearing should be performed as a neonate. In patients raised as females, remnant testicular tissue left behind will cause virilization at puberty. Verification that all testicular tissue was removed may be ascertained by monitoring serum testosterone after hCG stimulation or by the measurement of MIF secretion. At this time, approximately one-third of true hermaphrodites are raised as males because of extensive virilization of the fetus, an abnormal or absent uterus, or familial desires. If raised as a male, the hypospadias is repaired and all testicular tissue is lowered into the scrotum. Testicular tumors, gonadoblastomas, dysgerminomas, and germ cell tumors will develop in approximately 1% of the patients. In children raised as males, testosterone supplementation at puberty or early adulthood is usually required because of progressive testicular fibrosis. If the infant is raised as a female, clitoroplasty and vaginoplasty are performed. Hormonal supplementation in true hermaphrodites raised as a female is rarely necessary (7,15,24,43,75,76,98,115,206).

True Hermaphroditism and Its Relationship to 46,XX Sex Reversal

Estimated to be present in 1 in 20,000 to 1 in 30,000 men, 46,XX sex reversal is a fairly common abnormality. Of these patients, 90% have a normal-appearing male phenotype and are diagnosed because of complaints of infertility, gynecomastia, or failure of fetal genotype to match the neonatal phenotype. Ten percent of the patients will have hypospadias, micropenis, or genital ambiguity. Translocation of the SRY gene is found in one-third of the cases. The remaining two-thirds are believed to be due to either loss of the testis inhibiting gene (DAX-1) or a gain in the function of a non-SRY testes-determining gene. Several cases of both true hermaphroditism and XX sex reversal have been found to exist within the same family, causing scientists to hypothesize that these disorders are a spectrum of one single genetic defect that could produce either disease. Affected males are shorter than normal because a Y-linked growth gene is absent. Serum testosterone and the response of the testis to hCG are normal during puberty and early adulthood, but they become abnormal with time because of progressive maturational-induced testicular fibrosis. No increase in the risk of testicular malignancy is associated with this disorder. Prepubertal diagnosis is made when genital ambiguity is associated with a 46,XX karyotype. Laboratory studies reveal a neonatal elevation in serum testosterone. Stimulation tests with hCG reveal an appropriate rise in testosterone values. Gonadal exploration and biopsy reveal normal testes. Affected patients should be raised as a male. Testosterone replacement therapy is necessary in adulthood because of progressive fibrotic replacement of the testis (15,108,112,165,167).

Conditions Associated with Dysgenetic Gonads

Gonadal dysgenesis is a spectrum of disorders ranging from complete to partial gonadal dysgenesis. The current clinical and genetic data suggest that these various syndromes are different phenotypic manifestations of a common disease process. Karyotypes may vary from normal 46,XX and 46,XY to a variety of mosaic defects.

Complete Gonadal Dysgenesis

XX Gonadal Dysgenesis or Pure Gonadal Dysgenesis

Patients with XX gonadal dysgenesis classically are diagnosed following a workup of delayed puberty/primary amenorrhea. Affected individuals have a female phenotype, the absence of Turner's stigmata, a 46,XX karyotype, the presence of müllerian ductal structures, and bilateral streak gonads. The condition arises as either a spontaneous mutation or is inherited in an autosomal-recessive manner. Genetic mutations known to cause this disorder include partial deletions of the X chromosome, isolated mutations in the WT-1 gene, and mutations in the FSH receptor. Unlike the patients with 46,XY gonadal dysgenesis, risk for gonadal tumor

formation is not increased. Treatment is with hormonal replacement (131,187).

Turner's Syndrome

Turner's syndrome occurs in 1 of every 2,000 female births. This syndrome is characterized by the findings of complete or mosaic X monosomy (45,X or 45,X/46,XX), along with one or more of the characteristic Turner's stigmata of web neck, congenital lymphedema, shield chest, aortic valvular defects, coarctation of the aorta, horseshoe kidney, impaired somatic growth, and absent puberty. “Anti-Turner stigmata genes” are located on the short arm of the Y chromosome and the long arm of the X chromosome. The homologous genes located on the X chromosome are not subject to X-inactivation. The presence of two active anti-Turner's genes prevents the development of Turner stigmata. In Turner's syndrome in which one X is missing, the haploinsufficiency of the anti-Turner gene results in the expression of Turner stigmata. Pathologic studies of infants with Turner's genotype reveal that ovaries differentiate within the fetus but degenerate to streak gonads with maturation. Pregnancy has been reported in rare individuals with Turner's syndrome because of failure of the ovaries to completely regress. The streak gonads are not at risk for malignant degeneration and are subsequently left *in situ.* Growth hormone therapy is initiated in early childhood, with estrogen therapy begun at late adolescence (187,196,223).

XY Gonadal Dysgenesis (Swyer Syndrome) and Male Turner's Syndrome

Infants with 46,XY gonadal dysgenesis (Swyer syndrome) are characterized by the absence of testicular development despite the presence of the Y chromosome. This intersex disorder is typified by a high risk of the gonads developing a testicular malignancy, up to 60% occurrence, if the patient is not diagnosed until early adulthood. A variety of testicular tumors have been reported, the most common of which is gonadoblastoma; however, dysgerminomas, seminomas, and nonseminomatous germ cell tumors have been reported to occur in approximately 15% of these patients. Classically, gonadoblastomas or dysgerminomas are found in the neonate or infant, whereas the more malignant germ cells are seen in late adolescence to adulthood. Only 20% of patients with 46,XY gonadal dysgenesis have an identifiable genetic mutation. These are usually found to be either a mutation in the SRY gene, a Y chromosomal deletions/translocation, or a mutation in the autosomal genes WT-1 or SOX-9. Occasionally, patients with this disorder have the clinical features of Turner's syndrome, resulting in a clinical entity known as the male Turner's syndrome. This latter disorder is due to a deletion of the short arm of the Y chromosome that encompasses both the SRY region and the anti-Turner gene. Classically, the infant with 46,XY gonadal dysgenesis has a female phenotype. Patients come to clinical attention because either the phenotypic expression of the infant does not match the fetal genotype, a hormonally functioning tumor causes precocious puberty (either estrogen or testosterone secreting gonadal tumors), or there are complaints of delayed onset of puberty/primary amenorrhea. Müllerian ductal structures usually are present (failure of MIF secretion), and wolffian ductal structures are vestigial to absent (lack of testosterone secretion). Endocrine studies reveal female levels of testosterone and no response to hCG. LH and FSH levels are elevated. Karyotype analysis reveals a 46,XY configuration. Surgical exploration reveals streak gonads, a uterus, and fallopian tubes. Because of the high risk of malignancy, gonadectomy should be carried out at the time of diagnosis. Patients should be raised as females and estrogen replacement therapy begun at puberty (60,79,134,179,186,202).

Partial Gonadal Dysgenesis: Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis bridges the gap between Turner's syndrome (45,X/46,XX and bilateral streak gonads) and testicular dysgenesis (46,XY with bilateral partial testicular dysgenesis). Affected patients usually have a mosaic karyotype of 45,X/46,XY, with one streak gonad and one testicle. Patients with this disorder typically present in one of two fashions: (a) the most common is the infant referred for evaluation with ambiguous external genitalia and one palpable gonad, and (b) the other classic presentation is a prenatal consultation for a mosaic genotype found on amniocentesis or chorionic villus sampling. It is interesting for the physician to note that in the latter circumstance, almost 90% of the infants with a 45,X/46,XY genotype found on fetal evaluation will be born with normal male external genitalia (35,174,176,198). When faced with a prenatal consultation for fetal mosaicism with 45,X/46,XY karyotype, several key points need to be remembered: (a) A normal masculine phenotype will be present in 90% of the affected males. (b) Close follow-up of these individuals has failed to reveal an increased incidence for gonadal malignancy; however, this may just be due to inadequate length of follow-up. (c) As maturation develops the patient is at risk for the development of progressive gonadal dysgenesis, decreased fertility, and low testosterone levels. (d) The most worrisome finding is that approximately 20% of the infants with this genotypic abnormality have either mental retardation or autism (35,192,198).

In individuals with mixed gonadal dysgenesis presenting with ambiguous genitalia, the phenotype usually reveals a penoscrotal or more proximal hypospadias, associated with small phallic size, one palpable gonad, and asymmetric labial scrotal folds with a palpable gonad located either inguinally or within the scrotal fold on the more developed side. Endocrinologic workup reveals elevated levels of testosterone in the newborn. A prompt response to hCG stimulation will be found. MIS expression is variable, but in our experience, it is usually in normal male range.

On surgical exploration, patients are found to have a unilateral salpinx and a rudimentary unicornuate uterus associated with the nonpalpable streak gonad. In addition, as many as one-third of the patients are found to have coexisting rudimentary mesonephric ductal structures, a finding suggesting that at one time testosterone secretion may have been present from the streak gonad. On the contralateral side with the palpable gonad, gonadal biopsy usually reveals either a normal or partially dysgenetic testis. Persistent müllerian structures or partial absence of the mesonephric ducts frequently is associated with the testicle. This latter finding suggests that abnormal hormonal function of the testis is present. The risk of gonadoblastoma development in the dysgenetic testis or streak is estimated to be 15% to 30%, respectively (179,202). Because of the increased risk of malignancy, all streak gonads or partially dysgenetic testes are removed. The risk of tumors developing in a fully descended testis with a normal histology on biopsy is low but above normal. It is noteworthy that even in the neonatal testis with a normal histology, long-term follow-up will show development of poor Leydig cell function and poor to absent spermatogenesis. Almost invariably, infants with mixed gonadal dysgenesis who are raised as males will have infertility and require the need for supplemental testosterone in adulthood (45,164,198).

In a well-virilized male with the gonad descended into the scrotum, it is our preference to raise these individuals as males. Laparotomy is performed to remove the streak gonad, fallopian tube, and rudimentary uterus in infancy. Gonadal biopsy of the descended gonad is performed to confirm the presence of a normal testis. If the testis is normal, we leave the testis *in situ.* If the testis is partially dysgenetic, we remove the gonad and opt for placement of a testicular prosthesis at a latter point. Reconstruction of the phallus is performed between 8 and 12 months of age. Long-term follow-up of these individuals is mandatory to both assess for the eventual hormonal functional capability of the testis at puberty and to instruct the patient in the importance of self-testicular examination (45,164,198).

In undervirilized patients, rearing as a female is preferred due to the increased risk of gonadal malignancies and the chance of fertility being almost nonexistent. We will usually perform a laparotomy and biopsy both gonads in infancy. If histologic confirmation of a streak gonad and a dysgenetic testis are noted, simultaneous bilateral gonadectomy and feminizing genitoplasty are performed. Hormonal replacement therapy with estrogen will be necessary in late adolescence (28,82,198).

Mixed Gonadal Dysgenesis: Deny-Drash Syndrome

The classic triad of Wilms' tumor, ambiguous genitalia, and progressive glomerulopathy is found in approximately 5% of patients with mixed gonadal dysgenesis and is known as *Deny-Drash syndrome.* Classically, this syndrome is revealed by the presence of hypertension and nephrotic syndrome in an infant with a history of ambiguous genitalia. Renal biopsy usually reveals diffuse mesangial sclerosis. Wilms' tumor development often occurs within the first 2 years of life and is more often bilateral. Genetic evaluations reveal a mutation in the WT-1 gene, with inappropriate activity of the WT-1 gene eventually leading to both renal and gonadal maldevelopment (45,50,124,130).

Partial Gonadal Dysgenesis: Testicular Dysgenesis

Testicular dysgenesis, also known as *dysgenetic male pseudohermaphroditism,* is characterized by ambiguous genitalia that may range from a female phenotype with mild clitoral hypertrophy to a male with hypospadias and bilateral cryptorchidism. The genotype is 46,XY without mosaicism. The testes are partially dysgenetic, resulting in inadequate secretion of MIS and testosterone. Invariably, both müllerian and wolffian ductal structures are present. This disorder can be differentiated from true hermaphroditism by gonadal biopsy. In testicular dysgenesis, gonadal histology reveals disordered seminiferous tubules, a paucity of Leydig cells, and excess stromal tissue. No ovarian tissue is identified. Malignant transformation of the testis into gonadoblastoma or dysgerminoma may occur in up to 30% of individuals if the gonads are left *in situ.* Endocrine testing in the neonate usually reveals testosterone levels to be in the female to low male levels. A blunted response of testosterone to hCG stimulation usually is seen. MIF levels usually are in the female range. Sex of rearing is decided by the degree of virilization present. Irrespective of the sex of rearing, the dysgenetic gonads should be removed as a neonate. If raised as a male, phallic reconstruction is carried out between 9 and 12 months of age. If raised as a female, feminizing genitoplasty and vaginoplasty are performed simultaneously with gonadectomy. Hormonal replacement is initiated in late adolescence (29,100,106).

SURGICAL MANAGEMENT OF INTERSEX

Gender Assignment

The gender assignment of the infant is performed in consultation with pediatric urology, endocrinology, genetics, child psychology, and the informed consent of the parents. Each case should be evaluated individually, and the gender assignment decided on by the infant's degree of virilization, gonadal function, the predicted efficacy of hormonal therapy, and the natural history of the primary intersex abnormality. We believe that early and long-term counseling of the patient and the patient's family with a group of physicians that both the parents and patient may bond with is critical for a successful long-term outcome (2,46,63,64 and 65,133,143,145).

Clitoroplasty

Phallic reduction to form a clitoris is usually performed in the neonatal time period. To initiate this procedure, the adherent prepuce is freed from the glans and a stay suture is placed through it. Depending on the physician preference, a transverse circumcising incision is made either completely around or three-fourths of the way around the phallus, preserving a 5-mm mucosal collar. (Note: Some surgeons prefer to preserve the ventral cutaneous aspect of the clitoral shaft, similar to preserving the urethral plate in hypospadias. Personally, I find this interferes with the visualization for resection of the subtunical erectile tissue and prefer the complete circumcising incision.) The corpora then are mobilized to their bifurcation, proximal to the pubic bone. Two lateral coporotomies are performed, and the erectile tissue is removed as far proximally and distally as possible. Removal of the cavernosal spongy tissue with preservation of the tunical component allows the physician to preserve innervation to the glans. If bleeding arises from the central corporal arteries, it can be controlled by electrocoagulation or suture ligatures. The glans may be large in caliber and a wedge resection is frequently necessary to achieve a normal clitoral diameter. Because the dorsum of the glans has the most innervation, a wedge resection is taken from the ventral aspect and the glans is reapproximated. Following its reduction, the dorsal portion of the clitoris is secured to the ventral perichondrium of the pubic bone with two subcutaneous sutures, and the ventral portion of the clitoris is secured with two subcutaneous sutures to the residual corporal bodies. As these sutures are tied, the excess empty corporal tunics will accordion upon themselves below the pubic bone. The dorsal phallic skin is cut in the midline in the manner of Byar's flaps. Care is taken not to extend this cut too far dorsally. The slight excess of dorsal phallic skin will serve as a clitoral hood. Extending the incisions on either side of the ventral midline skin carries out a vulvoplasty. These incisions are made caudally in a horseshoe configuration. This allows a ventral U-shaped flap to exist that may be used to simultaneously perform a flap vaginoplasty if necessary (see the following section). The redundant phallic skin is subsequently brought down to form labia minora (Fig. 52C.5) (16,17,18,82,107,166).

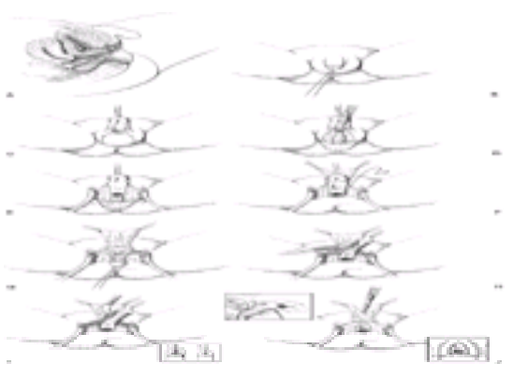

FIGURE 52C.5. Simultaneous clitoroplasty and U-shaped flap vaginoplasty for a low-lying vaginal confluence and an enlarged glans. **A:** Cross section of low-lying vaginal confluence. **B:** Stay suture placed in glans with skin marked for eventual circumcising incision. **C:** Markings for perineal U-shaped flap and preservation of urethral groove. **D:** Incision of urogenital sinus to expose urethral and vaginal openings. **E:** Visualization of urethral and vaginal ostium. **F:** Approximation of U-shaped flap to vaginal vault and extension of ventral urethral incisions into a circumscribing incision to expose corpora. **G:** Dorsal exposure of corpora down to corporal bifurcation. **H:** Incision on lateral aspects of corpora to “shell out” spongy tissue. **I:** Removal of spongy tissue. Alternative incisional markings noted on ventral urethral groove to enhance visibility for corporal dissection. *Inset* reveals ventral glandular wedge removed to reduce size of glans. **J:** Fixation of glans to ventral pubic periosteum and residual corporal bodies. Completion of vulvoplasty.

Low Vaginoplasty

A U-shaped flap or “cut back” vaginoplasty is frequently performed simultaneously with the clitoroplasty for a low-lying vaginal confluence. Before the vaginoplasty, simultaneous cystoscopy and vaginoscopy are performed to assess the position of the vagina with the perineal skin. If this examination confirms a low-lying vagina (i.e., distal to the external sphincter), we place a catheter into the bladder to aid in identification of the urethra and proceed with the operation. A U-shaped flap is dissected free from the urogenital sinus with a combination of sharp and blunt dissection. If this procedure is performed in an adolescent or adult, infiltration of the incision with 1% lidocaine with epinephrine aids the dissection and hemostasis. It is often easier to define the plane between the U-shaped flap and the urogenital sinus on the lateral aspect of the dissection and work medially. Mobilization of the urogenital sinus is performed as far proximally as the surgeon can visualize. Care must be taken not to injure the rectum that lies immediately posterior to the vaginal vault. After adequate mobilization of the vagina, the UG sinus is cut in the ventral midline position. The midline incision into the UG sinus/vagina is then approximated to the apex of the U-shaped flap. Labia minora and majora are created with the dorsal phallic skin as previously described (Fig. 52C.5) (82,150,157).

Midvaginoplasty

If the cystoscopy and vaginoscopy suggest a mid to high vaginal confluence (i.e., at or slightly above the external sphincter), we usually perform the clitoroplasty alone in infancy with plans for vaginal reconstruction deferred until the patient is 2 to 3 years of age. When ready for reconstruction, cystoscopy and vaginoscopy are again performed. In these circumstances, we prefer to place two catheters, one into the bladder and the other into the vagina. Incisions are made to remobilize the labia minora. A U-shaped incision is then made in the perineum and a circumferential incision around the common urogenital sinus is performed. Stay sutures are placed into the UG sinus, and the entire sinus is mobilized. As the urethra is mobilized from the pubis, some dense avascular attachments are usually noted that will need to be sharply divided. By a combination of blunt and sharp dissection, a total of 3 to 4 cm of urogenital sinus can be mobilized easily. Similar to the U-shaped cut back procedure, care should be taken when mobilizing the vaginal vault posteriorly not to injure the rectum. Once the vaginal Foley balloon is easily palpable, a ventral midline incision into the urogenital sinus and vagina is made. The deepest cut into the UG sinus/vagina is then approximated to the apex of the U-shaped flap. The labia minora subsequently are reapproximated (Fig. 52C.6) (127,155).

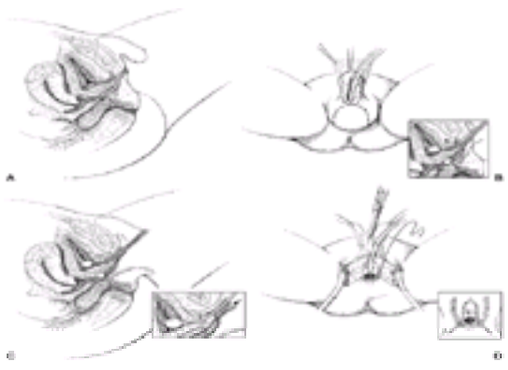

FIGURE 52C.6. Complete urogenital sinus mobilization for a mid-lying vaginal confluence. **A:** Cross section of mid-lying vaginal confluence. **B:** Catheters placed into bladder and vagina, with skin markings for U-shaped perineal incision and circumferential incision around the common urogenital sinus opening. Cross-sectional diagram demonstrating pathway for urogenital sinus mobilization. **C:** Urogenital sinus mobilized for 3 to 4 cm. Ventral incision into urogenital sinus, exposing urethral

and vaginal ostium. **D:** Approximation of perineal U-shaped flap to vaginal ostium and completion of labioplasty.

High Vaginoplasty

In patients with adrenal genital syndrome and full phallic masculinization, repair of the vagina can be extremely complex. These patients usually have a long narrow UG sinus, with the vaginal vault opening just below the bladder neck. Although we have repaired these individuals in infancy or early childhood using either the Passerini-Glazel maneuver (creation of vagina via inverted penile skin) or buttock skin flaps, the long-term follow-up of our patients has revealed profound vaginal stenosis to develop at or following puberty. This experience has significantly tempered our enthusiasm for repair of the high urogenital sinus vaginal confluence in infancy and early childhood. At present, in the patients with full masculinization and adrenal genital syndrome, we perform the feminizing genitoplasty and defer the vaginoplasty until after puberty, usually when the patient is older than 13 years of age. It is noteworthy that in some of these patients, intermittent catheterization of the urogenital sinus may be necessary to prevent recurrent episodes of pyovaginitis before repair. Reconstruction is initiated by placement of a 200-mL tissue expander with a remote access port into both labia. Care is taken to position the expander flat to prevent buckling or displacement during expansion. Three weeks after its placement, expansion is initiated with normal saline. The volume of saline used is determined by the patient's tolerance to the injection. Our goal is for a volume of approximately 100 to 150 mL per expander, with a total volume of 200 to 300 mL. While expansion is occurring, we have the patient limit their physical activity and keep the labial region and inner thighs well lubricated with A and D ointment to prevent the development of skin abrasions. At the time of vaginal reconstruction, cystoscopy and vaginoscopy and placement of catheters over glide wires into the bladder and vagina are the initial steps. Two labial flaps approximately 6 cm in width and 8 to 10 cm in length are raised by incising the expanded labia. Care is taken to verify that the labial margins may be reapproximated without tension and that the integrity of a 2- to 3-cm perineal based vascular pedicle is maintained. The implants are removed preserving the newly developed vascularized sheath around the expander. A U-shaped perineal incision is made, along with a circumferential incision around the UG sinus. Circumferential dissection of the UG sinus is performed until the balloons within the bladder and vagina can be palpated. If one can easily palpate the separation between both balloons per the perineal incision, the vagina can be dissected free from the common urogenital sinus/urethra. The connection of the urethra to the vagina subsequently is closed in layers to prevent fistula formation. The vagina is further mobilized with a combination of sharp and blunt dissection. When mobilization is complete the vagina is incised at 6 o'clock to prevent a circutarial scar. The labial flaps are rotated medially, attaching their base to the U-shaped perineal flap, then to the contralateral labial–based flap and eventually attaching the flaps circumferentially to the proximal vagina. A “dog ear” may be present on the medial aspect of the perineal-based labial flap. The epithelium from this dog ear may be removed safely; however, care should be taken to preserve the underlying subcutaneous tissue and the labial skin reapproximated. In our experience, this approach usually can be successfully used to repair the *de novo* high vaginal take off from the urogenital sinus without resultant vaginal strictures developing (Fig. 52C.7). In the patient with a history of surgical failures, separation of the strictured vagina from the urethra may be extremely difficult, if not impossible. In this situation, a Pfannenstiel incision is made, and the posterior aspect of the bladder is mobilized free from the uterus and vagina. Mobilization of the vagina from the bladder and rectum is performed. In most cases, the combination of vaginal mobilization from the abdominal position along with the perineal flaps developed by the tissue expander is adequate to construct the vagina. Unfortunately we have had patients where the proximal vagina still did not reach the perineal-based flaps. In these circumstances, we have had to resort to interposing a segment of sigmoid colon between the vagina and the labial flaps to prevent recurrent vaginal stenosis (12,21,37,49,58,59,80,82,153,154).

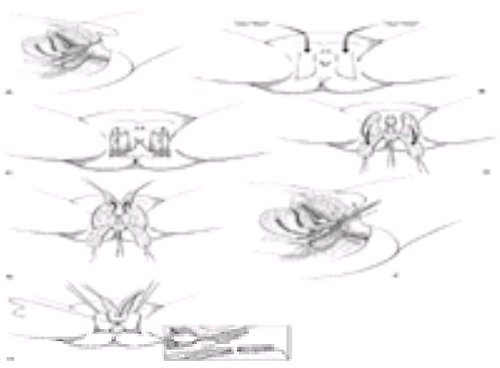

FIGURE 52C.7. Combination of complete urogenital sinus mobilization and labial flap vaginoplasty using tissue expanders for a high-lying vaginal confluence. **A:** Cross section of high-lying vaginal confluence. **B:** Placement of bilateral labial tissue 150-mL capacity expanders. **C:** Outline of labial flaps, base of 2- to 3-cm flap is maintained, flap heights of 8 to 10 cm and 6 cm in width usually can be obtained. Care is taken to verify that the residual labial margins can be reapproximated without undue stress. A U-shaped perineal incision is again made. **D:** Circumscribing incision around urogenital sinus. **E:** Mobilization of medial residual labial tissue for eventual labial reconstruction along with mobilization of labial flaps and U-shaped perineal flap for formal vaginoplasty. **F:** Lateral view of mobilization of urogenital sinus with transection of vagina from urethra. **G:** Formation of distal vagina via combination of perineal-based U-shaped flap and labial tissue. Lateral view demonstrating closed urethral vaginal confluence and anastomosis of proximal vaginal to labial flaps.

Vaginal Agenesis

In children with complete vaginal agenesis, the vagina may be formed with gradual vaginal dilation, skin graft techniques (i.e., a McIndoe procedure) with labial tissue expanders or with bowel vaginoplasty. In our experience, sequential vaginal dilation and skin graft techniques have not been successful in the prepubertal patient because of the need to pursue vigorous self-dilation to maintain vaginal patency. Labial tissue expanders are extremely useful, but to date, these have only been applied to the postpubertal patient. If construction is to be performed in infancy or early childhood, we believe that bowel vaginoplasty, especially using the sigmoid colon, has the best long-term result. In postpubertal patients, the combination of perineal tissue expanders and sigmoid vaginoplasty can produce both an excellent cosmetic appearance and functional vagina (Fig. 52C.8) (15,30,37,41,58,59,81,89,182).

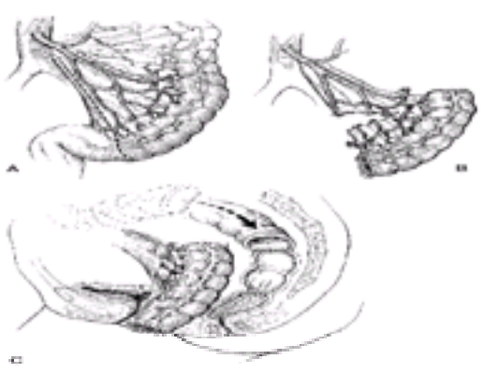

FIGURE 52C.8. Sigmoid vaginoplasty for vaginal agenesis. **A:** A 15- to 20-cm segment of sigmoid colon is chosen for vaginoplasty. **B:** Mobilization of mesentery with preservation of collateral vessels close to colonic wall. **C:** Fixation of colon to perineum and reanastomosis of descending to residual sigmoid colon.

Construction of Male Genitalia

Assignment of the intersex patient to the male gender requires the ability to construct cosmetically acceptable male external genitalia. If the testes have been removed because of the risk of malignant transformation, scrotoplasty and placement of testicular prosthesis will be required. Phallic reconstruction is a major task. Various techniques have been used, including tubed abdominal flaps with cartilaginous stiffeners or penile prosthesis, rectus abdominis myocutaneous flaps, and more

recently, innervated vascularized free graft forearm skin flaps. When using free graft forearm flaps, the radial artery and vein may be anastomosed to either the inferior epigastric artery and vein or, alternatively, to the internal pudendal artery and vein. The lateral cutaneous nerve of the forearm is anastomosed to the pudendal nerve. Although good results have been reported, our own experience with this procedure has been fraught with complications, predominantly urethrocutaneous fistula, poor neural sensation, and erosions of the penile prosthesis. At this time, the surgical results using this technique are still in doubt. Indeed, even if this procedure can be performed successfully, the microsurgical techniques applied are technically difficult and should not be attempted until late adolescence or early adulthood. It is currently unknown what the delay in phallic reconstruction into adulthood will have on psychologic development of the infant/child who will undergo this procedure (36,53,61,62,77,152).

THE EMBRYOLOGY AND ENDOCRINOLOGY OF EPIDIDYMAL-TESTICULAR DEVELOPMENT AND DESCENT IN HUMANS

Since John Hunter's original description, there have been ongoing attempts to establish definitively the mechanisms involved with testicular descent. Many theories have been postulated, beyond the scope of detailed discussion here. These theories include the role of the gubernaculum and epididymis; the changes resulting from the androgen environmental milieu, either directly or indirectly mediated through the spinal nucleus of the genitofemoral nerve innervating the gubernaculum; the role of estrogens and müllerian-inhibiting substance (MIS); and the effects of abdominal pressure and differential body growth on the descending testis. Cryptorchidism is a heterogenous disorder with a variety of causes. Furthermore, knowledge of the normal embryology is essential to understand the changes involved with abnormal testicular descent (Fig. 53.1).

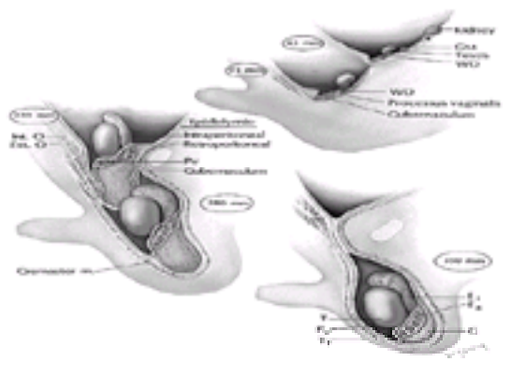

FIGURE 53.1. Testicular descent in humans. The wolffian duct *(WD)* differentiates into the epididymis, which is clearly recognizable at a 230-mm crown-rump length. The gubernaculum never herniates through the abdominal wall. EI, intraperitoneal section of epididymis; ER, extraperitoneal section of epididymis; Ext. 0, external oblique; GM, gubernaculum; Int. 0, internal oblique abdominal muscle; Pv, processus vaginalis; T, testis; TT, tunica dartos.

The Bipotential Period

The Fourth Postfertilization Week: Mesonephric Body, Mesonephric Duct, and Attachment of the Future Tail of the Epididymis to the Embyronic Inguinal Region

Sexual differentiation begins as part of blastogenesis during the fourth postovulatory week. Blastogenesis is the process by which the blueprint of the basic body plan is laid down in successive craniocaudal waves of differentiation, growth, degeneration, resorption, and remodeling (207). This process is under the control of homeobox genes.

The onset of sexual differentiation is marked by the appearance of the paired mesonephric bodies and mesonephric ducts—the embryonic precursors of the gonads and male ductal system, respectively. By postfertilization day 22, the mesonephric bodies begin to differentiate from within the nephrogenic cord of the intermediate mesoderm in the cervical region. Their caudal growth and differentiation proceed with that of the somites and follow the dorsal caudal curve of the embryo. By day 28, their distal ends reach the midlumbar region in the caudal curl of the embryo simultaneously with the appearance of the midlumbar somites (64,242,261). By day 24, the mesonephric ducts appear at the posterolateral borders of the mesonephric bodies in the cervical region in direct contact with the ectodermal ring of the surface ectoderm (128,210). The mesonephric ducts remain in contact with the ectodermal ring during their caudal growth, which is more rapid than that of the mesonephric bodies and somites. By day 26, the mesonephric ducts have grown around the distal ends of the mesonephric bodies in contact with the ectodermal ring of the future embryonic inguinal region and genital swellings and have turned medially, losing contact with the surface ectoderm, to reach the lateral walls of the cloaca to which

they fuse (208,209,211).

That segment of the mesonephric duct that curves around the distal end of the mesonephric body is referred to as the *first curve* of the duct (64,242). It will become the tail of the epididymis and remains attached to the anterior wall of the caudal curl in the future inguinal region of the embryo. At this point, the gubernaculum and inguinal canal will develop in the next 2 weeks (6). The segment of the mesonephric duct cranial to the first curve will become the head and body of the epididymis. The segment distal to the first curve will become the vas deferens. The mesonephric bodies will degenerate and be replaced by the bipotential gonads.

By the end of the fourth week, the blueprint for gonadal and gubernacular development is complete. The embryonic anlage and relationships necessary for epididymal-testicular descent are in place. An intimate ectodermal-mesodermal association between the ectodermal ring and the future tail of the epididymis in the inguinal area and genital swelling is present (210). The observation that the future tail of the epididymis and the future lower pole of the testis are attached to the future internal inguinal ring in the anterior abdominal wall provides extremely strong evidence against the theory of transabdominal testicular descent at a later developmental period in humans (64,211,284).

The Fifth Through Seventh Postfertilization Weeks: Development of the Gonad, Gubernaculum, Abdominal Wall, and Paramesonephric Duct

Proliferation and migration of primordial germ cells from the yolk sac into the ventromedial surface of the mesonephric bodies begins in the fourth week. These processes accelerate during the fifth and sixth weeks, forming the bipotential gonad. The enlarging gonad replaces the regressing mesonephric body by the end of the sixth week (128,211,279).

Undifferentiated lateral plate mesoderm grows between the mesonephric duct and the surface ectoderm in a craniocaudal direction during the fourth week. During the fifth and sixth weeks, the abdominal muscles, the cremaster muscle, and aponeuroses gradually differentiate within this mesenchyme. At the same time, the gubernaculum appears as a column of mesenchyme within the developing abdominal wall at the point of attachment of the first curve of the mesonephric duct to the anterior wall of the caudal curl referred to earlier. The gubernaculum protrudes into the abdomen, and its tip is attached to the first curve of the mesonephric duct (i.e., the future tail of the epididymis). A wisp of mesenchyme, the scrotal ligament, extends from the distal end of the gubernaculum to the dermis of the genital swelling. The gonadal ligament attaches the lower pole of the gonad to the first curve of the epididymis at the site of the gubernacular attachment. The muscles of the abdominal wall and the gubernaculum differentiate simultaneously. The muscles and aponeuroses develop around the gubernaculum, forming the inguinal canal and the internal and external rings. These structures are recognized histologically by the end of the seventh week and continue to mature for the next few weeks (6,64,170).

During the sixth week, the paramesonephric duct differentiates along the lateral border of the mesonephric duct. It crosses medially ventral to the first curve of the mesonephric duct and comes to lie medial to the mesonephric duct in the pelvis. At their point of crossing at the first curve of the mesonephric duct, both ducts are attached to the gubernaculum below and to the gonadal ligament above (64,128,211).

By the end of the seventh postfertilization week, the bipotential organogenesis of the gonad, mesonephric duct, abdominal wall, and gubernaculum is complete. Development of the paramesonephric duct has begun but will not be complete until the end of the eighth week. The anatomy is identical in male and female embryos. The first curve of the mesonephric duct and the developing paramesonephric duct are attached to the lower pole of the gonad by the gonadal ligament above and below to the gubernaculum in the internal ring. The gubernaculum fills the inguinal canal. Its caudal extension, the scrotal ligament, fuses with the dermis of the labial-scrotal fold. The presence of the lower pole of the gonad and the future tail of the epididymis at the internal ring even before the seventh week excludes transabdominal descent in humans (64,211). The embryo is ready for male sexual differentiation.

Male Sexual Differentiation

The Seventh and Eighth Postfertilization Weeks: Testicular Differentiation

Continued development of the structures necessary for epididymal-testicular descent depends on testicular differentiation, which begins during the end of the sixth week under the influence of the testicular-determining factor or the sex-determining region on the Y chromosome. The bipotential gonad is remodeled into an oval, smooth-surfaced testis covered by a tunica albuginea. Testicular cords containing Sertoli cells appear, and primordial germ cells migrate into the cords and differentiate into gonocytes. Rising levels of human chorionic gonadotropins (hCG) stimulate the differentiation and maturation of fetal Leydig cells. Histologic testicular differentiation is complete by the end of the eighth week, and testicular endocrinologic function begins with production of MIS by Sertoli cells and testosterone by fetal Leydig cells (128,211,266).

The Ninth Through Twelfth Postfertilization Weeks: Masculinization of the Gonadal Ducts and External Genitalia and the Appearance of the Processus Vaginalis

Testicular production of MIS and testosterone causes masculinization of the gonadal ducts and external genitalia. Rising local levels of MIS in the ninth week initiate regression of the paramesonephric duct. Resorption begins at the point where the paramesonephric duct crosses ventral to the first curve of the mesonephric duct and proceeds in cranial and caudal directions (128). With the disappearance of the paramesonephric duct in the tenth week, the anatomic attachment of the junction of the lower pole of the testis, first curve of the mesonephric duct, and the gubernaculum to the upper midline of the pelvis is lost. Simultaneously, local testosterone stimulates differentiation of the mesonephric duct into the male ductal system. The first curve of the mesonephric duct becomes the tail of the epididymis. The segment of the duct cranial to the first curve becomes the head and body of the epididymis. The segment distal to the first curve becomes the vas deferens. Fusion of the testicular and epididymal ducts does not occur until midpregnancy, and epididymal maturation continues throughout fetal life (101). Systemic testosterone induces masculinization of the external genitalia, which is completed by the end of the twelfth postfertilization week (128,254). The processus vaginalis appears as a dimplelike invagination of peritoneum into the inguinal canal ventromedial to the gubernaculum (101). At the end of the twelfth postfertilization week, the lower pole of the testis and the tail of the epididymis are attached to the bipotential gubernaculum and lie in the internal ring. Before inguinal-scrotal descent can occur, the gubernaculum must be masculinized.

The Thirteenth Through Twentieth Postfertilization Weeks: Maturation of Gonocytes and Gubernacular Swelling

During the thirteenth week, the level of hCG, the number of fetal Leydig cells, and the level of testosterone are at their highest levels noted during fetal life. The high level of testosterone stimulates gonocytes to begin differentiation into fetal spermatogonia (62). The gubernaculum, which has been a thin cord, begins to swell by accumulation of water and hyaluronic acid and attains a diameter equal to that of the testis (6,101,121,170). The control mechanisms of gubernacular swelling are not well described. The details of the changing histology of the gubernaculum with increasing gestational age are not documented. By 19 weeks postfertilization age (21 menstrual weeks), the stage is set for inguinal-scrotal descent.

The Twenty-first Through the Fortieth Menstrual Week: Final Masculinization of the Caudal End of the Fetus and Inguinal-scrotal Descent

Final masculinization of the caudal end of the fetus is part of inguinal-scrotal descent and includes scrotal enlargement, growth of the three layers of the abdominal wall (including the cremaster muscle) and the processus vaginalis into the scrotum, and elongation of the spermatic vessels and vas deferens. Following or simultaneous with these events, the testicular-epididymal-gubernacular unit descends rapidly from the internal ring through the inguinal canal and into the scrotum (6,101). Autopsy and prenatal ultrasound studies of the timing of descent show remarkably similar results. Descent is complete in a few fetuses by 21 weeks; in 30% by 25 weeks; in 75% by 28 weeks; in 95% by 32 weeks; and in 98% to 99% by 40 weeks (3,109). Some consider failure of descent by 28 weeks to be abnormal. Failure of descent by 40 weeks can reasonably be considered as abnormal even if descent occurs during the first year of life. Failure of epididymal-testicular descent is a congenital malformation, and its causes are prenatal in origin.

The mechanical forces responsible for descent are poorly understood. Gubernacular motility, gubernacular contraction, gubernacular resorption, cremaster contraction, epididymal development and contraction, increased intraabdominal pressure, and normal skeletal muscle function have all been implicated. Normal development of all the embryologic structures described earlier, including masculinization of the caudal end of the embryo, is a prerequisite for descent. The endocrinologic and molecular control mechanisms responsible for the development of those embryologic structures and for the initiation and completion of descent are also poorly understood. Androgens, calcitonin gene–related peptide mediated through the genitofemoral nerve and nucleus, MIS, and Hox genes have all been implicated as molecular controls for descent. Hypoplasia of germ cells noted in undescended testes from the last trimester of pregnancy (47) supports the view that androgens play an important role in the control of descent. This supports the rationale for the hormonal treatment to induce descent (as discussed later). The theories

concerning the mechanical forces and control mechanisms involved stimulate controversy and are the subjects of numerous reviews (101,108,121). Much of the data is derived from animal models and may not apply to humans. More anatomic, endocrinologic, and molecular data in humans are needed to fully understand the complex process of inguinal-scrotal descent of the testicular-epididymal-gubernacular unit.

Endocrinology and Histology of Germ Cell Development

The development of testicular histology and endocrine function begins during the seventh postfertilization week, continues into adulthood, and is characterized by five brief dramatic spurts of activity, or steps in maturation, separated by longer intervening periods of less dramatic activity. The five steps in maturation occur in the seventh postfertilization week, the thirteenth postfertilization week, the second postnatal month, and the fifth postnatal year, and then at puberty. The two prenatal landmarks are intimately related to the embryologic steps described previously; refer to the preceding sections for references. Each landmark is a major step in germ cell maturation. The first is initiated by testicular determining factor or the sex-determining region of the Y chromosome. Each of the remaining steps are initiated by a preceding surge in the level of gonadotropin, number and maturation of Leydig cells, and level of testosterone. Each step is accompanied by a step in maturation of Sertoli cells.

The maturation of germ cells is depicted in Fig. 53.2. The histologic and hormonal features of the steps in maturation are shown in Fig. 53.3. The total germ cell count (the number of all germ cells of all subtypes) is an important indicator of the health of the testis and is often expressed as the number of germ cells per tubule. Figure 53.4 shows the normal number of germ cells per tubule by postnatal age. The differential count tabulates the number of each subtype individually.

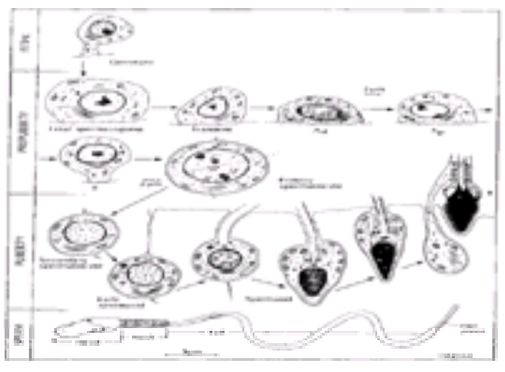

FIGURE 53.2. Development and differentiation of germ cells from fetal life until puberty.

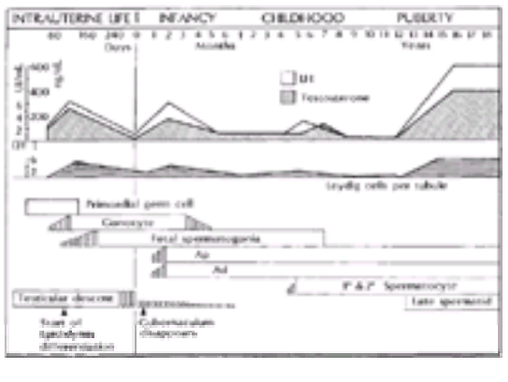

FIGURE 53.3. Testicular development. Luteinizing hormone *(LH)* and testosterone in relation to age. The five steps in maturation can be recognized at less than 60 postfertilization days, 990 postfertilization days, 2 months postnatal age, 5 years, and 12 years, respectively.

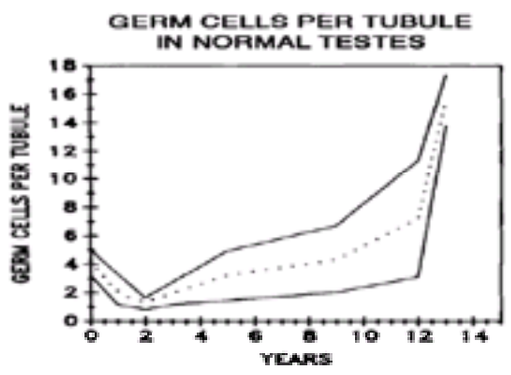

FIGURE 53.4. Germ cells per tubule in normal testes. (*Dotted line* is mean, ±1 SD.)

First Step in Maturation, Seventh Postfertilization Week: Development and Expansion of the Fetal Stem Cell Pool (Gonocytes)

During the differentiation of the bipotential gonad into the testis, under the control of the sex-determining region of the Y chromosome, primordial germ cells enter the emerging testicular cords and differentiate into gonocytes. The gonocytes constitute the fetal stem cell pool of germ cells. They lie in the centers of the testicular cords. hCG stimulates fetal Leydig cell development, proliferation, and testosterone secretion. Gonocyte proliferation expands the fetal stem cell pool. Simultaneously, fetal Sertoli cells differentiate and secrete MIS. Masculinization of the mesonephric duct, paramesonephric duct, and external genitalia begins.

Second Step in Maturation, Thirteenth Postfertilization Week: Gonocytes Begin Maturation into Fetal Spermatogonia

The level of hCG, number of fetal Leydig cells, and the level of testosterone reach their peaks. Gonocytes, the fetal stem cell pool, begin to migrate to the basement membranes of the seminiferous tubules and differentiate into fetal spermatogonia. As stem cells, the gonocytes simultaneously replenish their own numbers. Masculinization of the external genitalia and resorption of the paramesonephric duct are complete by 13 weeks. Masculinization of the mesonephric duct into epididymis continues. Masculinization, or “swelling,” of the gubernaculum begins. The differentiation of fetal spermatogonia continues throughout fetal life.

Third Step, Second Postnatal Month: Disappearance of the Fetal Stem Cell Pool (Gonocytes), Development of the Adult Stem Cell Pool (Adult Dark Spermatogonia), and Reduction in Numbers of Germ Cells

At 2 months postnatal age, the seminiferous tubules contain numerous germ cells. Approximately 50% of the germ cells are gonocytes; the rest are fetal spermatogonia (89). At this time, a surge in levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) stimulates proliferation of fetal Leydig cells. The activated fetal Leydig cells produce a surge in the level of testosterone, which then triggers the transformation of gonocytes (70,71,278). Only a minority of gonocytes differentiate into adult dark spermatogonia; the majority undergo apoptosis and disappear. As a result of this change, gonocytes constituting the fetal stem cell pool are replaced by adult dark spermatogonia, constituting the adult stem cell pool (41). The total number of germ cells falls because of the death of most gonocytes. The transformation and disappearance of gonocytes is normally complete by 6 months of age. Then the level of gonadotropins falls. Fetal Leydig cells regress into inactive

juvenile Leydig cells. The level of testosterone falls. The adult stem cell pool expands while some adult dark spermatogonia mature into adult pale spermatogonia. Fetal spermatogonia begin to disappear. Fetal Sertoli cells mature into type Sa Sertoli cells.

The histology of the testis is fundamentally changed (Fig. 53.5). Before the event, histologic sections show large numbers of activated fetal Leydig cells and seminiferous tubules filled with large numbers of germ cells with many gonocytes and no adult dark spermatogonia (94,99). After the event, only a few small juvenile Leydig cells remain; the seminiferous tubules contain only a few germ cells with no gonocytes and increasing numbers of adult dark spermatogonia (89,118). This transformation of the fetal stem cell pool into the adult stem cell pool is a prerequisite for future maturation of the testis.

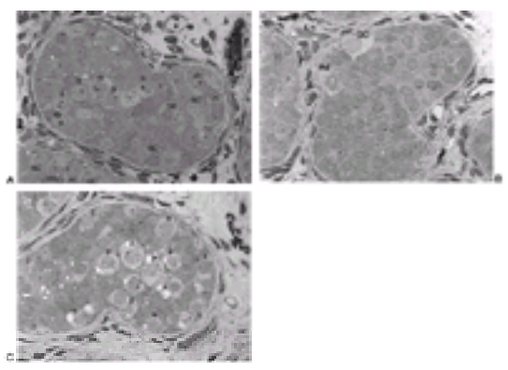

FIGURE 53.6. Normal testicular histology. **A:** Before maturation of gonocytes into adult dark spermatogonia at 2 months of age. Large fetal Leydig cells *(L);* tubule filled with numerous germ cells *(GC),* including gonocytes *(G);* no adult dark spermatogonia. **B:** After maturation of gonocytes at 1 year age. Small juvenile Leydig cells *(L);* tubule with few germ cells *(GC),* including adult dark spermatogonia *(Ad);* no gonocytes. **C:** After onset of meiosis at age 5 years. Large juvenile Leydig cells *(L);* tubule containing spermatogonia *(Sp);* and primary spermatocytes *(P)* in the center of the tubule.

Fourth Step, The Fifth Postnatal Year: Onset of Meiosis

At 5 years of age, simultaneous transient peaks are seen in urinary LH (268), number and size of juvenile Leydig cells, and level of testosterone. The increased testosterone stimulates an increase in the number of total germ cells and of adult dark spermatogonia and triggers the maturation of the mitotic adult spermatogonia into primary spermatocytes, which are germ cells in the prophase of the first meiotic division. Sa Sertoli cells mature into Sb Sertoli cells (101). The onset of meiosis at age 5 years, a process of fundamental importance, is often overlooked.

The concept that the prepubertal testis is quiescent is erroneous. The adult stem cell pool is established at 2 months of age, and meiosis is initiated at 5 years of age. Final germ cell maturation at puberty depends on completion of these two prepubertal developmental landmarks.

Fifth Step, Puberty: Complete Spermiogenesis

The pubertal surge in LH and FSH stimulates the inactive juvenile Leydig cells to proliferate and mature into adult Leydig cells. Activated adult Leydig cells produce the massive pubertal surge in testosterone, which triggers rapid proliferation of germ cells; final maturation to secondary spermatocytes, early spermatids, late spermatids, and sperm; and final maturation of Sertoli cells from Sb to Sc forms. Complete spermiogenesis is seen in most boys by the age of 13 to 15 years. These maturational steps demonstrate the principle that rising levels of gonadotropins stimulate proliferation and maturation of Leydig cells, rising testosterone levels, and proliferation and maturation of germ cells and Sertoli cells.

CONGENITAL AND ACQUIRED SCROTAL ABNORMALITIES

Congenital Developmental Anomalies

The paired genital swellings on each side of the genital tubercle give rise to the future scrotum, which is initially filled with a compact undifferentiated mesenchymal ground substance before the testis descends. Congenital scrotal anomalies occur when normal posterocaudal migration of the paired labioscrotal folds is impaired. This occurs in intersex conditions, severe hypospadias, cloacal exstrophy, and tail anomalies of the embryo, and sometimes occur as an isolated defect. These instances suggest that both hormonal and mechanical influences may affect scrotal development.

Scrotal Hypoplasia

Scrotal hypoplasia is sometimes seen in association with cryptorchidism or absent testes. The scrotal skin is often completely flattened and quantitatively deficient. Prominence of the surrounding pubic and perineal skin may suggest a greater overall size to the scrotum, although the consistency and appearance of this skin is different. Scrotal hypoplasia makes orchiopexy or testicular prosthesis placement more difficult. Testes placed dependently at orchiopexy in a hypoplastic scrotum may appear to be in a nondependent position, although over a few years of follow-up, the scrotum seems to grow and accommodate the testes. Prostheses sometimes remain high and appear asymmetric when placed in a hypoplastic scrotum, even when the patient is followed through puberty, resulting in an unsatisfactory cosmetic appearance. Pretreatment with testosterone has been suggested to enlarge the hypoplastic scrotum in anorchid boys (143).

Scrotal Ectopia

Scrotal ectopic may occur on the inner thigh, on the perineum, or in the pubic region lateral to the penis. This condition is most commonly seen in males with cloacal exstrophy with diphallus (Fig. 53.6) as well as in myelodysplastic boys. Mininberg and Richman (194) encountered it in “syndromes,” and Lamm and Kaplan (162) encountered it in otherwise normal children. The testis normally lies within the ectopic scrotum, although it sometimes may be hypoplastic. Treatment usually consists of excision when the ectopic scrotum is distant.

FIGURE 53.6. Scrotal ectopia *(arrowheads*) in 46,XY male with cloacal exstrophy.

Bifid Scrotum and Penoscrotal Transposition

Bifid scrotum and varying degrees of penoscrotal transposition occur most often associated with severe hypospadias, intersex conditions, and caudal regression syndrome, and rarely occur as an isolated finding (193) (Fig. 53.7). Failure of fusion or caudal migration results in separation of the two hemiscrotal compartments in the former instance and envelopment of the penis in the latter. Bifid scrotum is usually corrected naturally as part of a hypospadias repair or feminizing genital reconstruction in intersex. Minor degrees of penoscrotal transposition can be left untreated, although more severe degrees should be corrected with an M- to Y-type of scrotal recession. Techniques for simultaneous correction of chordee, hypospadias, and coexisting penoscrotal transposition have been described (58).

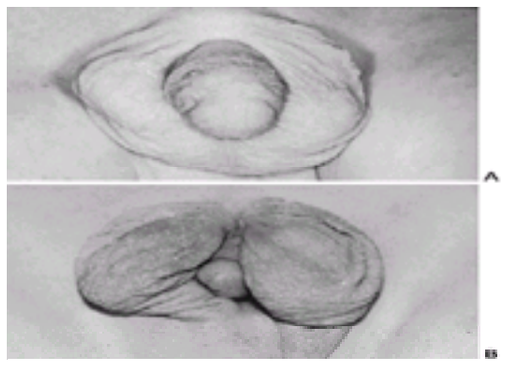

FIGURE 53.7. Penoscrotal transportation. **A:** Incomplete. **B:** Complete.

Scrotal Wall Swellings

Scrotal swellings may result from conditions involving either the scrotal wall or the intrascrotal contents. Scrotal wall swellings occur less often than swellings of the intrascrotal contents but may be painful and may simulate the latter. In some cases, the differential diagnosis may be made only by surgical exploration.

Acute Idiopathic Scrotal Wall Edema

Acute idiopathic scrotal wall edema is an uncommonly encountered scrotal swelling involving one or both hemiscrotal compartments. The overlying skin may be thickened, edematous, and discolored, with a peculiar violaceous hue (61,134). In some instances, the swelling and erythema may extend onto the abdominal wall or into the perineum. The underlying testis, epididymis, and cord usually are easily palpated, are always nontender, and are not swollen, allowing differentiation from more serious acute intrascrotal conditions. An inflammatory cause has been suggested (e.g., secondary to insect bite or contact), but documentation of these suggested causes is lacking. The actual cause is unknown. Treatment with antibiotics, antihistamines, and corticosteroids has been advocated, but it appears that this condition resolves spontaneously without treatment and without sequelae. Its importance lies in its distinction from the more serious acute intrascrotal catastrophic conditions that it may simulate.

Acute Vasculitis

Acute vasculitis of the scrotal wall from Henoch-Schönlein purpura (HSP) is uncommon but also simulates an intrascrotal catastrophe. Both the scrotal wall and the testis are involved in up to 15% of patients, and genital findings may precede the onset of the characteristic rash elsewhere (138,212). The scrotum is purpuric and erythematous and is usually tender and swollen, often making examination difficult. The testis, when involved, is often exquisitely tender, is swollen, and may completely mimic the findings seen in spermatic cord torsion. Unfortunately, to further complicate matters, spermatic cord torsion has been reported to occur in HSP (177). A high index of suspicion is needed in making this diagnosis. Adjunctive diagnostic aids, especially isotope scrotal scanning, should be used to ensure the integrity of the testis when the diagnosis is not clear (257). This condition resolves with resolution of the generalized condition without genital sequelae.

Spontaneous Gangrene

Spontaneous gangrene of the scrotal wall is a rare but serious cause of scrotal wall swelling in childhood. Swelling, edema, and then frank necrosis progressing to gangrene may occur, resulting in fever and toxemia. Most cases have occurred in neonates and have been associated with an identifiable portal of entry, such as after circumcision (227,282). Treatment consists of intense antibiotic therapy, wet soaks, and sometimes incision or debridement.

Cutaneous Cysts and Tumors

Cutaneous cysts and tumors of the scrotal wall are uncommon in childhood. Sebaceous and epidermoid inclusion cysts are usually easy to identify from their intracutaneous position, completely separate from the underlying intrascrotal contents. Dermoid cysts occur in the scrotum along the midline raphe, similar to their midline position elsewhere in the body, and sometimes are difficult to distinguish from the intrascrotal structures because of their deeper position. Scrotal sonography aids in this diagnosis; operative excision is indicated for confirmation of diagnosis.

Swellings of the Intrascrotal Contents

Swellings of the intrascrotal contents are a commonly encountered problem in pediatric urologic practice and sometimes present a difficult differential diagnostic challenge. Acute swellings resulting from spermatic cord torsion or incarcerated hernia represent surgical emergencies and must be acted on expeditiously, whereas other swellings, such as reducible hernia, hydrocele, and varicocele represent entities in which proper diagnosis is important for appropriate elective treatment. Optimal treatment depends on an exact diagnosis and a clear understanding of the nature of the underlying problem.

Hernias and Hydroceles

Hernias and hydroceles result from failure of fusion and obliteration of the processus vaginalis (Fig. 53.8). When the entire processus vaginalis remains patent, as is commonly encountered in infants, a knuckle of bowel may protrude into the lumen of the hernia sac and may incarcerate or strangulate, the latter presenting as an acute painful erythematous scrotal swelling, inguinal swelling, or both. If the distal processus vaginalis is obliterated but the neck remains open, a groin mass rather than a scrotal mass will be encountered. For example, chronic incarceration of omentum may present as a nontender, nonreducible groin swelling, with the testis palpable separately below. A more common occurrence, however, is an intermittently palpable nontender groin swelling representing intermittent prolapse of bowel or omentum into a hernia sac, with spontaneous reduction. Sometimes, in these instances, the hernia may never be observed by the examining physician, and one must rely only on a good history from the parent to diagnose this condition.

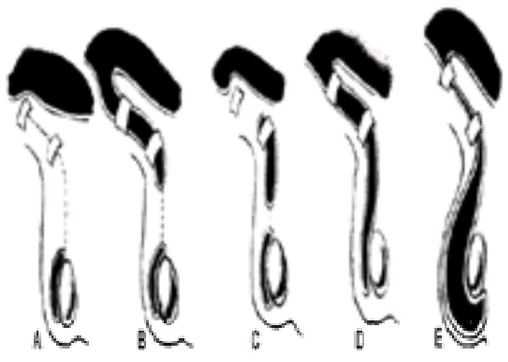

FIGURE 53.8. Diagrammatic representation of persisting patent processus vaginalis. **A:** Normal obliteration of patient processus. **B:** Patent processus proximally with inguinal bulge; processus obliterated distally. **C:** Closure proximal and distal with loculated hydrocele of cord. **D:** Complete patency with hernia sac extending into scrotum. **E:** Partial proximal closure, resulting in scrotal hydrocele and proximal patent processus. (From Lewis JE Jr: *Atlas of infant surgery.* St. Louis: Mosby, 1967, with permission.)

Strangulated hernias require immediate surgical exploration to prevent necrosis of the hernia sac contents. Infants with incarcerated inguinal hernias may be more prone testicular strangulation resulting from the increased pressure on their spermatic cord with resultant testicular atrophy (198,222). Children with incarcerated hernias should be admitted for observation, sedated, and placed in Trendelenburg position with subsequent attempts at manual reduction. Usually, these maneuvers result in successful reduction, but elective hernia repair should be done within a short period thereafter because reincarceration commonly occurs. Children with asymptomatic reducible inguinal hernias should undergo repair within a reasonable period after diagnosis to minimize the risk of incarceration or strangulation. The latter occurs commonly in infants, and surgical repair of inguinal hernias should not be deferred because of the patient's age.

Controversy exists regarding the necessity for exploration of the contralateral inguinal canal. In general, it is believed that closure of the processus vaginalis occurs in most infants during the first several months of age and that a persisting patent processus clinically evident thereafter should be surgically repaired. These figures have led some to believe that routine contralateral inguinal exploration is not advisable, a view based also on the added anesthesia time required for both repairs and the small but definite incidence of testis atrophy, vas injury, and secondary fixation of the testis in an extrascrotal position after inguinal hernia surgery (104). On the other hand, hernias *do occur* in boys who have undergone previous contralateral inguinal hernia repair. A contralateral patent processus vaginalis was found in 59% of boys up to age 16 years who underwent bilateral exploration for a unilateral clinically apparent hernia (195). These figures are somewhat age dependent, with a greater frequency of clinical hernias present in younger boys, especially those younger than 6 months. McGregor and colleagues (186) reevaluated 130 patients over a postoperative follow-up period averaging 20 years and found that 29% eventually developed a contralateral inguinal hernia after previous unilateral repair. The chance of contralateral occurrence was found to depend on which side had originally been repaired. If the left side had been repaired formerly, there was a 41% chance of a subsequent right-sided hernia requiring surgical correction; if the right side was repaired first, there was only 14% chance of a hernia subsequently occurring on the left. Furthermore, nearly half of the subsequent contralateral hernias occurred within 1 year of the original repair. Despite these observations, they believed that routine contralateral groin exploration was unwarranted because, statistically, two explorations yielding negative findings would be required for every right-sided exploration yielding positive findings, and six left-sided explorations yielding negative findings would be done—an unacceptably high figure in their view (186). However, current opinions diverge somewhat from their conclusions. In a survey of 48 experienced pediatric surgeons, 80% routinely explored the contralateral groin in boys and 90% in females (231). In general, most surgeons dealing with pediatric hernias believe that the contralateral groin exploration can be done safely and expeditiously (i.e., in the hands of a competent pediatric surgeon); both sides should be explored in cases in which only one hernia is clinically evident in boys younger than age 2 years.

More recently, this approach has been refined further using minimally invasive techniques. Intraoperative inguinoscopic evaluation of the contralateral internal inguinal ring (through the opened hernia sac) has been advocated. A 90-degree viewing lens facilitates this diagnostic maneuver. If the internal ring is dilated, contralateral inguinal exploration is performed. A simpler alternative is to simply perform a pneumoperitoneum by placing a small catheter into the peritoneal cavity through the opened hernia sac, producing temporary inflation pressures to 15 cm H_2O. Crepitus or a visible bulge in the contralateral asymptomatic groin is a positive indication for exploration. Although individual preference dictates which of these maneuvers is undertaken, most pediatric urologists currently use some form of evaluation of the contralateral asymptomatic groin.

Hydroceles

Hydroceles represent persistence of the processus vaginalis along its course with partial or complete fusion of the processus proximally. In children, virtually all hydroceles are communicating (i.e., a narrow persistent processus vaginalis that allows the hydrocele periodically to fill with fluid), resulting in intermittent enlargement (Fig. 53.8). Hence, a history of a childhood scrotal swelling that intermittently enlarges in the absence of a clinical hernia confirms the presence of a patent processus vaginalis. Therefore a related pediatric urologic caveat is that boys with hydroceles should always be explored through an inguinal incision rather than through the scrotum to allow for ligation of the coexisting processus vaginalis.

Most infants with a scrotal swelling caused by a hydrocele undergo spontaneous closure of the processus vaginalis with subsequent resolution of the hydrocele. Therefore surgical repair is usually reserved for persistent swellings beyond age 2 years because after this age, spontaneous closure of the persisting processus vaginalis occurs far less frequently. Size of the scrotal swelling should not influence a decision regarding early surgical correction because many of these swellings can be quite large yet will still resolve spontaneously. Observation of a clinical hernia, however, is an indication for prompt surgical repair, as is the rare occurrence of significant hydrocele enlargement.

Occasionally, an isolated scrotal hydrocele may be encountered in the absence of a proximal patent processus vaginalis. The cause of this may not be obvious but sometimes is the presenting sign of a serious underlying condition (e.g., a testicular tumor or chronic epididymitis). In these instances, proximal exploration through an inguinal incision still should be used rather than a scrotal or inguinoscrotal approach, as is commonly used in adults. This proximal approach allows for diagnosis and ligation of an occult patent processus vaginalis and for proximal spermatic cord occlusion if an unsuspected tumor becomes evident.

A loculated hydrocele (hydrocele of the cord) may occur anywhere along the spermatic cord, presenting as a firm groin swelling that is sometimes difficult to distinguish from an incarcerated inguinal hernia or paratesticular rhabdomyosarcoma of the cord. Transillumination of the mass and sonography may aid in this distinction and many swellings in this location usually require surgical exploration for confirmation of diagnosis and treatment.

Antenatal or Postnatal Peritonitis

Antenatal or postnatal peritonitis may present with scrotal findings. An *in utero* intestinal perforation may heal, but spillage of intraabdominal meconium may track down a patent processus vaginalis into the scrotum, causing an inflammatory mass. As an example, the case shown in Fig. 53.9 is a healthy term boy who presented with bilateral scrotal hydroceles at birth. As the hydroceles regressed over the first several weeks, a few hard nodular masses were palpated, related to the right testis and epididymis, raising the concern of an intrascrotal tumor. Scrotal sonography demonstrated several echogenic foci in both hemiscrotums, suggesting multiple areas of calcification. A plain film subsequently revealed multiple calcified areas in the scrotum and inguinal canal characteristic of meconium peritonitis (259). Similarly, acute appendiceal perforation in boys can track down a patent processus vaginalis and present as an acutely inflamed scrotum with minimal or no intraabdominal or inguinal signs. If pus is encountered in an exploration of an acutely inflamed scrotum, appendicitis with perforation should be considered. Similarly, idiopathic fat necrosis within the scrotum may mimic this condition (57).

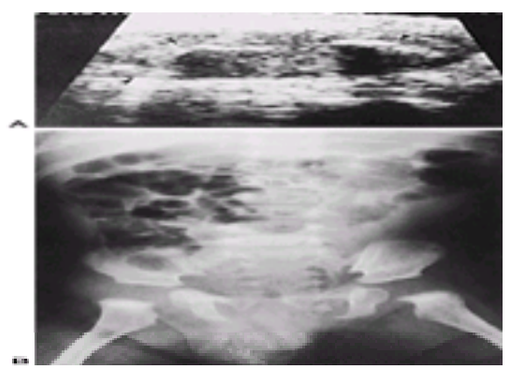

FIGURE 53.9. Meconium peritonitis and scrotal mass in a 4-month-old boy. **A:** Longitudinal sonogram of right hemiscrotum demonstrating multiple extratesticular echogenic foci *(arrows)* surrounding testis, suggesting calcification. **B:** Plain film indicating multiple calcified areas in scrotum and left inguinal canal along the processus vaginalis.

Orchitis

Orchitis as an isolated finding in boys is uncommon and usually results from a concomitant viral infection or as a reactive change to an adjacent epididymitis. The testis is acutely swollen and exquisitely painful, may be surrounded by a reactive hydrocele, and may mimic other acute intrascrotal processes completely. Testicular inflammatory swelling in mumps usually occurs in postpubertal boys and rarely occurs under age 10 years. Estimates of the frequency of mumps orchitis in the literature range from 3% to 100%, but in one carefully analyzed study, the frequency was 30%. One-third of those having orchitis developed subsequent atrophy (12). The risk of infertility is increased in this group, and there is a questionably increased risk of malignancy developing in these atrophic testes. The treatment is usually supportive, with analgesics, scrotal elevation, and ice packs used in the acute phase.

Epididymitis

Epididymitis is a more common cause of scrotal swelling in childhood than is usually believed. Gierup and colleagues (78) collected 48 cases over a 25-year period; more recently, Gislason and colleagues (84) reviewed an additional 25 childhood cases seen over 5 years. Most pediatric urologic referral practices encounter children with epididymitis regularly because this condition occurs more commonly in boys who have urinary infections, who have structural lesions of the urinary tract, or who undergo reconstructive surgery and have indwelling urethral catheters. When the findings from four series of acute scrotal swellings in boys were collated, epididymitis was noted as the underlying cause in 8% to 41% (23,133,166,197). The peak incidence is usually in adolescence.

Epididymitis may result from an acute urinary tract infection with retrograde spread of infection along the vas deferens. The common embryologic derivation of the ureter, vas deferens, seminal vesicle, and epididymis should be remembered, and in some boys, structural abnormalities of the termination of these organs in the trigone and posterior urethra may be present, predisposing them to retrograde vasitis and epididymitis (Fig. 53.10). Indwelling urethral catheters may sometimes precipitate an attack of acute epididymitis in boys with these structural abnormalities without previous urologic symptoms (Fig. 53.11). In older boys, epididymitis is a cause of acute, painful scrotal swellings, often in the absence of demonstrable bacterial infection. Numerous studies, including culture of direct epididymal aspirations, have generally failed to demonstrate organisms in these instances. In such cases, viral and atypical bacterial infections have been postulated as the cause. Uncommonly, epididymitis may be associated with an unusual organism (e.g., *Salmonella, Haemophilus*) in the absence of demonstrable urinary tract infection. In these circumstances, direct hematogenous seeding may be the cause. Purulent epididymitis or chronic epididymitis may occur, requiring surgical exploration for diagnosis or drainage of the epididymal abscess.

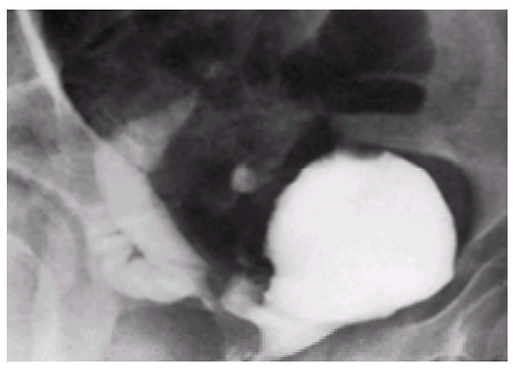

FIGURE 53.10. Persistent mesonephric duct in a 6-year-old boy with anorectal anomaly and rectourethral fistula. The voiding cystourethrogram demonstrates reflux into a markedly dilated convoluted vas deferens and ureter.

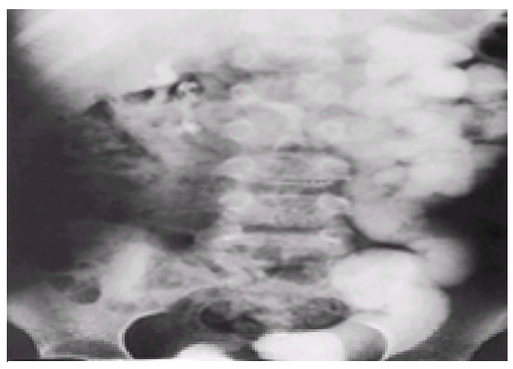

FIGURE 53.11. Left epididymitis in a 4-year-old boy who was previously asymptomatic with an indwelling urethral catheter after open-heart surgery. The intravenous pyelogram reveals previously unsuspected horseshoe kidney, gross left hydroureteronephrosis. A Y ureter was found draining the right side and isthmus.

These findings raise the issue of whether radiologic urinary tract screening to detect underlying structural abnormalities is indicated in boys who have epididymitis diagnosed at any age. Some have indicated that infants with epididymitis have an increased likelihood of having underlying structural genitourinary abnormalities and recommend that complete urologic investigations be performed (243,272). Others who have reviewed this problem in older children suggest that underlying structural problems are uncommon in this population (84). A selective approach to this problem should be practiced. Boys with epididymitis associated with an acute urinary infection are evaluated with a sonogram and voiding cystourethrogram, just as any other boy with an acute urinary infection. Preadolescent boys with epididymitis having sterile urine have a sonogram and voiding cystourethrogram done as well, although the number of abnormalities found in this group is smaller than in the former. Adolescent boys with epididymitis undergo screening sonography of the kidneys and pelvis to ensure normalcy of the upper urinary tract and to ensure that a rarely encountered wolffian or müllerian duct remnant is not present. Circumcision status seems to play a role: Epididymitis occurs three times as often in uncircumcised boys, regardless of age (15).

The diagnosis of epididymitis is made by direct physical examination; the epididymidis is usually found to be enlarged, firm, and exquisitely tender, usually with a normal adjacent testis. In some instances, the intrascrotal contents are obscured by a surrounding hydrocele, making the diagnosis difficult. Prehn's sign (relief of pain with elevation of the involved testis) in our experience has not proved to be a reliable diagnostic aid in children because of inaccuracies observed with this maneuver and the small size of the pediatric scrotum that naturally draws up the testis. Associated fever, leukocytosis, pyuria, and bacteriuria occur more commonly with epididymitis, helping distinguish epididymitis from other causes of acute scrotal swelling. However, these findings should be considered as supportive findings to the general clinical history and examination, rather than as absolute indicators that epididymitis is present. Two studies indicate that although 46% of their patients with epididymitis had pyuria, between 27% and 40% of the patients with spermatic cord torsion also had pyuria (2,256). Scrotal sonography, isotope scrotal scanning, or both may aid in the difficult case (see later discussion). Treatment with appropriate antibiotics should be provided based on urine culture and sensitivities, as well as scrotal elevation and restrained physical activity until the acute phase subsides. Worsening swelling and symptoms should raise the issue of a misdiagnosis, such as a missed spermatic cord torsion, and appropriate reevaluation or surgical exploration may then be indicated.

Varicoceles

The incidence of varicoceles in boys has been reported to range from 9.0% to 25.8%. A summation of the larger series in the world literature shows a mean of 16.2% in 21,878 boys of ages 10 through 25. Testicular damage related to an ipsilateral varicocele has been debated for years, but current thought focuses on the alterations in blood flow to both testes noted when a unilateral varicocele is present. Free communication is noted between the arteries at the testicular level, as well

as between the veins of the pampiniform plexus (Fig. 53.12). As venous blood flows up the spermatic cord, adjacent arterial blood is normally cooled from 37 degrees to 33 degrees by a countercurrent heat-exchange process (265). When a varicocele forms, the countercurrent heat exchange process is disrupted, and because pelvic venous crossover anastomoses are present, the arterial and testicular temperatures in both testes remain elevated even though the varicocele is unilateral. Intratesticular hormone production and spermatogenesis is disrupted as a result.

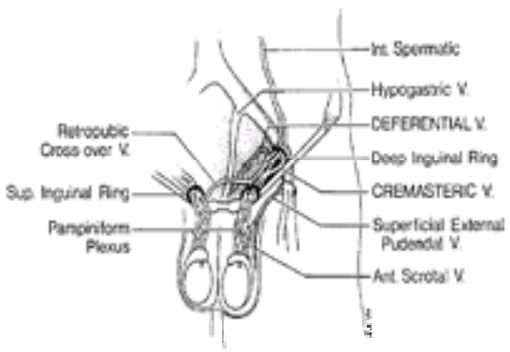

FIGURE 53.12. Venous drainage of the testes. (From Levitt SB, Gill B, et al. Routine intraoperative venography in the treatment of pediatric varicocele. *J Urol* 1987;137:716, with permission.)

In 1982, Lyon and co-workers (180) reported that the majority of boys with left varicoceles had small left testes. Pozza and colleagues (219) found that 74% of 35 boys younger than 16 years of age with varicoceles had atrophy of the testis and 90% had abnormal testis biopsies. On the other hand, Wyllie (283) found that in 50 normal boys without varicoceles between the ages 10 and 13, there was no significant difference in testis size. Sayfan and colleagues (233) found that young asymptomatic men with varicoceles had significantly lower testis volume (21.5 mL) and total sperm counts (71 million) than normal controls (30.0 mL; 186 million) and that their testis volume was similar to that for infertile men (21.3 mL; 35 million). Kass and Belman (135) found that of 20 boys who had varicocele repair, 16 were noted to experience an increase in the relative size of the left testis as compared with the right after the repair. Hosli (112) reported on 20 young men ages 20 to 29 who had had varicoceles repaired at ages 9 to 17. The two testes were equal in size, and the semen quality was better than in an untreated control group. Okuyama and co-workers (205) studied 40 boys with varicoceles, 24 of whom were treated surgically and 16 of whom refused operation. Testis size improved significantly in the treated boys and deteriorated in the controls. Semen quality was much better in the patients who had surgery. Laven and colleagues (165) did a randomized study of 88 adolescent males with varicoceles, of whom 33 were observed and 34 were treated. They also studied 21 controls. All patients were followed for a year. The right and left testis volume was smaller in the boys with varicoceles than in the controls. After treatment, both left and right testes caught up with the controls, whereas the testes of the untreated group remained smaller than those of the controls. Similar effects were seen on semen quality. These data strongly suggest that varicoceles can injure the testes in some adolescent boys; in addition, these data are substantiated further by the abnormal results of gonadotropin-releasing hormone (GnRH) infusion tests seen in some boys with varicoceles.

Spermatic Cord Torsion

Scrotal swellings secondary to spermatic cord torsion (Fig. 53.13) represent one of the most serious emergencies encountered in pediatric urology in terms of both the need for urgent management and the potential for long-term potential serious sequelae. Urgent accurate diagnosis is needed, followed by surgical exploration and detorsion of the testis. Time is a critical factor because testis survival relates directly to the duration of torsion (4,9,33,56,74).

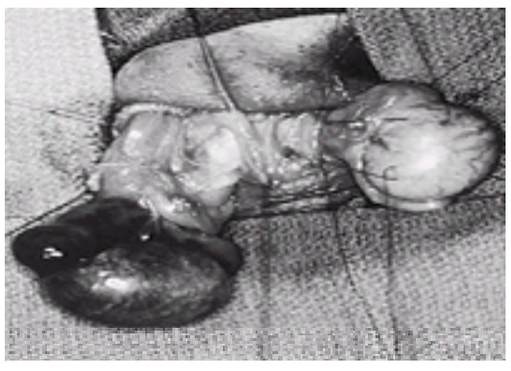

FIGURE 53.13. Right spermatic cord torsion in a 12-year-old boy.

The frequency of spermatic cord torsion has been estimated at 1 in 4,000 males younger than age 25 years, making it relatively common (274). This figure probably underestimates the true frequency because many episodes of missed torsion exist, as well as being misdiagnosed with other conditions. Furthermore, evidence now shows that many, if not most, cases of absent testes result from previous spermatic cord torsion (148). Although it has been stated that two-thirds of cases of spermatic cord torsion occur in boys between ages 12 and 18 years (274), torsion may occur at any age and has clearly been identified and reported antenatally, neonatally, throughout childhood, and in adulthood (127,137,271). An anatomic abnormality in which the peritoneal investiture of the testis inserts high on the spermatic cord rather than on the lower pole allows for poor testicular fixation and extreme testicular mobility (the bell-clapper deformity), predisposing to twisting (Fig. 53.14). Most instances of torsion occur intravaginally (i.e., within this sac); however, in the neonate, extravaginal torsion (i.e., a true twist of the entire spermatic cord and testis) is more common. Because this abnormality of the tunica vaginalis is believed to frequently exist bilaterally and because cases of sequential torsion on the opposite side have followed previous unilateral torsion in cases where the uninvolved side was not suture-fixed in place, bilateral suture fixation of the tests is mandatory in any case of unilateral torsion (14,105).

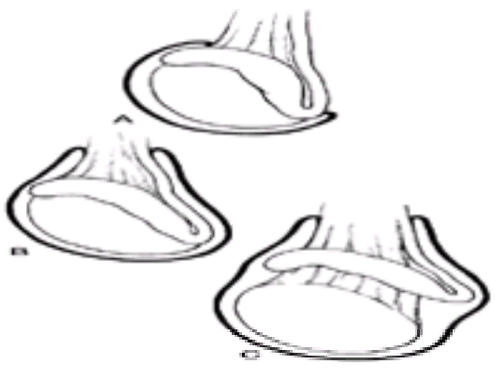

FIGURE 53.14. Diagrammatic representation of the anatomy of spermatic cord torsion. **A:** Normal anatomy. Tunica vaginalis does not envelop the epididymis. **B:** Bell-clapper deformity. Tunica vaginalis extends high on the spermatic cord, enveloping the epididymis and allowing the testis to twist within. **C:** Testis suspended from the epididymis, allowing twist to occur between the testis and epididymis.

Just how long can the testis in torsion survive without undergoing irreversible atrophy? Several experimental preparations examining the effects of complete torsion of rat and dog testes reveal that the “safe” period for recovery of germinal and tubular epithelium may be somewhere between 4 and 6 hours, although severe, irreversible abnormalities may be seen after even 1 hour (49,166,251,253,264). One classic article indicated that 17 of 19 boys had their testis saved when operated on within 24 hours of symptom onset, whereas in none of 31 boys operated on after that time was testis salvage feasible. In several additional reviews, maximum survival (70% to 90%) was noted in patients operated on within 12 hours of symptom onset. Survival decreased significantly during the next 12 hours but was still possible. After 24 hours of torsion in humans, testicular infarction is the rule. The degree of torsion influences survival because not all torsion results in complete ischemia; 720 degrees of torsion experimentally have been shown to be necessary for complete, irreversible cessation of blood flow (49,264). Furthermore, in humans, spontaneous incomplete or complete detorsion is not uncommon, explaining the occasional occurrence of testicular salvage after prolonged periods. Nevertheless, these data serve to illustrate graphically the effect of delayed diagnosis on testicular survival.

If time is so critical, why has therapy been delayed so often? Failure to suspect torsion as the underlying cause of the acute scrotal inflammation is the most common reason. Also, a lack of uniformity of symptoms and physical findings often suggests alternative diagnoses and has led to a variety of descriptive titles of literature dealing with this subject (166,273). The classic description of torsion includes a sudden onset of hemiscrotal pain, followed by swelling, acute nausea, and vomiting in the absence of fever and urinary symptoms. However, a painless swollen testis, which may occur in up to 10% of torsions (most often in newborns), can occur, causing delay in diagnosis (133). Failure to understand that torsion is the leading cause of acute scrotal inflammation in childhood, not epididymitis, can cause diagnostic delay and testicular wastage. An additional cause for delay in therapy sometimes results from the blind faith of treating physicians in the newer diagnostic modalities available to distinguish the various cases of scrotal inflammation. Conflict between clinical impressions and diagnostic testing has led to delay in exploration in some and even missed torsion in others. Further discussion of this aspect of management follows in the subsequent section on differential diagnosis of scrotal swellings.

Although the recognition of spermatic cord torsion may be somewhat complicated, management is completely straightforward and not controversial. Surgical exploration should be performed immediately. However, manual derotation as a temporizing maneuver may be attempted after administration of intravenous morphine (0.1 mg/kg of body weight) (17,73). It has been suggested that the anterior portion of each testis torts toward the midline; hence, it should be rotated outward to achieve detorsion (255), although not all agree and attempts can be made in each direction. Successful detorsion is usually associated with marked pain relief immediately and may be documented with Doppler examination. Surgical fixation with nonabsorbable sutures should follow within 24 hours to prevent retorsion, which commonly occurs. Cases have been reported in which retorsion has occurred when the previous suture fixation was done with absorbable sutures (157,187,267). Simultaneous fixation of the opposite, uninvolved testis is also mandatory because contralateral sequential torsion has been reported in more than 40% of cases in which the uninvolved testis was not fixed at the time of torsion (158,250).

Neonatal Torsion

Neonatal torsion represents a unique and distinct situation. The finding of a painless, discolored, hemiscrotal swelling in the neonate is indicative of spermatic cord torsion and should in no circumstances be considered a diagnostic problem. Unfortunately, bilateral synchronous and asynchronous cases may occur. The duration of torsion is difficult to determine in many of these circumstances, and in some instances, torsion may have occurred before birth. A review of this subject covered approximately 120 previously reported cases in the literature through 1983 (244). Attitudes concerning management of this condition were polled among the members of the Society for Pediatric Urology. Most believed that the diagnosis of this condition was self-evident and that exploration was indicated; however, the testicular salvage rate was disappointing. Further controversy over the frequency of contralateral torsion in these instances and the need to suture-fix the contralateral testis existed because most of these torsions occur extravaginally. This controversy led some to adopt a less aggressive attitude toward emergent exploration.

With increased recognition of this problem, antenatal torsion is similarly being diagnosed with increased frequency. Reports of calcified testes and hypoplastic testes at birth, as well as the report of a “free-floating necrotic intraabdominal testis” found at exploration of a newborn presenting with an acute abdomen and an ipsilateral empty scrotum (196), illustrate the spectrum of presentations of this condition. Further investigations indicate that many instances of unilateral absent testes result from antenatal torsion (114,152). Unfortunately, testicular salvage after antenatal spermatic cord torsion has not been reported and is unlikely.

The fate of the torted and contralateral untorted testes after correction of spermatic cord torsion has received considerable attention. Salvage rates of “viable” testes have varied, but some series reported atrophy in one-third to two-thirds of these testes. A correlation between duration of torsion and subsequent atrophy exists (158,182). These data suggest that in some instances, surgeons are preserving poorly viable testes that should have been removed. Furthermore, the incidence of morbidity (e.g., prolonged high fever, scrotal abscess, drainage of necrotic tubules through the scrotal incision) is high, approaching 20% in some series (274).

Some additional information suggests that the testis undergoing torsion can adversely affect the contralateral testis by a presumed immunologic process. Various adult rat experimental preparations, beyond the scope of full discussion here, have demonstrated contralateral histologic abnormalities in unilateral torsion (49,152,199) (Fig. 53.15). Raised antibody titers have been detected in rats and mice in some instances (106,152,258) but were not detected in rabbits (35). Diminished fertility was noted after mating in these circumstances (49,191,199). Orchiectomy (49), splenectomy and azathioprine administration (199), and corticosteroid administration (152) have attenuated these adverse findings, further suggesting that an immunologic process is operative. Data suggest that the prepubertal rat testis subjected to torsion does not result in these abnormalities (152,200). Human clinical correlates of these experimental findings exist. Eighteen patients who had prolonged prepubertal spermatic cord torsion who underwent detorsion with replacement of the testis in the scrotum were reviewed 7 to 23 years later. Of the five married men, all were fathers. Of the 13 unmarried men, only 3 had abnormal semen analyses. None showed any abnormal sperm autoantibodies. In another study, though, only 9 of 23 adults who had previous spermatic cord torsion had normal semen in their ejaculate (11,178). Some of these patients had elevated FSH levels, indicating abnormal testicular function. These studies demonstrate that the contralateral testis may be affected adversely by the torted testis and that orchiectomy should be done if a prolonged period has elapsed because the onset of symptoms or if a rapid return of blood flow is not seen after detorsion. Leaving a marginal testis in place probably causes more potential harm than benefit.

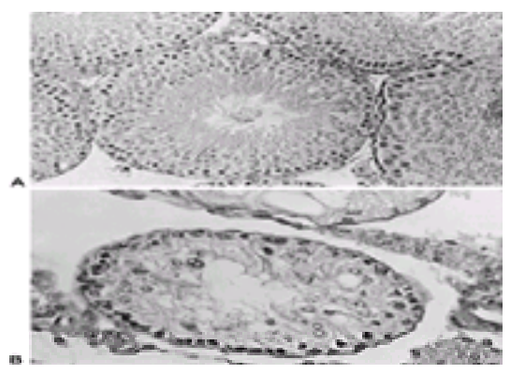

FIGURE 53.15. Histologic findings in the contralateral testis of adult rats (age 53 days) 30 days after undergoing chronic unilateral testicular torsion. **A:** Control contralateral testis with normal tubular diameter and spermatogenesis. **B:** Contralateral testis has absent spermatogenesis and reduced tubular diameter. (From Kogan SJ, Owens G, Tarter T, et al. Mechanisms of injury in unilateral testis torsion. *Eur Urol* 1986;12:184, with permission.)

Torsion of the Testicular Appendages

Torsion of the testicular appendages occurs frequently and may totally mimic the inflammatory findings of spermatic cord torsion. When an inflammatory, painful hydrocele occurs, obscuring the testis completely and precluding adequate examination, concern must be exercised to exclude spermatic cord torsion. Testicular appendages tend to twist when they are long and pedunculated. Venous engorgement occurs, followed by arterial occlusion and then appendiceal infarction. In some instances, the appendage may become strikingly enlarged, sometimes as large the testis (Fig. 53.16). When the appendage in torsion is easily seen and palpated through the scrotal skin (blue-dot sign) and the underlying testis feels normal, spermatic cord torsion may be excluded with complete confidence despite the surrounding inflammation.

FIGURE 53.16. Torsion of the testicular appendage in an 8-year-old boy presenting with 6 hours of acute scrotal pain and inflammation. A large, infarcted intrascrotal mass protrudes **(A),** followed by the testis **(B).** In this unusual case, the infarcted appendix testis is as large as the testis.

Testicular appendages exist at both the superior and inferior testicular poles (Fig. 53.17), and any may undergo torsion. Clinically, the appendix testis is the most commonly encountered appendage, occurring in 92% of one autopsy series, and also is the most common appendage undergoing torsion (230,249). Embryologically, this appendage represents the remnant of the cranial part of the müllerian duct. The appendix epididymis represents a remnant of the cranial end of the wolffian duct, as do the paradidymis and vas aberrans.

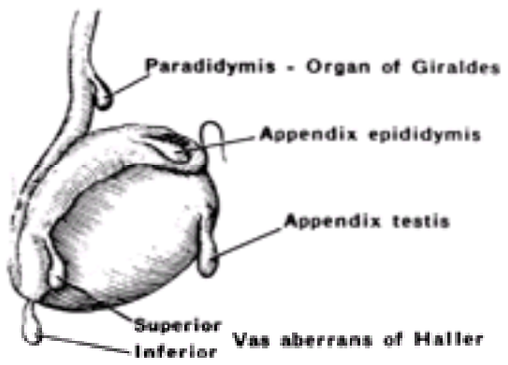

FIGURE 53.17. Anatomic distribution of the testicular appendages. (From Rolnick D, Kawanoul S, Szanto P, et al. Anatomical incidence of testicular appendages. *J Urol* 1968;100:755, with permission.)

Although many surgeons advocate emergent exploration of all cases of acute scrotal inflammation, those boys having testicular appendiceal torsion may be spared this inconvenience providing the diagnosis is made with accuracy (e.g., by clearly palpating a normal testis or finding a blue-dot sign). Virtually all cases of testicular appendiceal torsion resolve spontaneously, often with autoinfarction of the appendix. Supportive analgesics are offered and a follow-up reexamination is important to document resolution of the swelling. The rare instance in which pain is persistent or recurrent after a previous bout has resolved may be dealt with by an ambulatory surgical excision. Although asynchronous contralateral appendiceal torsion occurs, it is uncommon and most surgeons do not elect to remove both appendages when operating for this condition.

Testicular and Paratesticular Tumors

Testicular and paratesticular spermatic cord tumors are an important but uncommon cause of scrotal swellings in children. They may present insidiously and may not be apparent at an initial examination done for nonspecific scrotal pain. Alternatively, a tumor may be obscured by a hydrocele of recent onset, making palpation of the tumor mass impossible. Testicular tumors also may have an inflammatory presentation, with chronic erythema and thickening of the overlying skin and underlying swelling. More often, they initially present as a bland, firm, nontender asymptomatic scrotal mass.

Differential Diagnosis of Scrotal Swellings

The differential diagnosis of these scrotal swellings requires a thorough working knowledge of the underlying conditions as well as an attempt to characterize the swelling at hand. Evaluation of physical characteristics such as consistency, nodularity, and ability to transilluminate the swelling are helpful in arriving at correct diagnosis. Accurate localization of the swelling to an intratesticular or paratesticular position and determination of reducibility of the mass similarly help characterize the swelling. The key factor in these instances of scrotal swelling is to determine whether the underlying testis is palpably normal because testicular swelling usually indicates serious disease. Useful differential diagnostic points are listed in Table 53.1.

	Spermatic Cord Torsion	Epididymoorchitis	Appendiceal Torsion
Age	First year and adolescence	Adolescence and after	9–12 yr
Symptoms and signs			
Pain	Acute, severe onset	Gradual localization to upper or posterior of testis	Usually gradual
	Frequent antecedent similar pains Localized to testis and radiates to groin and lower abdomen	Uncommon Usually localized to epididymis and testis, sometimes to groin	Occasional Localized to appendix or general scrotal region
Fever	Rare	Common	Rare
Vomiting	Frequent	Rare	Rare
Dysuria	Rare	Common	Rare
Physical examination	Testis may be high-riding, swollen, exquisitely tender	Testis and epididymis are firm, tender, swollen	Testis usually normal; firm mass may be seen and felt at upper pole; distinct from epididymis
Laboratory examination			
Pyuria, urinary infection	Rare	Common	Rare
Blood flow (Doppler; isotope scrotal scan)	Diminished	Increased	Normal or increased

TABLE 53.1. DIFFERENTIAL DIAGNOSIS OF ACUTE SCROTAL SWELLING IN CHILDHOOD

Chronic persisting scrotal swellings that cannot be accurately diagnosed clinically should be explored surgically because serious disease often underlies in these circumstances. When one is dealing with acute swellings, it is helpful to characterize the swelling as being either *ischemic* or *inflammatory* in nature. This principle has also formed the basis for noninvasive adjunctive diagnostic tests developed to diagnose these swellings nonoperatively. Radionuclide scrotal scanning with technetium-99m pertechnetate, first introduced in 1973, has gained wide acceptance in this context. Imaging of the scrotum after injection of this agent allows for rapid distinction between inflammatory conditions with an increase in vascularity and ischemic conditions such as torsion, where a cold “hole” in the isotope distribution is noted (Fig. 53.18). The Doppler ultrasonic stethoscope was introduced shortly thereafter based on the same principle. With this instrument in the emergency room, the examiner could make a rapid distinction between torsion (ischemic) and other inflammatory conditions resulting in an increased blood flow. The latter procedure would seem to represent the ideal way to diagnose torsion were it not for a significant incidence of both false-positive and false-negative results (202,216). A chronically torsive testis often develops a surrounding hyperemic shell of vessels from the spermatic cord, causing a Doppler reading of intact flow. Technique seems to affect the results, and proper probe position and compression of the spermatic cord above (funicular compression test) are important to prevent confusing pulsations from inflamed overlying scrotal skin from blood flow through the spermatic vessels (107). Formal Doppler ultrasound examination of the acutely inflamed

scrotum is more accurate, although still harboring a definite potential for error. A recent review using color Doppler ultrasound in this context in expert hands achieved a 90% sensitivity and 99% specificity in diagnosis (8). The authors indicate appropriately that the ideal use of this test is to add an adjunctive objective measure to the clinical evaluation where an equivocal or low suspicion of torsion is present.

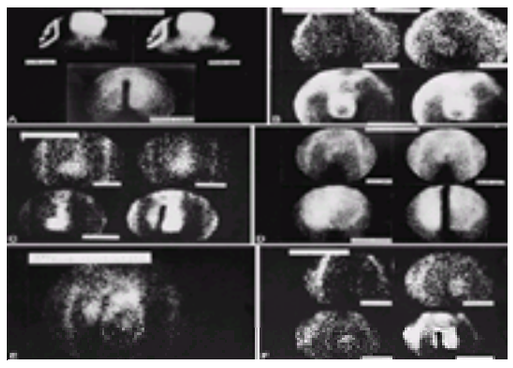

FIGURE 53.18. Radionuclide scrotal scanning. **A:** Acute (right) torsion. Cold central photopenic area is evident *(arrowheads)*. **B:** Chronic (right) torsion. Central defect is evident with hyperemic surrounding shell of vessels. **C:** Epididymitis (left). Diffusely increased flow on dynamic and static images. **D:** Torsion of (right) testicular appendage. Dynamic imaging may show normal or increased flow; static imaging shows increased flow. **E;** Hernia hydrocele may simulate cold, central defect seen in torsion. **F:** Scrotal abscess may simulate inflammatory changes of epididymitis or sometimes the cold central defect seen in torsion. (**A** and **D** courtesy of Drs. K.J. Chun and D.M. Milstein.)

Radioisotope scrotal scanning has proved highly accurate in trained hands; however, this examination is not readily available in all clinical settings and requires skill in interpretation. Proper imaging of the intrascrotal contents is critical; in particular, a pinhole converging collimator should be used to obtain sharp, enlarged images. A review of 464 cases of acute scrotal inflammation indicated that in only 4% was an incorrect diagnosis reached (107). False-positive isotope scans, in which torsion is incorrectly believed to be present, may result from overlying hernias or hydroceles and sometimes are seen with epididymitis. False-negative scans may result from abscess formation, from late torsion with surrounding hyperemia, or from recent detorsion-retorsion (Fig. 53.18). Two reviews contrasted the diagnostic accuracy of isotope scanning and Doppler flowmetry (85,229). In the first, the scan findings were correct in 100% of cases, whereas the Doppler findings were indeterminate in 30% of 20 patients explored for torsion (229). In the second, 7 of 32 consecutive patients with an acute scrotum had spermatic cord torsion (85). Five of seven had the diagnosis confirmed by both modalities; six of seven Doppler studies were consistent with torsion, and five of seven isotope scans were positive. These authors concluded that neither examination was accurate enough to be used individually.

A longstanding personal experience with radioisotope scrotal imaging demonstrated the accuracy of scrotal imaging in correctly diagnosing testicular torsion and the correct scan parameters for predicting that torsion was not present. In a review of 19 patients originally and in numerous other instances surgical exploration or long-term clinical follow-up has demonstrated a 100% scan accuracy in predicting patients with nontorsion. No patient was subsequently found to have torsion or to show evidence of testicular atrophy. In this manner, the scrotal scan was found to be extremely helpful in complementing the clinical impression and in minimizing explorations in all but clear-cut necessary cases. By contrast, in 45 patients suspected of having torsion who were operated on immediately, 40 had torsion at surgical exploration, giving a clinical diagnostic accuracy of 88%. We believed that the 5 patients who underwent an “unnecessary” surgical exploration did not justify routine use of scrotal scanning in this group to confirm an already obvious diagnosis (150,151). This experience has been formulated into an approach that can be used in managing boys with acute scrotal inflammation (Fig. 53.19). Those boys whose clinical history and examination strongly indicate spermatic cord torsion undergo surgical exploration without any delay for adjunctive diagnostic testing. For those boys with equivocal findings, a radionuclide scrotal scan is expeditiously obtained. If the scan findings indicate a photopenic central defect compatible with torsion, the patient undergoes immediate surgical exploration because experience indicates that this finding seldom occurs in other conditions. Different findings (e.g., hyperemia, normal flow) when correlated with the clinical history allow for a more conservative observation approach to be used with a high degree of certainty that spermatic cord torsion is not present. Furthermore, delay from diagnostic testing of strongly suspected cases of torsion is eliminated by this approach. As stated previously, a similar approach can be used based on emergency use of Doppler ultrasound; however, this study is more operator dependent and subject to both false-positive and false-negative misinterpretations.

CONGENITAL ABNORMALITIES OF THE VAS DEFERENS AND EPIDIDYMIS

Once considered a rarity, congenital abnormalities of the epididymis and vas deferens are now recognized with frequency, especially in situations in which the testes are abnormal, such as infertility and cryptorchidism. Scorer and Farrington (238) and Marshall and Shermeta (184) devised classifications of these abnormalities, which have been further revised and addended by Kroovand and Perlmutter (159), creating a comprehensive working classification of mesonephric duct abnormalities (Table 53.2). In this section, abnormalities solely of the vas deferens and epididymis are discussed.

I. Agenesis of all mesonephric duct derivatives
II. Epididymis
A. Agenesis of epididymis
B. Failure of urogenital union: agenesis or loss of continuity
1. Nonunion between the head of epididymis and testis
a. Gross
b. Microscopic
2. Agenesis or atresia of the midepididymis
3. Agenesis or atresia of the tail of epididymis
C. Elongated or looped epididymis
D. Epididymal cyst, with or without loss of continuity
III. Vas deferens
A. Agenesis of vas deferens
1. Complete
2. Segmental
B. Persistent mesonephric duct: ureter entering vas deferens
IV. Seminal vesicle
A. Agenesis of seminal vesicle
B. Seminal vesicle cyst
C. Ureter entering seminal vesicle
V. Ejaculatory duct
A. Agenesis of ejaculatory duct

TABLE 53.2. CONGENITAL ANOMALIES OF THE MESONEPHRIC DUCTS IN THE MALE

Congenital Unilateral Absence or Atresia of the Vas Deferens

Congenital unilateral absence or atresia of the vas deferens occurs in approximately 0.5% to 1% of the general population (36,192,238). The latter has been encountered in 1% of boys undergoing herniorrhaphy (178) and in 20% of boys with congenital rubella undergoing orchiopexy (221). Bilateral absence has been estimated with a frequency of 1% to 10% in azoospermatic men (122,204). Azoospermia occurs with regularity in boys with cystic fibrosis and may be accompanied by rudimentary development of the entire mesonephric ductal system (36,111). In general, absence of the vas is associated with epididymal abnormalities (192). With bilateral absence, the body and tail of the epididymis are usually also absent; the globus major is usually intact (238). An absent vas deferens should also raise the suspicion of a possible upper urinary tract abnormality because the ureter and vas deferens are both derived from the mesonephric duct (59). Ipsilateral renal agenesis occurs more commonly in these instances and may be identified by sonography in these boys. A persistent common mesonephric duct occurs when the terminal excretory duct fails to separate into the ureter and vas deferens, resulting in a persistent common single orifice located somewhere between the trigone and the verumontanum. This is associated with recurrent urinary tract infections and epididymitis and may be diagnosed by voiding cystourethrography (188) (Fig. 53.10). The ipsilateral seminal vesicle is often cystic, and the ipsilateral kidney is often dysplastic, suggesting total dysplasia of the mesonephric duct and metanephros in these instances (226,237).

Congenital Abnormalities of the Epididymis

Congenital abnormalities of the epididymis are varied, ranging from total absence to segmental atresias to gross structural abnormalities of the intact organ. Most abnormalities of the epididymis have been identified in patients with obstructive azoospermia and cryptorchidism. The latter has now been extensively studied in children, and numerous references confirm a spectrum of epididymal abnormalities in association with this condition. Epididymal abnormalities occur in approximately 33% to 50% of cryptorchid boys (184,238) and are especially associated with testes in an intracanalicular or intraabdominal position. The most common abnormality is an extended epididymis (Fig. 53.20) (159). In some instances, the looped epididymal tail may be markedly elongated, extending down the entire inguinal canal into the scrotum. In these circumstances, the epididymis may be mistaken for a blind- ending spermatic cord or an atrophic testis and may be inadvertently injured or excised, leaving an undiagnosed cryptorchid testis intraabdominally (Fig. 53.21) (155). Varying degrees of separation of the epididymis from the cryptorchid testis are also common, with the epididymis suspended on a mesentery (Fig. 53.22). Some of these abnormalities may have functional significance because they may result in occult microscopic ductal obstruction or may affect sperm capacitation.

FIGURE 53.20. Congenital structural abnormalities of the epididymitis and vas deferens. **A:** Agenesis of all mesonephric duct derivatives. **B:** Nonunion between the globus major of the epididymis and the testis. **C:** Agenesis at the midepididymis. **D:** Atresia at the midepididymis. **E:** Agenesis or atresia at the tail of the epididymis. **F:** Extended or looped epididymis and vas deferens. **G:** Extended or looped epididymis and vas deferens, a more severe abnormality. **H:** Epididymal cyst of globus major. (From Kroovand RL, Perlmutter AD. Congenital anomalies of the vas deferens and epididymis. In: Kogan SJ, Hafez ESE, eds. *Pediatric andrology.* Boston: Martinus Nijhoff, 1981:173, with permission.)

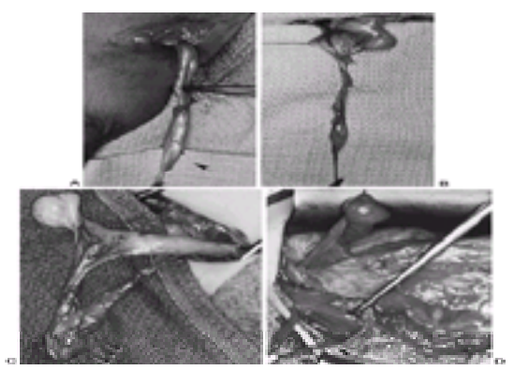

FIGURE 53.21. Epididymal structural abnormalities mistaken for blind-ending spermatic cord. **A:** Long-looped vas deferens with nubbin at end *(arrowhead).* The testis lies within the internal ring. **B:** Similar example with long-looped vas deferens and nubbin at end, extending down inguinal canal. The testis was intraabdominal. **C:** Older child with structure mimicking atrophic testis with collapsed surrounding tunica vaginalis at end *(arrowheads)* that had exited through the external inguinal ring. **D:** Blind-ending gubernacular-like structure *(arrowhead)* passing down through inguinal canal. The testis lies above within the abdomen. (From Kogan SJ. Cryptorchidism. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology,* 2nd ed. Philadelphia: WB Saunders, 1985, with permission.)

CONGENITAL AND ACQUIRED DISORDERS OF THE TESTES

Congenital disorders of the testes in childhood are one of the most common problems dealt with in pediatric urologic practice. In this section, they are arbitrarily classified into disorders of number, size, and location.

Unilateral Congenital Absence of the Testes

Unilateral congenital absence of the testes occurs uncommonly, with an estimated frequency of 4.0% in cryptorchid males. Unilateral congenital absence (monorchia) occurs more commonly (1:25) than bilateral absence or anorchidism (1:20,000) (175). Absence of the testis may occur from either agenesis (i.e., total development failure of the gonadal ridge) or early deterioration of the testis at some time after initial formation (i.e., by torsion). Because normal fetal testis function is responsible for ipsilateral regression of the müllerian duct and stimulation of the ipsilateral mesonephric duct, examination of these structures gives inferential information about abnormal development of the ipsilateral testis. When the testis is found to be absent at surgical exploration, several distinct developmental findings may be encountered: a blind ending tuft of spermatic vessels, blind ending ductal structures (epididymis, vas, or both), blind ending spermatic cord (vas and vessels), or absence of all structures. In a review of 65 cases of surgically diagnosed monorchia, a blind ending spermatic cord was the most commonly encountered pattern, occurring in 69% of patients (Table 53.3). Absence of all structures, possibly indicating testicular agenesis, was extremely uncommon (14%), and müllerian remnant structures were not seen at surgery (148). Because the testis is necessary to induce ipsilateral formation of the wolffian (mesonephric) duct and cause regression of the müllerian duct, these surgical findings suggest that the testis formed initially but deteriorated subsequently (i.e., after the fourteenth week, when vas formation is completed). Furthermore, in 20% of patients, microscopic examination of a nubbin of tissue at the end of the excised spermatic cord revealed hemosiderin, calcification, or hyalinized tissue compatible with old testicular infarction, suggesting that an *in utero* vascular accident had occurred (i.e., secondary to testicular torsion) (Fig. 53.23). These findings suggest that *in utero* testicular torsion may be the cause of most cases of congenitally "absent" testes and that most cases of testicular absence result from degeneration of a previously formed testis rather than primary agenesis (118).

Findings	Number	Percentage
Minispermatic vessels	47	72
Wolffian structures	54	83
Vessels and wolffian structures	45	69
Vessels and vas	20	31
Vessels, vas, and epididymis	12	18
Vessels, vas, epididymis, and terminal nubbin of tissue	13	20
Vas only	9	14
Vessels only	2	3
Absence of vessels and wolffian structures	9	14
TOTAL	65	100

TABLE 53.3. FINDINGS IN 65 PATIENTS WITH UNILATERAL ABSENT TESTES

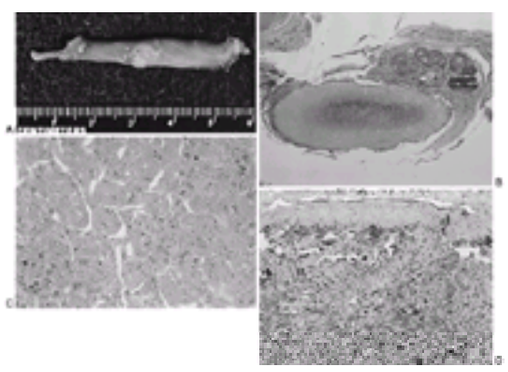

FIGURE 53.23. Gross and microscopic findings in congenitally absent testes. **A:** Surgical specimen of scrotal nubbin *(arrowhead)* in 3-month-old infant with impalpable testis. **B:** Microscopic view (reduced magnification from ×20) demonstrating necrotic debris with partial calcification in the center with adjacent epididymis. **C:** Higher-power view shows calcification and ghosts of remaining tubules (reduced magnification ×300). **D:** Infarcted testis parenchyma with focal calcification and hemosiderin. Tunica is present along with serosal surface superiorly (reduced magnification ×125). (From Kogan SJ, Gill B, Bennett B, et al. Human monorchidism: a clinicopathological study of unilateral absent testes in 65 boys. *J Urol* 1986;135:758, with permission.)

Bilateral Congenital Absence of the Testes

Similar findings are encountered in bilateral congenital anorchia, where vasa are usually found at surgical exploration (173). In this syndrome, absent testes are encountered in an otherwise normal 46,XY phenotypical male. Because testis formation is necessary *in utero* to stimulate external genital development, these findings imply that the testes deteriorated at some point in time after completion of masculinization (i.e., after the twelfth to fourteenth week). This syndrome has therefore been appropriately called the *vanishing testis* or *testicular regression syndrome* (1). Gonadotropin levels in anorchic boys are usually elevated, even early in life (Table 53.4). Even at birth, FSH levels may be elevated, as seen in boys with bilateral neonatal torsion (153) and boys with congenital bilateral anorchia; however, LH levels may not elevate until puberty. Testosterone levels in anorchic boys do not rise in response to hCG stimulation; whereas most boys with testes present usually respond to hCG stimulation. When anorchidism is suspected, measurement of basal FSH and LH levels and the response of testosterone secretion to hCG stimulation have predicted the absence of functioning testicular tissue (5,173). When there is a failure to respond to hCG and an elevated FSH (and LH) level, bilateral congenital anorchia may be diagnosed and surgical exploration for confirmation of diagnosis is not necessary. In these instances, rather than performing an extensive exploratory laparotomy, testicular prostheses are placed through an inguinal incision. When both components of this test are not fulfilled, however (i.e., when a testosterone response to hCG occurs or when gonadotropin levels are not elevated even though a testosterone response does not occur), a thorough search must be made because a testis (at least one) lies within.

Age (yr)	LH (ng/mL)	FSH (ng/mL)	hCG Stimulation Testosterone	
			Before	After
4	21	318	25	24
5	29	330	31	32
5	29	320	43	41
5.5	61	475	40	40
6	24	308	23	21
7	25	321	25	25
7	27	328	42	44
9	80	900	36	40
10	37	370	44	43
12	180	2,100	62	65

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

TABLE 53.4. ENDOCRINE STUDIES IN 10 ANORCHIC BOYS

Confusion regarding the interpretation and diagnostic accuracy of this test has arisen (154). Three cases with apparently false and misleading evaluations in which testes were found at surgical exploration have been published (10). In these instances, however, careful analysis reveals that both components of the strictly defined criteria of a negative test were not fulfilled. The editorial comment after publication also suggested that gonadotropin levels in bilateral anorchics may fall into the normal range between ages 4 and 8 years, resulting from relative pituitary-hypothalamic inactivity at this age. Although the latter information was extrapolated from

anorchic 45,XO females who demonstrated this phenomenon and no similar data from anorchic boys were presented, the implication was made that normal gonadotropin levels might occur in the absence of testes. A subsequent review of gonadotropin levels in 30 congenitally anorchic males revealed that one prepubertal patient had normal gonadotropin levels, although the remainder all had elevated levels, indicating that normal levels in prepubertal boys cannot exclude the diagnosis of anorchia. One of two pubertal patients with elevated levels had hypoplastic testes present, indicating the gonadotropin levels alone cannot diagnose anorchia in the postpubertal male (124). Similarly hCG testing alone will not distinguish between anorchia and bilateral impalpable cryptorchidism because a lack of hCG-induced response may occur in hypogonadotropic hypogonadal patients with testes present. Therefore caution must be exercised in analyzing data from postpubertal patients because secondary gonadal failure from damaged testes may be present, resulting (rarely) in elevated gonadotropin levels and failure of response to hCG. In summary, the endocrine diagnosis of bilateral anorchia rests only on demonstration of raised gonadotropin levels and a negative testosterone response to hCG. In other circumstances, a testis may be present (Table 53.5).

	FSH, LH	Testosterone After hCG
Testes Absent		
Bilateral congenital anorchia	↑	0
Possible in prepubertal bilateral congenital anorchia (i.e., ages 3–9 yr)	Normal	0
LHRH→	↑	0
Testes Present		
Bilateral impalpable cryptorchidism	Normal	↑
Possible in hypogonadotropic hypogonadism	Low	0
Prolonged hCG →	—	↑
Possible in postpubertal bilateral hypoplastic/damaged testes present	↑	0

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone.

TABLE 53.5. FINDINGS IN DIAGNOSTIC HORMONAL TESTING FOR BILATERAL CONGENITAL ANORCHIA

Hormonal testing is not sufficiently accurate to predict unilateral testicular absence. Measurement of FSH and LH levels in 44 patients with monorchia revealed that mean levels were slightly higher than published control values, although too much variation in individual levels existed to make isolated measurements a clinically useful test. Peak-stimulated FSH and LH levels after GnRH stimulation in boys with unilateral impalpable testes who were subsequently found to have a testis present at surgical exploration were contrasted with those in boys having unilateral absent testes subsequently documented surgically. The results in both groups were indistinguishable, making it an insufficiently accurate clinical discriminatory test (Fig. 53.24) (148,213a).

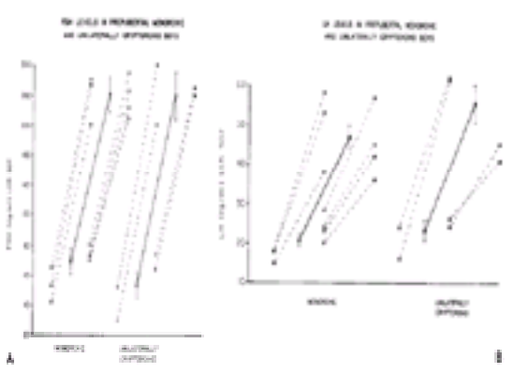

FIGURE 53.24. Follicle-stimulating hormone *(FSH)* **(A)** and luteinizing hormone *(LH)* **(B)** levels in prepubertal monorchic and unilaterally cryptorchid boys, both with clinically impalpable testes, after gonadotropin-releasing hormone (GnRH) stimulation. *Solid lines* represent mean values; *dotted lines* represent individual values. (From Palmer LS, Gill B, Kogan SJ. Endocrine analysis of childhood monorchism. *J Urol* 1997;158:594.)

Polyorchidism

Polyorchidism is a rare abnormality that probably results from division of the gonadal ridge early in development, as evidenced by the fact that both testes usually have a common proximal blood supply. Occasionally, a common vas deferens is present, although usually the epididymis and vas deferens are separate (189). In a review of 53 cases, Plender and colleagues (218) found that in 15% of patients, at least one of the ipsilateral testes was cryptorchid. Therefore, in most instances, the supernumerary testis is descended and discovered as an asymptomatic swelling in the scrotum. The usual indication for surgical exploration is for confirmation of diagnosis. Instances of torsion and malignancy also have been reported.

Abnormalities of Testicular Size

Abnormalities of testicular size are uncommon at birth. Newborn boys normally have testes measuring about 1 mL. The testes enlarge somewhat during the first few months of life, probably secondary to the postnatal testosterone surge that occurs at 2 months of age, and then decline slightly in size remaining about 1 to 2 mL until puberty onset (34). Both hypoplastic and enlarged testes uncommonly occur at birth, the former usually the result of partial or complete antenatal torsion and the latter as a finding when the contralateral testis is hypoplastic (117). Testicular enlargement is the earliest sign of pubertal onset in boys, and successive pubertal stages are marked by progressive further testicular enlargement. Abnormalities of testicular size may be noted in both prepubertal and pubertal boys. Measurements of the testes may be accurately done with an orchidometer (Fig. 53.25), with the measured volume compared with published measurements in normal boys at varying ages (235).

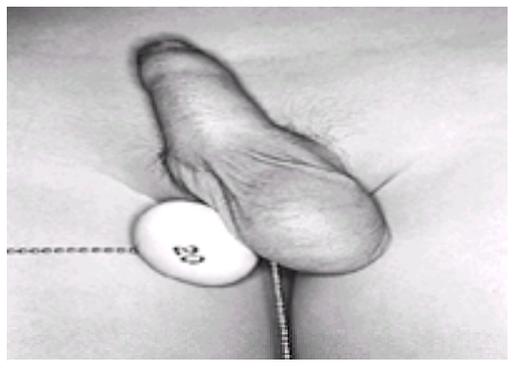

FIGURE 53.25. Compensatory hypertrophy of the descended testis of a 12-year-old boy with unilaterally absent contralateral testis. A testis of 20 mL represents the ninety-ninth percentile. At age 13 years 2 months, the testis had grown to 50 mL. (From Kogan SJ. Fertility in cryptorchidism. In: Hadziselimovic F, ed. *Cryptorchidism: management and implications.* New York: Springer-Verlag, 1983:71, with permission.)

Microorchidism

Microorchidism may be congenital or may be associated with various syndromes. Najaar and colleagues (201) described a syndrome of bilateral hypoplastic rudimentary testes and micropenis in siblings in whom the testes were markedly diminished in size and hormonally deficient. The testes are noted to be smaller than expected in Klinefelter's syndrome, even prepubertally (28), and in abnormalities of the hypothalamic-pituitary-gonadal axis (hypogonadotropic hypogonadism). Failure of growth may also result in microorchidism, as is often seen in boys with cryptorchidism and with varicoceles. Smaller-than-normal testes were seen in 19% of cryptorchid boys at stage P2 puberty, 28.6% at stages P3 and P4, and 38% at stage P5 (54). Abnormally small ipsilateral testes have been described in 33% to 50% of boys with varicoceles, with this finding occurring more commonly after puberty and in association with large varicoceles (136,156,180). Testicular atrophy also may cause small testes, such as atrophy secondary to previous hernia repair with partial vascular compromise to the testis or testicular torsion. The latter may be a common cause of “idiopathic” testis hypoplasia (148).

Macroorchidism

Unilateral macroorchidism usually results secondarily from a disorder of the contralateral testis, that is, from atrophy or absence, secondary to congenital monorchia or previous torsion (117,148), or from cryptorchidism. Unilateral compensatory hypertrophy was found in 12% of boys with undescended or absent contralateral testes and was associated with FSH hypersecretion. Adult follow-up of seven men revealed oligospermia, suggesting that the hypertrophied testis was abnormal as well (163). Bilateral testis enlargement is sometimes associated with various syndromes. Precocious puberty (i.e., resulting from an intracranial mass) may cause premature skeletal growth and secondary sexual development and testicular enlargement commensurate with the patient's pubertal stage. Hypothyroidism uncommonly causes precocious puberty and bilateral testicular enlargement. Boys with mental retardation have an increased frequency of bilateral macroorchidism. Some have a rare chromosomal disorder in which a small, almost detached portion of the long arm of the X chromosome is seen (fragile-X syndrome) (263). Measurement of testis size in mentally retarded males has been suggested as a simple screening test for this condition. Occasionally, a patient is encountered with unilateral or bilateral macroorchidism in the absence of an identifiable cause (“idiopathic”) (24,168). Gonadotropin measurements and a thorough thyroid evaluation should be done, as well as scrotal sonography, to exclude a subtle intrascrotal neoplastic process. If these are normal, there is usually no indication for scrotal exploration or biopsy.

Adult-onset or acquired congenital adrenal hyperplasia is another rare cause of unilateral testicular enlargement (39). More commonly, in children, this condition results in bilateral testicular enlargement, usually with testicular nodularity resulting from islands of benign hyperplastic adrenal tissue within the testis (141,203). The latter conditions are sometimes difficult to distinguish from testicular Leydig cell tumors, which may have similar clinical and endocrinologic manifestations (269). Serotal sonography is useful in diagnosing these conditions and in evaluating potential neoplastic causes of unilateral and bilateral testicular enlargement.

Cystic Testicular Dysplasia

Cystic dysplasia is an uncommon cause for painless testicular enlargement in childhood but one that is now recognized with increased frequency. Failure of fusion between the efferent ducts and the rete testis and the epididymal ducts, which results from abnormal mesonephric duct connection with the testis, is the presumed cause. The frequent finding of ipsilateral renal agenesis, dysplasia, duplex kidneys, and seminal vesicle cysts supports this theory. This testis is enlarged, with a sonographic finding of multiple tiny punctate cystic lesions compressing the normal adjacent parenchyma. Providing the diagnosis is established with certainty, observation or subtotal or complete orchiectomy is indicated and treatment must be individualized (171).

Abnormal Descent of the Testes: Cryptorchidism

Incidence

Available data suggest that the incidence of cryptorchidism in premature boys is 9.2% to 30.0%, whereas the incidence of cryptorchidism in term boys is 3.4% to 5.8%. Kleinteich and colleagues (144) have combined several previous studies and found that after 1 year, 1.82% of 88,526 patients had undescended testes. The percentage remained the same until puberty. Scorer and Farrington (238), however, found that at the end of 12 months, 28 of 3,612 babies (0.8%) still had cryptorchidism, and the incidence remained the same up to puberty. These findings underline that after the first year spontaneous descent is unlikely to occur.

Locations

Abnormal descent causes the testis to occupy an ectopic or truly undescended position outside the scrotum. Ectopic testes descend normally through the external inguinal ring but are misdirected in the subsequent descent to an extrascrotal position. Fibrous obstruction of the scrotal inlet and abnormalities of the gubernacula have been described in association with this condition. The most common site of ectopia is the superficial inguinal pouch between the external oblique aponeurosis and the subcutaneous tissue. Perineal, prepenile, transverse scrotal, femoral, and abdominal positions are other less common sites of ectopia. By contrast, true cryptorchid testes are arrested in their normal line of descent and may occupy an intraabdominal, intracanalicular, or suprascrotal position. Whereas the latter testes may be responsive to hormonal treatment, the former (ectopic) testes are mechanically fixed in place, therefore requiring operative treatment (Fig. 53.26).

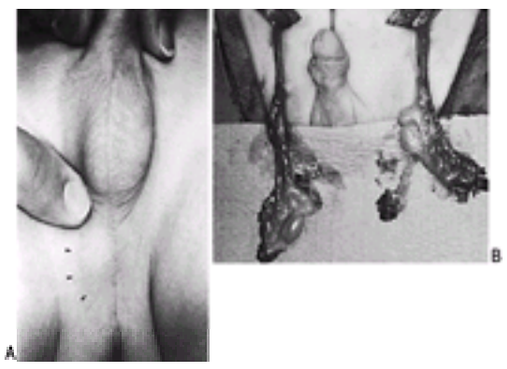

FIGURE 53.26. A 3-year-old boy with (right) perineal ectopic undescended testis and (left) inguinal cryptorchid testis. **A:** Gross examination reveals perineal bulge *(arrowheads)*. **B:** Surgical exposure demonstrates differences in spermatic cord length and in testis size.

Cryptorchidism, or incomplete testicular descent, can be described as unilateral or bilateral, and the position of the testis as abdominal, inguinal, prescrotal, or gliding. The gliding testis is not a retractile testis but rather one that upon being manipulated to the upper portion of the scrotum immediately retracts. However, these testes have the same histology as the cryptorchid testes arrested in their true line of descent, in contrast to true ectopic testes, which have a normal histology. Therefore the term *ectopic testis* should be used only for those testes that descend normally through the external inguinal ring but are misdirected in their subsequent descent to perineal, prepenile, transverse scrotal, femoral, or umbilical positions.

One-third of boys with true cryptorchidism have bilateral cryptorchid testes; two-thirds are unilateral. The right side seems to be affected more often than the left side (70% versus 30%). Abdominal cryptorchidism has been found in 8% of patients, inguinal cryptorchidism in 72%, and prescrotal cryptorchidism in 20%. In 2.6% (156 of 6,127) of patients, testicular aplasia or anorchia has been observed (144).

Histology and Endocrine Pathology

Reduced number of germ cells is the most clinically significant histopathologic feature of the cryptorchid testis (96). In some hands, the degree of germ cell reduction is prepubertal biopsies is used to predict future fertility and to select patients for hormonal treatment to stimulate germ cell maturation and proliferation. The reduction in number of germ cells becomes apparent during the second year of postnatal life and persists thereafter. Several large series show a remarkably similar reduction in numbers of germ cells expressed as the number of germ cells per tubule (Fig. 53.27 and Fig. 53.28) (234). The origins of this germ cell depletion lie in impaired function of the hypothalamic-pituitary-gonadal axis and resultant failure to establish an adequate adult stem cell pool (adult dark spermatogonia) during the second month of postnatal life, failure to initiate meiosis during the fifth year, and failure to establish complete spermiogenesis at puberty. Intrauterine germ cell hypoplasia

extends the endocrinopathy back into the prenatal period. These endocrine abnormalities are the rationale for the hormonal treatment of the reduced numbers of germ cells characteristic of the cryptorchid testis (97,103).

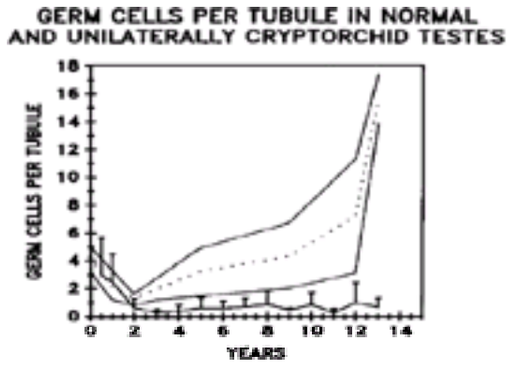

FIGURE 53.27. Germ cell counts in unilateral undescended testis (bottom line) compared with normals. (*Dotted line* = mean ± 1 SD.)

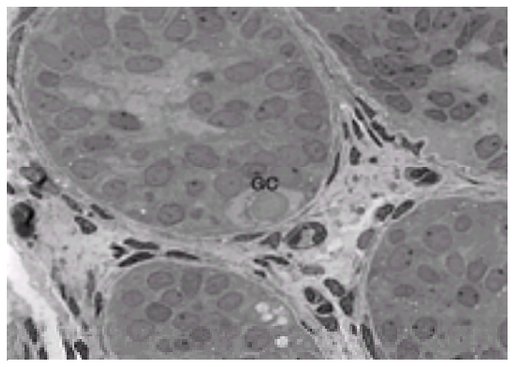

FIGURE 53.28. Histopathology of undescended testis. Absence of juvenile Leydig cells. Tubule with rare germ cells *(GC)* and absence of adult spermatogonia and primary spermatocytes. (Semithin section, toluidine blue; 600× magnification.)

Intrauterine Abnormalities

Little is known regarding possible abnormalities of the first two steps in maturation. Germ cell hypoplasia in 23% of cryptorchid testes in the third trimester of pregnancy is the earliest histologic abnormality described (47), suggesting an intrauterine abnormality in the endocrine control of Leydig cell proliferation and reduced testosterone secretion (92). Confirmation of these findings would add to the existing evidence that reduced levels of testosterone may contribute to failure of testicular descent in addition to failure of proliferation and maturation of germ cells.

Abnormalities of the Third Step in Maturation, Second Postnatal Month: Failure to Develop an Adequate Adult Stem Cell Pool

Transformation of the fetal stem cell pool (gonocytes) into the adult stem cell pool (adult dark spermatogonia) normally seen in the second postnatal month is defective and delayed in cryptorchid boys. The LH and FSH surge does not normally occur (76). Fetal Leydig cells remain hypoplastic and unstimulated (89,93,115,118). The normal testosterone surge does not develop (7,75,88). Therefore gonocytes neither mature into adult dark spermatogonia nor disappear through apoptosis; rather, they persist through the first year of life. This causes the characteristic cryptorchid testis pathology during the first year: increased numbers of total germ cells, increased numbers of gonocytes, absence of adult dark spermatogonia, and hypoplasia of Leydig cells (115,116). When the abortive transfer occurs at around 12 months, many fewer gonocytes than normal mature into adult dark spermatogonia while many more than normal undergo apoptosis and disappear. This causes the characteristic appearance of the cryptorchid testis after the first year of life: reduced numbers of all germ cells and a disproportionately severely reduced number of adult dark spermatogonia. Failure to develop a normal adult stem cell pool (adult dark spermatogonia) during the first year causes the continued reduction in germ cell counts which persists thereafter.

Abnormalities of the Fourth Step, Fifth Postnatal Year: Failure to Initiate Meiosis

The peaks in numbers of juvenile Leydig cells, adult dark spermatogonia, and total germ cells that normally appear at 5 years of age fail to appear in cryptorchid testes. Primary spermatocytes, which normally appear at this time, fail to appear (115,116,118). Failure to establish meiosis during this maturational step contributes to the continued low numbers of germ cells in the cryptorchid testis.

Abnormalities of the Fifth Step, Puberty: Failure to Obtain Complete Spermatogenesis

The response of the cryptorchid testis to pubertal gonadotropin stimulation varies. In some, the response is so weak that proliferation of the adult stem cell pool (adult dark spermatogonia), meiosis, and spermiogenesis fail to occur. In others, a partial response leads to transient abortive meiosis and spermiogenesis. During early puberty, many cryptorchid testes have a severely reduced number or complete absence of germ cells. Rarely, a cryptorchid testis may show focal spermiogenesis only to the spermatid stage, and the spermatids show severe morphologic abnormalities. The histopathology becomes more severe with age so that by early adulthood all untreated cryptorchid testes completely lack germ cells.

The failure to establish a normal adult stem cell pool during the first year of life, the reduced numbers of germ cells, and the failure of spermiogenesis during puberty cause the subfertility of cryptorchidism. A direct correlation exists between the number of germ cells in prepubertal cryptorchid testis biopsies and the quality of spermiograms in late adolescence and early adulthood, with boys who have the most severe reduction in germ cell numbers having the poorest spermiograms and greatest risk for subfertility (47,98).

Histology in Relation to Position of the Testis

The number of tubules with germ cells and the number of the spermatogonia per tubule change considerably with the position of the testicles. The higher the testis location, the worse its histology (101,238). By the onset of puberty, more than 90% of all intraabdominally located testes completely lose their germ cells, whereas in inguinal and prescrotal testes, a total absence of the germ cells was noted in 41% and 20% (101).

Histology of the Contralateral Descended Testis in Unilateral Cryptorchidism

Unilateral cryptorchidism is a bilateral disease. The contralateral descended testis in unilateral cryptorchidism is abnormal, demonstrating similar abnormalities to those in the cryptorchid testis, but to a lesser degree (Fig. 53.29) (115,116). The contralateral descended testis affects fertility. A nearly normal contralateral descended testis may provide adequate fertility even in a patient with a severely abnormal cryptorchid testis. A contralateral descended testis with an inadequate adult stem cell pool, failure of meiosis, inadequate numbers of germ cells, and failure of spermiogenesis will ensure subfertility in a patient with a severely involved cryptorchid testis.

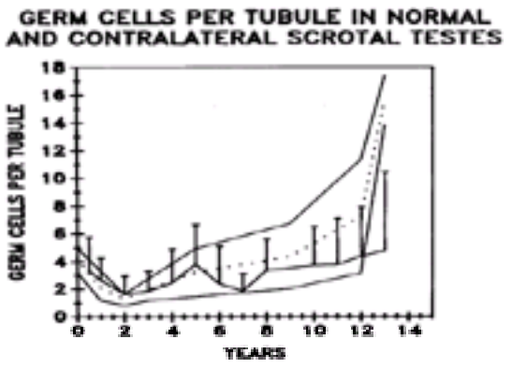

FIGURE 53.29. Germ cell counts in contralateral descended testes (line with spikes) in unilateral cryptorchidism compared with normals. (*Dotted line* = mean ±1 SD.)

Biochemical Evidence for Hormonal Involvement

A normal increase in plasma testosterone in the early postnatal period does not occur in most boys with undescended testes (75). Furthermore, an impaired LH and FSH response to GnRH has been observed in boys with cryptorchidism (29). Finally, impaired testicular testosterone response to hCG has also been noted in cryptorchid boys (69). This deficiency of LH and consequently of testosterone secretion disappears after puberty (29). Some of the patients with the most pronounced hypogonadotrophic hypogonadism in prepuberty develop hypergonadotropic hypogonadism after puberty (90).

Diagnosis

Examination Technique

Every general pediatric examination in boys should include examination of the testicular position. The room and the examiner's hands have to be warm, the boy being examined should be given time to relax, and the examination should not be hurried. If cryptorchidism is suspected, the patient should be examined in the cross-legged position. Once the patient is sitting comfortably in this position, most retractile testes descend spontaneously without being manipulated by the examiner. The gonad may be manipulated gently into the scrotum with the thumb and forefinger. Another helpful approach, particularly in older boys, is application of pressure on the femoral artery in the groin. If the testis is retractile, it should immediately descend and remain in the scrotum for a while. Testicular volume can be established by estimating the length and short diameter of the testis or by measuring the testis with an orchidometer. Testes that do descend into the upper portion of the scrotum but immediately upon release return to the prescrotal position are gliding testes and need to be treated.

High scrotal testes have an increased tendency to glide, and the scrotum may be less developed on the affected side. The management of these high scrotal testes is difficult. Most have normal histology, but in a small proportion, considerable damage to the gonad develops with time. Therefore a careful annual check of the development and position of these gonads is recommended. If any doubt concerning lack of proper growth and position arises, hormonal treatment should be started, particularly if the testis becomes a gliding one.

Diagnostic Tests

Ultrasound has been frequently used in the diagnosis of impalpable testes; however, clinical experience indicates a very high rate of misdiagnosis. In many instances, the testis will be reported as absent but is easily palpable in the groin or scrotum at clinical examination. Because ultrasound demonstration of a testis demands that a surgical procedure follow anyway and because of the high false-negative rate (testis present despite negative ultrasound) and need for surgery to follow, ultrasound diagnosis is unuseful in most instances (113).

Computed tomography (CT) scanning has been reported as being more accurate, but its radiation burden to the small child is significant and it still falls short of the essentially 100% accuracy needed in these instances. Similarly, magnetic resonance imaging (MRI) evaluation is involved, cumbersome, and expensive and can be justified only in select cases (e.g., extremely obese individuals in whom the surgical morbidity may be outweighed by the potential information gained). These experiences have led to our abandoning routine radiologic evaluations for impalpable testes, because they are not sufficiently accurate and are not cost-justifiable. Instead, we practice selective diagnostic laparoscopy in certain instances.

Laparoscopy

The use of laparoscopy for the diagnosis of impalpable testes was first suggested by Cortesi and co-workers (48) as an outgrowth of cystoscopy. In recent years, the explosive growth of laparoscopic surgery has led to its enthusiastic application to patients with impalpable cryptorchidism. In approximately 20% of cryptorchid boys, the testis is impalpable; in approximately one-fourth to one-third of boys, these the testes will be found to be intraabdominal. Here, one would hope laparoscopy would have its greatest utility. In a survey of the American Academy of Pediatrics, Urology Section, covering 5,428 cases, 75% of the members used laparoscopy for evaluating impalpable testes. The minor complication rate was about 4%, and a significant complication (bleeding; bowel, bladder, or vascular injury; or omental herniation) occurred in about 1% (217). With refinements in technique, added experience, and further miniaturization of instruments, even the neonate can now safely undergo laparoscopy.

The real issue then is whether *routine* use of laparoscopy for diagnosing impalpable testes is justified or whether *selective* use is more rational. Opinions vary widely, but the data indicate that routine use for diagnosis alone is not warranted unless laparoscopic surgical treatment is to follow as well. Proponents of the “routine” view claim that the procedure adds little time and helps them decide better incision placement and plan the surgery better. Advocates of the “selective” viewpoint indicate that laparoscopy is not cost-effective or patient-friendly because many “unnecessary” laparoscopies are done (i.e., routine inguinal exploration would have provided the same information in virtually all instances).

Diagnostic laparoscopy is most useful when it obviates the need for further surgery. In Fig. 53.30, summarizing the locations of 432 impalpable testes, it appears to be helpful in only 10% (the intraabdominal vanishing testis group and absent vas and vessels group). Exploration was required in all abdominal and inguinal testes to perform orchidopexy and to confirm the diagnosis in the inguinal vanishing testis group. However, additional consideration must apply, incorporating the benefits for those who alter their incision locations when an abdominal testis is present and for those performing laparoscopic orchidopexy, which is a logical treatment following laparoscopic diagnosis and which would benefit an additional 27% (intraabdominal testis group). Other similar analyses echoes these findings (42).

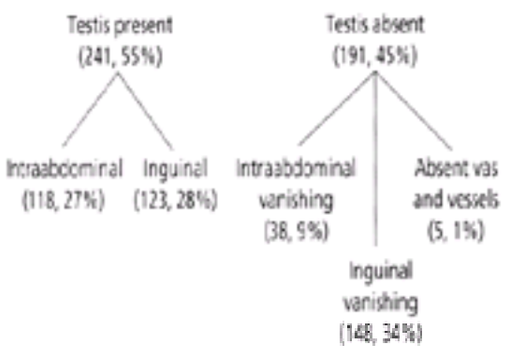

FIGURE 53.30. Laparoscopic findings in 432 impalpable testes: a collation of five series.

Our experience indicates that exploration through a standard inguinal incision, with intraperitoneal extension, when necessary, demonstrates all of the needed information in most instances. In younger boys who have a hint of atrophic testicular tissue in the scrotum and who demonstrate contralateral testicular hypertrophy, laparoscopy is superfluous. In older obese boys with normal scrotal development, laparoscopy is also usually unnecessary because the testes are present, although impalpable. We believe that laparoscopy is useful in reoperative cases in which an incomplete exploration has preceded (failure to visualize spermatic vessels or explore intraperitoneally). Therefore the decision for laparoscopy rests on the personal experience of the operator: whether a standard inguinal incision is used routinely, whether a testicular prosthesis will be inserted (requiring a suprascrotal incision anyway), and whether laparoscopic orchidopexy will be undertaken. Therefore surgeon's bias plays a significant role.

Treatment

Indications

Once cryptorchidism is diagnosed, early treatment (age 8 to 12 months) should be initiated. The main indications for early treatment are the increased infertility risk in both unilateral and bilateral cryptorchid patients, increased malignancy risk, and increased risk testicular torsion. Treatment of the often-associated inguinal hernia is an additional benefit. Prevention of the psychologic problems because of an empty scrotal sac plays a lesser but still important role. Early hormonal treatment and early surgical treatment have not been shown to engender any increased risk.

Fertility Outcome

In 1960, Charny (37) stated:

> Testicular biopsy in a large number of testes brought into the scrotum by a variety of techniques failed to reveal a single instance of normal spermatogenesis. The prevailing methods of treatment of cryptorchidism are not satisfactory and the operative techniques as practiced by most surgeons yield better cosmetic than functional results. If the surgical technique cannot be improved sufficiently, boys with asymptomatic cryptorchidism without clinically recognized hernia should be spared the hazard and inconvenience of orchiopexy.

Identical observations were promulgated by Mack and colleagues (181), Canlorbe (30), and Sizonenko and co-workers (246). Patients completely lacking germ cells will, in all probability, develop sterility, and even a successful prepubertal orchiopexy cannot significantly improve the number of germ cells in their gonads or their fertility. These observations have been confirmed in prospective studies that reaffirmed the poor fertility prognosis for either unilaterally or bilaterally cryptorchid patients lacking germ cells who underwent orchiopexy during the prepubertal period (90). As a consequence of undescended testes, some investigators find infertility rates as high as 32% in unilateral cryptorchid patients and 59% in bilateral cryptorchid patients (100,146). By adulthood, previously cryptorchid testes have only 10% of the germ cells found in the normal population despite prepubertal orchiopexy (144). Although some improvement in the germ cell content of cryptorchid testes that were successfully operated on was achieved, biopsy results showed that not a single testis out of 235 (79 unilateral cryptorchid testes, 78 bilateral cryptorchid testes, and 78 contralateral descended testes) that was intrascrotal 1 or several years after surgery achieved the normal level of germ cells (144).

During the last 20 years, early orchiopexy (by 1 year of age) has become the standard of treatment for boys with cryptorchidism (240). Published studies and general experience indicate that with appropriate training, orchidopexy can be performed as safely and efficiently in these earlier years as in the older child. By performing early orchidopexy, it is hoped that the progressive histologic deterioration noted in cryptorchid boys will be arrested and that early scrotal testis placement ultimate fertility will be preserved.

Cryptorchid Testis and Malignant Changes

One indication for correction of cryptorchidism is the recognized increased risk of neoplasia. It is difficult to determine the true incidence of cancer in cryptorchid patients because the data are not precise and calculations are often based on statistical assumptions; accordingly, statistics vary. There is evidence that the risk of testicular cancer is increasing in the United States and in Denmark. The current lifetime risk for all American males is approximately 0.2%, or 1:500 (285). The combined risk for all cryptorchid males, irrespective of the location of the testes, has been calculated at 20 to 46 times greater than for patients with normally located testes (38). Other epidemiologic studies suggest that the lifetime risk is only about ten times that of men with descended testes (63,236). In a case-control study of 108 cases of testicular cancer in men younger than age 30 years, cryptorchidism was a major risk factor, with a relative risk (RR) equal to 9.0 (53). A reasonable summary of these data, which can be given to parents, is that men with descended testes have a 1 in 500 lifetime risk of developing testicular cancer, whereas men with cryptorchid testes have a 1 in 50 incidence. The multiple factors that affect germ cell development may result in various degrees of atrophy and tubular dysgenesis, which may later result in malignant changes (50).

There are reasonably strong data indicating that the abdominal cryptorchid testis has a significantly higher risk of developing cancer than the inguinal cryptorchid testis; therefore these patients require increased lifelong surveillance. Abdominal undescended testes showed a fourfold increased risk over inguinal undescended testes in one series (50). In about 10% of individuals with unilateral cryptorchidism and cancer, the tumor develops in the contralateral testis, suggesting a possible genetic predisposition. Similarly, there is an increased frequency of carcinoma *in situ* in the cryptorchid and contralateral descended testis (248). These findings were found in less than 1% in prepubertal and adolescent biopsies of cryptorchid testes (91); however, in one study, 8% of men had a previous orchidopexy (247). When a unilaterally cryptorchid testis is the site of a testicular cancer or carcinoma *in situ,* biopsy of the contralateral descended testis may be indicated.

The issue of the malignant potential should be discussed with the patient's parents. If he is prepubertal, the parents should be informed that orchidopexy will not reduce the risk of cancer; that the risk, although low, is higher than in a descended testis; that orchidopexy will allow for early diagnosis if a malignancy develops; and furthermore, that such tumors have an extremely high cure rate. If the patient is postpubertal, a careful discussion of the risks and the benefits of orchiectomy versus orchidopexy should be presented so that the family may make an informed decision.

Hormonal Treatment

Hormonal therapy has been used for two purposes: (a) induction of testicular descent and (b) stimulation of germ cell maturation and proliferation to improve fertility in those boys at greatest risk for subfertility (less than 0.2 germ cells per tubule). Testicular descent and germ cell maturation and proliferation are thought to be androgen dependent. hCG treatment was the only treatment used for testicular descent until approximately 1975. Bergada (16) reported the largest series of hCG-treated boys. He obtained a success rate of 40% in boys with bilateral cryptorchidism and 33% in those with unilateral cryptorchidism. Experience indicates that the success rate is higher in older children, which argues against its use because current practice is to treat cryptorchid boys by 12 months of age. Furthermore, if retractile testes are carefully excluded from the groups undergoing treatment, data indicate that the overall success rate is low. In addition, a 20% subsequent retraction rate in “successfully” treated boys has been reported.

Treatment with GnRH nasal spray was introduced in Europe in 1975 for treating testicular descent, with variable success rates (13% to 78%) reported. The drug was never released in the United States for this purpose. European investigators then began treating cryptorchid boys with GnRH nasal spray (Kryptokur) in combination with hCG (87). Boys with retractile testes were excluded. The success rates for induction of descent were measured in a meta-analysis of 33 trials, 11 of which were randomized, published between 1958 and 1990. The success rates were 12% for Kryptokur versus 5% for a placebo. The success rates in all randomized trials were 21% for GnRH, 19% for hCG, and 45% for placebo (223).

The Basel treatment protocol combines Kryptokur 1.2 mg per day for 28 days, followed by hCG 1,500 IU per week for 3 weeks. The success rate reported for permanent testicular descent 4 years after completion of treatment was 65%. Nearly identical results (67%) were reported by Waldschmidt and colleagues (270) after a follow-up of 5 years. The effectiveness of a low-dose LH-releasing hormone (LHRH) analog (Buserelin) was evaluated in a double-blind, placebo-controlled study. Matched patients were assigned randomly to receive Buserelin, placebo, or surgery. Buserelin (20 µmg) was administered daily in a nasal spray, and some patients were treated subsequently with hCG. Twenty-eight percent of the Buserelin-treated cryptorchid testes descended, contrasting with none in the placebo group. hCG influenced descent in both groups but was more efficacious when administered after treating with Buserelin. Boys treated with Buserelin had the highest number and the best maturation of germ cells; hCG did not further affect germ cell maturation. The results of these treatments were better the lower the position of the testis and the younger the patient before treatment. Those who responded to hCG treatment had better spermiograms than those who had surgery alone or received no treatment (91).

These results indicated the beneficial effect of Buserelin on the germ cells. Therefore one rational approach for treatment of cryptorchidism is to initiate treatment with GnRH (Kryptokur) followed by hCG. This can be expected to induce complete permanent descent in 20% to 65% of patients, depending on the pretreatment position of the testis. No further treatment is needed in this group other than routine follow-up. The remaining nonresponders undergo orchidopexy and testicular biopsy. If fewer than 0.2 germ cells per tubule are found, the outlook for fertility is poor, and patients are treated with Buserelin nasal spray (10 µmg by nasal spray every other day for 6 months after orchidopexy) to stimulate germ cell maturation and proliferation and thereby improve the outlook for future fertility. This approach forms the basis for contemporary medical treatment of boys at high risk for subsequent subfertility (fewer than 0.2 germ cells per tubule at biopsy), as practiced in some countries, but this approach is not an option presently in the United States, where Kryptokur and Buserelin are not available for these treatments (20,91).

Temporary penile enlargement has been reported with hCG use but not as a side effect of GnRH treatment. Occasionally, testicular pain may be encountered as well during treatment. If this occurs, treatment should be terminated and orchidopexy performed to minimize the possibility of testicular torsion (102).

Recent reports of increased germ cell apoptosis in patients treated with hCG but not with primary surgery have led some to conclude that hormonal treatment may injure the testis and impair fertility. These findings were not confirmed in our studies, in which apoptosis of Sa Sertoli cells during hormonal treatment were noted; however, these cells usually undergo increased apoptosis during testicular maturation (95). Others have found that a higher number of spermatogonia per tubule were present in biopsies of 1- to 3-year-old cryptorchid boys undergoing surgery alone versus those pretreated unsuccessfully with hCG or GnRH, concluding that hormonal treatment may be deleterious in this age group (46). Alternatively, hormonal treatment in this context may be selecting out treatment failures whose biopsies may be expected to demonstrate poorer histopathology.

SURGICAL ASPECTS OF PEDIATRIC ANDROLOGY

Surgical Aspects of the Testicular Vasculature

Studies investigating the significance of the vascular supply of the human testis have been limited. Studies of testicular blood supply in the fetus with cryptorchidism, in patients with varicoceles, and in patients with cryptorchidism offer interesting and contrasting insights into clinical significance.

The normal adult descended testis is supplied by three arteries: the internal spermatic artery, derived from the aorta; the vasal artery, derived from the inferior vesical artery; and the cremasteric artery, derived from the inferior epigastric artery. Dissections in fetuses between 13 and 33 weeks of gestation demonstrated that all testes had an intact internal spermatic artery and vasal artery, and about three-fourths had all three arteries present, whether they were in an abdominal undescended position or were descended. Fetal testes with only two arteries present were always within the abdomen (232). Another study done in cadavers of all ages, including 11 children, demonstrated that the vasal and internal spermatic arteries were equal in size and that large-caliber anastomoses between the internal spermatic and vasal arteries were present in 87% of specimens (167). The testicular veins follow similar patterns, intercommunicating within the pampiniform plexus at the testicular level. Intraoperative venographic studies performed at the time of varicocelectomy have defined well the characteristic venographic patterns of the testis (Fig. 53.12), and experimental venographic studies have indicated that the main collateral drainage from the descended testis (i.e., after ligation of the internal spermatic vein) is through the cremasteric veins, not the vasal veins (132).

However, some have questioned whether the vasculature in cryptorchid patients corresponds to the normal descended testis. High ligation of the internal spermatic artery and vein (i.e., at the time of radical nephrectomy for Wilms' tumor) is not associated with atrophy of the descended testis. Similarly, high ligation of the internal spermatic artery and vein at the suprainguinal ring level at the time of varicocelectomy (Palomo procedure) does not generally result in testicular atrophy. In cryptorchid boys having a long-looped vas, major intercommunications between the internal spermatic artery and vasal collaterals are present, allowing for reasonably safe high or low vessel ligation in most instances (140,145). In the true abdominal testis without a long-looped vas, internal spermatic artery ligation may be less reliable, explaining the divergent results that have been reported when this procedure is applied without making this distinction. In this circumstance, the main collateral arterial supply may be from the vasal artery because the cremasteric arterial collaterals may be developed only in the normally descended testes (26). If these collaterals are underdeveloped, microvascular orchidopexy, staged internal spermatic vessel transection orchidopexy, or staged orchidopexy may be considered. Previous inguinal surgery also may alter the normal venous and lymphatic drainage.

Studies of the intratesticular arteries demonstrate also that the main artery lies posteriorly underneath the epididymis, then coursing anteriorly in a very superficial position before branching and penetrating deeply. The superficial location, especially at the lower pole, makes it vulnerable to damage from traction sutures (i.e., during orchidopexy), so awareness of the course of the artery and individual visualization in each case is important (125). This and the previous information regarding the arterial and venous supply of normal and descended testes is of practical importance in performing (individualized) testicular surgery.

Surgical Inguinal Anatomy

A knowledge of the anatomy of the inguinal canal helps keep the surgeon out of trouble. A better understanding of the retroperitoneal fascial anatomy permits an improved understanding of the anatomic basis for orchidopexy and herniorrhaphy (120). The essential concept is that the retroperitoneal fascia outside the peritoneum is a continuous layer acting as a “felt” in which the spermatic vessels and vas, as well as the ureter, are imbedded and bound (Fig. 53.31A). This fascia, also known as the *endoabdominal fascia,* has a number of areas of condensation. In the floor of the inguinal canal, it is condensed as transversalis fascia. It is then reflected in a thinner form as the internal spermatic fascia enveloping the vas, vessels, and processus vaginalis within the inguinal canal. This layer is just inside the cremaster muscle, which is an extension of the internal oblique muscle.

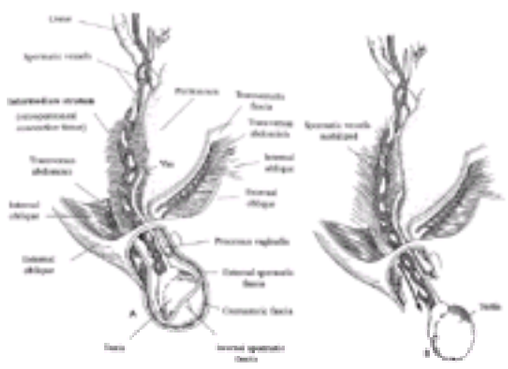

FIGURE 53.31. A: Surgical anatomy of the inguinal canal. The spermatic vessels and vas are imbedded and bound in the retroperitoneal fascia outside the peritoneum. **B:** An undescended testis must be freed by freeing the vas and vessels from the retroperitoneal endoabdominal fascia. This permits even intraabdominal testes to be placed within the scrotum.

When the testis stops short of a normal descended position, the vas and vessels are enveloped in the retroperitoneal endoabdominal fascia. Freeing these structures from their fascial attachments permits even intraabdominal testes to be placed within the scrotum (Fig. 53.31B). The vas and vessels are rarely so short as to make scrotal placement of the testis impossible (142). Laparoscopic orchidopexy permits high retroperitoneal mobilization of the spermatic vessels and emphasizes this point (131).

Within the inguinal canal, the first anatomic consideration is to divide the cremaster muscle to gain access to the spermatic cord and the internal inguinal ring. Dissection within the internal ring will achieve almost all the mobilization required for a successful orchidopexy. The internal spermatic fascia must be divided to permit access to the processus vaginalis, which is separated in the inguinal canal from the vas and vessels. As the dissection proceeds through the internal ring, the vas and vessels are elevated out of the posterior enveloping portion of the endoabdominal fascia as they move forward with the peritoneum. This step has been referred to by varying terms such as *division of the lateral spermatic fascia* or *division of the bands of Denis Browne.* To complete the mobilizations of the vas and vessels from the enveloping endoabdominal fascia, or conceptually, the retroperitoneal feltlike layer in which they become embedded when descent stopped, the spermatic vessels and vas are dissected posteriorly from the undersurface of the peritoneum. As the delicate fibers are teased away from the vas and vessels,

adequate mobilization to permit the testis to reach the scrotum is almost always achieved. Rarely today is division of the inguinal canal floor required. The old concept of collapsing triangles to create a straighter course for the spermatic vessels into the scrotum (Prentiss maneuver) appears much less important than the concept of adequate retroperitoneal mobilization of the spermatic vessels. These findings are reemphasized in observing that the most common cause for inadequate testis placement identified during reoperative orchidopexy is the failure to perform an adequate high retroperitoneal dissection (183). In doing this, however, it is important to prevent dissection too closely to both the vas and vessels because this will result in unsatisfactory outcomes.

Surgical Incisions

The incisions used for surgery on the testis, scrotum, and cord structures are similar and hence are discussed here in common.

Standard Inguinal Incision

The standard inguinal incision is used for entry into the inguinal canal to perform hernia repair, orchiopexy, or varicocelectomy, as well as for delivery of the testis from the scrotum to perform hydrocelectomy or radical orchiectomy for tumor. This incision is best placed transversely in the lower abdominal skin crease, where it usually results in an indefinable linear scar. Oblique incisions paralleling the inguinal canal should be avoided because they do not follow Langer's lines and often result in broad unsightly scars. The argument that oblique incisions can be used to extend the surgical dissection higher, as in treating high undescended testes, is not founded. In children, the same exposure can usually be obtained by using a transverse incision of adequate length or even placed higher above the inguinal skin crease. This same incision may be placed slightly lower to obtain delivery of the testis and spermatic cord for subinguinal microscopic varicocelectomy.

Following the skin incision, Scarpa's fascia is divided and the external oblique aponeurosis is exposed and opened parallel to the inguinal ligament. Care must be taken to avoid transection of the underlying ilioinguinal nerve, which often hugs the underside of the external oblique fascia, especially in older children. At this point, herniorrhaphy, orchiopexy, or varicocelectomy may be accomplished, as detailed in the following sections. Closure of the external oblique and the subcutaneous tissue and skin is done with an absorbable suture of appropriate size. Bilateral inguinal incisions may be used for simultaneous repair of bilateral defects. In general, these incisions are extremely well tolerated in children and heal without difficulty.

Suprainguinal Retroperitoneal Muscle-splitting Incisions

Suprainguinal retroperitoneal muscle-splitting incisions have been described mostly for “high ligation” of the internal spermatic vein for varicocelectomy. Some advocate this approach directly above the internal inguinal ring at a level above the divergence of the vas deferens because the internal spermatic vein is more likely to be single at this level (214). A transverse skin incision is made and then retracted superiorly, and the external oblique aponeurosis is incised, followed by splitting of the underlying muscles to gain entry to the retroperitoneal space. Alternatively, a true lower quadrant or flank incision (123) may be made to approach the internal spermatic vein higher in the retroperitoneum. In these approaches, care must be taken to identify and protect the adjacent ureter. These muscle-splitting incisions are closed thereafter in layers with absorbable sutures, resulting in a very strong closure.

Lower Abdominal Incisions for Simultaneous Exposure of Both Testes

Various lower abdominal incisions for simultaneous exposure of both testes have been described and are used primarily for orchiopexy when both testes are high or impalpable, when simultaneous separate inguinal incisions may not give adequate exposure for safe dissection. Flynn and King (68) recommended a midline transperitoneal approach for dissection of the intraabdominal testis, followed by creation of a new inguinal ring just lateral to the pubic tubercle so that the spermatic cord might assume the most direct route into the scrotum (Fig. 53.32). This incision may also be used to approach the testis preperitoneally by dissection along the rectus sheath laterally until the retroperitoneum is entered and then mobilizing the testis and cord at that level (22,119,176). In some instances, especially when an extensive exposure of bilateral intraabdominal testes is necessary, both lower rectus muscles may be totally transected, resulting in wide preperitoneal or intraperitoneal exposure. The latter is the ideal incision to use in boys with prune-belly syndrome who are undergoing orchiopexy because their lower abdominal muscles are already attenuated.

FIGURE 53.32. Technique of transabdominal orchiopexy. **A:** Intraabdominal view showing testis intraperitoneally at pelvic brim. **B:** Testicular mobilization from posterior peritoneum and restraining bands. **C:** New external ring created at the level of lateral rectus muscle border and superior pubic ramus. **D:** Testis brought through the opening and placed within the scrotum. (From Kogan SJ. Cryptorchidism. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology,* 2nd ed. Philadelphia: WB Saunders 1985, with permission.)

Minimally Invasive Access

Laparoscopy has added a new dimension for accessing the testis and spermatic cord. Improvements in technique, miniaturization of instruments, and added experience have facilitated laparoscopic access to these structures as an alternative approach to standard open surgery. Laparoscopic access is best suited for treating the intraabdominal undescended testes. However, this approach can be used for either transperitoneal or preperitoneal varicocele repair as well. The major benefit of laparoscopic minimal access approach is the wide operative field accessed through the minimal abdominal incision. The techniques of trocar placement are described subsequently under treatment of each individual condition.

Incisions into the Scrotum

Incisions into the scrotum are made to allow direct access to the testis and paratesticular structures. In children, the most common indications are for exploration of suspected testicular torsion or torsion of a testicular appendage. Although individual transverse scrotal incisions may be made for direct access to each hemiscrotal compartment, a vertical midline raphe incision is preferred because it is simpler and more cosmetic. The midline raphe is incised, with care taken to avoid carrying the incision onto the base of the penis. Following dissection deeper between the hemiscrotal compartments, a separate incision is made into each, through which each testis is delivered separately. Following biopsy or detorsion and suture fixation, the separate incisions are each closed with interrupted absorbable sutures. The midline raphe incision is then closed separately in one layer with interrupted absorbable sutures. It is important to reemphasize that, in children, scrotal incisions are not used to perform testicular biopsies when solid tumors are suspected. Furthermore, in children, hydrocelectomy is usually performed through an inguinal incision because of the high likelihood of a patent processus vaginalis. Scrotal incisions are also made to fix the testis in place as part of an orchiopexy procedure. Previously described practices of testicular fixation to the contralateral thigh by direct suture or by rubber band traction are not advised because a high frequency of testicular atrophy results in these instances. Fixation of the testis into the contralateral hemiscrotal compartment across the midline septum has been described (206) and continues to have its advocates. However, the most popular method of fixation is the subcutaneous pouch method, with fixation of the testis beneath the skin and above the dartos muscle (164). Following adequate mobilization of the spermatic cord and testis, a short transverse ipsilateral scrotal incision is made through the skin. A plane is developed with a hemostat between the skin and the underlying dartos, creating a pocket to accommodate the testis and epididymis. An incision of sufficient size to pull the testis within is then made in the underlying dartos with the aid of a previously placed traction suture. The testis is positioned in the pouch, and the traction suture is passed through the dependent scrotal skin and then tied to itself or fastened to a button or gauze pledget. Some prefer to suture the testis

directly to the dartos internally rather than using a transscrotal suture. Thereafter, the scrotal incision is closed with interrupted fine chromic sutures in one layer.

Specific Situations

Hernias and Hydrocele Surgery

The scrotum is always prepped and draped into the operative field. This permits access to the scrotum during the operative procedure, which is often necessary. The skin incision is usually just a little longer than the length of the inguinal canal and is placed directly over it. The medial end of the incision may be easily determined by feeling the position of the cord structures as they exit the external ring immediately lateral to the pubic tubercle. Blunt and sharp dissection is carried down to the fascia of the external oblique, which is cleared at the pubic tubercle to expose the cord structures as they exit the external ring. This step ensures that the incision made in the external oblique fascia will be properly positioned over the canal. If the external ring is not identified, it is easy to inadvertently place the fascial incision too high or medial, causing the cord structures to be missed. The external oblique fascia is opened through the external ring. By doing this, the delivery of an associated hydrocele is much facilitated. The cremaster muscle is mobilized off the undersurface of the external oblique and the transversalis muscles. This permits the cord structures to be raised. By teasing the cremaster fibers off the cord at the internal ring, a small retractor may be inserted later to expose the peritoneum, ensuring a high ligation of the processus vaginalis at its junction with the peritoneum. The next step is to open the internal spermatic fascia by superficially elevating the tissues over the vas and vessels to prevent injury to these underlying structures. Once the internal spermatic fascia is opened, the processus vaginalis can be separated. It is always wise to check that the vas and vessels are reidentified separate from the processus and that there is nothing in the processus before dividing it. The processus is then divided between hemostats and dissected up to the internal ring, where it is twisted and doubly ligated at its junction with the peritoneum. If the surgeon has trouble identifying the processus vaginalis, a simple solution is to place a small retractor through the internal ring; then, with gentle traction on the cord structures, the peritoneum can be readily identified. This permits a proximal to distal dissection to identify the processus or confirm its nonpatency.

The surgeon now must deal with the collection of fluid within the tunica vaginalis in a communicating hydrocele. The testis is delivered through gentle traction on the distal end of the processus and the cord structures. The plane of dissection is kept immediately adjacent to the tunica vaginalis, which makes this procedure avascular. If there has been fluid collection in the tunica vaginalis, as is seen in a communicating hydrocele, the tunica vaginalis will be thicker than in an uncomplicated hernia. Here, the risk of a persisting hydrocele increases if the tunica vaginalis is not widely opened and securely maintained open. For this reason, the tunica vaginalis is then turned back behind the cord structures with a single stitch in a bottle technique. Usually, there is no need to excise any of the tunica vaginalis unless it is very bulky and thickened. With an inguinal hernia, the tunica vaginalis is often much flimsier, and a wide opening often is adequate to ensure the edges do not recoapt, permitting the formation of a reactive hydrocele postoperatively. After this step, gentle traction on the scrotum will use the gubernaculum and its attachment to the testis to reinvert the testis within the tunica vaginalis and then return the testis to a dependent scrotal position. This should be confirmed by careful palpation of the testis in the scrotum before inguinal closure is begun. If any question exists, the testis should be redelivered inguinally and, if necessary, the gubernaculum divided and the testis sufficiently mobilized to be placed into a subdartos pouch. There is no substitute for a secure scrotal positioning of the testis in the first instance in groin surgery carried out in children. Reconstruction of the inguinal canal is accomplished by reapproximation of the external oblique fascia; however, a good check of the transversalis fascia constituting the floor of the inguinal canal at the internal ring is important. If the ring is excessively large, one or two stitches to close the transversalis fascia at this level may prevent a later direct hernia, although this is indeed a rare complication of groin surgery in children.

Scrotal Exploration for Acute Torsion of the Spermatic Cord or Testicular Appendages

Scrotal exploration for acute torsion of the spermatic cord or testicular appendages is accomplished through two separate transverse hemiscrotal incisions or a single midline raphe incision. The successive scrotal layers are incised, and the testis is delivered. Intravaginal torsion may not be evident until the tunica vaginalis is opened (Fig. 53.33). Detorsion and application of warm saline soaks is accomplished, during which time the contralateral testis is delivered. The tunica vaginalis is opened, and suture fixation of the testis is done in at least two places between the testis capsule and the dartos of the scrotum. A nonabsorbable suture must be used because both experimental and clinical evidence indicates that torsion may recur after previous suture fixation with absorbable suture material. Thereafter, the torsive testis is reassessed, and a decision is made regarding orchiectomy versus preservation and suture fixation. Removal of questionably viable testes should be considered in light of current information suggesting that the contralateral testis may be adversely affected by a retained damaged testis in some instances. When appendiceal torsion is encountered, the appendix is ligated or fulgurated carefully and excised. Contralateral appendiceal excision and suture fixation of the testis are not usually done.

FIGURE 53.33. Acute spermatic cord torsion in a 3-year-old boy. **A:** Inflamed testis is delivered, but twist is not evident. **B:** Incision of surrounding tunica vaginalis reveals intravaginal torsion.

Varicocelectomy

Multiple techniques for treating pediatric varicoceles have been described; however, some (e.g., retrograde femoral vein catheterization with embolization or sclerotherapy) are not widely used. Those used frequently by pediatric urologists are high retroperitoneal ligation and laparoscopic or microsurgical varicocelectomy. A proximal inguinal approach may be associated with increased risk of varicocele recurrence (81).

Open transinguinal repair consists of opening the inguinal canal in standard fashion, mobilizing the entire spermatic cord over a Penrose drain, and then carefully identifying and ligating the offending varicosities, which at this inguinal level are usually multiple. Positioning the patient in a reverse Trendelenburg position and using optical loupe magnification aids in identifying the dilated veins. The artery is identified and preserved. In some instances, when arterial identification is difficult, warm saline or papaverine drip directly on the vessels is helpful. Care must be taken to avoid the ilioinguinal nerve and the vas deferens and its vessels. Use of intraoperative venography may aid in avoiding unrecognized “bypass collaterals,” which will result in a persistent varicocele (81,172).

Open high retroperitoneal exposure offers advantages over the transinguinal route. The incompetent internal spermatic vein is more often single, and the exposure is above the vas deferens and its accompanying vessels, thereby avoiding them completely. A transverse abdominal incision is made one to two fingerbreadths medial to the anterior superior iliac spine and the same distance above the estimated position of the internal inguinal ring. A muscle-splitting technique is used to enter the retroperitoneum. Reverse Trendelenburg position and a slight contralateral tilt of the abdomen on the operating table aid in exposure, which is obtained with appropriate-size right-angle retractors retracting the muscles. The internal spermatic vessels are identified on the posterior aspect of the peritoneum and are looped with a Penrose drain or holding sutures. This exposure may prove difficult in the obese adolescent; traction on the ipsilateral testicle often will aid in identifying the elusive vessels in this circumstance. At this level, the vas and its surrounding vessels are well inferior. Ligation is performed in the manner described previously and is complemented by using internal spermatic venography.

Transperitoneal laparoscopic varicocelectomy has been adopted preferentially by some pediatric urologists. The advantages provided by this minimally invasive surgical route are obvious: rapid patient recovery and mobilization, minimal morbidity and pain, and rapid return to all normal activities. Additional benefits are that a direct, magnified visualization of the internal spermatic vessels and collaterals high above the vas deferens and surrounding vessels occurs. This approach is especially useful in the rare circumstance when bilateral varicoceles are present. Disadvantages of this approach are the longer operative time, increased cost, and potential for injury of abdominal viscera and vessels resulting from trocar insertion and/or dissection. As with other aspects of laparoscopic surgery, evolutions in

technique and instrumentation have occurred. Miniaturization of laparoscopic ports and instrumentation has lessened morbidity without compromising surgical technique and safety. Improved camera optics have significantly facilitated surgical visualization.

For transperitoneal laparoscopic repair, an incision is made at the umbilicus and deepened down to the infraumbilical midline fascia, which is incised. A vertical incision on the inferior crest of the umbilicus is made when the umbilicus is deep, and a curvilinear incision following the crest when it is flat. Pneumoperitoneum is produced either by Veress needle insertion while elevating the umbilicus and abdominal wall with towel clips, when checking the needle position with the open saline drop and direct injection techniques, or by continuing the dissection into the peritoneum with port insertion under direct vision. A 5-mm video port is then established. Pneumoperitoneum is established using a maximum pressure of 12 cm H_2O. A second 5-mm port is placed in the midline just over the pubis under direct vision, a position that ultimately will be hidden in the pubic hairline. A third 3-mm port is placed midway between the other ports in the midline or midway between the umbilicus and the anterior superior iliac spine, superior to the internal inguinal ring. The bowels are retracted with steep Trendelenburg's position and tilting the table slightly to the right. The posterior peritoneum is incised over the internal spermatic vessels using a T incision, and the spermatic veins are mobilized. A 5-mm clip applier is passed through the lowest port, and the veins are elevated, clipped, and divided. Some surgeons will clip the entire arterial and venous pedicle without attempting to isolate the artery, simplifying the procedure considerably. After reducing the pneumoperitoneum pressure and ensuring that the operative field is dry, the surgeon removes the trocars under direct vision. Fascial closure is made for the umbilical and lowest incisions; the 3-mm port requires skin closure only, along with the others.

Preperitoneal laparoscopic repair avoids injury to intraabdominal structures because the internal spermatic vessels are isolated extraperitoneally. Following infraumbilical incision in the manner described earlier, a subcutaneous plane is developed over the left anterior rectus sheath, which is then incised for a short distance to the left of the midline. The left rectus muscle is retracted laterally, and a peanut dissector is passed posterior to the left rectus muscle to the level of the pubis, establishing a pathway for the 10-mm preperitoneal balloon dissector, which is then inserted and manually inflated. The preperitoneal space is developed under direct vision using a 0-degree viewing lens. The balloon dissector is deflated and removed, and a Hassan 10-mm port is placed and pneumopreperitoneum at 12 cm H_2O pressure is established. Two additional ports are placed under direct vision in the midline, as described for the transperitoneal approach. The internal spermatic vessels are identified, aided by traction on the testicle, which is draped into the sterile operative field. The vessels are grasped and elevated well above the vas deferens and its vessels, which can be seen coursing medially; varicocelectomy proceeds as described for the transperitoneal laparoscopic repair. Using this technique eliminates the risks of bowel injury and postoperative hernias because the peritoneum is not opened and the testicular artery can be identified and preserved in most cases.

As with other surgeries, opinions vary greatly regarding the benefits of each approach for varicocelectomy. A recent extensive multicenter report of 195 children undergoing laparoscopic varicocelectomy indicated the overall benefits (e.g., comparable operating time to open surgery, comparable low recurrence rate, minimally invasive surgery, precision of operative procedure) outweighed the disadvantages of this approach (e.g., recurrent hydroceles, potential for increased expense) (60). Recent publications for (169) and against (66,169) microsurgical varicocelectomy also support this approach.

Cryptorchidism

Although there have been many refinements in the incisions and operations used for orchiopexy, successful surgical placement of the testis within the scrotum continues to depend on the surgical principles first enunciated by Bevan (18) in 1899, namely adequate mobilization of the testis and spermatic vessels, repair of the associated hernia, and adequate fixation of the testis within the scrotum. The choice of surgical procedure to achieve these goals is determined to a great extent by the location of the testis; therefore the procedures for palpable and impalpable undescended testes are considered here separately.

Palpable Undescended Testes

Palpable undescended testes are usually located within the superficial ectopic space or within or emerging from the inguinal canal; therefore they are best approached through the standard inguinal incision (Fig. 53.34A). The distal attachments to the scrotum are divided sharply, observing carefully to avoid a long-looped vas that sometimes extends distally beyond the testis. Occasionally, these attachments may be ectopic (i.e., extending toward the thigh or pubis). The testis and cord are then sharply dissected up to and into the internal inguinal ring (Fig. 53.34B). No attempt is made to dissect within the cord substance because it does not result in any significant cord lengthening and actually may endanger the spermatic artery. In some instances, as when the undescended testis is quite distal or lies in a superficial ectopic position, no additional dissection is needed; adequate spermatic cord length exists for satisfactory scrotal placement of the testis. Further dissection is necessary in some cases, especially along the lateral attachments of the spermatic cord (lateral spermatic fascia). Anatomic dissections have demonstrated that this extracanalicular dissection can provide up to three-fourths of the entire potential length obtainable during orchiopexy, with only one-fourth from the intracanalicular dissection (220). The internal inguinal ring may be opened with the cautery to allow higher dissection within the ring if additional length is needed. This dissection is essentially the mobilization of the spermatic vessels and the vas out of the enveloping endoabdominal fascia. In most cases, extending this mobilization allows sufficient lengthening of the spermatic vessels and vas deferens to be achieved so that even intraabdominal testes can be placed into the scrotum. The hernia sac, which is virtually always present with a true undescended testis and often present with an ectopic testis, is sharply dissected proximally off the cord, divided, twisted, doubly ligated at the internal ring with an absorbable suture, and then dropped back into a retroperitoneal position (Fig. 53.34C and Fig. 53.34D). Occasionally, this dissection of the hernia sac may be difficult, resulting in a proximal peritoneal tear extending within the internal ring. In such circumstances, the ring must be opened, as described previously, to obtain better visualization and a sound peritoneal closure. A pathway is made into the scrotum with the dissecting finger to ensure that there are no obstructing bands of tissue remaining. Scrotal fixation of the testis is done by the method described previously, and the groin incision is closed (Fig. 53.34E and Fig. 53.34F).

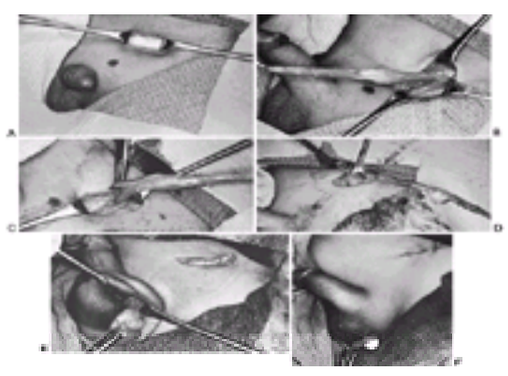

FIGURE 53.34. A–F: Technique of orchiopexy for palpable undescended testes (see text for description). (From Kogan SJ. Cryptorchidism. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology,* 2nd ed. Philadelphia: WB Saunders, 1985, with permission.)

The important elements, then, in obtaining adequate spermatic cord length for orchiopexy are mobilization up into the internal inguinal ring, division of the hernia sac, dissection of the cord off the posterior peritoneum, and division of the enveloping fascia for an adequate distance. It is often surprising how high the spermatic cord can be dissected through the standard inguinal incision, and the dissection may be carried almost up to the lower pole of the kidney in young children when necessary. The limiting factor in these instances is not the skin incision but rather the internal inguinal ring, which should be opened generously to give adequate exposure. When these maneuvers still do not achieve adequate spermatic cord length for successful scrotal placement of the testis, the floor of the internal ring may be taken down, dividing the internal epigastric vessels and transversalis fascia to create a mild increase in spermatic cord length. The floor of the inguinal canal is then closed over the cord, superimposing the internal and external inguinal rings. Skeletization of the vas deferens to achieve additional cord length should not be attempted because the vas deferens is seldom short enough to be an impediment to successful orchiopexy and because of the inherent dangers to the vas deferens occurring by this manipulation (241).

A recent series of boys with palpable undescended testes undergoing orchidopexy by accessing the testis thorough a single high scrotal incision calls attention to the experience that, in many instances, the cryptorchid testis and hernia sac can be safely treated in this manner. The short inguinal canal and reasonable testis mobility in many allows for tension-free testis placement in the scrotum and a high ligation of the hernia sac, saving an additional inguinal incision. Although this approach was used in this series also for treating previously operated upon cryptorchid testes (i.e., those resulting from previous hernia repair or failed orchidopexy), caution must

be advised in this setting because the possibility of vas or vessel injury is definitely increased (32).

Impalpable Testes

In the patient with a unilateral impalpable undescended testis, we have been disinclined to use laparoscopy primarily because of our facility in resolving the findings through a standard inguinal incision. In most cases in which the testis is absent, we have found that the vas and vessels ended distal to the internal ring (262). With aggressive mobilization of the spermatic vessels by a transperitoneal approach done through the same inguinal incision, we have been able to place almost all intraabdominal testes into the scrotum in a primary operation. When there are bilateral impalpable testes, however, the situation is different. Here, there appears to be a much stronger rationale for the use of initial laparoscopy because it does indeed let one plan an appropriate strategic approach. We do not believe that the decision concerning the placement of incisions is very critical, because we have consistently been able to deal with all types of undescended testes through a standard inguinal incision with at most a minor lateral extension. This permits the internal ring to be opened, providing excellent exposure for even an extensive mobilization of the spermatic pedicle.

If at laparoscopy two intraabdominal testes within 2.5 cm of the internal ring are located, these should be able to be mobilized to place them in the scrotum without division of the spermatic artery (217). This can be accomplished by laparoscopic orchiopexy (131) or by open surgery. In the older boy, a laparoscopic orchiopexy may produce less discomfort than one carried out with two inguinal incisions. In the small boy, however, recovery is so rapid as to make this consideration a minor one. If at laparoscopy two very high intraabdominal testes are located, this could perhaps be the most justifiable case for the use of primary laparoscopic approach to orchiopexy. A primary clipping of the spermatic artery will cause the vasal artery to hypertrophy and make a subsequent staged orchiopexy more successful (21,27). The experimental work by Pascual and colleagues (215) provides a good physiologic rationale for this approach. A secondary laparoscopic orchiopexy in this staged fashion has been shown to be highly successful. In the boy who is found at laparoscopy to have only one intraabdominal testis, our approach is to be very conservative concerning the possible loss of that testis, because hormonal replacement is not trouble free. Laparoscopic or microvascular orchidopexy offer the safest approaches in this circumstance.

Unilateral Impalpable Testes

Unilateral impalpable testes are explored through a standard inguinal incision, with lateral extension if necessary, although some prefer an initial higher transverse incision in the lower abdominal quadrant. If the testis or a small tongue of protruding peritoneum is not encountered within the inguinal canal, the internal inguinal ring is immediately opened, as previously described. This tongue of peritoneum often is the harbinger of an intraabdominal testis within, and further mobilization of this protrusion often results in prolapse of the testis out of its intraabdominal position. When the testis is still not evident, no further dissection is done through the internal ring because the vas associated with an intraabdominal testis often runs close by the internal ring and the vas or the vasal artery may be injured by retroperitoneal dissection. Instead, the peritoneum knuckle that presents at the internal ring is opened; this transperitoneal exposure permits rapid identification of an intraabdominal testis. Although the testis is a retroperitoneal organ, it is often more easily visualized intraperitoneally, just as the ovary is visualized suspended on its mesentery intraperitoneally in the female. Once identified, a suture is taken through the capsule of the testis, and gentle traction is applied to assess the spermatic cord length so that the appropriate method of orchiopexy may then be chosen.

Bilateral Impalpable Testes

When bilateral impalpable testes are present, they can be approached through any one of the previously described transverse lower abdominal skin crease incisions. Because the protruding peritoneal processus or the testis itself is often encountered within the inguinal canal, both canals are opened initially. When no structures are evident, the skin and subcutaneous fascia are dissected superiorly off the rectus fascia, and a midline vertical incision is made, followed by preperitoneal or transperitoneal exposure. Because direct visualization of the proximal spermatic vessels is helpful in these instances, a transperitoneal exposure is preferred. In the course of exploring for an impalpable testis, it may become evident that the testis is not present. Various anatomic patterns may be found, indicating that monorchia exists (Table 53.3). If structures resembling a blind-ending spermatic cord, vas deferens, or vessels alone are found within the inguinal canal at the onset of exploration, they are traced within the internal ring to the point of divergence of the vas deferens and accompanying vessels to ensure that the miniature vessels visualized are, in fact, the spermatic vessels and are not cremasteric, vasal, or otherwise. This is an extremely important surgical point because blind-ending spermatic vessels are the *sine qua non* of testicular absence, and there are no recorded cases in which these vessels were present and a testis was found elsewhere (174). Therefore identification of the spermatic vessels coursing up the posterior retroperitoneum signals the end of the exploration; it is unnecessary to carry the exploration further, provided accurate identification of spermatic vessels is made. If a vas deferens alone is encountered, exploration is carried further as previously indicated because a wide separation of the vas deferens and the testis is possible with the testis lying higher within the abdomen (Fig. 53.35). Similarly, initial apparent absence of all structures demands that the exploration proceed further.

FIGURE 53.35. Testis *(t)* located immediately adherent to mesentery of appendix *(a)* medial to cecum. Rudimentary epididymis was present; vas deferens was absent. (From Wu RHK, Kogan SJ, Levitt SB. Testicular failure in an adolescent with a mesoappendicular testis. *Urology* 1966;27:434.)

An additional reason for accurately identifying the spermatic vessels within the internal inguinal ring is the common misleading appearance of these higher located undescended testes. Jones (130) has clearly stated this problem best:

> It should be mentioned that at operation, even when it appears that an atrophic testis had been located, a thorough exploration in the region of the internal ring is still necessary for the macroscopic findings are sometimes bizarre and misleading. Segments of the vas may be absent; a structure resembling the spermatic cord may lay a false scent into the scrotum while the testis lies in the abdomen. Conversely it is sometimes helpful to invaginate the scrotum into the inguinal incision to inspect the contents before proceeding to further exploration.

The surgical implications of this problem are very clear. Structures within the inguinal canal consisting of a looped epididymis or vas deferens may resemble a blind-ending spermatic cord or atrophic testis and may be mistakenly excised. An absent testis may be misdiagnosed, where the testis may actually lie above within the abdomen (184). Occult undescended testes have been discovered above the internal inguinal ring at reexploration after the initial exploration failed to accurately define these structures within the inguinal canal or to include an intraperitoneal exploration (147).

Following completion of this extensive exploration when the testis is identified gentle stretch with a traction suture will allow assessment of spermatic vessel length. If this assessment indicates that adequate length may be achieved by a standard high dissection of the spermatic cord, this approach should be pursued as the most favorable choice. Many surgeons do not appreciate that a conventional high dissection of the spermatic cord will allow for successful orchiopexy of most intraabdominal testes (Fig. 53.36). If the initial assessment reveals that the vessels are too short, precluding satisfactory scrotal placement by this means, a primary orchiopexy by transection of the testicular vessels, with or without microvascular anastomosis, or a staged orchiopexy will be required.

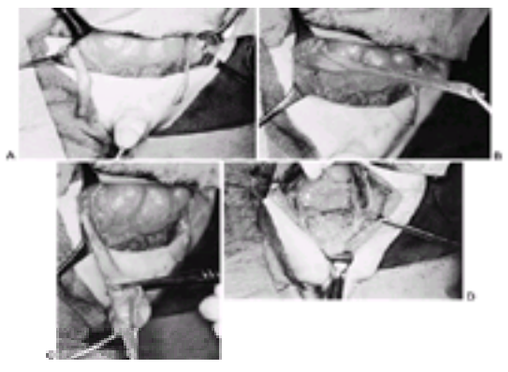

FIGURE 53.36. Technique of orchiopexy of impalpable intraabdominal testes by high retroperitoneal dissection. Excellent exposure is provided by complete rectus muscle transection. **A:** Processus vaginalis extending down inguinal canal often indicates higher intraabdominal testis. **B:** Testis extruded from its intraabdominal position into processus. **C:** High retroperitoneal dissection allows for adequate spermatic cord length for testis to reach scrotum. **D:** Direct course of each spermatic cord into scrotum following scrotal fixation.

Orchiopexy by Spermatic Vessel Transection

Bevan (19) originally described orchiopexy by spermatic vessel transection in 1903; however, because of poor results, it rapidly fell out of favor until Fowler and Stephens (72) in 1959 better characterized the vascular anatomy of these high-undescended testes using intraoperative angiography to demonstrate vascular anastomoses between the vasal and spermatic arteries. They recommended temporarily occluding the internal spermatic vessels to test the capability of this collateral blood supply (Fowler-Stephens test). Using these principles, they achieved successful scrotal placement of the testis in 8 of 12 patients. Brendler and Wulfson (25) further refined this procedure by indicating that the spermatic vessels should be ligated high away from the testis, avoiding dissection within the cord itself achieving scrotal placement in all five of their patients. Clatworthy and colleagues (40) reported on the results of 32 testicular vessel transections, which were divided into those done as a “premeditated” procedure and those done as a “salvage” operation following unsuccessful extensive previous cord mobilization. In the former group, 18 of 21 operations were successful; in the latter, only 6 of 11 did not undergo atrophy, leading to the recommendation that the epigastric vessels and floor of the inguinal canal be left intact and that mobilization of the posterior wall of the hernia sac off the spermatic cord be avoided. Johnston (129), in discussing orchiopexy of the intraabdominal testis in prune-belly syndrome, further refined this procedure by indicating that a broad strip of medially based peritoneum along the vas deferens should be left intact, along with its extensive collateral blood supply (Fig. 53.37). Additional series incorporating these important modifications of the original operation have proved even more successful (149). Gibbons and colleagues (77) reported success in 22 of 27 patients with intraabdominal testes, with most failures encountered initially when the vessel transection followed extensive spermatic cord mobilization. These authors retrospectively analyzed the possible pitfalls in performing this procedure as (a) failing to leave the wide, medially based peritoneal strip attached to the vas deferens; (b) doing the procedure as a salvage operation; (c) ligating the internal spermatic vessels too close to the testis; and (d) directly injuring the vasal artery in the course of mobilization.

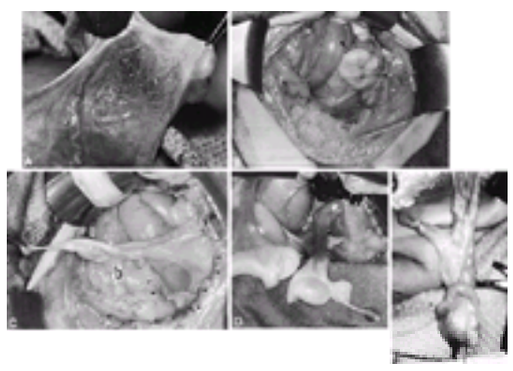

FIGURE 53.37. Technique of orchiopexy of intraabdominal testis by testicular vessel transection technique. **A:** Close-up showing collateral vascularity in the peritoneal strip between the spermatic and vasal vessels. **B:** Transabdominal exposure demonstrating high intraabdominal tests *(arrowhead).* Bladder is at inferior margin of figure. **C:** Left intraabdominal testis, spermatic vessels, and medially based peritoneal strip *(arrowheads)* along the vas deferens. b, bladder. **D:** Nontraumatic bulldog clamp applied high on spermatic vessels. **E:** Testis brought down on collateral blood supply within medially based peritoneal strip along vas deferens. (**A** from Kogan SJ. Cryptorchidism. In: Kelalis PP, King L R, Belman AB, eds. *Clinical pediatric urology,* 2nd ed. Philadelphia: WB Saunders, 1985:864, with permission.)

In a more recent review of orchidopexy by this technique, King (140) obtained success in 23 of 24 patients. He used an approach that preserves the medial strip of peritoneum along the vas deferens and its blood supply. Koff and Sethi (145) modified the traditional approach by indicating the testicular artery could be safely ligated low, adjacent to the testis, as long as the vasal collaterals were avoided. Woodard and Trulock (281) have listed the conditions that preclude doing an orchiopexy by testicular vessel transection as (a) the presence of a short, limiting vas deferens; (b) a hypoplastic testis with an uncertain blood supply; (c) segmental vas atresia; and (d) a detached epididymis.

Ransley and co-workers (224) described a variation of this operation in which the internal spermatic vessels are first ligated without mobilization at an initial stage. Several months later, the vessels are divided, and orchiopexy is completed as described previously. This approach allows for enhanced collateral vessel development and may be more reliable, especially in very small patients. Woodard and Parrott (280) have also indicated that orchiopexy of the intraabdominal testes found in patients with prune-belly syndrome may often be done in the neonatal period by mobilization of the intact spermatic pedicle without the need for division of the spermatic vessels.

Microvascular Orchiopexy

Microvascular orchiopexy has given an added dimension to the treatment of intraabdominal testes. The reestablishment of an intact blood supply to the testis by anastomosing the internal spermatic artery to the inferior epigastric artery would seem to offer additional safety beyond reliance on the collateral blood supply accompanying the vas deferens. The microsurgical equipment needed includes a good operating microscope with a foot control for focus, zoom, and positioning. Microvascular clamps, microscissors, a microneedle-holder, and 10-0 nylon sutures with fine microneedles are also required. The donor vessels are usually the inferior epigastric artery and vein. Topical agents such as lidocaine and papaverine may be applied to the vessels, and systemic anticoagulation may be used. For microsurgical orchiopexy, the initial exposure and procedure are the same as for testicular vessel transection; however, in this case, the internal spermatic vessels are dissected up toward their juncture with the aorta or vena cava before ligation. This procedure is especially important in younger children because these vessels are extremely small. The medial peritoneal pedicle along the vas deferens is developed. The inferior epigastric vessels are exposed by incising the floor of the inguinal canal, with dissection superiorly under the rectus muscle to achieve an adequate length for anastomosis. The vessels are dissected out at 5 to 10× magnification and are kept moist with warmed saline. Branches are coagulated 2 mm away from the donor vessel. It is important to have 1 to 3 cm of the vessel dissected free of the surrounding tissue. The next step is to remove the perivascular connective tissue. Arterial spasm can be relieved by 1% lidocaine irrigation. Once isolated, the clamp approximator is applied to the vessels, leaving adequate room for suturing. The clamp must be placed so that it can be flipped over without difficulty. The artery is transected, and the adventitia is pulled over the lumen at several points, after which it is pulled forward and cut flush with the lumen and removed. The lumen is then irrigated with heparinized saline to remove clots and debris and then is stretched with a small jeweler's forceps. The clamp is adjusted to leave an appropriate distance between the two vessel ends so that suturing can be done without tension.

Several techniques of vessel anastomosis are satisfactory. The sutures should be symmetric full-thickness bites. A jeweler's forceps in the lumen guides the suture. Gentle traction is placed on the first suture while the next is placed 180 degrees apart. After the guide sutures are placed, the anterior wall between them is sutured and the vessel flipped to proceed with the posterior wall. After the anastomosis is completed, it is wrapped in clear plastic or a silicone cuff. The distal clamp is

removed first to watch for backflow; then the proximal clamp is removed. If the anastomosis is patent, expansile pulsations and wriggling distal to the anastomosis are evident. If there is a discrepancy in vessel size, a smaller vessel can be transected in an oblique fashion to make the lumens more proportional (Fig. 53.38). The vein is done thereafter in a similar manner. Fixation of the testis in the scrotum should be done within a dartos pouch and the addition of two permanent sutures between the scrotal septum and the tunica albuginea of the testis. Closure of the abdomen is performed as previously described.

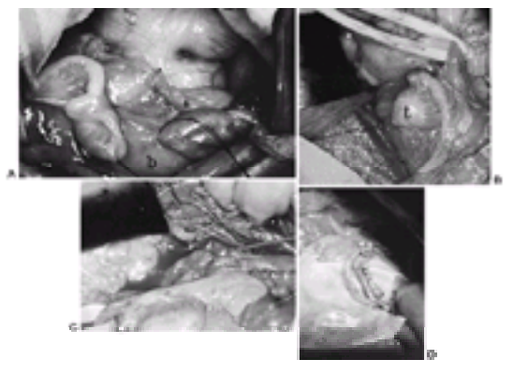

FIGURE 53.38. Technique of orchiopexy of intraabdominal testis by microvascular reanastomosis. **A:** Bilateral intraabdominal testes found adjacent to bladder *(b)*. **B:** Spermatic vessels (Penrose drain), testis with traction suture *(t),* processus mobilized from within inguinal canal *(lower right).* **C:** Inferior epigastric artery and vein *(arrowheads)* mobilized from under rectus muscle. **D:** Microvascular anastomosis of testicular artery and vein to epigastric vessels. Testis is already positioned inferiorly.

The results of microvascular orchidopexy have been reported, ranging from 55% to 100% successful scrotal testis placement of these abdominal tests without atrophy (26). In a recent review assessing the published results of orchidopexy for the abdominal testis, an overall success rate of 80% for microvascular repair is cited, contrasting favorable with other techniques (55). As with other orchidopexy techniques, however, each has its advocates and detractors. Only someone skilled in the method should undertake microvascular orchidopexy because the procedure is technically demanding. The microscope is seldom available “routinely” for impalpable cases especially when unilateral, and a separate readmission is often necessary after initial laparoscopic diagnosis. Absolute indications for a microvascular procedure include solitary abdominal testis and contralateral atrophy following previous orchidopexy. This procedure should be reserved for the truly high testis not amenable to extended high mobilization.

Staged Orchiopexy

When neither of the previous procedures is possible or appropriate, a staged orchiopexy may be performed. With improved awareness of the surgical anatomy of cryptorchid testes and expanded surgical techniques (e.g., laparoscopic mobilization), the need for staged orchidopexy has diminished dramatically. Previous estimates describing the need for this operation have ranged form 0.6% (86) to 21.5% (43,67); this discrepancy probably represents the percentage of very high testes present in these series. Two series of staged orchiopexies have indicated a success rate between 82% and 90%, testifying to the efficacy of this approach (139,286). Following maximal mobilization of the cord and testis, the testis is sutured to its most dependent position obtainable without tension, such as the pubic tubercle, inguinal ligament, or scrotum, with a nonabsorbable suture, left long for subsequent identification. The second-stage exploration is done after an interval of at least 1 year. Considerable scarring may be present, and these reoperations are difficult procedures, with a definite risk of vas and vessel injury. The testis and spermatic cord must again be mobilized completely at the second stage, with the expectation that the time interval has allowed for additional lengthening of the spermatic cord that will result in successful scrotal testicular placement. In a careful, critical review, Redman (228) suggested that staged orchiopexies represent instances of less-than-complete initial explorations, with a more extensive secondary procedure needed thereafter. He further questioned the concept that further spermatic and cord lengthening occurs after the first procedure. Experience with a select limited number of patients in whom both the initial and second stages were personally performed suggests that this phenomenon of cord lengthening does occur; however, because scrotal testicular placement was successful in all following the second stage. With the more extensive dissection that accompanies contemporary orchiopexy techniques as well as selective use of more specialized techniques for intraabdominal testes, staged orchiopexies are undertaken far less frequently than were done in the past.

Laparoscopic Orchidopexy

This procedure is an inevitable extension of the increased use of diagnostic laparoscopy. After visualization of an abdominal testicle, two additional trocars are placed lateral to the rectus muscle, either one or both on the contralateral side. A subjective assessment of the spermatic vessel length is then undertaken: If traction on the testis indicates that it will reach over to the contralateral internal inguinal ring, it suggests that the spermatic vessels are long enough that single-stage orchidopexy may be successful. The distal extension of the processus vaginalis is then freed from the inguinal canal, taking care to identify and protect the long-looped vas that is often present. The peritoneal lining lateral to the testis and spermatic vessels is dissected after making an L-shaped incision over the internal ring, extending the longer limb proximally along the vessels. A higher dissection may be accomplished if necessary by incising the peritoneum lateral to the adjacent colon and reflecting it medially. Extreme care is used in protecting the medially based pedicle of peritoneum along the vas deferens and the bladder. When adequate mobilization is achieved, a new course is made into the scrotum immediately lateral to the pubic tubercle. A variety of techniques may be used, including tunneling a grasper retrograde into the scrotum then passage of an additional trocar into the abdomen, grasping, and pulling the testis into the scrotum; or using graduated Teflon dilators retrograde in a similar fashion; or using a radially dilating trocar to enlarge the new passage. The testis is then fixed in the manner described before, and the trocar incisions are closed with absorbable sutures if they are greater than 3 mm in size.

If the testis is found initially to be too high for primary laparoscopic orchidopexy, a staged interruption of the vessels should be undertaken before any extensive mobilization is undertaken. This may be done with laparoscopic clips or by laser coagulation, which is used to prevent thermal injury to adjacent structures. After a minimal interval of 4 months, during which time the collateral blood supply along the vas deferens is established, laparoscopic access is reestablished and orchidopexy is accomplished as described earlier. This staged approach offers increased safety and success when higher testes are present than a single-stage laparoscopic approach.

Initial reports indicate as good, if not better, overall success rates using these techniques as those reported with open surgical orchidopexy. A trend toward overuse of the two-stage technique and increased orchiectomy rate by surgeons performing laparoscopic orchidopexy has been described (65).

Reoperative Orchidopexy

A reoperative orchidopexy may be required after previous inguinal hernia repair in which the testis becomes scarred to a position above the scrotum or alternatively following a failed attempt at primary orchidopexy. Experience with these problems has led to the evolution of a technique that seems especially suited to the anatomic challenges presented by a reoperative orchidopexy (31). After closure of the external oblique fascia at the initial surgery, the anterior surface of the cord often is densely scarred to its undersurface, resulting from the inherent inflammation associated with suture placement and perhaps the usual lack of fat within the inguinal canal. The posterior surface of the spermatic cord generally is less adherent to the floor of the canal and the transversalis fascia, making this a safer point for reoperation.

The previous inguinal incision is reopened and dissection is carried within the subcutaneous fat till a position distal to the testis is reached. The testis is elevated, and the adherent scar is carefully teased off the testis, cleaning toward the testis to avoid excessive traction on the spermatic cord. Once the testis is elevated, the course of the spermatic cord distal to the pubic tubercle can be appreciated. An en bloc dissection toward the pubic tubercle is undertaken staying some distance from the cord. The pubic tubercle is a useful landmark because it marks the point of insertion of the floor of the inguinal canal (the transversalis fascia) to the bony pelvis. At this point, a plane of dissection is established posterior to the spermatic cord because this plane is less adherent than the anterior plane (Fig. 53.39A). If dense scarring is present posteriorly, the transversalis fascia is freed en bloc with the cord. Although this is rarely necessary, reconstruction of this area in children is easily carried out.

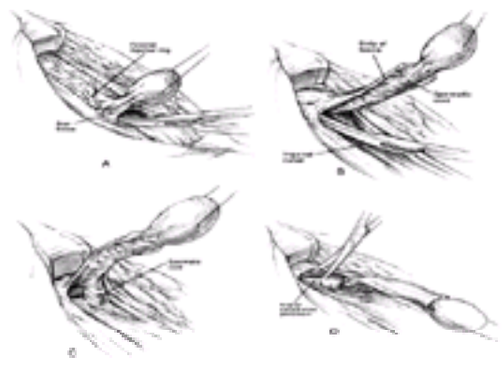

FIGURE 53.39. A: Initial dissection elevates the testes, and scar tissue is divided, staying away from the cord structures. A posterior plane of dissection is established at the pubic tubercle (insertion of the transversalis fascia—the floor of the inguinal canal). *Dotted lines* mark incisions in external oblique fascia. **B:** A strip of external oblique fascia is mobilized with the underlying adherent spermatic cord. **C:** When the external oblique muscle is visualized beyond the spermatic cord, the external oblique fascial strip can be divided without risk to the cord. **D:** When the peritoneum is opened above the site of the previus ligation of the processus vaginalis, unoperated tissue is reached and the operation may proceed as a routine orchidopexy.

As the posterior plane is developed, a strip of the external oblique fascia adherent to the underlying spermatic cord is defined by making parallel incisions in the external oblique fascia and raising this strip with the underlying cord (Fig. 53.39B). This dissection continues until the musculature of the internal oblique lateral to the internal ring is visualized (Fig. 53.39C). At this level, the strip of fascia is freed, allowing visualization of the peritoneum through the internal inguinal ring (Fig. 53.39D). The peritoneum is opened above the site of its previous closure where adhesions to the underlying vas and vessels are usually present, allowing rapid and accurate identity of the course of the vas and vessels. Dissection from above completes any posterior dissection that is incomplete from below, allowing the cord to be mobilized into the area of the retroperitoneum that has not previously been approached. A Deaver retractor underneath the peritoneum permits it to be lifted forward so that the spermatic vessels can be mobilized completely from the enveloping endoabdominal fascia, as has been described in the previous segment dealing with anatomy.

This en bloc mobilization of the testis and then spermatic cord with its overlying fascia is the essential step in avoiding reoperative injury to the vas and vessels. It is often surprising to see how much distal testis placement can be achieved once the dissection proceeds into virginal territory in the retroperitoneum. In the initial report of this experience in 1993, a good result was achieved in 24 of 25 patients (31). By adhering to this approach, continued experience suggests that at least a 90% success rate is achievable in these difficult cases.

Role of Testicular Biopsy

It is well recognized that testicular biopsy is an invaluable tool at all ages for assessing the nature and degree of damage to the testis. Testicular biopsy might be used in pediatric urology at the time of orchidopexy to assess the fertility potential of the cryptorchid and contralateral testis, at the time of varicocele repair, during scrotal fixation for torsion to determine ipsilateral testis viability and contralateral testis damage, in the diagnostic assessment of unexplained intratesticular masses, and in the evaluation of the contralateral testis when a testis tumor is present.

Opinions vary regarding the desirability of performing testicular biopsy at the time of orchidopexy. Studies indicate that prepubertal testis biopsy correlates directly with later semen density (47,102). Data also indicate that testis biopsy at the time of prepubertal orchidopexy can define a subgroup of patients who can be expected to be infertile and whom may benefit from adjunctive hormonal treatment, making this a worthwhile pursuit when additional medical treatment is offered. Biopsy of boys with bilateral cryptorchidism is essential because they are at highest risk for infertility. An additional group of unilaterally cryptorchid boys with severe germ cell depletion in the cryptorchid testis would benefit as well because germ cell counts in the contralateral descended testis correlate well with counts in the cryptorchid mate (115).

Testis biopsy should be performed in the least-vascular-appearing part of the testis. Studies suggest that the anterosuperior portion in general is best, but each testis should be assessed individually, visualizing the superficial vascular distribution. A sharp capsular incision with a short beveled cut into the underlying parenchyma allows the protruding tubules to be excised with a microscissors. The capsule is closed with fine (6-0) absorbable sutures. Persisting oozing is controlled by pressure; thermal cauterization is avoided. Immediate fixation is done to prevent desiccation of the tiny specimen. When biopsy is performed in this manner, testis damage is not evident subsequently. Theoretical risks of inducing serum or seminal antibodies have not been substantiated (45).

A small number of boys initially treated for cryptorchidism, varicocele, monorchidism, testicular neoplasm, or testis loss from inflammation or trauma will ultimately suffer a second sequential condition of a similar nature affecting the ipsilateral or contralateral testis, which may potentially affect later fertility. Testicular biopsies play an important role in evaluating some of these patients because their antifertility effect in some instances may be additive. In a personal series of 29 patients of this nature seen over a 3-year period, 33% of patients had abnormal numbers of germ cells in both testes, some with severe reductions. These data indicate that an aggressive approach to diagnosis is important when sequential conditions exist, including testicular biopsy, because the ultimate fertility effect is unpredictable in any individual instance and timely interventional treatment may be important.

Insertion of a Testicular Prosthesis

The preceding descriptions indicate that a plethora of surgical approaches exist to successfully treat the intraabdominal undescended testis. Orchiectomy of the undescended testis is not indicated in the prepubescent child except when there is a major separation of the testis and its ductal structures. In postpubertal boys, the abdominal testis often is atrophied, is devoid of germ cells, and harbors an increased chance of malignant degeneration. Orchiectomy is often the procedure of choice in these circumstances, even though successful orchiopexy may be technically feasible (185). In these circumstances, insertion of a testicular prosthesis is indicated. Other boys born without functioning testes and those with atrophy or loss from trauma, cancer, torsion, or previous inguinal surgery are similar candidates. Although few studies exist documenting the psychologic efficacy and importance of prosthesis placement (13), it is our strong impression that prosthesis placement is important in the monorchic or orchiectomized boy.

Controversy existed regarding the safety of the silicone components of testicular prostheses resulting from the medicolegal issues that surrounded implanted silicone breast prostheses. Whereas most pediatric urologists have not encountered long-term problems with silicone-filled testicular prostheses, their safety had not been studied thoroughly. In 1995, saline-filled silicone shell prostheses were introduced, and implantation at selected centers was undertaken under a U.S. Food and Drug Administration–mandated prospective study protocol. As part of a greater group including adult patients, 73 pediatric patients underwent implantation. Approximately 84% were missing their testicles at the onset; about 25% of the total had both testes missing (bilateral anorchia). This study was discontinued because of the lack of serious adverse events and general good results. The data and results for the pediatric patients have been recently reported (213). Presently, both a saline-filled testicular prosthesis (Mentor Corporation) and a semisolid silicone carving block device (Silimed Corporation) are available for pediatric and adult implantation.

In general, the largest prosthesis that does not look unsightly is implanted. Many patients do not indicate a desire for replacement with a larger prosthesis after puberty because the dependency of the existing one often lends a normal cosmetic appearance. Testicular prostheses should not be implanted through a scrotal incision, especially through the prepubertal thin scrotum, because the chance of spontaneous extrusion is significantly increased. The scrotum is dilated with the aid of the dissecting finger, a moist gauze sponge, or both. The scrotum is inverted, and an absorbable suture is passed through the prosthesis suture tab and then carefully through the dartos, with precautions taken that the suture does not penetrate the overlying scrotal skin. If the latter occurs, the suture should be removed and placed again. After the prosthesis is positioned dependently, the neck of the scrotum is closed with two or three absorbable sutures to prevent spontaneous or traumatic upward migration. The wound is irrigated with an antibiotic solution, and a broad-spectrum antibiotic is prescribed for 72 hours. With use of these techniques, no patient has experienced a scrotal infection following prosthesis placement or has had prosthesis extrusion or displacement, including a few who previously had infected or extruded prostheses elsewhere and who were subsequently reoperated on after appropriate interval treatment.

Surgical Complications After Orchiopexy

Surgical complications after orchidopexy (e.g., atrophy, inadequate scrotal location, ductal system injury) have been analyzed in a number of reports (51,179,183,190). Orchiopexy was possible in almost 90% of 207 patients having either palpable or impalpable undescended testes, with 187 patients (also almost 90%) achieving a satisfactory scrotal position. In 6 of these patients undergoing orchiopexy, the testis was in a high scrotal position and was retracted into an inguinal position, and in 13 (7%) postoperative atrophy occurred. In this series of 233 patients, 12 underwent orchiectomy rather than orchiopexy because of dysplastic or primary atrophic appearances. No intraoperative complications were noted (179). In another series of 492 patients, results were graded as “good,” “fair,” or “poor” according to the testis size, position, consistency, and mobility. Only 60% of testes had a good result, with 22% characterized as poor. Of the overall group, 16% were clearly atrophic (51). Of course, postoperative atrophy in undescended testes must be related to the preoperative size of the testis because some undescended testes are small to begin with; hence, it is likely that some of the “atrophic” testes in this series do not represent surgically induced atrophy. A brighter outlook regarding atrophy is seen in Mengel and Hecker's (190) series, in which a 2% atrophy rate was encountered. Surgical complications occur more frequently with impalpable undescended testes and are cited as high as 20% to 50% in the older literature (174). With the techniques currently available, however, significantly reduced complication rates are encountered.

Maizels and co-workers (183) examined the reasons for inadequate testis position following orchiopexy in a series of 350 boys, finding a 10% frequency of failure of the initial surgical procedure. Retroperitoneal dissection adequately corrected the initial failure in 58%, whereas local inguinal dissection was adequate in 37%. They concluded that incomplete initial dissection appeared to be the cause of inadequate position after orchiopexy and that aggressive high surgical dissection should prevent inadequate scrotal testicular placement in most instances. Docimo (55) also published a meta-analysis of the results of surgical therapy for cryptorchidism, noting that after 1985, results of surgery stratified by initial position of the testis considerably improved. The results for testes located around the pubic tubercle are now reported to be between 95% and 100% achieving a scrotal position. By contrast, the abdominal testes achieved a 77% success rate. More recently, incorporation of the principles of extended retroperitoneal mobilization as described previously resulted in a 90% success rate for abdominal testes (142). In Docimo's review, there was a statistically significant difference based on age at orchidopexy, with children older than 6 years of age demonstrating a 10% worsened result. This might reflect the greater difficulty of achieving a satisfactory retroperitoneal mobilization in the older child. Present experience suggests that laparoscopic high mobilization of the spermatic vessels will achieve comparable success rates to those results seen in younger boys (131).

Figures regarding intraoperative injury to the vas deferens are difficult to come by. Mengel and Hecker (190) cite a 1% to 2% frequency in their series. Vas deferens injury during orchiopexy is completely preventable, and even these figures should be considered excessive.

Surgical Complications from Hernia/Hydrocele Repair

Postsurgical complications of spermatic cord surgery consist mainly of injury to the vas deferens and spermatic artery and retraction of the testis. Care must be taken in dissecting the hernia sac off the cord, ensuring that undue traction or pressure is not put on the spermatic vessels. When the internal inguinal ring is narrowed to prevent herniation as part of the repair, an adequate lumen must still be left to allow the spermatic cord to pass without compression. Extreme care must be used to ensure that the testis occupies a dependent scrotal position after hernia repair because secondarily undescended testes can occur with the testis fixing to the overlying scar. In these circumstances, secondary changes in the testis may occur similar to those occurring in truly cryptorchid testes as a result of the continued extrascrotal position (100). Similar perils may be encountered during the hydrocelectomy, especially when the hydrocele is chronic and thick walled. In these circumstances, it is better to lay open the hydrocele and suture-evert the sac behind the spermatic cord and testis rather than to excise the sac and risk accidental incision/excision of a meandering hidden vas deferens. Occasionally, pathologic examination of an excised hernia or hydrocele sac will indicate that a segment of vas deferens is inadvertently included. In one study of pediatric hernia sacs, 6% of specimens included a vas or vaslike structure; however, analysis suggested that many represented wolffian remnants and not the vas deferens (80). Another report (260) in which bilateral vas integrity was confirmed at reexploration after the excised hernia sacs from bilateral inguinal hernia repair contained “vasae” also indicates that these structures may be misinterpreted easily and that diligence during surgery is essential as well as in review of the subsequent pathology.

WILMS' TUMOR

Nephroblastoma, or Wilms' tumor, is an embryonal tumor that develops from remnants of immature kidney. Renal childhood tumors were described more than 150 years ago, but it was surgeon Max Wilms who proposed that all the various elements of the tumor were derived from the same cell (193). It is the most common primary malignant renal tumor of childhood and typically affects children younger than 6 years of age. At the beginning of the twentieth century, most children with Wilms' tumor died of their disease. Over the past decades, the survival of children with Wilms' tumor has improved rapidly.

Current treatment emphasis is on reducing the morbidity of treatment for low-risk patients, reserving more intensive treatment for selected high-risk patients in whom survival remains poor. This chapter reviews recent advances in the understanding of the biology and pathology of Wilms' tumor. The current management of children with all stages of nephroblastoma is discussed in detail.

Epidemiology

The annual incidence of Wilms' tumor is 10 cases per million children younger than 15 years of age or about 450 to 500 new cases annually in the United States (31). This tumor represents 5% to 6% of childhood cancers in the United States and is the most common malignant renal tumor of childhood. Nephroblastoma is a disease of young children, with a peak incidence of 36.5 months for males and 42.5 months for females with unilateral tumors. The disease occurs nearly equally in girls and boys worldwide, but the frequency is slightly higher among girls in the United States (32). Evidence of a consistent association of Wilms' tumor with any parental environmental exposure has not been provided.

Associated Syndromes

An increased incidence of Wilms' tumor has been noted in several recognizable syndromes (Table 54.1) (40,130). These may be divided into those characterized by overgrowth and those lacking overgrowth. Syndromes with overgrowth features include hemihypertrophy, which may occur alone or as part of the Beckwith-Wiedemann syndrome (BWS). BWS is a rare disorder consisting of developmental anomalies characterized by excess growth at the cellular, organ, (macroglossia, nephromegaly, hepatomegaly) or body segment (hemihypertrophy) levels (6,191). Although most cases of BWS are sporadic, up to 15% exhibit heritable characteristics with apparent autosomal- dominant inheritance. The incidence of tumor development in BWS is 10% to 20% including Wilms' tumor, adrenocortical neoplasms, and hepatoblastoma. The risk of Wilms' tumor development in patients with hemihypertrophy and BWS is estimated to be approximately 4% to 10% (14,55). Children with BWS found to have nephromegaly (kidneys greater than or equal to the ninety-fifth percentile of age-adjusted renal length) are at the greatest risk for the development of Wilms' tumor (56). Other overgrowth syndromes, Perlman, Soto's, and the Simpson-Golabi-Behmel syndromes, also are associated with the development of Wilms' tumor (136,147).

Anomaly	Rate (per 1,000)
Aniridia	7.6
Beckwith-Wiedemann syndrome	8.4
Hemihypertrophy	33.8
Genitourinary anomalies	
?Hypospadias	13.4
?Cryptorchidism	37.3
?Hypospadias and cryptorchidism	12.0

TABLE 54.1. INCIDENCE OF CONGENITAL ANOMALIES IN PATIENTS WITH WILMS' TUMOR REPORTED TO THE NATIONAL WILMS' TUMOR STUDY GROUP

With or without the stigmata of BWS, 3% of patients who develop Wilms' tumor also may be affected by hemihypertrophy (31). The risk of Wilms' tumor development in patients with hemihypertrophy is estimated to be on the order of 3% to 5% (180). Isolated involvement of the leg is the most common manifestation in these patients (80) and may not become clinically apparent until after the diagnosis of Wilms' tumor. Hemihypertrophy may be ipsilateral or contralateral to the tumor. The mean age at diagnosis of Wilms' tumor in patients with BWS and hemihypertrophy is similar to that of the general Wilms' tumor population (31).

Genitourinary anomalies (renal fusion anomalies, cryptorchidism, hypospadias) are present in 4.5% of patients with Wilms' tumor (31). Because many of these disorders are common in children, prospective evaluation for the development of Wilms' tumor is not carried out in most children with genital anomalies. One specific association of male pseudohermaphroditism, renal mesangial sclerosis and nephroblastoma is the Denys-Drash syndrome (DDS) (63). One should have a high index of suspicion for the development of these conditions in patients with male pseudohermaphroditism (181). Although XY individuals have been reported most often, the DDS has been reported in genotypic/phenotypic females as well as in cases of gonadal dysgenesis. This syndrome is associated with mutations of the 11p13 Wilms' tumor gene (45).

The incidence of aniridia in Wilms' tumor patients is 1.1%. Aniridia and Wilms' tumor are most commonly associated in patients with the Wilms' tumor, aniridia, genital anomalies, and mental retardation (WAGR) syndrome (40). Most affected individuals have a constitutional deletion on chromosome 11 and the incidence of Wilms' tumor formation is 42% (97).

An association between Wilms' tumor and horseshoe kidney has been noted. A review of National Wilms' Tumor Study Group (NWTSG) patients found that patients with a horseshoe kidney have a sevenfold increased risk of developing a Wilms' tumor (129,137).

Periodic imaging with renal ultrasound has been recommended in children with hemihypertrophy, BWS, and aniridia. Review of most studies suggests 3 to 4 months is the appropriate screening interval resulting in lower-stage tumors at diagnosis (39,80). There were not enough patients in these retrospective reviews to determine whether early detection had an impact on patient survival. Two recent reports have called attention to the increased incidence of nonmalignant renal lesions in children with BWS (27,39). Nonmalignant lesions included medullary renal cysts in 13% of patients, hydronephrosis in 12%, and nephrolithiasis in 4%. In two patients, nephrectomy was performed for benign disease due to false-positive screening (39).

Genetics

The role of genetic alterations in Wilms' tumor development has been studied extensively. Nephroblastoma was once thought to have a substantial heritable fraction because of the frequency of bilaterality and association with congenital anomalies and specific syndromes. The diagnosis of Wilms' tumor is generally at an earlier age in patients with congenital anomalies and also in children with bilateral tumors (31). It was thought that these children had a germline mutation that predisposed to both the development of multiple tumors and an earlier age of onset than the general population, as had been noted for children with retinoblastoma (111).

Analysis of these differences between groups of Wilms' tumor patients led to the two-event theory for Wilms' tumor formation, which predicts that two genetic events are rate limiting for tumor formation (111). Individuals with a genetic predisposition carry an initial lesion in their germline. Because all body cells have already been affected by the first event, only one new event in any one cell is required for tumor development. These patients would be expected to have an earlier age of onset and have a greater incidence of multiple tumors. By contrast, in individuals who are not genetically predisposed (sporadic cases), two relatively rare independent events are required in the same cell. Subsequent genetic studies in several tumors have confirmed the Knudson model (47). The clearest example of tumorigenesis following the inactivation of both copies of a single tumor suppressor gene is the development of retinoblastoma following the inactivation of the retinoblastoma gene RB1. However, it is now recognized that the heritable fraction of Wilms' tumor is small (less than 1%) (78). This falls far short of the 30% incidence predicted by the Knudson-Strong model. Unlike the genetic mechanism leading to the development of retinoblastoma, which only requires the inactivation of one single gene, the biologic pathways leading to the development of Wilms' tumor are complex and likely involve several genetic loci (48).

Several chromosomal regions have been associated with Wilms' tumor, including chromosome 11p13, which harbors the Wilms' tumor suppressor gene WT-1; chromosome 11p15, which includes the putative Wilms' tumor gene WT-2; chromosome 16q; chromosome 1p; and chromosome 17p (49). The first two loci have been implicated in the actual development of Wilms' tumor.

The first recognized cytogenetically visible chromosomal abnormality in Wilms' tumor was in patients with the WAGR syndrome (155). These children were shown to have heterozygous germline deletions at band p13 of chromosome 11. With use of cloning techniques, the Wilms' tumor suppressor gene WT-1 was identified (24,37). The genetic consequences of WT-1 inactivation appear to be restricted to organs that normally express this tumor suppressor gene. WT-1 is expressed transiently in the developing kidney and also in specific cells of the gonads. The characterization of WT-1 has not only provided insight into the mechanisms underlying the development of Wilms' tumor, but also in those involved in genitourinary development (46,151).

A recent report reviewed the incidence of constitutional WT-1 mutations in 201 patients with Wilms' tumor (59). Of these, eight were identified as carriers of mutations in the WT-1 gene. Patients with genitourinary anomalies had an increased risk for carrying a WT-1 mutation. Of 28 boys with Wilms' tumor with cryptorchidism, 7 had WT-1 mutations. No increased risk was observed for patients with nephrogenic rests, bilateral tumors, a history of secondary cancers, or family history of Wilms' tumor. This suggests a constitutional WT-1 mutation encodes truncated WT-1 proteins predisposed to the development of cryptorchidism, hypospadias, and Wilms' tumor. Four of the seven patients with WT-1 mutation and undescended testis also had hypospadias. Germline mutations in WT-1 gene are found most consistently in patients with DDS (44,145). More than 90% of DDS patients investigated to date harbored germline WT-1 mutations. It is postulated that the mutation in DDS patients results in an abnormally expressed protein, which alters regulation of transcription and urogenital development. Of interest, the affected gonads and kidneys in patients with DDS are heterozygous for germline mutations, implying that the WT-1 mutation acts dominantly with respect to genitourinary abnormalities (101).

Deletions and mutations of 11p13 have been shown to occur in tumor DNA from sporadic Wilms' tumors, as well as in the germline of patients with a genetic predisposition to cancer. Approximately 50% of tumors show loss of heterozygosity (LOH) for DNA markers on 11p13 (102,113), implying that these tumors had only one copy of the 11p gene suggesting that the two genetic events in the two-hit mutation occurred at the same locus. Tumor formation occurred after inactivation of one allele of an 11p13 gene and the subsequent mutation or loss of the homologous allele.

A second Wilms' tumor locus, WT-2, has been identified on the short arm of chromosome 11, 11p15.5 (154). This locus has been linked to the BWS with the finding of 11p15 triplication in some BWS patients and the mapping of familial BWS to 11p15 (114). Whether the BWS gene and WT-2 are one and the same gene or two distinct but closely linked genes, still needs to be elucidated. Many types of tumors show LOH in the 11p15 region (102), and the WT-2 gene may be important in the development of many different tumor types.

Other molecular genetic abnormalities have been found, including LOH for the long arm of chromosome 16q, which has been noted in approximately 20% of tumors (127). Similarly, loss of the short arm of chromosome 1p has been found in approximately 10% of cases. These genes are suspected to play a role in tumor progression rather than initiation of tumors. Studies are under way to assess the correlation between the different genetic abnormalities with histopathologic features and staging to determine whether molecular genetic studies are an additional indicator of clinical behavior and outcome.

Clinical Presentation

The typical presentation of a child with Wilms' tumor is that of an abdominal mass (Fig. 54.1). The tumor is palpable on physical examination in more than 90% of children. The tumor is generally quite large relative to the size of the child and not always confined to one side of the abdomen. The outline of a Wilms' tumor on examination is smooth and spherical. Other signs and symptoms at diagnosis are abdominal pain, gross hematuria, and fever. Hematuria occurs in one-fourth of children at diagnosis. Several tumors have been discovered during exploration for presumed appendicitis. Rupture of the tumor with hemorrhage into the free peritoneal cavity can result in the presentation of an acute abdomen.

FIGURE 54.1. Typical large bulging abdominal mass in a child with nephroblastoma.

Additional symptoms may result from compression or invasion of adjacent structures. The propensity of Wilms' tumor to grow into the renal vein and inferior vena cava can produce atypical presentations. Varicocele, hepatomegaly due to hepatic vein obstruction, ascites, and congestive heart failure were found in less than 10% of patients with intracaval or atrial tumor extension in NWTS-3 (156). Occasionally, children with Wilms' tumor present with symptoms suggesting the production of bioactive substances by the tumor (46). Hypertension is present in 25% of cases and has been attributed to elevated plasma renin levels (185). During the physical examination, it is important to note signs of associated Wilms' tumor syndromes such as aniridia, hemihypertrophy, and genitourinary anomalies.

Preoperative Evaluation

Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. Laboratory evaluation should include a complete peripheral blood count, platelet count, renal function tests, liver function tests, serum calcium, and urinalysis. Elevation of serum calcium can occur in children with congenital mesoblastic nephroma and rhabdoid tumor of the kidney (RTK). Acquired von Willebrand's disease has been found in 8% of newly diagnosed Wilms' tumor patients (45).

Imaging—Abdomen

Preoperative imaging studies are ordered with the intent of obtaining the correct diagnosis before surgical exploration, but an equally important goal is to establish that the contralateral kidney is functioning before performing a nephrectomy. Few distinguishing radiographic features allow a precise preoperative diagnosis of the histology of a renal mass. However, defining the exact histology is probably not as important as establishing that a solid renal tumor is present, which will help the surgeon plan for a major cancer operation. The preoperative diagnosis was incorrect in 2.5% of NWTS-3 patients (the child had Wilms' tumor but there was an erroneous diagnosis before surgical exploration), and the majority of these patients did not have any preoperative imaging studies performed (158). This group of patients was found to have an increased incidence of surgical complications, which underscores the importance of the imaging evaluation.

Advances in imaging have resulted in ultrasound and/or computed tomography (CT) supplanting the intravenous pyelogram (IVP). Classically, the IVP reveals distortion of the renal contour with splaying of the collecting system. Ultrasonography is performed routinely in most children with abdominal masses and can distinguish between solid and cystic lesions. Ultrasound can generally identify the kidneys and determine whether the mass is of renal origin. Another important role of imaging is to exclude intracaval tumor extension, which occurs in 4% of Wilms' tumor patients (Fig. 54.2) (156). Magnetic resonance imaging (MRI) is the study of choice if extension of tumor into the inferior vena cava (IVC) cannot be excluded by ultrasound (189). If vascular invasion is not present, cystoscopy with retrograde pyelography is warranted to exclude ureteral extension in children with a nonfunctioning kidney, particularly if hematuria is present. Recognition of ureteral invasion before nephrectomy will facilitate a complete en bloc resection.

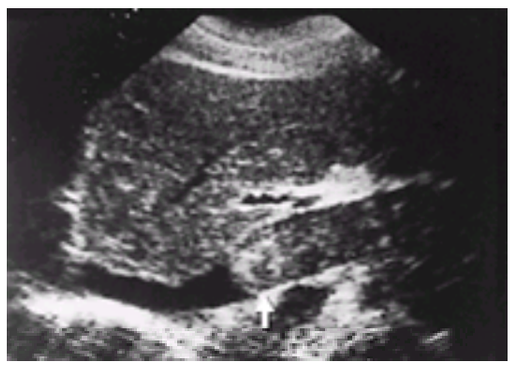

FIGURE 54.2. Ultrasound that depicts intracaval thrombus *(arrow).*

CT and MRI can further define the extent of the lesion (Fig. 54.3), but many childhood renal tumors have similar appearances (35,71,190). The role of CT and MRI in staging of the renal tumor continues to be defined (41,54,61). Accurate staging of children with Wilms' tumors is essential to define tumor extent before initiating treatment because outcome is highly correlated with stage (53). However, these data are derived most accurately from the findings at surgery as confirmed by pathologic examination. The local tumor burden (regional lymph node involvement, residual disease, diffuse tumor spillage) determines whether the child receives abdominal irradiation and also the intensity of the chemotherapy regimen.

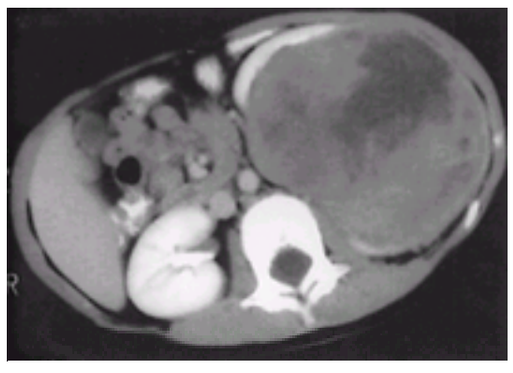

FIGURE 54.3. Computed tomography scan of a large left Wilms' tumor with a small rim of functioning renal parenchyma.

Preoperative CT can reveal evidence of regional adenopathy and suggest extrarenal tumor extension into the perirenal fat and into adjacent structures. However, prospective correlation with pathologic findings to validate the utility of CT staging has not been done. Most children identified as having possible invasion of the liver on CT are found at the time of surgical exploration to have hepatic compression, rather than hepatic invasion (138). Enlarged retroperitoneal benign lymph nodes are common in children, which can create significant diagnostic error. Correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms' tumor patients have found false-positive and false-negative error rates of 18% and 31%, respectively (142). It should not be expected that current imaging modalities

will have greater accuracy. A recent report using positron emission tomography with the glucose analog 2-deoxy-2-fluoro- D-glucose does show promise in imaging of renal tumors (173). This technique can provide anatomic imaging of both the primary tumor and metastatic disease, but at present, experience in childhood malignancies is limited.

Assessment of the contralateral kidney in Wilms' tumor patients is necessary to exclude bilateral disease. Both CT and MRI are more accurate than ultrasound in identifying small lesions (nephrogenic rests or Wilms' tumor) in the opposite kidney, but a review of children with synchronous bilateral Wilms' tumor enrolled in NWTS-4 found that 7% of bilateral lesions were missed by preoperative imaging (163).

Imaging—Metastatic Disease

Plain chest radiographs should be obtained to determine whether pulmonary metastases are present. Most centers obtain CT of the chest in the initial evaluation of children with Wilms' tumor. Additional imaging studies are recommended to detect the presence of metastases in selected renal tumors with unfavorable histology (54). Clear cell sarcoma of the kidney (CCSK) and renal cell carcinoma (RCC) have a propensity to metastasize to the skeleton. Skeletal surveys and bone scans are both recommended after the histologic diagnosis is confirmed. RTK and CCSK are associated with brain metastases and MRI of the brain should be obtained in the early postoperative period.

Additional imaging studies are helpful under specific conditions. A radionuclide bone scan and x-ray skeletal survey are obtained postoperatively on all children with CCSK to exclude skeletal metastases (54). Cranial CT or MRI is performed on all children with CCSK or with RTK because both are associated with intracranial metastases (188).

Differential Diagnosis

Nephroblastoma accounts for more than 90% of renal tumors in children. Distinguishing radiographic features that will allow a precise preoperative diagnosis of the histology of a renal mass are few. Other clinical parameters will aid the clinician in narrowing the diagnostic possibilities in a child with a renal mass. The development of a renal tumor in a child known to have aniridia, hemihypertrophy, or other syndromes associated with an increased incidence of nephroblastoma safely can be assumed to be a Wilms' tumor. Bilateral or multicentric tumors are more typical of Wilms' tumor, but renal lymphoma can present in this fashion. Congenital mesoblastic nephroma (CMN) is the most likely diagnosis in a neonate with a renal mass. However, favorable histology Wilms' tumor and RTK also can present in the first few months of life. RTK and CCSK tumors should be considered in patients that present with brain or skeletal metastases. RCC is more common in the second decade of life (35).

Pathology

The gross appearance of Wilms' tumor is that of a spherical mass (Fig. 54.4) with a light gray or tan color on cross section. Wilms' tumor usually compresses the adjacent normal renal parenchyma forming a pseudocapsule composed of compressed, atrophic renal tissues. Most tumors are soft and friable with necrotic or hemorrhagic areas frequently noted. Wilms' tumor is characterized by tremendous histologic diversity. The classic triphasic pattern includes varying proportion of three cell types: blastemal, stromal, and epithelial. The proportion of each of these components varies, with some consisting of only biphasic or even monomorphous patterns (170). Wilms' tumors with predominantly epithelial differentiation have a low degree of aggressiveness, and most are stage I tumors (15). However, these tumors may be more resistant to therapy if they present as advanced stage disease. Blastemal predominant tumors are highly aggressive but very responsive to chemotherapy. In addition to expressing a variety of cell types found in a normal developing kidney, Wilms' tumor often contains tissues such as skeletal muscle, cartilage, and squamous epithelium. These heterotopic cell types likely reflect the primitive developmental potentials of metanephric blastema that are not expressed in normal nephrogenesis. Most Wilms' tumors are unicentric, but 7% are multicentric unilateral tumors. Extrarenal locations are rare and are thought to arise from displaced metanephric elements or mesonephric remnants.

FIGURE 54.4. Gross specimen of a Wilms' tumor.

Analysis of early NWTSG patients identified a group of tumors with “unfavorable” histologic features (7) that were responsible for 50% of tumor deaths, but account for only 10% of patients (29). These characteristics included tumors of extreme nuclear atypia (anaplasia), and monomorphic sarcomatous appearing tumors. These latter tumors have been reclassified as the RTK and CCSK and are now considered to be distinct entities from Wilms' tumor (see the following discussion). These unfavorable features occurred in approximately 10% of patients, but accounted for almost half of the tumor deaths in early NWTSG studies (29).

The cytopathologic features of anaplasia are threefold or greater nuclear enlargement, hyperchromasia of enlarged nuclei, and increased mitotic figures. Anaplasia is associated with resistance to chemotherapy. This is evidenced by the similar incidence of anaplasia (5%) in the NWTSG and International Society of Paediatric Oncology (SIOP) studies (186). It is rare in the first 2 years of life, but the incidence increases to 13% in children age 5 years or older (23). Anaplastic features can occur focally, requiring thorough sampling of the primary tumor to avoid missing this poor prognostic feature (7). The definition of focal anaplasia is based on a topographic principle and requires that the anaplastic nuclear changes be confined to a specified region of the primary tumor and absent from the surrounding portions of the lesion (68). Diffuse anaplasia is diagnosed when anaplasia is present in more than one portion of the tumor or if it is found in any extrarenal or metastatic site. When the anaplastic component is completely removed, stage I, the outcome is generally excellent (194). This confirms the observation that anaplasia is more a marker of chemoresistance than inherent aggressiveness of the tumor. When anaplastic changes are not present, the tumor is referred to as being of favorable histology (FH) because of the generally good outcome for these patients (7).

Alterations of the p53 tumor suppressor gene and its encoded protein have been reported in anaplastic tumors (5). It has been suggested that the p53 tumor suppressor gene might underlie the development of a histopathologic variant of Wilms' tumor with poor prognosis. Another study however, identified a p53 mutation in a Wilms' tumor with favorable histology, the most common histologic variant and carrying an excellent prognosis (126). In this latter study, p53 mutations were found in tumors from patients with advanced disease, suggesting that p53 mutations are associated with advanced stage disease in Wilms' tumor, rather than with histologic features.

Precursor Lesions of Wilms' Tumor

Nephrogenic rests (NRs) are defined as foci of abnormally persistent nephrogenic cells that can form a Wilms' tumor (10). They have been found in 1% of kidneys in infants on postmortem examination (17) and in 30% to 40% of kidneys removed for Wilms' tumor (13). Two distinct categories of NRs have been identified, perilobar nephrogenic rest (PLNR) and intralobar nephrogenic rest (ILNR). This classification is based on the position of these lesions within the renal lobe. The developing renal lobe matures in a centrifugal fashion with each generation of nephrons added sequentially to the periphery. PLNR are found in the periphery while ILNR can be found anywhere within the renal lobe (Fig. 54.5). It is inferred that ILNR situated deep in the renal lobe reflect an earlier developmental event. The presence of multiple or diffuse NRs will lead to the diagnosis of nephroblastomatosis.

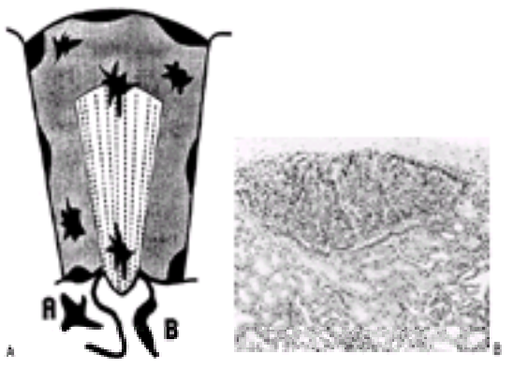

FIGURE 54.5. A: Illustration of renal lobe showing characteristic locations of intralobar nephrogenic rest (dark gray) and perilobar nephrogenic rest (black). (From Beckwith JB. Precursor lesions of Wilms' tumor: clinical and biological implications. *Med Pediatr Oncol* 1993;21:158, with permission.) **B:** Perilobar nephrogenic rest composed of blastemal cells just beneath the renal capsule (hematoxylin and eosin, 40× magnification).

ILNR and PLNR differ in several epidemiologic characteristics, summarized in Table 54.2. The age at diagnosis is lower for Wilms' tumor arising in association with ILNR, and children with WAGR and Drash syndromes are more likely to have ILNR. In contrast, PLNR is of higher prevalence in hemihypertrophy and in BWS. Both types of NRs are associated with bilateral Wilms' tumor in which the incidence of NRs is much higher than seen in unilateral Wilms' tumor. Multiple rests in one kidney usually implies that NRs are present in the other kidney. Children younger than 12 months diagnosed with Wilms' tumor who also have NRs have a significantly increased risk of developing contralateral disease (49). An increased risk of metachronous Wilms' tumor was found in patients with BWS, hemihypertrophy, and aniridia. These patients need regular imaging surveillance to detect contralateral recurrence (Table 54.3). Because metachronous Wilms' tumor does occur in patients previously treated with conventional chemotherapeutic regimens, NRs cannot always be eradicated.

Metachronous bilateral Wilms' tumor	42	63–75
Beckwith-Wiedemann, hemihypertrophy	70–77	47–56
Aniridia	12–20	84–100
Drash syndrome	11	78

TABLE 54.2. APPROXIMATE PREVALENCE OF NEPHROGENIC RESTS

Tumor Type	Study	Schedule following therapy
Favorable histology Wilms' tumor,	Chest films	6 wk and 3 mo postop, then q3mo × 1,
Stage I anaplastic Wilms' tumor		q6mo × 2, yearly × 2
Irradiated patients only	Irradiated bony structures[a]	Yearly to full growth, then q5yr indefinitely[b]
Without WAGR, stages I and II	Abdominal ultrasound	Yearly × 8
Without WAGR, stage III	Abdominal ultrasound	As for chest films
With WAGR, any stage[c]	Abdominal ultrasound	q3mo × 10, q6mo × 5, yearly × 5
Stages II and III anaplastic	Chest films Abdominal ultrasound	As for favorable histology q3mo × 8, q6mo × 4
Renal cell carcinoma	Chest films Skeletal survey and bone scan	As for favorable histology As for CCSK
Clear cell sarcoma of the kidney (CCSK)	Brain MRI and/or opacified CT Skeletal survey and bone scan Chest films	When CCSK is established, then q6mo × 19 As for favorable histology
Rhabdoid tumor	Brain MRI and/or opacified CT Chest films	As for CCSK As for favorable histology
Vincristine/adriamycin-responsive[d]	Abdominal ultrasound	q3mo × 6

[a] To include any irradiated osseous structures.
[b] To detect second malignancies, benign (osteochondromas) or malignant.
[c] See panelists at the First International Conference on Molecular and Clinical Genetics of Childhood Renal Tumors, Albuquerque, New Mexico, May 1992—summarized in refs. q3mo for 3 yr or until age 7, whichever comes first.
[d] Data from the Tiles of Dr. J.B. Beckwith reveal that 20 of 252 vincristine/adriamycin-responsive (VAR) patients (7%) relapsed or had metastases at diagnosis. 4 of the 20 in the lungs, 1 of the 4 at diagnosis; all but 1 of the 16 relapses occurred within 1 year. Chest films for VAR patients may be limited use + schedule such as q3mo × 4, q6mo × 2.
CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 54.3. RECOMMENDED FOLLOW-UP IMAGING STUDIES FOR CHILDREN WITH RENAL NEOPLASMS OF PROVEN HISTOLOGY AND FREE OF METASTASES AT DIAGNOSIS

NRs have a varied life and most do not form Wilms' tumor. A rest can undergo maturation, sclerosis, involution, and complete disappearance. NRs display a spectrum of appearances. Hyperplastic NRs can produce a renal mass that can be mistaken for a small Wilms' tumor. Incisional biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms' tumor. The biopsy should include the interface of the rest with the normal renal parenchyma. Wilms' tumor generally compresses the normal kidney with a pseudocapsule at their interface (16). Neoplastic induction of cells of an NR will produce Wilms' tumor and possibly other benign or malignant renal neoplasms. Given that the incidence of NRs is much greater than that of Wilms' tumor, it is not surprising that regression of the rests is common. Sclerosing ILNR can be indistinguishable from focal renal dysplasia (13). NRs also have been found in 4% of multicystic dysplastic kidneys (139), but only 1 in 2,000 are expected to develop a Wilms' tumor (12).

Prognostic Factors

Chromosomal Abnormalities

Because most patients with FH Wilms' tumor have excellent survival rates, it becomes increasingly difficult to find any particular histologic feature of a given tumor that will predict the risk of relapse. The current focus of the NWTS-5 study of Wilms' tumor is to evaluate potential biologic factors that may predict tumor behavior. A tumor bank maintains specimens from all patients entered on the study. This has provided a valuable resource for molecular biology investigators. An intense research effort is under way to identify other biologic markers that could further stratify FH Wilms' tumor patients into low- and high-risk groups for relapse. Such a marker would allow a further reduction in treatment intensity for a large number of patients.

LOH for a portion of chromosome 16q has been noted in 20% of Wilms' tumor patients (127). This was not found to be a germline mutation, which suggests that this region may play a role in tumor progression rather than tumor initiation. A prospective study of 232 patients registered on the NWTSG found LOH for 16q in 17% of the tumors (91). Patients with tumor-specific LOH for chromosome 16q had a statistically significantly poorer 2-year relapse-free and overall survival than for those patients without LOH for chromosome 16q. This difference in outcome persisted after adjustment for histology and stage. If this information is confirmed in a larger prospective study, molecular markers may serve to further stratify Wilms' tumor patients for treatment. Patients identified with unfavorable molecular findings could be selected for alternative forms of therapy.

Dome and others (62) investigated telomerase levels in patients with Wilms' tumor. Telomerase is a reverse transcriptase that maintains chromosome ends, compensating for the loss of DNA that occurs in replication. High telomerase activity has been found to be an unfavorable prognostic feature for several types of cancers. In a case-cohort study of 78 patients with FH Wilms' tumor, telomerase enzyme activity; expression of human telomerase (hTR), the RNA component of telomerase; and mRNA expression of high telomerase reverse transcriptase (hTERT), the gene that encodes the catalytic component of the enzyme, were measured. All had detectable expression of hTR and 97% had detectable hTERT transcript. The hTERT mRNA levels correlated with the risk of recurrence even after adjustment

is the most common malignancy in the second decade of life. It has been reported in infants younger than 1 year of age (148). There is no sex predilection in contrast to the male predominance seen in adult patients. The signs and symptoms are similar to that of other solid renal tumors, with an abdominal mass being the most common presentation in a child. Hematuria is more common in RCC than in Wilms' tumor (35). Imaging studies cannot differentiate RCC from other solid renal tumors.

Survival of children with RCC is dependent on the ability to completely resect the tumor. Raney and co-workers (152) found that all children with stage I lesions survived, and others have reported 64% to 80% survival for stage I and II tumors, respectively (38,58). Overall survival was about 50%. Age is also a prognostic factor, with improved survival in children younger than 11 years (153). These tumors do not appear responsive to chemotherapy or radiation therapy.

Miscellaneous Tumors

Renal *angiomyolipoma* is a hamartomatous lesion that is only rarely seen in childhood. There is a clear association with the tuberous sclerosis complex (TSC) and the lesion is more often bilateral in these patients (20). The renal lesions of the TSC include angiomyolipoma, simple cysts, polycystic kidney disease, and RCC. Angiomyolipoma develops in up to 80% of patients with the TSC. Two genes have been identified in the TSC on chromosome 9 (TSC1) and chromosome 16 (TSC2) (149). It has been postulated that these genes act as tumor suppressor genes and that the LOH of TSC1 or TSC2 may explain the progressive growth pattern of renal lesions seen in these patients.

The incidence of angiomyolipoma increases with age. Ewalt and others reported on 60 patients with TSC who were followed with periodic ultrasound. The average age at which a normal ultrasound became abnormal was 7.2 years. Angiomyolipomas were found in 45 children. Growth of the lesion was observed in 28 children. Girls were more likely to have an increase in the size of the lesion. All patients with lesions greater than 4 cm in diameter were postpubertal. Annual ultrasounds are recommended after puberty. Children with growing lesions (Fig. 54.10) can be managed with embolization or partial nephrectomy before they become symptomatic with bleeding (118). The risk of serious bleeding appears to correlate with a diameter of greater than 4 cm (20). Nephron-sparing approaches are recommended in children with TSC because of the presence of multiple, bilateral lesions and the risk of development of new lesions.

FIGURE 54.10. Angiomyolipoma of the right kidney in a patient with tuberous sclerosis.

Tumors of the renal collecting system also are very uncommon in childhood. *Transitional cell carcinoma* of the renal pelvis has been reported, and these lesions are managed with nephroureterectomy (100). Fortunately, most filling defects of the upper collecting system represent benign lesions. The most common lesion is a *fibroepithelial polyp* (72). These patients typically present with symptoms secondary to obstruction (Fig. 54.11). Management consists of segmental resection and reconstruction of the urinary tract.

FIGURE 54.11. Fibroepithelial polyp at the ureteropelvic junction, causing intermittent obstruction of the right kidney.

NEUROBLASTOMA

Neuroblastoma is known to arise from cells of the neural crest that form the adrenal medulla and sympathetic ganglia. Tumors derived from the sympathetic nervous system are differentiated along two lines: the pheochromocytoma line and the sympathoblastoma line. The latter includes neuroblastoma, ganglioneuroblastoma, and ganglioneuroma. Neuroblastoma and ganglioneuroblastoma are most notable for the potential to regress or mature spontaneously. The ability of neuroblastoma to transform into benign ganglioneuroblastoma and ganglioneuroma was first reported in 1927 (210). The incidence of spontaneous regression in childhood neuroblastoma has been reported to be 1% to 2% (216). Most cases of regression or maturation of neuroblastoma occur in the first year of life.

Genetics

It is suggested that 20% of neuroblastoma cases occur in patients with an inheritable mutation (245). The familial cases reported are postulated to represent an autosomal- dominant pattern of inheritance. The median age at diagnosis of unselected patients with neuroblastoma is 21 months, contrasting with the median age of 9 months in familial cases of neuroblastoma (248). Twenty percent of patients with familial neuroblastomas have bilateral or multifocal primary tumors. The risk of neuroblastoma developing in a sibling or offspring of a patient with neuroblastoma is less than 6% (248). Some of the difficulties in detecting the incidence and penetrance of an inheritable susceptibility to neuroblastoma are due to the frequent spontaneous regression and maturation of the tumor, the high mortality rate, and the complications of therapy, which preclude reproduction of multigenerational pedigrees for evaluation.

Numerous karyotypic abnormalities have been found in neuroblastoma. These changes occur in the forms of chromosomal deletions, translocations, and cytogenetic evidence of gene amplification. Deletion of the short arm of chromosome 1 is found in 70% to 80% of neuroblastomas (204). This deletion is thought to represent the loss of a gene, the putative neuroblastoma suppressor gene that prevents tumor development. Unlike the WT-1 gene associated with Wilms' tumor, there has been no evidence of constitutional deletions of this gene in neuroblastoma patients or of any chromosome 1p deletion syndrome.

Pathology

Ganglioneuroma

A ganglioneuroma is a histologically benign neoplasm that is quite rare compared with other benign neural tumors such as neurofibromas and schwannomas. Most ganglioneuromas are diagnosed in older children and usually are located in the posterior mediastinum and retroperitoneum, with only a small number arising in the adrenal glands (212). Because of their site of origin, the ganglioneuromas tend to have a paravertebral location. In the retroperitoneum, the presacral space is the

most common site. Ganglioneuromas generally grow to a very large size before they cause symptoms due to compression of adjacent structures (199). Catecholamine excretion is elevated in 20% of patients and appears to increase as a function of tumor size (251).

The pathology of ganglioneuroma is that of a well-circumscribed tumor with a fibrous pseudocapsule. These tumors are very firm and rubbery in consistency on cross section. Careful examination of a ganglioneuroma is necessary to exclude ganglioneuroblastoma, which can have a similar gross appearance. On microscopic examination, mature ganglion cells with abundant cytoplasm are scattered throughout a mature Schwann cell matrix.

It is unclear whether a ganglioneuroma arises *de novo* or by maturation of a preexisting neuroblastoma or ganglioneuroblastoma. Cases of metastatic lesions that have been observed to develop the histology of mature ganglioneuromas support the latter theory (234). In rare cases, a ganglioneuroma has undergone malignant transformation into a malignant peripheral nerve sheath tumor or malignant schwannoma. Some of these patients have received antecedent abdominal radiation (242). Ganglioneuroblastoma is intermediate between neuroblastoma and ganglioneuroma. Distinguishing between neuroblastoma and ganglioneuroblastoma is often difficult.

Neuroblastoma

The gross morphology in neuroblastoma can vary considerably. Small adrenal tumors usually appear well encapsulated. The adrenal gland may be draped over the tumor, but larger tumors generally preclude precise identification of the anatomic site of origin. On cross section, the tumor will vary in appearance and consistency, depending on the degree of stromal elements. The tumor may rupture during removal, spilling out friable and hemorrhagic tumor. Cystic degeneration may be a prominent feature.

Neuroblastoma is the prototypical small “blue-cell” tumor of childhood (Fig. 54.12). The most common histologic pattern is that of lobular growth, but it may have a more diffuse or solid pattern. Neuroblastoma can be confused with lymphoma, Ewing's sarcoma, or embryonal sarcoma. A characteristic feature of this tumor is the arrangement of the nuclei into pseudorosettes. The nuclei are separated by fibrils, which can appear as a meshwork. The nuclei vary in size and have a stippled nuclear chromatin pattern. Ganglion cell differentiation in neuroblastoma is evidence of maturation. Special staining may help characterize neuroblastoma cells. Neuron-specific enolase staining of the tumor is reported to be specific for neuroblastoma (265). Neuroblastoma usually lacks glycogen, which will help differentiate it from some of the sarcomas.

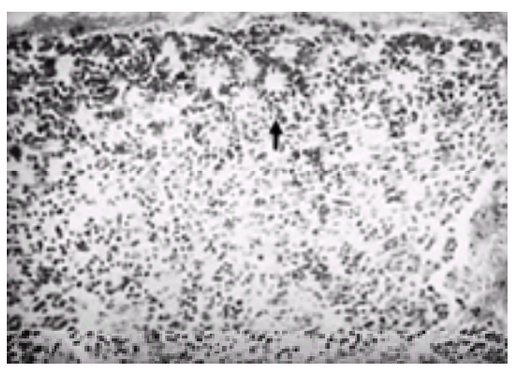

FIGURE 54.12. Microscopic (hematoxylin and eosin) view of neuroblastoma, demonstrating pseudorosette formation *(arrow).*

Various antibodies are used to detect the presence of certain structural products, cellular products, and membrane-associated antigens. Most antibodies used are monoclonal. Although no specific neuroblastoma monoclonal antibody is available, a battery of antibodies can be used in the diagnostic evaluation of neuroblastoma or a similarly appearing neoplasm (244). Although these immunohistochemical stains have some limitations, they can help differentiate neuroblastomas from other small blue-cell tumors of childhood.

In 1984, an age-linked histopathologic classification of neuroblastoma was introduced with definition of subtypes of ganglioneuroblastoma (278). One of the important aspects of the Shimada classification is determining whether the tumor is stroma poor or stroma rich. Stroma-rich tumors can be separated into three subgroups: nodular, intermixed, and well differentiated. The last category consisted of tumors that more closely resemble ganglioneuroblastomas or immature ganglioneuromas. The survival rates of stroma-rich patients were as follows: well-differentiated, 100%; intermixed, 92%; and nodular, 18%. The stroma-poor tumors can be divided into favorable and unfavorable subgroups based on the patient's age at diagnosis, degree of maturation, and the mitosis-karyorrhexis index (MKI). This index is based on a differential count of the mitoses in the tumor. Patients with stroma-poor tumors with unfavorable histopathologic features (higher MKI, higher age, undifferentiated histology) have a very poor prognosis, with less than 10% survival. Patients with stroma-poor favorable tumors have an excellent survival rate (greater than 90%) (278).

In addition to maturation of clinically evident cases of neuroblastoma, spontaneous regression of *“in situ”* neuroblastoma may occur far more often. Beckwith and Perrin (198) coined this term in 1963 for small nodules of neuroblastoma cells found incidentally within the adrenal gland that histologically are indistinguishable from neuroblastoma. In infants less than 3 months of age undergoing postmortem examination, neuroblastoma *in situ* was found in 1 per 224 infants. This represents an incidence of *in situ* neuroblastoma about 40 to 45 times greater than the incidence of clinical tumors. If these lesions clearly are neoplastic, then the majority undergoes spontaneous involution, mature, or remain clinically occult. Notably, no known instances of *in situ* neuroblastoma have been identified in an extraadrenal site. Neuroblastic nodules are considered a normal part of the fetal adrenal gland. In the developing fetus, the adrenal goes through a stage in which clusters of neuroblasts are seen that resembles neuroblastoma *in situ.* This reaches a peak level at 18 to 20 weeks of gestation (283). There is some difficulty in distinguishing *in situ* neuroblastoma from nodules of neuroblast cells that linger into early infancy. The relationship of neuroblastic nodules to *in situ* neuroblastoma is unclear.

Incidence

Neuroblastoma is one of the more common solid tumors, accounting for 7% to 8% of all childhood malignancies (286). In the United States, the annual incidence is 10 per 1 million live births. There are no sex-related differences in incidence rates. It is the most common malignant tumor of infancy, with 50% of cases occurring in children less than 2 years of age, and 75% are noted by the fourth year of life (221). Associated congenital anomalies are few, although an association with neurofibromatosis has been reported (246).

Clinical Presentation

The clinical manifestations of neuroblastoma vary widely with the site of the primary tumor, the presence of metastases, and secretion of biochemical products. More than one-half of neuroblastomas originate in the abdomen, and two-thirds of these arise in the adrenal gland (Fig. 54.13). Patients with an abdominal tumor may present with an abdominal mass, pain, or weight loss. The mass is typically hard and irregular, often extending across the midline. Pelvic neuroblastoma accounts for only 4% of tumors. Extrinsic compression of the bowel and bladder produces symptoms of urinary retention and constipation. Mediastinal and paraspinal retroperitoneal tumors that arise from sympathetic ganglia have a propensity to grow into the intervertebral foramen in a dumbbell configuration. A presentation of extradural spinal cord compression is more common for thoracic neuroblastoma than other locations (194,195). Unilateral Horner's syndrome may develop in cervical or upper mediastinal tumors (Fig. 54.14). There may also be asymmetric coloration of the iris because the sympathetic nervous system is involved in iris pigmentation (240). About one-half of mediastinal tumors are diagnosed incidentally (194).

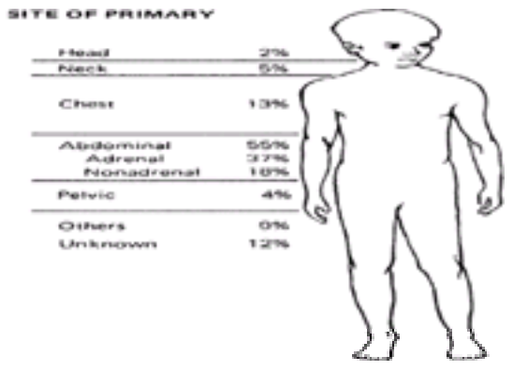

FIGURE 54.13. Anatomic sites of origin of neuroblastoma. (From Williams TE, Donaldson MH. Neuroblastoma. In: Sutow WW, Vietti TJ, Fernbach DJ, eds. *Clinical pediatric oncology.* St. Louis: Mosby, 1973:388, with permission.)

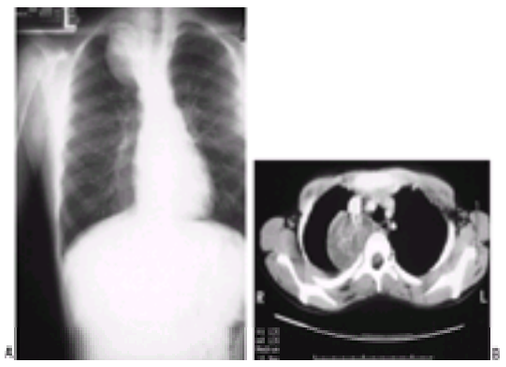

FIGURE 54.14. Neuroblastoma arising from the upper mediastinum. **A:** Chest radiograph. **B:** Computed tomography scan.

Metastases are present in 70% of neuroblastoma patients at diagnosis and can be responsible for a variety of the clinical signs and symptoms of presentation. Fever, lethargy, weight loss, and bone pain are among these findings. The skull and long bones are most commonly involved. Radiographs will reveal lytic lesions that are frequently bilateral and asymmetric. More than 50% of patients with neuroblastoma will have involvement of the bone marrow (218), and anemia is found in more than one-third of children.

Retrobulbar soft tissue involvement can result in another unique presentation of metastatic neuroblastoma. The tumor produces proptosis and periorbital ecchymosis. Subcutaneous nodules are common in infants with stage 4s disease (279). These have been described to have the appearance of blueberry muffins because of their bluish color.

Neuroblastoma is a biochemically active tumor with catecholamine secretion by over 90% of tumors. Symptoms may mimic pheochromocytoma, with paroxysmal hypertension, palpitation, flushing, and headache. Secretion of vasoactive intestinal peptide (VIP) by the tumor can produce severe watery diarrhea and hypokalemia (209). Another unusual presentation of neuroblastoma is acute myoclonic encephalopathy (217,276). These patients develop myoclonus, rapid multidirectional eye movements (opsoclonus), and ataxia. The etiology of these symptoms is most likely antibodies against tumor antigens that cross-react with the cerebellum (219). These symptoms often do not resolve even with successful treatment of the primary tumor; however, tumors associated with this syndrome generally have a good prognosis.

Diagnosis

Laboratory Evaluation

A complete blood count is essential. Anemia is noted in children with widespread bone marrow involvement. Coagulation abnormalities may be present as a result of massive liver metastases. Bone marrow aspiration is performed in all children with suspected neuroblastoma. Metastatic tumor to the bone marrow can occur in the absence of skeletal metastases (218).

Twenty-four-hour urine collection will detect elevated levels of the two major metabolites of catecholamine production, vanillylmandelic acid (VMA) and homovanillic acid (HVA) in 90% of tumors (284). It is surprising that hypertension is not more common in neuroblastoma patients, but increased serum levels of norepinephrine are not present in neuroblastoma. This is attributed to breakdown of the catecholamines in the tumor. It has been noted that catecholamine storage vesicles are relatively lacking in patients with neuroblastoma as compared with patients with pheochromocytoma (267). Because these storage vesicles protect the catecholamines from degradative enzymes, norepinephrine and epinephrine concentrations are much higher in pheochromocytoma, leading to the clinical symptoms. Another explanation for the lack of clinical signs and symptoms related to catecholamines could be the absence of periodic massive catecholamine release by tumor vesicles in neuroblastoma patients.

Urinary levels of HVA and VMA can be monitored throughout treatment. Therapy with various modalities has been shown to produce a reduction in catecholamine metabolite excretion in the majority of patients (223). These metabolites also can be followed to detect tumor relapse. Biochemical evidence of relapse has been found before clinical evidence of a recurrent mass or other symptoms.

Imaging

Imaging studies play an important role in the evaluation of a child with neuroblastoma. The diagnosis is suggested on excretory urography, which reveals inferior displacement of the kidney by a suprarenal mass. The kidney generally lacks the calyceal distortion typically seen with Wilms' tumor. Currently, abdominal ultrasound and CT are used more commonly than excretory urography. Invasion of the renal parenchyma is not uncommon and can be detected radiographically by CT (196). A speckled pattern of calcification is noted in 50% of cases on plain abdominal films. An even greater percentage of patients will have calcifications noted on CT (Fig. 54.15). Ultrasound and CT both demonstrate the solid nature of the mass and the location of the tumor. Examination of the liver for metastases is accomplished with either of these studies. Ultrasound is not as helpful for defining anatomic relationships of the tumor, particularly in extraabdominal sites. Prenatal diagnosis of neuroblastoma is possible with ultrasound (241). MRI has advantages over CT in the evaluation of intraspinal tumor extension (197). MRI also can define involvement of the major vessels and central nervous system. Cystic forms of neuroblastoma are well delineated with CT imaging (Fig. 54.16).

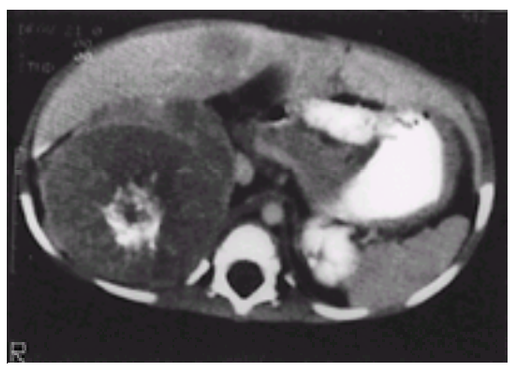

FIGURE 54.15. Computed tomography scan demonstrating calcifications within a neuroblastoma.

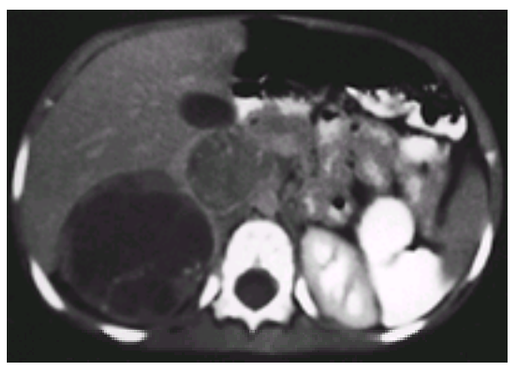

FIGURE 54.16. Cystic neuroblastoma.

A skeletal survey is routinely obtained to exclude metastases. These lesions are found most commonly in the long bones and skull. If the skeletal films are negative, a radionuclide bone scan may detect earlier metastases. Another method of imaging both the tumor and metastatic sites is with radiolabeled ^{123}I metaiodobenzylguanidine (MIBG) (222,235). MIBG bears structural similarity to norepinephrine and is taken up by the adrenergic secretory vesicles of the tumor cells both in primary and metastatic sites. MIBG scintigraphy can be used to determine the extent of disease and also to detect recurrence of tumor after completion of therapy (222). Not all tumors have uptake of MIBG, and false negatives occur. It appears that maturation of the neuroblastoma to more mature forms such as ganglioneuroma also results in the loss of an ability to concentrate MIBG.

An interesting subset of patients is those diagnosed on prenatal ultrasound. As ultrasonography becomes more routine during pregnancy, the number of prenatally diagnosed neuroblastomas is increasing (241). In the Italian Neuroblastoma Registry, 17 patients were identified (224). Primary tumor site was most often adrenal (16 of 17). Thirteen were stage 1, one was stage 2a, one was stage 2b, and two patients were stage 4s. All patients had primary tumor resection at a mean age of 4 weeks. Only one patient had *N*-myc amplification. Two of these patients died, one of bleeding after tumor resection and one from progressive disease despite aggressive multimodal treatment. This mode of diagnosis may have future implications in the screening of patients for neuroblastoma.

Screening

Mass population screening for neuroblastoma has been advocated to detect disease at an earlier stage and thus improve survival. This was initiated in Kyoto, Japan, in 1974 (270) and has been used widely in Japan since 1985 (261). Screening is generally performed at 6 months of age. An increased number of infants younger than 1 year of age have been diagnosed with the mass screening program (238), and most of these patients have lower-stage tumors (271). Before mass screening started, 20% were diagnosed at less than 1 year of age, whereas after mass screening was instituted 55% were diagnosed at less than 1 year of age. A decrease in the percentage of primary adrenal gland tumors has been noted in the postscreening era. This suggests an increase in the diagnosis of tumors at other sites that could possibly have regressed undetected if screening had not been instituted.

An unanswered question is whether early detection of tumors will have an overall impact on survival (258). It is clear that patients less than 1 year of age when diagnosed with low-stage tumors have a better outlook (201). In addition, tumors diagnosed by screening have other striking biologic differences from tumors detected clinically (232). In a review of 48 cases discovered by screening, none were observed to have amplified *N*-myc oncogene expression (see Prognostic Factors) (239). In addition, 80% had a diploid chromosome pattern, which is associated with a favorable prognosis. All 48 patients were still alive without tumor. Altogether 357 patients from Kyoto have been diagnosed by mass screening, and the overall survival is 97% (271). Given the favorable biologic characteristics of tumors discovered by screening, it is possible that these patients would have the same excellent survival if they were discovered later in life as a result of clinical symptoms. There is also some concern that many of the unfavorable histology tumors destined to present clinically at an older age go undetected by mass screening (281). In a Canadian study, population screening was found to increase the incidence of neuroblastoma but did not decrease the incidence of unfavorable advanced-stage disease in older children (285). The optimal screening regimen for neuroblastoma has yet to be determined.

Staging

As with most solid tumors, staging of neuroblastoma patients is an important aspect of management because the stage of the disease is a significant prognostic variable. Currently four anatomic staging systems are used for neuroblastoma: the Evans classification (213); the St. Jude Classification (233); the TNM classification; and the International Staging System (INSS), which is most widely used currently (Table 54.6) (206). This system relies on anatomic features of the tumor, its resectability, and also on histopathology of the resected specimen. As more knowledge of the biologic prognostic features of neuroblastoma is gained, it is apparent that staging systems based solely on anatomy of the tumor are inadequate and these factors must be considered in determining a risk-grouping system.

Stage	Characteristics
Stage 1	Tumors are confined to the organ or structure of origin. Complete gross excision with or without microscopic residual disease is recommended. Identifiable ipsilateral and contralateral lymph nodes are microscopically negative.
Stage 2a	Unilateral tumor with incomplete gross excision. Identifiable ipsilateral and contralateral lymph nodes are microscopically negative.
Stage 2b	Unilateral tumor with complete or incomplete gross excision, with positive ipsilateral regional lymph nodes. Identifiable contralateral lymph nodes are microscopically negative.
Stage 3	Tumors infiltrating across the midline with or without regional lymph node involvement. Or unilateral tumor with contralateral regional lymph node involvement. Or midline tumor with bilateral lymph node involvement.
Stage 4	Dissemination of tumor to bone, bone marrow, liver, distant lymph nodes, or other organs (except as defined in stage 4s).
Stage 4s	Localized primary tumor as defined for stage 1 or 2, with dissemination limited to liver, skin, and/or bone marrow.

TABLE 54.6. STAGING SYSTEM FOR NEUROBLASTOMA

Prognostic Factors

Many variables have an impact on the prognosis of neuroblastoma. The site of origin is of significance. Nonadrenal primary tumors are associated with better survival than are those that originate from the adrenal. Most children with thoracic neuroblastoma present at a younger age with localized disease and have an improved survival, even with correction for age and stage (194). Overall survival was 88% at 4 years in 96 patients with thoracic neuroblastoma studied by the Pediatric Oncology Group.

Age at diagnosis is another powerful prognostic indicator. Survival is inversely correlated with age at diagnosis. Children less than 1 year of age have a far better survival than those diagnosed later in life (201). This may be attributed to more favorable biologic parameters in tumors diagnosed at this age. Spontaneous regression also is more likely to occur in children less than 6 months of age.

Stage of the disease is also an important prognostic factor. Virtually all stage 1 patients with complete resection of the primary tumor will survive. Stage 2 patients also

have a more favorable survival, even though excision may be incomplete (254). Advanced regional disease, stages 3 and 4, fares less well and requires more aggressive treatment. Clearly, tumors that can be completely resected have a more favorable prognosis. Whether this is independent of biologic factors is unclear.

DNA content of tumor cells and ploidy number have been reported to have prognostic value. Studies of DNA content measured by flow cytometry showed that DNA aneuploidy correlated with better prognostic factors (age younger than 1 year; stage 1, 2, or 4s) and a good outcome (247,250). Diploidy and tetraploidy were associated with poor prognostic indicators (age older than 1 year and advanced clinical stage) and decreased survival.

Several cytogenetic abnormalities have been identified in neuroblastomas, with the most consistent structural abnormalities noted on the short arm of chromosome 1 (207). Loss of heterozygosity for chromosome 1 is found in the majority of children with neuroblastoma but does not correlate as well as other prognostic factors with advanced stages of disease (220). Also noted in about one-third of neuroblastoma tumors was the presence of homogeneously staining regions (HSRs) and double minute chromosomes (DMs) (203). These abnormalities are cytogenetic manifestations of gene amplification that led to the investigation of tumor oncogenes in neuroblastoma. DMs and HSRs are found in approximately 30% of neuroblastomas, and it was subsequently found that the *N*-myc oncogene was mapped to these regions. Amplification of the *N*-myc oncogene has been recognized in approximately one-third of patients (205). The association of *N*-myc amplification with the pathogenesis of neuroblastoma is unclear, but the level of expression and amplification of the oncogene is important in determining prognosis (274). It has been noted that *N*-myc amplification is associated with high levels of expression of the gene for the multidrug-resistance protein (200), which account for the association between *N*-myc amplification and poor outcome (264).

N-myc amplification is associated with a poor prognosis independent of patient age or stage of disease at presentation, and appears to remain constant regardless of therapy or tumor status (274). Children with multiple copies or genomic amplification of the *N*-myc tumor oncogene generally present with clinically advanced tumors that progress rapidly and respond poorly to therapy. In a recent study of stages 1 and 4s tumors, not one of the patients was found to have multiple copies of *N*-myc and the tumors were associated with a good prognosis (229). On the other hand, 50% of patients with stage 3 or 4 disease have *N*-myc amplification (197). There was an 18-month progression-free survival of 70% when there was no genomic amplification, compared with 30% in those patients with 3 to 10 copies of *N*-myc and only 5% in those with more than 10 copies of the oncogene. However, many advanced-stage tumors lack *N*-myc amplification at diagnosis, and recurrence or progressive disease develops in the majority of these patients. Therefore it is important that other prognostic factors involved in the pathogenesis of neuroblastoma be identified.

Several other biologic markers have prognostic value. Elevated levels of serum ferritin have been found in patients with neuroblastoma (231). Serum ferritin levels are elevated in 40% to 50% of patients with stage 3 or 4 disease. Only 4% of stage 4 patients with levels above 140 ng/mL survive 2 years, compared with 30% survival in children with levels less than 75 ng/mL. If the serum ferritin is not elevated in stage 3 disease, survival is significantly better (76% versus 23% 2-year disease-free survival). Patients also can be subdivided based on age and serum ferritin levels. Patients with normal serum ferritin and age less than 2 years have a 93% 2-year survival; patients older than 2 years of age with normal serum ferritin levels have 38% 2-year survival; and patients of any age with abnormal serum ferritin levels have a 19% 2-year survival (231). Neuron-specific enolase (NSE) is elevated in more than 90% of patients with metastatic neuroblastoma at diagnosis (287). In infants younger than 1 year of age, the survival rate was only 25% with high NSE levels compared with almost 100% survival in those infants in whom NSE was less than 190 g/mL. However, NSE is more difficult to assay, which has limited its widespread application.

Another prognostic factor is the transmembrane glycoprotein tyrosine kinase receptor (TRK), which may be critical in allowing the differentiation and regression of neuroblastoma (253). An association between high levels of the TRK gene and favorable outcome in patients with neuroblastoma has been observed (257).

Stage 4s

Stage 4s (“s” stands for special) comprises a distinct group of infants with distant liver, skin, and bone marrow metastases without radiologic evidence of bone metastases. Eight to 12% of all children with neuroblastoma present with this stage of disease. These children typically have a small intraabdominal adrenal primary, but in 10% of cases no primary can be identified. The median age of these infants is about 3 months, but occasionally they present after 1 year of age. This group of patients has an overall good prognosis, ranging from 80% to 87% (280). Many of these tumors undergo spontaneous regression (215,225). This regression can occur without treatment even in patients with a significant tumor burden. It is suggested that these patients do not have metastases but simply have collections of nonmalignant neural crest cells in these other sites. Studies of children with stage 4s neuroblastoma have not revealed significant cytogenetic abnormalities or other adverse prognostic findings, such as *N*-myc oncogene amplification or elevated serum ferritin typically seen in children with stage 4 neuroblastoma (229,230).

Treatment

It was not until an appropriate staging system was available that patients could be separated into groups for stratification of treatment (213). The identification of biologic and other prognostic factors has allowed further separation of patients into favorable and unfavorable categories of tumors. The INSS staging classification relies on anatomic features, resectability, and pathology of the tumor. Based on the INSS classification and on the biologic markers with known prognostic significance, patients can be grouped into low, intermediate, or high-risk populations (Table 54.7).

Risk Group	Factors
Low risk	INSS stage 1, 2, or 4s Age usually <1 yr No *N*-myc amplification Hyperdiploid/triploid with DNA index >1.25 No 1p LOH High TRK >90% cure
Intermediate risk	INSS stage 3 or 4 Age usually > 1 yr No *N*-myc amplification Near-diploid or tetraploid Low TRK Presence of 1p allelic loss or other structural change >25%–50% cure
High risk	INSS stage 3 or 4 Age 1–5 yr *N*-myc amplified Near-diploid or tetraploid Presence of 1p allelic loss Low TRK <5% cure

INSS, International Staging System; LOH, loss of heterozygosity; TRK, tyrosine kinase receptor.

TABLE 54.7. RISK LEVEL BASED ON INSS CLASSIFICATION AND BIOLOGIC MARKERS WITH KNOWN PROGNOSTIC SIGNIFICANCE

Low-risk Disease

Localized neuroblastoma can be treated by surgical excision alone with excellent results. Stage 1 patients with complete excision have an excellent prognosis (266). The Pediatric Oncology Group reviewed 101 children with localized neuroblastoma who had complete gross excision of the primary tumor (263). The overall disease-free survival rate at 2 years was 89%. Nine patients developed relapses, but six were salvaged with chemotherapy. Although chemotherapy is not used initially in stage 1 patients, it has a high rate of inducing remission and extending disease-free survival rates in patients who relapse following excision (286).

Stage 2 tumors, by definition, have residual disease either because of incomplete resection (stage 2a) or because of positive ipsilateral lymph nodes (stage 2b). Radical resection is probably not justified in this group of patients. Formal lymph node dissection is not necessary, but diagnosis of contralateral lymph nodes is an important aspect of staging. Radiation of the local tumor bed has been advocated for treatment of residual disease in stage 2 patients. A report of 156 patients with stage 2 neuroblastoma found a 90% 6-year progression-free survival whether or not radiotherapy was used (254). Therefore surgical excision alone may constitute adequate therapy for the majority of stage 2 tumors, and chemotherapy and radiation may be reserved for those with relapse. A recent study reports that children with stages 1 and 2 neuroblastoma have a 98% survival with surgery alone as primary therapy (269). This study found that *N*-myc amplification, age older than 2 years, and either unfavorable histopathology or positive lymph nodes were poor prognostic variables.

In stage 4s tumors, resection of the primary is not mandatory and is of unknown benefit. A retrospective review of 37 patients did demonstrate that removal of the primary can be safely accomplished (252), and after resection a 95% survival rate was noted. However, information regarding histologic prognostic factors was not available for all of these patients. Others have found that stage 4s patients do very well whether or not their primary tumors are resected or they are given chemotherapy (215,259). Using the Shimada classification, all stage 4s neuroblastomas studied by Hachitanda and others were in a favorable-prognosis group of stroma-poor tumors (229). A recent study of 80 stage 4s patients found no *N*-myc amplification (58 of 80 tested) and favorable Shimada histopathology in 96% of

patients (260). Supportive care only was provided for 55% of these 80 patients, and their 5-year survival was 100%. Patients with symptoms were treated with cyclophosphamide for 5 days, with or without hepatic irradiation, and their survival was 81%. Five of six deaths occurred in infants younger than 2 months at diagnosis and were due to complications of extensive abdominal involvement with respiratory compromise or disseminated intravascular coagulation. Patients with extensive metastatic disease who are *N*-myc positive represent a high-risk group (252). These patients should be considered for a more aggressive treatment with multimodal therapy. Treatment of symptomatic infants with massive hepatic involvement using radiation therapy or chemotherapy can initiate tumor regression (214). Temporary abdominal wall augmentation by surgical placement of a prosthetic patch also can be used to decrease intraabdominal pressure in these infants (214).

Intermediate-risk Disease

Among patients with INSS stage 3 or 4, additional factors determine whether they are intermediate of high-risk patients. Those without *N*-myc amplification, with low serum ferritin and neuron-specific enolase, and with negative bone marrow are at intermediate risk. Younger patients have more favorable outcomes as with other stage tumors. These patients usually require multiagent chemotherapy as primary therapy and often receive irradiation to metastatic sites. In one study, infants with INSS stage 4 tumors treated aggressively with chemotherapy, and irradiation to metastatic sites, had a survival of 75% (268).

A recent study evaluated the utility of treatment stratification based on biologic prognostic factors among patients with Evans stage 3 neuroblastoma (255). Risk stratification was performed using age, *N*-myc gene copy number, Shimada histopathologic classification, and serum ferritin level. Based on the presence or absence of these prognostic factors, patients were treated with either low-intensity chemotherapy or intensive multimodality therapy, including in some cases autologous bone marrow transplantation. Event-free survival was 100% at 4 years for patients with favorable biologic factors at any age, compared with 54% for patients older than 1 year of age with unfavorable biology. Only *N*-myc copy number and age were independent factors in multivariate analysis. Although the survival rate for the unfavorable patients is low, it is better than historical controls, indicating that intensive chemotherapy may be beneficial.

High-risk Disease

Older patients with INSS stages 3 and 4 tumors and those with *N*-myc amplification or other adverse biologic markers are at highest risk. These patients require aggressive multimodal treatment. There is some debate on the intensity of the surgical resection required for stage 3 lesions. A report of 58 patients with stage 3 disease found that 8 of 12 with initial complete excision and 12 of 14 with subsequent resection of the primary tumor were long-term survivors (226). This contrasts with only 9 of 32 survivors among patients in whom complete tumor excision could not be accomplished. Significant morbidity was reported in association with the surgical procedures, with 21 major complications. Nephrectomy also was required for complete excision in 6 of the patients. In a retrospective review, Kieley compared the results of radical tumor resection versus more conventional surgery (243). In a large group of stage 3 and 4 patients, he found no difference in survival of 46 patients treated with radical surgical procedures versus 34 patients treated with more conventional surgery. Both groups had 30% long-term survival rate. Biologic factors remain very important in patients with advanced-stage disease. In a recent Children's Cancer Group study, 134 patients with stage 4 disease were evaluated and found to have an overall survival of 71% (272). However, overall survival among patients without *N*-myc amplification had a 3-year event-free survival of 93%. Those with *N*-myc amplification had an event-free survival of only 10%.

Usually, the safest approach for advanced tumors is to defer tumor resection until after initial chemotherapy. There is no clear advantage to debulking or cytoreductive surgery in this disease. Neuroblastoma is a highly vascular tumor, but it does respond to chemotherapy. After chemotherapy, the tumors are smaller and firmer with less risk of rupture and hemorrhage. Timing of surgery is generally 13 to 18 weeks after initiation of chemotherapy (197). There is evidence that delaying surgical resection until after chemotherapy significantly reduces the risk of nephrectomy in these patients (277). Many children with bulky unresectable tumors or with widespread metastases at diagnosis can benefit from delayed attempts at surgery. This is particularly true in regard to debulking patients before bone marrow transplantation. Other attempts at local tumor control for unresectable diseases have included the use of intraoperative radiation therapy. This technique has the advantage of delivering a higher dose of radiation to the operative field while sparing normal adjacent tissues. Intraoperative radiation therapy has been used at Denver Children's Hospital in 30 children with neuroblastoma (228). Nine of 14 patients with advanced disease remain alive at a mean of 40 months.

Chemotherapy

Several different agents have been used in the treatment of neuroblastoma. However, the long-term survival in patients older than 1 year of age with metastatic disease remains poor. A reduced response of neuroblastoma to chemotherapy is believed to be due to a large number of nonproliferating tumor cells (249). Most regimens now use a combination of nonspecific and cell cycle–specific drugs. The most common agents used include cyclophosphamide, VCR, DOX, cisplatin, carboplatin, and etoposide. Although the initial response is often good, relapse continues to be a major problem, with 4-year overall-survival at 20% in stage 4 disease (227,237). Chemotherapeutic regimens are limited by dose-related toxicities and side effects, and much effort is now directed toward developing methods of increasing dosages to improve response while controlling toxicity to survivable levels.

Peripheral blood stem-cell infusion, augmented by hematopoietic agents such as granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, or the reinfusion of purged autologous bone marrow cells (ABMT) may allow increased delivery of chemotherapeutic agents while controlling potentially lethal neutropenia. Autologous bone marrow transplantation following sublethal chemotherapy or total body irradiation has resulted in complete remission in up to 50% of patients with recurrent stage 4 disease (211,228,275). A recent study found improved event-free survival in high-risk patients randomized to receive myeloablative chemotherapy, total body irradiation, and ABMT, when compared with those receiving conventional chemotherapy (256). One problem that is becoming apparent with this treatment, however, is the late risk of relapse. The presence of bulky disease results in increased failure. Tumor debulking with surgery or radiation therapy is warranted before ABMT. Toxicity of bone marrow transplantation can be lethal, but these risks are necessary given that long-term survival is difficult to achieve in these patients.

Another option in the treatment of metastatic neuroblastoma is the use of ^{131}I MIBG (236). The finding that both the primary tumor and metastatic areas take up this radiotracer suggested the possibility that therapeutic doses can be delivered to the tumor. Preliminary analysis indicates that objective responses do occur in terms of reduction of tumor volume. Little toxicity and few side effects have been reported.

TESTICULAR TUMORS

Malignant germ cell tumors occur in both gonadal and extragonadal sites. Testicular tumors account for 1% to 2% of all pediatric solid tumors. The peak incidence of childhood testicular tumors is 2 years of age (330). The incidence tapers after 4 years of age, but then begins to rise again at puberty. Benign testis lesions occur much more commonly in prepubertal children than in adults (Table 54.8). Germ cell tumors account for only 65% of prepubertal testicular tumors. Testis tumors are rare in African American and Asiatic children.

Germ cell tumors	Tumors of supporting tissues
Yolk sac	Fibroma
Teratoma	Leiomyoma
Mixed germ cell	Hemangioma
Seminoma	Lymphomas and leukemias
Gonadal stromal tumors	Tumorlike lesions
Leydig cell	Epidermoid cysts
Sertoli cell	Hyperplastic nodule secondary to congenital adrenal hyperplasia
Juvenile granulosa cell	Secondary tumors
Mixed	Tumors of the adnexa
Gonadoblastoma

TABLE 54.8. CLASSIFICATION OF PREPUBERTAL TESTICULAR TUMORS

Embryology and Classification

The gonads first become evident in the yolk sac by the fourth week of gestation. Primordial germ cells originating in the yolk-sac endoderm migrate to the genital ridge at 4 to 5 weeks of gestation. Arrested migration of these germ cells accounts for the development of extragonadal germ cell tumors. During the sixth week, the indeterminate gonads differentiate into testes under the influence of the Y chromosome. The movement of the germ cells is accompanied by the development of the sex cords derived from the celomic epithelium. These form the rete testis and seminiferous tubules. Sertoli cells are probably derived from the primitive sex cords.

The germ cell and non–germ cell tumors arise from the primordial germ cells and celomic epithelium, respectively. Embryonal carcinoma is capable of differentiating into extraembryonic (yolk-sac and choriocarcinoma) and embryonic (mature or immature teratomas). Yolk sac tumors account for the majority of prepubertal testicular tumors. Seminoma or dysgerminoma is a primitive germ cell neoplasm that lacks the capacity for further differentiation. These tumors are unusual in childhood except when related to gonadal dysgenesis. Teratomas represent the most common histologic type of pediatric germ cell tumor. Teratomas are defined by the presence of all three embryonic layers, although one layer may be predominant. The sacrococcygeal location is the most common site of all prepubertal teratomas and the testis accounts for 3% of cases.

Genetics and Risk Factors

The etiology of testicular cancer is unknown. There is clearly a link between cryptorchidism and germ cell tumors of the testis, but these are quite rare in childhood (323). Patients with intersex disorders have an increased incidence of gonadal tumors. These disorders include androgen insensitivity syndromes, such as complete testicular feminization and gonadal dysgenesis. The risk of tumor formation in gonadal dysgenesis is increased if there is a Y chromosome present, with the incidence of tumor development approximately 10% by age 20 years. Intratubular germ cell neoplasia has been noted in 6% of children with intersex disorders, with a higher incidence after puberty (346). The incidence of testicular cancer has been increasing in the past few decades (337). It is suggested that early or prolonged exposure to some carcinogenic stimuli might be implicated.

Testicular germ cell tumors of adolescents have the same chromosomal abnormalities seen in adult germ cell tumors. The most common chromosomal abnormality is the isochromosome of 12p or i(12p), characteristically composed of two copies of 12p. Other abnormalities include loss of chromosomes 11, 13, and 18, and gain of chromosomes 7, 8, and the X chromosome (296). Testis tumors of infants and young children fail to show the presence of i(12p). Endodermal sinus tumors have been noted to have a deletion of the short arm of chromosome 1, specifically 1p36 in 80% to 100% of cases (343). DNA ploidy analysis reveals that most infantile testicular endodermal sinus tumors are diploid or tetraploid, whereas adult germ cell tumors are typically aneuploid (351).

Clinical Presentation and Diagnosis

The most common presentation of patients with testicular tumors is a painless scrotal mass. The mass is typically nontender and does not transilluminate. Disorders that must be excluded are epididymitis, hernia, hydrocele, and torsion. The latter condition can present as a painless mass in the neonate with little scrotal wall inflammation if the event occurred prenatally. There is often a delay from first recognition of the scrotal swelling by the parents and initiation of treatment (295). Some patients with hormonally active tumors may have small intratesticular lesions that are not palpable on physical examination. Acute abdominal pain can be the presenting symptom with torsion of an abdominal undescended testicle containing a tumor (Fig. 54.17).

FIGURE 54.17. Teratoma arising from an abdominal undescended testis. The patient presented with acute abdominal pain.

Imaging

Ultrasound is very helpful in the evaluation of testicular abnormalities. Hydrocele fluid around the testicle may prevent palpation of the testes. Ultrasound can detect small lesions not palpable on examination and is particularly useful in identifying cystic components of a teratoma of the testis or epidermoid cyst (Fig. 54.18). If a benign lesion such as teratoma or epidermoid cyst is suspected preoperatively, a testicular-sparing procedure can be considered (313,349). Color Doppler ultrasound has been reported to be more effective than gray-scale ultrasound in detecting intratesticular neoplasms in the pediatric population (331). Very small functioning Leydig cell tumors that are not evident on ultrasound have been detected with MRI (324).

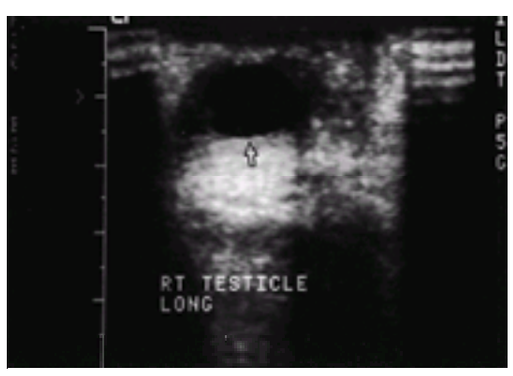

FIGURE 54.18. Testicular ultrasound demonstrating cystic lesion *(arrow)* that proved to be a teratoma of the testicle. The patient underwent a testis-sparing procedure.

Examination of the retroperitoneum for metastatic disease is indicated in patients with malignant tumors. Abdominal CT is most commonly used. Chest radiograph or chest CT is mandatory to exclude pulmonary metastases.

Tumor Markers

a-Fetoprotein (AFP) is a single-chain glycoprotein produced by the fetal yolk sac, liver, and gastrointestinal tract. Various benign and malignant conditions can produce elevations of AFP, including yolk sac tumors of the testis. AFP has a half-life of 5 days, and degradation curves can be followed after orchiectomy to assess for residual disease. One precaution is that the age of the patient must be taken into consideration when monitoring serum levels of AFP because the normal adult reference laboratory values do not apply to young children (294,328,362). AFP synthesis does not stop at birth, and some hepatocytes produce AFP in infancy. Reference normal values for infants have now been established (Table 54.9) (362). Normal adult levels (less than 10 mg/mL) are not reached until 8 months of age. Recognition of this may avoid unfounded concern regarding residual disease following orchiectomy for yolk sac tumor in a young infant. Levels are monitored to

detect tumor recurrence.

Age	Number	Mean ± SD (ng/mL)
Premature	11	134,734 ± 41,444
New born	55	48,406 ± 34,718
Newborn–2 wk	16	33,113 ± 32,503
Newborn–1 mo	43	9,452 ± 12,610
2 wk–1 mo	12	2,654 ± 3,080
2 mo	40	323 ± 278
3 mo	5	88 ± 87
4 mo	31	74 ± 56
5 mo	6	46.5 ± 19
6 mo	9	12.5 ± 9.8
7 mo	5	9.7 ± 7.1
8 mo	3	8.5 ± 5.5

TABLE 54.9. AVERAGE NORMAL SERUM a-FETOPROTEIN OF INFANTS AT VARIOUS AGES

The b-subunit of human chorionic gonadotropin (b-HCG) is a glycoprotein that is produced by embryonal carcinoma and mixed teratomas. The normal value for b-HCG is less than 5 IU/L. The half-life of b-HCG is approximately 24 hours.

Carcinoma in situ

Carcinoma *in situ* (CIS) occurs in the majority of adult patients with testicular tumors, suggesting that it is a precursor to the development of invasive germ cell tumor (352). An increased incidence of CIS has been noted in children with dysgenetic gonads and androgen insensitivity disorders (340,346). Jorgensen and associates (322) noted that CIS was frequently noted in adolescent cases of germ cell tumor. CIS has not been noted in children with endodermal sinus tumors of the testis. The seminiferous tubules adjacent to germ cell tumors in prepubertal children frequently contain cells with enlarged nuclei and clear cytoplasm. Staining of seminiferous tubules adjacent to germ cell tumor for CIS markers, c-kit, and placental alkaline phosphatase (PLAP), was negative in 28 prepubertal testes (317). These cells can be proliferating cell nuclear antigen (PCNA) positive suggesting that they are proliferative and not neoplastic in nature. These differences suggest that the etiology of germ cell tumor in infants is different than in adults.

The diagnosis of CIS is determined by histologic examination of the testis. Testicular biopsies in adults who have previously undergone orchidopexy reveal an incidence of 1.7% (308). In the prepubertal patient, identification of CIS is more difficult. Biopsies at the time of orchidopexy in prepubertal children only rarely have demonstrated CIS (316). The prepubertal patient with CIS should be followed with a repeat biopsy after puberty because the natural history of the disease in younger patients is unknown (307). An exception is the patient with androgen insensitivity or dysgenetic gonads.

Germ Cell Tumors

Yolk Sac Tumor

Yolk sac tumor is the most common prepubertal testicular tumor, accounting for 60% of all tumors (323). More than 75% of childhood yolk sac tumors occur in the first 2 years of life. It is known by several other eponyms, including *endodermal sinus tumor, embryonal adenocarcinoma, infantile adenocarcinoma of the testis, orchidoblastoma,* and *Teilum's tumor.* These tumors are believed to arise from the yolk sac elements. Grossly, the tumor is firm and yellow-white on cross section and hemorrhage is unusual. The characteristic histologic finding in yolk sac tumors is Schiller-Duval bodies (361). Eosinophilic cytoplasmic inclusions are common and specialized staining techniques demonstrate the presence of AFP.

The clinical behavior of yolk sac tumor is quite at variance with its adult counterpart, embryonal carcinoma, despite the histologic similarities. Unlike adult tumors, spread to the retroperitoneal lymph nodes is quite uncommon with an incidence of only 4% to 6% (293,295). Approximately 80% to 85% of prepubertal children present with stage I disease. When distant metastases do occur, they are most likely to be hematogenous metastases to the lung, which are found in 20% of patients.

Radical inguinal orchiectomy is the standard initial therapy for all children with yolk sac tumors. The need for RPLND both for staging and treatment has been controversial. Historically, the addition of RPLND has been associated with increased survival. Staubitz and co-workers reported that patients with retroperitoneal disease could be cured with orchiectomy and RPLND (354). Hopkins and associates (319) found a better survival with orchiectomy and RPLND compared with orchiectomy alone (84% versus 50%). However, all of these patients were given adjuvant chemotherapy and radiation therapy if nodes were involved. Others reported similar survival advantage of node dissection plus orchiectomy in comparison to orchiectomy alone (302). Treatment options considered for retroperitoneal disease included radiation therapy and chemotherapy. A radiation dose of 2,000 to 3,000 cGy has achieved an 84% survival (320). Adjuvant chemotherapy also has been advocated to prevent relapse, but this has not been performed prospectively in a large number of patients.

The need for RPLND began to be questioned based on low incidence of metastases to the retroperitoneal lymph nodes, improved imaging of the retroperitoneum for staging purposes, and availability of a reliable tumor marker for the presence of residual or metastatic disease. It is interesting that most authors who reported improved survival with RPLND did not find evidence of nodal disease (319). CT imaging of the retroperitoneum can identify most patients that have lymph node metastases, but there is a 15% to 20% false negative rate (345). Another justification for omitting RPLND was the development of effective combination chemotherapy that allows salvage of relapsed patients with clinical stage I disease (315,325,332).

The current staging system used by the Children's Oncology Group is listed in Table 54.10. AFP levels are determined at diagnosis and monitored after radical inguinal orchiectomy to determine whether there is an appropriate half-life decline. CT scans of the retroperitoneum and chest are obtained to exclude metastatic lesions.

Stage	Extent of Disease
I	Tumor is limited to the testis. If scrotal orchiectomy has been performed, all margins are negative after resection of proximal cord structures to the level of the internal inguinal ring. Tumor markers are negative after appropriate half-life decline.
II	Microscopic residual disease is present in the scrotum or spermatic cord. Tumor markers remain elevated after appropriate half-life interval. Tumor rupture or scrotal biopsy should occur before complete orchiectomy.
III	Presence of retroperitoneal lymph node involvement.
IV	Distant metastatic deposits.

COG, Children's Oncology Group.

TABLE 54.10. COG STAGING SYSTEM FOR TESTICULAR GERM CELL TUMORS

Clinical stage I patients do not receive additional adjuvant treatment after radical orchiectomy. Chest radiograph, CT, or MRI of the retroperitoneum is recommended monthly for 3 months and then once every 6 months. This surveillance is continued until the patient is 36 months posttreatment. Tumor markers and physical examination are performed at more frequent intervals. Scrotal orchiectomy with negative margins can be treated as stage I, but the proximal cord structures should be resected to the level of the internal ring.

Patients who have undergone prior scrotal biopsy are considered stage II. A completion orchiectomy with removal of all cord structures is performed. This approach has proven to be beneficial in adult patients with gross contamination during removal of germ cell tumors (297,306). All patients undergo abdominal CT to examine for retroperitoneal lymphadenopathy. Patients with enlarged lymph nodes should undergo lymph node sampling or biopsy. Patients that have persistent elevation of AFP and retroperitoneal adenopathy are presumed to have metastatic disease. These patients can be treated as stage III.

Chemotherapy regimens used for pediatric patients with advanced germ cell tumors are similar to those used in adults. Combination chemotherapy using platinum-based therapy is recommended (289). An intergroup study for the treatment of localized and advanced germ cell tumors in children conducted by the Children's Cancer Group and the Pediatric Oncology Group was recently completed (347). All stage II patients are given chemotherapy (cisplatin, etoposide, and bleomycin). At 12 weeks, patients with evidence of recurrent disease or elevation of tumor markers will undergo surgery. Residual retroperitoneal masses postchemotherapy are uncommon (357), but they warrant resection to establish a histologic diagnosis. Patients with persistent viable tumor are then switched to another treatment regimen.

Children with stage III and IV germ cell tumors initially undergo retroperitoneal lymph node sampling. Those patients that develop relapse after initial treatment of a stage I tumor also should undergo biopsy for histologic confirmation. All patients with stage III and IV germ cell tumors receive chemotherapy. Patients with elevated tumor markers or clinically evident retroperitoneal disease after chemotherapy undergo biopsy and/or resection. Radiation therapy is not a routine part of the protocol for treatment of yolk sac tumors. A similar regimen has been used by United Kingdom Children's Cancer Study Group (332). Carboplatin also has been used instead of cisplatin in the UK studies with equivalent success (344). Survival in stage III and IV germ cell tumors (all sites) was 83% and 67%, respectively. However, overall survival for 68 patients with yolk sac testis tumors was 99%.

Mature Teratoma

Teratoma is a germ cell tumor with recognizable elements of more than one germ cell layer: endoderm, ectoderm, and mesoderm. The incidence of teratoma is lower than in adults, but it is the second most common testis tumor in children (295). Teratomas are classified as mature, immature, and malignant. Immature teratomas often have been considered to be malignant tumors, but in children they appear to be benign unless they have foci of malignant cells.

Mature teratomas generally appear well encapsulated on gross examination. Multiple cysts are present, but consistency on cross section varies with the amount of solid tissue present between the cysts. The microscopic appearance varies with the relative amounts of tissue derived from the different germ layers and the degree of maturation (339). Cartilage, bone, mucous glands, or muscle may be evident.

Prepubertal mature teratomas have a benign clinical course, which contrasts with the clinical behavior of teratomas in adults, which have the propensity to metastasize (309,312,315,339). In past years, the majority of these tumors have been managed with radical orchiectomy. However, ultrasound of the testis can demonstrate the cystic nature of this lesion, suggesting the diagnosis of teratoma. Other cystic lesions of the testis such as simple cysts or epidermoid cyst must be considered in the differential diagnosis. The latter lesions generally have a hyperechoic center surrounded by an outer hypoechoic rim (336). Teratoma appears more as complex hypoechoic areas surrounded by highly echogenic signals (326). If the preoperative evaluation suggests a benign intratesticular lesion, then a testicular-sparing procedure can be considered (290,314,334,349). Although only a limited number of patients have been treated with enucleation of the tumor, no recurrences have been reported to date (349). Theoretic concerns include tumor seeding, incorrect diagnosis, or multifocal microscopic disease within the testis. However, frozen section diagnosis of teratoma is possible because of the characteristic histologic features of the tumor. In addition, a detailed review of 21 cases of prepubertal teratoma at the Armed Forces Institute of Pathology did not reveal evidence of multifocal disease or CIS of the adjacent testis (349).

Immature Teratomas

A less common tumor of the testis is immature teratoma. The most common extracranial site is in the ovary, with only 10% occurring in the testes. Immature teratomas have a gross appearance similar to that of mature teratomas. Recently, the pathologic characteristics of immature teratomas in children were reviewed (318). The reviewers found that the incidence of foci of yolk sac tumor increased with the grade of the tumor teratoma, and these patients frequently had elevated serum AFP levels preoperatively (318). Evidence of yolk sac tumor was found in all but one testicular immature teratoma. Recurrence of immature teratomas after resection occurs almost exclusively in patients with elevated AFP or foci of yolk sac tumor in the initial resection specimens. Recurrent tumors typically are yolk sac tumors. Because most patients with recurrent tumor can be salvaged with platinum-based chemotherapy, observation alone is recommended for completely resected immature teratoma (309,335).

Gonadal Stromal Tumors

Leydig Cell Tumor

Gonadal sex-cord stromal tumors are the most common nongerminal testicular tumors in children (299,310). These tumors may show differentiation toward Leydig cells, Sertoli cells, or granulosa cells. Pathologic diagnosis can be difficult because of incomplete differentiation and the presence of some areas that can resemble other entities. *Leydig cell tumors* are the most common gonadal stromal tumor both in children and adults. The peak incidence is age 4 to 5 years. Leydig cells produce testosterone, and the tumor may continue production of the hormone, resulting in precocious puberty. Leydig cell tumors account for approximately 10% of all cases of precocious puberty in boys (358). In addition, the boys may have accelerated skeletal and muscle development, which may not resolve after removal of the tumor (338). Other hormones produced by Leydig cell tumors include estrogens, progesterone, and corticosteroids. These may cause gynecomastia, which occurs more often in adults with Leydig cell tumors (321).

Differential diagnosis of precocious puberty includes pituitary lesions that can be excluded by the finding of prepubertal LH and FSH levels with an increased serum testosterone. Leydig cell tumors also must be differentiated from large cell Sertoli cell tumors, Leydig cell hyperplasia, tumors of adrenal rest tissue, and hyperplastic testicular nodules that develop in boys with poorly controlled congenital adrenal hyperplasia (CAH) (Fig. 54.19) (300,353,359,360). Leydig cell hyperplasia can be distinguished by normal levels of urinary 17-ketosteroids. Testicular nodules in CAH often present in the second decade of life. These lesions tend to occur bilaterally, but bilateral Leydig cell tumors have been reported (292). A family history of CAH is helpful in making the diagnosis. The hyperplastic nodules that develop in CAH resemble Leydig cells histologically but behave biochemically like adrenal cortical cells. Urinary ketosteroids are elevated in patients with 21-hydroxylase deficiency and serum levels of 17-hydroxy progesterone are elevated. Urinary pregnanetriol levels are absent in patients with Leydig cell tumors. Glucocorticoid replacement in CAH generally produces regression of the hyperplastic nodules, but this is not universal (353,359). This may be due to the presence of fibrosis or calcification in the nodule.

FIGURE 54.19. Precocious puberty in an 11-year-old boy due to hyperplastic Leydig cell nodules. (Photograph courtesy of Dr. David Bloom.)

Leydig cell tumors appear well encapsulated with compression of the adjacent testicular tissue. They appear yellow to brown on cross section, reflecting the steroid production by the tumor. The pathognomonic histologic feature of Leydig cell tumor, Reinke's crystals, is present in only about 40% of tumors (339). Increased mitotic

figures or other features suggestive of malignancy are absent in prepubertal Leydig cell tumors. Because malignancy has not been reported in children, orchiectomy is adequate treatment (295).

Sertoli Cell Tumor

Sertoli cell tumors are the next most common gonadal stromal tumor in children. These tumors are not as metabolically active as Leydig cell tumors, but gynecomastia has been reported (305). The typical presentation is usually a painless testicular mass, and these tumors present at an earlier age than Leydig cell tumors. There are limited series of patients with Sertoli cell tumors in children (305,310). Most recommend observation in infants because metastases have not been reported. Histology does not correlate with outcome because they often have features of high mitotic rates, nuclear pleomorphism, and increased cellularity. Treatment is orchiectomy, but examination of the retroperitoneum is warranted to exclude retroperitoneal spread (348). Large cell Sertoli cell tumors have been noted with increased frequency in patients with Peutz-Jeghers syndrome and the Carney complex (298). Large cell Sertoli cell tumors can be confused with Leydig cell tumors. Both tumors are characterized by cells with abundant eosinophilic cytoplasm. The tumors of the adrenogenital syndrome are also another confusing entity in the differential diagnosis.

Gonadoblastoma

Gonadoblastomas occur in children with dysgenetic gonads and are associated with the presence of a Y chromosome in the karyotype (333). Gonadoblastomas are small benign tumors that are bilateral in up to one-third of cases. The tumor is composed of germ cells, sex cord derivatives resembling immature granulosa and Sertoli cells, and occasionally stromal elements. These are the most common tumors found in association with intersex disorders. The risk of tumor formation in patients with mixed gonadal dysgenesis is 25% (350), and the incidence increases with age (333). The germ cell component of gonadoblastoma is prone to malignant degeneration into seminoma and nonseminomatous tumors. It has been recommended that all streak gonads in patients with gonadal dysgenesis be removed (288). Patients with gonadal dysgenesis raised as females should have the gonads removed at diagnosis (311,342). In addition, all undescended testes should be removed, but scrotal testes can be preserved because they are less prone to tumor development. Early gonadectomy is advocated because tumors have been reported in children younger than 5 years of age (311,342). CIS has been demonstrated in gonadal biopsies of children with gonadal dysgenesis, and this has been suggested as a means of identifying those at risk for development of malignant germ cell tumors (340). However, recognition of CIS in prepubertal gonadal biopsies can be difficult, and a negative biopsy does not preclude the later development of a germ cell tumor.

Other Lesions

Leukemia and *lymphoma* are the most common malignancies to spread to the testicle in children. Patients with acute lymphoblastic leukemia who have bulky disease at diagnosis have up to a 20% incidence of testicular relapse (291). Routine biopsies of the testis to help determine further chemotherapy and the need for radiation to the testes are no longer recommended (356). Positive testis biopsies early in remission identify patients at a slightly higher risk for adverse events, but do not influence survival. Testicular involvement occurs in 4% of boys with Burkitt's lymphoma and may be the initial clinical presentation (329). Follicular lymphoma may occur as a primary tumor of the testis (303). The prognosis is favorable if the tumor is localized.

Testicular cystic dysplasia is a rare benign lesion in boys that has been reported with increasing frequency (341,355). It is distinguished by the presence of multiple small irregular cysts localized in the rete testis. More than half the cases are associated with renal agenesis or multicystic renal dysplasia. One proposed the etiology is a defective connection between the efferent ductules originating from the metanephros and the rete testis tubules originating from the gonad. Testis-sparing surgery has been possible in a few cases, and nonoperative treatment has been proposed (341). If the latter approach is used, follow-up with serial testicular ultrasound is advised.

Testicular microlithiasis has been reported in association with testicular tumors. It has been noted rarely in children. Recommendations have been made for noninvasive ultrasound follow-up until adult age (301,304).

GENITOURINARY RHABDOMYOSARCOMA

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in infants and children. RMS accounts for approximately half of all pediatric soft tissue sarcomas and 15% of all pediatric solid tumors. RMS can arise from almost any site and has a peak incidence between the ages of 2 and 5 years. Genitourinary RMS accounts for approximately 20% of these tumors (400). The most common genitourinary sites are paratesticular, vagina, bladder, and prostate. Survival varies by site, and special sites such as vagina and paratesticular have a better prognosis than bladder/prostate primaries (372,413). There is a male predominance for genitourinary RMS (399).

The treatment strategy for RMS requires a multidisciplinary approach involving surgeons, oncologists, radiation-oncologists, and pathologists. As with most uncommon tumors, large clinical trials conducted by groups such as the Intergroup Rhabdomyosarcoma Study Group (IRSG), have led to improved outcomes. The protocols used by the IRSG include multiagent chemotherapy, radiotherapy, and surgical treatment, and have led to current long-term overall survival approaching 70% (373).

Molecular Biology and Genetics

The etiology of RMS is unknown, but subgroups of children with a genetic predisposition have been identified (408). The two major histologic subtypes, embryonal and alveolar, have each been demonstrated to have characteristic genetic alterations that may in part explain their clinical behavior. Evaluation of DNA content in RMS tumors has shown that hyperdiploid tumors are usually embryonal and those with hyperdiploid DNA content may be more sensitive to chemotherapy and irradiation than embryonal tumors without this feature (408). Tumors with tetraploid DNA content are almost always alveolar and may have a worse prognosis (415).

Embryonal and alveolar tumors can often be distinguished by structural chromosomal abnormalities. Alveolar tumors often have a translocation involving chromosomes 2 and 13, the +(2;13) (q35; q14), which affects the PAX3 and FKHR genes (378,416). The reciprocal translocation fuses the PAX 3 gene to the FKHR gene, and this may result in inappropriate activation of PAX3 transcriptional targets, resulting in dysregulation of cell growth. Several alveolar RMS tumors have had another translocation, +(1;13) (P36; q14) (370), which results in fusion of PAX7 to the FKHR gene, which may result in similar dysregulation of cell growth. Identification of these translocations by reverse-transcriptase polymerase chain reactions of fluorescence *in situ* hybridization techniques may allow improved identification of patients with poorer prognosis.

Other genetic abnormalities have been identified in RMS. Mutations of the p53 oncogene have been identified in both RMS and RMS cell lines and may be present in as many as 50% of tumors (377). Dias and co-workers showed amplification of *N*-myc in 4 of 6 alveolar RMS tumors but no embryonal tumors (375). No amplification of *C*-myc was identified in this study. Mutations of the N-ras and K-ras oncogenes have been reported in embryonal tumors (4/8).

The Li-Fraumeni syndrome associates childhood sarcomas with mothers who have an excess of premenopausal breast cancer and with siblings who have an increased risk of cancer (396). A mutation of the p53 tumor suppressor gene was found in the tumors in all patients with this syndrome (398). An increased incidence of RMS has been found in association with neurofibromatosis (401).

Pathology

RMS cells arise from indifferentiated mesodermal tissue and may appear in any part of the body, including tissues that do not ordinarily contain striated muscle. Histologically, it is classified within the category of small, round, blue-cell tumors of childhood, a category that also includes neuroblastoma, Ewing's sarcoma, small-cell osteogenic sarcoma, non-Hodgkin's lymphoma, and leukemia. It may be difficult to distinguish among these tumors by light microscopy alone, and other studies, including electron microscopy, cytogenetics, immunohistochemistry, and DNA flow cytometry may be needed (415).

Gross features of RMS are neither characteristic nor helpful in distinguishing it from other soft-tissue tumors, with the exception of sarcoma botryoides, which is a mass of grapelike clusters arising from within a hollow viscus. These RMS tumors are usually firm, nodular, and of varying size but may be of varying consistency and appearance. They tend to form pseudocapsules, but the tumor often extends outside the pseudocapsule.

There are several histologic variants of RMS. Embryonal RMS is the most common subtype seen in children and accounts for more than 60% of genitourinary tumors

(399). When including the botryoid variant, more recent studies have reported that more than 90% of genitourinary tumors in children are embryonal (405).

The second most common subtype in children is alveolar, which occurs more commonly in extremity and trunk lesions, than genitourinary sites and has been reported to have a worse prognosis (382,405). Recent studies have suggested that site may be a more important predictor of prognosis than histology (365,404). A less common subtype in children is pleomorphic RMS. This tumor is no longer considered a separate entity, but rather an anaplastic variant of the more common embryonal or alveolar RMS (392).

Metastatic spread of RMS is usually through the lymphatics. Regional lymph node metastases may be fairly common and vary with the site of the primary tumor.

Clinical Grouping and Preoperative Staging

Clinical grouping has been used in all IRS studies and is based on the extent of disease and the operative outcome (Table 54.11). Initially, it was based on the premise that total tumor extirpation at the original operation offered the best hope for cure. As the treatment for RMS has evolved and the chemosensitivity and radiosensitivity of this tumor has been recognized, many patients with large tumors or difficult to resect tumors have had biopsy only as the initial operation. After chemotherapy, further resection is considered, and in some locations (i.e., vagina), chemotherapy may be the only form of treatment (364,367). This results in the shifting of more patients from group I to group III. This system depends on the surgical aggressiveness of the surgeon and may result in mutilating surgery. It does not take into account the biologic nature or the natural history of the tumor. A pretreatment staging system that relies on physical examination and imaging studies and examines tumor site, size, invasion, nodal involvement, and distant metastasis was devised (Table 54.12) (394). This pretreatment staging system has been shown to be more predictive of outcome and better reflects the risk by site (404). Low-risk (stage I), intermediate-risk (stage II, III), and high-risk groups are thus identified, and treatment can be tailored to the risk group.

Group I:	Localized disease, completely removed a. Confined to muscle or organ of origin b. Infiltration outside organ or muscle of origin; regional nodes not involved
Group II:	Total gross resection with evidence of regional spread a. Grossly resected tumor with microscopic residual b. Regional disease with involved nodes, completely resected with no microscopic residual c. Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual and/or histologic involvement of the most distal regional node in the dissection
Group III:	Incomplete resection, or biopsy with presence of gross disease
Group IV:	Distant metastasis

TABLE 54.11. IRS CLINICAL GROUPS OF RHABDOMYOSARCOMA

Stage	Sites	Tumor Size	Regional Nodes	Metastasis
I	Orbit Head and neck (superficial) Genitourinary (non-BP)	a or b	N_0, N_1, or N_x	M_0
II	BP Extremity, trunk Parameningeal Other	a	N_0 or N_x	M_0
III	BP Extremity, trunk Parameningeal Other	b N_1, or N_x	N_1	M_0
IV	All	a or b	Any N	M_1

a, ≤5 cm in diameter; b, >5 cm in diameter; BP, bladder/prostate; head and neck, entire area excluding nonparameningeal tumors; M_0, no distant metastasis; M_1, distant metastasis present; N_0, not clinically involved; N_1, clinically involved; N_x, clinical status unknown; other, all other sites; TNM, tumor/node metastasis.

TABLE 54.12. TNM PRETREATMENT STAGING CLASSIFICATION OF PATIENTS WITH RHABDOMYOSARCOMA IN IRV-IV TUMOR SIZE REGIONAL NODES METASTASIS

Treatment: General Principles

Radical surgical excision was the first effective treatment for RMS. For pelvic genitourinary tumors, this consisted of total pelvic exenteration. It was later noted that RMS was radiosensitive (417), but high doses were required for local tumor control. In the 1960s, following surgical excision, adjunctive chemotherapy and radiotherapy were used (409). These efforts showed that survival was significantly enhanced if chemotherapy was routinely administered after surgery (388).

Cooperative trials for RMS began in 1972 with IRS-I (399). This multimodal approach to treatment over the last 28 years has significantly improved survival at all sites in these children (373).

Once it was recognized that RMS was chemosensitive, investigators explored the use of primary chemotherapy to avoid the exenterative surgery performed for genitourinary RMS (407,420). A major aim of these protocols for patients with genitourinary tumors in IRS-II (1978–1984) was the preservation of a functional distal urinary tract with maintenance of the high survival rates achieved in IRS-I (381,411). Unfortunately, primary chemotherapy with vincristine, dactinomycin, and cyclophosphamide (VAC) did not obviate the need for radiation therapy or radical surgery for patients with pelvic RMS. The percentage of patients alive after 3 years was the same for IRS-II as for IRS-I (23). In IRS-III (1985–1992), more intensive chemotherapy was used—VAC plus DOX and cisplatinum—and radiation therapy was initiated sooner. With intensification of treatment for pelvic RMS in IRS-III, there has been an increased rate of salvage of functional bladders with overall survival maintained (386). Bladder RMS was shown to be responsive to chemotherapy and fewer bladders had to be removed for residual tumors (390). It also was demonstrated that partial cystectomy after chemotherapy could be used with good survival (384,387).

The surgical treatment of RMS is site specific, and as mentioned, treatment is directed at the risk group, which is influenced by site and stage. Secondary excision after initial biopsy and readjuvant therapy has a better outcome than partial or incomplete resection and should be planned in cases in which primary excision is not possible. Second-look operations have been used for several types of pediatric tumors to evaluate therapeutic response and to remove any residual tumor after completing initial therapy (366,384).

Specific Sites

Bladder and Prostate Tumors

RMS of the bladder and/or prostate may present with urinary dysfunction, pain, constipation, or a mass, which may be quite large at presentation (Fig. 54.20). Tumors of the bladder usually occur as a botryoid form and grow intraluminally, usually at or near the trigone (381). Urachal and bladder dome RMS are seen less frequently and lend themselves to partial cystectomy. Prostatic RMS tends to present as a solid mass rather than the botryoid form seen in the bladder. Extension into the bladder neck or compression may lead to bladder outlet obstruction. The bladder may be displaced significantly to one side and ureteral obstruction, unilaterally or bilaterally can occur. Determining the actual site of the primary can be difficult. Contrast studies reveal bladder-filling defects within the bladder, or elevation or displacement of the bladder in prostatic RMS (Fig. 54.21). Ultrasound or CT may show the extent of the tumor and reveal evidence of ureteral obstruction and/or hydronephrosis. Biopsy via cystoscopy may establish the diagnosis.

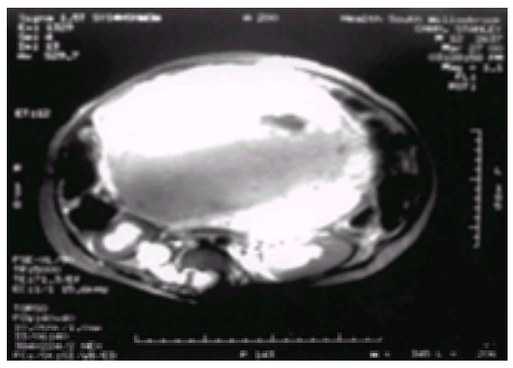

FIGURE 54.20. Computed tomography scan of a large prostatic rhabdomyosarcoma extending into the upper abdomen with bilateral hydroureteronephrosis.

FIGURE 54.21. Excretory urogram demonstrating filling defects in the bladder due to rhabdomyosarcoma. (Photograph courtesy of Dr. Stanford Goldman.)

Historically, many bladder/prostate patients underwent anterior pelvic exenteration. This was associated with a high rate of serious complications (403) and is no longer recommended for initial therapy (412). Biopsy, chemotherapy, and attempts at bladder salvage are keys to surgical management today. This has led to increased bladder salvage while maintaining excellent survival (385,386). Partial cystectomy in 40 patients was reported to achieve a 78.5% survival compared with 79.5% of 131 patients treated with total cystectomy (387). This has been confirmed by others (368). Bladder augmentation or substitution has been used in some of these patients with good functional results (391).

Unfortunately, many of these tumors arise from the trigonal area and are not amenable to local or partial cystectomy. Pelvic exenteration has been used selectively in relapsed tumors (386). Prostatectomy without cystectomy has been performed in selected patients with persistent disease or local relapse (386,402). Local recurrence, however, may be a problem (402).

Retention of the bladder may minimize some of the long-term problems of sexual dysfunction associated with cystectomy for bladder RMS. Cystoscopy and CT or MRI are used to follow and evaluate the tumor response to chemotherapy. If the primary tumor mass is decreasing in size and if histologic review of the biopsy specimens shows a decrease in cellularity, absence or reduction in tumor cells, presence of benign tissue (fibrosis, necrosis, or edema) as maturing rhabdomyoblasts, treatment should be continued with cystoscopic examinations at 1- to 2-month intervals. These favorable histologic findings at 6 months of therapy or later are consistent with a good long-term outcome or cure with a retained bladder. If cystectomy is warranted based on documented persistence of tumor by imaging studies or examination and verified by histologic sections, structures outside the bladder, particularly in the female, should not be removed unless directly invaded by the tumor itself. Thus few bladders will be removed unnecessarily, and few patients will escape tumor control without a needed surgical resection (390).

Exenteration is rarely required for RMS of the prostate. Delayed surgical excision after initial biopsy and chemotherapy can result in bladder salvage in most patients (397).

Paratesticular RMS

Paratesticular RMS arises in the distal portion of the spermatic cord and may invade the testis or surrounding tissues. The majority of paratesticular tumors are of the embryonal subtype, with a high percentage being of the favorable-histology spindle-cell variant. These tumors are generally stage I, low-risk tumors. They account for 70% of childhood RMS and 12% of childhood scrotal tumors (421,422).

Presentation is often a unilateral painless scrotal swelling or mass above the testis. On physical examination, a firm mass is found that is usually distinct from the testis. Ultrasound can confirm the solid nature of the lesion (Fig. 54.22).

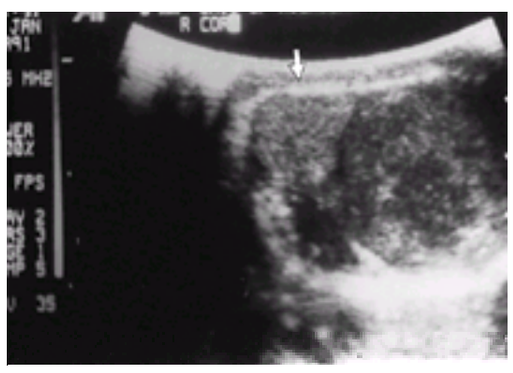

FIGURE 54.22. Scrotal ultrasound of a young boy presenting with a painless mass that shows compression of the testicular parenchyma *(arrow)* by the paratesticular rhabdomyosarcoma.

Initial management includes inguinal orchiectomy with high ligation of the cord structures as with any suspected scrotal tumor (Fig. 54.23). Frozen section of the proximal end of the cord resected should be clear of tumor. If positive, a higher resection should be attempted. Scrotal incisions for biopsy or orchiectomy should not be performed because they violate tissue planes and are associated with an increased risk of local recurrence and systemic lymphatic metastasis. If cord elements remain, removal of the spermatic cord and partial hemiscrotectomy should be considered. In a review of 14 hemiscrotectomy specimens at Memorial Sloan-Kettering Cancer Center, 29% had residual tumor identified (393).

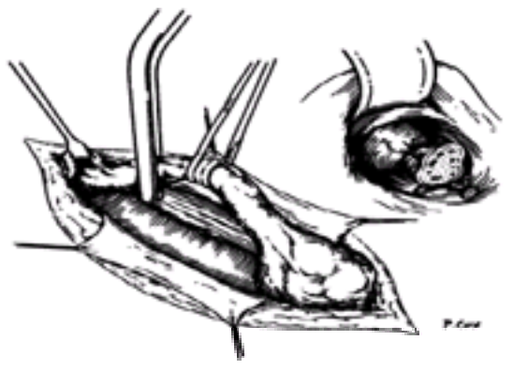

FIGURE 54.23. Drawing showing technique of high ligation of the spermatic cord with vascular occlusion of the cord vessels.

Before the advent of effective systemic therapy, surgery alone produced a 50% relapse-free survival at 2 years (419). With the introduction of multimodal treatment, chemotherapy and occasionally radiation therapy, the survival rates are over 90% (379,422). A metastatic evaluation is performed at diagnosis. CT imaging of the retroperitoneum evaluates the retroperitoneal nodes. Lymphatic spread has been reported to be as high as 28% to 40% in the past (395,410). CT may significantly underestimate nodal status and should be used with caution. RPLND initially was recommended to stage the disease (369). Patients with positive nodes receive radiation therapy to the involved area.

The role of RPLND for paratesticular RMS is controversial (406,414,422). Significant morbidity has been reported with routine RPLND (389). This may be reduced by newer methods of dissection (376,393). Wiener and co-authors (422) reported on 121 patients in IRS-III with nonmetastatic paratesticular RMS who underwent RPLND. Of the patients who had clinically normal nodes, 14% were shown to have lymphatic metastases. Only two experienced regional node recurrence. It was initially felt that RPLND was not necessary in patients with clinically negative nodes and that CT surveillance would be adequate (414,422). IRS-IV revealed that CT underestimated the nodal status in patients and relapse was seen in patients not treated with radiation to the retroperitoneum. Patients over age 10 were particularly at risk and recommendations now include RPLND in patients over 10 years of age (423). Consideration of sentinel lymph node mapping has been discussed and appears feasible but there is little experience to date with this technique for paratesticular RMS (404). Survival of patients with paratesticular RMS with or without positive RPLNDs has been excellent.

Vaginal/Vulvar RMS

Vaginal RMS presents with vaginal bleeding, discharge, or a polypoid, grapelike mass (sarcoma botryoides) (Fig. 54.24). It most commonly originates from the anterior vaginal wall in the middle or distal third of the vagina. Embryologically, this is part of the urogenital septum that ultimately becomes the anterior wall of the vagina and the posterior wall of the bladder. The posterior bladder wall is the most common location for bladder RMS (364,366). Vaginal tumors may invade the vesicovaginal septum or bladder wall because of proximity. Cystoscopy and vaginoscopy are warranted during initial evaluation and at intervals during follow-up (364).

FIGURE 54.24. Mass protruding from the vaginal introitus in a young girl with vaginal rhabdomyosarcoma.

Before 1972, pelvic exenteration was the accepted surgical approach for vaginal RMS. Beginning in 1972, the IRS Group began to enter patients on prospective trials. The first eight patients entered with nonmetastatic vaginal RMS and all underwent primary surgical intervention followed by postoperative chemotherapy with VAC (380). Because vaginal RMS appeared to be responsive to chemotherapy, IRS-II (1978–1984) consisted of a primary chemotherapy regimen followed by delayed surgical intervention and selected radiation. Fourteen of 20 patients (70%) eventually underwent surgical resection. Primary chemotherapy consisted of VAC plus DOX (383).

During IRS-III (1984–1988), three patients were given primary chemotherapy consisting of VAC plus DOX and cisplatin after initial biopsy (clinical group III, stage 1). Only 7 of 23 patients (30%) underwent surgical resection after primary chemotherapy. Six of these seven patients had no viable tumor in the resected specimen and one had maturing rhabdomyoblasts. The presence of rhabdomyoblasts may not signify persistent active cancer. At M.D. Anderson Cancer Center, we have continued chemotherapy without resection when rhabdomyoblasts are found. No viable tumor or rhabdomyoblasts were found after further chemotherapy or subsequent biopsy in these patients. Only six patients in IRS-III underwent radiotherapy (367).

During IRS-IV (1988–1996), only 3 of 21 patients (13%) underwent surgical resection after primary chemotherapy. Three patients had rhabdomyoblasts only, whereas one patient who underwent early second-look surgery had rhabdomyoblasts and a small amount of viable tumor. The indications for these surgical procedures are unclear. No patient in IRS-IV had a cystectomy, and all but one patient are alive with no evidence of disease (NED) (367).

Thus the trend over 25 years of consecutive IRS trials is for less surgical resection, using primary chemotherapy as the means for both local and systemic control. Occasionally, surgeons continue to perform vaginectomy and hysterectomy, but currently there is evidence that this is unnecessary except for relapsed disease. Confusion regarding the significance of maturing rhabdomyoblasts at second-look surgery may encourage these physicians to pursue more radical intervention. Heyn and others found evidence of cellular maturation in tumors of the bladder on chemotherapy (390). They hypothesized that given adequate time, tumor cells increased maturation after therapy will further mature and ultimately disappear. d'Amore and co-workers also found maturation in biopsy specimens after just 6 weeks of chemotherapy (374). They concluded that chemotherapy of RMS tumors causes tumor-cell maturation that follows the pathways of normal muscle cell development. Others have observed no progression of disease when maturing tumor cells were found (368).

Some lessons from review of these patients include the following: (a) Biopsy and primary chemotherapy constitute the initial treatment of choice; (b) resection of organs (vaginectomy or hysterectomy) rarely is required for vaginal RMS; (c) limited vaginal wall resection is acceptable if the tumor can be removed without significant surgical injury; (d) lymph node dissection for vaginal RMS usually is unnecessary unless the nodes are clinically positive, in which case a biopsy should be performed; and (e) the presence of rhabdomyoblasts may be evidence of response to chemotherapy, and continuing chemotherapy without resection appears to provide adequate treatment.

Vulvar RMS presents as a firm nodule embedded in the labial folds, or it may be periclitoric in location. Vulvar lesions may have alveolar histology, but because most are localized, they also have a good prognosis.

Uterine RMS

Previous studies have suggested that uterine RMS represents a distinct group of patients who present at an older age and have less response to treatment and thus poorer prognosis compared with vaginal RMS (380,383). A review of IRS III and pilot IRS IV treated by primary chemotherapy and delayed resection, suggests that these previously held beliefs may not be true (371). Patients with uterine RMS in recent studies also may present as younger patients and respond well to chemotherapy. With a primary chemotherapy approach and conservative surgical therapy, it may be possible to salvage the uterus in selected patients much like in vaginal RMS (371).

Appendix 1
Appendix 2

Most patients seen by a pediatric urologist begin their care in the office, which may be academic or private practice based, and either closely tied to a children's hospital or geographically separate. The purpose of this chapter is to present some basic aspects of current office practice in pediatric urology. Patient problems and the structural components of office practice will be discussed. The physical plant, office personnel, documentation, and record-keeping pertaining to pediatric urology will be presented along with the basics of Current Procedural Terminology (CPT) and International Classification of Diseases (ICD) coding in pediatric urologic billing. Particular attention is given to establish compliance with federal regulations. Patient demographics based on ICD-9 codes and procedural codes will be reviewed. These data will provide insight into the day-to-day clinical practice of pediatric urology and the variety of outpatient services provided. The clinical practice, such as procedures presently performed in the office (e.g., neonatal circumcision, lysis of adhesions, meatotomy), are discussed as well as essentials of the pediatric office laboratory.

The “back office” organization, including the examination rooms and personnel necessary to complete the patient's evaluation and treatment, and the role of the pediatric urology nurse and medical assistant will be reviewed. Special attention to “compliant” record-keeping and documentation is stressed.

Eighty percent of children seen in the office will not require an operation. Patient diagnoses in this nonoperative group include voiding dysfunction, hematuria, enuresis, urinary tract infection (UTI), genital problems in the male and female, and some forms of urolithiasis and hydronephrosis. An extensive exposition on singular conditions or diagnoses is not attempted because they are addressed in other portions of this text, but an office-based methodology to all aspects of the management of children with ambulatory urologic problems is provided.

Office Practice of Pediatric Urology

Patients are referred to the pediatric urologist by their general practitioner, family practice physician, and pediatrician, and as secondary referrals from other urologists. In both rural and urban practices, an increased number of referrals will be from physician extenders such as nurse practitioners and physician's assistants. The referral is often in the form of a consultation, with limitations on the number of visits and procedures that are approved before the visit. These potential limitations must be realized by the treating physician to prevent adding expense to the patient or the office and associated institutions. Unfortunately, this process may work in opposition to the delivery of appropriate care.

The common problems referred to the pediatric urologist are recorded in the literature (Table 55.1). In this author's office practice, the most common problems seen are voiding dysfunction, enuresis, UTIs and vesicoureteral reflux, penile anomalies, scrotal anomalies, and hydronephrosis. Many patients have more than one urologic complaint. This most commonly is observed in patients with voiding dysfunction, UTI, and/or vesicoureteral reflux. The initial urinary tract infection often leads to the discovery of voiding dysfunction and vesicoureteral reflux (105). Overall, 42% to 45% of the new patients seen were sent for evaluation of urinary infection, wetting and voiding dysfunction, and vesicoureteral reflux (Table 55.2).

	Knound, 1981	Rabinowitz, 1982	Skoog, 1999	Scherz, et al., 1999[a]
Total patients seen	2,295	1,574	1,483	11,354
New patients	682	533	534	5,684
Voiding dysfunction and/or UTI	257	256	192	2,374
Hypospadias	102	71	62	1,457
UDT/hemiatrophy/cryptorchidism	109	82	79	2,553
Meatal stenosis	34	32	31	542
Surgical cases	694 (29%)	330 (21%)	306 (21%)	3,875 (27%)

[a]Includes patients of six pediatric urologists.
UDT, undescended testicles; UTI, urinary tract infection.

TABLE 55.1. PATIENT DEMOGRAPHICS

		New Patient Visits (1999)	
Category	ICD-9	Skoog (%)	Scherz et al. (%)
Voiding dysfunction and wetting	596.54, 596.59, 788.1, 788.30, 788.36, 788.37, 788.39	23	26

ICD, International Classification of Diseases; UTI, urinary tract infection; VUR, vesicoureteral reflux.

TABLE 55.2. DIAGNOSIS OF NEW PATIENTS BY PERCENTAGE

Penile anomalies run the gamut, with the largest number of patients referred for preputial issues. Questions relating to circumcision or complications of circumcision, such as inadequate resection, penile adhesions, and meatal stenosis, are most common, followed by hypospadias and issues related to repair.

Scrotal abnormalities constitute 15% to 22% of new patient visits. The diagnosis of undescended testis predominates, followed by inguinal hernia, hydrocele, and varicocele. Hydronephrosis, usually diagnosed prenatally, constituted 8% of all new patients. The etiology of the hydronephrosis varied, but most commonly was associated with posterior urethral valves, ureteropelvic junction obstruction, duplication anomalies, and vesicoureteral reflux. Complex problems (i.e., the “other” category), including bladder exstrophy, cloacal exstrophy, multicystic kidney, renal agenesis, urachal anomalies, vaginal abnormalities, myelodysplasia, sacral agenesis, ambiguous genitalia, urogenital sinus, and imperforate anus, were least commonly seen.

THE PEDIATRIC UROLOGY OFFICE

The pediatric urologist's office serves several functions, the most important being a site of patient evaluation and care. Other activities will depend on whether the practice is university-based or a private practice. In the former, data entry and evaluation may be emphasized, whereas in the latter, business activities may predominate.

The personnel are selected with focus on the needs of children and their parents. The average pediatric urologist employs 3.7 full-time equivalents in the office. Group practices may be able to economize on scale. The staffing for most offices might be something as follows:

Front office:	Check-in
	Check-out
	Receptionist/phone
Back office:	Nurse
	Operating room (OR) scheduler
	Physician extender
	Transcriptionist
Business office:	Billing
	Collections
	Office manager

The actual number of employees in the office may differ dramatically in a university-based practice, where many of the aforementioned jobs will be performed centrally. In smaller private-practice offices, some of these jobs may be combined by multitasking. In larger offices, other employees may perform specialized tasks that are not listed, such as information-technology specialists, research coordinators, managed-care specialists, and the like.

Successfully running a medical practice has become increasingly difficult—many factors contribute to this. Managed care typically is cited as the chief reason for the difficulty, and that may be true. The reimbursement given to physicians for the work that they do has decreased steadily over the past two decades. Furthermore, effort expended to collect these payments has dramatically increased; reasons for this include increased paper work and “red tape” required to see patients, perform tests, and schedule surgery. This bureaucracy results in delays and/or reimbursement denial. All result in inefficiency and increased overhead.

Issues that also weigh heavily on most practicing physicians include concerns with federal and state regulations involving medical practices, adequate record-keeping and documentation, and precise coding of office medical services to ensure proper reimbursement. Unfortunately, the list of non–patient-related issues continues to expand, which tends to increase overhead and reduce time available for patient care.

There are two important related strategies for dealing with some of these issues: time management and standardization. An electronic medical record (EMR) seems to be the key to both. The greater the ability to integrate all demographic information with clinical information, the greater the ability of the practice to defend against all of the impediments. Information is power when it is accurate and easily accessible, and it now is vital to the practicing physician.

Standardized forms are the basis of data capture and ensure practice uniformity. This enables consistent collection of demographic information about patients, as well as clinical, coding, and billing information. EMRs obviate the need for forms because the information can be entered directly. In addition, specialized information can be scanned into the medical record. Patient identification and medical history forms can be sent to patients before their appointments to expedite flow through the office.

When an EMR is not available, standardized history and physical forms may improve efficiency and facilitate thorough documentation of the office visit as required by Medicare, Medicaid, and insurance carriers (Forms 1 to 3, Appendix 1). Compliance with the Health Care Financing Administration (HCFA) regulations ensures that claims are filed properly and maximizes the potential for reimbursement. The level of service is dictated by the documentation of the history, physical examination, and decision-making process (i.e., the three elements of the encounter). Without the proper documentation, justification for an appropriate level of service cannot be made. Therefore it is important to be thoroughly familiar with the grids that determine the level of service for evaluation and management (E/M) codes. A sample grid, which should be posted to assist in proper coding, is shown in Forms 4 to 8 in Appendix 1 (127).

The *superbill* is the critical form in the office. It is found in almost every office and lists the commonly seen diagnoses (ICD-9) and CPT codes. It is extremely important that the codes are accurate and current and that they reflect the services rendered. The superbill can be modified to suit a particular practice, but it is critical that the physician has a clear understanding regarding proper coding of services provided. Office personnel may check for errors, but errors in coding most often occur when this task is delegated to someone other than the physician. When communication between the physician and billing personnel breaks down, the result is usually undercharging of the patient. Unfortunately, if overcoding occurs, the physician is liable. Inefficiency in billing is a lose–lose situation for the physician and the office. Modifiers can be used to more accurately code procedures that are unique (4). These two-digit codes are added to the five-digit CPT designation, which informs the payer that a unique service was rendered. Numerous modifiers should be understood by the practicing physician to ensure appropriate potential for reimbursement (Table 55.3).

22	Unusual procedural services Service provided is greater than that usually required for the listed procedure.
24	Unrelated E/M service by the same physician during a postoperative period For service that is unrelated to the original procedure
25	Significant, separately identifiable E/M by same physician on the same day of other service or procedure
50	Bilateral procedures
51	Multiple procedures
52	Reduced services
57	Decision for surgery An E/M service that resulted in the initial decision to perform surgery.
62	Two surgeons: 270-7

E/M, evaluation and management.

TABLE 55.3. COMMON CODING MODIFIERS USEFUL TO THE PEDIATRIC UROLOGIST

Patients often request more information and appreciate educational materials. These may take the form of disease- or problem-specific pamphlets, reprints of articles that the physician has written, key general references, or reference to websites containing more information (some practices are developing their own websites with such information). When surgery is planned, standardized information (e.g., pamphlets or even videotapes) can be very useful. This information can include preoperative and postoperative instructions and can be individualized to the anticipated procedure. Such information can save time and save some telephone calls, as well as ease parental anxiety with specifics of postoperative care and expectations.

Back Office and Equipment

Examination Room

The examination room must be appealing, friendly, and comfortable for the parents and patients. It needs to be warm, not hot or uncomfortable. Every effort must be made to make the child relaxed and comfortable in the examination-room setting. Children frequently are resistant to hospital examination gowns, and the child's parent or caregiver is the first person to enlist to help get the child into the appropriate attire.

Plenty of distractions, such as a chalkboard, in-room toys, puzzles, and books, will keep the child and his or her siblings at ease and occupied. Caregiver involvement in playful activities while the physician obtains measurements and vital signs aids patient confidence and promotes acquisition of accurate data, especially the blood pressure (BP). If the child is old enough, he or she can be kept at ease by allowing him or her to participate in the history taking and allowing contact between the parent and child, especially if the child is between 2 and 5 years of age. Many children will look forward to returning to a well-planned and well-equipped office, because going there previously was a “fun” experience.

The examination room itself should have an examination table with potential for lithotomy positioning. A bright light source adjacent to the table will allow illuminated perineal examination. This is a necessity when inspecting female patients for interlabial masses, urethral prolapse, urogenital sinus, and ectopic ureteral orifices. An x-ray viewing box and an erasable chalkboard should be placed in the room. These are both indispensable in showing parents the “hydronephrotic kidney,” or for drawing the duplication anomaly so that they can better understand their child's condition and how it can be corrected. A well-stocked cabinet should contain tape, K-Y Jelly, povidone-iodine (Betadine) swabs, alcohol swabs, cotton swabs, tongue blades, sterile urine cups, 4 × 4's, adhesive remover, and adhesive liquid. Adjacent to the examination room are a scale to weigh the patient, sphygmomanometer with appropriately sized cuffs, and a stadiometer to measure height. The nurse or medical attendant will record these results on the patient's records and growth chart as necessary.

Equipment

A dedicated minor-procedure room is ideal, because all equipment can be located there. A good light source, examination table, and cautery are essential. Commonly performed procedures are listed in Table 55.4. Basic operating instruments include a “circumcision tray” with scissors, fine hemostats (both straight and curved), a needle holder, surgical-knife handle, probe and director, and Gomco clamps with all three diameters available (1.1, 1.3, and 1.45 cm). This tray will provide most of the equipment needed for the majority of in-office procedures (Fig. 55.1). The infant/child “papoose board” is effective and well-tolerated in the restraint of small infants. Either an electrocautery device or disposable battery cautery also should be available.

TABLE 55.4. OFFICE PROCEDURES

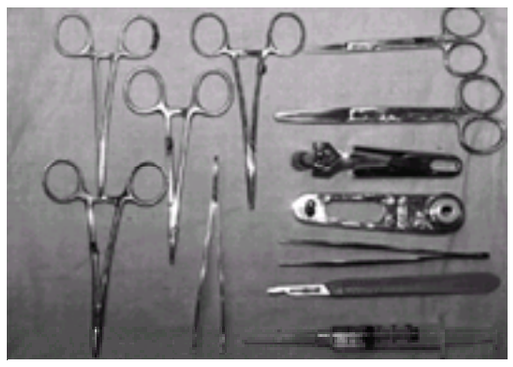

FIGURE 55.1. Basic in-office operative procedural tray.

Pain management is an extremely important aspect of office surgery. In general, topical anesthetics or locoregional nerve blocks (penile block) are used. For topical use, a cream containing lidocaine and prilocaine [eutectic mixture of local anesthetics (EMLA)] decreases the pain associated with a variety of minor procedures, such as lysis of adhesions and meatotomy (75). For topical analgesia to succeed, at least 1 hour must elapse between application and the time of the procedure. The analgesia may last 1 to 2 hours. Application of the EMLA cream under a Tegaderm transparent dressing keeps the cream in apposition to the operative site; the cream can be applied at home before the procedure. A single application of the cream is associated with few complications and has not been shown to cause clinically important methemoglobinemia in term neonates (56).

The two most commonly used local anesthetics for local regional penile blocks are lidocaine and bupivacaine, without epinephrine. The maximum dose of lidocaine is 4.5 mg/kg and for bupivacaine is 2.5 mg/kg. A ring block of local anesthetic placed into the skin at the base of the penis provides effective analgesia for circumcision (100), but does not necessarily provide analgesia for the glans. The classic dorsal penile nerve block (DPNB) with a subpubic injection under Buck's fascia provides effective total penile analgesia but has the potential complications of bleeding, injury to the neurovascular bundle, and rarely, gangrene (60). *Epinephrine should not be used in any penile block.*

Patient catheterization to obtain a urine specimen or for teaching intermittent self-catheterization requires a supply of catheters available in the office. All catheters, gloves, and surgical stock supplies should be latex-free. The catheter assortment should include straight, coudé tipped, and Foley, and sizes from 3 to 16 Fr. Specialty catheters such as the hydrophilic “Lo-Fric” catheters also should be available. An assortment of small bougies from 6 to 12 Fr and meatal dilators can be used in a variety of clinical situations and sometimes obviate the need for surgical intervention for meatal stenosis.

In-office ultrasound for bladder-volume assessment is an absolute necessity. It can offer a noninvasive means of determining postvoid residuals and also can be used for behavior-modification teaching programs in children with voiding dysfunction. Formal in-office ultrasound is expensive and requires additional training. However, it can provide on-site evaluation of the kidneys and bladder, and is particularly useful in monitoring postoperative patients. Furthermore, patients with refractory day and/or nocturnal enuresis can be screened in the office for upper tract anomalies and effective bladder emptying. With special probes, the testes can be evaluated for size and lesions (185).

Urodynamic equipment varies considerably in its cost, complexity, and utilization. In a university-based practice, the equipment is integrated with the fluoroscopy unit in radiology. Complex cystometrograms with intraabdominal pressure manometry, electromyography (EMG), and voiding cystourethrography are recorded and monitored simultaneously. In this author's office space, a uroflowmetry measurement is available with remote monitoring so urination can be completed in an

unobtrusive manner. In sensate patients, sedation may be necessary for complex studies. Consequently, complex urodynamics may be difficult to perform in an outside office setting unless a specific center for pediatric assessment (pediatric continence center) is established. This type of center can offer full urodynamic testing and biofeedback and behavior modification treatment of incontinence and voiding dysfunction (109).

The pediatric office laboratory is focused primarily on urine evaluation. The typical laboratory consists of a centrifuge, microscope, refrigerator, and urinalysis multisticks. The standard analysis includes pH, protein, blood, nitrites, leukocyte esterase, glucose, and specific gravity and sediment analysis for white blood cells (WBCs), red blood cells (RBCs), casts, crystals, and bacteria. All results are recorded in the patient's office record. Subsequent cultures may be performed in a central laboratory or the office. The federal government has provided clinical laboratory improvement amendments (CLIA), which regulate laboratory testing. A specific current list of provider-performed microscopic (PPM) procedures is available at www.phppo.cdc.gov/dis/clia/ppm.asp.

Medications are administered in the office setting by the physician and/or nurse. Testosterone injections to stimulate penile growth before hypospadias or epispadias repair occasionally are necessary. Testosterone cypionate 40 to 50 mg/m ^{2} given 2 and 5 weeks before surgery has been used (63). Pediatric dosage for transdermal testosterone is unavailable. Human chorionic gonadotropin (hCG) in various dosage schemes is used in patients with cryptorchidism (132). Sequential intramuscular (IM) administration is necessary. IM or intravenous (IV) antibiotics are administered to children at risk for infection at the time of tube removal or office procedures.

Minor Surgical Procedures

Most office procedures, such as circumcision, lysis of adhesions, and meatotomy, do not require general anesthesia. If a local regional anesthetic or topical anesthetic are judged inadequate after discussion with the patient's parents, the patient is better served in a formal outpatient operating-room setting.

Newborn Circumcision

Contraindications to circumcision include any penile abnormality. This includes hypospadias, epispadias, chordee, megalourethra, and webbed penis. A history of bleeding diathesis or recent acute illness precludes office circumcision.

The four guiding principles in the performance of circumcision include aseptic technique, removal of an appropriate amount of inner and outer preputial skin, hemostasis, and cosmesis.

All neonates undergoing circumcision experience pain from the procedure. Neuroanatomic components and neuroendocrine systems are sufficiently developed to allow transmission of painful stimuli in the neonate. A lack of behavioral responses (including crying and movement) does not necessarily indicate a lack of pain (5). Preterm and term infants demonstrate similar or exaggerated physiologic and hormonal responses to pain compared with those observed in older children and adults (30). Consequently, all patients undergoing penile procedures require an anesthetic. In studies comparing EMLA with locoregional nerve block, the nerve block was superior to EMLA as measured by changes in physiologic and behavioral monitors. Dorsal penile nerve block or penile ring block is preferred (100).

The infant is restrained on a papoose board, which inhibits movements of the extremities. His genital area is scrubbed with a warm Betadine scrub and painted with Betadine solution. The area is draped in a sterile fashion. A bilateral dorsal penile nerve block is performed by injection of a small amount of lidocaine or bupivacaine laterally beneath Buck's fascia; alternatively, a ring block at the base of the penis is performed. At least 10 minutes should be allowed for anesthetic set-up.

The circumcision is performed with one of three devices: the Gomco, Plastibell, or Mogen clamps (Fig. 55.2). The Mogen clamp should be used only by individuals experienced with its use; it can result in serious injury to the glans penis. All of these devices rely on compression for hemostasis. The first step is to release the inner preputial skin from the glans penis. Failure to perform this simple task will leave too much inner preputial skin or remove too much skin from the shaft of the penis. On most occasions, a dorsal slit of the preputial skin is necessary for placement of the bell after takedown of the inner preputial skin adhesions. The surgeon must ensure that the inner skin is retracted proximal to the coronal sulcus.

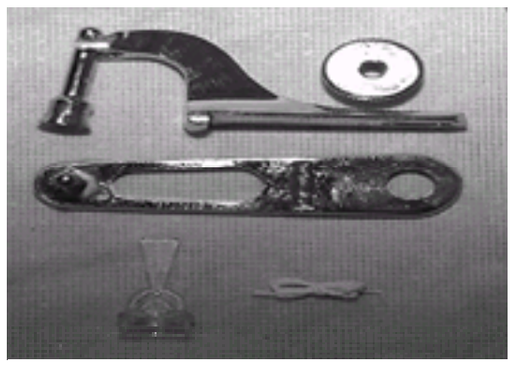

FIGURE 55.2. Gomco clamp *(top)* and Plastibell clamp *(bottom).*

At this time, the appropriate-size Plastibell clamp is positioned over the glans penis. A suture is tied over the ring to compress the skin edges. The distal prepuce is excised. The ring remains in place for 5 to 7 days as the edges heal. Using a ring that is too small should be avoided because it will compress the glans and lead to ischemia. If a Gomco clamp is used, the appropriate-sized bell is positioned over the glans penis. The bell over the glans penis is positioned in the clamp, and the prepuce to be excised is pulled distally through the hole in the clamp. Care is taken to ensure that an equal amount of inner and outer preputial skin is clamped onto the bell. The clamp is tightened and the prepuce distal to the clamp is excised. *Never excise with electrocautery with a metal bell in place* (124). The crushing of the vessels between the clamp and bell provides hemostasis. It is important to leave the tissue clamped for 5 to 7 minutes. The most common problem immediately seen with the compressive devices is bleeding. Use of cautery, direct pressure, or suture ligation usually is successful. Other methods include topical thrombin, Gelfoam, dilute epinephrine sponges (1:10,000), and silver nitrate.

The overall complication rate is 0.2% to 5% for neonatal circumcision. Complications range from simple bleeding to Fournier's gangrene. In a large series of patients, Gee and Ansell noted the Plastibell to have a higher rate of infectious complications than Gomco circumcision (65). Bleeding complications are similar between the two methods. Wound separation is more common with a Gomco clamp (41,62,65).

Lysis of Adhesions

Penis. Penile adhesions are of two varieties: those resulting from inadequate takedown of the inner preputial skin at circumcision, and the dense attachment of penile shaft skin to the coronal sulcus or glans penis (Fig. 55.3). The latter is caused by a skin bridge between the crushed shaft skin and the denuded corona or glans penis. It can be prevented by retraction of the shaft skin following neonatal circumcision. Problems arise resulting from the accumulation of smegma under the bridge and infection.

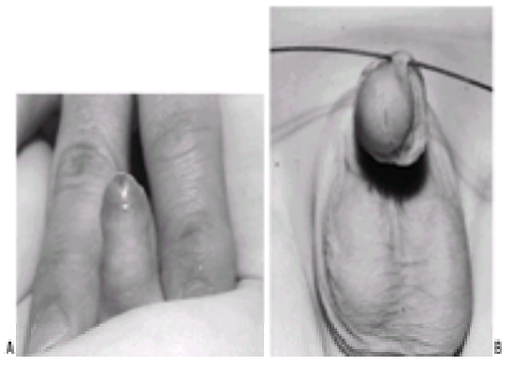

FIGURE 55.3. A: Loose penile adhesion. **B:** Dense penile adhesion.

In the office, EMLA cream is applied to the penis under a Tegaderm occlusive dressing. It is left in place for 60 minutes. The filmy adhesion caused by previous inadequate lysis can be pushed back easily with a gauze or gentle blunt dissection. The “thick” skin bridge requires a good aseptic cleansing followed by application of a hemostat across the bridge. If pain is noted, a local injection of lidocaine is necessary. The clamp is removed and the skin bridge is incised with scissors. An absorbable suture on the shaft and coronal sulcus may be necessary. Topical bacitracin ointment is applied until healing has occurred.

Labia. Labial adhesions are estimated to occur in 0.6% to 3.0% of prepubertal girls. The peak incidence is at 13 to 23 months of age (103). The cause of labial adhesions is not known, but probably is related to low estrogen levels in prepubertal children. Local irritation results in a denuded labia minora edge. Contact between the edges result in reepithelialization and midline fusion.

Children with labial adhesions usually are asymptomatic, but many have dysuria, UTIs, or recurrent vulva or vaginal infections (102,164). Urinary retention rarely has been present. Labial adhesions can be a result of sexual abuse. This should be considered when treating a child with this condition (92,108,117).

Topical treatment with conjugated estrogen has been the mainstay of therapy, with a success rate of up to 88% (7). Conjugated estrogen (Premarin) vaginal cream 1% applied to the area of adhesion with a cotton swab and gentle pressure twice daily for 2 to 4 weeks usually results in separation. Slight vulvar pigmentation and increased vascularity will be noted. Topical treatment should not exceed 8 weeks.

When symptoms persist and topical estrogen therapy does not work, surgical lysis of adhesions is indicated. Topical application of EMLA cream under a Tegaderm transparent dressing provides adequate local anesthesia (75). The diaphanous adhesion usually is separated easily with a moistened cotton swab or sterile probe with midline pressure. The thicker, nontransparent adhesion may require a hemostat to spread the adhesion. Postoperatively, the application of conjugated estrogen cream to the perineum with a cotton applicator twice a day for 1 week will allow reepithelialization of the edges of the labia without refusion in the midline.

Meatotomy

Meatal stenosis is the most common long-term complication of circumcision (30). It likely results from recurring meatitis with epithelial loss at the meatal edge and side-to-side adherence. A pinpoint meatus develops, which deflects the urinary stream dorsally and can cause dysuria or blood spotting in the underwear (Fig. 55.4).

FIGURE 55.4. Meatal stenosis with only a 24-gauge intracatheter able to enter the meatus.

Office meatotomy using EMLA cream has proved to be effective, simple, and cost-effective (26,157). The cream is applied generously to the glans penis and held in place with an occlusive transparent membrane (Tegaderm). The patient remains quiet for 60 minutes as the local anesthetic takes effect. Home application may streamline this process. After the dressing is removed, a prong of a straight hemostat is placed within the urethral lumen on its ventral surface and an appropriate amount of tissue is clamped in the hemostat. The clamp is left in place for 1 minute then released. The crushed tissue is cut with sharp scissors. It usually is not necessary to use any other form of hemostasis. A small amount of antibiotic ointment is applied to the edges of the meatus; this application is repeated at least twice a day for 1 week after surgery.

History and Physical Examination: General Principles

In spite of all the technologic advances in medicine, a well-performed history and physical examination remain the clinician's most important tools. The physician's initial entry into the examination room sets the stage for the encounter. Knowledge of the patient's name and a cordial greeting to the parents and/or caregivers will alleviate some of the tension of a first visit. The clinician should take the time to preview available patient information. An obviously informed physician instills confidence in the patient and family.

History

An older child should participate in the interview process. The clinician should listen carefully to the parent because they usually provide the information that is critical to making an accurate diagnosis. In the younger patient prenatal history, including the results of antenatal ultrasound studies, should be addressed. The birth history and possible complications should be elicited. The results of the postnatal physical examination may provide clues in patients with cryptorchidism, hernias, hydroceles, and neonatal torsion. Family history of genitourinary abnormalities is important because many of the encountered abnormalities are inherited. This is particularly true in hypospadias, renal disease, cryptorchidism, and vesicoureteral reflux (24). Before the patient's visit, screening of relevant medical records and imaging studies will direct the subsequent interview and imaging needed in the patient's evaluation.

Physical Examination

Skilled physicians begin their observations of physical characteristics, dexterity, coordination, and mental aptitude during the interview. An active child climbing over the examination table or hiding under the sink demonstrates normal coordination and gross motor ability. The patient's interactions with surrounding objects and people, response to sounds, and speech pattern give clues about mental development. The age of the child dictates the different techniques to employ to gain patient cooperation. For infants and toddlers, a parent should be close at hand or holding the child, which will provide a comfortable setting for evaluation. Toys, picture books, or food will distract a 2- to 4-year old. Asking the patient's mother for advice is invaluable. Patients who have had previous poor experiences in the physician's office offer the greatest challenge. This situation is common in patients with voiding dysfunction, urinary infections, and ambiguous genitalia. Undue or inappropriate acting out may be a sign of significant psychosocial stress or personality disorder and should be recognized before examination. In severe cases, several visits may

be necessary before physical examination is possible. The physician should ask the child's permission and be gentle.

Standard measurements of height, weight, pulse, and BP should be taken. Patients who will be followed for a lifetime (e.g., for exstrophy or posterior urethral valves) should have their growth and weight charted on standardized growth charts. This allows assessment of normal development. Pulse varies with age; up to 3 months, the range is 90 to 200 beats per minute; from 3 months to 2 years of age, it is 100 to 190 beats per minute; from 2 years to 10 years of age, pulse ranges from 60 to 140 beats per minute; and older than 10 years of age, from 60 to 100 beats per minute (169). A heart rate that is higher than normal may indicate primary cardiac disease, an underlying systemic or metabolic disorder, infectious disease, or fever. The BP is an important measurement because a variety of abnormalities treated by the pediatric urologist may be the cause of hypertension. A normal BP is defined as systolic and diastolic BP below the ninetieth percentile for age and sex. Hypertension is defined as average systolic or diastolic BP greater than or equal to the ninety-fifth percentile for age and sex measured on at least three separate occasions. The keys to accurate BP measurement are proper cuff size; a controlled environment; and a resting, quiet patient. The age- and sex-related normal values, as well as specific recommendations for the measurement of BP, are published in the National Institutes of Health (NIH) publication no. 96-3790 (171).

The general physical examination and single organ system examinations must have specific content documented in the medical record. This documentation allows for compliance with billing of evaluation and management services. The highest level of a physical examination is the comprehensive examination, defined as a general multisystem examination or a complete examination of a single organ system. (The elements of the genitourinary system are listed in Appendix 2.) Unfortunately, this examination is geared toward adults and not children; however, it provides the government's view of appropriate content.

The skin should be inspected for color, turgor, lesions, masses, and defects. Essentially all lesions originating in the skin of children are benign. A mass that moves freely over the underlying fascia is likely benign. A lesion fixed to the underlying tissues is possibly malignant and requires appropriate referral. Pigmented lesions of interest to the pediatric urologist are hypopigmented ash-leaf spots seen with tuberous sclerosis. Light-brown macular lesions (café au lait spots) greater than 10 cm in size or more than five in number are consistent with neurofibromatosis. Diffuse neonatal hemangiomas with cutaneous and visceral lesions may result in urinary tract bleeding (79). Perineal genital condylomata or herpetic lesions should alert the examiner to possible sexual abuse.

Low-set ears, where the superior rim of the pinnae is below a line drawn posteriorly from the superior orbital rims, may be associated with renal anomalies.

Breast examination is important in precocious puberty and normal sexual development. Up to age 8, there is no discernible difference between boys and girls in size and shape of the nipples and the chest wall. In early adolescence, a tender subareolar nodule develops in boys and girls. In males, this can be the precursor of adolescent male gynecomastia. Gynecomastia can result from adrenal and gonadal lesions as well as renal disease (55). In females, the mean age for the start of breast development is 8.5 to 10 years of age (70).

Examination of the chest and heart is performed to ensure absence of acute respiratory illnesses or signs of congenital heart disease such as gallops, extra heart sounds, or murmurs.

Abdominal examination is an integral aspect of the genitourinary evaluation. The abdomen is observed for laxity as seen in prune-belly syndrome and cutis laxa. Umbilical abnormalities include hernias, masses, or drainage. In the neonate, drainage from the umbilicus may be a result of a patent urachus, omphalomesenteric duct, or urachal sinus. Auscultation allows assessment of bowel activity and bruits. Palpation for organ enlargement, masses, kidneys, costovertebral angle tenderness, and location of the bladder should be performed. The back should be inspected for occult midline spinal lesions as lipomas, hairy patches, dermal sinus, or signs of spina bifida occulta. Flattened buttocks with shortened gluteal cleft is indicative of sacral malformation or agenesis. Having the patient stand, bend at the waist, and touch his or her toes allows detection of scoliosis.

Genitourinary examination requires a cooperative, trusting patient. The male patient, especially the adolescent, should be examined supine and upright to detect varicoceles. The penis should be inspected and prepuce retracted, if possible, to expose the meatus. The prepuce is fully retractable in 90% of 5-year-old boys (34). The location and size of the meatus is noted. The meatal size may be difficult to assess, and the ability to gently evert mucosa at the meatal edge suggests normal anatomy. Observing the patient void can be critical to the assessment of meatal anatomy. The location of the meatus and urethra should be noted clearly, as well as the location of the median raphe along the shaft of the penis and completeness of the prepuce. The stretched length of the penis and its width are measured in cases of ambiguity or microphallus. Standards for penile length based on gestational age are established (44).

The scrotum and its contents should be inspected and palpated. Scrotal development and degree of rugation is noted. Palpation of each scrotal half between the thumb and index finger with occlusion of the internal ring will assist in testicular palpation. The location of each testis, its size, and consistency is recorded. The Prader orchidometer, a series of comparative ovoids, is used to measure testicular size, especially if a size difference is noted on palpation (ultrasound also can be used to obtain testicular measurement, particularly in the patient with a hydrocele). A ballotable mass should be transilluminated and assessed for communication of the fluid with the abdominal cavity. Hernias and communicating hydroceles should be reducible, whereas hydroceles do not decompress easily. Infants and children can be examined in the squatting or knee–chest position to enhance scrotal and testicular evaluation.

Genitourinary examination of young girls is accomplished with the patient in the supine position and the legs in the froglike position. Gentle separation of the labia majora will expose the introital anatomy. The size of the clitoris is noted, as well as the location of the urethral meatus and the hymenal ring. Labial adhesions prevent visualization of these structures. A bifid clitoris suggests female epispadias. Occasionally, an ectopic ureteral orifice will be seen leaking clear urine near the urethral meatus or from the vagina. Anatomy of the hymen should be established. The location of any interlabial mass and its characteristics are noted. A lesion exiting the meatus may be urethral prolapse, urethral caruncle, a protruding ectopic ureterocele, inclusion cyst, or sarcoma botryoides. Vaginal masses include imperforate hymen, Gartner's duct cyst, vaginal cysts, and sarcoma botryoides.

PROBLEM SOLVING

Hematuria

Hematuria can be described as asymptomatic microscopic hematuria, symptomatic microscopic hematuria, gross (macroscopic) hematuria, blood spotting on diapers or underwear, and traumatic hematuria (which is discussed in other parts of this text). The clinical approach to each is different.

Asymptomatic Microscopic Hematuria

The source of hematuria in children is most often the kidney (28). It usually is found incidentally during a school or sports physical examination. The definition of microscopic hematuria is more than five RBCs per high-power field on a centrifuged specimen, and it is preferred that two subsequent urinalyses show the same results.

Frequently, the hematuria is detected by dipstick analysis for hemoglobin on the basis of a pseudoperoxidase reaction. This methodology is very sensitive and can detect insignificant hematuria. False-positive results can be caused by the presence of other oxidizing agents in the urine. Free hemoglobin and myoglobin also are detected. Therefore the positive dipstick finding requires microscopy to confirm the presence of erythrocytes (31). Furthermore, microscopy offers other information that may lead to a specific diagnosis, including WBCs, casts, epithelial cells, bacteria, and crystals.

Once the presence of hematuria has been documented, its source is sought. In general, if the microscopic hematuria is associated with proteinuria, cellular casts, and brown-tea discoloration of the urine, a glomerular origin is likely (122). Phase-contrast microscopy can be used to distinguish glomerular from nonglomerular bleeding based on finding dysmorphic RBCs (139).

Children with asymptomatic microscopic hematuria have been studied longitudinally in two large population studies. These studies suggest that (a) if three samples are required to demonstrate the hematuria, the prevalence falls from 4.0% to less than 0.5%; (b) of those children with three positive samples, only 37% had hematuria 1 year later, and 7.6% had it 5 years later; (c) significant renal disease was almost nonexistent when microscopic hematuria was the only abnormality found (48,174). Based on the natural history described, the first step is to repeat the urinalysis to confirm the finding and follow the child with repetitive examinations to detect new, if any, signs and symptoms. With persistent microhematuria, one should exclude idiopathic hypercalciuria, especially if a family history of nephrolithiasis is present. A random urine for a calcium-to-creatinine ratio is recommended (162). The other entity that needs to be addressed is familial or hereditary hematuria, because it can present with microscopic hematuria without proteinuria. This can be assessed by dipping the urine of family members and, if positive, confirming with

microscopy (16,142).

If the patient has microscopic hematuria combined with proteinuria, he or she is more likely to have significant renal disease. Microscopic hematuria does not cause proteinuria. The presence of proteinuria strongly suggests a renal glomerular origin of the hematuria. The amount of protein excreted is quantified by either determining the ratio of protein to creatinine in a random sample or quantification in a timed urine collection. The significance of renal involvement is, in most cases, proportional to the degree of proteinuria (46). These patients benefit by referral to a pediatric nephrologist.

Symptomatic Microscopic Hematuria

Children with symptomatic microscopic hematuria present with signs or symptoms of systemic or renal/urologic disease and their urine contains RBCs. The clinical manifestation may be general (e.g., fever, malaise, pain, hypertension), unrelated specifically to the urinary tract [e.g., rash, arthritis, gastrointestinal (GI)], or urinary tract specific (e.g., dysuria, urgency, frequency, enuresis, flank pain). The role of the pediatric urologist is to exclude anatomic, structural, and functional causes of the patient's symptoms and hematuria.

The history and physical examination provide important information to direct the urologic evaluation. Dysuria, urgency, frequency, and enuresis suggest an inflammatory process. Stranguria, intermittency of the urinary stream, and dribbling urination suggest an obstructive process. Flank pain may indicate a stone, ureteropelvic junction obstruction, or symptomatic vesicoureteral reflux. A history of recent upper respiratory infection followed within a few days by hematuria suggests a renal parenchymal cause, such as immunoglobulin A (IgA) nephropathy. A family history of renal disease, renal cysts, nephrolithiasis, deafness, and sickle cell disease may suggest a cause in the child. A history of recent athletic endeavors may indicate exercise hematuria related to distance running and strenuous workouts. Avoiding the activity for 48 to 72 hours usually will solve the problem, and further work-up is unnecessary (119).

Physical examination should include a well-taken BP, because hypertension is a frequent finding in glomerulonephritis and tubulointerstitial disorders. The skin should be evaluated for rashes, a frequent finding in Henoch-Schönlein purpura and systemic lupus erythematosus. The abdomen should be inspected for flank masses and a palpable bladder. The urethral meatus needs to be assessed for obstructive lesions and, in the female, the vaginal introitus evaluated for masses.

Gross Hematuria

Gross hematuria is alarming to the child and the parent. Initial gross hematuria suggests a urethral origin, whereas total hematuria implies a more proximal origin. Trying to distinguish bright-red bleeding from tea-colored urine is important, because it suggests a different origin as its cause. The most common cause will be a UTI, which is suggested by the finding of pyuria and bacteriuria. As mentioned previously, the history and physical examination will direct the subsequent evaluation, because the differential diagnosis will not change from the symptomatic patient with microscopic hematuria. This includes bleeding of glomerular, nonglomerular, urinary tract, and systemic origins.

Urethrorrhagia

Blood spotting the underwear of prepubertal boys, also known as *idiopathic urethritis,* is associated with dysuria and the finding of microscopic hematuria on urinalysis. The condition is self-limited and has a benign course (120). If the urine culture is normal and the patient has a normal history and physical examination, no further evaluation is necessary.

The etiology of the “urethritis” remains obscure. Urine cultures for bacteria, mycoplasma, and chlamydia have been negative (59). Reiter's syndrome should be considered in those boys with arthritis or conjunctivitis (86). In patients who underwent cystoscopy, a circumferential inflammation was found in the bulbar urethra, which may be associated with a “stricture.” The stricture has been attributed to the trauma induced by dilation and endoscopy (47).

The course of the disease is variable and often protracted. Dysuria and spotting lasting up to 3 years or more is seen in 39% of patients (43). Most patients have resolution of their symptoms as puberty progresses, which has suggested that the prepubertal hormonal milieu combined with an inflammatory source is the etiology of this obscure condition (47). In general, the symptoms are specific, and caring observation is the best treatment. Cystoscopy and voiding cystourethrograms have been of low yield unless a stricture is suspected. Antibiotics are not useful, because cultures are normal.

Evaluation

The evaluation is tailored to the individual patient and the type of hematuria. In patients with asymptomatic microscopic hematuria, repetitive urinalyses, calcium-to-creatinine ratio, and family screening for hematuria is all that is necessary. Follow-up examination to exclude changes in history, physical findings, and urinalysis findings are essential. Screening of the urinary tract with ultrasound and/or voiding cystourethrography is not necessary if the child remains asymptomatic.

Patients with symptomatic microscopic hematuria and gross hematuria should have a urine culture performed and, if it is normal, a renal and bladder ultrasound with prevoid and postvoid bladder assessment is needed. This will exclude masses, hydronephrosis, and other structural causes of hematuria. Bladder emptying ensures a functional normal lower urinary tract. The urine should be sent for a calcium-to-creatinine ratio. Hypercalciuria is the most frequent cause of noninfectious, nonglomerular hematuria in Caucasian children (161,163). Approximately 30% of children whose hematuria is isolated will be hypercalciuric. Hypercalciuria can be associated with episodic gross hematuria in the absence of demonstrable renal calculi. The mechanism of bleeding probably is irritation or damage to the renal tubule by calcium crystals.

A calcium-to-creatinine ratio of more than 0.21 is indicative of hypercalciuria. If the ratio is elevated, a 24-hour urine collection for quantitative measurement of calcium should be performed. Calcium excretion of more than 4 mg/kg per day should be treated with hydration and a low-sodium diet. Hydrochlorothiazide may be necessary if initial treatment does not lower urinary calcium (135).

If the urinalysis demonstrates red cell casts or more than 5% dysmorphic RBCs, laboratory measurement should include complete blood count (CBC) with platelet counts, serum electrolytes, creatinine, blood urea nitrogen (BUN), ASO titer, C_3,C_4, antinuclear antibodies (ANA), and sickle cell screen in selected patients. If total serum protein and albumin globular ratios are evaluated, referral to a pediatric nephrologist is appropriate (120).

Those patients who have a positive urine culture will need a voiding cystourethrogram (VCUG) following a course of antibiotics. A VCUG will be necessary in those patients with abnormal screening ultrasounds, gross hematuria, or symptoms suggestive of obstruction. If a stone is suspected, a flat plate of the abdomen followed by spiral computed tomography (CT) is indicated. The results of the sonogram and VCUG will determine the need for subsequent imaging studies such as CT scans, nuclear scans, and magnetic resonance imaging (MRI).

Cystoscopy is not indicated in the evaluation of asymptomatic microscopic hematuria (59). Children with symptomatic microscopic hematuria, but normal renal ultrasound, intravenous pyelography (IVP), and VCUG, usually do not require cystoscopy. Patients with gross hematuria that persists or symptoms suggestive of lower urinary tract abnormalities undergo cystoscopy that usually confirms the normal imaging studies. Infrequently, a bladder lesion, bladder hemangioma, bulbar stricture, or urethral polyp will be recognized. In general, cystoscopy must be tailored to the individual patient based on interpretation of his or her history, physical examination, and imaging and laboratory findings. Cystoscopy ideally would be performed at a time of bleeding.

The well-performed history and physical examination guide the investigation of hematuria. This investigation should never be allowed to pose a greater risk to the child than does the problem itself. Consequently, cystoscopy, angiography, and renal biopsy rarely, but selectively, are performed. The urinalysis with microscopic examination of the urinary sediment is the cornerstone of the evaluation process. Red cell casts are the hallmark of glomerulonephritis and obviate further urologic evaluation. Subsequent imaging is specific to the individual patient's needs.

Urinary Tract Infection

Patients sent for evaluation of UTIs constitute 15% to 22% of all patient referrals (Table 55.2). Most of these patients are on antibiotics or have finished antibiotics for their acute infection. They often have poor documentation of the UTI, have not been imaged, and may have suffered more than one infection. It is important to obtain

all documentation of the urinary infection and any imaging studies before the visit.

Patients frequently are referred based on symptoms alone, which may be unreliable in establishing the diagnosis of true infection (21). Frequency, urgency, dysuria, and enuresis may be caused by vulvitis, urethritis, or dysfunctional voiding, for example. Usually, urine samples obtained in the primary care physician's office are from a “bag” specimen or voided urine, and subsequent diagnosis of a UTI is based on an enzymatic assessment of leukocyte esterase and nitrite. When both tests are positive, they have a sensitivity of 78% to 92% and a specificity of 60% to 98% of predicting a UTI (125). Unfortunately, not all of these urines are sent for culture. The potential for contamination with bag urine collections due to preputial, vaginal, and/or stool is high. Midstream-voided samples in older girls, circumcised boys, and boys with retractable foreskins are fairly reliable for culture; however, these same specimens from young girls and uncircumcised boys may reflect periurethral and preputial skin bacterial colonization. When cultures are difficult to interpret, especially in the setting of voiding dysfunction and incontinence, reliable specimens obtained by catheterization or suprapubic aspiration are necessary to proceed with appropriate evaluation and management. A diagnosis of significant bacteriuria from a voided specimen is defined as greater than 10^5 colony-forming units (CFU)/mL (87). Colony counts of less than 10^4 CFU/mL in children may be significant, regardless of the method used in collection.

Once the diagnosis of a significant UTI is ascertained, it is important to establish whether it represents a first infection or recurrence. Reinfection with the same organism may be a result of inadequate treatment, acquired bacterial resistance, or an unrecognized anatomic site of persistent infection (e.g., stone). Most recurrent infections represent a reinfection with or without the same organism.

The natural history of UTIs predicts that 25% of patients will suffer a second infection within 1 year; the risk increases as the number of documented infections increases so that after three infections the risk is 75% (179). In school-aged girls, recurrence of UTI within 18 months was 80% for Caucasian girls and 60% for African American girls (98). The risk of recurrent infection in infant males is related to preputial bacterial colonization, which is highest immediately after birth and decreases after 6 months. This explains the tenfold increased incidence of UTI in uncircumcised versus circumcised boys. The added risk for UTIs in uncircumcised boys persists until age 5 (17). Periurethral colonization in female infants is associated with a 0.57% incidence of UTIs (152). The risks for increased colonization in older children is unclear but likely is related to the presence of certain blood group antigens on uroepithelial cells that serve as bacterial receptors and allow bacterial adherence, colonization, and subsequent UTI (85).

In children with asymptomatic infections, the majority will have normal radiologic studies (82,110). Twenty-five percent of children with renal scarring have normal VCUGs (82). Twenty-five to fifty percent of children with culture-documented UTIs will have vesicoureteral reflux, whereas only 0.4% to 1.8% of children without UTIs have vesicoureteral reflux (152). When carefully interviewed, children with “covert” or asymptomatic bacteriuria frequently have lower urinary tract symptoms such as enuresis or urgency, and 20% have a history of previous UTI. Approximately 50% of these children will have normal urinary tract imaging (154).

Evaluation

It is important to discover if the patient had previously undiagnosed infections. Mothers are quick to remember if a fever was “poorly explained” by an upper respiratory infection or the flu, which may have prompted use of an antibiotic and masked the diagnosis of a UTI. A detailed bowel and bladder history to discern voiding dysfunction and constipation are critical. An “elimination diary” (Table 55.5) kept for a few days before the appointment will greatly facilitate identifying these children. Most children between 3 and 12 years old void five to six times per day and have a bowel movement each day (14). The age at toilet training and problems encountered need to be elicited. Toilet training ages range from 9 months to 5 years, with a mean of 2.4 years (14). A family history of recurrent UTIs and vesicoureteral reflux are conditions with strong heredity implications for the patient.

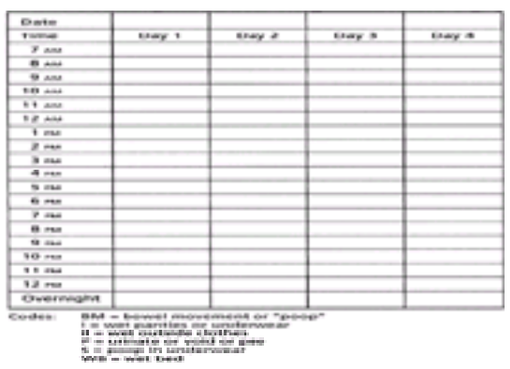

TABLE 55.5. VOIDING LOG

The physical examination of children with UTIs should include palpation of the abdomen for masses, bladder distention, or fecal impaction. The meatus should be examined to rule out stenosis. The circumcision status should be noted. In the female, important findings of vulvovaginitis and labial adhesions predispose the patient to perineal colonization and potential contamination of voided urine specimens. The spine should be inspected for signs of occult dysmorphism. A rectal examination needs to be performed if constipation or encopresis is present.

All children 5 years of age or younger with a culture-documented UTI should undergo imaging of their urinary tract (144). Prepubertal males with symptomatic infections and older females with recurrent or febrile UTIs should be imaged. Evaluation should identify those patients at risk for renal damage or conditions that predispose to recurrent infections.

Initial studies should include a renal bladder ultrasound and a VCUG. In the office setting, the acute infection has likely been treated. The VCUG can be performed as soon as the urine is sterile. It does not require a delay of 4 to 6 weeks after the infection (128). The sonogram evaluates renal size, hydronephrosis, masses, and duplication anomalies. A prevoid and postvoid bladder volume measurement assesses bladder emptying. A significant renal size discrepancy on ultrasound or low-grade hydronephrosis can be associated with vesicoureteral reflux. In girls, either a contrast or isotope cystogram may be obtained. In boys, a contrast study is necessary to visualize the urethra. In general, an initial contrast VCUG will provide anatomic information and grade of vesicoureteral reflux if present. The VCUG is evaluated for capacity and emptying. The volume instilled is compared with estimated bladder capacity. This will provide information concerning voiding dysfunction.

Any subsequent imaging is dictated by the finding of the VCUG and sonogram. Children with higher grades of vesicoureteral reflux should have a dimercaptosuccinic acid (DMSA) scan to evaluate for renal scarring (165). The presence of hydronephrosis and/or hydroureter requires assessment by a mercapto acetyl triglycine (MAG-3) renal furosemide (Lasix) scan. In children with a normal VCUG and ultrasound, there is no indication for cystoscopy.

Management

Acute infections encountered in the office are classified as complicated or uncomplicated. Uncomplicated UTIs include cystitis, recurrent UTIs, and asymptomatic bacteriuria. Complicated UTIs include structural abnormalities, pyelonephritis, and operatively reconstructed patients.

If an infection is diagnosed in a neonate or ill infant, hospitalization for parenteral broad-spectrum antibiotics is recommended. These agents include an aminoglycoside plus ampicillin or a cephalosporin, or a third-generation cephalosporin such as ceftriaxone (Table 55.6). Treatment of acute infections depends on the child's age and severity of symptoms. Regardless of age, if the child is acutely ill with fever, pain, and poor hydration, or infected with a highly resistant organism, parenteral antibiotics are indicated and hospitalization is needed. The duration of parenteral therapy is guided by the clinical course of the child. Generally, it is continued until the patient is afebrile for 24 to 48 hours (4a).

Antibiotics for Parenteral Treatment of UTIs		
Antimicrobial	Dosage	Interval
Ceftriaxone	75 mg/kg/day	Divided q12h
Cefotaxime	150 mg/kg/day	Divided q6h
Ceftazidime	150 mg/kg/day	Divided q8h
Gentamicin	7.5 mg/kg/day	Divided q8h
Ampicillin	100 mg/kg/day	Divided q6h
Antibiotics for Oral Treatment of UTIs		
Amoxicillin	20–40 mg/kg/day	Divided q8h
Cefixime	8 mg/kg/day	Divided q12h
Cephalexin	50–100 mg/kg/day	Divided q6h
TMP-SMX	6–12 mg TMP; 30–60 mg SMX per kg/day	Divided q12h
Antibiotics for Prophylaxis of UTIs		
TMP-SMX	2 mg TMP, 10 mg SMX per kg	Once daily
Nitrofurantoin	1–2 mg/kg/day	Once daily
Sulfisoxazole	10–20 mg/kg/day	Divided q12h
TMP	2 mg/kg/day	Once daily

TMP-SMX, trimethoprim-sulfamethoxazole; UTIs, urinary tract infections.

TABLE 55.6. ANTIBIOTICS FOR TREATMENT OF UTI

Oral antibiotics follow IV therapy; the choice is based on the sensitivity analysis of the cultured bacteria. Oral therapy should continue for 10 to 14 days. Prophylactic antibiotics are recommended until imaging studies are complete.

For children with uncomplicated UTIs, treatment will depend on the child's age and severity of symptoms. The majority will have bladder irritative symptoms and cystitis. The optimal duration of treatment of acute uncomplicated infection is controversial. The range is from a single dose of IM aminoglycoside to 10 days of an oral agent (144). A 3- to 5-day course of an appropriate agent with sensitivity confirmed by the culture results is this author's method of treatment.

If the child has two or more documented UTIs within 6 months, prophylactic antibiotics may be considered, because the child has established his or her propensity for recurrent infections. Table 55.6 lists some of the agents of value for prophylaxis. These drugs have high urinary concentrations and avoid antimicrobial resistance patterns in the gut at the prescribed dosage. These same antibiotics should be avoided as primary treatment agents when used prophylactically, because the higher dosages will result in bacterial resistance (154).

Prophylactic antibiotics are the mainstays of medical treatment in children who are discovered to have vesicoureteral reflux. In children with recurrent infections and voiding dysfunction, prophylaxis is combined with specific treatment of their voiding disorder that may include timed voiding, anticholinergics, and behavior modification (94). It also is important to treat constipation, which often coexists with urinary infection and infrequent voiding (123).

Voiding Dysfunction and Wetting

Children with inappropriate wetting and voiding habits are common, constituting 20% to 25% of new patients seen in the pediatric urology office setting (Table 55.2). A myriad of structural, neurogenic, and functional disorders can result in a wet child. In the office setting, the majority of these children will have functional abnormalities without overt neuropathies or anatomic disease. A thorough history, physical examination, and an understanding of the normal development of urinary control direct the evaluation of these children. In the absence of associated urinary infection, invasive or complex procedures or imaging rarely are necessary. The focus of this discussion is on the normal child who presents with wetness after an age when toilet training should have been accomplished.

Acquisition of Bladder Control

The neurophysiologic mechanisms resulting in continence are discussed elsewhere in this text. These processes result in various observed developmental stages of urinary control. In newborns, micturition is a reflex occurring 20 or more times per day (67). Bladder filling to an appropriate degree stimulates the efferent response of emptying, with detrusor contraction preceded by relaxation of the sphincteric mechanism with complete bladder emptying. By 6 months of age, a noticeable increase in voided volume and decrease of urinary frequency is seen. This is attributed to unconscious inhibition of the voiding reflex (184). Between 1 and 2 years of age, the child develops a conscious sensation of bladder fullness that sets the stage for voluntary control of voiding. Volitional voiding and inhibition of voiding at any degree of bladder fullness develops in the second and third years of life. By the age of 4 or 5 years, most children have developed an adult pattern of urinary control. The usual sequence of attainment of bowel and bladder control is (a) nocturnal bowel control, (b) daytime bowel control, (c) daytime urinary control, and (d) nocturnal urinary control (145). Children between 3 and 12 years of age void five to six times per day and have a bowel movement each day (14). Normal voiding volume is more difficult to define, but bladder capacity can be approximated by the following formula: age (years) + 2 = volume (ounces) (93). Comparison of expected bladder capacity with measured bladder volumes provides insight into voiding dysfunction patterns and treatment.

Involuntary voiding beyond the age of anticipated control is called *enuresis. Diurnal enuresis* is daytime wetting and *nocturnal enuresis* is nighttime wetting. Primary enuresis implies no interval of dryness, whereas secondary enuresis implies a 6- to 12-month dry interval. Twenty percent of wet children have diurnal enuresis, and children with secondary enuresis comprise 25% of all wet children, but their evaluation, treatment, and response to therapy are no different than for primary enuresis (76).

Evaluation

The patient's history combined with the voiding log are the mainstays in separating patients with functional enuresis from those with anatomic and neurogenic incontinence. Most parents have poor knowledge of the specifics of their child's bowel and voiding habits. Sending a voiding log to keep for a few days before an appointment will clarify the frequency of voids, the degree of wetness, and bowel accidents (Table 55.5).

Continuous wetness between normal voiding episodes is a classic history in the female patient with an ectopic ureter. Continuous wetness without voiding is seen in patients with neurogenic bladders and in female and male epispadias.

Children with episodic wetness are questioned regarding frequency of voiding, urgency, and posturing. Leg crossing, squirming, or heel sitting (Vincent's curtsy) is used to suppress the urgency associated with uninhibited bladder contractions. A small spot on the underwear immediately after voiding in females may signal pseudoincontinence caused by vaginal voiding. This also is seen in boys with urine trapped in the bulbar urethra and prepuce. Infrequent voiders usually will not empty their bladders upon awakening. The quality of the voiding effort is questioned. A dribbling urination may signify obstruction, a staccato character implies intermittent contraction of the external sphincter, and the use of Valsalva maneuver may suggest overflow incontinence or detrusor decompensation.

Other historic features important to note are the birth history and other conditions such as imperforate anus, vesicoureteral reflux, neurologic disease, and duplication anomalies. A history of a normal prenatal ultrasound suggests structural integrity of the urinary tract. A history of UTI and constipation will need to be considered in the treatment program (105).

How the family has dealt with the child's wetting and their immediate and future concern will help guide subsequent treatment. A family history of nocturnal enuresis in the parent, and when the parent stopped wetting the bed, assist in helping the child.

The physical examination usually is normal. However, abdominal examination and assessment of a palpable bladder, flank masses, or stool will help typify the elimination dysfunction. Careful examination of the spine for signs of occult spinal dysraphism includes inspecting for cutaneous lesions, dimples, lipomas, hairy tufts, and asymmetry of the gluteal cleft. Anal sphincter tone and anal wink are assessed. The gait is observed with testing of lower-extremity reflexes. A high-arched foot or slight leg length discrepancy are significant signs of a tethered cord. The external genitalia are inspected for epispadias, ectopic ureters, labial adhesions, and interlabial masses such as a ureterocele.

A urinalysis and culture are performed. If infection is present, it is managed as previously discussed. If no infection is present and the child is older than 5 years with daytime wetting, a screening renal bladder ultrasound with prevoid and postvoid bladder assessment is performed (180). This will assess volitional voiding efficiency, residual urine, and the integrity of the upper urinary tract. A VCUG is performed on those children with a prior history of UTI and daytime incontinence. A kidneys, ureters, and bladder (KUB) examination as part of the VCUG detects vertebral abnormalities and constipation. The VCUG rules out vesicoureteral reflux and urethral

abnormalities.

If a spinal abnormality is detected, a neurologic origin is suspected, or the VCUG depicts an abnormal bladder, then formal urodynamics are performed. The results of urodynamics may confirm a neurologic origin and assist with management. These patients usually are studied with an MRI of the spine and referred to the pediatric neurosurgeon.

Management

The intent, interests, and cooperation of the child and family must be determined as treatment is planned. The length of treatment and commitment to various programs, such as behavior modification with an alarm system, needs to be explained.

Diurnal Enuresis

Patients with urge incontinence are wet day and night. They may posture and, when urine volume is assessed, have a low functional bladder capacity. They may have a staccato type of urination due to contraction of the external sphincter during voiding. Many have concomitant UTIs. Initial treatment consists of a timed voiding schedule, emptying the bladder every 2 to 3 hours. If this is not successful, anticholinergic medication to treat the unstable bladder is helpful. Parents are instructed to listen to the child's voided stream and alert the child to intermittency and staccato urination. Overall, 87% of children with isolated overactive bladders will improve over a mean of 2.7 years (39). It is important that the child and parents understand this time commitment. Biofeedback training with reflex inhibition of detrusor contractions also has shown success in this group of patients (109).

Infrequent Voiding

As stated previously, children with wetting and infrequent voiding are placed on a timed voiding schedule. These children frequently do not void upon awakening and have associated UTIs and constipation, which require ongoing treatment. A voiding log documenting time, wetting episodes, and volume of urine is kept by the child under parental supervision (Table 55.5). The ultrasonic bladder scan to assess emptying has been used in the office and at home, providing immediate feedback on bladder emptying to the patient (185).

Hinman Syndrome

The extreme form of dysfunctional voiding is the nonneurogenic neurogenic bladder or *Hinman syndrome* (72,73). These patients have upper and lower urinary tract involvement resulting from detrusor instability and significant learned detrusor sphincter dyssynergia (145). The lack of coordination results in high-pressure inefficient voiding. High-pressure voiding leads to bladder decompensation, vesicoureteral reflux, residual urine, UTI, and in the worst-case scenarios, renal failure. Most of these patients also have constipation and encopresis. They often come from families with abusive or overbearing parents. Treatment ranges from that previously discussed to adjunctive medications such as a-blockers to relax the bladder neck, clean intermittent catheterization, behavior modification, and psychologic assistance (8). Help from the pediatric gastroenterologists to develop a good bowel program is sought (183). Behavior modification to teach relaxation of the external sphincter with voiding also is successful (126). Occasionally, construction of a continent stoma (Mitrofanoff) to facilitate clean intermittent catheterization for bladder emptying or even urinary diversion is necessary.

Giggle Incontinence

Complete loss of urinary control precipitated by laughter during the daytime is the hallmark of this voiding dysfunction. It usually is not associated with UTIs or anatomic abnormalities. Giggle incontinence is not stress related, because there is not urinary loss with coughing, sneezing, or straining. It often is seen in adolescent girls and is a source of great embarrassment. Its cause is unknown. Giggle incontinence is very difficult to treat with behavior modification, and expedient bladder emptying is the most effective therapy (178). Anticholinergic agents usually are not efficacious. Methylphenidate (Ritalin, 0.3 to 0.5 mg/kg every 4 to 6 hours while awake) has been successful in some patients with this disorder (153). Fortunately, the incontinence abates spontaneously in some girls.

Nocturnal Enuresis

Control of urination at night is the last step in the development of acquiring social continence. The standard for acquisition of nocturnal continence is 5 years of age in our society. Fifteen to twenty percent of 5-year-old children wet the bed. Of these, 75% have always done so and 25% have secondary nocturnal enuresis. Fifteen percent of these children become dry at night each year, attesting to its developmental nature (74). It is important to remember that nocturnal enuresis is a symptom and not a disease. The family history is one key, because if one parent wet the bed, 44% of his or her children will do so and if both parents wet the bed, 77% of their children will do so (9). The age of attainment of nocturnal control will be similar to that of the parent.

The etiology of nocturnal enuresis is likely multifactorial. Conceptually, the triad of relatively small bladder capacity, poor sleep arousal, and increased urine volume are the determinants of wetness at night (74). In simple terms, the bladder capacity is exceeded. The child is not aroused in response to the full bladder. Thus the bladder empties while the child continues to sleep. The pattern of sleep as measure by electroencephalogram (EEG) is normal; however, all of the parents of these children will attest to how difficult it is to awaken the child. The daytime functional bladder capacity is decreased in some of these children (143). In addition, a group of these children have increased nocturnal urine production resulting from a deficiency in the amount of antidiuretic hormone (ADH) secreted at night. This loss of a normal diurnal increase in nocturnal ADH secretion combined with poor arousal results in a wet bed (121).

The evaluation of children who wet the bed has been outlined previously. Most require a good history, physical examination, and urinalysis; no further imaging or studies are necessary if the history, examination, and urinalysis are normal. The decision to treat these children is based on the family's and child's perception of the social and personal consequences of the bedwetting. If it prevents normal socialization or affects the child's self-esteem, then treatment is warranted. Many of the families just want to know that the condition will improve, and reassurance is all that is necessary.

The mainstay of treatment of primary nocturnal enuresis is behavior modification because it provides the best long-term success (115). Motivational therapy, consisting of positive reinforcement and active patient involvement, is combined with conditioning therapy with an alarm. The alarm, which is positioned on the pajamas, is triggered by urine contact with a sensor in the underwear. When wetting occurs, the alarm sounds and the patient must awaken, which sometimes initially requires the assistance of his or her parents. The patient will stop urination upon awakening and voids into the toilet. This process results in awakening in response to a full bladder and a dry bed. The conditioning may take up to 15 weeks to occur. This author requires 25 consecutive dry nights before removal of the device. Numerous studies have reported a 65% to 100% cure rate after 4 to 6 months of treatment (88,115,166). Relapse may occur in up to 30% of children, but re-treatment is successful if relapse occurs. Unfortunately, many families and patients are not willing to put in the time and effort to ensure success with conditioning therapy (145).

The primary pharmacologic agents used in treating nocturnal enuresis are anticholinergics, tricyclic antidepressants, and desmopressin acetate (DDAVP). Anticholinergics, specifically oxybutynin, decrease or abolish uninhibited bladder contractions and increase functional bladder capacity. Oxybutynin is of particular help in the child with both day and night wetting. However, its use in children with nocturnal enuresis only rarely is beneficial (88). In children with small functional bladder capacity, anticholinergics with an alarm system has proven successful (27). In children 6 years of age or older, the dose of oxybutynin is 5 mg taken two to three times daily (0.2 mg/kg two to three times a day). Parents need to be alerted to the facial flushing, dry mouth, and heat intolerance associated with its use.

Imipramine, a tricyclic antidepressant, has success in the treatment of nocturnal enuresis. Its pharmacologic actions appear to be multiple because it acts centrally to effect arousal from sleep and it has weak anticholinergic effects on the bladder and mild a-adrenergic effects to close the bladder neck. It also may stimulate the secretion of ADH from the posterior pituitary. The dose of imipramine given 1 to 2 hours before bedtime should not exceed 50 mg in children 6 to 12 years of age, nor exceed 75 mg in children 12 to 14 years of age. On a weight basis, the usual recommended dose is 0.9 to 1.5 mg/kg per day (145). Initial success with imipramine is as high as 50%; however, only 25% of patients have a long-term cure. Imipramine works best in older children who have minimal daytime wetness. Its effects are immediate and it can be used on an as-needed basis for a dry night. Side effects include anxiety, insomnia, dry mouth, and personality changes. The medicine must be safely guarded and administered by the parents because fatal overdoses have occurred, with death due to cardiac arrhythmias, conduction blocks, and hypotension (115).

DDAVP, a synthetic analog of arginine vasopressin, is the only other medication with U.S. Food and Drug Administration (FDA) approval to treat nocturnal enuresis. In some patients with decreased nocturnal secretion of ADH, it is used as replacement therapy. In theory, the use of DDAVP combined with fluid restriction will result

in a reduction in nocturnal urine output to a volume less than bladder capacity, resulting in a dry bed. It does not explain the sleep arousal–related problem in enuretic children. DDAVP is available as a spray or tablet. The spray delivers 10 µg per spray; the initial dose is 20 µg (one spray in each nostril). This can be titrated to a total of 40 µg (two sprays in each nostril). The tablet contains 200 µg of DDAVP. Treatment begins with 1 tablet and can be titrated to a total of 3 tablets per night (600 µg). In a number of blinded controlled studies, a significant improvement (defined as greater than 50% reduction in wet nights) is attained in greater than 50% of patients (114,156). Improved response to DDAVP is noted in older patients, with fewer wet nights per week, and in patients with greater than 70% of predicted bladder capacity for age (143). This medication, like imipramine, has a high relapse rate when discontinued. It acts swiftly and can be used on an as-needed basis. The side effects of taking DDAVP have been negligible when strict fluid restriction is performed. Rare cases of hyponatremia and seizures have been seen (140). Fluid restriction beginning at least 2 hours before bedtime and voiding before going to bed are a important aspects of treatment with DDAVP. Patients with refractory nocturnal enuresis persisting into adulthood have been treated with various combinations of alarm system with pharmacotherapy (19,20). A recent study using hyoscyamine and DDAVP reported success in 78% of patients (27). Combining the alarm system with oral DDAVP is particularly effective in children with the most severe bed wetting, which is defined as in excess of 6 wet nights per week (19).

Genital Problems in the Male

Prepuce

The prepuce begins to form at 10 to 12 weeks of gestation. The inner epithelial layer of the fold of skin is fused with the glans epithelium and will not retract in most newborns. Complete development of the prepuce occurs after formation of the urethra. Abnormalities in urethral formation result in ventral deficiency of the prepuce as seen in boys with hypospadias. Issues related to the prepuce concerning removal and care constitute many patient visits to the office. The intention of this section is not to discuss the pros and cons of circumcision, but rather to review the normal process of preputial retraction and problems related to the circumcised and uncircumcised phallus.

Many observers have recorded the timing of complete separation of the inner preputial skin from the glans penis. It is variable and may not be complete well into adolescence (30). It is not pathologic to have an incompletely retractable prepuce. Forceful separation as frequently advocated in the primary care office is the harbinger of future phimosis and penile adhesions. The accumulation of desquamated epithelium recognized as keratin pearls (i.e., infant smegma) is part of the natural process of separation of the two layers. The most frequent reason for visits related to the prepuce is phimosis. The vast majority is “physiologic” phimosis with incomplete separation. The meatus is clearly visible and there is no ballooning of the prepuce with voiding. Circumcision is not medically necessary under these circumstances. The care of the uncircumcised phallus should be clearly presented to the parents. This includes common sense hygiene and a hands-off approach without forceful retraction of the prepuce, and normal bathing. Explaining to the parents how the process occurs completes the visit. A fact sheet provided by the American Academy of Pediatrics entitled “Care of the Uncircumcised Penis” can be given to the parents.

Patients with pathologic phimosis have experienced previous balanoposthitis and/or traumatic scarring as a result of previous forceful attempts at preputial retraction. At times, a dense, white cicatrix forms at the outlet of the prepuce, resulting in ballooning of the prepuce with voiding. Obstructive uropathy resulting from phimosis is rare (173). This condition has been treated with variable results with topical steroids (116,181). Circumcision is generally felt to be the treatment of choice.

Paraphimosis develops when the prepuce is retracted behind the corona of the glans penis and left in place. Subsequent swelling and edema prevent easy return of the prepuce to its covering position. Initial treatment with compression and manual distraction usually is successful. Penile compression with an elastic bandage or pediatric BP cuff maintained at diastolic pressure for 10 minutes makes reduction easier (11). Dorsal band traction with Adson forceps has proved useful (170). Rarely, performance of a dorsal slit is necessary to release the constricting band. Subsequent circumcision can be performed on an elective basis if desired.

The performance of in-office circumcision has been discussed previously. The issues involved with this decision will not be further addressed. However, many visits to the office will be with patients who were circumcised elsewhere. These procedures have resulted in a number of cosmetically less-than-perfect results. The most common of which is too little skin removed, resulting in a partially circumcised phallus. The parents are unhappy with the result and the referring physician is concerned about his unhappy parents. The surplus of retained prepuce is of consequence only if it results in problems with hygiene. Readherence of the retained inner preputial skin to the glans penis can occur. Many of these patients require recircumcision.

Separation of the skin edges following circumcision results from removal of too much skin from the shaft of the penis. The uncovered shaft of the penis alarms the parents and physician. Fortunately, conservative management with wet to dry dressings and antibiotic ointment allows for healing by secondary intention without resultant chordee. Skin grafting or suture reapproximation is not necessary.

Circumcision can result in the shaft and glans of the penis becoming buried under the penile skin. This is distinguished from the unoperated “buried or concealed” penis that results from an abnormally large suprapubic fat pad and dense dysgenetic dartos fascial bands that tether and retract the penis inward, but may be related to the same pathophysiology (52). When the buried penis results from circumcision, there may be a tight band in the proximal prepuce similar to that of the buried penis anatomy. Surgical repair is indicated to release the penis from the circumferential scar and resurface the shaft of the phallus. Usually, a variety of Z-plasties are necessary and, rarely, a full-thickness skin graft is required. If the buried penis is not caused by prior circumcision, then its surgical correction combines removal of the suprapubic fat pad and release of the dysgenetic dartos fascial bands, and release of the proximal preputial stenosis. In both conditions, the penile shaft skin is tacked to the corporal bodies.

The most common complication of circumcision is meatal stenosis, which is seen rarely, in uncircumcised males. The lesion can result in hematuria, dysuria, urethral irritation, urinary infection, and rarely, hydronephrosis. It is best diagnosed by observation of a thin, upward deflection of a high-velocity urinary stream, because many boys referred for meatal stenosis have a normal meatal caliber. See the previous discussion in this chapter for treatment.

Balanoposthitis

Acute infection of the prepuce and glans penis is seen most commonly in toilet-trained, uncircumcised preschool boys. The cause usually is infectious but may be a result of contact irritation or contact dermatitis. Infectious causes include candida, b-hemolytic streptococcus, and Gram-negative pathogens (1). The preschool male often complains of dysuria and penile pain and tenderness. Purulent material is visible at the preputial meatus. A Gram stain of the exudate may be helpful, but a culture of the material will disclose the pathogen.

Treatment consists of application of a topical antibiotic ointment such as bacitracin zinc or Neosporin. In more severe cases with localized cellulitis, an oral second-generation cephalosporin is prescribed (61,149). Penile cellulitis in its most severe form can lead to necrotizing fasciitis and should be treated with hospitalization and IV antibiotics. In general, however, mild forms can be treated with oral antibiotics and penile cleansing with soap and water combined with parental and patient education concerning penile hygiene. Most boys suffer a single episode only. Recurrent balanoposthitis with or without ballooning of the prepuce and/or associated phimosis is an indication for circumcision.

Hypospadias and Chordee

Hypospadias, usually recognized at birth, is the most common penile anomaly referred to the urologist's office (see Chapter 52B). Parental anxiety is high because the defect in urethral location and abnormal curvature is visibly apparent. Hypospadias is usually an isolated abnormality with a low incidence of associated upper tract anomalies; screening the kidneys is not necessary (141). Most pediatric urologists restrict x-ray evaluation to those patients who would otherwise undergo radiographs for other indications, such as a UTI. If the patient has proximal hypospadias, an enlarged utricle may be present. This can cause problems with catheter placement at the time of surgical correction (29). Patients with proximal hypospadias and undescended testes, especially if nonpalpable, may have an intersex condition, and a complete evaluation including karyotype is necessary (84).

Abnormal curvature of the penis or chordee may be present with or without hypospadias. Chordee without hypospadias usually is associated with a spongiopenile urethral deficiency, but can be seen with normal urethral anatomy. Penile curvature associated with hypospadias or abnormal urethra is in a ventral direction, whereas the curvature with a normal urethra noted early in life may improve spontaneously. Chordee has three potential causes: (a) abnormal development of the urethral plate, (b) fibrosis of the dartos fascia, and (c) growth disproportion between the normal corporal tissue and abnormal urethral plate (51).

A family history of hypospadias is important, and potential risk to future male infants needs to be discussed. The surgical correction should be detailed with diagrams and drawings. The need for urinary drainage with a tube through the penis and its postoperative care must be taught. The “double diaper” open drainage technique

should be discussed. The timing of surgery is key. Surgery on the genitalia is optimally performed from 6 to 18 months of age. This avoids anxiety separation, allows correction before the child perceives his genital defect, and diminishes any recollection of the surgical experience. This age window for surgery is recommended by the Section on Urology of the American Academy of Pediatrics as providing the greatest benefit and minimizing the psychologic effects of surgery and anesthesia (5a).

Inguinal and Scrotal Problems

Hernia and Hydroceles

Scrotal swelling or bulges in the groin are among the most common types of problems seen in the pediatric urologist's office. Inguinal hernias are one of the most common problems seen in children; the vast majority of which occur in boys. They result when the processus vaginalis fails to close, an event typically observed in the third trimester of gestation (151); hence the high incidence of hernias in premature infants. Hernias also are commonly found in association with undescended testes (54).

Office evaluation of the child who presents with an enlarged scrotum first requires a thorough history. Many babies with hydroceles at birth will present to the office with a tense, enlarged scrotum (Fig. 55.5). Parents will report that their baby appears irritable, and it may be difficult to differentiate scrotal enlargement due to an incarcerated hernia from other causes of irritability, such as colic. This may cause crying, then increased abdominal pressure, resulting in scrotal enlargement from peritoneal fluid being forced through the open processus vaginalis. The same phenomenon may be seen in babies with constipation. Calming the baby by offering a pacifier often is helpful to allow reassessment to determine whether the problem is in fact acute.

FIGURE 55.5. Communicating hydroceles. Scrotum is tense and enlarged. This often is indistinguishable from an incarcerated hernia.

Examination is important to differentiate a hernia from more serious problems. Transillumination of the scrotum using a penlight in a darkened room will determine whether the mass is fluid filled or is solid. The testis often is difficult to palpate in a tense hydrocele, but can be identified by transillumination, or better with scrotal ultrasound. Not infrequently, a child will present with an inguinal mass along the spermatic cord, and differentiation between an incarcerated hernia and a hydrocele in the cord can be difficult. Transillumination again may help establish the diagnosis, but if this is equivocal, auscultation with a stethoscope may pick up bowel sounds. Ultrasound may be useful in this clinical situation as well. Fluid seen without internal echoes in the mass is characteristic of a hydrocele.

The age at which the child presents influences management. Neonates and infants with very large hernias may have symptoms that warrant early surgery, such as irritability or feeding problems. An incarcerated or strangulated hernia is a medical emergency that requires urgent reduction. Successful reduction of an incarcerated hernia allows time to prepare the baby for an urgent, but more elective, operation rather than emergency surgery. In children with asymptomatic hernias, observation is reasonable; however in neonates and children younger than 1 year of age, repair on an urgent but not necessarily emergent basis is indicated because of the increased potential for incarceration in this group. Children with communicating hydroceles may be followed for the first year of life in anticipation of closure of the processus vaginalis. Should this fail to occur by age 1 year, the likelihood of closure is slim (150). If the hydrocele is large and shows no sign of diminution in size by 6 months of age, surgery is justified. It is at this age that the anesthetic risk has reached its nadir.

Undescended Testes

Many boys are referred to the pediatric urologist because of suspected cryptorchidism, or undescended testes. This can be a difficult diagnosis to make, because retractile testes and undescended testes may be indistinguishable clinically. Yet it is critical to attempt to make this distinction (57,99,133).

The diagnosis of cryptorchidism is made on physical examination. Many children referred for consultation have already had some imaging studies (e.g., sonogram, CT scan, MRI scan) in attempts at either identifying or localizing a testis that the primary care physician could not identify. Unfortunately, these studies have low specificity and sensitivity and consequently are of little use. The overall accuracy of radiologic testing has been reported to be 44% compared with 53% accuracy of physical examination by the referring physician and 84% by the pediatric urologist (77). The diagnosis is made during a thorough and carefully performed physical examination. First, the child should be relaxed. Attempts should be made to gain the patient's trust and to convince him that there will be no pain. The room should be warm to minimize the cremasteric reflex. Observation of the scrotum is the most important part of the examination. The testes should lie in a dependent position. Next, bimanual examination with one hand over the inguinal region and the other on the scrotum will allow the examiner to palpate the testis and “milk” it into the scrotum. The undescended testis usually will not be able to be manipulated into the scrotum, and if it can, it will not remain there, springing back into its original position.

In situations where the diagnosis is not clear, other diagnostic measures should be undertaken. Examination of the child should not be limited to the supine position. For example, the patient can be examined standing, sitting on the examination table with legs crossed or with the legs hanging from the end of the table, or resting on the examiner's lap. All are ways of minimizing the cremasteric reflex and therefore facilitating the differentiation between a true cryptorchid testis and retractile testis. Valsalva maneuver, initiated by having the patient bear down, also can dampen the cremasteric reflex. Another helpful diagnostic trick is to put liquid soap on the examining fingers to enhance tactile sensation, which often is useful in palpating a testis high in the inguinal canal or buried in fat. Scrotal hypoplasia may indicate true cryptorchidism, but also may be associated with peripenile adipose.

When the diagnosis is still inconclusive (mobile versus true undescended testis), the use of hCG can be of further diagnostic assistance (133). Many protocols have been described for administration of hCG for such purposes (81). Presumably, a retractile testis will descend after a course of hCG, but an undescended testis will not. This is based on the empiric observation that at puberty, a retractile testis previously not palpable in the scrotum will indeed be in the correct position (131). This is not true of undescended testes. One distinguishing feature of puberty is testosterone production, which establishes the rationale behind giving hCG as a diagnostic test. It is safe, and any virilizing side effects usually are mild and reversible after discontinuation of hCG. When giving the hormone in this manner, strict criteria should be used when interpreting the clinical results. After a course of hCG, the testis should be in a dependent position at the base of the scrotum. If this is not the case, the diagnosis of retractile testis cannot be made with assurance.

In patients with bilateral, nonpalpable testes, the diagnosis of bilateral anorchia needs consideration. If serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are elevated in boys younger than 9 years of age, no further evaluation is necessary to make this diagnosis (80). If gonadotropins are not elevated, hCG administration of 2,000 IU daily for 3 days, with measurement of preinjection and postinjection serum testosterone will determine the presence of testicular tissue (68,176). Some caution should be exercised in the interpretation of this test because testes have been reported in cases where there has been no testosterone response to hCG (158,175). This is presumed to be so in cases in which the testis fails to recognize hCG, such as 5-a-reductase deficiency. Treatment in such cases is controversial. There has been some enthusiasm for the use of hCG in patients with unilateral, nonpalpable testes, in an attempt to stimulate some descent, effectively making them palpable, undescended testes and obviating the need for more extensive surgical procedures. Therapeutic options are simpler in such cases, and it has been reported that the testosterone effect on the spermatic vessels makes them less apt to suffer from trauma during surgery (15).

Undescended testes may occur in association with other problems of the external genitalia, such as hypospadias. When these two conditions occur together, there

should be concerns of ambiguous genitalia and intersex. Consequently, a karyotype analysis is essential (84,134).

Once the diagnosis of cryptorchidism has been established, treatment needs to be instituted. Orchiopexy is the treatment of choice in North America, whereas in Europe, hormonal treatment with hCG and gonadotropin-releasing hormone (GnRH) is quite popular. The choice of surgical procedure depends in large part on the location of the testis; the other decision is the timing of surgery. Currently, surgery is recommended before age 2 years, in attempts to prevent damage to the primary spermatogonia, an observation made with increasing frequency the later the surgery is performed after 2 years of age (112). Over the past decade, the trend has been to operate at an even earlier age if the diagnosis is obvious, and it appears unlikely that the testis will descend with further observation (95). Consequently, it is not unreasonable to perform surgery as early as 6 months of age in selected cases.

The surgical options depend on a variety of factors. Testes that are palpable can easily be approached inguinally, and generally are easy to bring down into the scrotum. Intraabdominal testes, especially if solitary, pose greater challenges. Many approaches have been described, including stages 1 and 2 Fowler-Stephens orchiopexy, laparoscopic-assisted orchiopexy, and microvascular orchiopexy. Detailed descriptions of these operations are beyond the scope of this chapter.

The Acute Scrotum

The child who is referred to the office with a painful scrotum needs prompt evaluation in the event that the cause of the pain is torsion of the spermatic cord (33). Testicular torsion is the most common pediatric urologic emergency. However, this is not the most common reason for scrotal pain or swelling. Time is critical in establishing the diagnosis and instituting treatment, because testicular viability is measured in hours once the blood supply to the testis is compromised. The likelihood of testicular salvage is greater if the duration of the torsion is less than 6 hours (96,168).

As in all cases, evaluation begins with a careful history. Pain is the typical symptom and is sudden in onset, often awakening the patient from sleep. Nausea and vomiting are common. The scrotum often becomes erythematous and enlarges, and a reactive hydrocele often is encountered. A history of trauma should be excluded, as should other signs and symptoms such as irritative voiding symptoms, fevers, or rashes. It is not uncommon to learn that patients have had previous painful episodes of less severity, suggesting intermittent torsion.

Physical examination obviously is important in making an accurate diagnosis. The earlier in the course of the event the examination takes place, the easier it will be to establish the diagnosis without any ancillary diagnostic studies. Once edema and induration occur, the reliability of the physical examination alone diminishes. A reactive hydrocele also may occur, further obscuring the examination. When present, it usually is bloody. Testicular position in the scrotum is an important diagnostic criterion. The testis may appear “high riding,” because as the spermatic cord twists, it draws the testis up out of the scrotum (Fig. 55.6). The orientation of the testis likewise may be abnormal. The epididymis may be located in a position other than its typical posterior location; however, this may be variable, because the torsion can occur 360 or 720 degrees. The testis may assume a horizontal lie in the scrotum, also suggestive of torsion. The testis typically is extremely tender to palpation, often with extension into the inguinal canal. The cremasteric reflex usually is absent, but this is not a reliable finding because it may still be present in early torsion, or may be absent in conditions other than torsion.

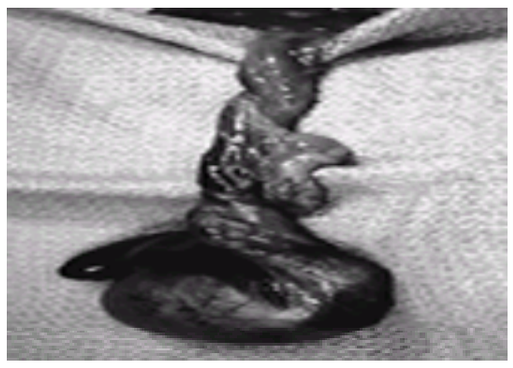

FIGURE 55.6. Torsion of spermatic cord. Note that there are several twists in the spermatic cord, elevating it into a “high-riding” position in the scrotum.

Laboratory tests usually are unnecessary in most patients presenting with an acute scrotum, with the exception of a urinalysis to exclude pyuria and bacteriuria, typically found in patients with epididymitis. However, an abnormal urinalysis is not pathognomonic for epididymitis. Crystals in the urine should make one suspicious of a stone, with the testicular pain being referred. In such cases, there is usually no erythema or edema of the testis or scrotum.

The etiology of the acute scrotum often can be determined in the office, and if testicular torsion is present, detorsion can be attempted to temporize the situation until definitive surgery can be performed. Rotating the testis outward from the midline when viewing the patient from his feet does this, because torsion usually occurs inward. In the small child with an acute scrotum, these maneuvers rarely are successful. If the diagnosis is equivocal, emergency scrotal exploration should be performed as soon as possible to reestablish blood flow to the testis. However, if further evaluation does not appear to pose much risk regarding the eventual outcome, scrotal sonography with Doppler has proven to be a useful diagnostic tool in the hands of experienced examiners (91,182). Flow to the interior of the testis rules out testicular torsion and usually saves the child an emergency operation. Nuclear testicular scan is another reliable testicular imaging study that can determine whether blood flow is present, but it usually is more time consuming than sonography, and involves some radiation exposure (42). False-positive and false-negative findings have been reported with both studies (18). Furthermore, these studies should be used only in the clinical situation where a nonoperative approach seems most likely, and these studies serve as justification of this approach. If surgery is seriously considered (i.e., if testicular torsion seems a real possibility), neither test is indicated. The patient should be taken to the operating room as soon as possible.

Torsion of the appendix testis is the most common cause of the acute scrotum and testicular pain, and is a self-limited condition. In most cases of an acute scrotum, torsion of the appendix testis is a diagnosis of exclusion in all but the most obvious cases. Early in the course of torsion of the appendix testis, point tenderness may be elicited over the anterosuperior pole of the testis, the area where the appendix testis is expected to be found (Fig. 55.7). Before scrotal edema ensues, the necrotic appendix can be visualized through the skin, giving the blue dot sign (50).

FIGURE 55.7. Torsion of appendix testis. The testis and epididymis are normal, but the appendix testis demonstrates hemorrhagic infarction.

Once acute testicular torsion and torsion of the appendix testis have been excluded, other etiologies for testicular pain need to be considered. Intermittent testicular torsion is a difficult diagnosis to prove, and a high index of suspicion is necessary to make this diagnosis. Intermittent torsion usually occurs in adolescents and teens. The most obvious cases are those in which there is sudden-onset scrotal pain and swelling, which can last several minutes or longer, and then completely revert back

to normal just as quickly as it came on. A transverse orientation of the testis in the scrotum further supports this diagnosis. This may be the cause of longstanding intermittent, transient pain in the scrotum but it is very difficult to prove. The problem may be one of degree and may be related to the extent of torsion of the cord. When the cord twists 360 degrees, there is little doubt about the diagnosis, but if the testis partially twists, symptoms will vary accordingly.

The differential diagnosis of acute scrotal pain also includes epididymitis and other inflammatory processes of the testes. The epididymal inflammation may be bacterial, viral, or chemical. Epididymitis is uncommon in prepubertal boys, and when found should suggest some anatomic abnormality involving the urinary tract (155). In the evaluation of the acute scrotum, a urinalysis consistent with infection is strongly suggestive of this diagnosis, but epididymitis may occur with a normal urinalysis. This has been observed when there is urethral obstruction, resulting in increased voiding pressure and reflux of urine into the ejaculatory ducts. Hemophilus influenza has been reported to cause epididymitis in association with otitis media. The presence of a prepuce has been reported as a possible risk factor for epididymitis (13). The onset of symptoms in children with epididymitis is typically more insidious than in those with testicular torsion, and may be associated with fever, urethral discharge, or other constitutional symptoms. These patients often have pyuria, leukocytosis, and bacteriuria. Indwelling urethral catheters are a risk factor for epididymitis. Viral orchitis most commonly seen with mumps and testicular/epididymal vasculitis, such as is seen with Henoch-Schönlein purpura, also can present as an acute scrotal processes and often results in unnecessary scrotal exploration. Thorough history and physical examination usually will help in making these diagnoses, however.

Antenatal Torsion

The clinical presentation of a child with antenatal torsion depends on when the event took place. If torsion occurred weeks before delivery, it is likely that the testis will have atrophied already and the scrotum may be relatively normal in appearance. If the event was perinatal, the examination may be similar to that of an acute scrotum in an older child. Unlike torsion in older children that is intravaginal, antenatal torsion typically is extravaginal. The likelihood of testicular salvage in antenatal torsion is remote because the event usually occurs well before delivery, and irreversible ischemia is likely (Fig. 55.8). Consequently, early surgery is controversial (101). Some have speculated that an immunologic effect on the contralateral testis may warrant removal of the ischemic testis (2). Others have argued that approximately 10% of antenatal torsion is intravaginal (40), increasing the risk of contralateral torsion and justifying early surgery to remove the affected testis and for contralateral orchiopexy. The risk of contralateral metachronous torsion is highest in the first 4 to 8 weeks of life.

FIGURE 55.8. Antenatal torsion. Testis has completely twisted extravaginally.

Most cases of torsion in infants are antenatal, but approximately 30% have been reported perinatally. These have a greater chance of being salvaged if they are recognized promptly.

Varicocele

Varicoceles are rare in prepubertal males (12). The incidence of varicoceles in adolescents is between 15% and 20%, which is the same as has been reported in adults (22). They often first present in the teenage years, and occasionally in prepubertal males. They represent dilated veins in the pampiniform plexus and almost always are found on the left, because of the anatomy of the left spermatic vein draining into the left renal vein. The characteristic clinical description is a “bag of worms” appearance (Fig. 55.9).

FIGURE 55.9. Left varicocele. Scrotum has a “bag of worms” appearance.

Most varicoceles in adolescents are discovered by a parent or on a routine physical examination. Most varicoceles are asymptomatic, but data strongly suggest that varicoceles can result in testicular damage in some adolescent boys. As many as 75% of boys presenting with a varicocele have testicular atrophy (107), and 90% have abnormal testicular biopsies. Careful measurement of testicular size rather than simple estimation is very important. Although the orchidometer is of some use, sonography is much more reliable in assessing testicular volume (37,45).

There is no consensus regarding the appropriate management of adolescent varicoceles. In asymptomatic boys with normal testes, the treatment should be individualized, and those boys not undergoing surgery should be followed with an annual examination to measure testicular growth. Surgery should be performed in boys who either complain of discomfort or have testicular growth retardation (90). When testicular atrophy is observed, surgery to correct the varicocele usually results in catch-up growth of the affected testis (89). It has been reported that ipsilateral testicular hypertrophy occurs in a substantial number of adolescents following varicocele ligation (66). Semen analysis should not be performed in the adolescent, but is reserved as a study to be used in adults as a criterion for surgery.

Spermatocele

Spermatocele is one of the more common scrotal masses seen in adolescents. It typically is cystic and nontender, and is paratesticular in location, most commonly in the head of the epididymis. Trauma, infection, or obstructions in the epididymal tubules all have been proposed as etiologies for spermatoceles. They occur in postpubertal boys, they transilluminate on physical examination, and they are filled with spermatozoa. Sonography confirms the diagnosis if there is any doubt on examination. No treatment is necessary unless there is significant discomfort, although in the teenage boy, any scrotal mass may arouse anxiety and warrant surgical excision. Spermatoceles are not associated with more serious problems.

The Red Scrotum

Many children will present to the office with a red scrotum, sometimes with associated pain, but usually fairly easy to distinguish from torsion of the testis or the

testicular appendages. Conditions that should be considered in the differential diagnosis include Henoch-Schönlein purpura, idiopathic scrotal edema, orchitis, cellulitis, insect bites, and trauma including sexual abuse.

Henoch-Schönlein purpura is a systemic vasculitis characterized by nonthrombocytopenic purpura with involvement of the genitourinary and GI systems, skin, and joints (Fig. 55.10). The etiology is unknown and is associated with pain and swelling in the spermatic cord and scrotum in up to one-third of affected patients. Seventy-five percent of the patients are younger than age 7 years. The problem may persist for more than 4 weeks. Other symptoms include purpura, arthralgias, hematuria, hematemesis, and abdominal pain. The problem is self-limited, requiring no specific treatment. The diagnostic dilemma is distinguishing Henoch-Schönlein purpura from testicular torsion because of the similarity of the clinical presentation in some cases. In 25% of patients, both problems occur concomitantly (106). Doppler ultrasound usually will exclude torsion by confirming flow to the testis.

FIGURE 55.10. Henoch-Schönlein purpura. Note the petechial hemorrhages over the scrotum and thighs. The erythema is confined to the scrotum.

Acute idiopathic scrotal edema often is difficult to diagnose because it may mimic testicular torsion. However, close inspection will disclose no testicular swelling or tenderness. Scrotal edema is a diagnosis of exclusion. The onset usually is sudden and may be unilateral or bilateral. The erythema is confined to the scrotum. Boys with this condition usually are afebrile, but many may have a low-grade fever. The average age of presentation is between 4 and 7 years, with most younger than age 10. Urinalysis and WBC count usually are normal, but eosinophilia may be seen. Many etiologies have been suggested including insect bites, allergic reactions, contact dermatitis, and angioneurotic edema. The condition is self-limited, but supportive treatment involves analgesia, rest, and reassurance. Antihistamines may be of some help.

Orchitis is an unusual, isolated finding in boys. It may be seen in association with some viral conditions such as mumps, which is rare in boys younger than 10 years of age. It usually occurs as a sequela of some other condition, such as bacterial epididymitis or inflammation, seen as a result of torsion of a paratesticular appendage (Fig. 55.11). The testis appears swollen and may be very painful, and there may be an associated hydrocele. Treatment is supportive with analgesics, scrotal elevation, and ice packs.

FIGURE 55.11. Epididymoorchitis. There is diffuse erythema and edema of testis and epididymis.

Tumors

The finding of a firm, nontender scrotal mass strongly suggests a tumor. Although not sudden in onset, it may be perceived as a new onset mass, and consequently present as an acute scrotal mass. A testicular tumor needs to be differentiated from a paratesticular tumor. Seventy-five percent of testis tumors in prepubertal boys are germ cell tumors, the majority of which are yolk sac, followed by teratoma. Non–germ cell tumors include gonadal stromal tumors, adnexal tumors, and metastatic tumors. Testicular tumors in older boys are unusual until the late teens, when adult-type germ cell tumors predominate. Rhabdomyosarcoma is the most common paratesticular tumor, usually occurring in the spermatic cord. This tumor may present with scrotal erythema and induration. Tumors in the epididymis are virtually never seen in children.

Genital Problems in the Female

The pediatric urologist typically is relied upon to evaluate genital problems in girls, because other specialists lack the experience or interest in treating these problems. There is also a close relationship between the female genital and urinary tracts, making it quite natural and appropriate for the pediatric urologist to address these problems because of the intimate knowledge of the anatomy and problems encountered.

Labial Adhesions

Labial adhesions are the most common of all the problems associated with the female genitalia. These are acquired adhesions of the labia minora. They usually occur during the first 2 years of life and the etiology is multifactorial. The withdrawal of maternal estrogens renders the skin in the perivaginal area thin and very easily irritated. Contact of this skin with wet diapers or other irritants such as soaps or bubble baths results in erythema and rashes resulting in damage to the epithelial layer. When such surfaces are in contact for prolonged periods of time, they “heal” together (Fig. 55.12).

FIGURE 55.12. Labial fusion.

Girls with labial fusion may present with voiding complaints, incontinence, or postvoid dribbling of urine, or may be referred because of UTIs (102). The latter diagnosis may be dubious depending on the extent of the adhesions. When the labial fusion is almost complete, the urine specimen is questionable because of introital contamination due to urine trapping. Many girls with labial adhesions are referred because of the inability to catheterize them.

The most difficult issue regarding labial fusion is preventing recurrences. Educating the parents is very important, reviewing with them the elements of perineal care, which entails prevention of erythema and rashes in the perineum. Liberal use of diaper rash creams may help. Sitz baths using baking soda or oatmeal may help stabilize the fragile perivaginal skin.

Vulvovaginitis

Vulvovaginitis is the most frequent pediatric gynecologic problem. This, like labial fusion, occurs because the skin of the introital area is thin, delicate, and easily traumatized. Irritants such as urine and feces come in contact with this area in children wearing diapers or soiling themselves after toilet training. Some common chemical irritants include soaps, shampoo, bubble baths, and laundry detergents. Parasites such as pinworms, fungal infections especially after antibiotic therapy, and foreign bodies can all result in vulvovaginitis (10).

The typical presentation of vulvovaginitis is erythematous introital skin; a yellowish, thin discharge; and dysuria. It often is misdiagnosed as a yeast infection, and it is not uncommon to find that many of these girls have been on multiple courses of antifungal agents or antibiotics. Often, a UTI will be diagnosed based on symptoms and an abnormal urinalysis, which commonly is found when the urine collection is a voided specimen. A catheterized specimen in girls with vulvovaginitis must be performed to establish a diagnosis of UTI.

The treatment of vulvovaginitis consists of warm sitz baths, often with the addition of baking soda or oatmeal; liberal application of diaper rash creams that contain zinc oxide; and occasionally, short courses of estrogen cream. The recurrence rate of vulvovaginitis is high.

Vaginal Foreign Bodies

Vaginal foreign bodies should be considered in children with recurrent or persistent vaginal discharge or bleeding, and especially if it is associated with a foul odor. Many objects commonly are inserted into the vagina by little girls, such as cotton, toilet paper, tips of cotton swabs, beans, peas, BBs, twigs, pencils, crayons, and pebbles. Initial efforts should be made to culture the vaginal drainage. If the cultures do not reveal a single pathogen, or if the drainage or bleeding persists after antibiotics, the diagnosis of a foreign body should be strongly suspected, and sometimes can be made by careful examination.

If the foreign body is large enough, it may at times be detectable on rectal examination. However in most cases, examination under anesthesia and vaginoscopy are required to make the diagnosis and to remove the foreign body. The vagina should be lavaged out with irrigating fluid.

Interlabial Masses

Young girls often present with a mass in the interlabial area. These masses often are similar in appearance but must be distinguished to implement appropriate and timely treatment.

Urethral Prolapse

Urethral prolapse generally is seen in prepubertal girls, and occurs more often in African American girls than in Caucasian girls. It has been proposed that poor attachments between smooth muscle layers of the urethra in association with increased intraabdominal pressure results in eversion of the urethral epithelium. Urethral prolapse often is misdiagnosed as sexual abuse (83). Girls with urethral prolapse often present with introital bleeding (6). They may complain of pain, especially when the prolapse is large, and it often results in dysuria or perineal discomfort. These lesions are not obstructive. The diagnosis is established by putting a catheter into the urethra to demonstrate a symmetric protrusion circumferentially around the tube (Fig. 55.13). Once the diagnosis is made, initial therapy should be sitz baths and estrogen cream twice a day for 2 to 3 weeks to reduce the inflammation and to ameliorate the symptoms (136). Medical management rarely is definitive treatment, and surgical excision will be necessary.

FIGURE 55.13. Urethral prolapse. Note circumferential eversion of edematous urethral mucosa around urethral catheter.

Introital Cysts

Introital cysts typically are seen in neonates and represent obstruction of either Gartner's ducts or Skene's glands (Fig. 55.14). When large, these cysts need to be differentiated from a prolapsed ectopic ureterocele, which is best accomplished with sonography. These rarely, if ever, cause urethral obstruction or infection. Once the diagnosis is established, the cysts can be observed, because most will resolve once estrogen levels, which are of maternal origin, decrease over the first few months of life. If the introital cysts do not regress, the preferred treatment is marsupialization.

FIGURE 55.14. Introital cyst. Cyst is located at urethral meatus or superior to it.

Prolapsed Ectopic Ureterocele

Ectopic ureteroceles may extend into the urethra and protrude through the meatus. They appear as a cystic mass and can be distinguished from urethral prolapse because they are located eccentrically relative to the lumen, and the vagina appears to be normal relative to the urethra. This is the presenting symptom in 10% of girls with ureteroceles (25). Ectopic ureteroceles may be erythematous and can be associated with irritative voiding symptoms. They tend to be very tender, and sometimes can be reduced manually. The diagnosis is confirmed with sonography and on VCUG. These studies almost always will demonstrate an obstructed upper-pole ureter, and rarely, bladder outlet obstruction. Treatment involves either an intravesical approach or a supravesical procedure. All treatments involve decompression of the ureterocele. Transurethral resection rarely is employed and when it is, it is as an adjunct procedure to remove an obstructing lip of tissue left behind from either upper-pole heminephrectomy or intravesical treatment of the ureterocele (i.e., resection or marsupialization) (148).

Imperforate Hymen

An imperforate hymen usually is detected at birth as a bulging mass at the introitus (Fig. 55.15). The typical blue hue to the mass represents fluid in the vagina. It may be associated with an abdominal mass secondary to hydrometrocolpos and/or mucocolpos. It has been suggested that there may be an autosomal-recessive mode of inheritance and therefore may be familial. If these masses are very large, venous return from the lower extremities may be obstructed. The treatment is a simple hymenotomy, which can be performed in the office. Ultrasound should be performed first to confirm the diagnosis. If this condition is missed at birth and is allowed to persist, many of these girls present at puberty because of amenorrhea and distention of the imperforate hymen by menstrual blood (hematometrocolpos).

FIGURE 55.15. Imperforate hymen. Bulging mass completely obscures urethral meatus.

Rhabdomyosarcoma (Sarcoma Botryoides)

Rhabdomyosarcoma is the most common primary malignancy involving the vagina, uterus, or bladder within the first 5 years of life. It has the appearance of a cluster of grapes protruding from the introitus (Fig. 55.16). Girls with this lesion often present with vaginal bleeding or passage of sloughed tissue fragments. Rectal examination is mandatory to gauge the extent of the mass. Metastatic spread to lymph nodes, lung, liver, and bones are late manifestations. Treatment involves a combination of chemotherapy, radiation therapy, and surgery.

FIGURE 55.16. Vaginal rhabdomyosarcoma. Sarcoma botryoides, or “cluster of grapes,” originating from vagina.

Trauma

Trauma to the introital area can be accidental or intentional (i.e., sexual abuse). Typical examples of accidental trauma are straddle injuries, accidental penetration, and forced stretching (e.g., from falls or gymnastics). Injuries can involve any and all areas in the introitus: the mons, clitoris, urethra, labia majora and minora, and even the rectum. It is important to try to determine the mechanism of injury and to exclude sexual abuse (71). Many cases are associated with severe bleeding; therefore examination under anesthesia often is necessary, although small lesions can be examined and treated in the office. Traumatic hematomas of the vulva can be managed with ice and bed rest if they are not expanding. When very large, a Foley catheter may be necessary for bladder drainage. Suspected cases of sexual abuse need to be reported promptly to the proper agency or law enforcement, and examination under anesthesia with sampling of secretions and cultures, and with photographic documentation, are mandatory.

Urolithiasis

It generally has been assumed that urolithiasis is rare in children in industrialized nations. When present, they often are associated with metabolic disorders, anatomic abnormalities, infection, or obstruction. In developing nations, stone formation is quite common, with bladder stones composing a large percentage of the cases. However, it appears that the incidence of stones in the United States has likely been underreported (177) and that metabolic factors play a far greater role in stone formation than was previously suspected (49).

The age of the patient is an important factor influencing the clinical presentation. The older child often will have the typical symptoms seen in adults with calculus disease, such as flank pain, hematuria, and emesis. In younger children, the symptoms may be more subtle, such as vague abdominal pain or feeding problems. In any case, a high index of suspicion is necessary so that appropriate evaluation is initiated. The presence of fever should be considered serious and UTI should be suspected until proven otherwise, because obstruction from a stone and infection together put a child at higher risk of sepsis and renal damage. Other historic information important in considering the possibility of stones is a history of prematurity often associated with the use of diuretics such as furosemide. The risk of nephrocalcinosis and urolithiasis is increased significantly with this history.

The evaluation of the patient with suspected stone disease is twofold. First, imaging studies are necessary to make the diagnosis and to plan appropriate treatment.

Second, after successful treatment, evaluation of the patient is important to determine the etiology of the stone formation so that subsequent stone formation is prevented, if possible. The initial imaging study depends on the office capabilities. Renal sonography is very easy to perform, if available, and depending on the resolution of the probe used, stones 0.5 cm or larger usually can be identified easily, as can associated problems such as hydronephrosis. Unfortunately, small renal stones or ureteral stones are very difficult to image, which means that even when ultrasound is used, some other imaging study will still be necessary. Intravenous urography (IVU) has been the standard in the evaluation of renal colic. One of the best features of the study is the usual excellent visualization of the entire collecting system, but it also has some shortcomings. Small stones and radiolucent stones can be missed. These studies typically are performed in an unprepped patient and, as a result, there are often large amounts of fecal material and gas that hinder visualization. Finally, IV contrast must be given for the study, and problems such as contrast allergies are not rare. In light of these problems, spiral CT is considered by some as the procedure of choice in the evaluation of suspected stones (159). It is rapid (less than 2 minutes) and requires no contrast, although it may be combined with contrast after initial noncontrast images are obtained, to exclude obstruction. Small stones, often as small as 1 mm, can be identified, and radiolucent stones are seen better on CT scan than on IVU.

Once the correct diagnosis has been established, decision making is shifted to treatment, which again varies depending on many factors. Patients who are septic or who are in severe pain will require different management from a patient with mild intermittent colic. Other factors that are important in the decision-making process include age of the patient, size of the stone, location of the stone, composition of the stone, and anatomy of the urinary tract. Large stones, a large stone burden, or a staghorn calculus may make one treatment modality appear more favorable over another. Stone composition influences which treatment to recommend, as in the case of known cystine stones that are typically resistant to extracorporeal shock wave lithotripsy (ESWL). The anatomy of the urinary tract in children is probably the most important factor that influences treatment decisions. The incidence of stone formation is higher in patients with congenital malformation of the urinary tract. Furthermore, the small size of the pediatric urinary tract often makes treatment of stones a very challenging exercise. The limiting factor in the past typically has been the size of the instrumentation available. The surgical management of stone disease in children is now similar to that in the adult (32,97,104).

The various treatment modalities available in children are identical to those in adults. Of course with some, extreme modifications other than just size alone need to be made to accommodate patients who are very small or who may have significant associated congenital problems, such as spina bifida and severe kyphoscoliosis. The specific treatments are well-known to all urologists experienced in treating stones and have been employed successfully in children. These include ESWL (58,118), percutaneous lithotripsy (PCL), ureteroscopy (3,113), laser lithotripsy (137,146), ultrasonic lithotripsy, and electrohydraulic lithotripsy (EHL). Open surgical stone extraction is another reasonable treatment modality in children, especially when there are associated congenital problems, such as ureteropelvic junction obstruction, that need correction.

As previously mentioned, there are differences that need to be considered when employing these stone treatment modalities in children. ESWL, for example, generally cannot be performed in children without general anesthesia. Technical factors such as modifying the table so that the shock heads are adequately positioned also are involved when the patient is very small or has skeletal deformities. Passage of stone fragments may be less likely to occur through small ureters. In a recent series of 33 children, no stone in excess of 3 mm passed spontaneously (172). Excessive shock waves or high-intensity shock waves need to be avoided because of the sensitivity of the immature kidney, and in doing so, the treatment of the stone may be rendered inadequate. When PCL is being considered, the pediatric kidney is much more difficult to access adequately; consequently, an experienced pediatric interventional radiologist is a very important part of the team. The size of the tract that is established is usually the limiting factor for this procedure, along with the size and length of the instruments. Infusion of irrigating fluid needs to be monitored carefully, because the margin for error is much less in children than in adults (78). Multiple procedures are not uncommon with this approach, which is unappealing to most children and parents. Tubes required after PCL are more apt to fail either because of stone fragments and debris occluding the small lumen of the tube or because they are more tenuous and get pulled out accidentally. Ureteroscopy is excellent for stones below the true pelvis and has become more available to the pediatric endoscopist since the development of smaller, rigid telescopes that often can be passed without dilation of the ureteral orifice. Flexible ureteroscopes and the holmium laser also have contributed to the improvements in ureteroscopy.

The etiology of the stone is relevant both in treatment considerations acutely, and in terms of prevention subsequently. Stones may be either infectious or metabolic. The most common metabolic stones are typically calcium, oxalate, uric acid, or cystine. Other types of stones may be seen as part of underlying metabolic problems, such as xanthinuria, or xanthopurine stones found in Lesch-Nyhan disease. Calcium stones may be found in patients with hypercalciuria or normocalciuria.

Infection stones, also called *struvite stones* (magnesium–ammonium phosphate) typically are made in alkaline urine. Urease produced by bacteria produces large amounts of ammonium that buffers the urine to a constant alkaline pH. This leads to crystallization of magnesium and phosphorus. Antibiotics are unsuccessful in addressing these stones because causative bacteria are encased in the stone. Treatment involves complete stone removal and then subsequent antibiotics for sterilization of the urine. *Proteus, Providencia, Pseudomonas, Klebsiella, Streptococcus,* and *Mycoplasma* all have been implicated in struvite stone formation.

Calcium oxalate stones are the most common stones in children, and hypercalciuria is the most common etiology. Hypercalciuria most commonly occurs because of a renal leak, because of increased absorption from the gut, or resulting from the acidic form of renal tubular acidosis (i.e., distal RTA). Prolonged immobilization also can result in calcium stone formation.

In renal leak hypercalciuria, there is a high urinary calcium-to-creatinine ratio (Ca:Cr) in fasting patients in both spot and 24-hour urine specimens. The 24-hour urinary calcium exceeds 4 mg/kg per day, and the urinary Ca:Cr exceeds 0.21 (160). In absorptive hypercalciuria, there is increased absorption of calcium from the GI tract. It is detected on 24-hour urine by measuring Ca:Cr on a standard diet and then repeated. Finally, a third measurement is taken after a 14-day period of dietary sodium and calcium restriction (129,160). Normal children excrete less than 4 mg/kg per day of calcium in all three samples. Distal RTA is determined by checking voided urinary pH throughout the day. If the pH is ever less than 5.3, the diagnosis of RTA can be excluded (49). If this test is equivocal, an acid-loading test may be necessary to establish this diagnosis.

Two forms of hyperoxaluria exist: a primary type and a secondary type. The primary form is an autosomal-recessive trait, and children with this develop calcium oxalate stones early in life, often before 5 years of age. Oxalate excretion that exceeds 50 mg per day should call this diagnosis into question (147). Secondary hyperoxaluria almost always is associated with enteric disease such as malabsorption, irritable bowel disease, cystic fibrosis, or bowel resection (short gut). It also is seen in patients with high-oxalate diets or excessive vitamin C intake (i.e., greater than 4 g per day) (129).

Patients with calcium stones who have normocalciuria often form stones because of a deficiency of stone inhibitors such as magnesium or citrate. No studies show that the addition of magnesium or citrate in patients with low urinary levels of these stone inhibitors will decrease the incidence of subsequent stone formation.

Uric acid stones are formed in acid urine. Urinary pH less than 5.8 will promote crystallization of uric acid. Elevated serum uric acid will result in elevated urinary levels and is seen in familial hyperuricemia, bowel disease, certain inborn errors of metabolism (Lesch-Nyhan disease), or dietary abnormalities.

Cystine stones also are formed in acid urine. Cystine precipitates in urine with a pH of less than 7. Cystinuria is inherited, as an autosomal-recessive trait in which there is failure of the renal tubules to absorb four amino acids: *c*ystine, *o*rnithine, *l*ysine, and *a*rginine (COLA). Only cystine has poor solubility in the pH range of urine and consequently stones will form.

Once the patient has been rendered stone free, the emphasis is placed on prevention of further stone formation. If a specific cause for stone formation is determined, there is a possibility that specific treatment can be instituted. This may entail the use of drugs such as thiazide diuretics, or dietary modifications to attempt a reduction in the excretion of the offending substance. When no specific reason for stone formation is detected, the mainstay of treatment is to significantly increase fluid intake to increase urine output.

Antenatal Assessment

The widespread use of screening ultrasonography of the pregnant female detects anomalies in 1% of pregnancies, of which 20% occur in the genitourinary tract (69,138). When an anomaly of the urinary tract is identified, multiple specialists including the perinatologist, primary care physician, ultrasonographer, and pediatric urologist are involved in the assessment and subsequent management. The vast majority of anomalies are those causing antenatal hydronephrosis. The obvious stress and uncertainty this brings to the family requires close coordination with all physicians involved to provide the best care.

The pediatric urologist should provide counseling on specific urologic conditions such as exstrophy and hydronephrosis. A balanced view can be presented to the parents to minimize the ongoing stress. The physician should provide specific information and answer questions about the condition with the parents. The postnatal imaging and management need to be discussed in detail, because this knowledge will decrease anxiety after the baby is born. It is important to provide all requested

information to the parents so they can make informed decisions in conjunction with the perinatologist.

Before the office visit, it is incumbent upon the pediatric urologist to talk to the perinatologist and ultrasonographer. Specifics of the pregnancy and testing already performed should be ascertained. Sex of the fetus, other anomalies, results of amniocentesis, and any genetic testing are obtained. If the fetal bladder urine has been sampled for electrolyte content, these results are requested. The mother's prior obstetric history and urologic history also are obtained.

The prenatal ultrasounds are reviewed with the perinatologist and radiologist. The urinary tract measurements, including renal size, anteroposterior diameter of the renal pelvis, calyectasis, renal echogenicity, corticomedullary differentiation, ureterectasis, and amount of amniotic fluid on serial measurements are reviewed (53). Bladder filling and emptying should be present. Abdominal wall defects and penile anomalies, if detected, combined with absent bladder filling and emptying indicate exstrophy of the bladder (23,64). Currently, a renal pelvic diameter of greater than 4 mm *before* 33 weeks of gestation and greater than 7 mm *after* 33 weeks of gestation is considered significant hydronephrosis (36). Serial fetal ultrasounds demonstrating increased renal pelvic diameter imply increased severity of the process. The main considerations in determining the management of the fetus are overall fetal well-being, gestational age, amniotic fluid volume, and unilateral versus bilateral hydronephrosis (36).

If hydronephrosis is unilateral with normal amniotic fluid, no special delivery is required. The pediatrician is contacted concerning postnatal antibiotic prophylaxis. On rare occasions with unilateral hydronephrosis, predelivery renal pelvic aspiration is necessary to prevent dystocia (38). The primary life-threatening anomalies are those causing bilateral hydroureteronephrosis and bladder distention. These include posterior urethral valves, urethral atresia, and prune-belly syndrome. Urethral atresia is nearly always fatal, resulting from coexistent renal dysplasia. When oligohydramnios is present, normal pulmonary development does not occur and is a severe adverse prognostic sign. Neonatal demise in these circumstances results not from renal failure but from pulmonary hypoplasia. The fetus with bilateral hydronephrosis is at high risk and should be delivered at a center specializing in the care of high-risk pregnancies and with infant intensive care and surgical specialists.

Fetal intervention continues to evolve and includes termination of pregnancy, placement of a vesicoamniotic shunt, and open or fetoscopic surgery. Prenatal interventions to improve renal function and pulmonary development remain experimental and, although technically feasible, are associated with significant fetal and maternal risk. Complications occur in up to 45% of fetuses. There are few clinical data to prove that *in utero* intervention improves postnatal renal function or minimizes renal dysplasia. At present, the selection of patients for fetal intervention are based on the following fetal prognostic factors:

1. Renal cystic dysplasia
2. Fetal urinary electrolytes
3. Reduced lung area
4. Elevated b_2-microglobulins
5. Prolonged oligohydramnios

The best case scenario for fetal intervention is the male patient with bilateral hydronephrosis with distended bladder, no other anomalies, normal chromosomal analysis, second trimester onset of oligohydramnios, and “favorable” serial fetal urine electrolyte measurements. This fetus would have a poor prognosis, but theoretically has improvable renal parameters and renal outcome (35).

In summary, prenatal imaging alerts the physician to urinary tract abnormalities before the onset of symptoms. Postnatal evaluation allows for timely intervention if necessary. Prenatal intervention based on present knowledge rarely is indicated. This information needs to be given to the parents in a coordinated caring fashion to diminish their anxiety and fears.

APPENDIX 1

Observation or Hospital Inpatient Care Services

Oinitial)

(Admission and Discharge)

	Level 1	Level 2	Level 3
Observation Care	99218	99219	99220
Hospital Inpatient	99221	99222	99223
Admission & Discharge	99234	99235	99236

KEY COMPONENTS

MUST SATISFY ALL THREE KEY COMPONENTS

History	Content of Services		
History of Present Illness	4+*	4+*	4+*
Review of Systems	2–9	10+	10+
PFSH—Family and Social	1–2	3	3

*An extended can also be reached by documenting the status of at least 3 chronic or inactive conditions

Physical	System/Element	System/Element	System/Element
Single Organ System	1+/12+ 1+/9+ for eye & psych	examined/1	examined/1
Multisystem—General	1+/6–11	9+/x2 each	9+/x2 each

Medical Decision Making

MUST SATISFY TWO OF THE THREE ELEMENTS

Number of Diagnoses	Min./Lim.	Multiple	Extensive
Amount of Data	Limited	Moderate	Extensive
Amount of Risk	Min./Low	Moderate	High

CONTRIBUTORY COMPONENTS

Time

BECAUSE KEY COMPONENT AND INCREASED OTHER COMPONENTS OF OVER 50% OF SERVICE IS COUNSELING AND COORDINATION (TIME IS ESSENTIALLY APPLIED TO COUNSELING, NOT DOCUMENTING)

Time	30	50	70

Problem

PROBLEM MUST JUSTIFY TREATMENT

Risk of Morbidity	Low	Moderate	High
Risk of Mortality		Moderate	Mod–High

Consult/Follow–Up Inpatient Subsequent Hospital Care

	Level 1	Level 2	Level 3
Subsequent Hospital Care	99231	99232	99233
Consults/Follow–Up Inpatient	99261	99262	99263

KEY COMPONENTS

MUST SATISFY TWO OF THE THREE KEY COMPONENTS

History	Content of Services		
History of Present Illness	1–3	1–3	4+*
Review of Systems		Pertinent	2–9
PFSH—Family and Social			

*An extended can also be reached by documenting the status of at least 3 chronic or inactive conditions

APPENDIX 2

Genitourinary Examination

System/Body Area	Elements of Examination
Constitutional	■ Measurement of **any three of the following seven** vital signs: a) sitting or standing blood pressure, b) supine blood pressure, c) pulse rate and regularity, d) respiration, e) temperature, f) height, g) weight (may be measured by ancillary staff) ■ General appearance of patient (e.g., development, nutrition, body habitus, deformities, attention togrooming
Head and face	
Eyes	
Ears, nose, mouth, and throat	
Neck	■ Examination of neck (e.g., masses, overall appearance, symmetry, tracheal position, crepitus) ■ Examination of thyroid (e.g., enlargement, tenderness, mass)
Respiratory	■ Assessment of respiratory effort (e.g., intercostal retractions, use of accessory muscles, diaphragmatic movement) ■ Auscultation of lungs (e.g., breath sounds, adventitious sounds, rubs)
Cardiovascular	■ Auscultation of heart with notation of abnormal sounds and murmurs ■ Examination of peripheral vascular system by observation (e.g., swelling, varicosities) and palpation (e.g., pulses, temperature, edema, tenderness)
Chest (breasts)	[See genitourinary (female)]
Gastrointestinal (abdomen)	■ Examination of abdomen with notation of presence of masses or tenderness ■ Examination for presence or absence of hernia ■ Examination of liver and spleen ■ Stool sample obtained for occult blood test when indicated
Genitourinary	**Male:** ■ Inspection of anus and perineum Examination (with or without specimen collection for smears and cultures) of genitalia including: ■ Scrotum (e.g., lesions, cysts, rashes) ■ Epididymides (e.g., size, symmetry, masses) ■ Testes (e.g., size, symmetry, masses) ■ Urethral meatus (e.g., size, location, lesions, discharge) ■ Penis (e.g., lesions, presence or absence of foreskin, foreskin retractability, plaque, masses, scarring, deformities) Digital rectal examination including: ■ Prostate gland (e.g., size, symmetry, nodularity, tenderness) ■ Seminal vesicles (e.g., symmetry, tenderness, masses, enlargement) ■ Sphincter tone, presence of hemorrhoids, rectal masses **Female:** Includes **at least seven of the following eleven** elements identified by bullets: ■ Inspection and palpation of breasts (e.g., masses or lumps, tenderness, symmetry, nipple discharge) ■ Digital rectal examination including sphincter tone, presence of hemorrhoids, rectal masses Pelvic examination (with or without specimen collection for smears and cultures) including: ■ External genitalia (e.g., general appearance, hair distribution, lesions) ■ Urethral meatus (e.g., size, location, lesions, prolapse) ■ Urethra (e.g., masses, tenderness, scarring) ■ Bladder (e.g., fullness, masses, tenderness) ■ Vagina (e.g., general appearance, estrogen effect, lesions, pelvic support, cystocele, rectocele) ■ Cervix (e.g., general appearance, lesions, discharge) ■ Uterus (e.g., size, contour, position, mobility, tenderness, consistency, descent or support) ■ Adnexa/parametria (e.g., masses, tenderness, organomegaly, nodularity) ■ Anus and perineum
Lymphatic	■ Palpation of lymph nodes in neck, axillae, groin, and/or other location
Musculoskeletal	
Extremities	
Skin	■ Inspection and/or palpation of skin and subcutaneous tissue (e.g., rashes, lesions, ulcers)
Neurologic psychiatric	Brief assessment of mental status including: ■ Orientation (e.g., time, place, and person) and ■ Mood and affect (e.g., depression, anxiety, agitation)

Content and Documentation Requirements

Level of Examination	Perform and document
Problem focused	**One to five** elements identified by a bullet
Expanded problem focused	**At least six** elements identified by a bullet
Detailed	**At least twelve** elements identified by a bullet
Comprehensive	Perform **all** elements identified by a bullet, and document every element in a box with a shaded border and at least one element in a box with an unshaded border.

PEDIATRIC ENDOSCOPIC SURGERY

The pursuit of endourology (from the Greek word *endon* meaning “within”) exploits controlled manipulations within the urinary tract, often aided by either fluoroscopic or ultrasonographic imaging. Principles in this practice date back to urethral catheterization for relief of urinary retention due to bladder stone. For centuries, this treatment has been considered a preferable alternative to the terror and significant mortality of perineal lithotomy (25). Percutaneous nephrostomy, the cornerstone technique of endourology, also has a long history born of necessity. Dr. Thomas Hillier (1865), of Great Ormand Street Hospital for Sick Children, intermittently aspirated urine over a 4-year interval from the massively hydronephrotic right kidney of a young boy to ease the boy's suffering (27). The urge to comfort and help the sick by formulating rational methods of therapy are traits at the heart of human civilization (25) that have served as the muse for development of pediatric endourology.

HISTORY OF PEDIATRIC ENDOSCOPY

Evolution of the Pediatric Cystoscope

More than 120 years have passed since the first practical light cystoscope was constructed in Germany. Nitze (1879) combined the basic structure (candle holder in a box with a hollow tube used for viewing) proposed in 1806 by Philipp Bozzini (37) with an internal glowing platinum wire at the inner tip of the endoscope developed by Trouvé (375), and added an optical lens near the light source to provide magnification (283,326). The incandescent platinum wire became easily fused, requiring frequent exchange, and also could burn the bladder and urethra on removal of the cystoscope (280). After Edison invented the light bulb, the Mignon lamp was rapidly incorporated into cystoscope design and provided more reliable illumination. This eliminated the need for the complex and expensive internal cooling system developed by Nitze, and changed the cystoscope to an inexpensive and readily usable instrument (326).

Nitze developed a cystoscope for use in children, but its relatively large size (17 Fr) and standard adult length greatly limited its use. Edwin Beer constructed and promoted the first pediatric cystoscope (1907) with a shorter length and acceptable caliber (15 Fr). This design included a detachable catheterizing apparatus (195). In 1911, he reported on a large series of cystoscopic examinations in children as young as 14 months in girls, and 5 years in boys (15). Hugh Hampton Young performed the first endoscopic examination on a patient (17 years old) with posterior urethral valves in 1912. He also managed to pass the extra-long child's cystoscope (12 Fr) through a patulous right ureteral orifice (1.5 cm) and up a dilated ureter into the renal pelvis, thereby completing the first ureteropyeloscopy (75). When McCarthy (1931) added a movable lever controlling a cutting loop (252) to the resectoscope design first constructed by Stern (1926) (359), routine instrumentation for lower urinary tract pathology became possible (326).

In 1960, Hopkins patented the revolutionary rod lens system, which substituted solid glass rods with intervening air spaces for the delicately positioned glass lenses previously used (170). This design proffered enhanced light transmission from a higher refractive index and greater durability because these new cystoscope lenses were constructed primarily of glass. By 1961, the McCarthy miniature and infant cystoscopes had become a distinct asset in evaluating children with urinary infection for structural derangements of the lower urinary tract (353). An interchangeable fiber-optic light source available for both of these instruments was considered a very marked advance over the standard incandescent light source. Pediatric resectoscope sheaths ranging from 11 to 14 Fr using interchangeable telescopes and a variety of working elements were widely available by 1979 (345).

Development of Percutaneous Nephroscopy

The development of nephroscopy necessarily followed refinements in percutaneous renal access. Initial reports of percutaneous access for evaluation of renal cysts (394) led to the landmark article by Goodwin and others (1955) detailing temporary percutaneous nephrostomy drainage in 16 patients with severe hydronephrosis (145). Although intraoperative nephroscopy with a rigid endoscope through a pyelotomy incision was first reported in 1948 (374), the utility of nephroscopy was extended greatly when it could be performed through an existing nephrostomy tract (62). The 16-Fr flexible fiber-optic nephroscope, introduced in 1979, allowed enhanced renal access for electrohydraulic nephrolithotripsy (68).

Evolution of Flexible and Rigid Ureteroscopes

Breakthroughs in fiber optics and a perceived requirement to follow the contour of the ureter initially promoted the development of flexible rather than rigid ureteroscopes. However, enthusiasts found it hard to rally around early models because of limited visibility (no irrigation port, and limited flexibility) (8,80). Once a 39 cm long, rigid ureteroscope with an irrigation channel was used for ureteropyeloscopy (1980) (298), rapid advances for rigid and later flexible ureteroscopes were made, extending their use to therapeutic interventions (8). Flexible ureteroscopes currently offer working diameters of 6.8 Fr with large working channels (3.6 Fr), and active tip deflection in two directions, suitable for use in children.

As technical improvements in optics become rapidly accepted and adopted for use, traditional endoscopic boundaries blur. Percutaneous endoscopic fulguration of posterior urethral valves in a 22-week-gestation fetus has been demonstrated to be technically possible. A 2.5-mm steerable endoscope with a 1.3-mm operating channel was passed through a 10-gauge trocar placed under ultrasonographic guidance through the maternal abdomen into the fetal bladder, and advanced over a soft-tip 0.025-inch guidewire into the prostatic urethra. Posterior urethral valves were fulgurated under visual guidance using a 2-Fr ball-tip monopolar flexible electrode. Although ablation of the obstructing valves was noted on postnatal examination, in this case the child succumbed to complications of pulmonary hypoplasia at 31 weeks of gestation (318). Specific indications for evaluation and intervention continue to be refined as more advanced endoscopic equipment becomes available.

CYSTOSCOPY

Historical Indications

Lyon and Smith (244) described a consistent narrowing of the distal urethra in the majority of female children studied for urinary infection and invoked distal urethral stenosis as the cause of their malady. Cystoscopy with urethral dilation thus became routine practice in the evaluation and treatment for both recurrent urinary infection (148), and diurnal and nocturnal enuresis (7). Cystoscopic examination also was used to detect vesicoureteral reflux (VUR) evident visually after first filling (and then emptying) the bladder to capacity with indigo carmine (6).

Smith and Lattimer (353) recorded 4,088 endoscopic procedures in children over a 10-year interval from 1961 to 1971. Johnson and associates (187) noted that more than 95% of cystoscopies were performed independent of other open urologic procedures. Although some authors detected distal urethral stenosis in up to 96% of children with recurrent urinary infection (393), others found similarity in urethral calibration for groups of recurrently infected and normal children (148,174). Govan and Palmer (146) suggested that this finding merely represented “a normally narrowed area in the distal region of the urethra.” Recognition that routine correction of this perceived bladder outlet obstruction in girls failed to afford any protection from recurrent urinary infection (198,388) caused the pervasive use of cystoscopy in these children to wane. Other accepted indications besides voiding dysfunction also were reviewed, and some were discarded. Routine cystoscopy for initial evaluation of VUR, primary enuresis, and most cases of hematuria was and still is considered unnecessary (187,390).

Current Indications

Children with microscopic hematuria and normal radiographic studies (sonography and voiding cystourethrogram [VCUG]) most commonly have normal cystoscopic examinations (59). Although bloody urethral spotting (urethrorrhagia) in children does not mandate cystoscopy (196), urethral stricture should be suspected (26). Urethrorrhagia lasting longer than 6 months, and gross hematuria in the absence of infection, trauma, or stone disease should be evaluated (39). Children with recurrent gross hematuria and normal radiographic studies may require cystoscopy and ureteropyeloscopy to identify small vascular abnormalities, typically associated with the renal papilla (12,203).

Over the last two decades, cystoscopy has remained most useful in evaluating suspected urinary obstruction (urethral valves or strictures, congenital or postoperative ureteral obstruction) and severe congenital defects (intersex and cloacal anomalies) (187). Diagnostic cystoscopy also may be helpful in select cases in which urinary undiversion is planned, or to facilitate placement of a suprapubic cystostomy before urodynamic assessment. When massive VUR is present, cystoscopy should still be considered and may prove invaluable in identifying an unsuspected ureterocele (ureterocele disproportion), by allowing ureterocele puncture and opacification of the otherwise undetectable upper-pole moiety (81,347).

Instrumentation and Technique

Impressive technologic improvements in optics and size of instrumentation have further altered pediatric practice. Traditional pediatric cystoscopes with conventional lens telescopes are available in sizes ranging from 7 Fr up to 13.5 Fr and are accompanied by various accessories, such as grasping and biopsy forceps. Ureteral stents and guidewires, cauterizing electrodes, or laser fibers also can be passed through the cystoscopic working ports. Flexible cystoscopes ranging from 7 to 9 Fr outer diameters with steerable distal tips are available and may be especially helpful for use in children that have undergone urinary tract reconstruction. Neonatal and pediatric resectoscopes as small as 8.5 Fr have a variety of interchangeable cutting blades and cautery electrodes available to facilitate treatment for conditions such as posterior urethral valves or urethral strictures. Use of these instruments allows early and effective ablation of posterior urethral valves in infants.

Despite the small size of these instruments, it is critical that they be well lubricated, passed under direct visualization and that extreme caution be exercised during their use. The urethra is so fragile and delicate that minimal trauma may easily result in injury and subsequent urethral stricture formation. Passage of a cystoscope blindly with an obturator in place is rarely indicated. Pediatric cystoscopy usually requires general anesthesia. Infants can be placed in a frog-leg position, whereas older children are placed in a standard dorsal lithotomy position. In addition to the endoscopic evaluation, the anesthetized child presents an opportunity for careful examination of the lower abdomen, the genital area (including vaginoscopy) and rectum.

Each age group has a normal range of urethral calibers. The infant male urethra will usually accept a 9 Fr instrument, whereas preadolescent boys can accept instruments of 13 to 14 Fr. The urethral meatus is usually the narrowest portion of the male urethra (4,237). Inspection of the entire urethra from the lacuna magna to the bladder neck is important and may identify an unsuspected distal urethral diverticulum or polyp. The anatomic configuration of the external sphincter, verumontanum, and bladder neck also should be appreciated. Inspection of the prostatic urethra with irrigant flowing may aid in the diagnosis of a significant prostatic utricle or ectopic ureter. In males, inspection for urethral valves should be performed with both retrograde and antegrade flow of irrigant. In females, larger diameter instruments generally can be used because of the inherent elasticity and distensibility of the female urethra (174,175). A systematic examination of the bladder should include all surfaces, with the bladder in a full and partially emptied condition. The appearance of the epithelium, configuration of the trigone, and position of the ureteral orifices deserve specific attention. Careful examination for possible duplex ureteral orifices and identification of urine efflux from the orifices should be a routine part of cystoscopy.

Complications of cystourethroscopy are generally uncommon; however, urinary infection and urethral injury can certainly occur. Urethral stricture formation can present early with stranguria, split urinary stream or decreased force and caliber of urinary stream. Symptoms also may not become apparent until several months following cystoscopy. Bladder perforation from direct injury from cystoscope passage or overdistention of the bladder is rare but may represent a greater risk in children with augmented bladders. Irrigant fluid pressure should not exceed 60 cm of water. Furthermore, bladder overdistention in small children has been associated with arrhythmias and oxygen desaturation.

ENDOSCOPIC MANAGEMENT FOR LOWER URINARY TRACT PROBLEMS

Transurethral Incision of Posterior Urethral Valves

Transurethral incision of posterior urethral valves remains one of the most common indications for endoscopic surgery in infant and young boys. Open surgical excision of obstructing valves has now been entirely supplanted by the endoscopic approach, first demonstrated by Young (414) using a miniature punch, and Randall (319) using transurethral fulguration. After introduction of the fiber-optic light source allowed adequate illumination, use of the transurethral approach to posterior urethral valves was limited primarily by the relatively small caliber of the urethra in infant boys. Even as recently as 20 years ago, introduction of the (13 Fr) resectoscope often required use of a perineal urethrostomy. Alternatively, incisions could be made in the valve leaflets using a Bugbee electrode through a smaller cystoscope (10 Fr) (345). Even premature infants can now undergo transurethral incision of posterior urethral valves using either an 8-Fr resectoscope, or a 6.9-Fr cystoscope with a cold hook or 3-Fr Bugbee electrode (355). A neodymium:yttrium-aluminum-garnet (Nd:YAG) laser fiber also can be passed easily through a small working channel, and has proven effective in disrupting posterior urethral valves (107).

A cutaneous vesicostomy may be helpful in managing some premature infants with small-caliber urethras. This also offers a valuable opportunity to inspect the obstructing valve leaflets from proximal to the bladder neck. Antegrade disruption of the posterior urethral valves through the vesicostomy is an option (416), but complete disruption of the valve leaflets is often more easily performed using a retrograde approach. Because the valve represents a membrane with the perforation based posteriorly (adjacent to the verumontanum), incision of the posterior urethral valves should be performed at three points (at 12, 5, and 7 o'clock) (144). Antegrade valve incision also can be performed via percutaneous access (Fig. 56.1)(418,419). A flexible ureteroscope may be helpful in negotiating the angle beneath the symphysis pubis leading into the bladder neck region. This approach recently has been extended to *in utero* percutaneous fetal cystoscopy with antegrade fulguration of posterior urethral valves (318).

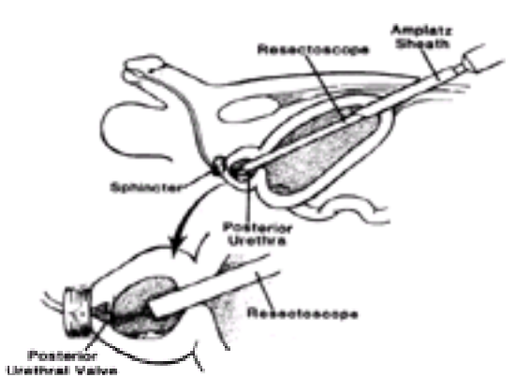

FIGURE 56.1. Percutaneous antegrade approach to posterior urethral valves. This method is preferred in neonates with very narrow urethras through which urethroscopy is not possible.

Endoscopic Incision of Urethral Stricture

Urethral strictures in children were only rarely reported before availability of the McCarthy miniature and infant cystoscopes (1961) (224). Subsequently, many more cases have been reported (284,285,338). Endoscopic urethrotomy using the cold-knife has become the preferred choice for initial treatment of discreet, short, and translucent urethral stricture disease in boys. Thermal injury secondary to electrosurgical urethrotomy is thought to be responsible for a high stricture recurrence rate (338). The Nd:YAG laser allows more precise and bloodless incision of the urethral stricture, and has proven effective (83% success) in treatment of boys failing cold-knife internal urethrotomy (120). However, recurrent strictures have developed following use of both the cold-knife and the Nd:YAG laser (120,197,285). More extensive stricture disease may require a combination of endoscopic incision and intermittent urethral dilation (284). Although adjunctive steroid injection has been thought to improve success following endoscopic urethrotomy (285), long-term benefit remains suspect (338).

Flexible cystoscopy performed through a suprapubic cystostomy tract can aid in localizing the proximal urethral segment in cases of complete traumatic disruption (328). Endoscopic Nd:YAG laser urethrotomy also can be considered in managing obliterative bulbar urethral strictures in children, yielding success in 7 of 8 adult men treated. This approach has been limited to strictures less than 2 cm in length, judged to have good urethral alignment (98).

Transurethral Incision of Ureterocele

Although endoscopic incision and unroofing of ureteroceles was recognized effective in alleviating obstruction, this procedure was not often advised because it consistently caused high-grade VUR in the affected ureter (52,356,397). Monfort and associates (264) described using a small horizontal meatotomy in the ureterocele positioned just above the bladder neck, and reported effective decompression without new VUR in six infants with intravesical ureteroceles, and one infant with a duplex ectopic ureterocele. One additional male infant with bilateral duplex ectopic ureteroceles was left with bilateral high-grade VUR following similar incisions. Transurethral incision of ureteroceles designed to relieve obstruction was then further popularized by Tank (370), who noted remarkable improvement in upper-pole renal function in half (20) of the infants and children in his series (40 duplex systems in 39 children). Improvement in function was based on the change in appearance of excretory urograms performed before and at least 6 months after incision of the ureterocele. Only 6 of 40 children subsequently required early reconstructive surgery to correct VUR and breakthrough urinary infection (370). Interestingly, Tank used an incision high and lateral on the ureterocele away from the bladder neck and willingly accepted VUR in nearly every case (370).

A low transverse puncture incision was later shown to effectively decompress intravesical ureteroceles (single and duplex) in more than 90% of cases, without creation of VUR in up to 85% of infants and children treated (28,77,329). Presumably, this minimal incision creates a better flap valve from the ureterocele remnant. Upper-pole renal function was preserved on nuclear renography in more than 95% of children undergoing endoscopic puncture of intravesical ureteroceles, including all 13 with single systems and 13 of 14 with duplex systems (28). Since then, endoscopic incision has proven successful and definitive for treatment of the vast majority of intravesical ureteroceles, especially those associated with single collecting systems (28,161,305).

The triumph achieved with endoscopic incision of intravesical ureteroceles has prompted renewed interest in endoscopic management for duplex ectopic ureteroceles. This may potentiate preservation of renal function by relief of obstruction and prevention of urinary infection. Employment of a limited incision also is expected to lower the risk for creation of new VUR following treatment. Unfortunately, neither objective can consistently be met.

Upper-pole renal function is often not actually quantitated in reports dealing with ureteroceles (5,28,370). When measured, function in upper-pole renal segments associated with duplex ectopic ureteroceles is often nominal (3,354,383). Blythe and co-workers (28) reported detectable upper-pole renal function in only half of their 24 cases following endoscopic incision of duplex ectopic ureteroceles. In 9 children treated by Smith and others (354), upper-pole renal function accounted for an average of 8.4% on preoperative nuclear renography and did not change significantly after endoscopic ureterocele incision. Vates and associates (383) also showed that upper-pole partial nephrectomy failed to significantly change renal function in 8 children when preoperative and postoperative nuclear renograms were compared. Because preoperative renograms are performed while the upper-pole system is actively obstructed, recovery of renal function after ureterocele incision may be better estimated by considering the sonographic appearance of the upper-pole system (184).

Urinary infection poses the greatest risk for damage to the normally functioning lower-pole renal segments. A large ectopic ureterocele obstructs its upper-pole renal segment, but also can obstruct the bladder neck, and thereby jeopardize additional renal segments (58). VUR into a lower-pole ureter partially obstructed by a large ureterocele further raises the risk of urinary infection and renal damage. Although a significant percentage of infants with duplex ectopic ureteroceles are diagnosed following antenatal ultrasonography (50% to 90%), urosepsis also remains a relatively common presentation (161,305). Endoscopic incision of the ureterocele is especially useful for emergency decompression of an infected and obstructed ureter (either upper or lower pole) blocked by an ectopic ureterocele. Occasionally, emergency decompression also is required in an infant with a solitary functioning kidney subtended by an ectopic ureterocele or with bilateral ectopic ureteroceles. Early postnatal radiographic evaluation and antibiotic therapy are mandatory. Husmann and co-workers (173) reported that only 1 of 33 infants receiving antimicrobial prophylaxis sustained a urinary infection while awaiting surgical treatment.

The endoscopic appearance of ectopic ureteroceles varies with bladder fullness. This impression ranges from a large diverticulum to a small mucosal fold to an obstructing promontory as the bladder changes from full to partially full to empty. Compression of the ipsilateral flank during the examination also may distend the ureterocele. The contralateral ureteral orifice may appear perched upon the ureterocele when that system is distended and may appear to recede laterally as the bladder is filled and the ureterocele collapses. It is occasionally difficult to discern which system gives rise to the ureterocele. Furthermore, identification of the ureteral orifice draining the ureterocele may not be possible. Transurethral puncture of the ureterocele with a 23-gauge needle wedged onto a 4-Fr ureteral catheter (after breaking off the hub of the needle) allows injection of contrast material and opacification of the ureterocele and contiguous ureter (77). A technically simpler alternative uses percutaneous puncture of the ureterocele under cystoscopic guidance using a 25-gauge spinal needle.

Incision of the ureterocele can be completed using a 3-Fr Bugbee electrode and the cutting electrocautery current. Complete decompression requires sufficient energy delivery to attain a clean cut through both surfaces of the ureterocele. Repeat endoscopic incision is required in 10% to 25% of ectopic ureteroceles incised endoscopically (28,184,354), and the presence of a “thick wall” may further increase this risk up to 35% (161). It is more difficult to preserve an effective nonrefluxing flap valve following endoscopic incision of an ectopic ureterocele, presumably because of its larger surface area, which forms a wedge defect across the bladder neck. Postoperative bladder neck incompetence may be suspected when the ureterocele remnant distorts the bladder neck radiographically, and stress urinary incontinence occurs after toilet training. These uncommon cases may obligate ureterocelectomy with bladder neck reconstruction and ureteral reimplantation.

Primary endoscopic decompression of ectopic ureteroceles creates new VUR in 30% to 46%, and requires secondary open surgery in 50% to 86% (28,161,173,305,354). Husmann (173) showed that endoscopic incision and puncture are equally efficacious, each creating new VUR in approximately 10% of intravesical, and 50% of ectopic ureteroceles. This rate of new VUR remains relatively stable despite modification of the endoscopic technique. Employment of a longitudinal incision in the ureterocele across the bladder neck (or alternatively, punctures of both the urethral and intravesical segments) yielded VUR in 46% of cases (28). More recently, a single puncture of only the intravesical segment of the duplex ectopic ureterocele has been advocated, which led to a slightly lower rate of VUR (38%) (161). This single intravesical puncture effectively decompresses the ectopic ureterocele (161), and avoids creation of an obstructing flap from the urethral portion of the ureterocele in the majority (90%) of cases (Fig. 56.2) (354). Precise placement of this perpendicular puncture along the lateral edge of the ectopic ureterocele away from the bladder neck (Fig. 56.3) can be facilitated by either using an angled Bugbee electrode (161) or pinning the ureterocele in position with a percutaneously placed 25-gauge spinal needle. New onset, recurrent, or progressive VUR may develop with extended surveillance over an interval as long as 48 months (184).

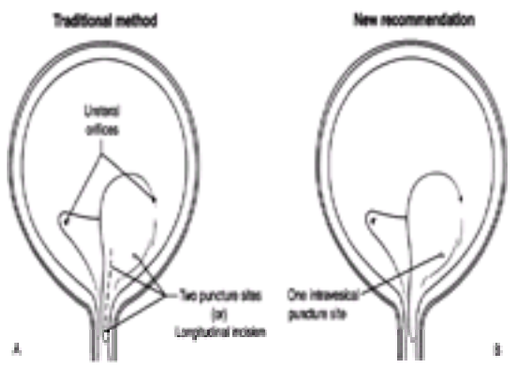

FIGURE 56.2. A: Traditional approach to transurethral incision of duplex ectopic ureteroceles uses either a longitudinal incision traversing the bladder neck or separate punctures of the urethral and intravesical portions of the ureterocele. **B:** A single puncture of only the intravesical portion of the duplex ectopic ureterocele also effectively decompresses the ureterocele and avoids creation of an obstructing flap from the urethral portion of the ureterocele in most cases.

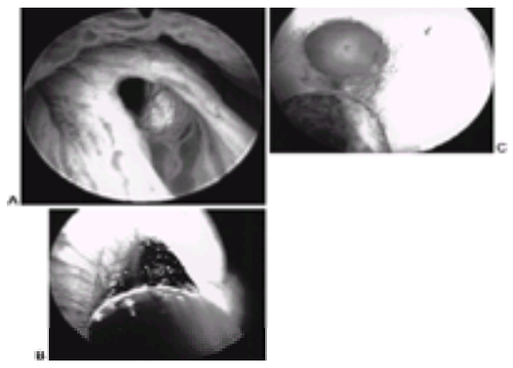

FIGURE 56.3. Duplex ectopic ureterocele. **A:** Cystoscopic view of an ectopic upper-pole ureterocele orifice within the urethra **B:** View of a 3-Fr Bugbee electrode positioned along the lateral edge of the ureterocele within the bladder **C:** Transurethral puncture through both surfaces of the ureterocele has been completed using electrocautery cutting current.

Some authors continue to advocate endoscopic decompression of all antenatally detected ectopic ureteroceles as initial therapy (161,305). However, endoscopic incision of duplex ectopic ureteroceles not associated with VUR is definitive therapy in only 36% of cases. In contrast, partial nephrectomy alone is definitive therapy in 85% of cases (173). Endoscopic incision in these select infants results in an increased risk for additional and probably unnecessary lower urinary tract reconstructive procedures. When initial radiographic studies demonstrate VUR, additional surgery is usually necessary regardless of the initial treatment modality. VUR present on initial radiographic studies resolves in only 16% of these children following either partial nephrectomy or endoscopic incision, presumably because of an intrinsic muscular defect of the trigonal region (173).

Treatment of duplex ectopic ureteroceles should be individualized according to patient age, clinical presentation, and presence of VUR. All patients should be treated with prophylactic antibiotic therapy while awaiting surgical intervention. Infants and children with ectopic ureteroceles and without VUR are best treated with partial nephrectomy. Endoscopic incision is especially appropriate for young infants (less than 6 months of age) with VUR, who either demonstrate bladder outlet obstruction from a large ectopic ureterocele or present with urosepsis. Because older children with duplex ectopic ureteroceles and VUR achieve equal and disappointing results with either partial nephrectomy or endoscopic incision, total urinary tract reconstruction by heminephroureterectomy, ureterocelectomy, and ureteroneocystostomy should be considered as a definitive surgical treatment (173,348).

Subureteric Injection for Vesicoureteral Reflux

Subureteric injection therapy (STING) has remained an option over the last two decades whenever surgical correction of VUR in children is considered (250), offering a very brief general anesthetic requirement on an outpatient basis. Although the STING procedure itself has become accepted as safe and effective (199,200,314), the implant materials chosen to effect this therapy have remained under continuous scrutiny. Teflon paste has been used most commonly, but significant experience also has been achieved using glutaraldehyde cross-linked (GAX) bovine collagen and dextran microspheres (Deflux). Injection of an autologous chondrocyte-alginate gel suspension recently has been used clinically in children (91). Success rates after a single injection (56% to 75%) (85,91,131,171,227,261,316,317,358) have so far fallen short of those achieved with extravesical ureteroneocystostomy (90% to 100%) (41,222,387,417), which currently allows release from hospitalization predictably on the day after surgery (Table 56.1).

Injectable Agent	No. of Patients	No. of Ureters	Single Injection Success Rate (%)
Teflon paste (316)	8,332	12,251	75
Collagen (47,85,130,131, 227,325)	617	953	71
Deflux (358)	75	101	68
Autologous chondrocytes (91)	29	46	56

TABLE 56.1. SUBURETERIC INJECTION FOR VESICOURETERAL REFLUX

A recent review of economic costs (in Sweden) associated with treatment of VUR comparing antibiotic prophylaxis, subureteric injection, and ureteroneocystostomy concluded that injection therapy was less expensive than ureteroneocystostomy (281). Although, subureteric injection therapy was performed as an outpatient, open ureteroneocystostomy required hospitalizations ranging from 6 to 11 days (four different hospitals studied). When the costs are adjusted for increased rates of failure with subureteric injection, and for an overnight hospitalization with ureteroneocystostomy, expense incurred for ureteroneocystostomy would actually have been less than subureteric injection at one of the two hospitals in the report (Hospital B). Length of hospitalization following ureteroneocystostomy was not documented in a similar report that also concluded the subureteric injection with glutaraldehyde cross-linked bovine dermal collagen was more cost-effective for treatment of VUR when single hospital treatment episodes were compared. Although intraoperative supplies were more expensive, very brief operative times and outpatient surgery for subureteric injection significantly reduced expense (229). However, cure was achieved in only 56% after a single subureteric injection, with an overall cure rate of 78% reported in 27 children after treatment failures received one to three additional injections.

Endoscopic correction of VUR relies on placement of a sufficient volume of submucosal bulking material in a position that effectively lengthens the course of the intramural ureter and promotes coaptation of the ureteral orifice during bladder filling and emptying. To be durable and effective, the injectable material must conserve its volume indefinitely and must not extrude or migrate. To be safely usable, the material must be biocompatible, nonantigenic, and noncarcinogenic. Unfortunately, no injectable material is currently available that meets all these requirements.

Subureteric Injection Technique

Endoscopic subureteric injection is performed with the child in the dorsal lithotomy position for cystoscopy, under general anesthesia. Preoperative antibiotic prophylaxis is indicated. A 14-Fr angled cystoscope was typically required during earlier series (199), but 9.5- or 11.5-Fr models are now available (131). After the position of the ureteral orifice is identified, a 22-gauge cystoscopic needle is advanced through the working channel of the angled cystoscope. When Teflon is used, the barrel of the injection gun and the needle are primed with glycerin and then filled with the Teflon paste. The needle tip is precisely inserted with a single puncture just caudal to the subureteric space approximately 5 mm distal to the ureteral orifice, and then advanced with the bevel up until it is positioned posterior to the ureteral orifice. Placement of a 3-Fr catheter into the ureter may facilitate proper needle placement.

As the bulking material is injected, the flattened orifice should appear as if it is on top of a volcano (the bead of material) (199). The needle should remain in position for approximately 2 minutes to minimize release of material through the injection site. The orifice is then viewed with the bladder full to identify incomplete support (229). Alternatively, fluoroscopic cystography can be performed after subureteric injection is complete, leaving the contrast material within the bladder as the child awakens. Repeat subureteric injection can then be pursued if VUR is detected during monitoring. Operative time is generally brief (less than 30 minutes), and children return home the same day as their surgery.

Correct needle positioning is critical to achieve correction of VUR. Rupture of the epithelium can occur during injection if the needle is too superficial, and migration of implant material outside the bladder can result when the needle is placed too deeply. Multiple injection sites must be avoided because they promote extrusion of the bulking material. Precise placement of the bead of injectable material is somewhat more difficult for children with duplex ureters or neuropathic bladder dysfunction, which may in part account for lower success rates reported (115,219,325). Subureteric injection of Teflon paste also has been used in three adults after endoscopic puncture of ureteroceles to prevent VUR, with its utility limited to only intravesical ureteroceles (384,403).

Injectable Materials

Teflon Paste

Teflon paste consists of a 50% suspension of polytetrafluoroethylene particles in glycerin, which acts as a vehicle and is rapidly absorbed (219). Polytetrafluoroethylene particles in the paste may vary in size from 5 to 100 microns, with more than 90% of particles less than 40 microns. Local migration of these particles can occur directly or as they are engulfed by phagocytes. These smaller particles also may be injected directly into capillaries and embolized to distant organs (1,89,219). Distant particle migration and resultant granuloma formation in pelvic lymph nodes and distant organs (lungs, brain, kidney and spleen) has been documented after periurethral injection in male monkeys and female dogs (246). Subsequently, distant particle migration has been reported in both experimental animals (1,89) and humans (61,90,219,260), including an ischemic stroke occurring in a previously healthy 6-year-old girl 1 year after subureteric injection of Teflon paste (35). Notably, no clinically adverse effects were reported in any patient from the endoscopic injection of Teflon paste for correction of VUR in the multicenter (41 centers) survey reporting results in more than 8,000 children (316).

Injection of Teflon paste was first introduced for correction of VUR for adults (1981) (250) and was later adopted for use in children (1986), achieving success rates of approximately 85% in more than 150 ureters (286,287). Larger series typically report resolution of VUR on cystography performed within 3 months of the last treatment in 75% to 85% of ureters after one injection, and 90% to 95% after additional subureteric injections (97,219,317,335). The most recent multicenter survey for endoscopic subureteric injection of Teflon paste reported that VUR resolved in 75% of more than 12,000 ureters treated after one injection. VUR resolved after two injections in 12%, and after three or four injections in 2% of ureters. No further treatment was administered when VUR improved to grade I in 6%, but ureteral reimplantation was performed for higher-grade VUR in treatment failures (4.5%). Ureterovesical junction obstruction required ureteral reimplantation in 41 additional ureters (316).

Cross-linked Bovine Collagen

Injectable collagen is composed of highly purified sterile bovine corium collagen (95% type I and 5% type III) that is cross-linked with glutaraldehyde to slow its degradation by endogenous collagenases (208,219). Fibroblast migration and neovascularization lead to endogenous collagen production (types I and III) at the injection site (132). Although mild inflammatory reactions may be evident, there are no reports of granuloma formation or migration of the cross-linked collagen (132,382). Skin testing is required before subureteric injection because the foreign bovine protein can provoke cellular and humoral responses in humans (76). New serum antibodies to bovine collagen were detected in 3 of 10 children within 2 years of subureteric collagen injection. No seroconversion to antibodies cross-reacting with human collagen occurred, and no systemic symptoms were reported (228). However, anaphylactic reactions have been reported with negative skin tests (236).

Initial success rates with subureteric injection of glutaraldehyde cross-linked collagen in children compare favorably with those reported for Teflon paste. Success rates within 3 months after subureteric injection of collagen in children range from 62% to 82% (average 71%) (47,85,130,131,229), with improvement to more than 90% after additional injections (325). However, recurrence of VUR was detected in 10% to 20% of ureters during the next year (47,229,236,325). Similar results can be achieved with subureteric collagen injection with duplex ureters (325). Haferkamp and others (159) reported an initial VUR resolution rate of 93% 1 month after subureteric collagen injection in 36 children with 58 refluxing ureters. After 1 year, this dropped to 35% VUR resolution and to 13% resolution at 3 years after the initial injection. Biodegradation and contraction of the injected implant results in higher VUR recurrence with time, despite apparent initial successful treatment (208,219).

Deflux System

Dextranomer microspheres (80- to 120-micron diameter) suspended in a 1% molecular weight sodium hyaluronan solution, called Deflux, forms a highly viscous solution that causes neither allergic nor immunogenic reaction when used for subureteric injection (219). These microspheres are made up of a network of cross-linked dextran polysaccharide molecules that prevents fragmentation and migration after subureteric injection (spherical shape and particles larger than 80 microns) (208,219). Sodium hyaluronan is a glucosaminoglycan present in human tissues that serves as a degradable carrier for the microspheres (absorbed within 2 weeks after injection). Contraction of the Deflux is balanced by a bulking effect from ingrowth of fibroblasts and production of endogenous collagen between the microspheres, effectively maintaining most of the original size of the injected implant (75%) (219,358).

Deflux is easily injectable through a 3.5-Fr polytetrafluoroethylene-coated needle passed through a 10-Fr cystoscope using a standard injection technique. Initial clinical trials with 75 consecutive patients (101 ureters) with grade III or IV VUR indicated success in correcting VUR in 68% of the ureters at 3 months following treatment. Recurrence of VUR occurred in 10% of children treated by 1 year. Treatment results were better for children with grade III VUR when compared with grade IV VUR. The response rate in duplex ureters was 60% (10/16) (208,219,358).

Autologous Injectable Materials

Subureteric injection of alternative autologous materials is being investigated experimentally because of concern for the long-term safety and effectiveness of the currently available materials. Use of autologous fat (249), collagen (53), chondrocytes (9) and bladder muscle cells (10) all have been investigated in laboratory animals. When used clinically, injection of autologous fat corrected VUR in only 3 of 19 ureters (16%) (54,293). Diamond and Caldamone (91) recently reported subureteric injection of autologous chondrocytes grown from a small cartilage specimen initially harvested from the child's own left ear in conjunction with a diagnostic cystoscopy. The alginate-cartilage paste could be injected through a 5-Fr needle passed through a 10-Fr cystoscope. Chondrocyte injection corrected VUR in 57% of ureters after a single injection, and 83% after additional injections in the 46 ureters studied (29 children) (91). Although an ideal material for use in children during subureteric injection has not yet been identified, many of the substances currently under development seem promising and deserve further attention (208).

Role in Neuropathic Bladder

Subureteric injection of Teflon paste has been used with more limited success (56% to 86%) for children with neuropathic bladder dysfunction (115,194,262,315). In the largest series of 53 children with neuropathic bladder dysfunction and VUR undergoing the STING procedure with Teflon paste, success in correcting VUR was achieved in 56% of ureters after a single injection. Although efficacy diminished with higher grades of VUR, it did not correlate with preinjection urodynamic parameters (115). A 70% success rate had previously been reported for the first 13 children in this group (199). An excellent initial success rate (92%) for correction of VUR also was achieved for 20 patients (26 ureters) with neuropathic bladder dysfunction using GAX-35 collagen. However, success rates fell to only 15% with ongoing surveillance over the next 2 years (160). Although others have suspected that late failure results from poor bladder compliance (411), Haferkamp and co-workers (160) showed that patients in this study failing subureteric injection had favorable bladder storage characteristics.

Endoscopic Injection for Urinary Incontinence

Stress urinary incontinence in children is most often due to intrinsic sphincter deficiency resulting from either congenital spinal dysraphism or from the exstrophy-epispadias complex. The risk for urinary incontinence may be further compounded by detrusor hyperreflexia or diminished bladder capacity and compliance. When anticholinergic therapy coupled with clean intermittent catheterization fails to control stress incontinence in a child with low bladder outlet resistance, surgical options include bladder neck reconstruction, placement of an artificial urinary sphincter, fascial bladder neck sling (or wrap), and bladder neck closure. Endoscopic injection therapy is an alternative, which can be used as an independent procedure to achieve continence or to recruit additional bladder capacity.

Vorstman (385) reported cure or improvement in 8 of 11 (73%) children (mean follow-up of 5 years) treated with endoscopic injection of Teflon paste at the bladder neck. Five of the children had previously undergone extensive bladder neck surgeries and were incontinent, while the remaining children had either spinal dysraphism (4) or exstrophy-epispadias complex (2) as their primary diagnosis. The only complication was a perineal abscess requiring incision and drainage (385). Concern for particle migration and granuloma formation after injection curtailed further use of Teflon (1,61,89,90,219,246,260).

Wan and associates (391) later reported on the endoscopic injection of glutaraldehyde cross-linked collagen in six children with urinary incontinence due to neuropathic bladder dysfunction. They recognized that this therapy works best within the first two injections, when the bladder neck and urethral epithelium are flexible enough to expand and retain the injected collagen material. At 1-year follow-up after injection, three were cured and two were improved (83% success) (391). Continence rates for children with neuropathic bladder dysfunction in other series ranged from 0% to 55%, with improvement reported in an additional 10% to 72% of children, generally resulting from more than one treatment session (33,47,230,299). Definitions for dry and improved status varied between reports, such that children reported as dry in some studies (44,47) would be categorized as improved in others (33,230,299,391). Stable detrusor function on urodynamic evaluation preoperatively is recognized to be important for achievement of urinary continence (299); however, detrusor hyperreflexia may develop after bladder outlet resistance is enhanced with periurethral collagen injection. Although resting leak point pressures changed little with collagen injection and did not correlate with response (33,299), Valsalva leak point pressures nearly doubled for those children with neuropathic bladder dysfunction that achieved improvement after periurethral collagen injection (33) (Table 56.2).

Reference	Boys	Girls	Range of Follow-Up (Months)	# Children Treated (Dry: Improved) Exstrophy/Epispadias		
				Neurogenic Bladder	With BNR	Without BNR
Wan[391]	4	4	6-33	6(3:2)	1(1:0)	7(1:6)
Calame[47]	3	13	18-48	8	16(7:3)	6(0:5)

BNR, bladder neck reconstruction.

TABLE 56.2. PERIURETHRAL COLLAGEN INJECTION FOR INCONTINENCE

Achievement of continence and improvement were reported more consistently for children with exstrophy-epispadias complex than for those with neuropathic bladder dysfunction (16,33,44,47,230,299,391). Although injection of collagen into the submucosal space of a previously operated bladder neck (Young-Dees-Leadbetter procedure) increases the risk for extrusion of collagen on injection, the more tubular and narrow urethra presumably promotes luminal coaptation (299). Persistence of the collagen implant may be aided by use of a temporary suprapubic cystostomy (33). Children with intrinsic sphincter deficiency and neuropathic bladder dysfunction typically have a patulous proximal urethra, which leads to lower rates of success. Failure also may be more likely in these patients because intermittent urethral catheterization may cause extrusion or deformation of the collagen implant (33).

ENDOSCOPIC RENAL SURGERY

Endopyelotomy

Open pyeloplasty remains standard treatment for correction of primary ureteropelvic junction (UPJ) obstruction in infants and young children (126). However, endopyelotomy has proven to be an effective alternative for treatment of the failed pyeloplasty (128,176,204) and can be considered in conjunction with percutaneous nephrolithotripsy (PNL) when renal calculi also are present. Success rates of endopyelotomy for primary UPJ obstruction in children (62%) are considerably lower

than for open pyeloplasty, with possible late failure of treatment (128). Endopyelotomy can be performed using a retrograde ureteroscopic technique (324), but visualization of the UPJ is optimized using an antegrade nephroscopic approach.

Control of the renal pelvis with a percutaneous guidewire is essential before endoscopic incision of the stricture is performed. Successful retrograde passage of a 5-Fr angiographic catheter through the obstruction into the renal pelvis is required for further progress to be made. After the patient is turned prone and percutaneous access established, the catheter is grasped and brought out through the flank. Two guidewires can then be placed traversing the obstruction. This splays the UPJ, clearly defining the level of obstruction, and allows accurate endoscopic incision between the guidewires, preferably using the hook knife. Electrocautery or laser incision can cause thermal injury, increasing the risk for recurrent stricture formation. A posterolateral incision avoids injury to the hilar vessels and ureteral branches that emanate anteromedially from basilar branches of the renal artery. The incision should be made away from any visible pulsations, and deep enough to reveal periureteral fat, thereby fashioning a funnel-shape appearance of the UPJ.

Alternatively, a low-profile (10-Fr) Acucise cutting balloon catheter (Applied Urology, Laguna Hills, California) can be passed up the ureter over the guidewire exiting the urethra. After proper positioning of the balloon and the cutting wire are confirmed, both by fluoroscopy and direct visualization, the balloon is inflated with contrast material and the cutting wire is electrified. The balloon is left inflated for 10 minutes to tamponade any small bleeding vessels (126). An antegrade nephroureteral stent (either a graduated 14/7-Fr endopyelotomy stent, or a 7-Fr single-J ureteral catheter passed through a 16-Fr council-tip nephrostomy catheter) is then positioned across the UPJ, and extravasation of contrast material is confirmed using fluoroscopic guidance. If no further extravasation is evident when a nephrostogram is completed 48 to 72 hours postoperatively, then the council-tip catheter can be removed, leaving only the percutaneous ureteral stent for 2 to 4 more weeks (217). Preliminary placement of the endopyelotomy stent also has been suggested to allow a more precise endopyelotomy incision using a Bugbee electrode passed directly over the stent (336).

Complications of endopyelotomy may include persistent or recurrent obstruction, bleeding, arteriovenous fistula, and urinary leakage resulting in fistula or urinoma. Risk factors for failure include a crossing renal vessel, long strictures (more than 2 cm), large pelvicaliceal volumes, and poor preoperative renal function (126,380). Because a crossing renal vessel may be present even after prior open pyeloplasty (233), a spiral computed tomography (CT) scan should be considered before endopyelotomy in all cases (119). Alternative treatment is preferable when crossing renal vessels are identified because of an increased risk for endopyelotomy failure and intraoperative hemorrhage associated with their presence (380).

PEDIATRIC STONE DISEASE

Selection of Treatment Modality

Although most renal and proximal ureteral calculi in children are currently treated with extracorporeal shock wave lithotripsy (ESWL), specific treatment for individual patients often depends on multiple factors, including the size and position of the stone, the presence of anatomic abnormalities, the severity of obstruction, and the level of renal function present in the affected kidney. Proximal ureteral stones can be treated in the supine position, and generally do not require pretreatment manipulation. Stones in the distal ureter can be effectively treated in the prone position (186), but ureteroscopic laser lithotripsy is often more efficient treatment, especially for stones smaller than 5 mm (300). Larger distal ureteral stones are more easily visualized fluoroscopically, but require an increased number of shocks (20). Although deleterious effects from shock waves on developing bone or ovaries have not been recognized in experimental animals, their effects in children are unknown (216,253,406). Stones associated with a horseshoe kidney, UPJ obstruction, or caliceal diverticula are often poorly treated with primary ESWL. Stone burdens greater than 2 cm in size, or composed primarily of cystine, calcium oxalate monohydrate, or calcium phosphate also may be problematic.

Stones smaller than 5 mm may be difficult to image fluoroscopically and often require either intravenous or retrograde ureteral contrast administration for localization. An acute infundibulopelvic angle or narrow infundibular neck may significantly limit passage of lower pole caliceal fragments after ESWL, making either PNL or flexible ureteropyeloscopy more optimal therapy (111). Cystine stones or ESWL failures are effectively treated with PNL, using either a standard or a minipercutaneous technique. Ureteropyeloscopy is generally reserved for ESWL failures with a stone burden less than 1 cm, or for small recurrent cystine stones to avoid a more morbid percutaneous approach. In addition, Jordan and co-workers (191) recently reported successful completion of a laparoscopic extended pyelolithotomy in a 16-month-old child with a large cystine stone filling the renal pelvis.

Staghorn Calculi

Struvite calculi in children typically fragment easily with ESWL; however, the larger stone burden present in these staghorn calculi can create ureteral obstruction and lead to urosepsis. PNL is often preferred over ESWL because it offers optimal upper tract drainage, and more efficient clearance of stone burden. Nonetheless, ESWL maintains a role in treatment of these special complex patients. Placement of a ureteral stent before ESWL may be helpful in preventing ureteral obstruction, especially for staghorn calculi involving the upper-pole renal segment. In these cases, placement of an urgent percutaneous nephrostomy following ESWL is more likely to be complicated by pneumothorax. Children with staghorn calculi involving the lower-pole renal segment, or associated with a dilated collecting are best treated with initial PNL followed by ESWL (344). Although partial and complete staghorn calculi have been treated effectively by ESWL monotherapy in children (greater than 70% stone resolution rate), the majority of children required multiple treatment episodes. Administration of shock waves at the pelvic portion of the stone initially was credited with enhanced passage of stone fragments, obviating the need for ureteral stent placement in all 15 children treated (291). Success rates for ESWL monotherapy in adults drop sharply as the surface area of the stone increases (221).

Pediatric Extracorporeal Shock Wave Lithotripsy

ESWL is effective in treating renal calculi in infants and children, with stone-free rates ranging from 50% to 95% (32,133,214,241,248,278,282,349,396). Complications are rare, and radiation exposure is comparable to routine diagnostic radiographic studies (214). Because pediatric ureters accommodate stone passage well after ESWL, preplacement of a ureteral stent in children with stones less than 1.5 cm in diameter is not recommended (313). Steinstrasse formation in children may require percutaneous nephrostomy when symptoms of pain, vomiting, or fever develop. Nijman and associates (282) noted that steinstrasse developed in only 8 of 86 renal units treated with ESWL (9%), and that only 2 of these children required nephrostomy drainage.

General anesthesia is required during ESWL in children to ensure patient cooperation and comfort because the shock waves produced by the spark gap electrode in the Dornier HM-3 lithotripter (Dornier Medical Systems, Kennesaw, Georgia) are painful. Use of newer-generation electromagnetic lithotripters with smaller focal zones like the Siemens Lithostar (Siemens Medical Systems, Iselin, New Jersey) may allow intravenous sedation to be used during ESWL in adolescent patients (291). Retreatment rates and shock requirements are generally higher with these less powerful units in adults (235). However, Van Horn and others (381) detected no difference in success rates when comparing ESWL performed with the Dornier HM-3 and the Siemens Lithostar in similar groups of children. Cass and associates (50) actually achieved greater stone-free rates using the Medstone STS (Medstone International, Aliso Viejo, California) (100%) compared with the Dornier HM-3 (71%). However, this difference was attributed to a larger number of children with abnormal urinary tract anatomy in the HM-3 treatment group (50). Modifications in lithotripter treatment regimen previously required for treatment of children on the HM-3 unit (flattening the gantry, lowering water levels and shielding the lungs with polystyrene to prevent lung contusion) also have been greatly simplified using these newer machines. A modified infant car seat with a hole cut in the back, and with polystyrene plastic pads affixed to the back affords both security and lung protection for small children treated on an unmodified Dornier HM-3 lithotripter (185).

Although both bruising at the shock wave exit site and hematuria are common in children undergoing ESWL, the incidence of clinically significant hematoma is rare (133,278). Neither hypertension, nor significant alteration in renal parenchymal function have been reported after ESWL in children (78,134,240,248,372). However, apparent growth impairment for both the treated and untreated kidney was reported in a recent series of 29 children undergoing ESWL (232). For ESWL in children, most authors use relatively low power settings (15 to 20 Kv), with the fewest shocks for effect (less than 2,000) (32,133,214,241,248,278,282,349,396). Multiple ESWL treatments on the same kidney should not be performed over a short interval, and bilateral ESWL at the same setting is not recommended.

Percutaneous Nephrolithotripsy

The first report of percutaneous stone removal in children (1985) (400) followed development of this technique in adults by almost 10 years (124). Woodside and associates (400) described successful direct removal of small or multiple stones, and lithotripsy fragmentation (electrohydraulic and ultrasonic) and removal of larger stones in 7 children, between the ages of 5 and 18. PNL offers safe and effective treatment when ESWL fails or is contraindicated. PNL should be considered for initial therapy in children with lower-pole renal calculi larger than 1 cm, especially when the lower-pole calix is drained by a long, narrow infundibulum, or exhibits an acute infundibulopelvic angle (111).

Some authors advocate a staged approach with percutaneous access and tract dilation followed by stone retrieval to optimize visibility and to limit blood loss (215). Others have performed the procedure in a single stage without excessive blood loss (270). Dilation of the nephrostomy tract to 24 or 26 Fr allows use of standard adult instrumentation to fragment or retrieve the stones (46,88,270). Both rigid nephroscopes with an offset lens (17 to 24 Fr), and flexible nephroscopes (15 Fr) are available, but flexible ureteroscopes also can be engaged to obtain access through a narrow infundibulum.

Hollow-core ultrasonic lithotrite probes are efficient at stone clearance because they aspirate stone fragments as they are created. Both the rotating ultrasonic burr-tip probe, and the ballistic probe (Lithoclast, Lausanne, Switzerland) can fragment extremely hard stones, but are limited to use through rigid nephroscopes (87). Electrohydraulic lithotripsy (EHL) probes are available in smaller sizes appropriate for use in flexible nephroscopes, but demand accurate positioning of the probe tip when used in small spaces. The EHL probe must be placed just off the stone to maximize the benefit of the cavitation bubble and shock waves produced with discharge. Because the energy is delivered spherically from the tip of the EHL probe, extreme caution must be exercised to avoid damage to the nephroscope lens, the guidewire, or the urothelium. Enhanced flexibility of the holmium:YAG laser allows its use through any percutaneously placed endoscope (322,399). Although most large renal stones (greater than 3 cm) can be removed with PNL, a second session may be required in up to half of the patients treated (88).

Technique of Percutaneous Nephrolithotripsy

Cystoscopic placement of a ureteral occlusion balloon at the beginning of the PNL procedure facilitates establishment of the percutaneous nephrostomy tract. Although this step generally requires a change in position from the dorsal lithotomy position (for cystoscopy) to the prone position (for PNL) in younger children, passage of the ureteral catheter through a flexible cystoscope with adolescent patients in the prone position is often possible. A urethral catheter is placed to decompress the bladder. Appropriate padding for protection of pressure points and for preservation of diaphragmatic excursion is critical. First air and then contrast material are introduced through the ureteral balloon catheter to outline the posterior and anterior collecting system, respectively. This allows percutaneous access to be secured, and eventually leads to establishment of both a working wire and a safety wire. Nephrostomy tract dilation is then completed over a Super-Stiff working guidewire using either a series of graduated coaxial dilators, or a fascial dilating balloon. The working sheath (18 to 26 Fr) is positioned inside the collecting system. Progress is monitored fluoroscopically at intervals to ensure proper alignment of the dilators and instruments with the renal parenchyma and collecting system.

Use of an adequate-sized percutaneous sheath ensures low working pressures within the renal pelvis during nephroscopy (333). Only warmed saline should be used as irrigant to avoid hypothermia, and dilutional hyponatremia. Injury to the renal pelvis also can require prolonged nephrostomy drainage (88) or cause UPJ obstruction (46). Although perioperative bleeding with PNL is usually controllable with gentle technique (88,215), significant blood loss requiring transfusion in up to 20% of children treated has been reported (46). Excessive torque on the nephroscope must be guarded against, because it can lead to parenchymal tearing and serious hemorrhage. Kaye and Clayman (206) described use of a tamponade nephrostomy catheter with a large-diameter occlusive balloon (36 Fr) carried on a 14-Fr nephrostomy tube. This can prove invaluable for temporary control of parenchymal bleeding, since it tamponades the entire nephrostomy tract as it drains the renal pelvis and maintains ureteral access (206). Intraoperative bleeding can sometimes be controlled merely by placement of a large nephrostomy tube, but significant bleeding presenting after nephrostomy removal may require percutaneous arteriography and embolization (297). The possible need for blood transfusion should be considered in all children undergoing PNL and prepared for by obtaining at least a type and screen for packed red blood cells and parental informed consent preoperatively.

A “mini-percutaneous” technique, with dilation of the nephrostomy tract to only 11 Fr (178) or 15 Fr (168), can be used in a small child with a lesser stone burden. This may limit the risk for significant bleeding or injury to the collecting system. Jackman and co-workers (178) achieved a stone-free rate of 85% and sustained no complications in children with a mean stone burden of 1.2 cm. No tube was left in place postoperatively in one of the 7 kidneys, in which the stone was removed intact. This approach requires use of either an offset 7-Fr pediatric cystoscope (5-Fr working channel) or a 7.5-Fr flexible ureteroscope (3-Fr working channel) to fit within the smaller sheath. Either a 3-Fr electrohydraulic lithotripsy probe (86), or a holmium:YAG laser fiber (399) must be used to fragment the stones, which can then be removed through the sheath using a 3-Fr 3-prong grasper.

Ureteropyeloscopy

Ritchey and associates (329a) reported the first successful ureteroscopic lithotripsy and removal of a distal ureteral calculus in a 4-year-old boy using an 8.5-Fr ureteroscope in 1988. Ureteroscopic laser lithotripsy has subsequently become standard treatment for distal ureteral calculi in children, but only limited experience exploiting ureteropyeloscopy for treatment of renal calculi in children has been described (151,218,331,399). Ureteropyeloscopy in children follows the development of small, actively deflectable ureteroscopes (149) and of laser fibers small enough to pass within their working channels. A primary ureteropyeloscopic approach may be best suited for treatment of lower-pole renal caliceal stones because of limited fragment clearance achieved following ESWL (111,150,218). Grasso and Ficazzola (151) reported complete fragmentation rates greater than 90% for renal stones smaller than 2 cm in diameter using the 7.5-Fr flexible ureteroscope, and the 200-micron holmium:YAG laser fiber in their 79 patients (including one 10-year-old child). Larger stones required a second-look endoscopy to increase fragmentation rates from 45% to 82%. In their series, a narrow lower-pole infundibulum or stricture could prohibit access to lower-pole renal calculi, but an acute infundibulopelvic angle was not problematic (151). Wollin and co-workers (399) reported holmium:YAG laser lithotripsy using a similar ureteropyeloscopic technique in six children with renal stones, including three with lower-pole caliceal stones. Russell and others (331) included 4 children with renal calculi in their series of 32 children undergoing ureteroscopy for treatment of upper tract calculi. An overall stone-free rate of 100% was achieved, including a second session in four patients.

Access to most pediatric upper tract stones is now possible using small caliber ureteroscopes and working instruments. Associated risk for ureteral perforation (0%) or stricture formation (0.5%) is small (152). Ureteral perforation and retroperitoneal migration of stone fragments occurs only rarely (less than 2%). Because aggressive attempts at retrieval of extravasated stone fragments generally are unsuccessful and can cause ureteral injury with stricture formation, these injuries are best managed with ureteral stent placement to allow the ureteral perforation to heal (117). The risk for postoperative VUR should now be negligible because dilation of the intramural ureter beyond 10 Fr is only rarely necessary. VUR had developed previously in up to 20% of adults undergoing dilation of the ureteral orifice to 24 Fr (136). Apprehension over a potentially prolonged ureteropyeloscopic procedure to fragment or retrieve renal calculi in children may limit its widespread use. However, its utility in managing lower-pole caliceal stones, or residual fragments after ESWL makes it a valuable addition to the pediatric endourologic armamentarium.

Technique of Ureteropyeloscopy

Effective ureteropyeloscopy requires an understanding of the ureteral and renal anatomy and strict adherence to endoscopic principles. Placement of the endoscopic and fluoroscopic monitors adjacent to each other is critical for efficient visual integration during ureteroscopy. Expected areas of anatomic or functional narrowing occur at the UPJ, iliac vessels, and intramural ureter. Ureteroscopy generally begins with passage of a guidewire into the collecting system. A hydrophilic guidewire can be substituted when a standard guidewire cannot be passed through a tortuous ureter or beyond an impacted stone. Use of a gauze sponge or a torque vise at the end of the guidewire aids in rotation of the slippery wire when necessary. Combining an angled hydrophilic guidewire with an angiographic catheter provides further control in negotiating the guidewire tip beyond an obstruction. After access to the upper collecting system has been attained, the hydrophilic guidewire should be replaced with a standard guidewire to minimize the risk for inadvertent dislodgement of the wire. Periureteral scarring from previous surgical procedures may limit ureteral distensibility and impede endoscopic access. Percutaneous access in line with the ureteral orifice may even be required if transtrigonal ureteral reimplantation with a long tunnel has been performed (334).

Ureteral stones located distal to the iliac vessels are best approached with a semirigid ureteroscope, whereas, use of a flexible ureteroscope provides safer and easier access to stones at or proximal to the iliac vessels. The semirigid ureteroscope is passed into the ureter adjacent to a single guidewire, which tends to straighten the ureteral course. Inverting the ureteroscope aligns the beveled tip along the floor of the ureter, aiding passage beyond the dorsal lip of the ureteral orifice. The lumen of the ureter should be visible at all times to prevent bowing of the ureteroscope or perforation of the ureter. Although a semirigid ureteroscope may be safely passed into the proximal ureter in select cases, the versatility of the flexible ureteroscope and the ability to advance safely into the kidney clearly favors its use for treatment of proximal ureteral stones.

Two guidewires should be used when passing a flexible ureteroscope. The flexible ureteroscope is passed in a monorail fashion over the working wire under fluoroscopic guidance, while the other is left as a safety wire to guarantee access to the collecting system. Introduction of the second guidewire is readily accomplished during dilation of the intramural ureter to 10 Fr using an 8/10-Fr coaxial safety wire introducer, which accommodates two guidewires. Use of a ureteral access sheath may be helpful if repeated entry and exit from the ureter is anticipated for retrieval of multiple stone fragments. Careful fluoroscopic monitoring during passage of the access sheath (12 Fr) is essential to prevent perforation of the ureter. An extrastiff guidewire with flexible tips at both ends may be helpful, both in preventing damage to the ureteroscope as the wire is introduced and angulation of the ureteroscope as it is passed up the ureter.

Flexible ureteroscopes with two working channels are preferred, because instruments can be passed without interruption of irrigant flow. Optimal visualization still depends on use of pressurized irrigation fluid, which can usually be accomplished by applying pressure to the irrigant bag with a pneumatic cuff or by using a piston irrigation syringe. Continuous or periodic bladder drainage helps lower intrarenal pressure during ureteroscopy. Inspection of the proximal ureter and renal pelvis during flexible ureteroscopy should be monitored fluoroscopically. Intermittent fluoroscopic imaging promotes accurate orientation of the ureteroscope within the collecting system. Instillation of dilute contrast material through the ureteroscope also creates a fluoroscopic map of the collecting system, allowing inspection of specific calices to be confirmed.

Introduction of the flexible ureteroscope into lower-pole calices with a shallow infundibulopelvic angle may often be accomplished through only active deflection. However, entry into a dilated lower-pole calix with an acute infundibulopelvic angle will generally require a combination of both active and passive deflection of the ureteroscope, and must be attentively monitored by fluoroscopy (Fig. 56.4). Passive deflection occurs when a portion of the flexible ureteroscope (approximately 5 cm from the tip) is allowed to bank off the upper-pole infundibulum, effectively redirecting the ureteroscope inferiorly toward the lower-pole calices. Maximal active deflection may not be possible when an instrument is present within the working channel.

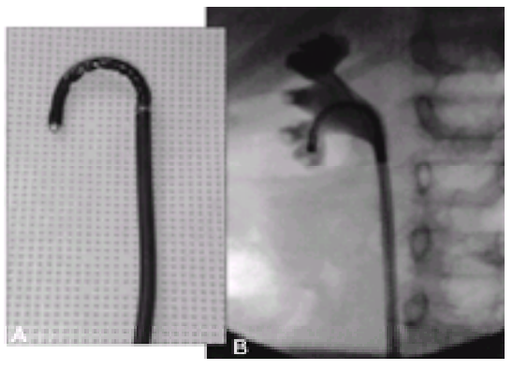

FIGURE 56.4. Actively deflectable, flexible, 7.5-Fr ureteroscope with 3.6-Fr working channel. **A:** Flexible ureteroscope with maximal retrograde deflection. **B:** Passage of flexible ureteroscope into a lower-pole calix (containing a 4-mm stone) with an acute infundibulopelvic angle is achieved by using a combination of active and passive deflection.

Use of a ureteral stent at the completion of ureteroscopy avoids ureteral obstruction from transient edema. Stenting is generally unnecessary following simple diagnostic ureteroscopy using either a semirigid or flexible ureteroscope. If more aggressive dilation of the intramural ureter is required or if significant ureteral edema results from multiple passes with the ureteroscope, then ureteral stenting will likely minimize the risk for postoperative flank pain from ureteral obstruction. When use of this stent is expected for only a few days, the attached string can be affixed externally to ease removal in the office setting. If a second ureteroscopy or prolonged ureteral stenting is anticipated, the string should be removed to minimize both discomfort and the risk for inadvertent stent dislodgement.

Transurethral Cystolithotripsy

Endoscopic lithotripsy in children is most commonly used for treatment of stones forming in augmented bladders (29,209). Both electrohydraulic and laser lithotripsy can effectively fragment stones larger than 2.5 cm in diameter. Some bladder stones consist of a calcified shell surrounding a core of mucus. However, most of the larger stones are extremely dense and require much higher energy settings for fragmentation (Fig. 56.5). A larger laser fiber (550 or 1,000 microns) can be passed easily through a pediatric cystoscope (14 Fr) and lends additional rigidity and surface area for energy delivery. The holmium:YAG laser initially should be set at a low energy setting (0.5 Joules) with a slow pulse rate (5 Hz), but settings may be safely tripled for larger and denser stones. Drawing the laser fiber across the stone surface promotes vaporization of the stone in layers and minimizes formation of large fragments. Injury to the bladder urothelium can result if the stone is pinned against the bladder wall, but then “dances” away from the fiber as the energy is delivered. Large numbers of stone fragments can be efficiently irrigated from the bladder through a cystoscope sheath using the Ellik evacuator. However, a percutaneous suction sheath can be placed, which can be very efficient in aspirating smaller to moderate-sized stone fragments under direct endoscopic control. Use of a percutaneous nephroscope with an angled lens as a cystoscope allows passage of the more rigid ultrasonic lithotripsy probe for controlled fragmentation and suction evacuation of bladder stones. This approach also can be used through percutaneous access after closure or reconstruction of the bladder neck (118). Access through a catheterizable bladder entry constructed from appendix, ureter, or reconfigured bowel significantly limits the size of usable instruments and may compromise the continence mechanism. Initial ESWL, followed immediately by endoscopic evacuation of stone debris also has proven effective for treatment of bladder stones larger than 3.5 cm (172). Although this combination of modalities may be effective, it is not likely to be more efficient than endoscopic lithotripsy alone. Open removal of larger stones in such cases may ultimately be the most efficient approach.

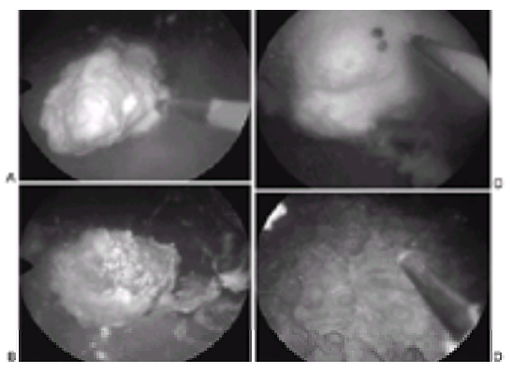

FIGURE 56.5. Transurethral cystolithotripsy of bladder stones in children with augmented, neuropathic bladders. **A:** Intact 3-cm bladder stone with adjacent 360-micron laser fiber (holmium:YAG laser) **B:** Fragmented bladder stone demonstrates a core predominantly composed of mucus. **C:** Intact 5-cm bladder stone with adjacent 550-micron laser fiber (holmium:YAG laser) **D:** Partially fragmented bladder stone demonstrates extremely dense core with surface scarred from laser lithotripsy.

LAPAROSCOPIC SURGERY IN PEDIATRIC UROLOGY

Development of Urologic Laparoscopic Surgery

Use of peritoneoscopy (laparoscopy) in children was introduced contemporaneously by two groups in 1973 (70,135). These two series included 20 infants and children with intersex abnormalities, who underwent diagnostic laparoscopy, and gonadal biopsies when necessary (biopsy technique not described). In their report, Gans and Berci (135) declared that open laparotomy for evaluation of intersex problems was an obsolete procedure. Then in 1976, Cortesi (79) moved the focus directly into the province of urology as they described the location of bilateral intraabdominal testes near the common iliac vessels in an 18-year-old man. Silber and Cohen (352) described intraabdominal, inguinal and vanished testes in three different patients (two adults and one 5-year-old boy) and suggested that laparoscopy should become a valuable tool in the surgical management of nonpalpable cryptorchid testes. Soon thereafter, laparoscopy was enthusiastically adopted as the preferred investigation for routine localization of nonpalpable testes by several groups (30,243,247,343,402). Further surgical exploration was considered unnecessary when a blind ending vas deferens and spermatic vessels were found above the internal inguinal ring at laparoscopy (30,243).

Diagnostic Laparoscopy

Diagnostic laparoscopy also was recognized as valuable in planning the location of the incision and the preferred surgical technique (microvascular autotransplantation, Fowler-Stephens orchiopexy, or the Jones approach) when an intraabdominal testis was discovered (112,138,163,188,275,371,386). Diamond and Caldamone (93) reported identification of testicular absence in 26% and detection of intraabdominal testes in 21% of 100 impalpable testes undergoing diagnostic laparoscopy. Blind-ending cord structures also were found above the internal inguinal ring in four boys after previous negative inguinal exploration. In their series, roughly half (51 testes) of the laparoscopic examinations were of significant value (93). Although laparoscopy suggested that an atrophic inguinal or canalicular testis was present in the remaining cases, an inguinal incision was still required for definitive management. Seminiferous tubules with occasional germ cells have been identified in roughly 5% to 10% of these testicular nubbins (147,306,371,376). In another large series, Moore and others (267) showed that an inguinal testis was present in 48% of cases when the vas deferens and spermatic vessels entered the internal inguinal ring. Similarly, Cisek and co-workers (60) found a salvageable testis in 45% of cases when normal appearing vas and vessels entered the internal ring, but found only atrophic testes when these structures were atretic. An absent testis was much more likely to be found when one, rather than both, testes were impalpable (60,93,267), and when the processus vaginalis was closed rather than patent (113).

Laparoscopy has largely supplanted radiographic imaging for evaluation of nonpalpable testes. Although use of scrotal and inguinal ultrasonography has recently been advocated to obviate the need for laparoscopic examination, only 7 of 21 atrophic inguinal testes could be identified with this modality (43). Gadolinium-enhanced magnetic resonance angiography offers a higher rate of diagnostic sensitivity. It is capable of localizing intra-abdominal, canalicular, and atrophic inguinal testes (409). Because surgical exploration continues to be indicated regardless of the outcome, this test may be most useful in rare cases in which spermatic vessels cannot be identified during laparoscopy.

After two decades of advancement, identification of nonpalpable testes and diagnosis of intersex problems continued to be the only widespread clinical applications of laparoscopy in pediatric urology. Clayman (67) recognized the great potential value that laparoscopic surgery could offer this specialty because more than 80% of the procedures are performed through an open surgical approach. He noted the preponderance of anecdotal experience in ablative and reconstructive surgical procedures (nephrectomy, orchiopexy, varicocelectomy, ureteroneocystostomy, autoaugmentation cystoplasty, appendicovesicostomy, and pyeloplasty), and called for careful studies comparing the surgical and laparoscopic outcomes for each procedure in patients of similar age, evaluating efficacy, cost, and patient morbidity. Subsequent comparisons of laparoscopic and open procedures have revealed higher operating room expenses for laparoscopic procedures, but also have suggested that overall expenses can be constrained by a shorter and simpler hospitalization (108,162,310). Operating room expenses also may be further limited by use of sterilizable (reusable) equipment (122). Although Peters (302) cautioned that judicious application of laparoscopic techniques in children is essential, he also predicted that its potential in pediatric urology practice is limited only by imagination and technology. In that spirit, Yeung and others (408) recently have extended the utility of laparoscopy to include investigation for and resection of suspected dysplastic kidneys associated with ectopic ureters in children with urinary incontinence (238).

Laparoscopic Orchiopexy

Vasal-pedicle Orchiopexy

Surgical treatment for intraabdominal testes has long been recognized as more exigent than treatment for palpable inguinal testes. Bevan (19) described a radical orchiopexy method for treatment of nonpalpable, intraabdominal undescended testicles almost a century ago, which involved ligation and division of the spermatic vessels. He recognized that the spermatic and vasal arteries anastomose freely, and that the spermatic vessels can be sacrificed without endangering the vitality of the testicle, but advised that this approach be used sparingly (18,19). Some of his contemporaries embraced this technique without reservation (271) and had dismal long-term surgical outcomes with almost complete atrophy of all testes treated (18). Fowler and Stephens (129) radiographically verified communication between the spermatic and vasal arteries, and also described the "bleeding test" using a vascular clamp to occlude the spermatic vessels temporarily during the surgical procedure. Bleeding after incision of the testicular tunic signaled a viable vasal-pedicle orchiopexy. Ransley and associates (320) introduced a staged Fowler-Stephens procedure involving preliminary ligation of the spermatic vessels, followed by orchiopexy several weeks to months later. Successful orchiopexy was reported for all 13 testicles in 10 boys (including 8 prune-belly patients) treated with this approach, in contrast to a recognized atrophy rate greater than 30% achieved with a concurrent procedure (96,129,223,273).

Primary Orchiopexy

Over the last decade, laparoscopic orchiopexy emerged as a practicable surgical option and progressed from continued technical refinement. Bloom (24) reported laparoscopic application of vascular clips to the spermatic vessels as the first stage of a two-step vasal-pedicle orchiopexy in ten boys with high intraabdominal testes. The second-stage was completed through an open incision in seven of the boys, and atrophy was detected in only one testicle. In this case, the vasal artery was suspected to have been inadvertently ligated consequent to a previous inguinal exploration. Jordan and others (189) later described an entirely laparoscopic (except for creation of the subdartos pouch) single-stage orchiopexy with preservation of the spermatic vessels in a 10-year-old boy using a 10-mm scrotal laparoscopic port to facilitate testicular transfer. Further mobilization of the spermatic vessels and vas deferens was then possible because pneumoperitoneum was preserved with this five-port technique. Soon thereafter, Bogaert (31) successfully performed a similar single-stage orchiopexy in two boys, and a two-stage vasal-pedicle orchiopexy in three additional boys, again using entirely laparoscopic techniques. Dissection of the spermatic vessels to the level of the renal hilum was achieved using 3 laparoscopic ports. Primary orchiopexy was feasible when mobility of the spermatic leash allowed transposition of the testicle to the contralateral internal inguinal ring (31,189).

Further experience with laparoscopic orchiopexy demonstrated that primary orchiopexy with preservation of the spermatic vessels was possible for the majority of intraabdominal testes (55,60,95,125,154,192,234,276,308,310,330) (Table 56.3).Vasal-pedicle orchiopexy was selected as an alternative when spermatic vessels were judged to tether the testicle high in the abdomen (31,45,55,60,192,234,310). Cumulative success rates reached 86% (19 of 22) for single-stage (55,234,310) and 95% (25 of 27) for two-stage (31,45,55,192,234,310) vasal-pedicle orchiopexy. The internal inguinal ring has been managed in various ways, including closure with laparoscopic clips (154,192,310) or endoloops (234). However, it is clear that no specific attention other than dissection of the processus vaginalis from the canal is required (95,125,308,330). In most cases, the testicle was transferred using a canula into the scrotum through a newly constructed canal, medial to the epigastric vessels (55,95,125,154,192,234,310) as Jordan and co-workers (189) originally described. However, the testicle was actually passed down the existing inguinal canal into the scrotum using a laparoscopic grasper in two series (45,276). Passage of a surgical clamp through the scrotal incision into the abdomen to accomplish transfer of the testicle can save one laparoscopic port (31,330), but risks loss of pneumoperitoneum and effective exposure. Use of smaller 2-mm instruments allows even less noticeable laparoscopic port scars (125,330). Poppas and others (308) recently described an ingenious "concealed" laparoscopic orchiopexy using only an umbilical and a scrotal port, using the operating laparoscope with its 5-mm working channel through the umbilical port to facilitate testicular dissection.

TABLE 56.3. CLINICAL SERIES OF LAPAROSCOPIC ORCHIOPEXY IN CHILDREN

Most children undergoing laparoscopic orchiopexy can be treated as outpatients (31,55,95,125,192,234,308,330). Reported complications have been limited to single

episodes of bladder perforation (during creation of a new inguinal channel) (31), and bowel perforation (Veress needle injury) (45). In a recent multiinstitutional analysis of laparoscopic orchiopexy involving 310 nonpalpable testes studied at 10 different pediatric centers, the success rate with primary laparoscopic orchiopexy exceeded 97%. A two-stage vasal-pedicle orchiopexy offered an 89% success rate (13). Clearly, laparoscopy will continue to play an important role in the surgical management of nonpalpable undescended testes.

Technique of Laparoscopic Orchiopexy

A careful physical examination under general anesthesia may detect a previously nonpalpable testicle and encourage completion of a standard inguinal orchiopexy. Bladder drainage and nasogastric decompression as well as abdominal and scrotal antiseptic preparation are routine. A 5-mm laparoscopic camera port is introduced directly into the peritoneum through an infraumbilical incision using an open access technique. Although use of this technique can seem more cumbersome when compared with insertion of the Veress needle, the minimal additional time requirement is more than justified by the safety margin attained. In this way, the laparoscopic camera port can be accurately placed even in children that have undergone previous transperitoneal surgical procedures. A figure-of-eight suture capturing the anterior rectus fascia ensures an adequate seal for pneumoperitoneum (10 mm Hg) to be maintained. Alternatively, a box-type suture pattern can be used to ensure adequate pneumoperitoneum (307,308). A radially dilating port introduction system (125,342) passed directly into a small peritoneotomy simplifies open port placement and creates a secure seal. Tethering each port to the skin with a stay suture passed around the insufflation valve limits excursion and prevents inadvertent removal during manipulation.

Although smaller laparoscopic cameras are available, optical transmission through a 5-mm camera seems optimal and only minimal cosmetic advantage is achieved from using a 2-mm port within the umbilicus. The position and condition of the undescended testicle is then evaluated laparoscopically with the operating table rolled toward the surgeon, and with the patient in the Trendelenburg position. When the vas deferens and spermatic vessels end blindly within the abdomen, no further intervention is required. If the testis appears viable and is judged to be within 2 cm of the internal inguinal ring, then a primary laparoscopic orchiopexy can likely be completed successfully. Laparoscopic orchiopexy is still appropriate when the spermatic vessels and vas deferens enter the internal inguinal ring if pressure on the inguinal canal delivers a peeping testicle. A staged vasal-pedicle orchiopexy should be considered for more cephalad intraabdominal testicles. Microvascular autotransplantation is clearly indicated when the integrity of the vasal artery has been compromised by prior surgical exploration (Fig. 56.6).

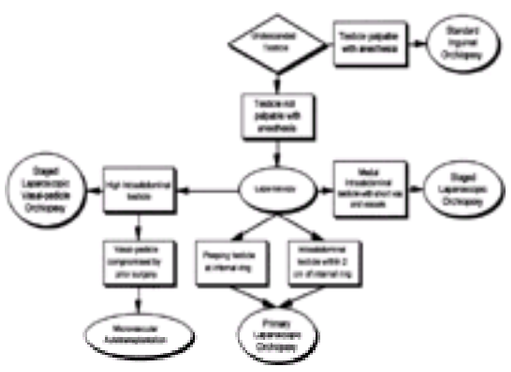

FIGURE 56.6. Management of the intraabdominal undescended testicle based on laparoscopic findings.

When proceeding with laparoscopic orchiopexy, two working ports (either 2 mm or 5 mm) are placed under laparoscopic guidance, just medial to the anterior superior iliac spines (Fig. 56.7). Transillumination of the abdominal wall allows identification and avoidance of the epigastric vessels. The peritoneum is incised with endoshears on either side of the spermatic vessels, extending cephalad to the renal hilum if necessary. The lateral incision is carried around the internal inguinal ring and then passes medial to the inferior epigastric vessels (Fig. 56.8). Elevation of the spermatic vessels then creates a flap of tissue, which includes the testicle. The gubernaculum is mobilized from within the internal inguinal ring and divided as far caudally as possible, as the processus vaginalis is everted. Both peritoneal incisions are then extended medially, flanking the vas deferens, to complete the dissection. Adequate mobility is achieved when the testis can be transferred intraabdominally to the contralateral internal inguinal ring, grasping the gubernaculum for traction. A new inguinal canal medial to the epigastric vessels can then be created. Passage of a laparoscopic dissector through the abdominal wall and out a scrotal incision allows retrograde loading of a laparoscopic port over this instrument (Fig. 56.9). Alternatively, passage of a mosquito clamp or a dissecting instrument (loaded with a laparoscopic port) allows direct access to the abdomen for transfer of the testicle. The testicle must be monitored laparoscopically during transfer to preclude torsion of the spermatic vessels and then can be secured routinely to the subdartos pouch.

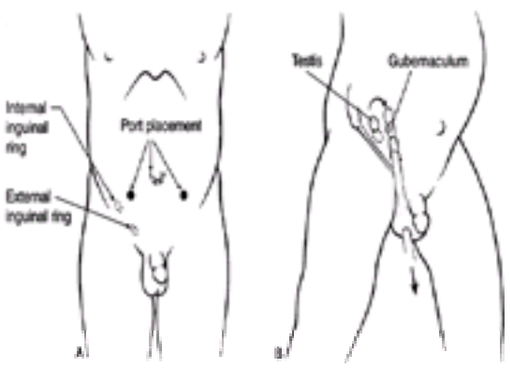

FIGURE 56.7. Port placement for laparoscopic orchiopexy. **A:** A 5-mm camera port is placed through an infraumbilical incision using an open access technique. Two working ports (either 2 or 5 mm) are positioned medial to the anterior superior iliac spines. **B:** Use of a 10-mm scrotal port facilitates testicular transfer, and preserves pneumoperitoneum, allowing additional intraabdominal dissection of the spermatic vessels if necessary.

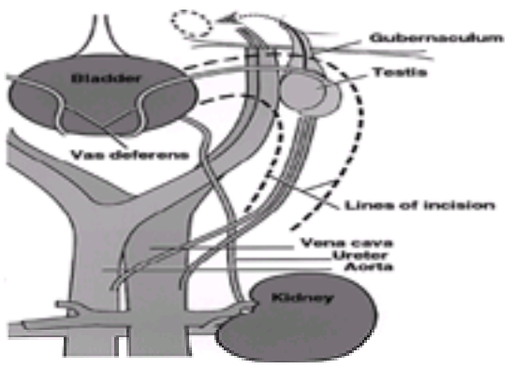

FIGURE 56.8. Lines of peritoneal incision for laparoscopic orchiopexy. The gubernaculum is mobilized from within the internal inguinal ring, divided distally, and transposed to a newly created inguinal canal medial to the inferior epigastric vessels.

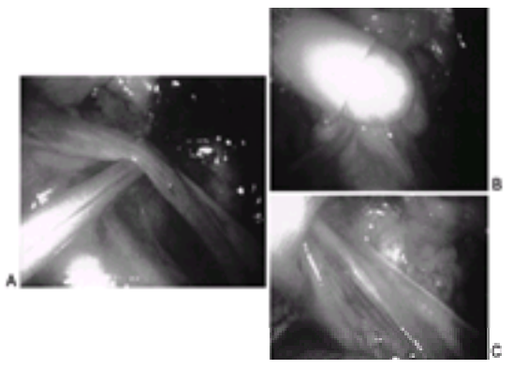

FIGURE 56.9. Laparoscopic orchiopexy. **A:** Spermatic vessels elevated with a 2-mm laparoscopic forceps after peritoneal incisions and mobilization have been completed **B:** Testicle fits within a 10-mm scrotal laparoscopic port passed intraabdominally through a newly created inguinal canal. **C:** View of spermatic vessels and vas deferens as they enter the newly created inguinal canal after testicular transfer to the scrotum.

If adequate spermatic vessel length is not attained for scrotal placement of the testicle after initial mobilization, further dissection of the peritoneum cephalad is often possible with the caudal traction now imparted on the testicle. Division of the spermatic vessels still can be considered if the spermatic vessels remain too short for a tension-free orchiopexy, because the vasal pedicle has not been compromised. However, reliance on a single-stage vasal-pedicle orchiopexy yields testicular atrophy in a troubling percentage of patients even with significant surgical experience (55). Best results are attained when insufficient length of the vessels is suspected early during dissection, allowing a staged vasal-pedicle orchiopexy to be selected. Intraabdominal testicles found medial to the umbilical artery typically have foreshortening of both the spermatic vessels and vas deferens, which makes them especially problematic. Staged laparoscopic orchiopexy with preservation of the spermatic vessels should be considered because all other options are limited. After completion of the laparoscopic orchiopexy, intraabdominal pressure should be lowered (below 4 mm Hg) to aid identification of existing bleeding. Closure of the internal inguinal ring with clips, suture, or an endoloop can be considered, but is generally unnecessary. Each working port site should then be observed laparoscopically as the port is removed. Bleeding can be controlled by placement of a figure-of-eight ligature through the fascia using a port closure device. All port sites (especially the umbilical port) should be closed to prevent herniation of the omentum.

Laparoscopy for Intersex States

Laparoscopy has a limited, but significant role in evaluation and treatment of children born with intersex conditions. A specific clinical diagnosis is often suspected after a thorough physical examination, and confirmed with karyotype, biochemical studies, and a genitogram (304). In select cases, laparoscopy may be necessary to discern internal anatomy, including the configuration of a uterus or müllerian duct remnant, and the appearance of intraabdominal gonads (71). Laparoscopy is most often helpful in the evaluation of true hermaphrodites or male pseudohermaphrodites. Although laparoscopy is generally not required to confirm the diagnosis of congenital adrenal hyperplasia, it may prove indispensable in rare cases with normal biochemical studies (304). Laparoscopic bilateral adrenalectomy also has been reported in a 14-year-old girl with 11b-hydroxylase deficiency refractory to medical adrenal suppression (274).

Gonadal biopsy can be performed laparoscopically when an ovotestis or gonadal dysgenesis is suspected. Because these biopsies must generally be longitudinal and deep to permit an accurate histologic diagnosis, a greater degree of surgical control and skill is required to complete the biopsy, close the biopsy site, and avoid injury to the remaining gonad. The biopsy can be completed using conventional methods and tactile control when the gonad is mobile enough to be exteriorized through a 10-mm port placed directly anterior to it. After closure of the biopsy site, the gonad can then be placed back into the abdomen through the laparoscopic port (Fig. 56.10). This method also allows accurate removal of discordant tissue when an ovotestis is detected. Gonadal biopsies also can be safely performed laparoscopically (22,415) using three ports in the lower pelvis, similar to those used for laparoscopic orchiopexy (304). Laparoscopic gonadectomy has been reported for patients with complete androgen insensitivity syndrome (256,377,415) and gonadal dysgenesis (213,245,346,415).

FIGURE 56.10. Laparoscopic-assisted gonadal biopsy. **A:** Intraabdominal gonad overlying a pelvic kidney in a child with intersex abnormality **B:** Gonad has been transferred through the abdominal wall using a 10-mm laparoscopic port placed anteriorly, and a longitudinal biopsy has been completed using standard techniques. **C:** Gonad has been replaced within the abdomen.

Orchiopexy in boys with failure of müllerian inhibiting substance (hernia uteri inguinalis) is problematic because the vas deferens and vasal artery are incorporated into the lateral aspects of their uterus (Fig. 56.11). Preservation of testicular function and possible fertility potential most often requires preservation of these persistent müllerian structures. A laparoscopic approach provides enhanced visualization of the shared vascular supply and allows assessment of the mobility of the uterine structures. Sufficient mobility for standard laparoscopic orchiopexy is present when the testis can be drawn over to the contralateral internal inguinal ring. Both the testis and associated müllerian structures can be removed laparoscopically when the testis is atrophic (395). Müllerian remnants usually are adherent to the vas deferens or seminal vesicles at their confluence with the prostate. McDougall and associates (255) described laparoscopic dissection of a müllerian duct cyst and separation of its attachments to the ureter and seminal vesicle in a symptomatic adult. The cyst was then transected using the gastrointestinal stapler where it joined the prostate. Yeung and co-workers (407) performed laparoscopic excision of large prostatic utricles in three boys using coincident cystoscopic illumination and manipulation to promote complete distal dissection.

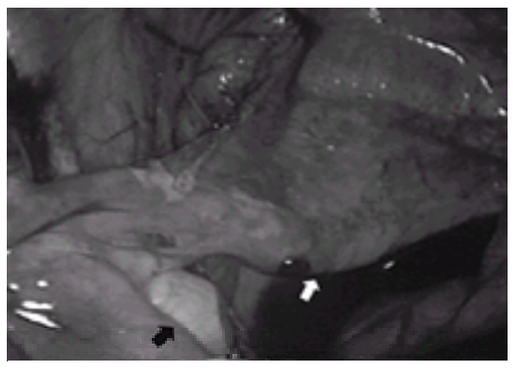

FIGURE 56.11. Failure of müllerian inhibiting substance (hernia uteri inguinalis). Intraabdominal testicle *(black arrow)* tethered by uterine structure *(white arrow)* encroaching on vas deferens.

Laparoscopic Varicocelectomy

Palpable varicoceles should be corrected in adolescent boys when they are very large, or when they are accompanied by ipsilateral testicular hypotrophy (337). Atrophy of the affected testis indicates thermal injury or growth retardation, and correlates with impaired motile sperm counts in adulthood (350). Testicular injury also may be inferred by an exaggerated gonadotropin response to a luteinizing hormone–releasing hormone stimulation test (201). Varicocelectomy performed during early adolescence offers reversal of testicular growth arrest, and rapid catch-up growth of the ipsilateral testis (202,225,292,337). Correction of a varicocele in patients with early changes (atrophy) in Leydig cell morphometry on testis biopsy leads to significant improvement in the postoperative spermiogram. This is not observed, however, in patients undergoing correction of varicocele after late changes (proliferation and hyperplasia of Leydig cells) are evident (158). Varicoceles can be effectively corrected using either percutaneous embolization or surgery. Although a percutaneous approach may be preferred for ablation of unilateral varicoceles (327), laparoscopic varicocelectomy generally is recommended when varicoceles are bilateral (2,116). Antegrade scrotal sclerotherapy can be performed in adolescent males under local anesthesia with excellent success reported (272). However, technical and anatomic obstacles may preclude placement of coils or sclerosing agent in up to 19% of boys (251,373). Success rates determined by telethermography are improved when the sclerosing agent is introduced into the caudal portion of the internal spermatic veins at the level of the internal inguinal ring (82%), rather than more cranially (68%) (351).

Varicocelectomy may involve division of both the spermatic artery and veins (295). However, preservation of the spermatic artery can offer the theoretic advantage of optimizing fertility potential. Furthermore postoperative hydrocele is less common when the spermatic artery and adjacent lymphatic vessels are left intact (116,225,364). Optical magnification and intraoperative Doppler ultrasonography aid identification of the spermatic artery (401). Venography to identify undivided spermatic veins intraoperatively offers little benefit, with varicocele persistence rates reported up to 9% despite its use during suprainguinal varicocelectomy (164,294). Microsurgical repair of the adolescent varicocele yields the lowest rates of recurrent varicocele and hydrocele formation postoperatively (225). Similar results (persistence rates less than 2%) can be obtained by experienced surgeons using a laparoscopic approach (99,183). The benefit of optical magnification obtained through laparoscopy is offset somewhat by increased difficulty incurred during dissection of small veins adherent to the spermatic artery. Persistence of these vessels likely accounts for the higher varicocele recurrence rate associated with spermatic artery preservation in a recent, large multicenter study of laparoscopic varicocelectomy (116).

Laparoscopic varicocelectomy is performed with the patient under general anesthesia in the supine position, with a single video monitor placed at the foot of the operating table. Unilateral or bilateral varicocelectomy then can be completed using an umbilical camera port and two working ports placed laterally (similar to the arrangement used for orchiopexy). Use of a curved scissor and a curved grasper promotes precise dissection of the spermatic vessels, and allows preservation of the spermatic artery. Electrocautery should only be used during longitudinal dissection of the peritoneum, to avoid injury to the spermatic artery. Spermatic veins are occluded using either 5-mm hemoclips (99) or permanent sutures passed through a working port and ligated with an extracorporeal knot-pusher. Mere fulguration of spermatic vessels with electrocautery or with the Nd:YAG laser is not recommended because it leads to higher varicocele recurrence rates and increases the risk for delayed bleeding associated with thermal injury to the spermatic artery (100,226). Diminutive venules adjacent to the spermatic artery must be delicately dissected and divided if complete venous ablation is to be achieved.

Eventually the spermatic artery remains the only intact vessel within the spermatic cord. Preservation of small lymphatic channels adjacent to the artery will likely reduce the risk for postoperative hydrocele. Although its pulsation generally allows visual identification of the spermatic artery, arterial spasm during the course of dissection may cause confusion and delay. Papaverine dripped onto the spermatic vessels through a percutaneously passed 25-gauge spinal needle restores a bounding pulse to the artery. The laparoscopic Doppler probe (5 mm) may further expedite identification of the artery because it can demonstrate an arterial pulse even when blood flow is reduced (242).

Laparoscopic Adrenalectomy

Although laparoscopy has dramatically changed the surgical approach to the adrenal gland in adults (362,369,413), laparoscopic adrenalectomy only occasionally has been reported in children (69,72,84,123,369,389,413). Laparoscopic adrenalectomy yields smaller incisions with less postoperative pain, less intraoperative blood loss, and diminished pulmonary and wound complications (69,362), and it can be performed using either transperitoneal or retroperitoneal access. Each approach has inherent advantages related to the exposure of the adrenal gland and its blood supply. Both are comparable in terms of operative time, intraoperative blood loss, and hospital course (362,365). The more commonly reported transperitoneal approach has generally been used for resection of pheochromocytomas in children (69,72,369,389). This approach also offers exposure to both adrenal glands and has been used to perform bilateral laparoscopic adrenalectomies in two children with congenital adrenal hyperplasia refractory to medical therapy (274,339). A retroperitoneal approach may be preferable for patients with previous abdominal surgery (123).

Laparoscopic adrenalectomy for pheochromocytoma in children was first reported in 1999 (69,72). Anesthetic management for one of these two boys was described in a separate report and indicated that the most significant intraoperative catecholamine release occurred during induction of pneumoperitoneum (312). Others have shown that intraoperative hemodynamic values during open and laparoscopic adrenalectomy for pheochromocytoma are comparable (369), with less severe and less frequent hypotensive episodes accredited to the laparoscopic approach (357). Regardless of the surgical approach for pheochromocytoma, intraoperative hemodynamic instability is most anticipated with right adrenal tumors (short adrenal vein) (369) and tumors secreting predominantly noradrenaline (72). Walther and associates (389) recently described partial adrenalectomy in a 16-year-old boy with von Hipple–Lindau disease manifesting multiple right adrenal and extraadrenal pheochromocytomas. Hemodynamic parameters remained stable following preoperative phenoxybenzamine and metyrosine blockade, despite an inability to selectively ligate the adrenal vein with this approach (389). Bilateral partial laparoscopic adrenalectomy, with preservation of adrenocortical function also has been reported in a 9-year-old child with familial pheochromocytoma (277). Although laparoscopic adrenalectomy generally is contraindicated for malignant adrenal lesions, laparoscopic adrenalectomy also has been reported in three infants found to have small neuroblastomas during a mass-screening program in Japan (404).

LAPAROSCOPIC RENAL SURGERY

Laparoscopic Nephrectomy

Laparoscopic nephrectomy has developed rapidly over the last decade, since Clayman and others (63,65) performed the first transperitoneal procedure in an 85-year-old woman with a 3-cm oncocytoma (1990). Shortly thereafter, the first retroperitoneal laparoscopic nephrectomy also was performed by Clayman and associates (64), but the transperitoneal approach was favored because it afforded a larger working space (207). Clayman and co-workers (66) described division of the distal ureter with a cuff of bladder using the laparoscopic GIA stapler. With this maneuver, he completed the first transperitoneal laparoscopic nephroureterectomy. The patient was an 82-year-old man with transitional cell carcinoma of the renal pelvis (1991). The first laparoscopic partial nephrectomy removed a lower-pole caliceal diverticulum containing a stone. This procedure used a novel adjustable renal tourniquet and a composite probe for electrocautery and argon beam coagulation (Birtcher Medical Systems, Irvine, California) (398).

Two groups completed the first laparoscopic nephrectomy procedures in children almost simultaneously (103,212). Koyle and Kavoussi (212) removed a multicystic kidney from an 8-month-old infant using three laparoscopic ports and a LapSac (Cook Inc., Spencer, Indiana) for retrieval. Ehrlich and others (103) removed a 15-cm multicystic kidney from a 3-year-old girl laparoscopically, by first establishing pneumoperitoneum with the Veress needle in the supine position, and then converting to a modified flank position. For subsequent cases, pneumoperitoneum was created using an open technique with the child already in a modified flank position (104). Included in this series of 17 procedures is an attempted retroperitoneal laparoscopic nephrectomy in an 11-month-old infant; however, limited working space thwarted the procedure, which was then completed transperitoneally (104).

Diamond and co-workers (92) reported the first series of retroperitoneal laparoscopic nephrectomy procedures using three ports placed in the posterior flank. The retroperitoneal space was developed with either a balloon fabricated from the finger of a glove [as described by Guar (153)], or with blunt digital dissection and placement of a balloon distention trocar (92). Improved visualization of the renal hilar vessels and elimination of the risk for intraabdominal adhesions were both cited as advantages for the retroperitoneal approach (92). Valla and associates (379) placed the camera port directly within the retroperitoneal space, and then created the working space by moving the tip of the telescope systematically (aided by insufflation pressure). A purse-string suture around the posteriorly placed camera port provided a secure seal. Both the balloon dilation method (34,169,211) and direct expansion of the retroperitoneum (108,109,156,379) provide excellent exposure. Peritoneal perforation has been reported with both techniques (108,109,156,169,211,379). Although no specific complications result from peritoneal transgression, some of the exposure to the renal hilum afforded by this retroperitoneal approach is lost, and an additional port may be required to achieve adequate retraction. Borer

and others (34) advocated prone patient positioning to optimize access to the renal hilum as the kidney settles ventrally, and they adopted 2-mm instrumentation to more effectively maneuver within the limited retroperitoneal space available in infants and children.

Laparoscopic Nephroureterectomy

Das and others (82) reported the first laparoscopic nephroureterectomy in a child. A refluxing kidney and ureter in an 11-year-old girl was dissected using a 5-port transperitoneal laparoscopic technique. The distal ureter was transfixed with an intracorporeal suture at the ureterovesical junction, and then transected. The specimen was retrieved intact through the 10-mm umbilical port. Suzuki (363) laparoscopically resected an atrophic pelvic kidney with an ectopic ureteral insertion into the vagina in a 4-year-old girl, using five ports and a fiber-optic endoscope within the ureter. Five additional cases in children with hydroureteronephrosis were reported by two groups contemporaneously, using the laparoscopic gastrointestinal anastomosis (GIA) stapling device to transect the distal ureter with a cuff of bladder (104,127). Current series advocate transection of the ureter at the ureterovesical junction, recognizing that preservation of the intramural ureter poses little risk (162). Although this can be accomplished using a hemoclip (169,181,311), suture ligation (intracorporeal or extracorporeal) of the distal ureter is a more reliable method (361,405). Resection of the distal ureter also has been completed through an open incision, either routinely (83) or when concomitant ureteroneocystostomy is required (34,83,181).

Access to the distal ureter is limited when a posterior retroperitoneal laparoscopic approach is used. Kobashi and co-workers (211) relied on cystoscopy with fulguration of the intramural ureter and ureteral stump when reflux nephropathy was present, but found and endoscopically re-treated persistent VUR in one of five children managed with this method. Furthermore, Borzi and others (36) noted that recurrent urinary infection occurred following incomplete resection of the ureter in two of their 58 children undergoing laparoscopic nephrectomy by a posterior retroperitoneal approach. The entire distal ureter can be accessed either by adding a fourth port placed anteriorly (108), or by positioning the array of three ports laterally on the flank (Fig. 56.12). Selection of approach (transperitoneal or retroperitoneal) for laparoscopic nephroureterectomy remains at the discretion of the operating surgeon. However, a transperitoneal approach favors cases where massive hydroureteronephrosis is present because it allows more space for dissection. Traction on the renal pelvis and aspiration of urine also can be accomplished by drawing the redundant renal pelvis through the abdominal wall via a 10-mm midaxillary port. A retroperitoneal approach should be chosen for children managed by peritoneal dialysis, or when extensive peritoneal adhesions are anticipated from prior abdominal surgery (Fig. 56.13).

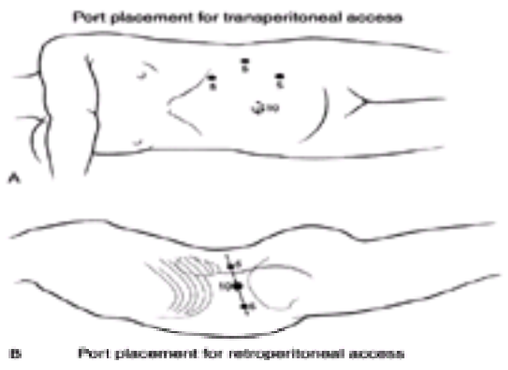

FIGURE 56.12. Port placement for laparoscopic nephroureterectomy. **A:** With the patient in a modified flank position, a 10-mm umbilical camera port and three 5-mm working ports are placed (two at the anterior axillary line, and one at the midaxillary line). **B:** With the patient in the flank position, one 10-mm camera port and two 5-mm working ports are placed on a line that would create a subcostal incision. The medial 5-mm working port facilitates manipulation of the distal ureter for ligation and transection.

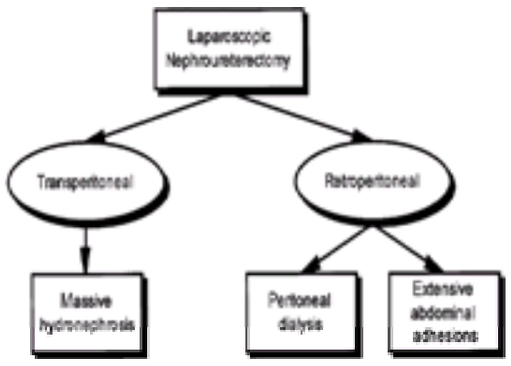

FIGURE 56.13. Proposed scheme for laparoscopic nephroureterectomy. A transperitoneal approach allows adequate space for dissection when massive hydroureteronephrosis is present. A retroperitoneal approach is ideally suited for children maintained on peritoneal dialysis or those with extensive intraabdominal adhesions. Either approach can be used for routine cases.

Laparoscopic Partial Nephroureterectomy

Jordan and Winslow reported the first laparoscopic partial nephroureterectomy in a child. They performed bilateral upper-pole partial nephroureterectomy procedures asynchronously in a 14-year-old girl, using four transperitoneal laparoscopic ports, and divided the renal parenchyma using a combination of electrocautery and the argon beam coagulation probe (190). Ehrlich (104) included four partial nephroureterectomy procedures in his initial series, and divided the renal parenchyma using three passes of the laparoscopic GIA stapling device. Before division of the renal parenchyma, individual vessels supplying the hydronephrotic pole of the kidney are dissected and controlled with hemoclips. More recently, atrophic upper-pole systems have been resected using bipolar electrocautery (181), the microwave coagulator (165), or the harmonic scalpel (143,162,405). Transection of the kidney in pigs using the harmonic scalpel (LaparoSonic Coagulating Shears, Ethicon Endo-Surgery, Cincinnati, Ohio) without first controlling segmental vessels caused a high incidence of significant hemorrhage (179). Only limited intraoperative complications have been reported with laparoscopic partial nephrectomy, through either a transperitoneal (104,143,181,311,368,405) or retroperitoneal (108,379) approach. However, two duodenal perforation injuries have occurred while retroperitoneoscopically dissecting the upper-pole renal vessels (108,379).

Although experience with laparoscopic nephrectomy in children is mounting (Table 56.4), the margin of benefit over an open surgical approach can be very slim. Elder and co-workers (114) reported a series of 34 infants and children that underwent open nephrectomy for either multicystic-dysplastic or nonfunctioning hydronephrotic kidneys as an outpatient through a small (2.5 to 3.0 cm) incision. Operative times were minimal (mean of 45 minutes), and all children did well postoperatively. However, one infant required appendectomy and hospitalization because the appendiceal artery was ligated during a search for the diminutive right kidney, this presumably linked to minimal surgical exposure offered by such a small incision.

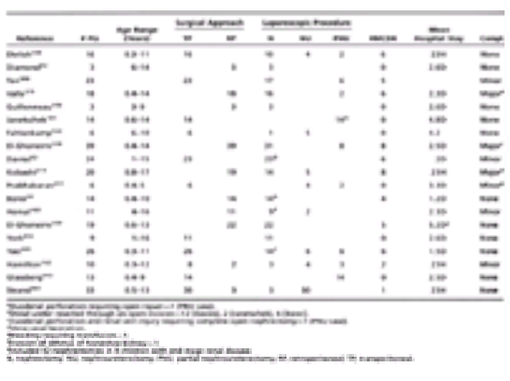

TABLE 56.4. CLINICAL SERIES OF LAPAROSCOPIC NEPHRECTOMY IN CHILDREN

Combined benefits of improved visualization and small incision size remain the most appealing aspect for laparoscopic nephrectomy in children (34,92,109,156,405). These advantages are especially evident for laparoscopic nephroureterectomy, which traditionally requires both a flank and lower abdominal incision to allow complete resection of the kidney and the entire ureter (73,102,361). In a direct comparison of laparoscopic (10 patients) with open (10 patients) nephrectomy or nephroureterectomy procedures in children, operative times were consistently longer (175 versus 120 minutes), but postoperative hospital stays were shorter (22 versus 41 hours) (162). With greater experience, operative times can decrease to less than 60 minutes for either a transperitoneal or retroperitoneal laparoscopic nephrectomy (211,368,405). Hospital stays can safely be reduced to 23 hours or less following laparoscopic nephrectomy or nephroureterectomy (104,162,211,361,405). Just as for open surgery, operative times, and hospitalization following laparoscopic partial nephrectomy are expected to remain longer. Even so, a laparoscopic approach to partial nephrectomy in infants or children has recently yielded excellent results with a mean operative time of 100 minutes (range of 70 to 135 minutes), and a mean hospitalization of 2.5 days (143).

Technique of Laparoscopic Nephroureterectomy

Transperitoneal Approach

The patient is placed in the modified supine position, with a pad placed under the appropriate flank. The operating table is rotated to allow placement of the 10-mm infraumbilical camera port using an open access technique with the patient roughly supine. Peritoneal insufflation with carbon dioxide to a pressure of 10 mm Hg is established. The table is then rotated the opposite direction to elevate the flank and allow the bowel to settle dependently. Two 5-mm working ports are then placed along the anterior axillary line under laparoscopic guidance. A fourth 5-mm port placed midway between these on the midaxillary line aids in dissection of both the renal hilum and the distal ureter. After the colon has been reflected medially, the ureter is readily identifiable as it crosses the iliac vessels. The ureter is dissected distally using the endoscopic scissors, and then doubly ligated at the ureterovesical junction using absorbable suture and the extracorporeal knot-pusher. Proper positioning of these sutures can be confirmed by filling the bladder through an indwelling urethral catheter accessible to the surgical field (Fig. 56.14). Division of the ureter distally then facilitates exposure of the renal hilum by upward traction on the proximal ureter using a grasper through the midaxillary port. Renal vessels are secured separately with endoscopic clips (two clips proximally) and divided. After transferring a 5-mm videocamera to one of the working ports, the distal ureter is grasped and removed along with the kidney through the 10-mm umbilical port. Removal of the entire port often aids in delivery of the atrophic kidney through the existing incision. When necessary, fragmentation of the kidney can be achieved by placing the kidney within an endoscopic confinement bag and disrupting the parenchyma using a large clamp passed through the umbilical port into the bag. Port sites are monitored laparoscopically as they are closed. The urethral catheter is removed the following morning, and the patient is discharged home.

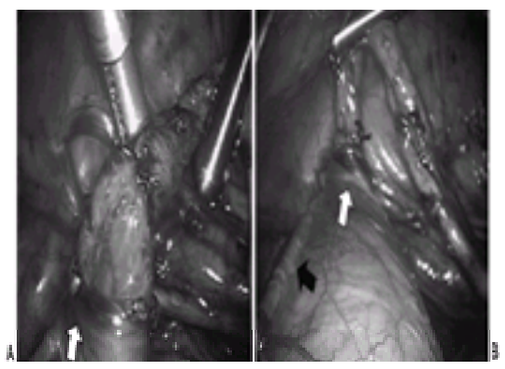

FIGURE 56.14. Transperitoneal laparoscopic nephroureterectomy. **A:** Distal ureter is ligated at the ureterovesical junction with a 3-0 absorbable suture secured using an extracorporeal knot-pusher. Position of the vas deferens is indicated *(white arrow)*. **B:** Proper placement of the sutures on the distal ureter can be confirmed by filling the bladder using a urethral catheter accessible to the surgical field. Position of the obliterated umbilical artery *(black arrow)* and the vas deferens *(white arrow)* is indicated.

Retroperitoneal Approach

With the patient in the modified flank position, direct placement of the 10-mm camera port through a 1.5-cm incision (positioned midway between the costal margin and the anterior superior iliac spine) into the retroperitoneum follows blunt dissection using two surgical clamps. A purse-string suture is placed to secure an adequate seal, and insufflation is initiated (10 mm Hg) with the port traversing the flank musculature. The retroperitoneal working space is then easily dissected by systematic separation of loose connective fibers using the tip of the camera itself. After the peritoneum has been mobilized medially, two additional 5-mm working ports are placed in a line that would create a subcostal incision. Again, the distal ureter is easily identifiable as it crosses the iliac vessels, and can be dissected distally to the ureterovesical junction using the endoscopic scissors. Lateral placement of the laparoscopic ports offers enhanced access to the distal ureter and allows the ureter to be ligated and divided as it joins the bladder (Fig. 56.15). After the lateral attachments of the kidney are separated, exposure of the renal hilum is improved (under adequate insufflation) as the kidney follows the peritoneum medially. Renal vessels are again secured separately with endoscopic clips (two clips proximally) and divided. The ureter also is grasped and drawn out through the 10-mm port to complete delivery of the entire kidney and ureter.

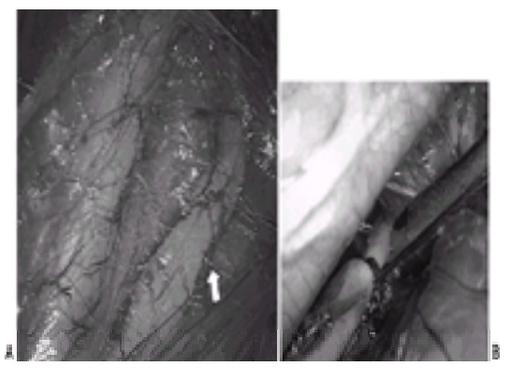

FIGURE 56.15. Retroperitoneal laparoscopic nephroureterectomy **A:** Visual identification of the distal ureter *(white arrow)* medial to the external iliac artery is easily accomplished after the retroperitoneal space has been expanded by systematic dissection with the tip of the camera. **B:** View of the distal ureter as it is secured with an extracorporeal ligature.

Laparoscopic Pyeloplasty

Laparoscopic pyeloplasty was first reported by Schuessler and others (341) using a transperitoneal approach in five adults with UPJ obstruction due to crossing renal vessels (two patients), a redundant renal pelvis (two patients), or a previously failed open pyeloplasty (one patient). Soon thereafter, Peters and associates (303) reported the first laparoscopic dismembered pyeloplasty in a child (7-year-old boy), again using a transperitoneal approach with four ports and interrupted sutures tied intracorporeally. Since then, laparoscopic pyeloplasty has remained an intriguing alternative to open pyeloplasty, with anticipated success rates greater than those

achieved by endopyelotomy. Improved technical outcomes are projected for cases involving crossing renal vessels, large pelvicaliceal volumes, or diminished renal function (157,380) when using a laparoscopic approach.

Optical magnification promotes excellent visualization of renal pelvic anatomy, allowing crossing renal vessels to be preserved and transposed after the obstructing UPJ segment is divided (17,56). When renal calculi are present, flexible nephroscopy with stone retrieval can be performed through one of the laparoscopic ports (268). UPJ obstruction in kidneys with abnormal anatomy such as a pelvic or horseshoe kidney also is amenable to laparoscopic pyeloplasty (180). However, perinephric scarring resulting from either previous surgical procedures, or pyelonephritis may interfere with dissection of the UPJ region, thereby prolonging operative time or necessitating conversion to an open surgical pyeloplasty (17,268,367).

The main disadvantage of laparoscopic pyeloplasty is the longer operative time required, predominantly a function of technical difficulty with manual laparoscopic suturing. Janetschek and co-workers (180) reported laparoscopic pyeloplasty procedures using both a transperitoneal and retroperitoneal approach, but suggested that dismembered pyeloplasty is too difficult and demanding to compete with either endopyelotomy or open surgery. Use of a nondismembered repair (Fenger-plasty) was considered preferably, especially with retroperitoneoscopy because of limited space available for suturing or knot tying. Although 8 hours was required to complete one of the first laparoscopic dismembered pyeloplasty procedures reported (205), operative times have steadily declined most notably because of systematic procedural refinements and acquired proficiency in laparoscopic suturing (56,57,366,410).

McDougall and associates (257) created unilateral UPJ obstruction in 16 pigs and then performed laparoscopic dismembered pyeloplasty, using either intracorporeal suturing and a suture clip knot (Lapra-Ty, Ethicon Endo-Surgery, Inc., Cincinnati, Ohio) or a semiautomatic suturing device (Endostitch, U.S. Surgical Corporation, Norwalk, Connecticut). Success and healing were similar with these two methods, and the time required to perform the pyeloplasty anastomosis was less than 40 minutes for both groups. Routine use of this suturing device (4-0 suture) is prevalent in adult laparoscopic pyeloplasty series (57), whereas manual intracorporeal suturing with finer suture material (5-0 or 6-0 suture) is preferred in series with infants and children (366,367,410).

Tan (367) has accumulated the largest experience with laparoscopic dismembered pyeloplasty in children, initially reporting clinical and radiographic improvement in 4 of the 5 children (2 to 15 years of age) undergoing transperitoneal laparoscopic pyeloplasty (1996). Operative times ranged from 90 to 160 minutes using either three or four ports, and a running sutured anastomosis over a double pigtail ureteral catheter introduced percutaneously. Additional experience with transperitoneal laparoscopic dismembered pyeloplasty was later recorded in 18 total children, including two infants only 3 months old (366). Operative times improved to a mean of 89 minutes, still using manual intracorporeal suturing of the anastomosis. The only treatment failures (2 patients) occurred in the 3-month-old infants. Both subsequently underwent successful reoperative laparoscopic pyeloplasty. Presumably because of these failures, Tan (366) advised against laparoscopic pyeloplasty in infants younger than 6 months of age. Yeung (410) more recently reported successful retroperitoneoscopic dismembered pyeloplasty in six infants and children (ages 3 months to 10 years), with operative times ranging from 140 to 245 minutes (mean of 175 minutes). Either three or four laparoscopic ports (5 mm) were used, and a running sutured anastomosis was again completed over a double pigtail ureteral catheter.

Retrospective comparison of laparoscopic (12 patients) and open (11 patients) pyeloplasty, with endopyelotomy (22 patients) in adults, demonstrated improved success rates overall with pyeloplasty, and a more rapid resumption of all normal activities with laparoscopic (2.3 weeks) versus open (10.3 weeks) pyeloplasty (40). A direct comparison of laparoscopic (70 patients) and open (35 patients) pyeloplasty primarily in adults concluded that long-term pain relief, improved activity level, and correction of obstruction was similar for the two groups (14). Although similar comparisons have not yet been made in children, laparoscopic dismembered pyeloplasty has become a feasible alternative to open surgery that should soon supplant endopyelotomy as alternative therapy for management of pediatric UPJ obstruction.

LAPAROSCOPIC BLADDER SURGERY

Vesicoureteroplasty

Laparoscopic vesicoureteroplasty for correction of VUR was first performed in pigs by Atala and others (11) using a modified Lich (231) extravesical technique. After a detrusor trough was created with endoscopic scissors and electrocautery, the ureter was placed within the trough, and the trough was closed over the ureter with metal staples. Correction of VUR without obstruction was reported in all four animals studied (11). McDougall and associates (258) subsequently used either staples or a running intracorporeal suture to close the seromuscular incision proximal to the ureter in their pig model. One of five animals studied 6 months postoperatively had persistent grade I VUR present. Schimberg and others (340) added ureteral advancement with suture fixation [detrusorrhaphy (417)] and used a running suture for closure of the detrusor trough routinely in six pigs. Ureteral obstruction occurred in one of their initial cases with this approach.

Ehrlich (106) applied extravesical vesicoureteroplasty to two children younger than 5 years, with operative times recorded at 135 and 195 minutes, respectively. At about the same time, laparoscopic ureteral reimplantation was performed to correct ureterovesical junction obstruction in a 74-year-old obese man. After distal ureteral transection, the ureter was reapproximated to the bladder over a percutaneously placed nephrostent using interrupted absorbable sutures, without any attempt to tunnel the ureter. Renal function was preserved at 1-year follow-up (321). Janetschek and others (182) subsequently reported laparoscopic correction of VUR in six girls (three bilateral cases). Postoperative ureteral obstruction developed in one child, but resolved after ureteral stent placement for 6 weeks. Laparoscopic vesicoureteroplasty was considered a technically demanding procedure, offering little benefit over conventional open ureteral reimplantation (182).

In an effort to simplify correction of VUR, endoscopic trigonoplasty using two percutaneously placed intravesical trocars, and a cystoscope in the urethra was then reported independently by Okamura and others (289), and Cartwright and co-workers (48). Following the Gil-Vernet principle (141), a transverse incision is made through the mucosa of the interureteric ridge. After undermining the mucosal edges, the lateral extent of the incision is approximated with a horizontal mattress suture. This anchoring suture converts the previously transverse incision into a vertical orientation and advances the ureteral orifices toward the midline. Ureteral catheters may be placed temporarily after trigonal incision to facilitate proper placement of the anchoring suture and removed after midline approximation has been completed (289).

Okamura and others (288) reported 100% success in correction of VUR using percutaneous endoscopic trigonoplasty in their initial 12 patients, including one child. However, a review of 28 of their patients (six children) with at least 1-year follow-up indicated only 79% correction of VUR (290). Delayed separation of the midline incision, allowing lateral migration of the ureteral orifices, has been implicated in failure of trigonoplasty (290). Cartwright reported 62.5% resolution of VUR in 22 children (10 with bilateral VUR preoperatively) at 1- to 6-month follow-up, with further decrease in successful correction of VUR to 47% by 37 months (137). Insufflation of the bladder with carbon dioxide was well tolerated, but significant intraperitoneal extravasation of irrigant, and resultant hyponatremia occurred after using sterile water in one initial case (48). This percutaneous endoscopic procedure was revised to include formal ureteral dissection and transtrigonal ureteral advancement in six children (all with bilateral VUR). Operative time was doubled, and a 1-year success rate of 83% was realized (137).

Laksmanan and Fung (220) have recently resurrected laparoscopic vesicoureteroplasty using a modified extravesical approach with one umbilical camera port and three lower abdominal working ports. In this approach, ureteral advancement is not performed. The ureter remains secured distally and an inverted-Y detrusor incision is made with laparoscopic scissors and electrocautery at the ureterovesical junction. The detrusor trough is closed with interrupted sutures tied intracorporeally. Successful correction of VUR without obstruction is reported in all 71 refluxing ureters (24 bilateral patients) in their series. However, two initial cases required open ureteral reimplantation because of ureteral injury. The authors stress careful handling of ureters during laparoscopic dissection and advocate use of a 3-mm adjustable Diamond-Flex retractor (Snowdon Pencer, Tucker, Georgia) for atraumatic ureteral retraction (220). Operative times were not mentioned.

LAPAROSCOPIC URINARY TRACT RECONSTRUCTION

Laparoscopic-assisted Appendicovesicostomy

Urinary tract reconstruction for children with neuropathic bladder dysfunction often involves augmentation cystoplasty using ileum, sigmoid colon, or stomach. Such urinary tract reconstruction and intermittent catheterization also may be necessary occasionally for children with bladder exstrophy, posterior urethral valves, and bilateral ectopic ureteroceles. Compliance with a prescribed intermittent urinary catheterization regimen is promoted by creation of a continent catheterizable bladder entry in children who have urethral stricture disease or intact urethral sensation. Children who are wheelchair-confined, or entirely caregiver dependent also should be considered good candidates for creation of alternative bladder access.

Appendicovesicostomy remains the preferred surgical approach because of limited perioperative morbidity (101,263). Mobilization of the cecum and appendix during appendicovesicostomy generally has been completed through a lower midline abdominal incision, which may then be extended cephalad when more extensive

surgical exposure is required (42,101,166,167). Positioning of the appendicovesicostomy stoma in the right lower quadrant of the abdomen or preferably at the umbilicus demands extensive mobilization of the cecum and often the entire right colon (166). Abnormal fixation of the cecum and appendix high in the right upper quadrant of the abdomen or extensive intraperitoneal adhesions consequent to a ventriculoperitoneal (VP) shunt frequently makes access to the appendiceal mesentery remarkably difficult through a small incision. Under these circumstances, the catheterizable urinary conduit can be fashioned from bowel (51), or alternatively, the appendix can be pursued through an extended midline incision.

A laparoscopic approach provides direct access to the entire right colon without the need for a large abdominal incision (Fig. 56.16). The first laparoscopically assisted appendicovesicostomy was completed (1993) in a 15-year-old girl born with bilateral ectopic ureteroceles who had undergone extensive prior surgical reconstruction, including right ureteroneocystostomy, left nephrectomy, and multiple bladder neck reconstructions (193). Laparoscopic creation of a cutaneous ureterovesicostomy also was reported in a 13-year-old girl with a similar history (360). The majority of other laparoscopically assisted appendicovesicostomy procedures have been accomplished in children with spina bifida, either as an isolated procedure (42), or in combination with augmentation cystoplasty (166). Limited formation of intraperitoneal adhesions with this approach was both suspected (269) and observed (166). Continence in four adults undergoing entirely laparoscopic nontunnelled appendicovesicostomy procedures (239) may be attributed to intrinsic appendiceal peristalsis, which creates a sufficient functional profile length (392).

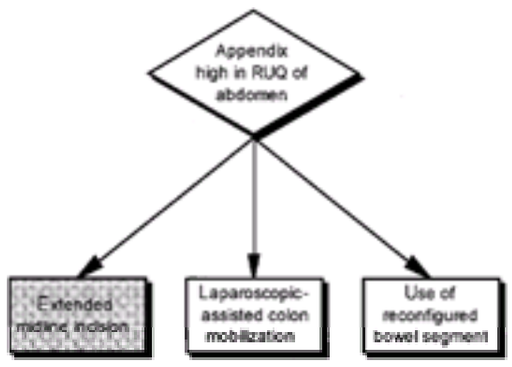

FIGURE 56.16. Proposed scheme for creation of a catheterizable urinary conduit for children with neuropathic bladder dysfunction. RUQ, right upper quadrant.

Twenty children (14 boys and 6 girls) ranging in age from 5 to 17 years old with neuropathic bladder dysfunction resulting from spina bifida have undergone laparoscopic-assisted urinary tract reconstruction at our institution. Appendicovesicostomy with an umbilical stoma was successful after laparoscopic mobilization of the right colon and appendix in 10 children. In the remaining 10 children, there was tethering of the appendiceal mesentery that could not be corrected with colon mobilization. Therefore an alternative catheterizable bladder entry was created using either the primary (51,265) or extended Monti (Casale) technique (49) (using ileum in 6 and sigmoid colon in 4). All 19 children with a VP shunt were noted to have intraperitoneal adhesions present in the right lower quadrant. Port placement (including creation of the umbilical U-shaped flap) and laparoscopic dissection time generally required 40 minutes. Augmentation cystoplasty also was performed through a Pfannenstiel incision in all 20 children (using ileum in 16, and sigmoid colon in 4), and 9 children also had a concomitant suspended bladder neck wrap procedure performed. No intraoperative or postoperative complications occurred, and intraoperative blood loss was negligible. Morbidly obese children were not considered for this laparoscopic approach because of the limited likelihood that the appendix could span the distance from the umbilicus to the bladder. Rather, the Casale technique (49) using reconfigured bowel was preferred in these children.

Postoperative pain control was subjectively improved using a laparoscopically assisted approach because the Pfannenstiel incision was often entirely below the sensory level for the child undergoing surgery (in contrast to a lower midline abdominal incision, which typically causes discomfort at its cephalad extent). Median postoperative hospitalization was 5 days (range of 4 to 6 days). Redman and Barthold noted that a Pfannenstiel incision is cosmetically superior to a midline incision for augmentation cystoplasty, and may be less prone to dehiscence. Return of bowel function and duration of hospitalization also are improved for children undergoing bladder augmentation through a Pfannenstiel incision (323). These benefits also are manifested when a laparoscopic-assisted approach through a Pfannenstiel incision is used (166). Use of laparoscopic dissection during appendicovesicostomy allows rapid assessment of the utility of the appendix, and provides unencumbered exposure for expeditious appendiceal mobilization.

Technique of Laparoscopic-assisted Appendicovesicostomy

A 10-mm camera port is initially placed using an open access technique through a semilunar incision within the inferior aspect of the umbilicus. Once pneumoperitoneum is established, two additional 5-mm working ports are placed under laparoscopic guidance. The most cephalad working port is placed in the midline approximately midway between the xiphoid and the umbilicus, and the caudal working port is placed to allow later incorporation into the planned Pfannenstiel incision (Fig. 56.17). The right colon is then mobilized along the white line of Toldt from the cecum to the hepatic flexure under laparoscopic guidance using endoshears and dissecting forceps. Laparoscopic portion of the case is concluded when the cecum can be brought dependently into the pelvis.

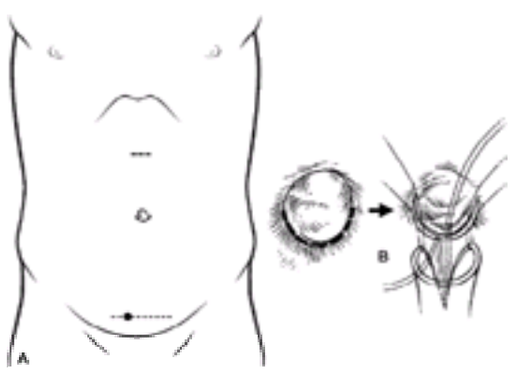

FIGURE 56.17. Port placement for laparoscopic-assisted appendicovesicostomy. **A:** A 10-mm camera port is placed through a semilunar incision within the inferior aspect of the umbilicus, using an open access technique. Two 5-mm working ports are utilized (one midway between the xiphoid and the umbilicus and one incorporated into the line for the Pfannenstiel incision). **B:** The semilunar umbilical flap is approximated to the spatulated appendix to create a widely patent, but concealed umbilical stoma.

Laparoscopic Autoaugmentation

Laparoscopic autoaugmentation was first described by Ehrlich and Gershman (105) using a transperitoneal approach, and later by McDougall and co-workers (259) using an extraperitoneal technique. Both reports used electrocautery to incise the detrusor muscle and to create the bladder diverticulum. The first case was complicated by a delayed intraperitoneal leak that was managed successfully by catheter drainage (105). McDougall and others (259) described use of a novel intravesical balloon. This is created from a 5-Fr angiographic catheter passed through an 18-Fr council-tip catheter coupled with the small finger of a size 8 surgical glove. It is used to aid in recognition of the plane separating bladder muscle and mucosal layers. Braren and Bishop (38) noted improved urodynamic parameters and relief of incontinence in 6 of 7 girls undergoing laparoscopic bladder autoaugmentation using electrocautery. Poppas (309) later used the KTP laser equipped with an angled backstop device to safely complete the detrusor incision while protecting mucosal integrity. Although adequate bladder capacity and compliance can be achieved with laparoscopic autoaugmentation (259), long-term results may be unacceptable and formal enterocystoplasty may be required (309).

Laparoscopic Augmentation Cystoplasty

Laparoscopic enterocystoplasty has the potential to become a viable alternative to open enterocystoplasty. Gill and others (142) described a primarily laparoscopic approach in three adults in whom mobilization of the bowel and then anastomosis to the bladder were completed laparoscopically. The interim steps of harvesting and reconfiguring the bowel segment and reapproximating bowel continuity were completed with the intestine exteriorized through a 2-cm infraumbilical incision. Previously, Hedican and associates (166) reported laparoscopic-assisted enterocystoplasty in six patients, using laparoscopic techniques for bowel mobilization, and then completing the bladder augmentation using either ileum (four patients) or sigmoid colon (two patients) through a Pfannenstiel (three patients) or low midline (three patients) incision. Although an entirely laparoscopic gastrocystoplasty had previously been completed in one of these patients (94), the gastrocystoplasty patch was resected when she developed the hematuria-dysuria syndrome (166). Development of a hand-assisted approach to gastrocystoplasty would allow use of a Pfannenstiel incision and should be feasible in children with abdominal cavities large enough to accept the surgeon's hand.

Pneumoperitoneum and Ventriculoperitoneal Shunts

Gas insufflation is performed at pressures greater than those normally present under physiologic conditions, and these pressures are transmitted equally to all intraperitoneal organs and structures. Distention of the peritoneum and displacement of the diaphragm further transmits this pressure to surrounding structures. Carbon dioxide is the most commonly used insufflating gas because of its ready availability and because of its rapid absorption and clearance with respiration. Although insufflation with carbon dioxide gas can increase the central venous pressure and mean arterial pressure, these changes are not clinically important in healthy individuals (140). In infants maintained at insufflation pressures of 10 mm Hg, transient cardiovascular impairment (decrease in aortic blood flow and increase in systemic vascular resistance) had no clinical consequences and was completely reversed after desufflation (155). The negative respiratory effect of carbon dioxide insufflation can be effectively monitored by pulse oximetry and capnography, and controlled by increasing respiratory rate and tidal volume during general anesthesia (139). Transient alterations in renal function causing oliguria are commonly observed with elevated insufflation pressures. These intraabdominal pressures are suspected to cause central venous compression and resultant renal vascular insufficiency (210). Insufflation pressures must be greater than 15 mm Hg in pigs for this effect to be observed (254), but only 10 mm Hg in rats (210). Oliguria is reversible after desufflation and is not associated with any persistent renal abnormalities (254).

Despite apprehension that intracranial hypertension may result from establishment of pneumoperitoneum in children with VP shunts (378), neurologic sequelae were neither detected in any published reports (42,166,167) nor observed in the 19 children with VP shunts in our experience. Review of intraoperative monitoring of 18 children with VP shunts undergoing laparoscopic surgery failed to detect any episodes of intraoperative bradycardia and hypertension during pneumoperitoneum and indicated that no specific neurologic deterioration associated with pneumoperitoneum occurred in any patient. Routine monitoring of intracranial pressure was therefore not recommended for children with VP shunts undergoing laparoscopic surgical procedures (177). Insufflation pressure limits should be set as low as feasible (generally 10 mm Hg) when operating on children with VP shunts, and laparoscopic operative times should be limited to minimize risk.

LAPAROSCOPIC COMPLICATIONS

As diagnostic and operative laparoscopy becomes firmly established in pediatric urology practice, complication rates are expected to reach a marginal baseline level, reflecting the experience of the surgeon and the complexity of the procedures performed. In a recent survey of complications sustained during laparoscopic procedures performed by pediatric urologists, overall complications were reported in approximately 5% of cases (301). However, when inadequate insufflation (primarily associated with use of the Veress needle) was excluded, the complication rate dropped to almost 1%, with surgical repair necessary in less than 0.4%. Limited laparoscopic experience (fewer than 20 cases) was the strongest predictor for occurrence of operative complications (301).

Intraoperative complications specific to laparoscopy are primarily associated with either port manipulation or use of laparoscopic instruments. Complications associated with access and insufflation are diminished significantly when the initial laparoscopic port is placed under direct vision into the peritoneal space (74,296). However, open access to the peritoneum remains difficult in obese children, and injury to adjacent bowel has been reported even using this open technique (332). Transillumination of the abdominal wall should be performed routinely to avoid injury to the epigastric vessels. This complication is more likely to occur in obese patients in whom transillumination is inadequate (296). Compression of an injured vessel can be accomplished by passage of a transfascial (but subcutaneous) figure-of-eight suture adjacent to the port site using either a 14-gauge angiocatheter or a port closure device (110). Removal of working ports and placement of port closure sutures should be monitored laparoscopically at the completion of the procedure to ensure hemostasis. After all the carbon dioxide gas is evacuated, the camera port is removed with the camera still in the abdomen to prevent migration of bowel or omentum through the channel. The last port site can then be sutured closed with previously placed fascial sutures (monitored laparoscopically from another port site), or under visual guidance. All laparoscopic port sites should be sutured closed in children because omental evisceration has been observed even using 4-mm ports (23). Closure also may prevent formation of adhesion at port sites (266).

Children must be properly grounded with an appropriate sized grounding pad during laparoscopic surgical procedures. Insufficient contact of the grounding pad can cause thermal injury, either at a local or distant site, during electrodissection using unipolar cautery. Inadvertent contact of intraperitoneal structures with uninsulated portions of electrified laparoscopic instruments must be avoided by constant vigilance and use of instruments with extensively insulated tips (21). This is especially important in small infants when working space is limited. Although reusable metal laparoscopic ports safely dissipate electrical current if applied transiently, port site burns can occur following prolonged exposure to electrocautery (121). Contact of the uninsulated portion of the instrument with the metal port should be considered immediately when electrocautery fails. Switching to bipolar cautery limits thermal injury to the tissue captured between the prongs of the forceps (121).

Laparoscopic bowel perforation occurs in only 0.2% of cases. Most often, they are recognized only postoperatively (69%) after symptoms of abdominal distention, severe trocar site pain, or diarrhea develop (21). Progression to leukopenia, sepsis, and cardiopulmonary collapse can occur within 96 hours of surgery. More than half result from inadvertent thermal injury to the bowel during laparoscopic dissection (21). Thermal injuries typically become apparent only postoperatively (21,121). Although most bowel injuries require laparotomy for repair, laparoscopic repair is possible when the injury is recognized early, and the patient has undergone preoperative mechanical and antibiotic bowel preparation (279). Major colonic injury to unprepped bowel mandates a diverting colostomy. Careful examination of adjacent structures must be performed to avoid missing additional subtle injuries. Abscess formation also can occur in areas near supposed insignificant serosal abrasions. Consequently, even relatively minor bowel injuries should be managed with caution and repaired to protect from fistulization or abscess formation (21).

Vascular injuries to the aorta or iliac vessels during trocar placement require immediate open surgical exploration and repair. Unfortunately, delayed recognition of vascular injury is a very real risk because of elevated intraperitoneal pressures and a Trendelenburg position, even after perforation of the aorta with the Veress needle (121). Intraperitoneal pressure should be lowered intermittently during the procedure and before final removal of the laparoscope to allow timely identification of significant bleeding. Bleeding during dissection of major vessels (renal hilum) resulting from injury to an unrecognized posterior branch often can be controlled by temporary occlusion with a laparoscopic instrument, and systematic dissection and control of all vessels present. Uncontrollable bleeding requires conversion to an open surgical procedure. This situation must be planned for preoperatively, and appropriate instruments must always be readily available.

The laparoscopic approach to many of the urologic problems in children is in still in its infancy. However, it is already clear that application of this new technology to testicular, renal and bladder surgery is a very real probability. The surgeon of the future will need to be facile with open, endoscopic, and laparoscopic technology.
