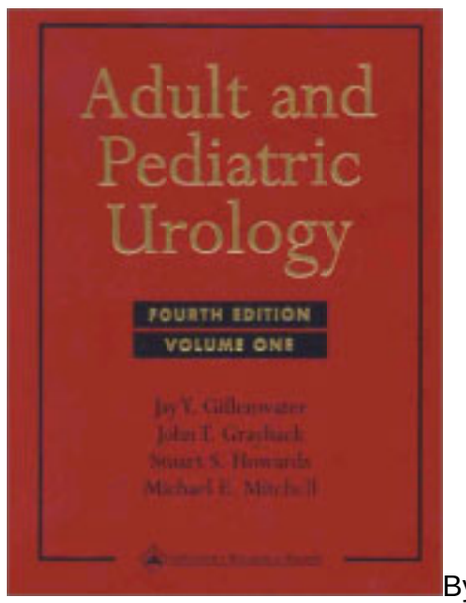
Adult and Pediatric Urology 4th edition (January 15, 2002): by Jay Y., Md. Gillenwater (Editor), Stuart S., Md. Howards (Editor), John T., Md. Grayhack (Editor), Michael, Md. Mitchell (Editor), Bauer By Lippincott Williams & Wilkins Publishers



By OkDoKeY

Adult and Pediatric Urology

CONTENTS

Editors
Contributing Authors
Preface

Color Figures

VOLUME I

SECTION I: ADULT UROLOGY

Chapter 1 Surgical Anatomy of the Genitourinary System
Georg Bartsch, H. Strasser, and Sepp Poisel

Chapter 2 Standard Diagnostic Considerations
Robert B. Nadler, Wade Bushman, and Arthur W. Wyker, Jr.

Chapter 3 Imaging

Chapter 3A Excretory Urography
Robert A. Older

Chapter 3B Cystography and Urethrography
Richard A. Leder

Chapter 3C Computed Tomography
Parvati Ramchandani and Susan E. Rowling

Chapter 3D Ultrasound
J. Patrick Spirnak and Martin I. Resnick

Chapter 3E Magnetic Resonance Imaging
Peter L. Choyke

Chapter 3F Vascular Imaging
J. Bayne Selby, Jr.

Chapter 3G Nuclide Studies
Barbara Y. Croft, Judith M. Joyce, Jayashree Parekh, and Charles D. Teates

Chapter 4 Urinary Tract Infections
Anthony J. Schaeffer

Chapter 5 Management of Urologic Problems in Pregnancy
Jay Y. Gillenwater and Jeffrey P. Weiss

Chapter 6 Urologic Laser Surgery
Douglas F. Milam and Joseph A. Smith, Jr.

Chapter 7 Genitourinary Malignancy: Etiology and Molecular Genetics, Natural History, and Treatment
McClellan M. Walther, Fredrick Leach, David K. Ornstein, Norman Zambrano, and W. Marston Linehan

Chapter 8 Calculus Formation
Alan D. Jenkins

Chapter 9 Surgical Management of Calculus Disease
Stevan B. Streem and Glenn M. Preminger

Chapter 10 Perioperative Care
W. Scott McDougal

Chapter 11 Renal and Ureteral Injuries

Chapter 11A Renal Injuries
Jack W. McAninch and Richard A. Santucci

Chapter 11B Ureteral Injuries
Joseph N. Corriere, Jr.

Chapter 12 Trauma to the Lower Urinary Tract
Joseph N. Corriere, Jr.

Chapter 13 The Adrenals
Andrew C. Novick and Stuart S. Howards

Chapter 14 The Kidney
W. Scott McDougal

Chapter 15 Alternative Medical Therapies for Urologic Diseases
Charles E. Myers, Jr.

Chapter 16 Renal Tumors
Chad W.M. Ritenour, Robert O. Northway, and Fray F. Marshall

Chapter 17 Urothelial Carcinoma of the Upper Urinary Tract
Meidee Goh, James E. Montie, and J. Stuart Wolf, Jr.

Chapter 18 Adult Laparoscopic Urology
Jaime Landman, Elspeth M. McDougall, Indiber S. Gill, and Ralph V. Clayman

Chapter 19 Endourology of the Upper Urinary Tract: Noncalculous Applications
Elspeth M. McDougall, Ralph V. Clayman, and R. Sherburne Figenshau

Chapter 20 Renal Cystic Disease
Marguerite C. Lippert

Chapter 21 Hydronephrosis
Jay Y. Gillenwater

Chapter 22 Renal Transplantation
Stuart M. Flechner and Andrew C. Novick

Chapter 23 Renovascular Hypertension and Ischemic Nephropathy
E. Darracott Vaughan, Jr., and R. Ernest Sosa

Chapter 24 The Ureter
Robert M. Weiss

VOLUME II

Chapter 25 Diseases of the Retroperitoneum
Brian E. Nicholson and Dan Theodorescu

Chapter 26 Voiding Function and Dysfunction

Chapter 26A Voiding Function: Relevant Anatomy, Physiology, Pharmacology, and Molecular Aspects
Stephen A. Zderic, Samuel Chacko, Michael E. DiSanto, and Alan J. Wein

Chapter 26B Voiding Dysfunction: Diagnosis, Classification, and Management
William D. Steers, David M. Barrett, and Alan J. Wein

Chapter 27 Spinal Cord Injury
Wade Bushman

Chapter 28 Inflammatory Diseases of the Bladder
Grannum R. Sant

Chapter 29 Urinary Fistulae
Kevin T. McVary and Fray F. Marshall

Chapter 30 Cancer of the Bladder
Donald G. Skinner, John P. Stein, Ronald Ross, Peter Nichols, Bernard Bochner, Derek Raghavan

Chapter 31 Urinary Diversions and Continent Reservoirs
Kiarash Michel and Jean B. deKernion

Chapter 32 Benign Prostatic Hyperplasia
John T. Grayhack, Kevin T. McVary, and James M. Kozlowski

Chapter 33 Carcinoma of the Prostate
James M. Kozlowski and John T. Grayhack

Chapter 34 Prostatitis
J. Curtis Nickel

Chapter 35 Male Infertility
Edward D. Kim, Larry I. Lipshultz, and Stuart S. Howards

Chapter 36 Strictures of the Male Urethra
George D. Webster and Suzie N. Venn

Chapter 37 Urethral Carcinoma
Jeffrey C. Applewhite, M. Craig Hall, David L. McCullough

Chapter 38 Gynecologic Aspects of Urology
Edward J. McGuire, Queena Chou, J. Quentin Clemens, Marko Gudziak, Helen O'Connell, and Vaseem Ali

Chapter 39 Urethritis: Etiology, Diagnosis, Treatment, and Complications
John N. Krieger

Chapter 40 Urologic Aspects of AIDS and HIV Infection
John M. Corman and John N. Krieger

Chapter 41 Tumors and Infectious Diseases of the Testis, Epididymis, and Scrotum
Randall G. Rowland and James R. Herman

Chapter 42 The Penis: Sexual Function and Dysfunction
George S. Benson and Michel A. Boileau

Chapter 43 Benign and Malignant Lesions of the Penis
Gerald Sufrin and Robert Huben

Chapter 44 Dermatologic Lesions of the Penis
Kenneth E. Greer and B. Dale Wilson

VOLUME III

SECTION II: PEDIATRIC UROLOGY

Chapter 45 Early Development of the Genitourinary Tract
Douglas E. Coplen and Joseph Ortenberg

Chapter 46 Perinatal Urology

Marc Cendron and Jack S. Elder

Chapter 47 Anomalies of the Kidney
Stephen A. Koff and Khaled H. Mutabagani

Chapter 48 The Ureter

Chapter 48A Ureteral Anomalies
Christopher S. Cooper and Howard M. Snyder III

Chapter 48B The Wide Ureter
H. Norman Noe

Chapter 48C Prune-belly Syndrome
Douglas E. Coplen

Chapter 48D Vesicoureteral Reflux and Urinary Tract Infection in Children
R. Dixon Walker and Anthony Atala

Chapter 49 The Bladder

Chapter 49A Bladder Development: Cellular Signaling
Laurence S. Baskin

Chapter 49B Exstrophy and Epispadias Anomalies
Richard W. Grady and Michael E. Mitchell

Chapter 49C The Valve Bladder
Clare E. Close

Chapter 49D Neurovesical Dysfunction and Disordered Micturition in Children
Mark F. Bellinger and Francis X. Schneck

Chapter 50 The Urethra

Chapter 50A The Female Urethra
Douglas A. Canning and Harry P. Koo

Chapter 50B The Male Urethra
John W. Brock III and Mark C. Adams

Chapter 51 Tools of Reconstruction

Chapter 51A Reconstruction of the Urinary Tract: General Principles
Michael E. Mitchell

Chapter 51B Vesicoureteral Reflux Surgery
Brent W. Snow and Patrick C. Cartwright

Chapter 51C Pyeloplasty, Pyeloureterostomy, Transureteroureterostomy, Megaureter, and Ureteral Reconstruction
Michael C. Carr

Chapter 51D Augmentation Cystoplasty
Michael E. Mitchell and J. Chadwick Plaire

Chapter 51E The Bladder Neck and Continent Channels
Beth Andersen, Richard W. Grady, and Michael E. Mitchell

Chapter 52 The Genitalia

Chapter 52A Genital Anomalies
Terry W. Hensle

Chapter 52B Hypospadias
Warren Snodgrass, Laurence S. Baskin, and Michael E. Mitchell

Chapter 52C Intersex
Douglas A. Husmann

Chapter 53 Pediatric Andrology
Stanley J. Kogan, Faruk Hadziselimovic, Stuart S. Howards, Dale Huff, and Howard M. Snyder III

Chapter 54 Pediatric Urologic Oncology
Michael L. Ritchey

Chapter 55 Office Pediatric Urology
Steven J. Skoog and Hal C. Scherz

Chapter 56 Pediatric Endourology
William R. Strand and David A. Bloom

Editors

Jay Y. Gillenwater, MD

Hovey S. Dabney Professor
Department of Urology
University of Virginia Medical School;
Professor of Urology
University of Virginia Hospital
Charlottesville, Virginia

John T. Grayhack, MD

Norman Zambrano, MD Instructor, Department of Urology, Catholic University of Chile, Santiago, Chile; Chief, Urology Service, Sotero Del Rio Hospital, Puente Alto, Santiago, Chile

Stephen A. Zderic, MD Associate Professor of Urology, Department of Surgery, University of Pennsylvania School of Medicine; Associate Professor, Pediatric Urology, Division of Pediatric Urology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

PREFACE

Adult and Pediatric Urology has been revised after only five years because of the rapid introduction of new information about urologic disease. The text, as in previous editions, has been written to serve as a practical reference for residents and practicing urologists. We have attempted to make the text readable and user-friendly and to provide a comprehensive description of the subject, rather than an encyclopedic dissertation. The authors have tried to assimilate all the important information about each subject and to evaluate it in order to reach the best conclusion or consensus. Practicing urologists and residents alike have commented favorably on the content and presentation of the material in the previous editions. We believe the new edition continues to present excellent coverage of the topics in a clear and concise manner.

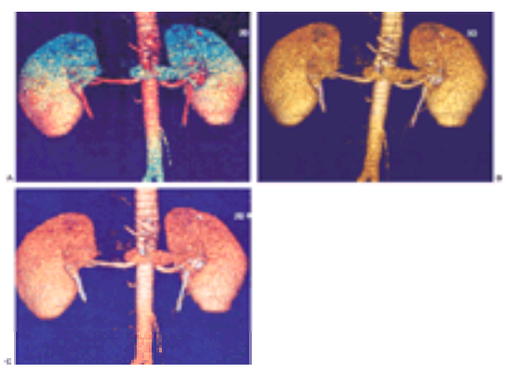
The fourth edition consists of three volumes. The first two volumes cover adult urology. Most chapters have been completely rewritten. The coverage on prostatic diseases has been expanded; completely new chapters on anatomy, diagnostic imaging, surgical management of calculus disease, bladder cancer, diseases of the retroperitoneum, alternative therapies, office urology, AIDS, and spinal cord injury have been included. The third volume, under the very capable leadership of Michael Mitchell, covers pediatric urology. We have arranged the pediatric volume by pathophysiology and treatment modality to facilitate easy clinical referencing. The sections on hypospadias, exstrophy, laparoscopic surgery, and reconstruction techniques have been radically changed to include current techniques in state-of-the-art technologies.

With this new edition, we are pleased to present a companion CD-ROM that contains all of the text, figures, and tables found within the three volumes. In addition, we have used the power of electronic publishing to provide material that cannot be presented in print by including video clips of surgical procedures. These video clips concentrate on aspects of the procedures that cannot be conveyed adequately in still images. We hope the adage that a picture is worth a thousand words will be proven true and that these videos will provide a valuable resource for our readers. We also hope that the portable and searchable nature of the CD-ROM will further enhance the user-friendly nature of the fourth edition of *Adult and Pediatric Urology.*

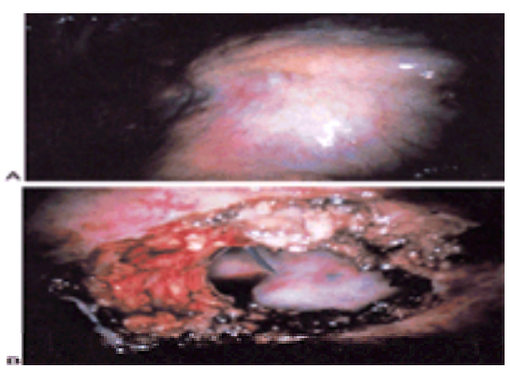
No text is any better than its authors, editors, and publishers. Working with Jack Grayhack, Stuart Howards, and Michael Mitchell has been both pleasant and intellectually stimulating. Each of the editors has worked closely with his authors to ensure the best coverage possible for a wide array of subjects. The authors enthusiastically responded and produced scholarly, critical, and informative chapters that are easy to read. Anne Sydor, Brian Brown, and Jenny Kim of Lippincott Williams & Wilkins have been invaluable partners in this endeavor. I know of no other group who could have transformed so much manuscript into a completed textbook in such a compressed time frame. We believe the result to be an up-to-date, thorough, and eminently readable textbook of general urology.

For the editors
Jay Y. Gillenwater, MD

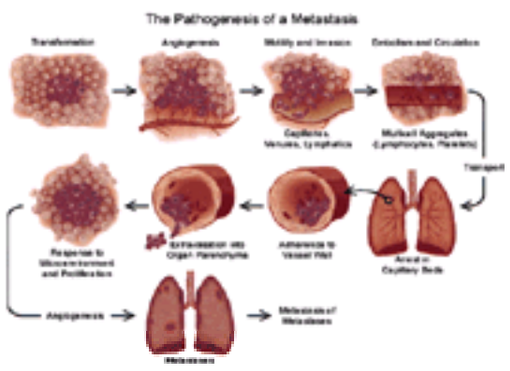
COLOR FIGURES



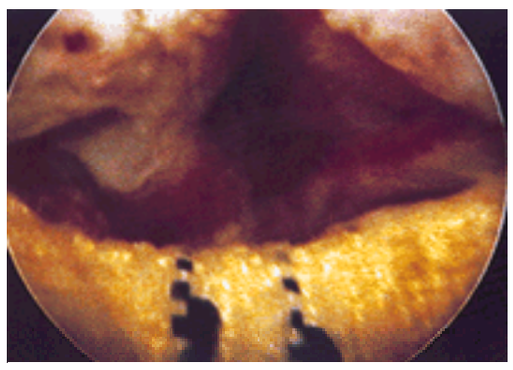
Color Figure 3F.4. Living renal donor computed tomography angiogram shows single arteries to each kidney and left renal vein passing anterior to the aorta. Different color schemes can be used depending on the preference of the viewing physicians. See also Figure 3F.4, page 178.



Color Figure 18.12. A: Laparoscopic inspection revealing the bluish-gray bulge of the lymphocele in the pelvis. **B:** Unroofed lymphocele with percutaneously placed needle visible within. See also Figure 18.12, page 685.

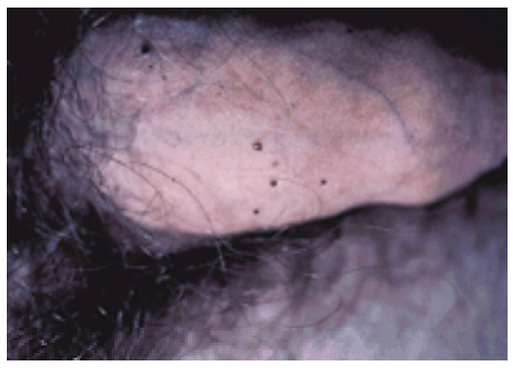


Color Figure 33.90. Successful completion of the metastatic process involves more than simply anatomic or “mechanistic” issues. It is now believed that an affinity exists between the tumor cell and the host microenvironment that is ultimately colonized. This phenomenon has been described as the “seed and soil” hypothesis. It should be emphasized that the process of metastasis consists of multiple sequential steps. All of these must be successfully completed to produce a clinically relevant metastasis. Angiogenesis must be induced to support the growth of both the primary neoplasm and its metastasis. See also Figure 33.90, page 1603. (From Fidler IJ, Kumar R, Bielenberg DR, et al. Molecular determinants of angiogenesis in cancer metastasis [Review]. *Cancer J Sci Am* 1998;4[Suppl 1]:S58, with permission.)



Color Figure 38.15. Cystoscopic view from urethra demonstrating entire eroded polyester sling within urethral lumen. See also Figure 38.15, page 1837.

Color Figure 44.1. Pearly penile papules are dome-shaped on the coronal margin and sulcus. See also Figure 44.1, page 2012.



Color Figure 44.3. Violaceous and erythematous papules with variable scaling located on the scrotum. See also Figure 44.3, page 2012.

ABDOMINAL WALL

Superficial Abdominal Muscles

Figure 1.1 shows an external view of the anterior abdominal wall.

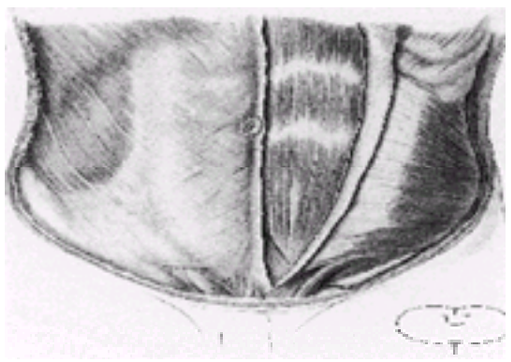

FIGURE 1.1. External view of the anterior abdominal wall. The anterior rectus sheath and external oblique muscle on the left side have been removed.

Lateral Group

External oblique muscle
Internal oblique muscle
Transversus abdominis

External Oblique Muscle

The external oblique muscle arises by eight slips from the external surfaces of the fifth through twelfth ribs. Its five upper slips interdigitate with the origins of serratus anterior, its three lower slips with the origins of latissimus dorsi. Its posterior fibers descend almost vertically to the iliac crest, and the adjacent anterior fibers pass obliquely forward and medially in their downward course.

About a fingerwidth from the lateral border of the rectus abdominis muscle, the external oblique fibers terminate in an aponeurosis. The aponeuroses of both external oblique muscles unite at the *linea alba,* where they attach to the pubic symphysis and the adjacent anterior surfaces of the superior pubic ramus.

The portion of the aponeurosis between the anterosuperior iliac spine and the pubic tubercle is thickened to form a tendinous band, the *inguinal ligament.* Just above and medial to the inguinal ligament is the *superficial inguinal ring,* bounded by the medial crus, lateral crus, and intercrural fibers. The latter are reinforcing fibers of the external oblique aponeurosis.

Internal Oblique Muscle

The internal oblique muscle originates from the deep layer of the lumbodorsal fascia, from the intermediate line of the iliac crest, from the anterorsuperior iliac spine, and from the lateral portion of the inguinal ligament. Its muscular fibers fan out broadly to their sites of insertion. The uppermost posterior fibers are inserted into the inferior borders of the last three ribs. The intermediate fibers form an aponeurosis at the lateral border of the rectus abdominis muscle. This aponeurosis splits into an anterior and a posterior layer that pass around the rectus abdominis to form the rectus sheath before uniting with the contralateral aponeurotic fibers at the linea alba. The posterior rectus sheath terminates about three fingerwidths below the umbilicus at the *arcuate line.* The lower fibers of the internal oblique are continued onto the spermatic cord in males to form the *cremaster muscle.* In females, a few muscle fibers accompany the round ligament of the uterus within the inguinal canal.

Transversus Abdominis

The deepest of the three lateral abdominal muscles, the transversus abdominis, arises by six slips from the internal aspects of the seventh through twelfth costal cartilages, interdigitating with the slips of the costal part of the diaphragm.

Fibers also arise from the deep layer of the lumbodorsal fascia, the inner lip of the iliac crest, and the lateral part of the inguinal ligament. The transversus abdominis fibers pass in a horizontal direction and terminate in an aponeurosis along the laterally convex *semilunar line.* Above the arcuate line, this aponeurosis forms the posterior layer of the rectus sheath. Below the arcuate line, it unites with the anterior lamina of the internal oblique aponeurosis and helps form the anterior layer of the rectus sheath. Each transversus aponeurosis fuses with its counterpart at the linea alba.

Medial Group

Rectus abdominis
Pyramidalis

Rectus Abdominis

The rectus abdominis muscle arises by three slips from the external surfaces of the fifth through seventh costal cartilages, from the xiphoid process, and from ligaments in this region. The muscle tapers in its straight, descending course, especially in its lower one-fourth, and inserts by a short, strong tendon into the pubic crest. The fiber mass of the rectus abdominis is interrupted by three or more transverse tendinous bands, the *tendinous intersections,* which are intimately attached to the anterior rectus sheath.

Rectus Sheath. The rectus sheath that envelops the rectus abdominis muscle is formed by the aponeuroses of the three lateral abdominal muscles. It is divided into an *anterior layer* (anterior rectus sheath) and a *posterior layer* (posterior rectus sheath). As noted, the aponeurosis of the internal oblique muscle splits into two parts that pass behind and in front of the rectus abdominis to reach the linea alba. Above the umbilicus, or more precisely above the arcuate line, the anterior wall of the sheath consists of the external oblique aponeurosis and, deep to it, the anterior layer of the internal oblique aponeurosis. Below the level of the arcuate line, the aponeuroses of all three abdominal muscles pass in front of the rectus abdominis muscle.

The posterior layer of the internal oblique aponeurosis is reinforced above the arcuate line by the aponeurosis of the transversus abdominis. Below the arcuate line, the posterior wall of the rectus sheath is formed entirely by the transversalis fascia.

Pyramidalis

The pyramidalis muscle arises broadly from the superior pubic ramus, anterior to the insertion of the rectus abdominis. It passes upward, gradually narrowing as it ascends, to insert on the linea alba. The pyramidalis is absent in approximately 20% of the population.

Lumbar Trigone and Variations

The lumbar trigone is a triangular interval bounded by the iliac crest, the posterior border of the external oblique muscle, and the anterior (lateral) border of the latissimus dorsi. The shape and size of the triangle are highly variable depending on the degree of overlap of its bordering muscles and their tendons of origin. If the musculotendinous plates overlap sufficiently, a lumbar trigone is not formed (Fig. 1.2A).

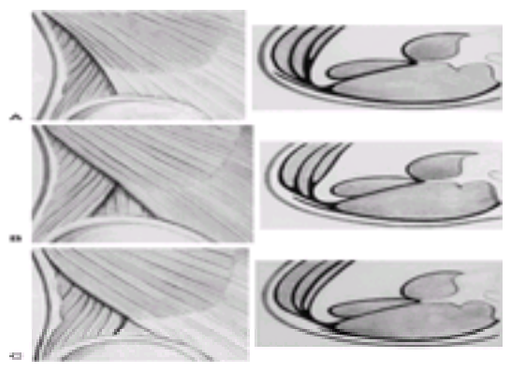

FIGURE 1.2. Variations of the lumbar trigone. **A:** Lumbodorsal fascia (superficial layer) overlies the external oblique muscle. **B:** Lumbodorsal fascia overlaps the internal oblique muscle. **C:** Lumbodorsal fascia forms a triangle (lumbar trigone) with the external oblique muscle.

If the muscles are less prominently developed, a lumbar triangle is present. The floor of the lumbar trigone may be formed by the internal oblique, if this muscle is well developed (Fig. 1.2B), or by the deep layer of the lumbodorsal fascia (Fig. 1.2C). In the latter case, the lumbodorsal fascia is the only solid structural component of the posterior abdominal wall in the lumbar trigone.

Latissimus Dorsi

The *vertebral part* of the latissimus dorsi muscle arises from the spinous processes of the fifth through twelfth thoracic vertebrae and its *iliac part* from the lumbodorsal fascia and the posterior iliac crest. The *costal part* of the latissimus dorsi muscle arises from the external surfaces of the tenth through twelfth ribs, and a variable *scapular part* originates from the inferior angle of the scapula. The fibers of the latissimus dorsi pass laterally upward with varying degrees of obliquity to the humerus, where they insert into the crest of the lesser tubercle (Fig 1.3 and Fig. 1.4).

FIGURE 1.3. External view of the lateral abdominal wall.

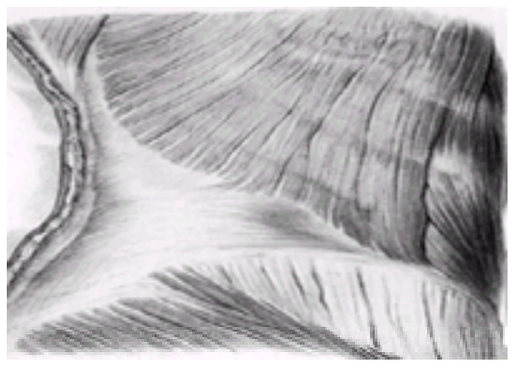

FIGURE 1.4. External view of the posterolateral abdominal wall, inferior portion.

Serratus Anterior

The serratus anterior muscle overlies the lateral chest wall and arises by nine and sometimes ten slips from the outer surfaces of the upper nine (or eight) ribs. It is inserted along the entire medial border of the scapula. Its tripartite insertion consists of a *superior part* to the superior angle of the scapula, an *intermediate part* to the medial scapular margin, and an *inferior part* to the inferior angle of the scapula.

Intercostal Muscles

The intercostal muscles partially occupy the intercostal spaces and are composed of an internal and an external layer.

The *external intercostal muscles* run forward from the costal tubercle to the margin of the rib cartilage. The external intercostals become membranous between the costal cartilages, each continuing forward to the septum as the *external intercostal membrane.* The external intercostal fibers run obliquely downward, passing laterally downward in their posterior portion and medially downward in their anterior portion.

The *internal intercostal muscles* extend obliquely forward and upward from the costal angle to the sternum. The last two internal intercostal muscles are often fused with the internal oblique muscle, showing no apparent boundary. In the intercostal space between the costal angle and vertebral column, each internal intercostal muscle is replaced by an *internal intercostal membrane.*

Serratus Posterior Inferior

The serratus posterior inferior muscle arises from the superficial layer of the lumbodorsal fascia at the level of the lower two thoracic vertebrae and the upper two lumbar vertebrae (Fig. 1.5). It runs obliquely upward and laterally to attach by four slips to the inferior margins of the lower four ribs, somewhat lateral to their costal angles.

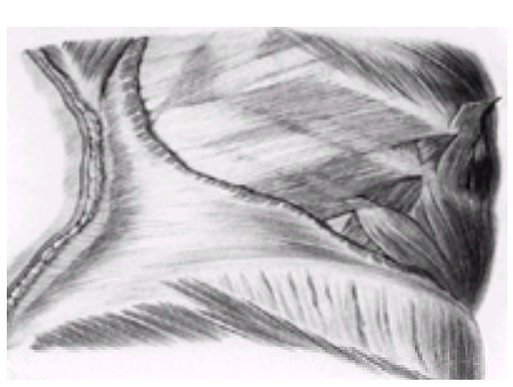

FIGURE 1.5. External view of the posterolateral abdominal wall, inferior portion. The latissimus dorsi has been removed to show the origins of the external oblique muscle.

Diaphragm

The diaphragm forms a musculotendinous partition between the abdominal and thoracic cavities (Fig. 1.6). Its central tendinous portion is termed the *central tendon,* and its muscular portion is divisible into a *sternal part,* a *costal part,* and a *lumbar part.*

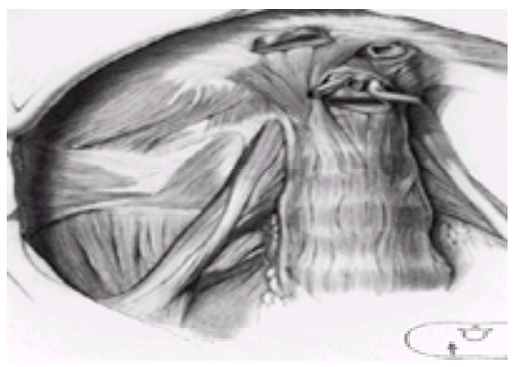

FIGURE 1.6. Internal view of the posterosuperior abdominal wall.

Lumbar Part

The lumbar part of the diaphragm arises by a *medial crus* and a *lateral crus.* A portion of the medial crus is sometimes split off to form an intermediate crus. The *right medial crus* arises from the anterior surfaces of the bodies of the first through fourth lumbar vertebrae; the *left medial crus* arises from the bodies of the first through third lumbar vertebrae. Both medial crura form the *aortic aperture* (aortic hiatus), which is bordered by the median arcuate ligament.

The *right medial crus* consists of three muscular bundles, the first arising from the lumbar vertebrae and merging directly with the central tendon. The second arises from the median arcuate ligament and forms the right border of the *esophageal aperture* (esophageal hiatus) of the diaphragm. The third muscular bundle, located posterior to the second, also originates from the median arcuate ligament and forms the left border of the esophageal aperture.

The *lateral crus* arises from the two tendinous arches of the medial and lateral arcuate ligaments. The medial arcuate ligament (medial lumbocostal arch or psoas arcade) extends from the lateral surface of the first (second) lumbar vertebral body to the first (second) costal process, passing over the origins of the psoas major muscle. The lateral arcuate ligament (lateral lumbocostal arch or quadratus arcade) extends from the costal process to the tip of the twelfth rib, passing over the quadratus lumborum muscle. The muscle fibers run steeply upward from both tendinous arches to the central tendon.

Costal Part

The costal part of the diaphragm arises from the inner surfaces of the cartilages of the lower six ribs, interdigitating with the transversus abdominis. The muscle fibers arch to their insertion at the anterolateral border of the central tendon.

Sternal Part

The sternal part, the smallest part, of the diaphragm arises by one or more small slips from the internal surface of the xiphoid process and from the posterior layer of the rectus sheath. The muscle fibers pass almost transversely to the anterior border of the central tendon.

Deep Abdominal Muscles

- Psoas major
- Quadratus lumborum

Psoas Major

The superficial part of the psoas major arises from the lateral surfaces of the twelfth thoracic vertebra and the first four lumbar vertebrae, and its deep part from the first through fifth costal processes. It unites with the fibers of the iliacus muscle and, enveloped by the iliac fascia, inserts into the lesser trochanter of the femur as the *iliopsoas muscle.*

The *psoas minor* is a variant present in fewer than 50% of individuals. It arises from the twelfth thoracic and first lumbar vertebrae and is attached to the iliac fascia and, via the fascia, to the iliopubic eminence.

Iliacus

The iliacus muscle arises from the iliac fossa and inserts conjointly with psoas major into the lesser trochanter of the femur. Their composite, the iliopsoas, passes through the *lacuna musculorum* (muscular compartment) beneath the inguinal ligament to reach the thigh.

Quadratus Lumborum

The quadratus lumborum is a flat muscle that lies adjacent to the vertebral column and stretches between the twelfth rib and iliac crest. It consists of two parts that cannot be completely separated from each other: a posterior part arising from the iliac crest and iliolumbar ligament and inserting into the costal processes of the first through third (or fourth) lumbar vertebrae and twelfth rib, and an anterior part passing from the costal processes of the lower three or four lumbar vertebrae to the last rib.

Pelvic Floor

The pelvic floor constitutes the posterior inferior boundary of the abdominal cavity (Fig. 1.7). It consists of the *pelvic diaphragm* and the *urogenital diaphragm.*

FIGURE 1.7. Internal view of the inferior abdominal wall (pelvic floor).

Pelvic Diaphragm

The pelvic diaphragm is composed of the *levator ani* and *coccygeus* muscles.

The *levator ani* muscle group consists of the puborectalis prerectal fibers, pubococcygeus, and iliococcygeus, which in some individuals are bounded superiorly by the sacrococcygeus and rectococcygeus muscles. The levator ani arises from the pubic bone lateral to the symphysis, from the tendinous arch of the levator ani (part of the obturator fascia), and from the ischial spine.

The most medial fibers of the puborectalis muscles form the *levator crura,* which bound the *levator hiatus* (genital hiatus). The prerectal fibers are attached to the perineum and separate the urogenital hiatus from the anal hiatus. The levator hiatus is traversed by the urethra in males and by the urethra and vagina in females. The rectum leaves the true pelvis behind the prerectal fibers. The pubococcygeus and iliococcygeus muscles are attached to the coccyx and anococcygeal ligament.

The *coccygeus* muscle passes from the ischial spine to the coccyx and completes the pelvic diaphragm posteriorly.

Striated Urethral Sphincter (Rhabdosphincter)

The rhabdosphincter and the transverse perineal ligament close the levator hiatus inferiorly. Contrary to standard descriptions, the muscle fibers of the rhabdosphincter are arranged in a loop-shaped fashion on the ventral and lateral aspects of the membranous urethra of the male and the caudal two-thirds of the female urethra. On gross anatomic and histologic examination, comparatively strong smooth muscular and connective tissue can be found dorsal to the membranous urethra (i.e., in the region of the perineal body). Both ends of the omega-shaped sphincter insert at the perineal body. The sphincter loop is continuous with muscle bundles that run along the anterior and lateral aspects of the prostate in the male and extend cranially to the bladder neck. Thus the rhabdosphincter of the urethra does not form a complete collar around the urethra. It should rather be described as a muscular coat ventral and lateral to the membranous urethra and the prostate of the male and the caudal two-thirds of the female urethra, the core of which is the omega-shaped loop around the urethra. Furthermore, the rhabdosphincter is separated from the ventral portions of the levator ani muscle by a sheet of connective tissue. Neither in anatomic dissections nor in serial histologic sections can any evidence of the classic muscular “urogenital diaphragm” be found. The transverse perineal ligament is traversed by the urethra and the rhabdosphincter.

RETROPERITONEAL SPACE

Anatomy

Definition, Boundaries, and Contents

The *retroperitoneal space* is the space between the posterior parietal peritoneum and the posterior abdominal wall. It is bounded superiorly by the diaphragm, and it blends inferiorly with the connective-tissue stratum of the subperitoneal space.

The lateral boundaries of the retroperitoneal space are imprecisely defined. They are essentially formed by the close apposition of the posterior parietal peritoneum to the transversalis fascia on the inner aspect of the lateral abdominal muscles, the thin subserous connective-tissue layer forming a virtual boundary in that region.

The contents of the retroperitoneal space can be described as having either a primary or a secondary retroperitoneal location. Portions of the duodenum, pancreas, and ascending and descending colon reach the retroperitoneum secondarily. Primary retroperitoneal structures are the kidneys and renal pelves, ureters, adrenal glands, and large nerves and vessels (Fig. 1.8).

FIGURE 1.8. Topography of the organs, vessels, and nerves of the retroperitoneal space and posterior abdominal wall.

Kidneys

Position. The kidneys are paired viscera that flank the vertebral column in the retroperitoneal space. Externally, the kidney presents a *medial border,* a *lateral border,* an *anterior surface,* a *posterior surface,* an *upper pole,* and a *lower pole.* The medial border presents a deep fissure, the *renal hilum,* which leads into the *renal sinus.* The upper pole of the kidney is more rounded than the lower pole because of its relation to the adrenal gland.

The terms of orientation for the kidney are somewhat imprecise because the organ is oriented at an angle to the cardinal planes. The anterior surface of the kidney is angled posterolaterally from the frontal plane, so the renal hilum normally is directed anteromedially. The long axes of both kidneys are convergent superiorly, so the upper poles of the kidneys are separated by a smaller distance (7 to 8 cm) than the lower poles (11 to 15 cm).

The level of the kidneys in relation to the vertebral column is subject to marked individual variations. Renal position also depends on individual body posture and the phases of respiration. Changes in renal position are more common and pronounced in children than in adults.

The right kidney in adults usually lies somewhat lower than the left kidney. The upper pole of the right kidney typically occupies a level between the body of the twelfth thoracic vertebra and the upper third of the first lumbar vertebra. The upper pole of the left kidney generally is higher than the right upper pole by half the height of a vertebral body. The lower pole of the right kidney usually is at the level of the third lumbar vertebra, and the lower pole of the left kidney occupies a correspondingly higher position (Fig. 1.9).

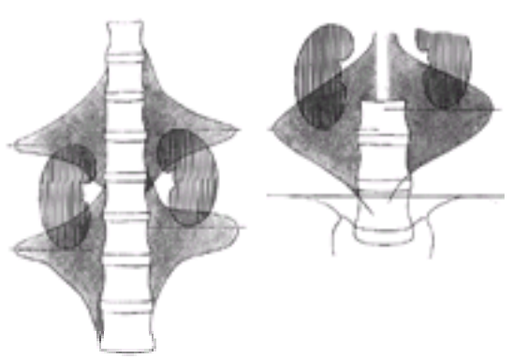

FIGURE 1.9. Range of variation in the levels of the renal poles. **A:** Position of the renal poles in relation to the lumbar spine. **B:** Position of the lower renal pole in relation to the iliac crest. The shaded areas indicate the range of variation.

The relation of the lower pole of the kidney to the highest point of the iliac crest is subject to the same individual variations. The right lower pole is approximately 3 cm above the iliac crest, on average, and the left lower pole is approximately 1 cm higher (Fig. 1.9).

Relations. The kidneys are embedded in the perirenal fat capsule, which is separated from the outer, pararenal fat by Gerota's fascia. The relations of the anterior surface of the kidney are shown in Fig. 1.10 and Fig. 1.11.

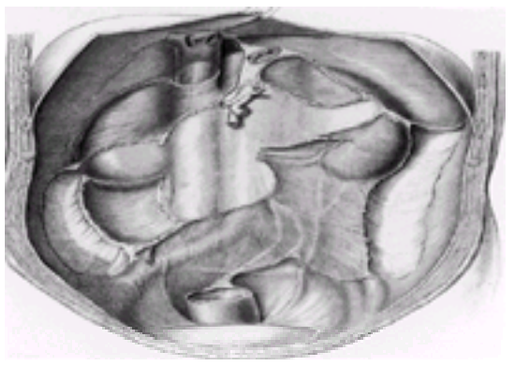

FIGURE 1.10. Relation of the kidneys to the parietal peritoneum and mesenteric roots.

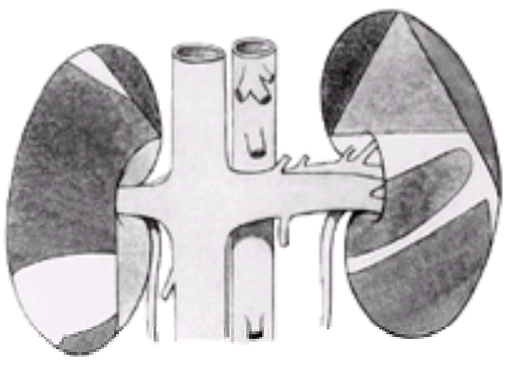

FIGURE 1.11. Contact areas of the kidneys, anterior aspect.

The posterior relations of the kidney are virtually identical on the right and left sides (Fig. 1.12). The cranial half of the posterior renal surface is in contact with the diaphragm. Their area of contact depends on the renal level and therefore is usually greater on the left side than on the right. The kidney apposes to the lateral crus of the lumbar part of the diaphragm. Between the lumbar and costal parts of the diaphragm is a variable amuscular interval, the lumbocostal trigone, which constitutes a site of least resistance. In this area, only the thin diaphragmatic fasciae separate the kidney and its fat capsule from the pleural cavity.

FIGURE 1.12. Posterior relations of the right kidney.

The caudal half of the posterior surface of the kidney is related to the quadratus lumborum muscle and the deep lumbodorsal fascia. The subcostal, iliohypogastric, and ilioinguinal nerves descend obliquely in a medial-to-lateral direction between the kidney and posterior abdominal wall.

The posterior part of the medial border of the kidney lies on the psoas major muscle. With a normal renal position, the twelfth rib passes obliquely downward and laterally to cross the upper third of the posterior renal surface. Between the twelfth rib and kidney are the diaphragm and the costodiaphragmatic recess of the pleural cavity. Attention must be given to the inferior reflection of the pleura in retroperitoneal approaches to the kidney that include a rib resection.

Capsules. Each kidney is enveloped by three capsules (Fig. 1.13): the fibrous capsule (capsule proper), the perirenal fat capsule, and Gerota's fascia (renal fascia, Gerota's capsule). The innermost *fibrous capsule* closely invests the renal parenchyma and is easily separated from the healthy kidney.

FIGURE 1.13. The transverse section through the abdomen at the level of the first lumbar vertebra (L1).

Surrounding the fibrous capsule is the *perirenal fat capsule,* which develops postnatally and is fully developed by puberty. The perirenal fat is connected to the inner fibrous capsule and the outer Gerota's fascia by loose connective tissue, which creates a mobile plane. The fat capsule is less well developed on the anterior surface of the kidney than posteriorly, and it envelops the kidney and adrenal gland. Composed of structural fat, the perirenal fat capsule has the primary function of keeping the kidney in place.

The outermost renal covering is *Gerota's fascia,* which forms a “sac” enclosing the kidney, adrenal gland, and perirenal fat capsule. Gerota's fascia is functionally and structurally distinct from the fascia that envelops the muscles and is more like the connective-tissue fascia that invests the organs in the true pelvis.

Gerota's fascia consists of two layers commonly termed the *prerenal (anterior)* and *retrorenal (posterior) fascia.* The fascial layers are fused approximately two fingerwidths lateral to the lateral renal border and above the adrenal gland. Gerota's fascia is also attached superiorly to the fascia of the diaphragm. The two layers of Gerota's fascia are separated below the kidney to allow passage of the ureter and blood vessels. The prerenal and retrorenal layers fuse medially with the connective tissue surrounding the major blood vessels and nerves of the retroperitoneal space. The retrorenal fascia is firmly adherent to the muscular fascia of the posterior abdominal wall.

Lateral to the saclike Gerota's fascia is the *pararenal fat,* which differs from the perirenal fat capsule in that it is not composed of structural fat, so its volume is subject to marked individual and nutrition-dependent variations.

Renal Vessels

Arteries. Normally, each kidney receives its blood supply from a single renal artery. Both renal arteries spring from the lateral aspect of the abdominal aorta, the right artery usually arising at a slightly lower level than the left. The origin of the renal arteries is usually situated below that of the superior mesenteric artery, between the inferior third of the first lumbar vertebra and the middle third of the second lumbar vertebra.

The right renal artery runs obliquely downward and laterally to the hilum of the kidney, passing behind the inferior vena cava. The accompanying renal vein is usually anterior to and above the artery, but in approximately 30% of cases, the artery is in front of the vein (Fig. 1.15). Anterior to the right renal hilum and vessels is the descending portion of the duodenum.

FIGURE 1.15. Typical patterns of aberrant and accessory renal arteries.

The left renal artery is shorter than the right and usually passes to the renal hilum above and partially behind the left renal vein. The hilum and renal vessels are covered anteriorly by the body of the pancreas and the splenic vessels.

The renal arteries divide at a variable distance from the hilum into two (57%) or three (43%) main branches (anterior, posterior, and inferior) that supply corresponding portions of the renal parenchyma. The branching of the renal arteries does not follow any consistent pattern in terms of right–left or gender distribution.

Variations in the number, course, and origin of the renal artery are common. In approximately 40% of cases, the kidney is found to have an atypical arterial supply. The presence of accessory or aberrant renal arteries is especially common. An “accessory” artery is a supernumerary artery that supplies the kidney as a separate vessel; “aberrant” arteries enter the renal parenchyma outside the hilum, generally at the upper or lower pole. Thus an accessory artery may or may not be aberrant. An aberrant artery may arise from the renal artery itself. Possible variations of the renal arteries are illustrated in Fig. 1.14, Fig. 1.15, Fig. 1.16 and Fig. 1.17.

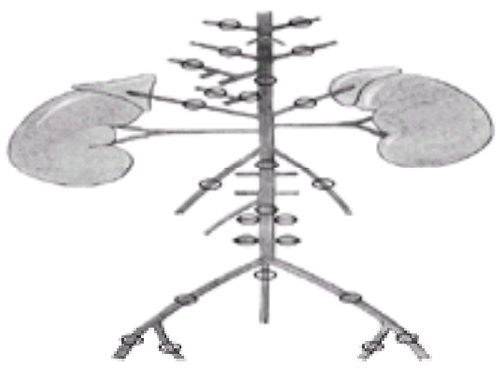

FIGURE 1.14. Schematic diagram of the abdominal aorta and kidneys. *Circles* indicate the potential origins of accessory (or aberrant) renal arteries.

FIGURE 1.16. Typical patterns of aberrant and accessory renal arteries.

FIGURE 1.17. Typical patterns of aberrant and accessory renal arteries.

Veins. The renal veins are interconnected by numerous anastomoses in the renal parenchyma and renal sinus, a pattern consistent with the general tendency for the venous system to form plexuses. The trunk of the renal vein is usually formed in the hilum by the convergence of two (53%) or three (34%) main tributaries that pass in front of the renal pelvis. A small tributary passing behind the renal pelvis occurs in approximately one-third of patients.

Outside the renal sinus, the veins usually are anterior to the renal arteries. The left renal vein commonly opens into the inferior vena cava at a higher level than the right renal vein. With a normally positioned inferior vena cava, the left renal vein is substantially longer (6 to 11 cm) than the right (2 to 4 cm). The right renal vein runs a straight, direct course from the hilum to the inferior vena cava; the left vein runs medially forward and passes in front of the aorta, just below the origin of the superior mesenteric artery, before entering the inferior vena cava. Phylogenetically, the left renal vein originates as part of the cardinal venous system and

consequently receives the left suprarenal and testicular (or ovarian) veins.

Lymphatics

The intrarenal lymph vessels of the kidney accompany the arteries to the renal sinus and present in the hilum as prevascular, retrovascular, and intervascular bundles. Regional lymph nodes encountered on the right side are the right lumbar (postcaval) lymph nodes and the intermediate nodes and rarely the preaortic nodes. The renal lymphatics on the left side drain into the left lumbar lymph nodes (lateral aortic and preaortic nodes) (Fig. 1.18).

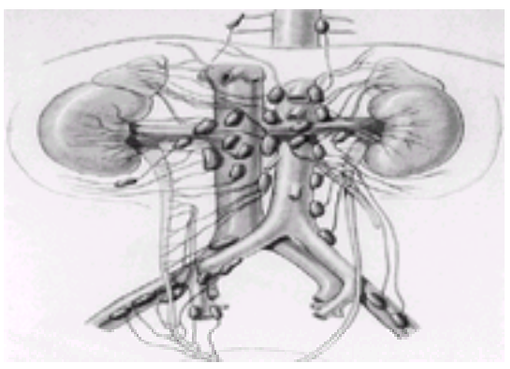

FIGURE 1.18. Lymph nodes and lymphatic vessels of the retroperitoneal space.

The lymph vessels draining the renal capsules pass to the lumbar lymph nodes separately from the lymph vessels of the renal parenchyma. A few lymph vessels from the renal capsule pass through the diaphragm and end in the intercostal nodes. Anastomoses have been described between the lymph vessels of the renal capsules and those of the liver, colon, cecum, and uterine tube.

Renal Nerve Supply

The kidneys derive their nerve supply from the renal plexus, which is formed by sympathetic and parasympathetic fibers from the celiac plexus and abdominal aortic plexus, as well as direct fibers from the sympathetic trunk (lumbar part). The renal plexus accompanies the renal arteries to the hilum. Autonomic nerve fibers can be identified along the arteries as far as the efferent vessels of the renal glomeruli.

Renal Pelvis

The *renal pelvis* is a hollow muscular organ that forms the initial segment of the excretory portion of the urinary tract. The tension of the muscular wall of the renal pelvis varies with its momentary functional state, so the shape of the renal pelvis also varies.

The renal pelvis begins with 7 to 13 *minor calices* at the renal papillae. The minor calices generally unite to form two or three *major calices* that make up the true renal pelvis (dendritic type). In some cases, all of the minor calices may open directly into the renal pelvis, which then exhibits an ampulelike dilation (ampullary type of pelvis). Forms intermediate between these extremes are common. At the time of operation, the renal pelvis is easily accessible at the hilum through a posterior approach, except for the rare cases in which all of the pelvis is contained within the renal sinus. The only structures that cross the posterior aspect of the renal pelvis are the main posterior branch of the renal artery and the variable posterior branch of the renal vein.

The renal pelvis derives its arterial supply (Fig. 1.8) from one or more branches of the renal artery and is drained by the renal vein. Lymphatic drainage (Fig. 1.18) is to the lumbar lymph nodes. The nerves of the renal pelvis are derived from the renal plexus.

Ureter

The renal pelvis becomes continuous with the ureter below the hilum, with no distinct ureteropelvic boundary. Their junction is at the level of the second or third lumbar vertebra.

The ureter is considered to consist of an *abdominal (proximal) part* and a *pelvic distal part* whose junction occurs at the point where the ureter is crossed by the iliac vessels.

The *abdominal (proximal) part* of the ureter passes downward and slightly medially from the renal pelvis on the fascia of the psoas major, encased within a sheath of fibrofatty tissue. The lateral distance of the ureter from the costal processes of the lumbar vertebrae is variable. In infancy, the proximal part of the ureter is tortuous and may even exhibit proximal kinks that disappear by approximately 1 year of age.

The topographic relations of the ureters to anterior structures are different on the right and left sides because of the asymmetric development of the abdominal viscera. At its origin, the *right ureter* is overlapped by the descending part of the duodenum. In its descent, it is crossed anteriorly by the right colic artery and ileocolic artery, which pass below the secondary parietal peritoneum (originally the ascending mesocolon) to the cecum and ascending colon. The right ureter passes below the testicular or ovarian vessels in its retroperitoneal course. Just before entering the true pelvis, the right ureter is crossed by the root of the mesentery, giving it an indirect relation to the terminal segment of the ileum. A mobile cecum and a transversely oriented appendix also may relate anteriorly to the right ureter.

The initial part of the *left ureter* descends lateral and posterior to the superior duodenal fold, which conveys the inferior mesenteric vein to the splenic vein. As it descends further, the left ureter is crossed by the branches of the inferior mesenteric artery (left colic artery and sigmoid arteries), which lie below the secondary parietal peritoneum (originally the descending mesocolon). The left ureter, like the right, is crossed at varying levels by the testicular or ovarian vessels. Just before entering the true pelvis, the left ureter is crossed by the attachment of the sigmoid mesocolon and can be found at this level within the *intersigmoid recess.*

The right ureter is usually adherent to the peritoneum and must be separated from it during surgery. The left ureter has no firm attachments to the secondary parietal peritoneum, and only the portion in the intersigmoid recess is directly apposed to the peritoneum.

Vessels and Nerves of the Ureter. The connective tissue surrounding the ureter (the adventitia) is permeated by an *arterial anastomotic network* (Fig. 1.8) composed basically of longitudinal vessels interconnected by transverse anastomoses. This periureteral arterial plexus is supplied by all arteries that have a close topographic relation to the ureter. The proximal part of the ureter is consistently supplied by one or two ureteral branches from the renal artery, from the testicular or ovarian artery, and occasionally by direct branches from the abdominal aorta. At the junction of the abdominal and pelvic parts of the ureter, the plexus is supplied by branches of the iliac vessels (common iliac, external or internal iliac).

In surgical procedures on the kidney or renal pelvis, care must be taken not to injure the ureteral branches of the renal artery. These branches provide the essential blood supply to the proximal part of the ureter, and their caliber and connections with the periureteral plexus give them the capacity to supply the entire proximal part of the ureter.

Vascular plexuses in the muscular and submucous coats of the ureter receive blood from the adventitial plexus and contribute to the ureteral blood supply.

The *veins* draining the proximal part of the ureter essentially follow the course of the arteries. The venous drainage is directed toward the renal veins and the testicular or ovarian veins.

The *lymph vessels* draining the proximal part of the ureter (Fig. 1.18) start at networks of lymph capillaries in the muscular wall and adventitia. They pass from the proximal ureter to the lumbar lymph nodes, on the right side draining into the lateral caval and precaval nodes and on the left into the lateral aortic and preaortic nodes. Lymphatics draining the lower portion of the proximal ureter are distributed to the common iliac nodes. Connections generally are present between these two drainage pathways.

The abdominal part of the ureter derives its *nerve supply* from the renal plexus superiorly and from the abdominal aortic plexus inferiorly. The adventitia of the ureter contains a dense network of nerve fibers that receive branches from the plexus surrounding the testicular or ovarian artery.

Adrenal Gland

The paired adrenal glands (Fig. 1.8) are set on the upper pole and anteromedial surface of the corresponding kidney. They are surrounded by the perirenal fat capsule and Gerota's fascia. Because of the close relation of the adrenal gland to the kidney and the confining renal fascial sac, adrenal tumors can produce a distortion of the renal outline.

The right adrenal gland has the approximate shape of a pyramid whose base rests on the upper pole of the right kidney. The left adrenal gland is semilunar in shape and apposes to the upper part of the medial border of the left kidney. It usually extends to the renal hilum and is in contact with the renal vessels.

The posterior surface of the *right adrenal gland* is in contact with the diaphragm, and its inferior surface is related to the kidney. The anterosuperior surface of the gland is related to the bare area of the liver. Its anterior surface is behind the inferior vena cava medially, and the inferior part of its anterior surface is covered by parietal peritoneum.

The *left adrenal gland,* like the right, is only partially covered by peritoneum, which invests the upper half of its anterior surface. Thus part of the gland projects into the omental bursa and may relate topographically to the abdominal part of the esophagus. The anteroinferior surface of the left adrenal gland is in contact with the body of the pancreas and the splenic vessels. The lateral part of the posterior surface of the gland apposes to the kidney, and the medial part is in contact with the left crus of the diaphragm.

Vessels and Nerves of the Adrenal Gland. Normally, at least three arteries contribute to the *arterial blood supply* of the adrenal gland (Fig. 1.8). These arteries are the superior, middle, and inferior suprarenal arteries, which arise from the inferior phrenic artery, abdominal aorta, and renal artery, respectively.

The superior suprarenal artery normally does not supply the gland as a single vessel (Fig. 1.8) but divides into 3 to 30 branches before entering the gland. Multiple superior suprarenal arteries also may occur. The middle suprarenal artery arises from the abdominal aorta at a variable level but always above the renal artery. The vessel may be absent or multiple (Fig. 1.8). The inferior suprarenal artery enters the undersurface of the adrenal gland by several branches that may arise separately from the renal artery or from accessory or aberrant vessels.

The *venous drainage* of the adrenal gland is generally handled by a single vessel, the suprarenal vein, which leaves the glandular tissue at the anterior surface of the adrenal gland. The right suprarenal vein takes a short, direct, transverse course to the inferior vena cava. The left suprarenal vein passes over the inferior part of the anterior surface of the gland and terminates at the left renal vein.

The *lymph vessels* (Fig. 1.18) from the adrenal cortex accompany the inferior phrenic and middle suprarenal arteries, and those from the adrenal medulla accompany the suprarenal vein. They terminate at the lumbar lymph nodes.

The *nerves* enter the posterior and medial aspects of the adrenal gland. The parasympathetic and sympathetic nerve fibers that form the *adrenal plexus* originate from the celiac plexus and the splanchnic nerves. Direct fibers from the sympathetic trunk can contribute to the formation of the adrenal plexus.

Major Vessels and Nerves of the Retroperitoneal Space

Abdominal Aorta. The descending aorta enters the retroperitoneal space through the aortic aperture in the diaphragm (Fig. 1.8). The thoracic duct traverses the aperture behind the aorta, and the aorta is occasionally accompanied by a splanchnic nerve.

The aorta usually enters the abdominal cavity on the median plane but deviates toward the left side as it descends further, apposed to the upper four lumbar vertebrae and intervertebral discs. It ends at the level of the fourth lumbar vertebra by dividing into its terminal branches—the common iliac arteries and the median sacral artery.

The inferior vena cava ascends to the right and slightly in front of the aorta. The left lumbar veins course between the vertebral column and aorta in a space that also contains the postaortic lymph nodes. The abdominal aorta is covered anteriorly by the autonomic aortic plexus (celiac, superior and inferior mesenteric) with corresponding ganglia and by the preaortic lymph nodes. Directly lateral to the aorta are the lateral aortic lymph nodes.

As the abdominal aorta descends, it passes behind the body of the pancreas, the left renal vein, and the horizontal (inferior) portion of the duodenum. Below the mesenteric root, the abdominal aorta is easily accessible to a transperitoneal surgical approach.

The branches of the abdominal aorta may be paired or unpaired, and the branches in both groups can be classified as visceral or parietal.

The unpaired visceral branches are as follows:

1. The celiac trunk, arising within the aortic aperture at the level of the twelfth thoracic vertebra
2. The superior mesenteric artery, arising at the level of the first lumbar vertebra
3. The inferior mesenteric artery, arising at the level of the third lumbar vertebra

The paired visceral branches are as follows:

1. The middle suprarenal arteries, arising at the level of the first lumbar vertebra
2. The renal arteries, usually arising at the same level from the aorta just below the suprarenal arteries
3. The testicular or ovarian arteries, arising at a variable level from the anterolateral aspect of the abdominal aorta and usually at different levels on the right and left sides

The unpaired parietal branch of the abdominal aorta is one of its terminal branches, the median sacral artery.

The paired parietal branches are as follows:

1. The inferior phrenic arteries, arising in the aortic aperture as the first branch of the abdominal aorta
2. Four pairs of lumbar arteries, arising from the back of the aorta at the levels of the first through fourth lumbar vertebral bodies

Inferior Vena Cava. The inferior vena cava (Fig. 1.8) is formed by the union of the two common iliac veins approximately one fingerwidth below and to the right of the aortic bifurcation. The lower part of the inferior vena cava is overlapped anteriorly by the right common iliac artery and relates posteriorly to the body of the fifth lumbar vertebra.

The inferior vena cava ascends on the right side of the aorta and parallel to it until reaching the level of the lower pole of the right kidney, where it diverges slightly to the right from the abdominal aorta and travels in a groove on the posterior surface of the liver. The inferior vena cava enters the thoracic cavity through the vena cava foramen in the diaphragm (at the level of Th 10) and immediately opens into the right atrium of the heart. It is accompanied through the diaphragm by the right

phrenicoabdominal branch of the phrenic nerve.

The anterior surface of the inferior vena cava is covered in its lower portion by peritoneum (primary parietal peritoneum) up to the level of the mesenteric root. As it ascends, the inferior vena cava loses its peritoneal covering (secondary retroperitoneal structure) and is apposed to the duodenum and pancreas (Fig. 1.10). Ascending further in the posterior wall of the epiploic foramen, the vena cava is again covered with peritoneum and is adherent to the bare area of the liver in the groove for the inferior vena cava.

The inferior vena cava has both parietal and visceral tributaries. The parietal tributaries are as follows:

1. The common iliac veins
2. The median sacral vein, which follows the course of the homonymous artery and may empty into the left common iliac vein
3. The lumbar veins, whose arrangement corresponds to that of the homonymous arteries
4. The inferior phrenic veins, which enter the inferior vena cava just before it pierces the diaphragm

The visceral tributaries are as follows:

1. The right testicular or ovarian vein, which opens into the inferior vena cava just below the termination of the right renal vein
2. The renal veins (discussed in connection with the kidney)
3. The right suprarenal vein
4. The hepatic veins, usually three in number, which generally enter the inferior vena cava in their course through the hepatic groove for the inferior vena cava

Variations of the inferior vena cava are common and usually result from developmental anomalies (Fig. 1.19). The retroperitoneal venous system develops from three paired, longitudinally oriented parallel channels: the caudal cardinal vein, supracardinal vein, and subcardinal vein, which are continuous caudally with the sacrocardinal vein. Further differentiation of the venous system is characterized by a progressive asymmetry in favor of the right side, with anastomoses between the right and left cardinal veins assuming key importance.

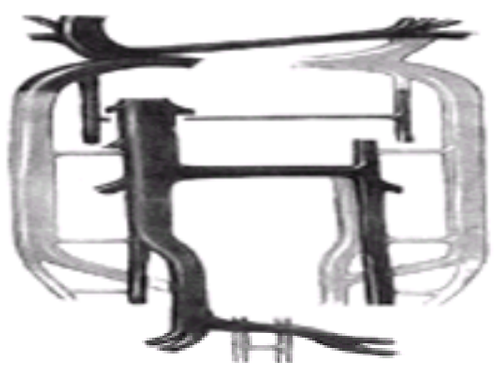

FIGURE 1.19. Development of the vena caval system. Vessels that do not persist are colored light gray.

The development of the vena caval system is shown in Fig. 1.19. It can be seen that the caudal cardinal veins largely disappear, whereas the supracardinal veins persist in part as the azygos and hemiazygos veins. Simply stated, the subcardinal veins develop into the inferior vena cava on the right side and into the suprarenal and testicular or ovarian veins on the left side.

Embryonic development of the inferior vena cava may be disrupted, arrested, or misdirected at any stage by extrinsic or intrinsic factors that are not yet fully understood. Each primarily formed cardinal vein (except for the lower portion of the caudal cardinal vein) may persist wholly or in part during definitive development, giving rise to such variants as a *double inferior vena cava* (2.2%) or *left inferior vena cava* (0.2%). All abnormal configurations of the inferior vena caval system are based on the persistence or anomalous involution of embryonic vascular channels.

Lymph Vessels. The *lymph vessels* and regional lymph nodes of the retroperitoneal space are discussed earlier in this chapter in connection with specific organs. The *thoracic duct* and its tributaries are discussed here.

The thoracic duct begins at the upper end of the cisterna chyli in the retroperitoneal space. The cisterna receives the lumbar and intestinal lymphatic trunks and is situated in front of the first and second lumbar vertebral bodies, behind and to the right of the abdominal aorta. The normally positioned cisterna chyli is found between the aorta and inferior vena cava, just below the left renal vein. After a short intraabdominal course, the thoracic duct enters the thorax through the aortic aperture, passing behind the aorta, and ascends through the posterior mediastinum.

Nerves. The large *nerve trunks* in the retroperitoneal space are derived mainly from the abdominal portion of the autonomic nervous system.

The anterior and posterior vagal nerve trunks enter the abdominal cavity through the esophageal aperture of the diaphragm. Only the posterior vagal trunk reaches the retroperitoneal space primarily, the bulk of its fibers passing between the left adrenal gland and the left medial crus of the diaphragm to the celiac ganglion.

Two nerves belonging to the sympathetic nervous system, the greater and lesser splanchnic, enter the retroperitoneal space through an aperture in the medial crus of the diaphragm. The greater splanchnic nerve runs between the medial crus of the diaphragm and the adrenal gland to the celiac ganglion. The fibers of the lesser splanchnic nerve terminate partly in the ganglion and may have direct connections with the renal plexus.

The two sympathetic trunks enter the retroperitoneal space after passing between the medial and lateral crura of the diaphragm. Both trunks lie on the psoas major muscles near their origin from the vertebral bodies. The left sympathetic trunk lies slightly behind and to the left of the abdominal aorta, and the right sympathetic trunk is posterior to the inferior vena cava. Connections between the right and left sympathetic trunks are generally present and course between the lumbar vertebral bodies and the aorta or inferior vena cava (Fig. 1.20).

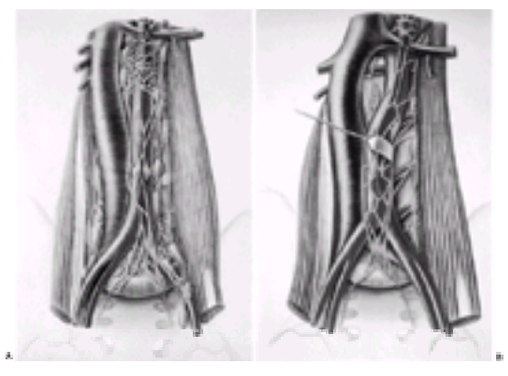

FIGURE 1.20. A: Right sympathetic trunk is situated dorsal to inferior vena caval vein, while left trunk is dorsal and lateral to abdominal aorta. **B:** L-3 ganglion is seen clearly on the left side because abdominal aorta is retracted medially.

The sympathetic trunks and their ganglia send branches (the lumbar splanchnic nerves) to the preaortic plexuses and their ganglia. The lumbar portion of the sympathetic trunk blends smoothly with the sacral portion at the arcuate line.

Application of Surgical Approaches

Supracostal Approach

The supracostal approach affords broad exposure of the retroperitoneal space (kidney, adrenal gland, proximal ureter) while avoiding the need for rib resection. Several anatomic circumstances make this approach possible: The eleventh and twelfth ribs terminate freely in abdominal muscle, both ribs articulate only with the corresponding vertebral body, and the twelfth rib is easily displaced downward following release of the muscles that insert on the twelfth rib or arise from it.

Exposure of the Lumbodorsal Fascia

After division of the subcutaneous fat, the thoracic fascia is divided, exposing the latissimus dorsi and external oblique muscles (Fig. 1.21).

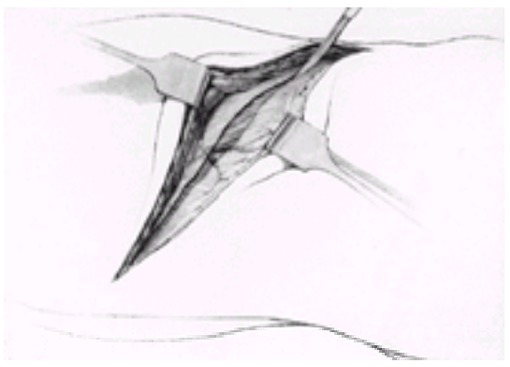

FIGURE 1.21. Exposure of the latissimus dorsi and external oblique muscles.

Incision of the Lumbodorsal Fascia

The lumbodorsal fascia is incised at the tip of the twelfth rib, exposing the pararenal fat between the lumbodorsal fascia and Gerota's fascia. The lumbodorsal fascia can be opened over the fat by bluntly dissecting forward (Fig. 1.22).

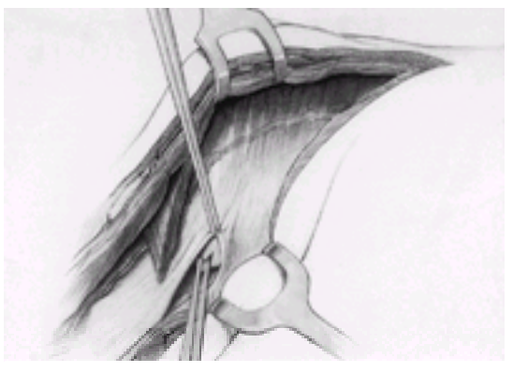

FIGURE 1.22. Incision of the lumbodorsal fascia.

As the twelfth rib is displaced downward and forward with a retractor, the lumbodorsal fascia is dissected from the inner periosteum of the rib (Fig. 1.23). This affords extrapleural entry to the thoracic cavity while sparing the intercostal nerves and vessels. The route of this approach is shown schematically in Fig. 1.24.

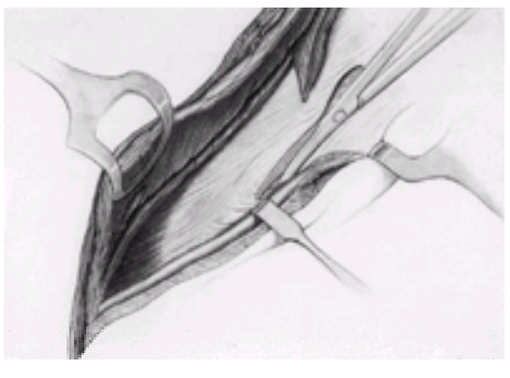

FIGURE 1.23. The thoracic cavity is opened extrapleurally, preserving the intercostal vessels and nerves.

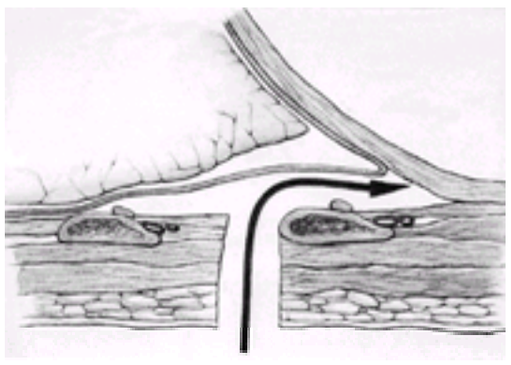

FIGURE 1.24. Schematic view of the dissection of the lumbodorsal fascia from the deep periosteum of the rib.

Dissection of the Lumbodorsal Fascia and Diaphragm from the Twelfth Rib

The lumbodorsal fascia and then the diaphragm are separated from the twelfth rib under vision, using the finger or a small sponge stick to guide the dissection. The incision at the twelfth rib can be carried over the quadratus lumborum muscle to the lateral arcuate ligament as part of the dissection, with the pleural cavity and lung remaining outside the operative field (Fig. 1.25).

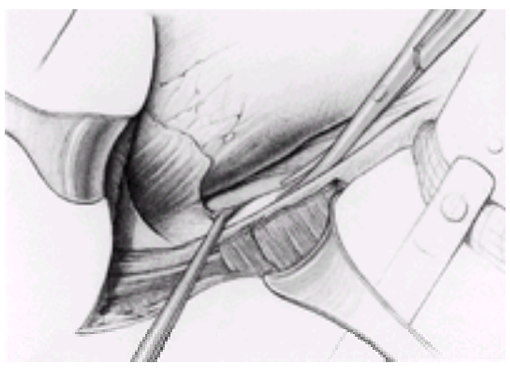

FIGURE 1.25. The pleural space and lung are outside the operative field. The quadratus lumborum muscle is visible below the lateral arcuate ligament.

Foley Muscle-splitting Approach

The Foley muscle-splitting approach gives access to the ureteropelvic junction and proximal ureter through a transfascial route.

Exposure of the Transversus Abdominis and Its Tendon of Origin

The latissimus dorsi and external oblique muscles are retracted, and a retractor is placed in the proximal part of the incision to expose the tendon of origin of the transversus abdominis and, anteriorly, the fibers of the internal oblique muscle (Fig. 1.26). The internal oblique is separated from the transversus abdominis along the line indicated and is retracted forward with a second retractor. The tendon of origin of the transversus abdominis is incised in the direction of its fibers (Fig. 1.27).

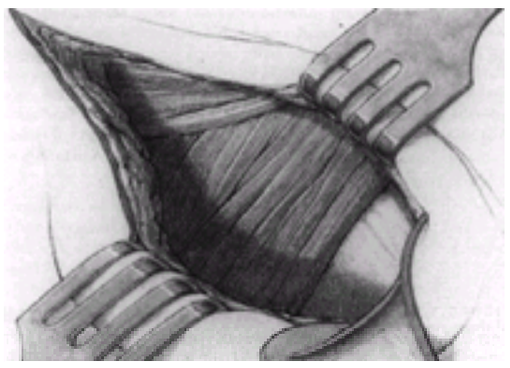

FIGURE 1.26. The internal oblique is separated from the transversus abdominis and its tendon of origin.

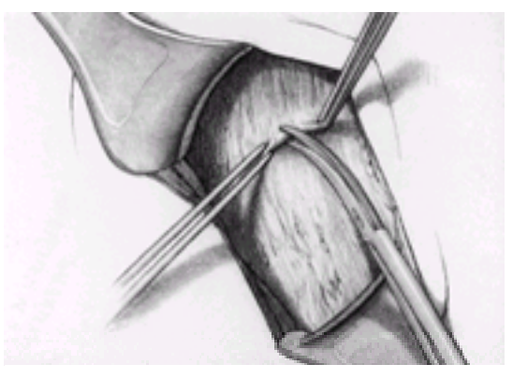

FIGURE 1.27. The transversus abdominis tendon of origin is incised, and the transversus muscle fibers are split.

Posterior Approach to the Adrenal Gland

The thoracic fascia is exposed. The latissimus dorsi and serratus anterior muscles are identified. Exposure is maintained with two retractors. The latissimus dorsi and serratus anterior are transected with a scalpel. The erector spinae muscle can be seen in the medial portion of the wound (Fig. 1.28).

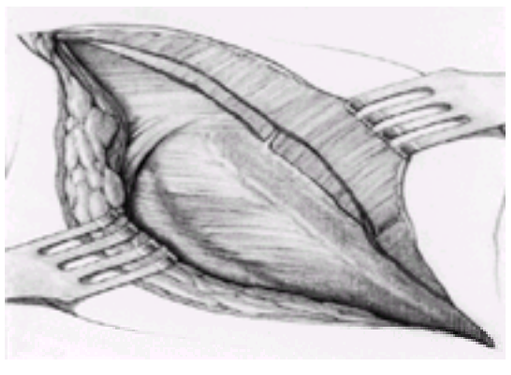

FIGURE 1.28. Exposure of the eleventh rib. The transected muscles are retracted.

The periosteum of the eleventh rib is divided with diathermy, and the rib is progressively isolated with a straight periosteal elevator and a curved stripper. The eleventh rib is resected as far medially as possible (Fig. 1.29).

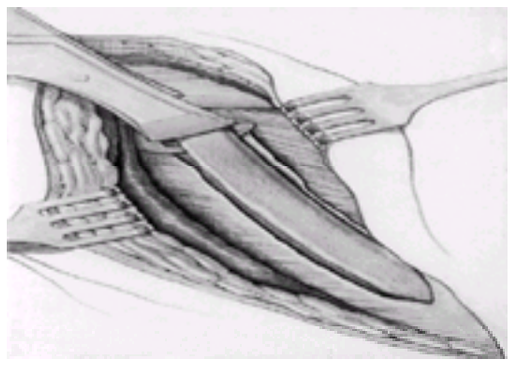

FIGURE 1.29. The eleventh rib is transected with rib shears.

Incision of the Rib Bed

The posterior rib bed is opened with a scissors, exposing the diaphragm. Care is taken to preserve the intercostal neurovascular bundle during incision of the rib bed.

With the aid of a wooden tissue protector or small sponge stick, the diaphragm is carefully divided with diathermy. The plane between the diaphragm and Gerota's fascia is carefully developed, and the diaphragm is incised anteriorly and posteriorly to establish entry into the retroperitoneal space. Gerota's fascia is identified (Fig. 1.30).

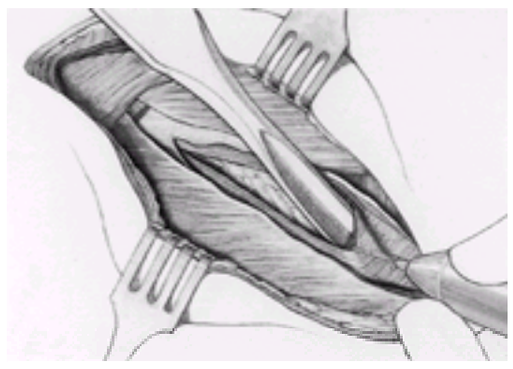

FIGURE 1.30. The diaphragm is divided with diathermy over a wooden tissue protector. Gerota's fascia is identified.

Thoracoabdominal Approach

The thoracoabdominal approach provides excellent exposure of the entire abdominal and retroperitoneal space. Because the intrathoracic portion of the inferior vena cava can also be exposed, this approach is useful for the removal of stage II and stage III tumor thrombi involving the vena cava. A modification, the primary thoracoretroperitoneal approach, is useful for lymph node dissection in patients with testicular tumors.

Laparotomy and Thoracotomy

Starting at the anterior axillary line, the latissimus dorsi, serratus anterior, and external oblique muscles are transected with diathermy in line with the skin incision. The external and intercostal muscles are visible on the chest wall. Starting at the costal arch, the incision is first extended inferomedially, dividing the fibers of the rectus muscle in the epigastrium. The rectus abdominis is then bluntly freed laterally while sparing the nerves and vessels; this technique prevents denervation of the rectus musculature. The superior epigastric vessels are ligated. The rectus muscle is retracted laterally to expose the posterior layer of the rectus sheath. Small retractors maintain exposure in both the abdominal and thoracic portions of the field (Fig. 1.31).

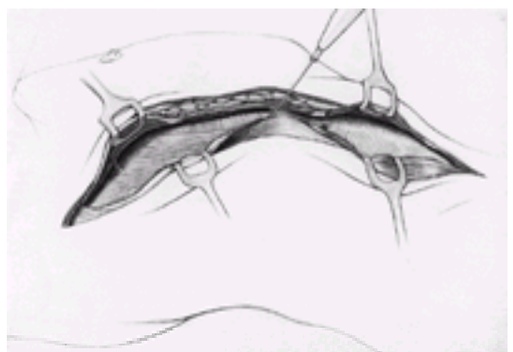

FIGURE 1.31. The serratus anterior and external oblique are transected, exposing the posterior rectus sheath.

In the abdominal part of the incision, the posterior rectus sheath is picked up with forceps on both sides along with the transversus abdominis fibers and peritoneum, and all three layers are transected to establish entry into the peritoneal cavity. The greater omentum can be identified. The abdominal cavity is opened to the level of the umbilicus (Fig. 1.32).

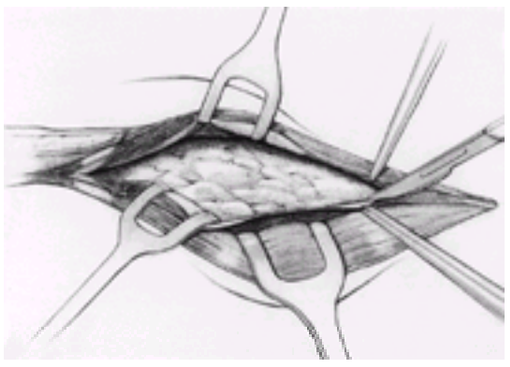

FIGURE 1.32. Entry into the abdominal cavity.

Division of the Costal Arch. Before the costal arch is divided, the plane defined by the transversus abdominis and diaphragm is exposed. Once this plane has been identified, the costal arch is undermined at the osteochondral junction and divided. With this maneuver, the underlying intercostal arteries and veins can be dealt with under direct vision.

This dissection of the transversus abdominis and diaphragm is important in the primary thoracoretroperitoneal approach. In this modification, which avoids primary entry into the abdominal cavity, the approach is begun inferomedial to the costal arch and the peritoneum is retracted medially (Fig. 1.33).

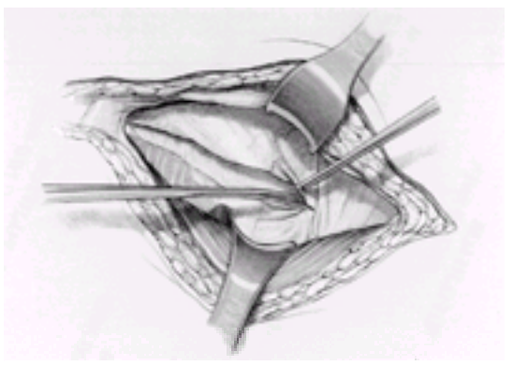

FIGURE 1.33. Primary thoracoretroperitoneal approach.

Division of the Diaphragm. The transversus abdominis fibers are divided close to the costal arch, followed by incision of the diaphragm. The diaphragm is incised as far laterally as possible to preserve the phrenic nerve branches (Fig. 1.34).

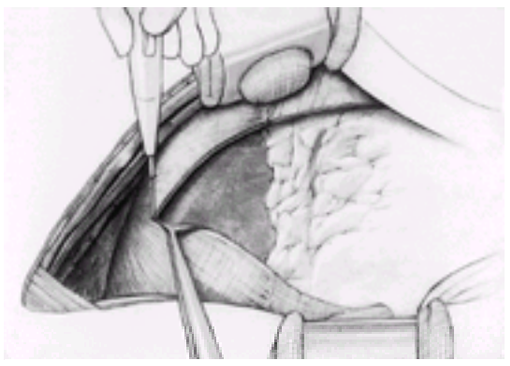

FIGURE 1.34. Division of the diaphragm.

Modification of the Thoracoabdominal Approach for a Stage II or III Tumor Thrombus in the Vena Cava. After the abdominal cavity and chest have been opened, the incision in the mesocolon is carried along the colon and is continued along the mesentery to the duodenojejunal flexure. This line of incision permits a general mobilization of the large and small bowels, establishing access to a broad area of the retroperitoneal space. The left renal vein can be identified over the aorta and elevated to expose the superior mesenteric artery. The right renal artery is identified in the aortocaval space.

The peritoneum is dissected off the diaphragm. The right triangular ligament is incised at its attachment to the diaphragm so that the right lobe of the liver can be mobilized and deflected medially upward, exposing the hepatic veins. In this way, the entire retroperitoneal course of the vena cava can be visualized (Fig. 1.35) together with the right adrenal gland and suprarenal vein.

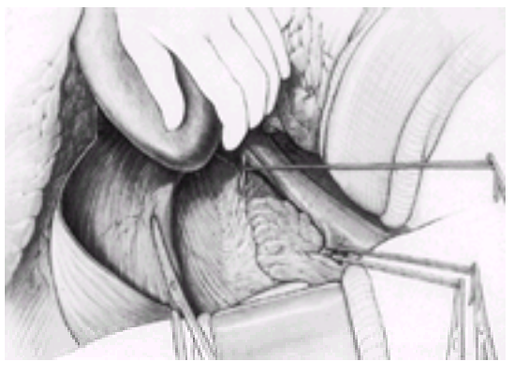

FIGURE 1.35. The right triangular ligament is sharply released from the diaphragm. The right adrenal gland and suprarenal vein are seen.

Use of the fifth interspace approach also permits exposure of the intrathoracic portion of the inferior vena cava. The parietal layer of the pericardium is incised above the diaphragm. After stay sutures are preplaced on both sides, the intrathoracic part of the vena cava can be freed and encircled with a tourniquet snare (Fig. 1.36).

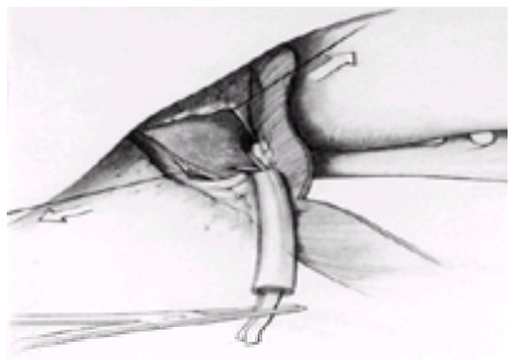

FIGURE 1.36. Exposure of the intrathoracic portion of the inferior vena cava.

Approach to the Retrocrural Lymph Nodes

Most positive suprahilar nodes are found in the retrocrural zone. The usual path of lymph flow from the retroperitoneum into the chest is periaortic and posterior (Fig 1.37 and Fig. 1.38). The lymphatic pathways traverse the diaphragm via the aortic hiatus. They first drain into the cisterna chyli and then into the posterior mediastinal nodes.

FIGURE 1.37. Path of lymph flow to the suprahilar region and the chest.

FIGURE 1.38. Transverse section. Location of retrocrural nodes in relation to the diaphragm and the aorta (schema).

The thoracic duct begins at the upper end of the cisterna chyli in the retroperitoneal space. The cisterna receives the lumbar and intestinal lymphatic trunks and is situated in front of the first and second lumbar vertebral bodies, behind and to the right of the abdominal aorta.

Dissection of the Lateral Crus, Exposure of the Inferior Phrenic Artery

The descending colon is retracted medially with the isolated left colic flexure. The left inferior phrenic artery and vein are identified at the lateral crus, dissected, and ligated (Fig. 1.39). A middle suprarenal artery from the aorta is also ligated, and the adrenal gland is then freed from the lumbar part of the diaphragm and lateral crus and displaced inferolaterally (Fig. 1.40).

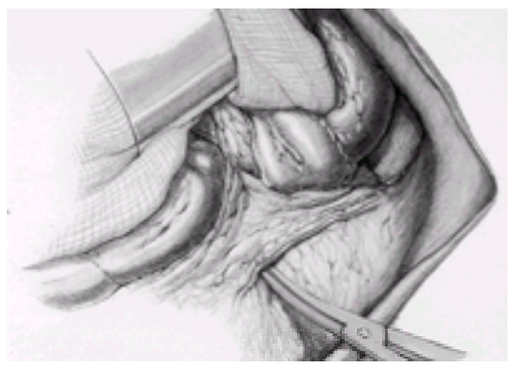

FIGURE 1.39. Exposure of the left inferior phrenic artery and vein.

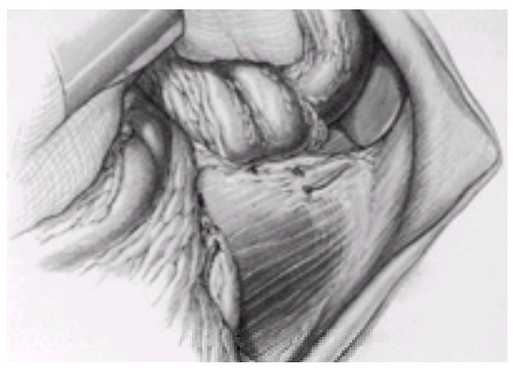

FIGURE 1.40. The left inferior phrenic artery and vein are ligated, and the lumbar part of the diaphragm is exposed.

Incision of the Aortic Aperture

After exposure of the abdominal aorta, the left renal artery is identified and dissected free. After ligation of the inferior phrenic artery, the aortic aperture is incised over the abdominal aorta, starting at the median arcuate ligament. If enlarged lymph nodes are found at the celiac trunk and superior mesenteric artery, both vessels must be dissected free (Fig. 1.41). The incision in the aortic aperture is carried to the esophageal hiatus. The inferior phrenic artery is again ligated close to the aorta (Fig. 1.42).

FIGURE 1.41. Dissection of the aorta and renal artery. The line of incision from the aortic hiatus to the esophagus is shown.

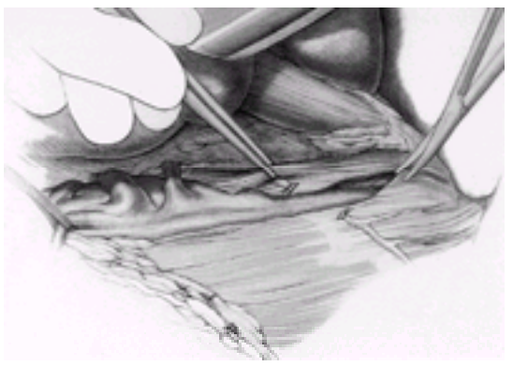

FIGURE 1.42. Incision over the abdominal aorta.

This approach provides exposure of the retroaortic space (Fig. 1.43). When the aorta is mobilized, attention must be given to the last two posterior intercostal arteries and first lumbar arteries at the lateral or posterior aspect of the vessel. These arteries may give origin to the great radicular artery (of Adamkiewicz), which contributes significantly to the blood supply of the spinal cord. Therefore segmental arteries must be preserved, especially on the left side of the body.

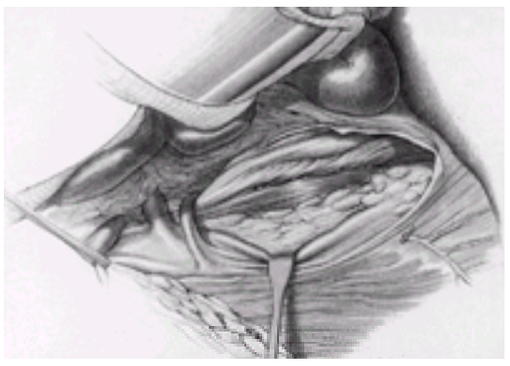

FIGURE 1.43. Exposure of the retroaortic and retrocrural spaces.

Anterior Subcostal Approach

Dissection of the Renal Vessels

For dissection of the renal vessels on the left side, the peritoneum is incised longitudinally between the aorta and inferior mesenteric vein, starting at the inferior duodenal fold (ligament of Treitz) (Fig. 1.44). This incision gives direct access to the vascular pedicle of the left kidney between the aorta and inferior mesenteric vein. The renal artery and vein can be dissected and snared (Fig. 1.45).

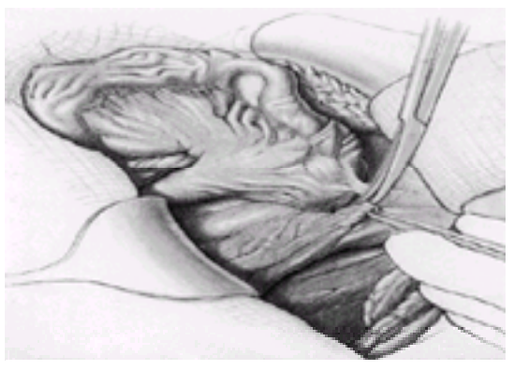

FIGURE 1.44. Incision of the inferior duodenal fold. The vascular pedicle of the kidney is approached between the aorta and inferior mesenteric vein.

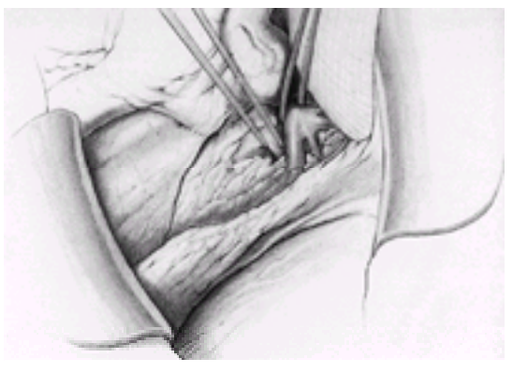

FIGURE 1.45. Exposure and isolation of the renal artery and vein.

Midline Transperitoneal Approach

Exposure of the Retroperitoneal Space

Starting at the inferior duodenojejunal fold, the retroperitoneal space is opened by incising distally along the root of the mesentery while the small bowel is packed away to the right side and the descending colon and left colic flexure are retracted to the left side (Fig. 1.46).

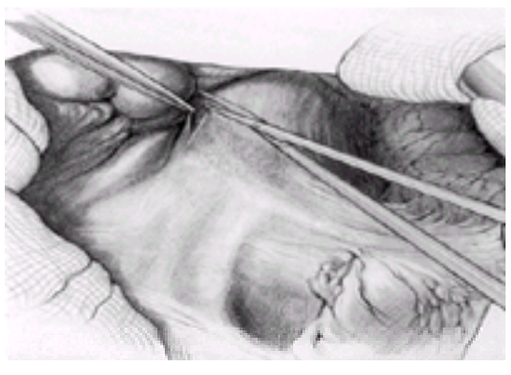

FIGURE 1.46. The retroperitoneal space is opened along the root of the mesentery, starting at the inferior duodenojejunal fold.

Next, the ascending part of the duodenum is dissected free along the line of the incision. For a suprahilar approach on the left side, the incision in the parietal peritoneum is extended farther upward and to the left so that the inferior mesenteric vein can be dissected and ligated (Fig. 1.47). This establishes broad access for the suprahilar lymph node dissection.

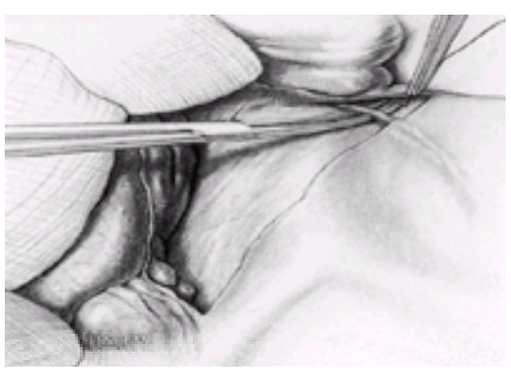

FIGURE 1.47. Left suprahilar approach. The inferior mesenteric vein is exposed and ligated.

The line of incision is now extended farther toward the right common iliac artery from the abdominal aorta so that the cecum can be dissected from the underlying retroperitoneal connective tissue (Fig. 1.48).

FIGURE 1.48. The incision is extended from the abdominal aorta over the right common iliac artery.

The incision is extended along the right paracolic sulcus and ended at the inferior border of the epiploic foramen (of Winslow) (Fig. 1.49). This provides access for dissecting the ascending colon and right colic flexure from Gerota's fascia.

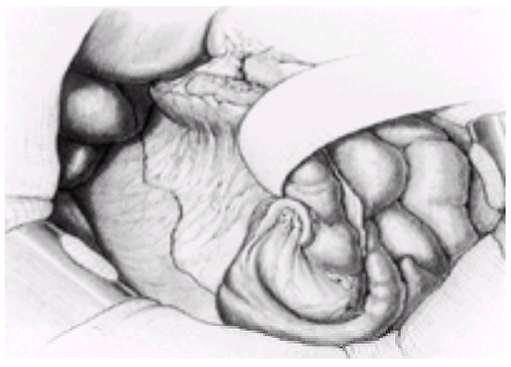

FIGURE 1.49. The incision in the right paracolic sulcus is extended to the inferior border of the epiploic foramen.

This extended incision (from the inferior duodenojejunal fold to the epiploic foramen) permits the entire small bowel, cecum, ascending colon, and right colic flexure to be mobilized (and if necessary exteriorized from the abdominal cavity). The abdominal aorta and inferior vena cava are visible below fibrous and fatty tissues, respectively, at the center of the retroperitoneal space (Fig. 1.50).

FIGURE 1.50. View of the incision from the ligament of Treitz to the inferior border of the epiploic foramen. The entire retroperitoneal space is visible.

Incision of the Retroperitoneal Fascia

The fibrous and fatty tissue overlying the center of the vena cava and abdominal aorta is now opened, and the lymph node dissection is carried out using a split-and-roll technique (Fig. 1.51).

FIGURE 1.51. Split-and-roll technique of retroperitoneal lymph node dissection.

Nerve-sparing Retroperitoneal Lymph Node Dissection

Seminal emission and ejaculation are primarily under sympathetic control. The efferent fibers originating from T-12 to L-3 travel to the superior and on to the inferior hypogastric plexus (or pelvic plexus). The pelvic plexus also includes parasympathetic fibers originating from the pelvic nerves.

The sympathetic trunk consists of a series of spindle-shaped ganglia interconnected by short interganglionic rami to form a continuous chain of ganglia (Fig. 1.20). This trunk extends along the spinal column on either side from the base of the skull to the tip of the coccyx. It is connected to the spinal cord via the rami communicantes, which may behave in a number of different manners. Often, there are branches that course not only to the corresponding ganglia of the sympathetic trunk but also to the adjoining ganglia. In the lumbar region, where the rami communicantes are relatively long, their course is particularly variable. They pass beyond the tendinous origins of the psoas major, and a variable number of ganglia can be found at different levels at the anterolateral aspects of the vertebral bodies medial to the psoas major. The right sympathetic trunk is situated dorsal to the inferior vena cava, and the left trunk is located dorsal and lateral to the abdominal aorta. The transverse rami connect the two sympathetic trunks. Only rarely are the two trunks arranged symmetrically in the lumbar region. Furthermore, fusions of ganglia occasionally are encountered. The lumbar splanchnic nerves are the continuation of postganglionic fibers of the lumbar ganglia. They travel to the large paraaortic nervous plexus and eventually reach the superior hypogastric plexus, a continuation of the abdominal aortic plexus, located on either side of the abdominal aorta between the origins of the superior and inferior mesenteric arteries.

The superior hypogastric plexus is situated ventral to the aortic bifurcation and extends across the common iliac vein in the direction of the promontory (Fig. 1.20). The right and left hypogastric nerves connect the superior hypogastric plexus with the inferior hypogastric plexus, which is on either side of the rectum in the lesser pelvis.

The afferent impulses triggering emission and ejaculation are conveyed via the pudendal nerve, whereas the efferent impulses inducing emission are transported to the target organs via the thoracolumbar sympathetic fibers (T-12 to L-3), the paravertebral ganglia, and the superior hypogastric plexus. The efferent impulses inducing ejaculation are conveyed via the parasympathetic fibers of the pelvic nerves (S-2 to S-3) and cause the bulbocavernous and ischiocavernous muscles to contract, which results in antegrade ejaculation.

The L-2 and L-3 ganglia are located close to each other; they may even fuse so that there is no interganglionic ramus. The lower margin of the L-3 ganglion is situated approximately one fingerwidth above the origin of the inferior mesenteric artery. If the abdominal aorta is displaced toward the median, the left L-3 ganglion is exposed medial to the psoas major on the lateral aspect of the L-3 vertebra. The right L-3 ganglion can be exposed by displacing the inferior vena cava toward the median (Fig. 1.20). The ganglion is located slightly ventral to the ventrolateral junction of the L-3 vertebral body. As mentioned, the two trunks are interconnected by the lumbar splanchnic nerves that arise from these ganglia.

Nerve-sparing Surgery

The aim of nerve-sparing surgery is to protect the sympathetic ganglia lying in the groove between the psoas muscle and the vertebral column. The sympathetic nerve fibers crossing over the distal aorta and its bifurcation must also be preserved (Fig. 1.52).

FIGURE 1.52. Nerve-sparing retroperitoneal dissection. Schematic drawing showing the sympathetic trunk, ganglia, and nerve fibers.

The sympathetic fibers can be identified with the help of magnifying lenses; the efferent fibers can be seen distally where they cross the common iliac artery. By reflecting the lymphatic tissue off the psoas muscle, the surgeon can identify the sympathetic trunk and trace the fibers distally from their origin at the sympathetic trunk. The sympathetic fibers are placed in vessel loops (Fig. 1.53). Subsequently, the lymphatic tissue is split over the aorta and rolled off.

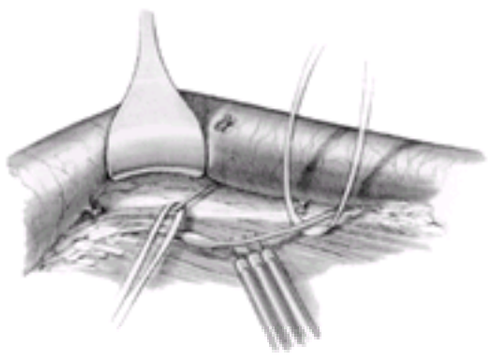

FIGURE 1.53. The nerve fibers to be spared are placed in vessel loops. Using an electric stimulator, ejaculation can be elicited intraoperatively.

The nerve-sparing technique can also be used in postchemotherapy surgery; however, in this type of elective surgery, patient selection is extremely important.

Suprahilar Node Dissection for High-stage Disease (Testicular Tumors)

Direct extension from an infrahilar tumor may project into the suprahilar zone; in this case, it is usually precrural and can be rolled down and away from the great vessels in the same way as tumors in the infrahilar region. Suprahilar disease can be managed by an anterior midline approach; the thoracoabdominal (thoracoretroperitoneal) approach should be used for tumors in the retrocrural zone.

In the anterior midline approach, the root of the small bowel mesentery is incised. The posterior attachments to the cecum and the mesocolon are dissected free using the plane of Toldt as an avascular field of dissection. After dissection of the duodenum and the head of the pancreas, the Kocher maneuver is performed.

On the right side, access to the suprahilar nodes is gained by an incision below the hepatoduodenal ligament, which is dissected free and placed in a vessel loop to expose the suprahilar portion of the vena cava (Fig. 1.54).

FIGURE 1.54. Exposure of the right suprahilar region; the hepatoduodenal ligament is placed in a vessel loop.

To gain access to the left suprahilar region, the left inferior mesenteric vein is ligated and divided, and the left colonic mesentery is incised and mobilized. The incision in the left mesocolon is made in an oblique manner, parallel to the inferior margin of the pancreas. After this maneuver, the lower vein of the pancreas can be fully mobilized and retracted from the anterior surface of Gerota's fascia (Fig. 1.55).

FIGURE 1.55. Anatomic approach to the suprahilar lymph node dissection, view from the right side.

The superior mesenteric artery is identified at the point where it crosses over the left renal vein (Fig. 1.55). Care must be taken to prevent excessive tension on this artery and to preclude injury to it by a retractor because it serves as a vascular pedicle for the small and large bowels. Therefore pads are placed on the pancreas and the pedicle of the superior mesenteric artery.

Dissection of the crura is started at the base of this pedicle and, on completion of the infrahilar node dissection, should be continued to the suprahilar region. The lymphatic connections between the infrahilar and suprahilar regions can be identified by elevating the renal vessels with malleable vein retractors.

PELVIS

Anatomy

Pelvic Part of the Ureter

The pelvic (distal) part of the ureter makes up approximately half of its total length. It follows basically the same course in males and females, but its relations are gender specific (Fig 1.56 and Fig. 1.57). The entrance of the ureter into the true pelvis is located anterior or slightly medial to the sacroiliac joint. There the ureter is related to the iliac vessels, crossing either the common iliac vessels or the external and internal iliac vessels, depending on the position of these vessels and the level of their bifurcation. Because of the left-sided position of the abdominal aorta, the right ureter typically crosses the iliac vessels below their point of bifurcation; the left ureter generally crosses the common iliac vessels (Fig 1.56 and Fig. 1.57).

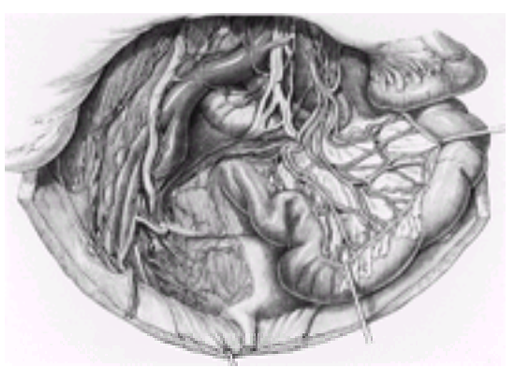

FIGURE 1.56. Pelvic dissection in a male. The peritoneum has been partially removed.

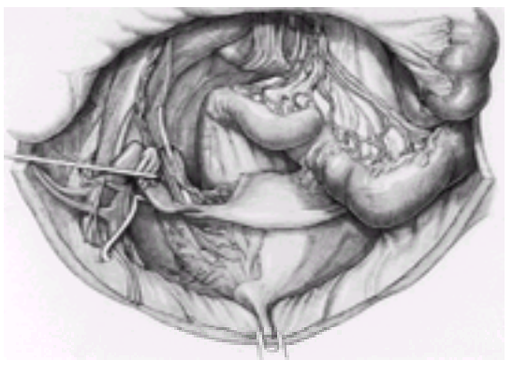

FIGURE 1.57. Pelvic dissection in a female. The peritoneum has been partially removed.

The first part of the pelvic portion of the ureter describes an anteriorly convex arch. It lies medial to the internal iliac artery and its branches, and it crosses the obturator nerve on the lateral pelvic wall just below the parietal peritoneum (Fig. 1.56). In the female, the ureter usually passes behind the ovary on the floor of the ovarian fossa (Fig. 1.57).

After crossing the pelvic vessels, the ureter diverges from the parietal peritoneum to enter the pararectal connective tissue (paraproctium). Just before or after this point, a sheet of connective tissue leaves the ureteral adventitia to establish a direct connection between the ureter and the rectal retinaculum.

After the ureter enters the pararectal connective tissue, its topographic relations display gender-specific differences.

In the male, the ureter passes through the pararectal connective tissue from behind forward, then turns slightly medially and closely approaches the tip of the seminal vesicle. There it crosses below the vas deferens. Surrounded by the veins of the vesical plexus, the ureter reaches and passes medially and obliquely through the bladder wall.

In the female, the ureter describes an inferiorly convex bend as it passes from the rectal retinaculum into the cardinal ligament (lateral cervical ligament). There it passes behind the uterine artery, which consistently gives off branches to the ureteral adventitia in this area. These branches travel in a thin sheet of connective tissue that is incorrectly termed the ventral *mesoureter* (Fig. 1.57).

Generally, the ureter runs approximately 1.5 to 2 cm lateral to the uterine cervix, although this distance can vary from 1 to 4 cm if the uterus occupies a paramedian position.

In its further course to the bladder, the female ureter is related to the fornix and anterior wall of the vagina. The left ureter generally is more extensively apposed to the front of the vagina than the right ureter, so it is more vulnerable to trauma in vaginal operations. In all discussions of ureteral relations, it should be kept in mind that a distended bladder or rectum can cause displacement and even tortuosity of the ureters.

Vessels and Nerves of the Pelvic Ureter

The *arteries* of the pelvic part of the ureter form a plexus in the ureteral adventitia that, in the initial part of the pelvic ureter, is supplied by ureteral branches of the iliac vessels. These may arise from the common iliac artery or from the internal or external iliac artery. Ureteral branches from the iliolumbar and superior gluteal arteries are less commonly observed.

As the ureter descends further, its adventitial arterial plexus receives blood from the superior vesical artery, the artery of the vas deferens or uterine artery, the vaginal

artery, and the inferior vesical artery. Branches from the middle rectal artery also may reach the connective-tissue sheath of the ureter (Fig 1.56 and Fig. 1.57).

The *veins* of the pelvic part of the ureter reach the veins accompanying the arteries either directly or by way of the venous plexuses of the pelvis (vesical, prostatic, uterine, and vaginal plexuses).

The *lymph vessels* of the pelvic ureter drain into the regional lymph nodes on the pelvic wall: the external iliac, internal iliac, interiliac, and common iliac nodes.

The *nerves* of the pelvic ureter form dense networks in the adventitia, muscular wall, and mucosal layer of the ureter. They originate from the pelvic plexus, which in turn receives sympathetic fibers via the lumbar and sacral splanchnic nerves and the hypogastric plexus. Parasympathetic fibers reach the pelvic plexus via the pelvic splanchnic nerves from the sacral cord (Fig. 1.58).

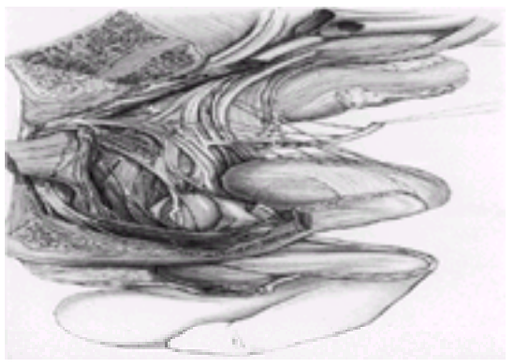

FIGURE 1.58. Nerves in a male pelvis, viewed from the right side: Portions of the coxa have been removed.

Relations of the Male Bladder to Adjacent Organs

The relations of the bladder to adjacent organs correlate closely with its relations to the pelvic connective tissue and peritoneum.

Peritoneal Covering of the Bladder

The bladder is attached to the peritoneum by loose connective tissue. This enables it to function as an expansile urinary reservoir that is mobile with respect to the peritoneum. Only a greatly distended bladder is fixed by its peritoneal covering (Fig. 1.59).

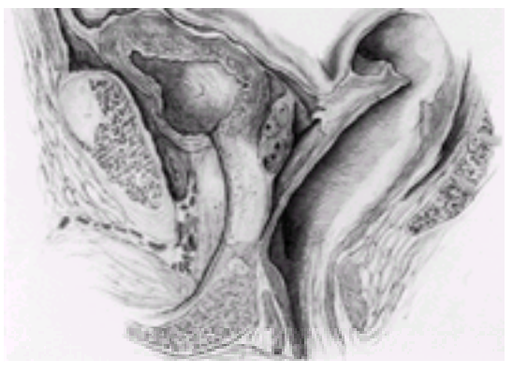

FIGURE 1.59. Midsagittal section through the pelvis.

The parietal peritoneum is continued from the anterior abdominal wall onto the bladder apex and covers the posterior surface of the bladder to the level of the tips of the seminal vesicles, sometimes extending to the level of the ureteral orifices. There the peritoneum is reflected onto the anterior wall of the rectum to form the rectovesical pouch, which is the lowest point of the peritoneal cavity. The entrance to the rectovesical pouch is bounded by the two sagittally oriented rectovesical folds. These peritoneal folds are backed with connective tissue that provides posterior support for the bladder base.

The peritoneum is recessed between the bladder and anterior abdominal wall to form the supravesical fossae (Fig. 1.59). The right and left supravesical fossae are separated by the median umbilical fold. The supravesical fossa is bounded laterally by the medial umbilical fold. The peritoneal covering of the posterior bladder wall contains a reserve fold of peritoneum, the transverse vesical fold, which is progressively obliterated as the bladder distends.

Bladder and Pelvic Connective Tissue

The pelvic connective tissue consists of three main parts: the pelvic fascia (parietal and visceral), the neurovascular sheaths, and the loose connective tissue occupying the spaces of the pelvic viscera.

The *visceral pelvic fascia* is derived from the parietal pelvic fascia above the urogenital diaphragm at the site where the urethra pierces the diaphragm. The visceral fascia is reflected onto the prostate, and it invests the bladder as the vesical fascia.

The *neurovascular sheaths* are sheetlike condensations of intrapelvic connective tissue that invest and transmit nerves and blood vessels and that also perform retinacular functions. Portions distributed to the bladder and prostate assist in the fixation of the bladder base. The *puboprostatic ligament* (pubovesical ligament) extends from the symphysis and adjacent portions of the pubic bone to the prostate and continues onto the bladder neck. It binds the prostate and bladder to the anterior pelvic wall. The *paracystic connective tissue* (bladder retinaculum) passes to the bladder from the lateral pelvic wall. Between the paracystic connective tissue and *pararectal connective tissue* (rectal retinaculum) is the *rectovesical septum,* which represents the central portion of the lateral neurovascular sheath.

Loose connective tissue occupies the *spaces* between the condensations of the neurovascular sheaths and visceral fasciae. The *prevesical space* located between the anterior abdominal wall and bladder is bounded anteriorly by the transversalis fascia and posteriorly by the vesical fascia. The prevesical space is continuous inferiorly with the retropubic space. This space is bounded anteriorly by the posterior surface of the pubic symphysis, posteriorly by the prostatic fascia, and inferiorly by the urogenital diaphragm.

The rectovesical and retropubic spaces communicate laterally with the *paravesical space.* This mobile tissue plane is bounded posteriorly by the paracystic connective tissue, medially by the vesical fascia, and laterally and inferiorly by the parietal pelvic fascia.

Between the rectum and bladder is the *rectovesical space.* The rectovesical septum and the seminal vesicles subdivide this space into two separate compartments termed the *vesicogenital space* and the *rectogenital space* (Fig. 1.59,Fig. 1.60,Fig. 1.61 and Fig. 1.62).

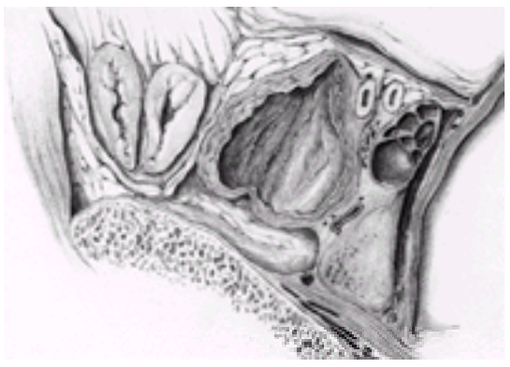

FIGURE 1.60. Paramedian section through the pelvis.

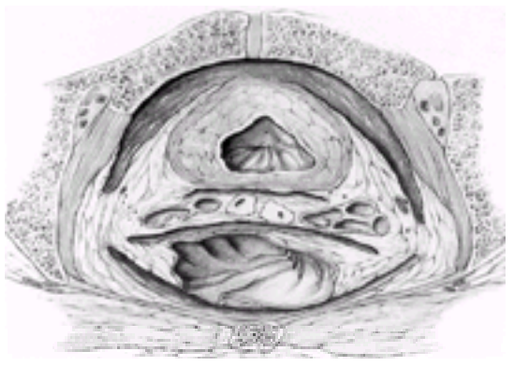

FIGURE 1.61. Transverse section through the pelvis at the level of the seminal vesicles.

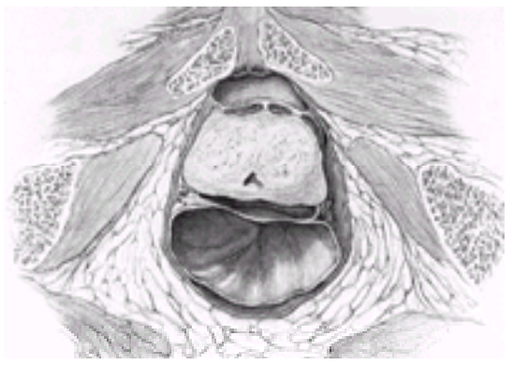

FIGURE 1.62. Transverse section through the pelvis at the level of the prostate.

Vessels and Nerves of the Bladder

The *arteries* of the bladder may arise directly from the internal iliac artery or from one of its visceral branches (Fig 1.56 and Fig. 1.58).

The superior vesical artery is almost always multiple. Usually, there are two superior vesical arteries, their number ranging from one to four. The superior vesical arteries generally arise from the patent, unobliterated portion of the umbilical artery but occasionally are derived from the obturator artery (4.5%). They supply the base and body of the bladder and generally anastomose with the inferior vesical artery.

The inferior vesical artery is usually a direct branch of the internal iliac but may arise from a nearby vessel such as the internal pudendal artery (25%) or inferior gluteal artery (4%). It supplies the bladder base in addition to the prostate and seminal vesicles.

The *veins* of the bladder commence as intramural plexuses. The larger vessels emerging from the bladder wall form the vesical plexus, which communicates with the venous plexus of the prostate. Both plexuses drain into the internal iliac vein.

The *lymph vessels* of the bladder communicate with one another in the paravesical space and may end directly at the external iliac and interiliac lymph nodes or may reach them by way of smaller nodes (anterior, lateral, and posterior vesical nodes). Connections with the internal iliac lymph nodes are occasionally observed.

The *nerves* supplying the bladder are derived from the pelvic plexuses (Fig. 1.59). The parasympathetic fibers (pelvic splanchnic nerves) of these plexuses originate from the second to fourth sacral segments and supply the detrusor muscle. The sympathetic fibers reach the vesical plexus from the first two lumbar segments by way of the hypogastric plexus.

Prostate

The prostate is enveloped by an external connective-tissue layer, the *prostatic capsule*, and by its visceral fascia, the *prostatic fascia.* The lateral portion of the prostatic fascia, the paraprostatic connective tissue, is well developed posteriorly to form Denonvilliers' fascia. Between the prostate and rectum is the *rectoprostatic space* (Fig 1.59 and Fig. 1.60).

The rectoprostatic space communicates superiorly with the *rectovesical space,* which is subdivided by the seminal vesicles and spermatic ducts into a *rectogenital space* and a *vesicogenital space* (Fig 1.61 and Fig. 1.62). The prostate is fixed to the symphysis anteriorly by the *puboprostatic ligaments,* and it is supported posteriorly by connective-tissue slips from the rectal retinaculum.

Relations of the Female Bladder to Adjacent Organs

The relations of the female bladder to the pelvic connective tissue are obviously gender specific. The parietal fascia of the pelvic floor is reflected onto the bladder at the bladder neck to form the vesical fascia.

The pubovesical ligaments in the female pelvis, derived from the intrapelvic neurovascular-retinacular sheaths, bind the bladder to the pubic symphysis.

The paracystic connective tissue passes from the lateral pelvic wall to the bladder. Tough connective-tissue fibers are distributed to this tissue from the cardinal ligament of the uterus.

The relation of the loose connective tissue to the female bladder is the same anteriorly (prevesical space) and laterally (paravesical space) as in the male. Posteriorly,

between the body of the bladder and the cervix, loose connective tissue occupies the *vesicouterine space.* The *vesicovaginal space* is located more caudally between the bladder base and the front of the vagina.

The relation of the female bladder to the pelvic connective tissue accounts in large part for its relations to adjacent organs.

The female urethra has two clinical subdivisions: a superior part and an inferior part. The superior part, comprising the cranial one-fourth of the urethra, can move relative to the vagina because of the loose connective tissue in the *urethrovaginal space.* The inferior part lacks a true space, and in that area, the vagina and urethra are fused together by their visceral fasciae. The anterosuperior portion of the female urethra is fixed by the lowermost fibers of the pubovesical ligaments, known also as the *pubourethral ligaments.*

Application of Surgical Approaches

Anterior Pelvic Exenteration in the Male: Approach to the Nerve-vessel–guiding Plates

Dissection of the Vesicoumbilical Plate

The urachus is isolated near the umbilicus and divided (Fig. 1.63). Entry into the peritoneal cavity at a more inferior level is established by dissecting the *vesicoumbilical plate* (medial umbilical fold, median umbilical fold, transversalis fascia, peritoneal fat, and peritoneum) downward *en bloc* to the lateral umbilical ligaments (Fig. 1.64).

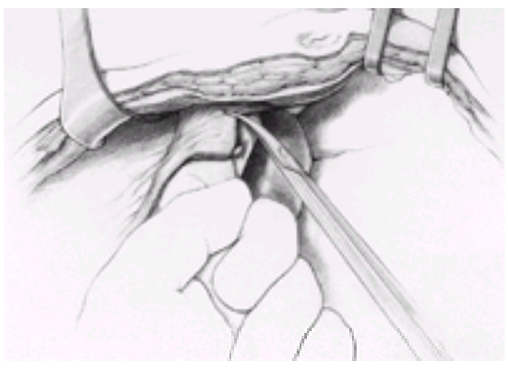

FIGURE 1.63. Dissection of the vesicoumbilical plate.

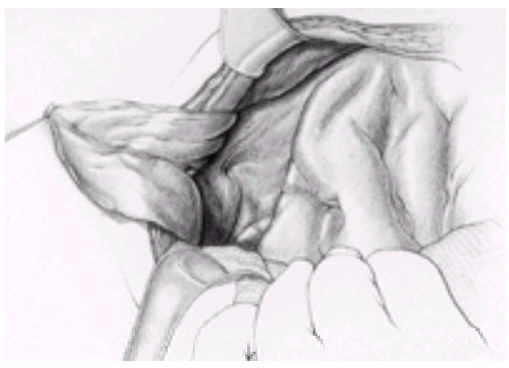

FIGURE 1.64. The freed vesicoumbilical plate is retracted inferiorly.

Dissection of the Lateral Bladder Pedicle (Lateral Bladder Retinaculum)

The right-handed surgeon places the fourth and fifth fingers of the left hand on the bladder and medial border of the lateral paracystic connective tissue with the third finger on the internal iliac artery. The index finger is swept medially behind the internal iliac artery into the depths of the pelvis. With this maneuver, the surgeon can displace the lateral retinaculum (lateral bladder pedicle) toward the bladder and the rectovesical septum (posterior bladder pedicle) toward the rectum. With the left index finger behind the lateral pedicle, the internal iliac artery is identified, followed by the anterior branches of the internal iliac artery, the lateral umbilical fold, the superior vesical artery, the inferior vesical artery, and the obturator artery. These vessels are individually isolated, identified, and ligated (Fig 1.65 and Fig. 1.66).

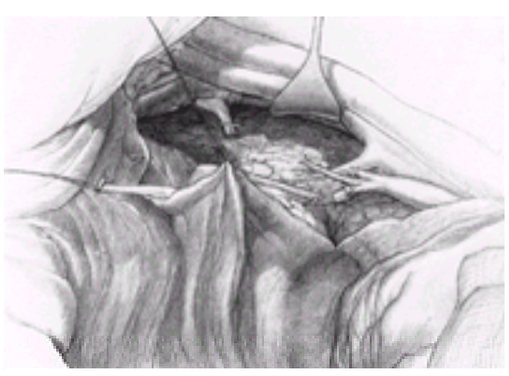

FIGURE 1.65. Dissection of the lateral bladder pedicle.

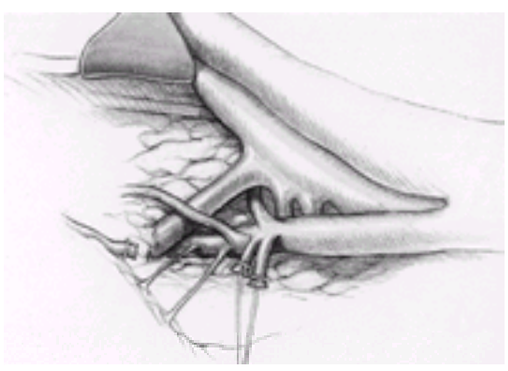

FIGURE 1.66. Close-up view of the dissection of the lateral bladder pedicle. The obturator artery, superior vesical artery, and inferior vesical artery are identified and

clipped.

Variants of the Internal Iliac Artery

The branching pattern of the internal iliac artery is extremely variable. The most common variants of the parietal branches of the internal iliac artery are shown in Fig. 1.67. The internal iliac artery usually divides at a variable level into an anterior and a posterior trunk. The origin of the obturator artery is largely independent of the primary bifurcation of the internal iliac artery.

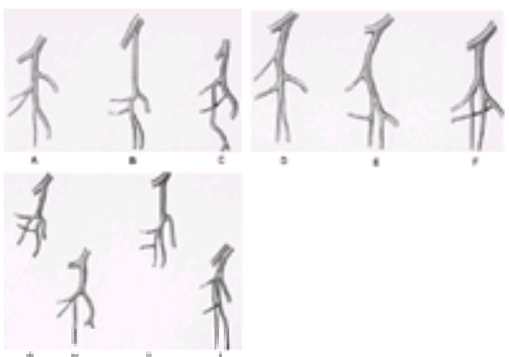

FIGURE 1.67. Variation in the branching pattern of the internal iliac artery. **A, D:** The superior gluteal artery leaves the pelvis through the suprapiriform foramen as the terminal branch of the posterior trunk of the internal iliac artery. The internal pudendal artery and inferior gluteal artery pass through the intrapiriform foramen as the terminal branches of the anterior trunk (49%). **B, C:** The anterior trunk does not divide unit it has passed through the intrapiriform foramen (10%). **E:** Both gluteal arteries and the internal pudendal artery arise by a common trunk (1.5%). **F, G:** The internal pudendal artery arises separately from the umbilical artery (0.5%). **G, H:** Both gluteal arteries form a common trunk that divides before (12%) or after (3.5%) leaving the true pelvis. **I, J:** The internal pudendal artery and the superior and inferior gluteal arteries arise separately in an irregular pattern (22.5%).

The *obturator artery* may arise from the anterior trunk of the internal iliac artery (Fig. 1.67A, Fig. 1.67B, and Fig. 1.67H; 41.5%) or from the posterior trunk (Fig. 1.67C and Fig. 1.67F). It also may arise from a common trunk for the internal pudendal and inferior gluteal arteries (Fig. 1.67E and Fig. 1.67I). The obturator artery springs from the internal pudendal artery in approximately 4% of cases (Fig. 1.67G and Fig. 1.67J) and from the inferior gluteal artery in 5% (Fig. 1.67).

In 19% of cases, the obturator artery arises from the inferior epigastric artery and in 1% from the external iliac. The obturator artery is duplicated in approximately 5% of cases, one vessel arising from the external iliac artery and the other from the internal iliac artery or its branches.

The visceral branches of the internal iliac artery are also subject to considerable variation:

The *umbilical artery (patent section)* consistently gives rise to the superior vesical arteries and the artery of the vas deferens. Rarely, it gives off a middle rectal artery, the vaginal artery, or both.

The *inferior vesical artery* may arise directly from the internal iliac artery or one of its anterior branches. It generally anastomoses with the uterine artery (86%).

The *artery of the vas deferens* may be a direct branch of the internal iliac artery (rare) but usually arises from the umbilical artery. It is absent in 23% of cases and may give origin to a superior vesical artery.

The *middle rectal artery* is rarely absent and normally springs directly from the internal iliac. It also may arise from the vaginal artery or, very rarely, from the sacral arteries.

The *superior vesical arteries,* numbering from one to four, usually arise from the patent section of the umbilical artery but may branch from the uterine artery (9%), the artery of the vas deferens (9%), or the obturator artery (4.5%). Anastomoses between the superior and inferior vesical arteries are generally present.

The *uterine artery* is usually a direct branch of the internal iliac but may arise conjointly with the vaginal or middle rectal artery. Duplication can occur. When necessary, the uterine artery can adequately assume the supply function of the vesical arteries.

Exposure of the Rectovesical Septum (Posterior Bladder Pedicle)

The neurovascular sheath transmits the arteries and veins of the seminal vesicles and prostate in addition to the pelvic splanchnic nerves. The space between the rectal fascia and Denonvilliers' fascia is developed. The posterior bladder pedicle is held between the second and third fingers as the second finger presses downward on the rectum, and the posterior pedicle is progressively ligated as far as the endopelvic parietal fascia. As traction is placed on the vas deferens and ureter to enlarge the space between the rectal fascia and Denonvilliers' fascia, individual portions of the posterior pedicle can be clipped or ligated under direct vision. The posterior pedicle is then progressively divided to the endopelvic parietal fascia (Fig. 1.68). The pelvic wall comes into view on the lateral side of these neurovascular bundles as they are progressively isolated and clipped or tied (Fig. 1.69).

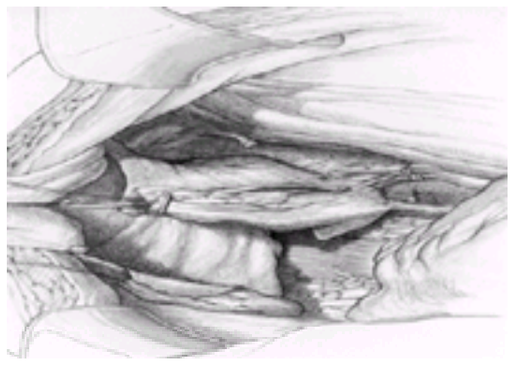

FIGURE 1.68. Exposure of the rectovesical septum (posterior bladder pedicle). The anterior branches of the internal iliac artery have been ligated, and the incision in the cul de sac has been completed. The right vas deferens and clipped ureter are retracted forward along with the freed lymph node package.

FIGURE 1.69. The posterior bladder pedicle is held between the second and third fingers while the second finger presses the rectum downward. The posterior pedicle is then progressively ligated.

Anterior Pelvic Exenteration in the Female

Exposure of the Posterior Bladder Pedicle

The peritoneum of the rectouterine pouch is incised from the pelvic wall aspect, and the specimen is retracted inferiorly by the vesicoumbilical plate and a uterine traction suture (Fig. 1.70). After division of the peritoneum over the rectum in the area of the rectouterine pouch, the posterior bladder pedicle, which includes the cardinal ligament in the female, is progressively ligated or clipped as far as the parietal pelvic fascia.

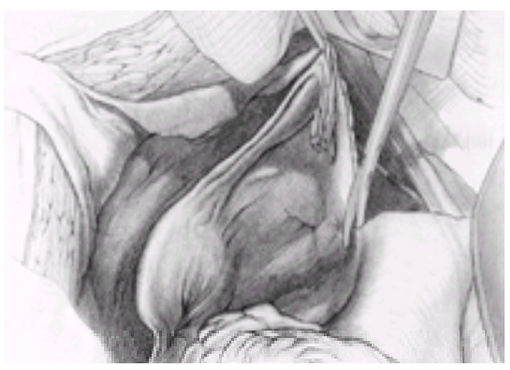

FIGURE 1.70. Line of incision in the peritoneum. Starting at the pelvic wall, the peritoneum is divided just over the rectum in the area of the rectouterine pouch.

Opening the Posterior Vaginal Wall

The posterior bladder pedicle is clipped or ligated approximately 3 to 4 cm past the cervix, and the posterior vaginal wall is opened (Fig. 1.71). Much as in an anterior exenteration in the male, the remaining posterior pedicle is encircled (the second finger is in the vagina) and progressively ligated forward to the parietal pelvic fascia.

FIGURE 1.71. Exposure and division of the posterior bladder pedicle, which in the female includes the cardinal ligament. The posterior vaginal wall is opened 3 to 4 cm caudal to the cervix.

Continence Following Radical Prostatectomy and Orthotopic Reconstruction Following Female and Male Anterior Exenteration

Anatomy and Innervation of the Rhabdosphincter: Male

Macroscopic Anatomy. The muscle fibers of the rhabdosphincter are arranged in a loop-shaped fashion on the ventral and lateral aspects of the membranous urethra (Fig. 1.72). On gross anatomic examination, comparatively strong smooth muscular and connective tissue can be noted dorsal to the membranous urethra (i.e., in the region of the perineal body). Both ends of the omega-shaped sphincter insert at the perineal body. The sphincter loop is continuous with muscle bundles that run along the anterior and lateral aspects of the prostate and extend cranially to the bladder neck. Thus, in the adult male, the rhabdosphincter of the urethra does not form a complete collar around the membranous urethra. It should rather be described as a muscular coat ventral and lateral to the membranous urethra and prostate, the core of which is the omega-shaped loop around the urethra. Furthermore, the rhabdosphincter is separated from the ventral portion of the levator ani muscle by a sheet of connective tissue.

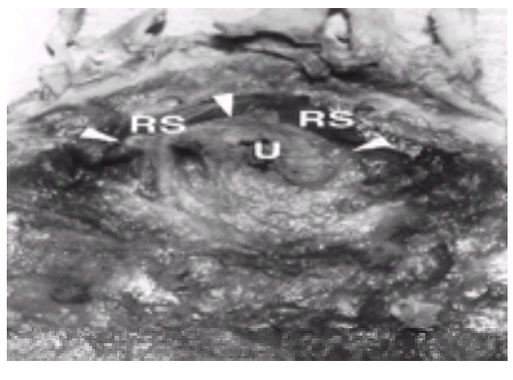

FIGURE 1.72. Anatomic specimen (adult rhabdosphincter, cranial view). RS, rhabdosphincter; U, urethra.

Histology. The histologic findings in adult men confirm the data gained by gross anatomic examination (Fig. 1.73). The rhabdosphincter is a vertical muscular coat ventral and lateral to the prostate and membranous urethra extending from the bulb of the penis toward the region of the bladder neck. In all investigated specimens, striated muscle fibers corresponding to the deep transverse perineal muscle cannot be identified.

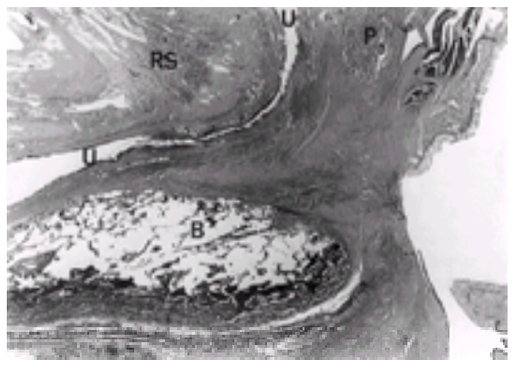

FIGURE 1.73. Histologic specimen (adult, sagittal section). B, bulb of penis; P, prostate; RS, rhabdosphincter; U, urethra.

Nerve Supply. The pudendal nerve derives from the second, third, and fourth sacral spinal nerves. It takes a completely different course than the autonomic fibers of the pelvic plexus. The rhabdosphincter of the male urethra is supplied by fine branches of the pudendal nerve. These branches are given off lateral to the rhabdosphincter and reach the muscle at its dorsolateral aspects; the mean distance from the membranous urethra to the point of entry of these fibers into the rhabdosphincter is 0.7 to 1.3 cm (Fig 1.74 and Fig. 1.75).

FIGURE 1.74. Anatomic specimen (adult, lateral view; the right hip bone has been completely removed).

FIGURE 1.75. Corresponding drawing to Fig. 1.74.

Anatomy and Innervation of the Rhabdosphincter: Female

On macroscopic examination, the sphincteric muscle is encountered on the ventral and lateral aspects of the urethra. Microscopically, this muscle corresponds to the omega-shaped rhabdosphincter in the male.

On histologic examination, in the cranial two-thirds of the urethra, three smooth muscle layers can be identified forming an outer and an inner longitudinal and a middle transverse layer. The inner longitudinal layer is delicate, thinning out toward the external meatus. The middle transverse layer is considerably thicker than the longitudinal layers (Fig. 1.76A, Fig. 1.76B and Fig. 1.76C). In serial transverse sections of the caudal urethra, there are abundant aspects, whereas dorsally there are mainly fibrous structures with only a few striated fibers. In transverse sections, the rhabdosphincter has an omega-like shape (Fig. 1.77).

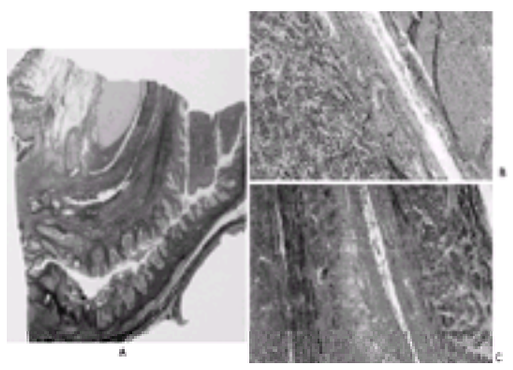

FIGURE 1.76. A: Median sagittal section of pelvic floor in fetal specimen. **B:** View of cranial two-thirds of female urethra: three layers of smooth muscle forming outer and inner longitudinal and middle transverse layers. **C:** In caudal third of the urethra, the rhabdosphincter is visible, with major portion in ventral and ventrolateral aspects of the urethra.

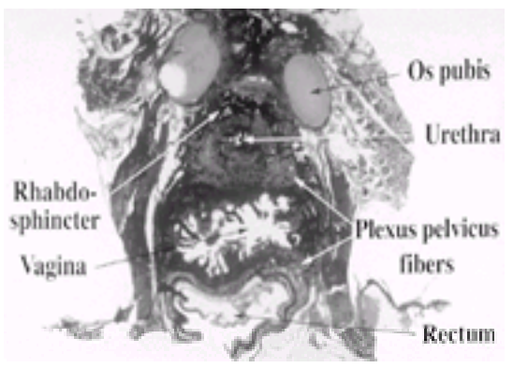

FIGURE 1.77. Transverse histologic section shows omega-shaped rhabdosphincter in caudal third of the urethra.

The autonomic fibers that supply the pelvic visceral organs emerge from the pelvic plexuses. They then course in a sagittal layer of connective tissue containing vessels and nerves (the vessel nerve plate) lateral to the rectum, in which they course to the ventral pelvic organs. The hypogastric and pelvic splanchnic nerves have been identified in this vessel nerve plate between the rectum and the pelvic wall. The cranial portion of the pelvic plexus is located close to the lateral margin of the rectouterine pouch; its ventral and caudal portions extend to the lateral aspect of the cervix (Fig. 1.78).

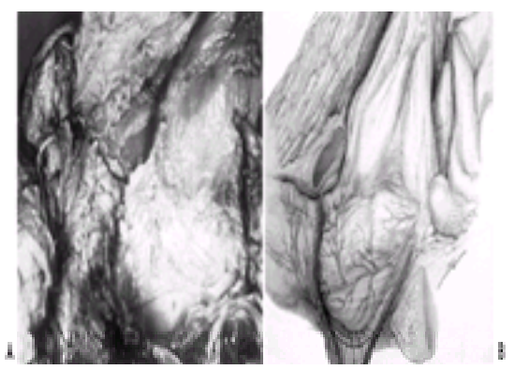

FIGURE 1.78. A: Lateral view of fetal specimen shows autonomic nerve supply to urethra relative to pelvic organs. **B:** Corresponding drawing to **A.**

The pudendal nerve courses alongside the internal pudendal vessels on the lateral aspects of the ischiorectal fossa inside the pudendal canal. The inferior rectal nerves, perineal nerves, and dorsal nerve of the clitoris branch off in the region of the pelvic floor. Arising from the terminal branch of the pudendal nerve, several thin branches run to the rhabdosphincter, which they enter on its lateral aspect (Fig. 1.79).

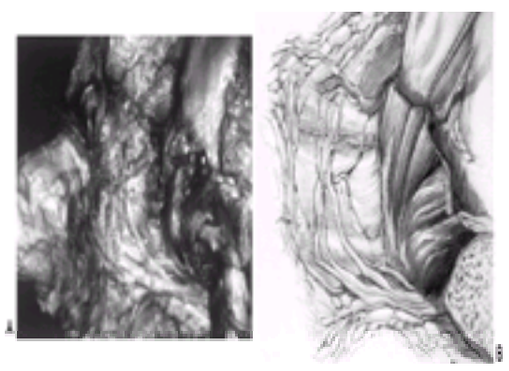

FIGURE 1.79. A: Several thin branches emerging from the pudendal nerve course to caudal third of urethra entering the rhabdosphincter at the lateral aspects. **B:** Corresponding drawing to **A.**

Radical Prostatectomy

Retropubic Versus Perineal Approach

The perineal approach, by preserving the paraprostatic tissue (lateral pelvic fascia), avoids injury to the dorsal vein complex. In a perineal prostatectomy, the prostate is removed within the paraprostatic tissue, whereas the retropubic prostatectomy removes the prostate together with all paraprostatic tissue. The retropubic approach involves incision of the paraprostatic tissue (lateral pelvic fascia) and division of the dorsal vein complex (arrow). Thus, in contrast to the perineal approach, the retropubic approach includes removal not just of Denonvilliers' fascia but also of the paraprostatic tissue (lateral pelvic fascia) (Fig. 1.80).

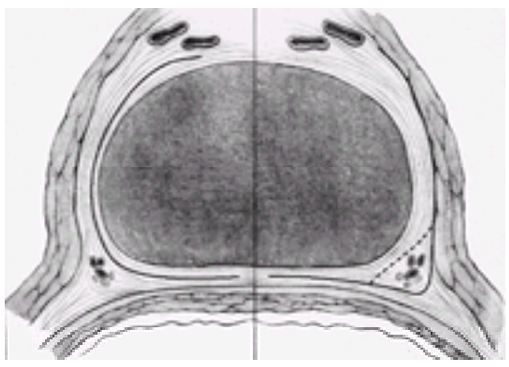

FIGURE 1.80. Approaches for perineal **(left)** and retropubic **(right)** prostatectomy. The significance of the paraprostatic tissue (lateral pelvic fascia) in each approach is shown (... = nerve-sparing approach for a retropubic radical prostatectomy).

Retropubic Radical Prostatectomy

Exposure and Division of the Striated Urethral Sphincter (Rhabdosphincter) and Membranous Urethra. After division of the dorsal venous complex, the anterolateral aspects of the striated urethral sphincter (rhabdosphincter) can be identified. It forms an omega-shaped loop anterior and lateral to the membranous urethra, its two crura inserting into the central tendon of the perineum (Fig. 1.81). In anatomic dissections, after the prostate has been removed, the membranous urethra, the omega-shaped rhabdosphincter, and the central tendon can be seen on the inner aspect of the transverse perineal ligament. The deep dorsal penile vein, the dorsal penile artery, and the dorsal penile nerve course between the inner and outer fasciae of the transverse perineal ligament. The deep dorsal penile vein runs between the arcuate ligament and transverse perineal ligament, and the dorsal penile artery and nerve run directly through the tissue of the transverse perineal ligament (Fig. 1.81).

FIGURE 1.81. The rectourethral septum is incised, Denonvilliers' fascia is exposed, and the rectogenital space is entered. The rectal fascia is visible in the depths of the field.

Exposure of the Rectogenital Space. The membranous urethra is divided on the line shown. The posterior prostatic fascia is divided at its attachment, the rectourethral septum (the apex of the wedge-shaped perineal body), and the rectogenital space is opened. The rectal fascia is identified at the posterior aspect of the rectogenital space.

Exposure of the Vesicogenital Space. The prostate is now resected with the paraprostatic tissue between the rectogenital space and levator ani muscle. The seminal vesicles and the ampullae of the spermatic ducts are dissected from the bladder detrusor, following the course of the rectogenital space. The prostate is transected at the bladder neck and dissected out of the rectogenital space.

Modification: Nerve-sparing Radical Prostatectomy

In the modification of the nerve-sparing radical prostatectomy, the neurovascular bundle (base of the paraprostatic tissue) of the prostate is preserved. This bundle contains the cavernous nerves, fibers from the pelvic plexus to the membranous urethra, arterial branches to the prostate, the venous prostatic plexus, and prostatic lymph vessels (Fig. 1.82); to approach the neurovascular bundle, the paraprostatic tissue on the lateral surface of the prostate is incised and released. Located on the posterolateral aspect of the prostate, the neurovascular bundle is deeply embedded in the parietal layer of the fascia (paraprostatic tissue).

FIGURE 1.82. In this anatomic specimen, the left neurovascular bundle has been dissected out of the posterolateral portion of the paraprostatic tissue.

INGUINAL REGION

Anatomy

The inguinal canal obliquely traverses the abdominal wall in the medial portion of the inguinal region. The canal has a lateral-to-medial orientation, its lateral part being situated more deeply than its medial part. It has an average length of 4 to 5 cm in men and is about 5 mm longer in women.

The external (superficial) inguinal ring forms the external opening of the inguinal canal. Located in the external oblique aponeurosis, the ring is bounded by two thickenings in the aponeurosis termed the *medial* and *lateral crura* (Fig. 1.83). Both crura join at the superolateral aspect of the external ring and are sometimes reinforced in that area by transverse intercrural fibers. The development and location of these fibers are subject to marked individual variations, and the fibers can be dissected at the external inguinal ring in only 27% of the population.

FIGURE 1.83. Inguinal region. Subcutaneous plane.

The external inguinal ring is exposed by incision of the external spermatic fascia. The ring is elliptical in shape and highly variable in size and length. In 80% of cases, the superolateral border of the external ring is located above the medial half of the inguinal ligament. In the remaining 20%, its boundary is more superolateral and, in extreme cases, may extend to the anterosuperior iliac spine.

The slitlike internal opening of the inguinal canal, the internal (deep) inguinal ring, represents an evagination of the transversalis fascia. It is covered internally by parietal peritoneum, so surgical exposure of the internal ring requires incision of the peritoneum.

The layers of the lateral abdominal wall contribute in varying degrees to the substance of the inguinal canal walls. The anterior wall is formed by the external oblique aponeurosis, which is continued onto the spermatic cord as the thin external spermatic fascia. The floor of the canal is formed by the inguinal ligament.

The caudal fibers of the transversus abdominis muscle form the roof of the inguinal canal. The internal oblique muscle does not contribute to formation of the canal roof. Its caudal fibers are continued onto the spermatic cord as the cremaster muscle. The cremaster, which forms the middle coat of the spermatic cord, varies greatly in development among different individuals, and the middle covering is considered to consist of both the spermatic fascia and the cremaster muscle. Normally, a definite plane of cleavage can be developed between the internal oblique and transversus abdominis muscles in the region of the inguinal canal.

The posterior wall of the inguinal canal is formed by the transversalis fascia. Medial to the internal ring this fascia is strengthened by the variable interfoveolar ligament (Hesselbach), whose fibers are derived from the transversus aponeurosis. The posterior canal wall is further strengthened by the inguinal falx (Henle's ligament). These fibers also arise from the transversus aponeurosis and blend inferiorly with the inguinal ligament and lacunar ligament. Another term for the inguinal falx is the *conjoined tendon.*

The layered dissections in Fig. 1.83, Fig. 1.84, Fig. 1.85, Fig. 1.86 and Fig. 1.87 serve to clarify the arrangement of the individual abdominal tissue planes in the inguinal canal. The firm subcutaneous fatty layer in the inguinal region, permeated by fibrous strands and known also as *Camper's fascia,* is removed to expose the external oblique aponeurosis. This aponeurosis is continued onto the spermatic cord as the external spermatic fascia (Fig. 1.83). Incision of the outer coat of the spermatic cord exposes the middle layer, composed of the cremasteric fascia and the cremaster muscle, which is a continuation of the internal oblique muscle. The genital branch of the genitofemoral nerve can also be identified in this plane (Fig. 1.84). The external oblique aponeurosis can now be split further laterally and superiorly to expose the anterior terminal branch of the iliohypogastric nerve. The middle coat of the spermatic cord is divided to expose the internal spermatic fascia, which intimately invests the cord structures (Fig. 1.85). Division of the caudal fibers of the internal oblique muscle uncovers the portion of the transversus abdominis that forms the roof of the inguinal canal (Fig. 1.86). As the last step in the dissection, the internal coat of the spermatic cord is incised to expose the cord structures themselves: the vas deferens, testicular artery, and pampiniform plexus (Fig. 1.87).

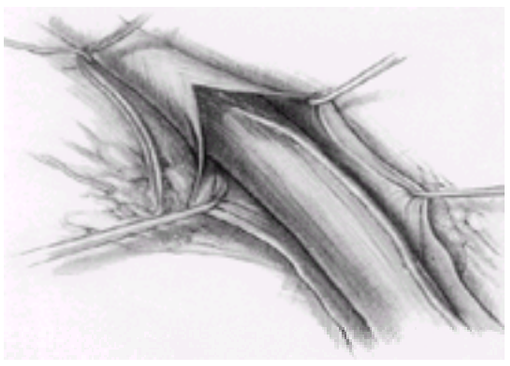

FIGURE 1.84. Spermatic cord after incision of the external spermatic fascia.

FIGURE 1.85. Spermatic cord after incision of the cremasteric fascia.

Inguinal Approach

Exposure of the External Inguinal Ring

The subcutaneous fat and Camper's fascia are divided along with branches of the superficial epigastric vessels and the superficial circumflex iliac vessels. The external oblique aponeurosis is identified (Fig. 1.88).

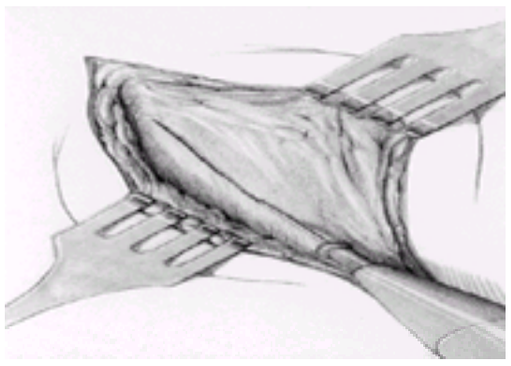

FIGURE 1.88. Exposure of the external inguinal ring.

Exposure of the Internal Inguinal Ring

The external oblique aponeurosis and the most anterior portion of the external spermatic fascia are divided, sparing the genital branch of the genitofemoral nerve on the cremaster muscle medially. The internal oblique muscle and cremasteric fascia are exposed (Fig. 1.89).

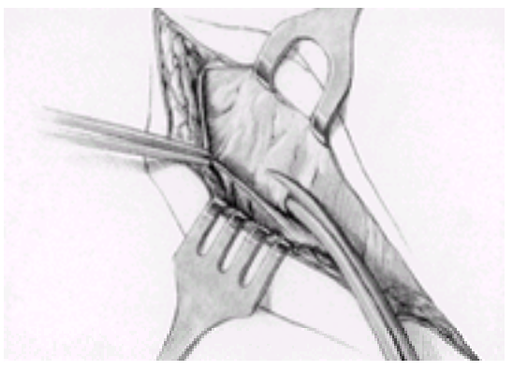

FIGURE 1.89. Division of the external oblique aponeurosis.

Further exposure of the inguinal canal is accomplished by incision of the cremasteric fascia and internal oblique muscle (Fig. 1.90). The iliohypogastric nerve and genitofemoral nerve are visible on the medial side.

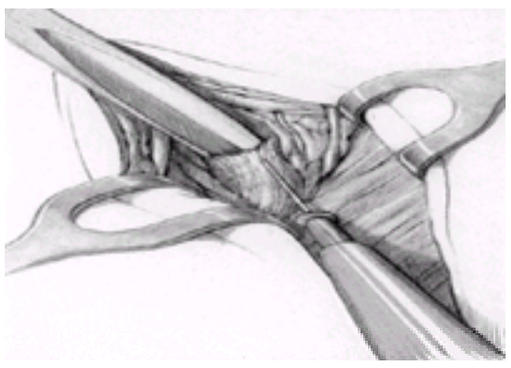

FIGURE 1.90. The cremasteric fascia and internal oblique are divided.

The internal oblique muscle is divided, exposing the transversus abdominis (Fig. 1.91). Following release of the cremaster muscle (whose fibers arise from the internal oblique), the spermatic cord with the surrounding internal spermatic fascia (derived from the transversalis fascia) is undermined and snared (Fig. 1.91). The internal fascia of the spermatic cord is dissected from the transversalis fascia to increase the length of the cord (Fig. 1.92). The external oblique aponeurosis and the incised internal oblique and transversus abdominis muscles are retracted upward in the proximal wound angle, allowing for further dissection of the spermatic cord, which is freed up into the internal inguinal ring (Fig 1.93 and Fig. 1.94). The inferior epigastric vessels can be seen medial to the inguinal ring.

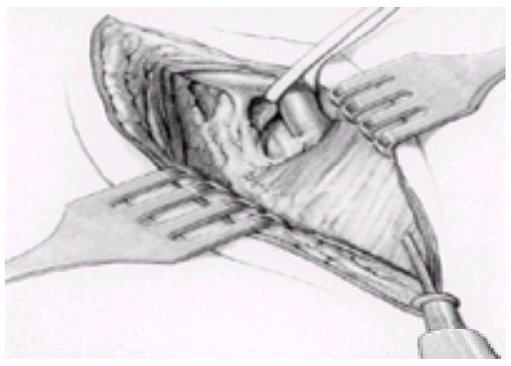

FIGURE 1.91. Mobilization of the spermatic cord and division of the transversus abdominis.

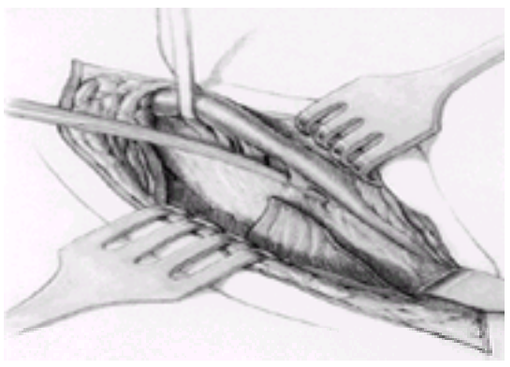

FIGURE 1.92. The spermatic cord is dissected from the transversalis fascia, and the internal ring is exposed.

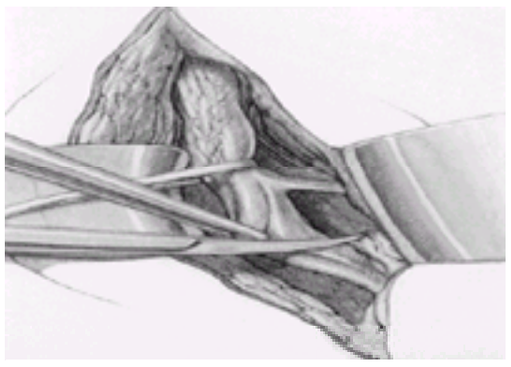

FIGURE 1.93. After incision of the internal spermatic fascia, the vas deferens and its artery are separated from the pampiniform plexus and testicular artery.

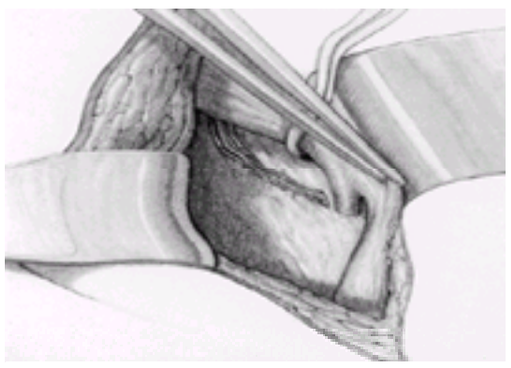

FIGURE 1.94. The inferior epigastric artery and the accompanying inferior epigastric veins are dissected free on the medial aspect of the spermatic cord.

EXTERNAL GENITALIA

Dorsal Approach to the Penis

Exposure of the Dorsal Neurovascular Bundle

The superficial and deep penile fasciae are dissected and incised to the tunica albuginea along the lateral side of the penis (Fig. 1.95). A counterincision is made on the opposite side, and the neurovascular bundle (deep dorsal vein, artery, and nerve) is underrun and snared with a tape (Fig. 1.96).

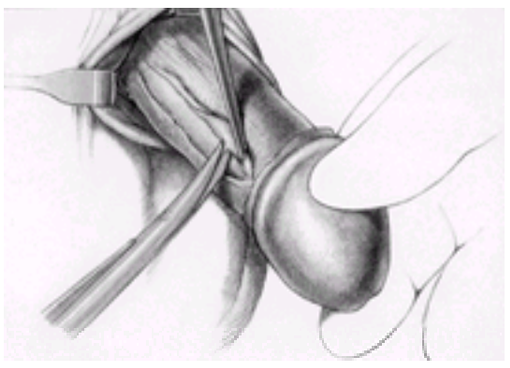

FIGURE 1.95. The superficial and deep fasciae of the penis are divided down to the tunica albuginea.

FIGURE 1.96. The neurovascular bundle is undermined and snared with a vascular tape.

The anatomic dissection in Fig. 1.97 shows the structures of the dorsal neurovascular bundle: the deep dorsal penile vein, the dorsal penile artery, and the dorsal nerve of the penis, located between the deep penile fascia and the tunica albuginea.

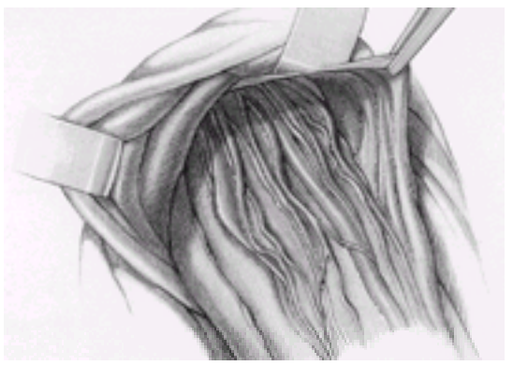

FIGURE 1.97. Anatomic dissection showing the structures of the neurovascular bundle: the deep dorsal penile vein, dorsal penile artery, and dorsal penile nerve.

The fascial planes of the penis are shown in schematic cross section in Fig. 1.98.

FIGURE 1.98. Schematic cross section of the penis.

PERINEUM

Anatomy of the Male Urethra and Pelvic Floor

The dissection shown in Fig. 1.99 demonstrates the relations of the corpus spongiosum to the pelvic floor. The corpus spongiosum is covered by the bulbospongiosus muscle and relates to the inferior aspect of the transverse perineal ligament, to which it is attached by loose connective tissue. The so-called “urogenital diaphragm” consists essentially of tough, transversely oriented connective-tissue fibers—the transverse perineal ligament. All pelvic muscles, as well as the levator ani of the pelvic diaphragm and the external anal sphincter, converge at the central tendon of the perineum. These structures are demonstrated more clearly by removal of the corpus spongiosum at the bulb of the penis along with the bulbospongiosus muscle (Fig. 1.100).

FIGURE 1.99. Anatomic dissection showing the pelvic floor structures from the inferior aspect.

FIGURE 1.100. Transverse perineal ligament after removal of the corpus spongiosum (anatomic dissection).

In another dissection (Fig. 1.101), the pubic bone has been partially removed to demonstrate the neurovascular supply of the penis (dorsal penile artery and nerve,

deep dorsal penile vein). Removal of the pubic symphysis and corpora cavernosa renders a view of the transverse perineal ligament (Fig. 1.102).

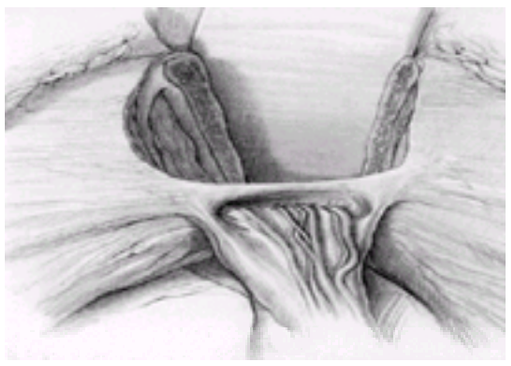

FIGURE 1.101. Dorsal neurovascular supply of the penis (anatomic dissection).

FIGURE 1.102. Appearance after resection of the corpora spongiosa and cavernosa (anatomic dissection).

Figure 1.103 shows the individual structures of the urogenital diaphragm in greater detail. Visible features include the pubic arcuate ligament, the transverse perineal ligament, and the external urethral sphincter, which forms a “horseshoe” about the anterior and lateral aspects of the membranous urethra. The structures that pierce the transverse perineal ligament are also seen: the deep dorsal penile vein, the dorsal penile artery and nerve, and the membranous urethra. The bulb of the penis has been divided, leaving a remnant on the diaphragm.

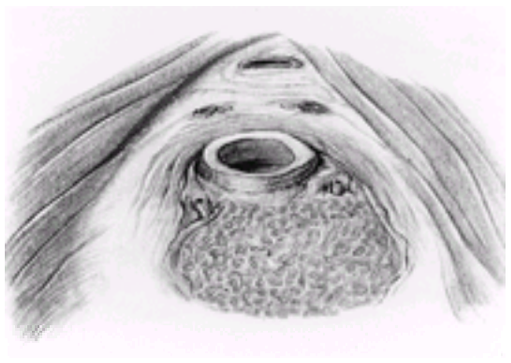

FIGURE 1.103. Close-up view of the transverse perineal ligament and rhabdosphincter (caudal view).

In Fig. 1.104, the anterior circumference of the membranous, urethra (from 9 to 3 o'clock) has been removed to demonstrate the lateral muscular portions of the striated urethral sphincter (rhabdosphincter). The artery of the bulb of the penis (bulbar artery) runs lateral to the membranous urethra. The dorsal penile artery and nerve perforate the transverse perineal ligament. The deep dorsal penile vein lies between the public arcuate ligament and transverse perineal ligament.

FIGURE 1.104. The urethral lumen is held open with a grooved probe. The lateral muscular portion of the rhabdosphincter can be seen.

Perineal Approach to the Posterior Urethra

Dorsal Approach Through the Perineal Body

The dorsal approach is made through the wedge-shaped perineal body, which extends from the central tendon to the rectourethral septum (Fig. 1.105). The dissected bulb of the penis is held upward by its posterior surface, and individual bulbospongiosus muscle fibers are severed. The dorsal aspect of the bulb is sharply separated from the inferior urogenital fascia and the transverse perineal ligament (Fig. 1.106).

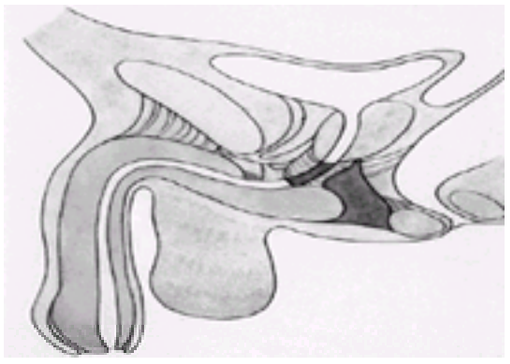

FIGURE 1.105. Schematic of the dorsal approach through the perineal body.

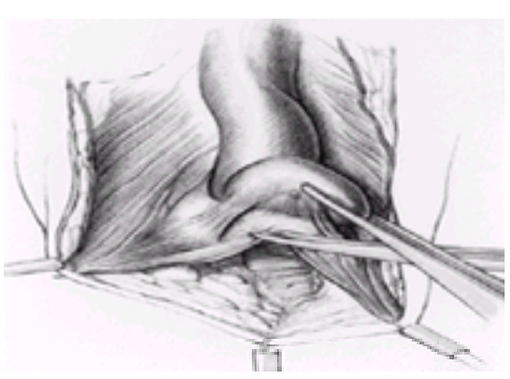

FIGURE 1.106. The bulbospongiosus muscle is removed. The tendinous origin of the bulbospongiosus is incised from front to back at the central tendon of the perineum.

Figure 1.107 illustrates the details of this approach. The corpus spongiosum is dissected free from the bulbospongiosus muscle, and the bulb is then dissected from the pelvic floor (transverse perineal ligament). The origins of the bulbospongiosus at the central tendon are divided. The bulbar artery and vein also are divided at this stage.

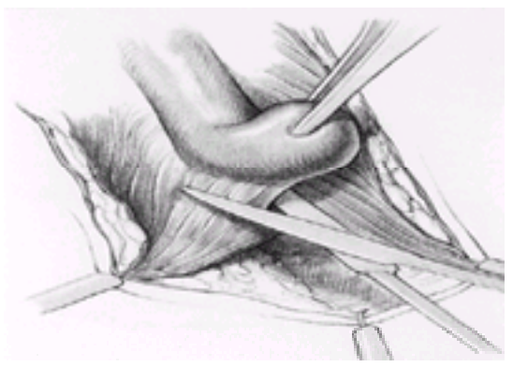

FIGURE 1.107. The bulbospongiosus fibers are detached from the dorsal aspect of the bulb.

Dissection of the Rectourethral Septum

Dissection of the rectourethral septum is used for the treatment of rectoprostatic fistulae or a very markedly displaced proximal prostatic urethral stump. The thick connective tissue at the apex of the perineal body is incised transversely.

Division of the rectourethral septum provides access for the dissection of Denonvilliers' fascia. The rectogenital septum is opened, and the posterior surface of the prostate is dissected free. A rectoprostatic fistula can be exposed by this perineal route.

In evaluating a patient, the urologist relies primarily on a skillfully taken history supplemented by a careful physical examination and appropriate laboratory studies. More often than not, a careful and detailed history of the patient's chief complaints indicates the probable diagnosis even before a physical examination is made or any laboratory test is performed. Because a thorough understanding of urologic signs and symptoms is critical to proper evaluation, they are analyzed here in some detail. A special effort has been made to explain the mechanism of each sign or symptom and to discuss the differential diagnosis.

SIGNS AND SYMPTOMS

Frequency

Frequency is the most common urologic symptom. When it occurs at night, it is termed *nocturia;* it is particularly bothersome and often is the reason for medical consultation. To properly evaluate these symptoms, the urologist should appreciate the wide range of frequency and nocturia in the general population. Study of a normal adult population revealed an average diurnal frequency of four to five times for men and five to six times for women. Ninety percent voided between three and nine times per day, and nocturia was common one to two times in both sexes (6). *Significant urinary frequency* is generally defined as voiding at least every 2 hours and *significant nocturia* as more than two times; however, normalcy varies with each patient. Usually, it is a significant increase in an individual's urinary frequency or nocturia that precipitates medical attention.

Etiology and Mechanism

A change in urinary frequency may result either from a decrease in functional capacity of the bladder or from an increase in urine production. An excellent screening test is the determination of *urine output per voiding.* The voided volume will be low when the bladder capacity is reduced and normal or high with polyuria. This information should be obtained as part of a 24-hour diary of fluid intake and voiding (Fig. 2.1).

FIGURE 2.1. Sample of a 24-hour form for a diary of fluid intake and voiding.

A reduced functional bladder capacity may occur secondary to inflammation of the bladder, pressure on the bladder from extravesical lesions, infravesical obstruction, radiation damage, or neurologic disease. Normal bladder mucosa is pain and pressure sensitive, and when inflamed, its threshold is greatly decreased, so it takes fewer stimuli to initiate the desire to void. Acute bacterial cystitis is by far the most common cause of bladder inflammation. Other causes include cancer, stones, foreign bodies, drugs (e.g., cyclophosphamide), nonbacterial cystitis (viral, fungal, parasitic, interstitial), and inflammatory processes in the adjacent bowel or vagina. Extravesical lesions pressing on the bladder may cause frequency by mechanically interfering with normal bladder expansion or by causing an irritable focus in the bladder wall. Common causes include pregnant uterus, fibroids, ovarian masses, and pelvic malignancies.

Infravesical obstruction provokes frequency by several mechanisms. Detrusor hypertrophy occurs along with changes in the neural regulation of bladder function such that the urge to void occurs at smaller than normal volumes. The result is an increase in urinary frequency. These patients typically note a decrease in the size and force of their urinary stream. With chronic obstruction, the bladder detrusor muscle may decompensate. Failure to empty the bladder, with elevated postvoid residual urine volumes, further diminishes the functional capacity of the bladder. Benign prostatic hyperplasia is the most common cause of infravesical obstruction. Other causes include carcinoma of the prostate, bladder neck obstruction, urethral stricture, and posterior urethral valves (in boys).

Neurologic disease causes urinary frequency by allowing uninhibited detrusor contractile activity during bladder filling. This may occur with disease affecting either the cerebral cortex (e.g., after a stroke) or spinal cord (e.g., spinal cord injury), as well as diseases affecting the central nervous system diffusely (e.g., multiple sclerosis). Urinary symptoms may be the presenting symptoms of an occult neurologic disease process, and a possible neurogenic cause should always be considered in the differential diagnosis of urinary frequency.

An increase in frequency, typically without any other urinary symptoms, will accompany increased urinary production. Causes of polyuria include ingestion of excess fluid, diabetes mellitus, chronic renal failure, and diabetes insipidus. In diabetes mellitus, the unreabsorbed glucose is an osmotic diuretic causing the polyuria. In chronic renal failure, there is impaired ability to concentrate the urine that causes *polyuria,* defined as a daily urine output in excess of 2,500 mL. Diabetes insipidus occurs with inadequate production or release of antidiuretic hormone (ADH) from the pituitary gland (central diabetes insipidus) or with inadequate fluid reabsorption by the kidneys despite normal ADH levels (nephrogenic diabetes insipidus) (36). The acquired concentrating defect in nephrogenic diabetes insipidus may occur with electrolyte disorders (hypokalemia and hypercalcemia), kidney disorders (pyelonephritis and obstructive nephropathy), drugs (e.g., lithium), and sickle cell disease and trait.

Emotional stress can cause urinary frequency. Characteristically, the patient experiences episodic frequency during stressful periods punctuated by periods of normalcy. Stress has been shown to induce a significant rise in intravesical pressure. Straub and associates (35) performed cystometrograms while interviewing normal subjects. Stressful topics evoked a significant rise in the intravesical pressure, usually accompanied by a desire to void. After reassurance and relaxation, the intravesical pressure returned to normal. Interestingly, discussion of emotion-laden material produced a bladder response only when it *disturbed the subject.* Some subjects seemed to enjoy venting their feelings, and they experienced no rise in their intravesical pressure.

Urgency

Urgency of urination is a sudden, strong desire to void. This symptom is usually attributed to an involuntary contraction of the detrusor muscle. Associated symptoms of urinary frequency are often attributable to lower-amplitude detrusor contractions occurring during bladder filling. When uninhibited detrusor activity occurs as a consequence of neurologic disease or injury, it is termed *detrusor hyperreflexia.* In the absence of neurologic disease, it is termed *detrusor instability.* It is a common feature of infravesical obstruction or inflammatory conditions of the bladder, but it is also commonly idiopathic in origin. Patients may prevent leakage and temporarily delay voiding by maintaining voluntary contraction of the external sphincter until the detrusor contraction has abated; however, urge incontinence is a regularly accompanying feature.

In patients with urgency, the urologist should look for evidence of irritative lesions of the lower urinary tract, intravesical obstruction, and neurologic disorders. Urinalysis is critical to look for pyuria and bacteriuria, which may indicate an infection, or hematuria, which might indicate a malignancy or stone. Similarly, an ultrasound or catheterized postvoid residual can rule out outflow incontinence and urgency in these patients.

Diminished Urine Flow

The determinants of urine flow during voiding are detrusor contraction strength, any contribution of abdominal straining, and infravesical resistance to urine flow. Although commonly referred to as *obstructive symptoms,* hesitancy, diminished or interrupted stream, need to strain, postvoid dribbling, and a sensation of incomplete emptying may occur with either impaired detrusor function or infravesical obstruction. There are many causes of detrusor hypocontractility. It may be idiopathic. It can also occur as a result of central nervous system disease (e.g., Parkinson's), peripheral neuropathy (e.g., diabetes mellitus), chronic overdistention, or longstanding infravesical obstruction. Infravesical obstruction, although uncommon in women, may occur with a large cystocele or tight urethral stricture. These are usually evident on physical examination. Among the causes of infravesical obstruction in men, bladder neck obstruction from benign prostatic hyperplasia is the most common. Although the constellation of irritative and obstructive voiding symptoms in men has generally been attributed to benign prostatic hyperplasia (BPH), a common diagnostic challenge is posed by men with obstructive symptoms in whom detrusor hypocontractility or infravesical obstruction may coexist. Measures used to assess the relative contribution of each factor include endoscopic evaluation of the urethra and bladder neck for visual evidence of obstruction and urodynamic pressure-flow studies to measure detrusor pressure and urine flow during voiding.

The American Urological Association (AUA) symptom index (Fig. 2.2) is a widely used measure to quantify irritative and obstructive symptoms in men. This measure is not specific for obstruction, and because a number of studies have shown that BPH or bladder obstruction is often not the cause of bladder symptoms (3,8,29,37), obstructive and irritative voiding symptoms are now commonly described by the nonbiased term *lower urinary tract symptoms* (LUTS) (1).

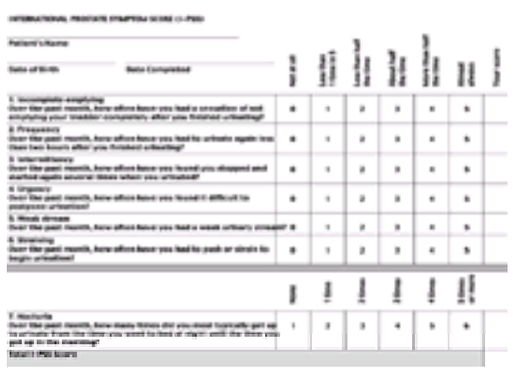

FIGURE 2.2. The AUA symptom index.

Urinary Retention

The patient with *acute* urinary retention typically experiences distress with an uncomfortably distended bladder and the inability to void more than small volumes of urine. Catheter drainage brings prompt symptomatic relief. Symptoms of patients with *chronic* retention usually include frequency, weak urine flow, and a sensation of incomplete emptying. Patients may experience the frequent leakage typical of overflow incontinence. The serum creatinine may be increased as a result of obstructive nephropathy. Generally, these patients experience little discomfort from their distended bladder, even though the residual urine volumes obtained by catheterization can be larger than those found in patients with acute urinary retention. Urinary retention, whether acute or chronic, can occur as a product of intravesical obstruction, impaired detrusor function, neurologic disease, or in rare cases, psychogenic causes. The role of the urologist is to provide bladder decompression and to identify the underlying condition or precipitating events that contribute to retention. Particular attention should be paid in cases of young men and women of all ages to rule out an occult neurogenic cause.

Urinary Incontinence

Urinary incontinence is the *involuntary* loss of urine. Blandy (4) described it as follows: “There is almost no symptom more degrading or miserable than incontinence of urine: it inevitably brings, at any stage after early childhood, shame, stink, soreness, and ostracism.”

Mechanism

The diagnostic approach to the incontinent patient emphasizes a careful history that notes the frequency and pattern of leakage, recognizes significant associated voiding symptoms, and identifies pertinent associated medical conditions. A careful physical examination and postvoid residual urine volume determination are essential.

Normal bladder function embraces two distinct activities: urine storage and urine evacuation. Incontinence may result from a problem with the urine storage phase because of an abnormal increase in bladder pressure during filling or because of a defective urinary sphincter mechanism. Alternatively, incontinence may result from a problem with the evacuation phase that prevents adequate emptying of the bladder. The classic forms of urge, stress, and overflow incontinence correspond neatly to this classification of incontinence mechanisms. Because most incontinent patients have one of these typical forms and a diagnosis usually can be made on the basis of history and physical examination alone, these types of incontinence are described in some detail. On evaluation, some patients are found to have atypical patterns of incontinence. These patients often have complex underlying mechanisms of voiding dysfunction and incontinence and may require more comprehensive urodynamic evaluation for accurate diagnosis.

Classification of Urinary Incontinence

Stress Incontinence

Women with stress incontinence have a characteristic history. They leak with coughing, sneezing, jogging, laughing, getting up from a chair, or engaging in other activities that cause a sudden rise in intraabdominal pressure. The normal mechanism to prevent leakage with straining depends on equal transmission of the increased pressure to the bladder and urethra. In women with the most common type of stress incontinence, a deficiency of pelvic support allows the urethra to herniate into the vagina (urethrocele). Less pressure is transmitted to the urethra than to the bladder, and the uncompensated rise in intraabdominal pressure results in leakage. The degree of leakage is proportional to the degree of straining. Characterized by leaking with minimal activities such as standing or walking, extremely severe stress incontinence is more likely the result of a deficiency in the intrinsic urethral sphincter mechanism rather than urethral hypermobility. Loss of the urethral sphincter function may occur with aging, from radiation therapy, from pelvic trauma, or from prior pelvic or antiincontinence surgery (5). The result is significant leakage with very small rises in intravesical pressure. Stress incontinence in the neurologically intact male without previous pelvic surgery is rare. Variable degrees of stress incontinence may be observed in men following prostatectomy; this incontinence is most often caused by deficient function of the intrinsic or extrinsic component of the distal urethral sphincter (30).

Overflow Incontinence

Overflow incontinence is distinguished by chronic failure of bladder emptying. This may occur with either intravesical obstruction or impaired detrusor function. Patients often have overt bladder decompensation with chronically high residual urine, often greater than 1,000 mL. The distended bladder is usually easily palpable and percussible in the lower abdomen. The intravesical pressure is consistently elevated, so slight increases in intraabdominal pressure may raise the intravesical pressure enough in women to overcome urethral resistance. Intermittent leakage may also occur because of uninhibited contractile activity in the stretched detrusor muscle. This is the mechanism of leakage in men with this form of urinary incontinence, most commonly seen with severe obstruction from BPH.

Urge Incontinence

Urge incontinence is an episodic form of urine leakage that occurs with involuntary contractions of the bladder detrusor muscle. The patient typically complains of a precipitous, unsuppressible urge to void. Patients may be able to forestall or minimize leakage for a brief period by contracting the external sphincter, but the typical patient experiences small- to large-volume leakage from what is essentially an involuntary voiding reflex. The most common cause is idiopathic detrusor instability. Specific causes also include inflammation adjacent to or in the bladder, longstanding intravesical obstruction, and varying forms of neurogenic bladder (detrusor hyperreflexia). Urge incontinence is particularly common in patients with a history of stroke and often occurs 3 to 6 months after the neurologic event. A careful history and 24-hour voiding diary usually reveal that episodes of leakage are most apt to occur with a full bladder, as a result of generous fluid intake, during periods of diuresis, or when regular toileting has been delayed. A cystometrogram may demonstrate uninhibited detrusor activity during filling. This can be useful in the cognitively impaired patient who cannot provide a useful history; however, the characteristic history provided by most patients makes this test superfluous.

Nocturnal Enuresis

Nocturnal enuresis is the repeated, involuntary loss of urine during sleep (17). If present since birth, it is termed *primary enuresis.* Bed-wetting spontaneously ceases with increasing age, being present in 15% of 5-year-old children, 5% of 10-year-old children, and 1% of 15-year-old children. If nocturnal enuresis follows a significant “dry” interval, it is termed *secondary enuresis.*

Etiology

Primary enuresis is caused by maturational lag of the central nervous system with delayed development of inhibitory control of the bladder. This delayed maturation theory is supported by the following findings in enuretics: (a) the high incidence of a spontaneous cure with time; (b) the presence of a bladder capacity smaller than that in normal children, with resultant increased frequency of voiding (Table 2.1 and Table 2.2); and (c) the documented hereditary aspect of enuresis. The evaluation of the child with uncomplicated primary nocturnal enuresis includes a physical examination, screening neurologic examination, urinalysis, and urine culture. If these are normal, reassurance and observation are indicated. In patients with a history of urinary infection or primary *diurnal* enuresis, evaluation should include an ultrasound of the bladder and kidneys to rule out obstruction.

TABLE 2.2. FREQUENCY OF VOIDING IN 24 HOURS

Secondary enuresis often occurs in association with emotional stress in the child's life, and a diligent search should be made for contributing emotional factors. Examples are a disruption of the family by divorce or the birth of a sibling. Other causes for secondary enuresis include neurologic disease and obstruction. Therefore the evaluation of the child with secondary enuresis should include a careful physical examination, screening neurologic examination, radiographs of the lumbosacral spine to detect vertebral abnormalities, urinalysis and culture, and an ultrasound of the bladder and kidneys.

Hematuria

Hematuria is a dramatic indicator of disease in the urinary tract, yet it is often ignored by patients and physicians alike. The passage of blood-stained urine may be the first sign of serious disease in the urinary tract, and a single episode of hematuria warrants a thorough urologic investigation.

Classification

It is helpful clinically to classify hematuria in two ways: first by quantity and second by the time of its appearance during voiding. Quantitatively, it is called *microscopic hematuria* if demonstrable only under the microscope and *gross hematuria* if it is evident to the naked eye. Microscopic hematuria is more commonly nephrologic in origin, whereas gross hematuria is more commonly urologic in origin. Blood noted chiefly at the beginning of urination is called *initial hematuria,* and it indicates disease in the urethra. Similarly, blood noted only between voidings or as stains on underclothing or pajamas, while the voided urine is clear, indicates disease at the urethral meatus or in the anterior urethra. Blood noted chiefly at the end of urination is called *terminal hematuria,* and it indicates disease near the bladder neck or in the prostatic urethra. Uniformly bloody urine, *total hematuria,* occurs with disease in the bladder, ureters, or kidneys.

Significance

The significance of hematuria varies with the age of the patient (Table 2.3). Gross painless hematuria is often the first manifestation of a urinary tract tumor. The episodic nature of the bleeding and the absence of other symptoms should not lull either the patient or physician into a false sense of security. In one review of 1,000 patients with gross hematuria (19), tumors were found in 21.5%. Two-thirds of these were bladder tumors.

TABLE 2.3. THE MOST COMMON CAUSES OF HEMATURIA BY AGE AND SEX

Microscopic hematuria may also signal the presence of a tumor. Although evaluation of 500 patients with asymptomatic microscopic hematuria revealed tumors in only 2.2% (15), a more recent study from the same institution evaluating 200 consecutive patients with asymptomatic microscopic hematuria found tumors in 12.5% (7). This figure reflects the newer diagnostic modalities available today, particularly urine cytology.

The other common urologic causes of hematuria are infection and stones. Less common causes include BPH, trauma, sickle cell disease or trait, tuberculosis, renal infarction, renal vein thrombosis, coagulation and platelet deficiencies, exercise-related causes (e.g., jogging), hypercalciuria, and vasculitis.

Diagnostic Approach

After a careful history and physical examination, the fundamental means of diagnosis are urinalysis, cytologic examination of the urine, intravenous urography, and cystoscopy. For gross hematuria, cystoscopy at the time of bleeding can be helpful in localizing the bleeding to the left or right upper urinary tract. After these fundamental studies have been completed, the diagnosis is apparent in approximately 75% of cases. For the remaining 25% with unexplained hematuria, further investigation can then be carried out with retrograde pyelography, ureteroscopy, and computed tomography (CT). Although hematuria cannot occur without a cause, in 5% to 10% of cases, no definite cause can be found (10).

Pain

Mechanism

The chief cause of pain in the urinary tract is distention from increased intraluminal pressure. The severity of the pain is not primarily related to the degree of distention but to the rapidity with which it develops. Gradual distention of the ureter, renal pelvis, or calyces may cause little or no pain. When intrapelvic pressures have been measured in patients with an acutely obstructing ureteral calculus, the higher the pressure, the more severe the pain. With longstanding obstruction, distention may be marked, but the pressure in the renal pelvis is normal or only minimally elevated and the patient experiences little or no pain. The concept that pain from obstruction is related to increased intraluminal pressure and distention is extremely useful clinically. Urologists are often asked to evaluate patients with pain in the back, flank, or abdomen. When an intravenous urogram at the time of a pain episode is normal with no dilation of the ureter, pelvis, or calyces and no delay of the nephrogram or excretory phase, one can state with confidence that pain is not caused by obstruction. Two other causes of renal pain are distention of the renal capsule and acute renal ischemia. Both produce steady, usually mild pain in the costovertebral angle region.

Type and Location

Pain caused by distention may be steady or intermittent. Intermittent pain, particularly when it is severe, is often termed *renal colic* and is most commonly caused by an obstructing stone in the lower ureter. With each peristaltic wave, more urine is pumped into the obstructed portion of the ureter, with a resultant increase in the hydrostatic intraluminal pressure and pain intensity.

Steady pain, most typical of distention of the renal capsule and acute renal ischemia, also occurs in up to 50% of patients with distention of the ureter, renal pelvis, or calyces. The constant level of pain with obstruction and distention is thought to reflect an absence of ureteral pressure waves.

The distribution of urinary tract pain has been carefully mapped out by distending the renal pelvis and various portions of the ureter with small balloon catheters (24). The location of renal and ureteral pain is shown in Fig. 2.3.

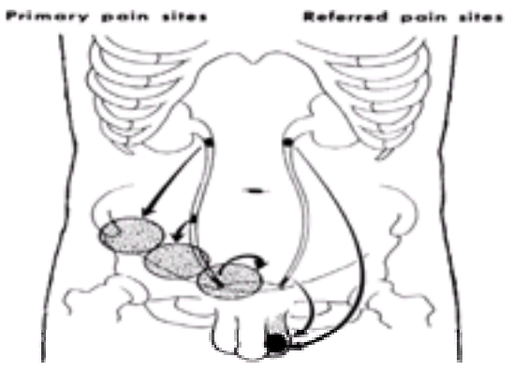

FIGURE 2.3. Sites of urologic pain. (Reprinted with permission from Wyker A, Gillenwater JY. *Method of urology.* Baltimore: Williams & Wilkins, 1975.)

Urinary tract pain does not occur in the central portion of the abdomen but is lateralized to the outer abdomen, flank, and costovertebral angle region. Ureteral pain follows a line along the lateral edge of the rectus muscle (Table 2.4).

Site of Balloon Distention	Site of Uretral Pain
Renal pelvis	Costovertebral angle
Upper ureter	Flank
Middle ureter	Middle inguinal canal
Lower ureter	Suprapubic area

TABLE 2.4. SITES OF URINARY TRACT PAIN

Pain Pathways and Referred Pain

Kidney and ureter pain impulses are carried in afferent fibers that accompany the sympathetic nerves and enter the spinal cord by means of the posterior spinal roots. Renal and ureteral pain can be abolished by sympathectomy of T-7 to L-3 or by sectioning posterior spinal roots T-11 and T-12 and L-1 and L-2.

Referred pain is pain projected to an area distant from the point of stimulation. It may occur in addition to or in the absence of true visceral pain. The exact mechanism of referred pain is unknown, but the site of painful stimulus and the site of referred painful sensation usually share a common segmental innervation. Spinal cord segments T-11 and T-12 receive sensory fibers from both the upper ureter and testis, so distention of the upper ureter may cause referred pain to the ipsilateral testis. In similar manner, distention of the lower ureter may cause referred pain to the ipsilateral scrotum.

Pain in the Lower Urinary Tract

Bladder distention initially causes fullness and then pain in the suprapubic region and end of the penis associated with an intense desire to void (urgency). Normal bladder mucosa is sensitive to stimuli, and this sensitivity is greatly increased by inflammation. Suprapubic discomfort is typical. Stimulation of the trigone, ureteral orifices, or anterior urethra causes referred pain to the end of the penis. Pain from prostatic inflammation is usually described as perineal discomfort, which may radiate to the inguinal regions and lower back. Acute testicular pain such as that with trauma, torsion, or epididymo-orchitis often radiates to the groin.

Pain on Urination

Pain on urination is usually caused by inflammation of the lower urinary tract. Patients may localize their discomfort to the suprapubic area or to the end of the penis or urethra. Milder degrees of pain are often described as a burning sensation. The most common cause is bacterial infection. Other causes include nonbacterial cystitis, cancer, stone or foreign body in the bladder or urethra, and excess phosphates in the urine (phosphaturia).

It is important to determine when pain or burning is noted during urination. If it begins with the onset and stops abruptly at the end, the primary pathology is probably in the urethra. When the bladder is primarily involved, as in acute bacterial cystitis, patients experience some discomfort during urination, but often the most severe pain occurs after voiding has ceased.

Chronic Pelvic Pain

Chronic pelvic pain syndrome (CPPS) is a more accurate subclassification of prostatitis and prostatodynia developed in 1995. The National Institutes of Health (NIH) prostatitis classification system is based on the presence of acute and chronic bacterial prostatitis and the presence of white blood cells (WBCs) in the expressed prostatic secretions (EPS) (28). Patients typically have any combination of perineal, penile, testicular, or low back pain. The classification is based on the following culture and EPS data. *Type I* refers to patients with acute bacterial prostatitis, as documented by culture. *Type II* refers to patients with chronic bacterial prostatitis as documented by culture of the EPS. *Type IIIa* refers to patients with CPPS, more than 10 WBCs per high-power field (HPF) (400×) in their EPS, and negative cultures. *Type IIIb* refers to patients with CPPS, no inflammation in their EPS (fewer than 10 WBCs), and negative cultures. *Type IV* refers to patients with asymptomatic inflammatory prostatitis (patients without CPPS who are found incidentally to have more than 10 WBCs per HPF in their EPS). The cause of CPPS, especially type IIIa, remains elusive, although oxidative stress (32) and cytokines (2,16,26) may play an important role. Treatment at this time is most successful with biofeedback (9) and nonsteroidal antiinflammatory medications. The NIH Chronic Prostatitis Symptom Index (NIH-CPSI) is a nine-part questionnaire developed and validated to quantitate the pain of urinary symptoms and effect that CPPS has on the quality of life in these patients (21). This questionnaire, similar to the AUA symptom index, is an important step for the practicing clinician to initially evaluate the patient and record the efficacy of the aforementioned treatments.

Sexual Dysfunction

Normal sexual function is difficult to define because of significant individual variation and the prevalence of age-related changes. However, most of these patients complain of diminished libido, erectile dysfunction, or both. Diminished libido may occur with acute and chronic illness or with psychologic or emotional stresses, and the existence of possible causative factors should be sought in the patient's history. The most common organic basis for diminished libido, a disturbance of the pituitary-gonadal hormonal axis, is evaluated by examining for evidence of hyperestrinism or hypogonadism (gynecomastia, decreased testicular volume) and obtaining a morning sample of serum testosterone. If the testosterone value is below the normal range, a free and total testosterone is repeated, along with measurements of follicle-stimulating hormone, luteinizing hormone, and prolactin. Hypergonadotropic hypogonadism (low testosterone, increased luteinizing hormone) is usually idiopathic, and pharmacologic testosterone supplement may yield a beneficial effect. Patients with hypogonadotropic hypogonadism (low testosterone, low luteinizing hormone) or with other evidence of pituitary endocrinopathy (elevated prolactin) merit a complete endocrine evaluation to rule out a hypothalamic or pituitary defect.

Erectile dysfunction, generally defined as failure to achieve and maintain an erection satisfactory for intercourse, is the most common complaint. The incidence increases with age, such that nearly 25% of men at age 65 are affected. There are many potential causes, and a careful history provides essential clues to the

diagnosis. The manner of onset of erectile dysfunction, the degree of difficulty in attaining erection during masturbation versus with a sexual partner, a progression in the degree of dysfunction over time, and the presence or absence of nocturnal erections often distinguish an organic versus a psychogenic etiology. Typically, an organic etiology shows a gradual onset with progressive dysfunction over time, equal difficulty with a partner or during masturbation, and a loss of nocturnal erection. Psychogenic impotence more typically shows an abrupt or stuttering pattern of erectile dysfunction without a gradually progressive pattern, a situational pattern of erectile dysfunction, or maintenance of nocturnal erections.

Medical conditions contributing to erectile dysfunction include diabetes mellitus, neurologic disease, hypertension, hypercholesterolemia, peripheral vascular disease, a heavy smoking history, and some medications (e.g., antihypertensives). Psychologic factors that can contribute to erectile dysfunction include strained emotional relationships, performance anxiety, and unresolved inner conflicts associated with sexual behavior.

An occasional patient will report absence of emission. This may occur with autonomic denervation of the accessory sex organs as a complication of retroperitoneal surgery or longstanding diabetes mellitus, incompetency of the bladder neck following surgery, or diminished ejaculate volume from hypogonadism. The complaint of penile curvature and pain with erection (Peyronie's disease) is typically due to the presence of a fibrous plaque between the tunica albuginea and corpus cavernosum. It is usually palpable at the site of curvature reported by the patient.

Fever

To the urologist, as to most physicians, fever suggests the presence of infection. The most common cause is an acute urinary tract infection where significant temperature elevation is usually taken to indicate upper tract involvement. High spiking temperatures with shaking chills and systemic signs of sepsis should prompt radiographic imaging, usually with CT or ultrasound, to rule out upper tract obstruction. Infection with obstruction is a urologic emergency. Prompt drainage with a ureteral stent or percutaneous nephrostomy tube is essential to avert sepsis and allow effective antimicrobial treatment.

Occasionally, a patient will have an obstructing stone and a low-grade fever. A small amount of urinary extravasation from the renal pelvis, which can occur with acute ureteral obstruction, may produce a low-grade fever. In men lacking bacteriuria on urinalysis, high spiking fevers, and other signs of infection, empiric antibiotic coverage with close observation is reasonable. In women, the incidence of asymptomatic bacteriuria is more common and the possibility of infection above the point of obstruction considerably greater. The risks and benefits of prompt intervention to relieve obstruction versus antimicrobial coverage and observation must be considered on a case-by-case basis.

Acute bacterial prostatitis usually manifests as an acute febrile illness characterized by perineal discomfort, urinary frequency, hesitancy, diminished force of stream, and dysuria. Urinalysis usually reveals pyuria, and examination reveals a markedly tender, boggy prostate. Acute bacterial prostatitis or prostatic abscess may also occur in hospitalized patients with indwelling Foley catheters and should be considered as an occult source of fever and bacteremia. Physical examination is usually sufficient for diagnosis but may be aided by the use of transrectal ultrasound or CT to document a prostatic abscess. Prostate-specific antigen (PSA) determination often reveals significant elevation as a result of the acute or chronic inflammatory prostatic process (26).

Epididymitis with scrotal pain and swelling may be accompanied by fever. In men younger than 35 years of age, epididymitis can be caused by sexually transmitted diseases such as gonorrhea or *Chlamydia.* In older patients and in patients with recent instrumentation, it is more likely due to urinary pathogens.

Renal Insufficiency

The urologist is often asked to evaluate patients with renal insufficiency for potentially reversible causes of renal dysfunction. Renal ultrasound is the best screening test for obstruction because it is neither nephrotoxic nor invasive and is very sensitive for detecting hydronephrosis associated with obstruction. When obstruction is the *sole* cause of renal insufficiency in a patient with two kidneys, it must be bilateral. Supravesical causes include conditions such as pelvic malignancy and retroperitoneal fibrosis causing bilateral ureteral obstruction, as well as obstructive processes (e.g., stone disease) affecting each unit independently. More commonly, bilateral hydronephrosis is seen with conditions affecting bladder function. These conditions include increased intravesical filling pressures from uninhibited detrusor contractions or diminished compliance, neurogenic bladder dysfunction, or severe outlet obstruction with failure to empty and elevated postvoid residual urine volumes. Therefore the screening evaluation for obstruction in the patient with renal insufficiency includes a postvoid residual determination by ultrasound or catheterization. Unilateral obstruction may contribute to renal insufficiency when only one kidney is present or when the normal compensatory response of the contralateral kidney is prevented by preexisting impairment of renal function. Clues to this possibility may be provided by a renal ultrasound showing a small (atrophic) contralateral kidney or one with echo-texture changes consistent with chronic intrinsic renal disease.

A renovascular cause of diminished renal function is another potentially reversible condition that the urologist may identify. It should be considered when there is no evidence of obstruction, no history or findings on urinalysis to support either acute or chronic intrinsic renal disease, or a history of conditions predisposing to vascular disease, such as hypertension, hypercholesterolemia, or diabetes mellitus, is present.

Medical History

Any urologic complaint must be framed in the context of the patient's medical history. In addition to inquiring about all previous genitourinary conditions or surgeries, the urologist must identify past or current disorders with potential effects on the genitourinary system (e.g., tuberculosis, diabetes mellitus). Each specific finding (e.g., microscopic hematuria) also prompts a search for pertinent conditions (e.g., sickle cell trait). The family history may be significant for genetic syndromes associated with urologic manifestations (autosomal-dominant polycystic kidney disease, Alport's syndrome, von Hippel–Lindau disease, tuberous sclerosis), as well as for diseases with known familial associations (stone disease, prostate cancer).

PHYSICAL EXAMINATION

Kidney

A kidney must be grossly enlarged or displaced to cause a perceptible bulge in the upper abdomen or flank. If a perinephric abscess is suspected, the patient should be in the knee–elbow position for an examination. The normal shallow depression below the lowermost rib may be obliterated by fullness and edema secondary to an underlying abscess.

Because of their location in the uppermost portion of the abdominal cavity, normal kidneys are usually not palpable. An exception is the newborn in whom both kidneys may be palpable during the first 48 hours of life because of the hypotonicity of all muscles. In approximately 10% of adults, usually thin women, the lower pole of the right kidney can be felt. Two maneuvers aid palpation: deep breathing and bimanual examination. The posterior hand lifts the soft tissue in the costovertebral angle, and the anterior hand presses deeply into the abdomen. The normal kidney is movable because it is fixed only by its vascular pedicle, and with deep inspiration, the descending diaphragm pushes the kidney down toward the examining fingers. The kidney is most easily felt between the fingers of both hands as a firm, smooth mass slipping upward as expiration starts. A renal mass is characteristically ballottable, unlike the liver and spleen, which usually can only be palpated with the anterior hand. Tenderness caused by inflammation in or around the kidney is best detected by exerting firm pressure in the costovertebral angle region.

In patients with hypertension, it is important to listen over the renal artery areas for the presence of a bruit. These murmurs are best heard anteriorly after complete exhalation.

Transillumination is occasionally helpful in newborns or small children with large, easily palpable abdominal masses. With the room as dark as possible, the mass should be manipulated against the abdominal wall with one hand while a high-intensity light (e.g., fiberoptic light cord) is firmly applied to the mass with the other hand. If the mass is cystic rather than solid, it will transilluminate, creating a reddish glow.

Ureter

In males, the ureter is not palpable by either abdominal or rectal examination, but in females, the lower ureter can be felt on vaginal examination. One or two fingers are gently pushed upward and outward, and at the limit of the fingertips, the ureter lies close to the bony pelvic wall and lateral to the ovary. From this point, the ureter can be followed to its junction with the bladder by carrying the fingers downward and inward. If the ureter is normal, it is usually not identifiable because it is soft and

nontender. If a stone is present, both the stone and ureter are usually palpable. The ureter can be felt as a tender tubular mass proximal to the stone.

Urinary Bladder

The normal empty or nearly empty bladder is neither palpable nor percussible because of its anatomic location in the pelvis. When it contains approximately 125 mL of urine, it rises out of the pelvis into the lower abdomen, projecting one fingerbreadth above the pubis. It rises progressively toward the umbilicus with further filling. If the bladder contains more than 500 mL of urine, it may be identifiable as a bulge in the middle lower abdomen. This swelling rising out of the pelvis is best appreciated by observing from the side, with the eyes more or less level with the lower abdomen. The distended bladder may be palpated as a firm, round, movable mass rising out of the pelvis into the lower abdomen. Whether or not a mass is palpable, the lower abdomen should be percussed from the umbilicus to the pubis. If the patient has a distended bladder, the normally resonant note is replaced by dullness. Percussion over a distended bladder may also cause the patient to experience a desire to void because of the sudden induced rise in intravesical pressure. An accurate measurement of bladder volume is obtained by catheter drainage or by bladder ultrasound.

To assess the extent of a bladder tumor, bimanual examination is performed when the patient is anesthetized and the bladder is empty. Intravesical masses are usually ballottable; fixation usually signifies gross perivesical extension.

Prostate and Seminal Vesicles

The prostate and seminal vesicles are palpated through the anterior rectal wall (Fig. 2.4). Rectal examination is best performed with the patient standing on the floor, knees slightly bent and elbows resting on the edge of the examining table. Bedridden patients are best examined in the lateral decubitus position, with their knees pulled up into their chest. The typical prostate is 4 cm wide, 2.5 to 3 cm high, and 4.5 cm long with a volume of 20 mL. Volume can be measured with the index finger, which is approximately 1.5 cm wide, or estimated based on the examiner's experience. Transrectal ultrasound with its accurate volume measurement allows the examiner a means to constantly evaluate his or her volume estimates. The normal gland is smooth, slightly movable, and nontender, and it has a rubbery consistency. Two distinct lobes can be felt separated by a median furrow with distinct lateral sulci. Indurated areas and nodules should be noted and a biopsy performed if appropriate. If the physician's finger is long enough, he or she may be able to feel the soft, tubular seminal vesicles above the prostate. Coming off the base of the prostate somewhat obliquely, they are most easily felt when they are distended or tender. EPS for microscopic examination can be obtained from most patients by deliberately massaging each prostate lobe in a lateral to medial direction.

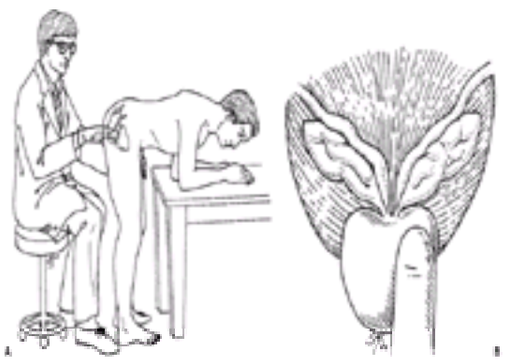

FIGURE 2.4. Palpation of the prostate and seminal vesicles. **A:** The prostate is best examined with the patient standing, knees slightly bent and elbows resting on the edge of the examining table. **B:** The examiner's index finger can be used to estimate the size of the prostate. (Reprinted with permission from Wyker A, Gillenwater JY. *Method of urology.* Baltimore: Williams & Wilkins, 1975.)

Scrotum and Testes

After the scrotal skin and perineum are inspected, the testes and epididymides should be palpated between the thumb and finger. The comma-shaped epididymis is closely attached to the posterolateral side of the testis. The physician can get his or her fingers into the groove between the epididymis and testis everywhere except superiorly, where the two structures are anatomically joined. In many men, a small ovoid lump, the rudimentary appendix testis, can be felt in or near the groove between the upper pole of the testis and the epididymis. The cord structures at the neck of the scrotum should be sifted through the physician's fingers. The solid cordlike vas is easily identified and followed to its junction with the tail of the epididymis. The other soft, stringy structures in the cord cannot be defined. To rule out the presence of the gravity-dependent varicocele, the cord must also be examined with the patient standing. If a varicocele is present, the intrascrotal varicosities secondary to valvular incompetence of the internal spermatic vein become distended in the upright position and feel like a bag of worms. Varicoceles tend to be left sided or bilateral due to the longer left gonadal vein attaching to the left renal vein. A solitary right-sided varicocele should alert the examiner to the risk of a retroperitoneal process.

Penis

If the patient is uncircumcised, the foreskin should be retracted to rule out phimosis with an obstructing, small aperture. To inspect the urethral meatus, the examiner must pinch the glans between the thumb and finger placed at the 6 and 12 o'clock positions. If the urethral meatus is not in the normal location, it can be found by following the midline raphe to its end on the undersurface of the penis. The shaft of the penis is palpated, looking particularly for the firm, fibrous plaques of Peyronie's disease. The floor of the urethra from the corona to the bulb should be palpated, looking for induration secondary to a stricture.

Pelvic Examination

Complete urologic examination of a woman includes a pelvic examination performed with the patient in lithotomy position. The vestibule and introitus are examined for evidence of mucosal atrophy, inflammation, or discharge. Any abnormal discharge is sampled for microscopic examination. The urethral meatus is examined and the urethra palpated for a mass or tenderness. Caruncle, a common benign finding in older women, is often seen as a purplish mass on the inferior aspect of the meatus. Calibration of the urethra is sometimes done to rule out urethral stenosis but is not a routine practice. Examination of the vaginal vault for cystocele, enterocele, or rectocele is performed in the course of a speculum examination of the cervix. Bimanual examination is carried out to identify any pelvic mass or tenderness.

URINALYSIS

A standard urinalysis consists of the following: determination of the physical characteristics of the urine, dipstick chemical tests, and microscopic examination of the urinary sediment. This key examination should not be delegated to uninterested laboratory personnel but should be performed by the physician. For reliable urinalyses, the urine must be collected properly and examined promptly.

Collection of the Urine Specimens

Of necessity, most urinalyses are performed on a random specimen freshly voided by the patient. However, the most information can be obtained if a first-morning specimen is examined. It is the best one for detecting formed elements in the urine and for determining whether urinary infection is present. The formed elements—red blood cells (RBCs), WBCs, and casts—are preserved in this characteristically acid and concentrated urine, whereas they may be lysed and disappear in dilute or alkaline urine. Bacterial colony counts are usually highest in this specimen because the bacteria have had more time to multiply during overnight incubation in the bladder.

For women, a voided sample is obtained by a clean-catch collection. The adequacy of the specimen for bacteriologic study depends on adequate cleansing with water of the periurethral areas to remove colonizing bacteria; avoiding bactericidal soap, which could produce a false-negative culture; and separation of the labia during collection. Only the midportion of the voided specimen should be collected. Urethral catheterization is performed when the patient is unable to perform the midstream

collection properly because of handicap or body habitus, when microscopic examination of the voided specimen shows evidence of contamination by abundant squamous cells or mixed bacterial flora, or when previous culture of a voided specimen was positive for multiple organisms. The relatively minor drawbacks to urethral catheterization are the discomfort of the catheterization procedure itself and the potential for iatrogenic infection in up to 2% of patients from bacteria introduced into the bladder during the catheterization procedure.

For men, examination of the midstream urine (voided bladder 2) is the minimum urine examination, but the four-glass urine collection technique allows for the most thorough examination of the urine and prostate fluid. Stamey, Govan, and Palmer (33) originally described the four-glass urine collection technique as a method to distinguish urethral, bladder, and prostate infection in men. This technique was later modified by Meares and Stamey to include the EPS and is regarded as the gold standard for the evaluation of the lower urinary tract in males (25). The technique provides samples for both microscopic analysis and bacterial culture, allowing for a quantitative assessment of the urine for leukocytes, erythrocytes, macrophages, and bacteria (27). General practice is for circumcised men to void into sterile containers, being careful not to touch their glans penis or hands to the inside of the container, which could introduce bacteria that typically colonize the skin. There is some debate among urologists whether cleansing the glans penis with an alcohol pad or bactericidal soap is necessary in circumcised men, but it is the authors' practice not to do so. However, uncircumcised men should retract the foreskin and clean the glans penis with an alcohol pad or bactericidal soap before providing a four-glass urine sample (27).

Voided Bladder 1

The voided bladder 1 (VB1) specimen should include the first 10 mL of urine. The VB1 represents the urethral cells and bacteria, which are washed out with the first 10 mL of urine. This specimen is important in the diagnosis of urethritis (27).

Voided Bladder 2

The voided bladder 2 (VB2) specimen represents the bladder urine. It should be collected from a midstream urine specimen by placing the sterile specimen container into the urine stream after voiding 100 to 200 mL (27).

Expressed Prostatic Secretions

The EPS should be collected into a sterile container while the examiner digitally massages the prostate. The uncircumcised patient should hold back his foreskin, and the examiner should be careful not to contaminate the sterile container by touching the patient's penis to it. Even with vigorous massage, the EPS may be unobtainable owing to anxiety and guarding on the part of the patient. Often, if the patient is left alone in a quiet room, he can relax his external sphincter and consequently “milk” his urethra manually and collect a drop or two of EPS for examination. The EPS should be examined at high power (400×) for leukocytes, erythrocytes, macrophages, RBCs, fat bodies, and bacteria (27).

Voided Bladder 3

The voided bladder 3 (VB3) specimen is another method to examine the EPS. It represents the first 10 mL of urine voided after massaging the prostate and includes any EPS that may be trapped in the prostatic urethra. It allows for the examination of the EPS when a drop of fluid is unobtainable by digital massage. No longer than 30 minutes should elapse after a prostatic massage to collect this specimen. The VB1, VB2, and VB3 specimens should be centrifuged for 5 minutes and the sediment examined at high power (400×) for leukocytes, macrophages, erythrocytes, bacteria, and fungal hyphae, with their numbers recorded. The VB1, VB2, EPS, and VB3 specimens should then be immediately plated and cultured or temporarily stored in a refrigerator at 4°C, until they can be cultured later that day (27).

For infants and small children, strap-on collection devices are used to collect specimens for routine analysis. However, these specimens are often unsatisfactory for culture, and specimens for culture are most often obtained by catheterization with a well-lubricated 5-Fr feeding tube. Suprapubic aspiration may be performed in small infants. Although this has the best reliability in terms of specimens for bacteriologic study, it is not practical for routine use.

Urine should be examined within 30 minutes of collection. If it is allowed to stand, bacterial growth may alkalize the urine with resultant destruction of RBCs, WBCs, and casts. If the urine cannot be examined promptly, it should be refrigerated.

Physical Characteristics of Urine

Color

The color of normal urine is determined by the concentration of urochrome, an endogenously formed yellow-brown pigment excreted at a uniform rate. Because the amount of pigment excreted each hour is the same, the color of the urine varies directly with the urine output. With high urine flow rates, the urine is pale, almost water colored, whereas with low urine flow rates it is a deep yellow color. The appearance of an abnormal urine color may occur from a number of causes. Certain urinary pigments may impart a pink-to-red color to the urine, mimicking hematuria. These include anthocyanins in beets and berries (beeturia), phenolphthalein (present in some laxatives), vegetable dyes (used for food coloring), heavy concentration of urates, phenazopyridine (Pyridium), and *Serratia marcescens* infection in infants (red diaper syndrome). Myoglobinuria occurring as a result of muscle breakdown is also a cause of nonhematuric tea-colored urine. Characteristically, the urinary sediment shows no RBCs, but the dipstick test is positive.

Pneumaturia

Pneumaturia is the passage of gas in the urine and generally is caused by a fistula between the intestinal tract and the urinary tract. Because gas is lighter than water, it always rises to the top of the bladder and consequently is passed at the end of urination (terminal pneumaturia). This fistula may occur at any level, from the stomach to the rectum of the intestinal tract and from the kidney to the urethra of the urinary tract, but the large majority involve the bladder and the sigmoid colon or terminal ileum. The most common causes are diverticulitis of the sigmoid colon, carcinoma of the colon, and Crohn's disease.

Urinary tract infections caused by gas-forming bacteria and prior introduction of air into the bladder by means of insertion of a catheter or cystoscopy are occasional causes of pneumaturia.

Chyluria (Milky Urine)

Chyluria is the passage of lymph or chyle in the urine caused by the presence of an intrarenal, lymphatic-urinary fistula (11). The cause of this fistula is obstruction of the lymphatics superior to the kidney, usually the thoracic duct. With obstruction, there is increased back-pressure in the retroperitoneal and renal lymphatics, and eventually they rupture into a calyceal fornix. The most common cause of chyluria is filariasis resulting from *Wuchereria bancrofti.* The adult filarial worms invade the suprarenal lymphatics, causing obstruction and severe inflammation. Less common causes include posterior mediastinal and retroperitoneal tumors, tuberculosis, and trauma.

The passage of milky urine occurs intermittently, varying with the amount of fat ingested and sometimes with the patient's posture. Chylous urine contains fibrinogen, and fibrin clots may cause renal colic or urinary retention. The milky-colored appearance of the urine is usually diagnostic but may be confirmed by tests that confirm the presence of fat in the urine.

Clarity

Freshly voided urine is usually clear. Cloudiness of the urine is fairly common, however, and is usually caused by excessive amounts of crystals—amorphous phosphate in alkaline urine or amorphous urates in acid urine. This crystalluria is usually not clinically significant. The crystals can be dissolved, rendering the urine clear, by adding acid to dissolve the amorphous phosphates or by heating to dissolve the amorphous urates. Heavy pyuria, usually secondary to a bacterial infection, is a less common cause of cloudy urine.

Specific Gravity

The specific gravity of a solution is the measure of its density, an approximate measure of total solute concentration. The specific gravity of water is 1.000, plasma 1.010, and urine 1.003 to 1.040. Normally functioning kidneys conserve and excrete water as needed, accounting for the wide range of 1.003 to 1.040. Poorly functioning kidneys lose this ability, so urine specific gravity remains fixed at around plasma level (1.010).

Determination of the specific gravity of a random urine specimen is useful not only in assessing a patient's hydration status but also in interpreting the significance of dipstick chemical tests and urinary sediment findings. Substances such as WBCs, RBCs, and protein are generally excreted into the urine at a fairly constant rate. When the urine specific gravity is less than 1.007 as a result of a high urinary flow rate, the urine concentration of these elements may be significantly reduced. Also, in this hypotonic environment, RBCs are lysed, so patients with microhematuria may lack RBCs in the urinary sediment.

Chemical Tests

The standard urinalysis includes a dipstick assessment of nine different parameters. The pH, glucose, protein, ketone, bilirubin, and urobilinogen semiquantitative chemical tests provide the urologist with a powerful screening tool for metabolic abnormalities. The nitrite test serves as a screening for bacterial infection. Dipstick tests for blood and leukocyte esterase are commonly used in many settings as screens to determine the need for microscopic examination, but in the urologist's office, they are always used to complement the microscopic examination of the urinary sediment.

Urine pH varies between 5.0 and 8.0. It is usually more acidic in the early morning because of the excretion of a fixed acid load in the smaller volume of urine produced at night, and it is typically more alkaline after meals (alkaline tide). Specific medical conditions may be associated with characteristic changes in the range of urinary pH. Patients who form uric acid stones usually have a consistently acidic urine with a pH below 5.5. Patients with renal tubular acidosis type I (distal) are unable to acidify the urine below pH 5.5, even in the face of acid loading. This is in contrast to patients with type II renal tubular acidosis (proximal), who display the normal range of urinary pH (31). Alkaline urine above pH 8.0 is often associated with infection by urea-splitting organisms such as *Proteus.* Because leukocytes are lysed in very alkaline urine (above pH 8), it may sometimes be difficult to identify WBCs in the urinary sediment of patients with *Proteus* infection.

Detection of glucosuria by dipstick test indicates that the renal threshold for glucose reabsorption in the renal tubules (approximately 180 mg/dL) has been exceeded. This can occasionally be seen in normal patients, but most commonly, it is the result of hyperglycemia caused by diabetes mellitus. Although the semiquantitative dipstick test provides an approximate measure of the concentration of glucose in the urine, the clinician should realize that the degree of glucosuria is not necessarily an accurate indicator of the degree of hyperglycemia. Further medical evaluation and serum glucose determination are required. Elevated serum ketones, which may occur in diabetic ketoacidosis and in catabolic situations such as starvation, result in ketonuria detectable by the dipstick test.

The test for bilirubin will be positive when there are significant amounts of conjugated bilirubin filtered by the kidney and excreted in the urine. This is most commonly seen in liver disease and biliary obstruction. Urobilinogen, absorbed via the enterohepatic circulation, is normally present in small amounts in the urine. Increased levels are seen with hemolysis, gastrointestinal hemorrhage, and hepatocellular disease. Diminished levels may result from antibiotic suppression of the gut bacterial flora, and urobilinogen may disappear with complete biliary obstruction.

The dipstick test is the most commonly used screening test for urinary protein, detecting protein concentrations as low as 10 mg/dL. Normal supernatant urine usually gives a negative test for protein because the daily protein excretion of normal individuals is usually less than 50 mg.

Proteinuria is defined as the excretion of more than 150 mg of protein in 24 hours. The dipstick has a pH-sensitive indicator dye that changes color with various concentrations of protein. Although more sensitive to negatively charged protein (albumin) than to positively charged protein (Bence Jones), it does give a positive test when the concentration of Bence Jones protein is greater than 50 mg/dL. When the dipstick is positive, the 24-hour protein excretion in the urine should be determined by analysis of a timed 24-hour collection.

There are four types of proteinuria: glomerular, tubular, overflow, and functional. Glomerular is the most common form of proteinuria, found in patients with significant glomerular damage. A defect in the glomerular filter permits increased filtration of normal plasma proteins, and because albumin has the highest concentration in the plasma, glomerular proteinuria is predominantly an albuminuria. Massive proteinuria with excretion of 4 g/day or more is characteristic of the nephrotic syndrome.

Proteinuria secondary to tubular or interstitial disorders of the kidney occurs when the proximal tubules are unable to reabsorb the normally filtered proteins. In tubular proteinuria, one usually finds increased amounts of low-molecular-weight proteins smaller than albumin in the urine, and the total protein excretion is usually 1 to 2 g/day.

Overflow proteinuria is caused by the presence in plasma of abnormal quantities of low-molecular-weight proteins that are filtered across the normal glomerular capillary wall and saturate the proximal tubular resorptive mechanism. Examples include Bence Jones proteinuria, myoglobinuria, and hemoglobinuria. This is the least common type of proteinuria.

When proteinuria occurs in the absence of any clear-cut renal or systemic disease, it is termed *functional* or *physiologic proteinuria.* The mechanisms responsible for this type of proteinuria are unknown but are probably hemodynamic. Functional proteinurias are characteristically intermittent and mild, with protein excretion rarely exceeding 1 g/day. Clinical states that may cause this type of proteinuria include fever, exercise, emotional stress, and renal venous hypertension (congestive heart failure). Orthostatic (postural) proteinuria is a special form of functional proteinuria seen in healthy young adults. These individuals excrete protein in their urine in the upright position but excrete little or none on recumbency.

Urinary Sediment

Examination of the urinary sediment is performed on a centrifuged sample of urine. All specimens should be mixed thoroughly before a sample is taken because formed elements fall to the bottom during storage. Approximately 15 mL is centrifuged for 3 to 5 minutes, the supernatant removed, the pellet resuspended in the residual fluid, and a drop placed under a cover slip for examination. Before the specimen is examined, the pH and specific gravity of the urine should be noted because of their potential to influence stability of the formed elements such as WBCs and RBCs in the specimen.

White Blood Cells

Pyuria is increased WBC excretion in the urine (20,22) and may be detected by a dipstick test for leukocyte esterase or by counting the number of WBCs in the centrifuged, unstained urinary sediment. A WBC excretion rate of 400,000 WBCs per hour may be considered the upper limit of normal. If this excretion rate of 400,000 WBCs per hour is divided by the average urine output per hour of 50 mL, the upper limit of WBC concentration in the urine would be 8,000 WBCs/mL. This translates to urinary sediment findings of 4 to 5 WBCs per HPF, and for clinical purposes, pyuria may be defined as more than 5 WBCs per HPF. This method of quantitating pyuria is imprecise. Factors that may alter the microscopic findings significantly include presence or absence of contamination of the urine specimen, urine production rate at the time the urine specimen was obtained, and the specifics of preparing and examining the urinary sediment.

Leukocyte esterase, an isoenzyme specific for leukocytes, is the basis for the leukocyte esterase test strip. Both false-positive and false-negative results may occur, and the dipstick test is best combined with microscopic examination of the urinary sediment. When leukocytes are not seen despite a positive dipstick test in the setting of alkaline urine (pH greater than 8.0), such as might occur with *Proteus* infection, alkaline lysis of the leukocytes should be suspected.

Pyuria is the body's response to the inflammation of the urinary tract, but it is not a particularly sensitive sign of infection. Although most patients with acute bacterial infection such as cystitis have pyuria, significant bacteriuria may be present without pyuria. A urine culture is the only reliable means to diagnose infection. Pyuria is also not a specific sign of infection. Although many physicians equate the two (pyuria and urinary infection), this is a dangerous concept that can lead to patients being inappropriately treated for long periods with antibiotics for presumed infection. Pyuria has numerous causes, including tumors, stones, glomerulonephritis, foreign bodies, drugs (e.g., cyclophosphamide), fungal infection, and tuberculosis. When pyuria exists with a negative culture, a diligent search must be initiated to discover and treat the underlying cause.

Red Blood Cells

The average individual usually excretes approximately 30,000 RBCs per hour but may excrete up to 100,000 RBCs per hour. If the urine output is 50 mL/hour (1,200 mL/day), up to 2,000 RBCs/mL may be excreted, and this concentration of RBCs gives urine findings of 1 or fewer RBC per HPF. Greater than 1 RBC per HPF may be considered microscopic hematuria, but a commonly accepted benchmark for clinically significant hematuria is greater than 3 RBCs per HPF (23).

Osmotic Rupture of Red Blood Cells by Hypotonic Urine

The dipstick test for hematuria complements microscopic examination of the urinary sediment. RBCs are relatively resistant to alkaline lysis but are readily lysed in hypotonic urine. When the urine specific gravity is 1.007 or lower, the dipstick test will be positive even though no RBCs can be seen in the urinary sediment.

Urine containing 100,000 RBCs/mL with a urinary sediment finding of 30 RBCs per HPF was used as the standard in Table 2.5.

Urine Specific Gravity	RBCs/HPF	Dipstick	% Lysis
1.001	0	++++	100
1.005	0	++++	100
1.007	0	++++	100
1.010	30	+	0
1.015	30	+	0
1.020	30	+	0
1.025	30	+	0
1.028	30	+	0

RBCs/HPF, red blood cells per high-power field.

TABLE 2.5. OSMOTIC RUPTURE OF RED BLOOD CELLS BY HYPOTONIC URINE

It is clinically important to know whether the RBCs present in the urinary sediment are glomerular or nonglomerular in origin because glomerular RBCs are diagnostic of glomerulonephritis. Two findings identify the glomeruli as the source of the RBCs: dysmorphic RBCs and RBC casts. Fairley and Birch (13) and Fassett and associates (14) used a phase microscope to study RBC morphology and reported that these dysmorphic RBCs were characteristic of glomerular bleeding. The marked RBC membrane distortions are thought to be caused by osmotic and physical changes during the passage of RBCs through the nephron. These findings have been confirmed by others. Stamey and Kindrachuk (34), in their excellent manual, showed many fine photographs contrasting dysmorphic RBCs of glomerular origin with RBCs of nonglomerular origin (Fig. 2.5). They also demonstrated that these dysmorphic RBCs could be identified under standard light microscopy, as well as phase-contrast microscopy.

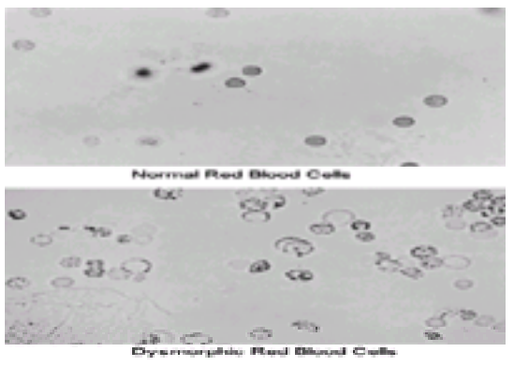

FIGURE 2.5. Normal and dysmorphic red blood cells. (Reprinted with permission from Stamey TA, Kindrachuk RW. *Urinary sediment and urinalysis: a practical guide for the health science professional.* Philadelphia: WB Saunders, 1985.)

Casts

The basic foundation of all renal casts is a special protein, Tamm-Horsfall globulin, secreted by the tubular epithelial cells. A small number of these basic hyaline casts are excreted normally, so their presence in the urinary sediment is not clinically significant. If RBCs, WBCs, or sloughed tubular epithelial cells are present in the renal tubular lumina, they may become incorporated within the cast. If these casts are detected in the urinary sediment, the presence of renal disease should be suspected. Because Tamm-Horsfall protein is soluble at a pH of 7.1 or higher, *all* casts disappear in alkaline urine.

Bacteria

Nitrite is a product of bacterial metabolism in many species of Gram-negative bacteria, and its presence in the urine is a strong indicator of significant bacteriuria. The false-positive rate for the dipstick test is low, and it may reliably be used as the basis for empiric antibiotic therapy pending results of culture and sensitivity. The more significant false-negative rate of the dipstick test, even in the presence of bacteriuria, can be due to a number of factors, including the presence of non–nitrite-producing organisms or very dilute urine. Urine culture is the only reliable means to exclude bacteriuria.

On microscopic examination, an effort should be made to detect bacteria because more than ten bacteria per HPF usually signifies greater than 10^5 colony-forming units (cfu) per milliliter (18). The morphology of any observed bacteria should be noted. A polymicrobial appearance or the presence of filamentous bacilli characteristic of lactobacillus in a woman's voided specimen strongly suggests contamination by vaginal or periurethral flora. In patients to be treated for suspected urinary tract infection, the identification of rods, streptococci (enterococci), or cocci (staphylococci) in the urine may guide the selection of antibiotic therapy. The presence of fungal elements or trichomonads should likewise be noted.

Because the most common uropathogens are aerobic species (Gram-negative rods, enterococci, and staphylococci), the standard urine culture is a test for aerobic organisms. A positive culture result is generally considered to be greater than 10^5 cfu/mL on a voided specimen, but as few as 10^3 cfu/mL may represent significant bacteriuria if the specimen is obtained in sterile fashion (e.g., catheterization). Similarly, localizing quantitative cultures on split-voiding fractions may reveal low-level bacteriuria in one fraction (e.g., VB3) that is nonetheless significantly greater than the other fractions, thereby showing bacterial infestation in the source of that fraction (e.g., prostate). Less commonly, fungi or microbacteria may be the cause of urinary tract infection. Fungi may grow on routine culture media with prolonged incubation; however, if fungal infection is suspected, the fungal culture should be specifically requested. Sterile pyuria with or without microscopic hematuria is a cardinal feature of genitourinary tuberculosis. Diagnosis is made by submitting at least three morning urine specimens to be examined for acid-fast bacteria and cultured for acid-fast bacteria for up to 8 weeks.

Indications for Excretory Urography

Chapter References

Excretory urography remains a basic radiologic examination of the urinary tract and is the foundation for the evaluation of suspected urologic disease. Despite development of the newer diagnostic modalities, such as isotope scanning, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI), excretory urography has maintained a prominent role in uroradiology. Some indications have been altered and will continue to change with the newer imaging modalities. Noncontrast spiral CT has become the study of choice for suspected ureteral stones (88). The initial evaluation of suspected urinary tract structural abnormalities, hematuria, pyuria, and renal calculus disease is performed with excretory urography. The examination is relatively inexpensive and simple to perform, with few contraindications.

When properly performed, excretory urography can provide valuable information about the renal parenchyma, pelvicalyceal system, ureters, and urinary bladder. Diagnostic results depend largely on the method by which excretory urography is performed. A closely monitored examination with specific radiographs determined by the needs of a patient provides the optimal examination. A study using only predetermined radiographs that are reviewed at a later time often provides inadequate diagnostic information. During urography, each radiograph should be evaluated immediately after it is obtained to determine which questions have been answered and which have not. Any necessary additional radiographs can then be obtained.

It is reasonable to have certain standard radiographs obtained in the immediate postinjection phase of a urogram. Further radiographs, however, should be determined on the basis of initial findings and not limited to a preset series.

CONTRAST MEDIA

Chemical Properties and Excretion

The first compounds introduced for clinical use in excretory urography during the early 1930s were diiodinated compounds that were hampered by low radiopacity and moderate toxicity. More often than not, retrograde pyelography was necessary to evaluate the urinary tract properly. The ability to achieve adequate opacification of the pelvicalyceal system and the renal parenchyma resulted from the introduction of the triiodinated benzoic acid derivatives in the early 1950s. Since then, several salts of triiodinated benzoic acid compound have been marketed for excretory urography with slight structural differences but similar physiologic and radiographic properties (Table 3A.1 and Fig. 3A.1).

Trade Name	Generic Name	Concentration (%)	Osmolality (mOsm/kg)	Iodine Content (mg/mL)
Renografin-60	Meglumine and sodium diatrizoate	60	1,400	280
Reno-M-60	Meglumine diatrizoate	60	1,500	282
Hypaque-50	Sodium diatrizoate	50	1,550	300
Hypaque-M-60	Meglumine diatrizoate	60	1,415	282
Conray-60	Meglumine iothalamate	60	1,400	282

TABLE 3A.1. COMMONLY USED IONIC CONTRAST MEDIA FOR EXCRETORY UROGRAPHY

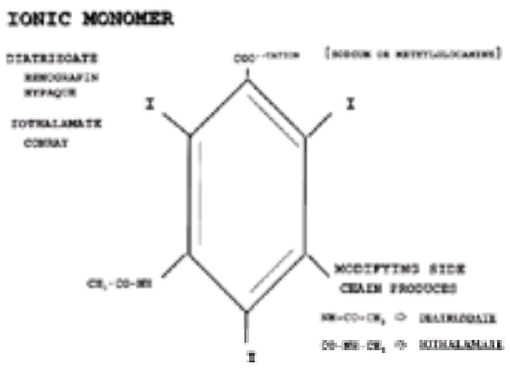

FIGURE 3A.1. Molecular structure of currently used ionic urographic contrast media. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

The ionic compounds are water-soluble salt solutions that are hypertonic with an osmolality 2.5 to 6.0 times that of plasma. The cations are either sodium or meglumine (methylglucamine). The large number of different ionic contrast media merely represents variations of concentration and cations for the anions diatrizoate or iothalamate. The name often denotes a specific iodine concentration along with the cation and anion used. For urography, only the 50% or 60% agents are routinely used.

Researchers have described objective differences in the pyelogram when comparing sodium and meglumine as the cation (9,21,75). In the laboratory, the sodium salt has produced higher urinary iodine concentrations, whereas meglumine has given better distention of the pelvicalyceal system because of a greater diuresis. Neither of the two cations produces any significant difference in the nephrogram (21,24,36). With the doses used in present-day excretory urography, the advantages and disadvantages are minimal. Good-quality urography can be achieved using either of the salts.

For urography, low-osmolar contrast and nonionic contrast are essentially the same. Ioxaglate, a low-osmolar, but ionic, dimer is used predominantly in angiography. Low-osmolar contrast media are now used in more than 60% of all radiographic procedures. They contain the same iodine concentration as the conventional agents but are much less hypertonic (Table 3A.2). These new compounds have approximately half the osmolality of the conventional compounds. To reduce the osmolality of the contrast media, two basic approaches are used. Three of these compounds (iohexol, iopamidol, and ioversol) are nonionic formulations that consist of three iodine atoms attached to a fully substituted, uncharged benzene ring (Fig. 3A.2). Because no balancing cation is needed, osmolality is reduced to half that of the conventional agents at the same iodine content. The fourth agent (ioxaglate) is an ionic dimer that consists of two linked benzene rings, each with three iodine molecules, and a single negative charge balanced by a cation. Thus there are two particles to six iodine atoms, also halving the osmolality at an equal iodine concentration. This feature is a definite benefit in angiography, where ioxaglate is used primarily because the lower osmolality of ioxaglate causes less pain in intraarterial injections. The lower-osmolality compounds also cause fewer physiologic responses. The newer media produce less peripheral vasodilation and less effect on myocardial contractility and cardiac electrophysiology. These decreased effects may be caused by the lower osmolality or due to a lower chemotoxicity (10).

Trade Name	Generic Name	Concentration (%)	Osmolality (mOsm/kg)	Iodine Content (mg/mL)
Omnipaque 300	iohexol	64.7	709	300
Omnipaque 350	iohexol	75.5	862	350
Isovue 300	iopamidol	61	616	300
Isovue 370	iopamidol	76	796	370
Optiray 320	ioversol	68	702	320
Hexabrix	ioxaglate (sodium 19.6%, meglumine 39.3%)	58.9	600	320

TABLE 3A.2. LOW-OSMOLALITY CONTRAST MEDIA

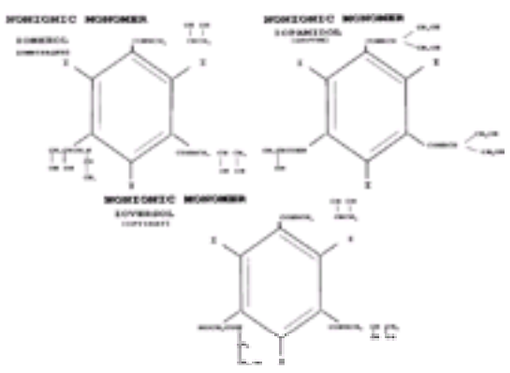

FIGURE 3A.2. Molecular structures of currently used nonionic urographic contrast. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

Clinical studies have demonstrated that the nonionic agents can produce a urogram equal to or better than ionic media (3,89). The lower osmolality and solute load allow the nonionic agents to produce a denser pyelogram with higher urinary iodine concentration (23,89). There is a potential for decreased distention of the collecting system because of reduced diuretic effect, but this has not been a significant problem. No significant difference in the nephrogram has been noted (23,89). Therefore using nonionic contrast does not decrease the diagnostic efficacy of urography.

Contrast material is almost entirely excreted by glomerular filtration with little or no tubular excretion. Approximately 0.5% to 2.0% is excreted by the liver and bowel. Most of this is excreted by the biliary system, although the small intestine, stomach, and salivary glands can excrete small amounts. *Vicarious excretion* is the term used when extrarenal excretion is apparent on the radiograph (8). Contrast medium may be seen in the gallbladder and colon 24 hours after injection in patients with decreased renal function, in whom extrarenal routes of excretion take on greater importance. Occasionally, this phenomenon is also seen in patients with normal renal function after they have received large doses of contrast medium (Fig. 3A.3) (70). The amount of contrast excretion by the kidney and collecting system with resultant radiopacity is related to plasma concentration and glomerular filtration rate (GFR) (17). Because GFR is fixed in the individual, only the plasma concentration can be manipulated. Increasing the amount of contrast material will increase the radiopacity of the urinary tract to a certain extent. At doses greater than 2 mL/kg, the radiopacity will not continue to increase significantly, but the risk of toxicity is increased. The method of injection will also alter the quality of the urogram. When a drip infusion is used, the plasma concentration plateau is slowly reached and falls off over a longer period. The drip infusion technique never achieves a plasma level as high as the bolus injection (Fig. 3A.4) (17) and is of no benefit, save convenience. The intensity of the nephrogram is related to the plasma concentration. Studies have shown that immediately after bolus injection, a peak plasma concentration is achieved, which then declines rapidly. The nephrogram will be maximal during this period of peak plasma concentration (32).

FIGURE 3A.3. Vicarious excretion of contrast material with opacification of the gallbladder *(arrowhead).* X-ray film taken supine 24 hours after large dose of intravenous contrast material.

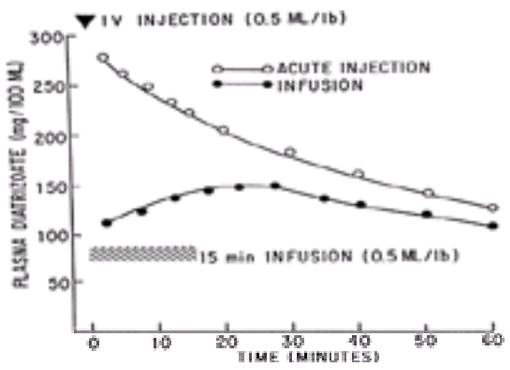

FIGURE 3A.4. Plasma diatrizoate concentration as a function of time and type of injection. IV, intravenous. (From Cattell WR. Excretory pathways for contrast media. *Invest Radiol* 1970;5:473, with permission.)

Following glomerular filtration, approximately 85% of the water resorption that concentrates the urine and increases radiopacity occurs in the proximal convoluted tubules. Additional resorption occurs in the distal convoluted tubules and collecting ducts, being regulated by antidiuretic hormone (ADH) and depending on the state of hydration. Because of this small contribution, the effectiveness of dehydration in increasing radiopacity is minimal, especially in light of the larger contrast doses used today. A comparison of patients with and without fluid restriction favored the fluid-restricted group in terms of radiographic scoring, but the difference was not statistically significant (22).

In most clinical situations, significant dehydration is not actually achieved. However, fluid restriction will limit fluid intake and the use of diuretic substances such as coffee, and it can avoid a state of excessive hydration with increased flow rate (43,64). We have found these urograms generally of better quality than those with no fluid restriction. Nephrotoxicity is the primary concern in fluid restricting a patient, and this should not be done in any patient with preexisting renal disease. Therefore, if it cannot be determined whether a patient has preexisting renal disease, fluid restriction should be avoided. In patients with normal renal function, overnight fluid restriction will probably improve the quality of the examination.

Physiologic Considerations

Following intravenous (IV) injection of ionic contrast material, there are several subjective effects, the intensity of which vary with the rate of injection and the individual. A sense of warmth and a “flushing” sensation are almost universal and may be misinterpreted as a reaction. A metallic taste and circumoral tingling are commonly observed. Sensations of pelvic and perineal warmth are not unusual and may be distressing to some patients. These uncomfortable side effects are virtually eliminated with nonionic contrast media.

Several physiologic responses have been noted with intravascular injection of contrast media. There is usually a mild and transient decrease in the systemic blood pressure along with a transient decrease in the heart rate (90). Pulmonary arterial pressure has been found to be transiently increased by contrast medium (76). Renal blood flow is initially increased but is followed by a decrease in renal blood flow proportional to the dose administered (31). A depressant effect on the myocardium has been shown with decreased myocardial contractility that is thought to be secondary to calcium binding and a depressant effect on the sinoatrial (SA) and atrioventricular (AV) nodes (46,79). It has been suggested that subclinical bronchospasm occurs in most patients (80). These effects are all transient and seem inconsequential but may play a part in the untoward reactions seen in a small percentage of patients.

CONTRAST MEDIA REACTIONS

Incidence and Classification

Adverse reactions to intravascular contrast media are well known and are a source of concern, but fortunately, most cases are mild and insignificant. Several large series of patients have demonstrated an overall incidence of contrast reactions of all types ranging from 5% to 8% (85,86,97). However, major respiratory or cardiovascular reactions are reported to occur in fewer than 1% of patients. The reported frequency of fatal reactions ranges between 1 in 14,000 and 1 in 75,000 (4,42,84).

Contrast reactions are usually classified as mild, moderate, or severe. In most series, 95% or more of all reactions are classified as mild to moderate. A sense of heat and flushing, along with most cases of nausea and vomiting, should not be considered adverse reactions but rather common side effects of the contrast material. Mild reactions include mild urticaria and minimal respiratory symptoms. Moderate reactions include extensive urticaria, angioneurotic edema, and bronchospasm. Severe reactions include intense bronchospasm with laryngeal edema along with potentially lethal cardiovascular responses such as marked hypotension, pulmonary edema, and ventricular arrhythmias that can lead to cardiovascular collapse.

Etiology

Although adverse reactions to contrast media have been studied extensively over the years, their pathogenesis remains somewhat obscure. Most evidence points toward a multifactorial concept in which several poorly understood responses to contrast media may lead to an adverse reaction.

Certain reactions such as urticaria, erythema, and bronchospasm appear to be allergic. They resemble an allergic reaction and respond as an allergic reaction to antihistamines and epinephrine. However, the allergy concept is controversial, with many researchers disputing its validity. Failure to find the classic immunoglobulin E (IgE)-type antibodies to contrast media in humans and the fact that individuals may react without prior exposure to contrast media do not support the allergy model (35,55,59). However, work by Brasch (11) supports the theory that contrast material may act as haptens and induce specific antihapten antibodies. Anticontrast media antibodies of both the immunoglobulin G (IgG) and IgE classes have been produced in rabbits. Contrast reactions in individuals without prior exposure are explained on the basis of antibody cross-reactivity, where the contrast media are similar to other antigens to which the individual has had prior exposure, such as other halogenated benzene rings found in food additives, pesticides, and other substances.

Some of the most severe reactions, however, do not resemble allergic reactions. Sudden major cardiovascular responses such as profound hypotension, pulmonary edema, ventricular arrhythmias, and myocardial infarction involve responses that are poorly understood. Hypertonicity and direct chemotoxicity of the contrast material have been suggested as etiologies (30,77). Enhanced vagal tone as the result of stimulation of the vasomotor center of the medulla and accentuation of contrast medium–induced myocardial toxicity has been suggested as the etiology in the sudden deaths of fluid-depleted dogs following IV injection of contrast material (47).

Lalli (52,53) has developed an interesting hypothesis based on the effect of contrast medium on the central nervous system (CNS) after crossing the blood–brain barrier. He believes that all reactions are ultimately neurogenic, centered on the hypothalamus and medulla. The combination of anxiety and contrast materials stimulating the hypothalamus can lead to a variety of neurogenic responses, such as hypotension, ventricular arrhythmias, and pulmonary edema. He thinks that anxiety plays a large role in contrast reactions and that examinations performed in a quiet, nonthreatening manner will reduce the number of adverse reactions.

A significant decrease in mild, moderate, and severe reactions has been demonstrated with nonionic contrast materials. The decrease is approximately a factor of 5 (45,73,98). Initially, there was controversy regarding the methodology of the comparative contrast studies, but the data have continued to indicate much greater safety for nonionic contrast materials (16), and safety is no longer a controversial issue.

Relationship to Previous Reactions and Hypersensitivity States

Studies have shown that individuals with known hypersensitivity states have contrast reactions on the order of twice those of the normal population, 10% to 12% versus 5%. Individuals who have had a previous contrast material reaction have a threefold increase; 15% to 16% of these individuals have a recurrent contrast

reaction (85,97). The nature of the recurrent reaction is variable, with minor reactions being repeated more often than life-threatening reactions.

Value of Pretesting and Premedication

IV injection of a test dose of contrast medium has not been proved useful as a screen for potential contrast reactions. Yocum, Heller, and Abels (99) demonstrated some value in high-risk patients with pretesting, but it involved a sophisticated protocol using multiple serial dilutions of the contrast material. A standard 0.5- to 1.0-mL IV test injection is of little use and may precipitate life-threatening reactions (85).

Investigators have shown that the incidence of recurrent reactions can be reduced by half or greater of the expected incidence with prophylactic antihistamines and corticosteroids (38,48,99). Steroid premedication can reduce the risk of an adverse reaction for ionic contrast to a level close to that of nonionic contrast. However, steroid premedications are not effective unless given for at least 12 hours before the administration of contrast (56,58), and this has limited the feasibility of routine premedication in all patients (25). The combination of a steroid preparation with a nonionic agent further reduces the risk of an adverse reaction (57); this is our approach to patients with previous adverse reactions to contrast or those with a significant allergy history in general. For convenience, we use Decadron 4 mg orally every 6 hours for 24 hours before the examination. Although steroid preparations and nonionic contrast can reduce the risk of an adverse reaction, they do not completely eliminate the possibility, and the need for a contrast examination should be examined closely in this group of patients.

Treatment of Contrast Material Reactions

Contrast reactions usually occur immediately or within minutes following the injection. However, severe reactions can occur after 15 minutes or even later. All physicians, nurses, and technologists involved in urography should be well trained in the recognition of the early signs of a contrast reaction and in resuscitation. Prompt recognition of a reaction and immediate treatment can be lifesaving. In all excretory urograms, the IV needle or catheter used for delivering the contrast should be left in place for the duration of the examination in case a reaction develops and IV access is needed. Blood pressure and electrocardiographic (ECG) monitoring equipment, as well as oxygen, should always be close at hand. In each room, there should be ready access to epinephrine, atropine, and diphenhydramine. In cases of cardiovascular collapse, a “crash cart” containing a defibrillator, an endotracheal set, and drugs useful during cardiac arrest should be nearby. Table 3A.3 summarizes therapeutic measures for contrast reactions with drug doses.

TABLE 3A.3. ACUTE REACTIONS TO CONTRAST MEDIA: TREATMENT

Mild reactions usually do not require treatment except for reassurance and comforting. One must cast a suspicious eye on all reactions, however, because they may progress to a more serious nature. If the urticaria is symptomatic, 25 to 50 mg of diphenhydramine given intramuscularly or intravenously is effective.

Progressive urticaria should be treated with diphenhydramine 0.25 to 50 mg intravenously or intramuscularly in adults. If urticaria is profound, one should consider cimetidine, ranitidine, or epinephrine (12,93). Bronchospasm alone can be treated with a b_2-agonist administered via metered-dose inhaler (13,14,93) or subcutaneous epinephrine (1:1,000) (20). Severe bronchospasm and evidence of laryngeal edema should be treated immediately with IV epinephrine because such a reaction may suddenly worsen and subcutaneous epinephrine at this point would be useless because of poor absorption. A dose of 1 mL of 1:10,000 epinephrine should be given intravenously (slowly, 2 to 5 minutes) (93). Epinephrine is short lived, and repeated doses may be necessary at 5- to 15-minute intervals.

Isolated hypotension may be treated initially with leg evaluation, oxygen, and fluids. If not responsive, IV epinephrine can be used (93). In hypotensive patients, it is extremely important to check the pulse rate. Bradycardia in a hypotensive patient indicates a vasovagal type of response, and treatment with 0.6 to 1 mg of IV atropine is usually extremely effective; 2 to 3 mg of atropine can be given over 10 to 20 minutes.

Severe cardiovascular reactions that involve hypotension, loss of consciousness, and airway obstruction require immediate therapy. In total cardiovascular collapse, additional IV lines and establishment of an adequate airway are mandatory when embarking on cardiopulmonary resuscitation. IV epinephrine is the treatment of choice for anaphylactoid reactions and should be given as soon as such a reaction is diagnosed. Prompt therapy can reverse an anaphylactoid reaction within minutes, whereas epinephrine given after full development of the reaction may not reverse it for hours. IV epinephrine is a potent medication, however, and is usually not needed for mild reactions. Rapid assessment of the patient as to the severity of a reaction is therefore essential.

Corticosteroids are of no value during the immediate reaction but may be helpful if the reaction takes a prolonged course. Methylprednisolone can be given (100 to 1,000 mg intravenously) (2).

Nephrotoxicity

Acute renal insufficiency following the use of intravascular contrast medium is a well-known potential complication that is fortunately uncommon in excretory urography. Acute renal insufficiency may be manifested by a transient rise in the serum creatinine or by acute oliguric renal failure. Some cases can be diagnosed during the urogram by development of an abnormally persisting, dense nephrographic pattern (Fig. 3A.5) (69,71). The true incidence of nephrotoxicity in excretory urography is not clear but is probably lower than 5% (66,94).

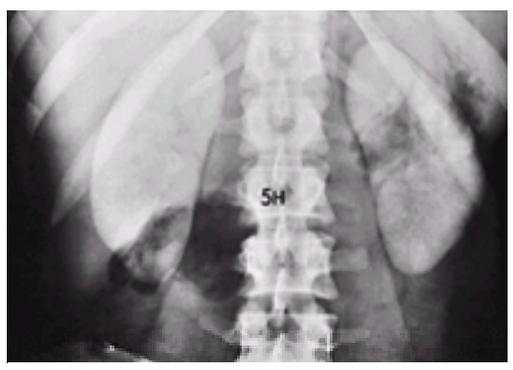

FIGURE 3A.5. Persistent dense nephrogram at 5 hours related to contrast-induced renal failure. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

Although renal toxicity is unlikely to occur from an IV injection of iodinated contrast material in a patient with normal renal function, patients with preexisting renal disease have consistently been shown to be at greater risk for contrast-induced nephropathy (7,37,60,94). VanZee and associates (94) found renal failure following urography to occur in only 0.6% of patients with normal renal function, but this increased to between 3.2% and 31% depending on the severity of preexisting renal disease. Minimal elevations of serum creatinine do not necessarily prohibit the use of iodinated contrast media when necessary for diagnosis, but preexisting renal disease does increase the risk of the examination, and this should be balanced against potential gain.

Studies have compared the nephrotoxicity of ionic and nonionic contrast media and have shown a decrease in nephrotoxicity with the low-osmolar contrast (41,60). A meta-analysis demonstrated significant benefit when low-osmolar contrast media are used in patients with prior renal impairment (7).

Acute renal insufficiency associated with contrast medium is generally self-limited. The serum creatinine usually peaks in 2 to 3 days and returns to the preexisting level within 1 to 3 weeks. Most patients completely recover, with few requiring dialysis.

The theories on the pathogenesis of contrast-induced renal failure include direct toxic effects of the contrast medium on the proximal tubular cells and ischemia resulting from damage to the renal microcirculation. Nephrotoxicity has been attributed to the hypertonicity of the contrast medium, resulting in a unique vacuolization of the cytoplasm of the proximal tubular epithelium termed *osmotic nephrosis* (67). Others think that acute tubular necrosis may result from ischemia due to vasoconstriction or sludging of the red blood cells in the renal microcirculation. Katzberg and associates (47) suggested that the hypertonicity of the contrast medium reduces the GFR by increasing the hydrostatic pressure in Bowman's capsule and the proximal tubules. In certain cases, precipitation of uric acid within the proximal tubules may lead to acute renal failure. Contrast material has a known uricosuric effect and may result in acute urate nephropathy in individuals with hyperuricemia.

A few cases of acute oliguric renal failure resulting in the death of patients with multiple myeloma have been reported following excretory urography. Because of these reports, some authorities considered multiple myeloma an absolute contraindication to excretory urography. However, excretory urography in patients with multiple myeloma is probably no different from that in patients with other forms of renal impairment (68,95). When necessary, excretory urography must be performed with caution, and dehydration should be avoided.

In high-risk patients who require a contrast examination, both dehydration and large contrast medium loads should be avoided. IV hydration performed overnight, as well as after the examination, may be helpful in preventing renal problems. Nonionic contrast media should be used in these patients. Sequential diagnostic studies that use intravascular contrast material should not be scheduled without allowing adequate intervals for observation and recovery (70).

Concurrent Use of Metformin (Glucophage) and Contrast Media

The concurrent use of metformin, an oral antihyperglycemic agent, and iodinated contrast media is of concern. A decrease in renal function could potentially decrease metformin excretion, which could subsequently lead to development of lactic acidosis. To prevent this potential complication, it is currently recommended that metformin be discontinued either before or at the time of a radiographic procedure in which iodinated contrast is to be used. The metformin should be withheld for 48 hours after the procedure and reinstated only after renal function has been reevaluated and shown to be normal (2).

Low-osmolality Contrast Media

Early experience with low-osmolar contrast demonstrated a decreased incidence of mild reactions and suggested a lower incidence of moderate and severe contrast reactions. However, the early studies contained relatively small numbers of patients, making it difficult to arrive at a consensus on significant contrast reactions. Two studies involving large patient populations found a significantly decreased incidence of serious contrast reactions. In a Japanese study involving more than 300,000 patients, the incidence of all contrast reactions was four times less with the new agents. Even more striking, the incidence of severe reactions was six times less with the low-osmolality agents (45). This was corroborated by an Australian study involving more than 100,000 patients (73). Significantly increased safety of the low-osmolar agents is now accepted worldwide.

The disadvantage of the newer compounds is their higher cost compared with the conventional agents. This cost difference, which has been as high as 20:1, has decreased to approximately 4:1. (74). In European countries, there is almost universal use of nonionic media (92). In the United States, there is still controversy (27,87) regarding universal use of low-osmolar contrast media, but the significant cost reductions have made this a more feasible alternative.

TECHNIQUE

Several parameters must be considered to properly perform excretory urography. An adequate number of well-trained personnel should be employed to obtain good-quality radiographs, as well as to closely monitor the patient during the entire procedure. Emergency drug boxes and monitoring equipment should be available in every room where urography is performed. A physician should supervise all contrast administration and should remain close by in case complications arise. Regularly scheduled x-ray machine maintenance with established quality control guidelines for the technologists is essential.

Before the examination, the physician should have a completed x-ray request outlining the current problem and pertinent medical history (e.g., diabetes, nephrolithiasis, allergies). Laboratory values to assess renal function, blood urea nitrogen (BUN), and creatinine are important baselines, especially in debilitated or elderly individuals. Old films should be requested and reviewed.

For many years, bowel preparation was used to improve image quality of the urogram. Although helpful in some patients, these preparations often were not successful, and at the University of Virginia, we no longer use routine bowel preparation. A randomized prospective study found no difference in terms of overall quality between a prepared and an unprepared group of patients (34). Other studies have shown not only a lack of significant improvement of quality but also significant unpleasant side effects to these preparations (6). The need for bowel preparation has been reduced by the routine availability of tomography, which allows visualization of the kidneys despite considerable overlying bowel content (Fig. 3A.6).

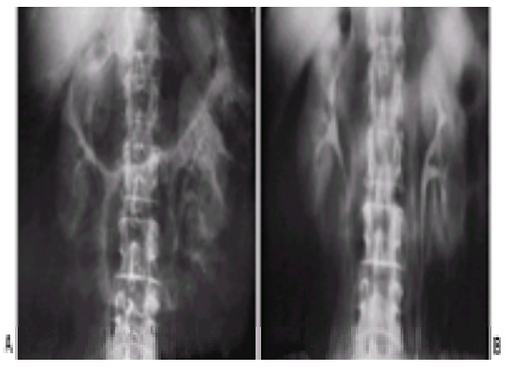

FIGURE 3A.6. A: Limited visualization due to overlying bowel content. **B:** Tomography dramatically improved visualization. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

Contrast Media: Dosage and Administration

An average dose of 0.5 to 1.0 mL of 60% contrast material per pound of patient's weight, with a maximum dose of 100 mL, is a generally accepted rule of thumb. Twenty grams of iodine was the dose recommended in the categorical genitourinary course at the 1978 Radiologic Society of North America (RSNA) Annual Meeting (63), and this dose has not changed significantly (64). This would be the equivalent of approximately 75 mL of contrast agent for a 150-pound patient. Dosage schedules for the newer nonionic contrast media were initially similar to the ionic agents because the concentrations were similar. However, cost considerations have

necessitated that there be no waste when the very expensive nonionic contrast is used, and many institutions have gone to a dose of 50 mL because most of the available nonionic media come in standard vials of 50 mL. A dose of 50 mL of iohexol was compared with a larger, weight-based dose and showed no significant diagnostic difference (33). Kennan, List, and Kengsakul (49) also evaluated lower dosages for nonionic contrast and found that with a 42% reduction in the amount of contrast, diagnostic images were still obtained. Currently, packaging of the nonionic media is more flexible, and a dose equivalent of 75 mL of a 60% solution could be used with no wasted contrast agent.

IV contrast is rapidly administered through a 19- or 21-gauge butterfly scalp vein needle or catheter-type needle, which is taped and left in place until the procedure is finished. Thus venous access is established throughout the examination in case of a reaction. The contrast medium should be administered as quickly as possible to demonstrate a good nephrogram phase. The antecubital fossa and dorsum of the hand are preferred sites for contrast injection, but central lines may be used as well. If venous access is unavailable, a foot vein may be cannulated. However, after the contrast material is given, the leg should be elevated and 100 mL of saline solution flushed through the line to decrease the possibility of thrombophlebitis. Ionic contrast medium is very irritating, and care should be taken to avoid extravasation into the subcutaneous tissues because skin slough can occur.

Radiographs: Technical Factors

Both the preliminary radiograph and the routine tomographic radiographs should be obtained using kilovolt peaks (KVPs) in the range of 60 to 70. The visibility of contrast media decreases with higher KVPs.

Many types of film–screen combinations are available; use depends on personal preference, as well as what is available at a particular institution. Radiation dose can be reduced by using a high-speed system, and high-quality urograms can be obtained with such a system. At the University of Virginia, we use high-speed film in combination with intensifying screens, which gives a speed of 600. This type of high-contrast film is well suited for stone detection.

Collimation to the area of interest is crucial to eliminate image degradation produced by scattered radiation. One of the most common errors in urography is failure to collimate properly, and technologists should be encouraged to collimate as close to the area of interest as possible.

Various radiographic views and maneuvers allow the physician the flexibility to tailor each examination to a patient's particular problem (54). The one mandatory film is “the scout,” or *kidney, ureter, and bladder preliminary* (KUB). This view is a supine abdominal radiograph (14 inches by 17 inches) taken before contrast injection that includes the kidneys to the pubic symphysis (Fig. 3A.7). Two exposures may be necessary in large patients to cover the entire anatomy. A careful review of the film for technique and underlying abnormalities is required. The size, shape, and position of both renal outlines should be observed. Abnormal calcifications (e.g., renal and ureteral calculi, gallstones, aneurysm, fibroids) should be identified. Oblique views before contrast administration may be needed to prove that a calcification is indeed renal in origin (Fig. 3A.8 and Fig. 3A.9). Bony architecture should be scrutinized for pathology, such as metastasis (Fig. 3A.10). The bowel gas pattern should be evaluated for possible obstruction and abnormal gas collections (Fig. 3A.11 and Fig. 3A.12). The lung bases are often included on the film and may reveal occult pulmonary disease. Radiopaque substances, such as tablets, foreign bodies, and recently administered barium, will be demonstrated and may even preclude the examination.

FIGURE 3A.7. A: The preliminary radiograph should include area from kidneys to pubic symphysis. Calcification overlying pubic symphysis *(arrow)* is a calculus within a urethral diverticulum. **B:** Coned-down bladder radiograph following contrast media injection demonstrating urethral diverticulum. The urethral calculus would have been missed if the radiograph before contrast injection did not include the pubic symphysis.

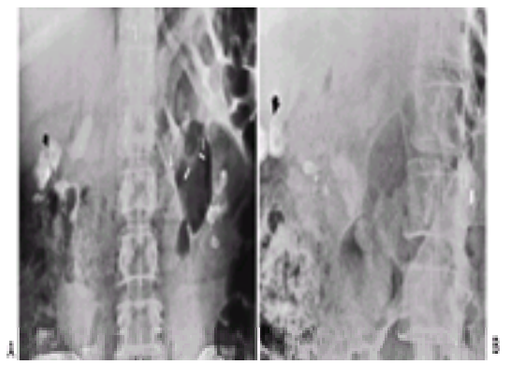

FIGURE 3A.9. A: Preliminary radiograph demonstrates calcific densities overlying both renal shadows. Two laminated calcific densities *(arrow)* overlying the right renal shadow are probably gallstones. **B:** Radiograph in the right posterior oblique projection confirms the presence of gallstones *(arrow)* in addition to renal calculi.

FIGURE 3A.10. Blastic metastases to pelvis *(arrow)* and spine (L-2).

FIGURE 3A.11. Preliminary radiograph demonstrates significant distention of the bladder with air within the wall *(arrows)* in a patient with emphysematous cystitis. Large calcified uterine fibroids are noted within the pelvis.

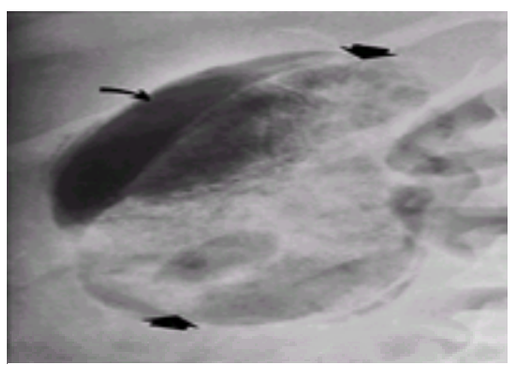

FIGURE 3A.12. Emphysematous pyelonephritis. Gas extends throughout the right kidney parenchyma *(black arrows)* and also to subcapsular space *(curved arrow).* (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

The nephrogram phase is evaluated with a collimated film (11 inches by 14 inches) immediately after injection. The nephrogram phase demonstrates the densest opacification of the renal parenchyma and should be obtained within 1 minute after injection (Fig. 3A.13). The kidneys are compared and evaluated for size, shape, and position. In lieu of a 1-minute film, however, nephrotomography is often preferred. Three tomograms at 1-cm intervals in the supine position are taken at 30, 60, and 90 seconds after injection, providing excellent visualization of the renal contours (Fig. 3A.14). The nephrogram can be delayed (obstruction) (Fig. 3A.15), misplaced (pelvic, thoracic/kidney), irregular (mass) (Fig 3A.16), or prolonged (hypotension).

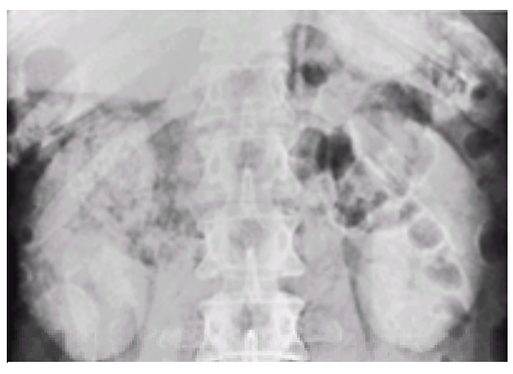

FIGURE 3A.13. The nephrogram phase demonstrates parenchymal opacification of both kidneys. Kidney size and contour abnormalities are best evaluated during the nephrogram phase.

FIGURE 3A.14. Immediate postinjection tomogram clearly demonstrates the renal parenchyma bilaterally.

FIGURE 3A.15. Left-sided obstruction with delayed visualization of calyces. Same patient as Fig. 3A.14

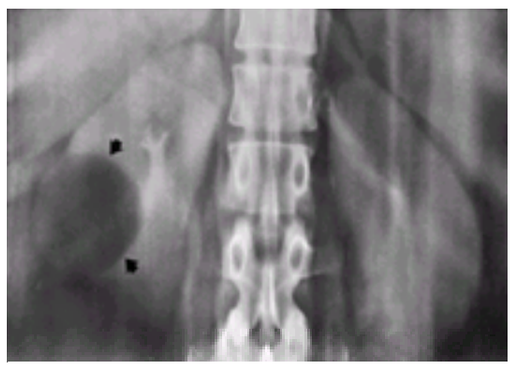

FIGURE 3A.16. Nephrotomography demonstrates a large, well-circumscribed mass in the lower pole of the right kidney *(arrows)* consistent with a renal cyst. Nephrotomograms provide excellent detail of renal contour abnormalities.

A 5-minute collimated film (11 inches by 14 inches) is obtained to demonstrate the pyelogram phase with opacification of both collecting systems and proximal ureters (Fig. 3A.17). Calyceal distortion, irregularity, or filling defect may signal underlying disease. Tomography can be used to better delineate the calyces, as can oblique views. Oblique views are also helpful in further evaluating filling defects and in clarifying pseudofilling defects such as might be related to overlapping calyces or crossing vessels. Posteriorly and anteriorly positioned masses may also be more apparent on oblique views because these present a different surface of the kidneys.

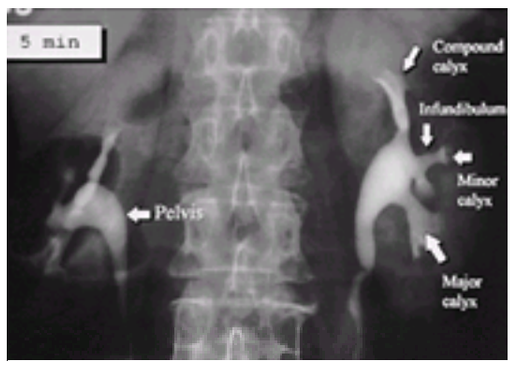

FIGURE 3A.17. Coned, 5-minute film of kidneys.

Relative obstruction of the ureters with an inflatable compression device placed across the lower abdomen after the nephrogram phase achieves optimal distention of the collecting systems and proximal ureters (Fig. 3A.18). Contraindications include suspected ureteral obstruction, abdominal aortic aneurysm, and recent abdominal or renal surgery. Another alternative is to place the patient in the Trendelenburg position after the 1-minute film to enable better filling of the collecting system. Both the compression device and Trendelenburg position are maintained until a 10-minute collimated kidney film is taken (14 inches by 11 inches). The patient is brought up into the reverse Trendelenburg position, or the compression device is released, and an immediate full (14 inches by 17 inches) film is taken in hopes of catching the contrast medium flowing down both ureters to the bladder. The ureters and bladder are usually well demonstrated (Fig. 3A.19).

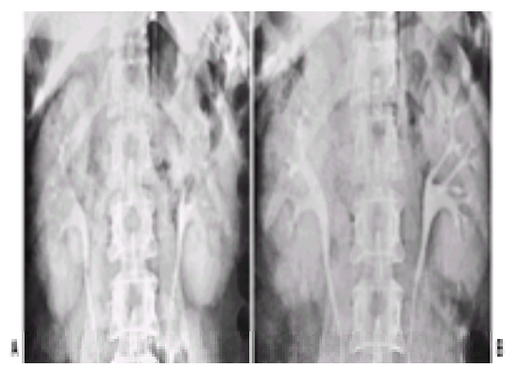

FIGURE 3A.18. A: Radiograph taken 5 minutes after contrast injection demonstrates the pyelogram phase with opacification of the collecting system and proximal ureters. **B:** Radiograph following the use of a compression device in the same patient. Note distention of collecting systems with improved visualization of the calyces and infundibula.

FIGURE 3A.19. Postcompression abdominal film demonstrating the ureters and bladder.

If necessary, the bladder can be evaluated with a collimated view (11 inches by 14 inches) for better anatomic detail (Fig. 3A.20). The lower ureteral segment and ureterovesical junction can be better delineated with oblique views either before or after voiding (Fig. 3A.21 and Fig. 3A.22). If there is inadequate definition or a suspicious finding in the distal ureters or bladder, a prone film (11 inches by 14 or 14 inches by 17 inches) will distend the anterior portions of the collecting system as they become dependent, that is, the middle and distal portions of the ureters. This is often helpful in localizing an obstruction (Fig. 3A.23). Lesions involving the anterior wall of the bladder are better visualized as well.

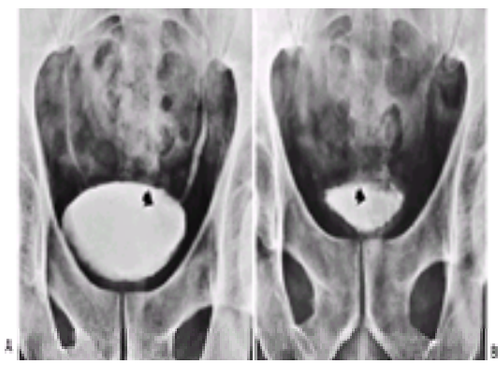

FIGURE 3A.20. A: The filled bladder suggests a filling defect near the left bladder wall *(arrow)*. **B:** The postvoid radiograph confirms the defect *(arrow)* proved to be bladder carcinoma.

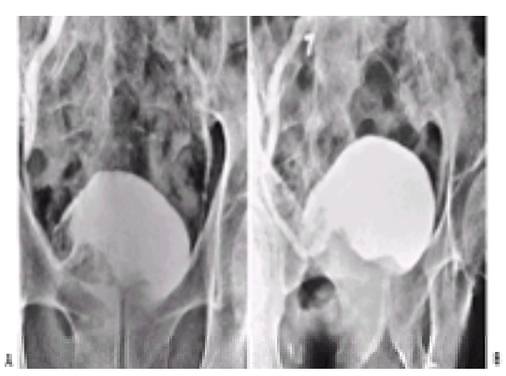

FIGURE 3A.21. A: Coned-down radiographs of the bladder suggest a mass involving the inferior aspect of the right wall of the bladder. **B:** Radiograph taken in the left posterior oblique projection confirms irregular mass near the insertion of the right ureter consistent with carcinoma.

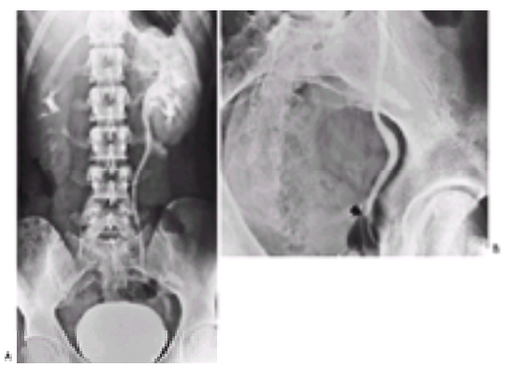

FIGURE 3A.22. A: Two-hour radiograph in a patient with left-sided renal colic. There is dilation of the left ureter down to the level of the bladder. The point of obstruction is not demonstrated. Note the peripelvic extravasation of contrast resulting from forniceal rupture. **B:** Postvoid radiograph in the left posterior oblique projection demonstrates the level of obstruction *(arrow)* due to a uric acid stone.

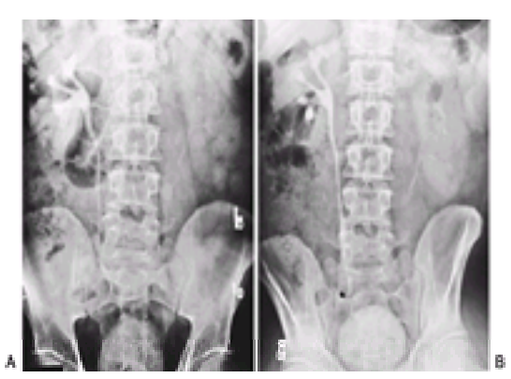

FIGURE 3A.23. A: Ten-minute radiograph in a patient with right renal colic. There is hydronephrosis and dilation of the ureter with poor definition of the level of the obstruction. **B:** Prone radiograph demonstrates excellent opacification of the ureter with identification of the level of the obstruction *(arrow)*.

Postvoid radiographs most often are used to assess bladder outlet obstruction resulting from prostatic hypertrophy in older adults. In the presence of a possible obstructive process involving the upper urinary tract, the postvoid radiograph can also be of benefit by demonstrating drainage. The combination of the patient's walking to the bathroom and emptying his or her bladder often aids significantly in evaluating the drainage of the upper tracts.

Fluoroscopy often provides additional information about urinary tract physiology. In combination with spot filming, fluoroscopy can reveal renal dynamics and relationships not seen with standard static radiographs.

TOMOGRAPHY

Tomography provides better visualization of the urinary tract by blurring out the surrounding structures. It is one of the most important refinements of the excretory urogram. Simple linear tomography is generally sufficient. We at Virginia use a short arc of 20 degrees, which will produce a tomographic cut of approximately 0.5 cm. Three such tomographic cuts are generally sufficient to visualize the kidneys.

The major contribution of tomography is in evaluating the renal parenchyma; therefore tomograms should be obtained immediately after the bolus injection of contrast when the nephrogram is most intense (Fig. 3A.14). This has been shown to increase detection of renal masses (39,72). Later in the urogram, during filling of the collecting structures, tomography can be used on a selective basis. It is most helpful when there is considerable overlying bowel content or poor concentration of the contrastmedium. This will often salvage an otherwise nondiagnostic examination.

DIGITAL RADIOGRAPHY

Two types of digital radiography are available for use in urologic diagnosis. At present, digital radiography is not used extensively in the diagnosis of urologic disease, but with the potential for dose reduction and more efficient storage, its use will probably increase.

Digital luminescent radiography (Fig. 3A.24) does not use standard film but rather uses photo-stimulable plates with substances such as phosphorous and barium-fluoro-halide europium-doped crystals. This system has the advantage of significant dose reduction. Because the imaging plates used have a much wider linear dynamic range than conventional screen–film combinations, imaging can be performed at decreased radiation doses (29,65,100). Dose reductions up to 50% for urography (65) and as great as 90% in urethrocystography (100) have been achieved. In addition, repeat examinations are significantly reduced, if not eliminated, by this system. Studies that have compared the diagnostic capabilities of digital systems with standard radiographic systems have shown no significant decrease in image quality or diagnostic accuracy with the digital systems (28,29).

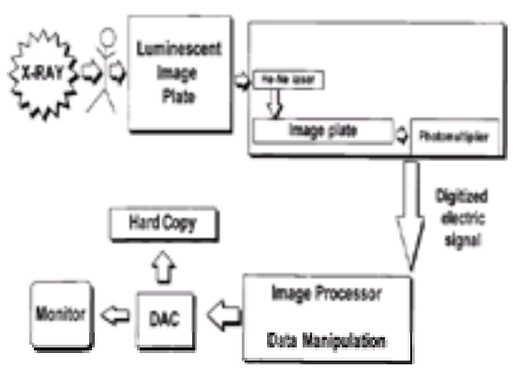

FIGURE 3A.24. Digital luminescent radiography. The luminescent plate is exposed and its energy state raised. Laser scanning releases radiation, which is converted to an electric signal and digitized. The digital image is processed and converted through a digital–analog converter to an analog image for the monitor or hard copy. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

The second type of digital system, digital fluororadiography, converts the fluoroscopic image to a digital image as shown in Figure 3A.25. The optical image of the TV tube is converted by an analog–digital converter into a series of electrical signals, which are then converted into the digital image. The digital image is converted back to an analog image and can either be sent to the monitor for viewing or printed out as a hard copy. The images can be manipulated later by changing window settings, brightness, or edge enhancement as needed. In contrast to standard radiography, the image is immediately available for review, allowing more rapid decision making as to further films.

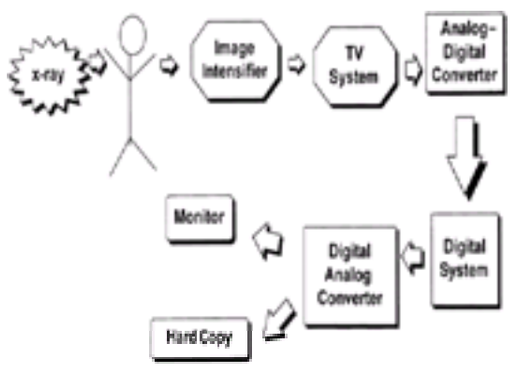

FIGURE 3A.25. Digital fluororadiography. (From Older RA, Resnick MI, eds. *Basic radiologic techniques in diagnosis of genitourinary disease,* ed 2. New York: Thieme Medical Publishers, 1994, with permission.)

THE PEDIATRIC PATIENT

Excretory urography in children requires special attention to several technical factors. First, establishment of rapport between the physician and the child and parents is crucial before obtaining radiographs. Explaining the procedure in a step-by-step fashion helps alleviate some of the anxiety regarding the examination. In the older age group, the clinician should direct the explanation primarily to the child.

Anesthesia or sedation is rarely indicated in excretory urography. In infants and preschool children, a “cradle” device is placed directly on the x-ray table for immobilization of the patient. Heat lamps, pediatric drug boxes, and resuscitative equipment should be available in each x-ray room.

Bowel preparation is not indicated in children. An adequate state of hydration is essential, especially in infants and younger children, to avoid dehydration from the diuresis caused by the excess solute load of the contrast medium. Abstinence from food for about 5 hours is sensible in most children to keep the stomach empty in case of emesis after contrast administration (19).

The contrast dosage in children is basically the same as for adults on a weight basis. Between 0.5 and 1.0 mL/lb (between 1 and 2 mL/kg) of patient's weight is a safe and effective amount of contrast medium to give a satisfactory urogram. Nonionic contrast is indicated for infants and also recommended for young children. Venous access in young children may be difficult to obtain. The veins on the dorsum of the hand or foot are usually the most accessible for cannulation with a 25-, 23-, or 21-gauge butterfly needle. Other sites include the antecubital fossa and scalp veins in infants. Pneumothorax is a complication of external jugular vein injections, and the femoral vein should be avoided because of the reported risk of septic arthritis of the hip (19). Bolus injection technique is recommended, and the needle should remain in place until the study is terminated. Immediately after giving the bolus, a carbonated beverage or juice may be given to the patient. This allows distention of the gastric bubble for optimal visualization of the kidneys, as well as providing calories and fluid intake for the child.

The filming sequence in the pediatric age group is aimed at obtaining the most information from a minimum number of radiographic exposures. Collimation should be used when possible.

A preliminary film, which includes the kidneys to the pubic symphysis, should be scrutinized carefully for underlying skeletal anomalies such as sacral agenesis and spinal dysraphism. A search for abdominal masses, an abnormal bowel gas pattern, and any calcifications should also be conducted.

In most cases, the entire pediatric excretory urogram can be completed with two postcontrast films. The nephrogram phase is demonstrated with a 1-minute collimated view of the kidneys. A large 10-minute film usually demonstrates both collecting systems, ureters, and the bladder. A postvoid bladder film is usually not obtained in children. However, additional views may be indicated for a particular clinical history or to clarify further abnormalities seen while performing the urogram.

Tomography is not used routinely for children but, if available, can often resolve a diagnostic problem, especially in a child with considerable overlying bowel content. There is a reluctance to use tomography in children because of radiation concerns. One or two tomograms actually may decrease the number of radiographs needed in a difficult diagnostic case and could possibly obviate the need for a follow-up imaging study, such as CT, which might involve even greater radiation.

INDICATIONS FOR EXCRETORY UROGRAPHY

The following list includes current indications for excretory urography. Some of these, such as obstruction, also use other technology; others, such as trauma, are controversial.

Stone disease
Preoperative extracorporeal shock wave lithotripsy (ESWL)
Acute abdominal pain or colic
Suspected obstruction
Blunt trauma thought to involve only the urinary tract
Hematuria, especially if abnormality of the collecting structures is suspected
Complicated or unusual infection, including tuberculosis
Postoperative evaluation of urologic procedures
Preoperative evaluation for endourologic procedures
Suspected transitional cell carcinoma
Questionable abnormality on isotope or ultrasound studies

These indications represent a combination of those indications that have persisted for many years, as well as relatively new indications, such as preoperative ESWL. Many previously accepted indications for urography are no longer considered justified. The evaluation of hypertension is one of these (51,78). Uncomplicated urinary tract infections, preoperative studies for various types of surgery (91), and enuresis are no longer studied routinely (51,78). Trauma has become a somewhat controversial indication with differing opinions regarding the value of urography.

Indications for urography have also been reduced by increasing availability of alternative methods of diagnostic imaging. A broad knowledge of the other imaging modalities is necessary to determine the proper examination. Urography is still widely used for obstruction, but ultrasound has become the primary screening study for this entity, and improvements in the diuretic renogram also erode the territory of urography. However, urography has the advantage of providing a unique combination of anatomy and function and for this reason continues to be used in suspected obstruction.

Urography and ultrasound are complementary examinations; this is particularly true in stone disease. There are those who have advocated replacement of the urogram by a combination of ultrasound and an abdominal film (40). However, a determination in each case as to which study would be most helpful is what should be done. Ureterovesical junction stones are detectable by a skilled ultrasonographer, but stones more proximal in the ureter are often difficult to find and can be demonstrated more easily by urography. Urography is generally more available, and interpretive experience also favors urography (18). To detect small ureteral stones, a sonographer with considerable experience and patience is needed.

Renal calculi can be evaluated by either technique. Some stones are more apparent with an abdominal radiograph or tomography, whereas others are better seen with ultrasound. Stone dimensions and degree of fragmentation following ESWL are better demonstrated with radiographs, but small stones, nonopaque stones, and small amounts of fragmented stone debris are often better demonstrated with ultrasound.

Noncontrast spiral CT has gained wide acceptance as the initial evaluation of renal colic and suspected ureteral stones. This has further reduced the use of intravenous pyelography (IVP), especially as an emergency procedure (88).

CT or ultrasound is used to study abdominal masses and retroperitoneal disease, which are no longer studied with urography. Similarly, urography is no longer used for evaluation of adrenal disease, but CT, MRI, or isotope techniques are used. Urography is still used as a primary study for hematuria. The urogram provides not only parenchymal information but also visualization of the collecting structures. Although sensitivity of excretory urography for detection of mass lesion is significantly less than CT (96), urography is excellent for lesions, such as transitional cell carcinoma, papillary necrosis, and other abnormalities of the collecting structures that might produce hematuria.

Patients in whom excretory urography may no longer be the study of choice are those with an above-average risk of complication. This may be an allergic reaction, abnormal cardiovascular response, or nephrotoxicity related to the contrast medium.

Urography can be performed in patients with a history of allergies to contrast media; however, if the reaction was severe, other modalities, such as ultrasound, CT without contrast, or radioisotope scanning, would probably be a better choice. Patients with significant heart disease have been shown to have a higher incidence of arrhythmias during bolus injection for urography; in these patients, other modalities should be considered. Urography is no longer used for evaluation of renal failure. Diagnostic ultrasound has improved to the extent that it can accurately determine whether obstruction is present, often the question being asked in a patient with renal failure (26,40,81,82). In addition, the potential toxicity of iodinated contrast media is now well established. Patients with mild renal failure are at significant risk for contrast-induced renal toxicity (1,5,7,15,50,60,69,70 and 71,83,94). Contrast-induced renal failure is a major cause of renal failure in the hospital population (44).

The indications for excretory urography in children have undergone changes in the past few years and are very limited. Ultrasonography and CT have virtually replaced the excretory urogram in the evaluation of abdominal and renal masses, hydronephrosis, and abdominal pain and as a screen for associated renal anomalies in children with other congenital anomalies (61). Ultrasonography is evolving into the initial screening procedure for pediatric urologic disease because of excellent detail in children and lack of radiation exposure.

Excretory urography is sometimes used in evaluating urinary tract infection in children in whom reflux has been demonstrated on voiding cystourethrography. The excretory urogram provides better definition of cortical scarring associated with vesicoureteral reflux (62), but ultrasound is often sufficient for this purpose. Excretory urography is also indicated in calculus disease, in nonmedical hematuria, and in children who have recently undergone urologic surgery.

INTRODUCTION

Cystography and urethrography are imaging studies performed of the bladder and/or urethra before, during, and after the administration of contrast material. The goal of cystography and/or urethrography is to detect abnormalities of the lower urinary tract. Abnormalities of the bony pelvis, or pelvic soft tissues that may affect the bladder or urethra, may also be detected. This should be accomplished using the minimum radiation necessary to provide sufficient anatomic detail for the diagnosis of normal or abnormal urinary findings.

These examinations are performed under the direct supervision of physicians who have received documented formal training in the performance, interpretation, and reporting of uroradiologic studies. The supervising physician must be familiar with multiple disease processes of the lower genitourinary tract and understand the cystographic and urethrographic manifestations of these diseases. Furthermore, the physician performing these studies must be knowledgeable of alternative imaging techniques that may be required, such as ancillary studies either after a cystogram or urethrogram or as a replacement for these techniques. In particular cases, the lower tract evaluation may be accomplished with ultrasonography, computed tomography, nuclear medicine, or magnetic resonance imaging (MRI).

The physicians and technologists performing these studies should have an understanding of and experience in proper film technique; film sequencing; and the volume, concentration, and method of administering contrast material. Cystography and/or urethrography should be performed after an appropriate history and preprocedure screening are performed. Risk factors must be assessed before these examinations are performed. Some patients may require a steroid premedication regimen. The signs and symptoms of an adverse reaction from the administration of contrast material must be well known to the physicians and support staff caring for patients undergoing these examinations. Understanding of and proficiency in the recognition and treatment of adverse contrast reactions are required. Medication and resuscitative equipment must be immediately available to treat adverse contrast reactions.

Imaging findings and interpretations should be reported in a timely fashion in compliance with the American College of Radiology standards on communications. Urgent or acute findings should be communicated promptly to the ordering physician (1).

CONTRAST MATERIAL

Contrast for urethrography must be sufficiently viscus and dense for proper visualization of the urethra. The meglumine salts of diatrizoate or iothalamate are most useful for this examination. Sixty percent (weight/volume) solutions are typically used in retrograde urethrography to provide maximal opacification of the urethra. Meglumine salts of diatrizoate and/or iothalamate are also the most widely used contrast agents for cystography. Solutions containing 15% (weight/volume) contrast media are optimal for cystography. Solutions that contain greater than 15% contrast media may result in very dense opacification of the bladder, and subtle abnormalities may not be detected. Higher concentrations of contrast media may be irritating to the bladder mucosa. Systemic reactions following retrograde urethrography are extremely rare. Although uncommon, systemic reactions to contrast media may occur during cystography (5). Patients who have had adverse reactions to intravenous contrast material may be studied using either nonionic low-osmolar contrast or potentially both a steroid premedication and nonionic contrast (25).

The initial interview of patients undergoing either cystography or urethrography must include an allergy history, particularly a history of allergic reactions to contrast material. If the patient is thought to be at sufficient risk for a allergic reaction, nonionic contrast can be used. For cystography, dilute Isovue-300 (iopamidol 61% Bracco Diagnostics Inc. Princeton, New Jersey) is used. For urethrography, nondilute Isovue 300 can be used for the injection of contrast into the urethra.

URETHROGRAPHY

Normal Anatomy

The male urethra extends from the bladder neck to the external meatus, extending through the prostate gland and urogenital diaphragm. The urogenital diaphragm attaches anteriorly and laterally to the inferior rami of the public arch and the ischia. Posteriorly, the triangle is attached to the perineum and is continuous with the anal fascia. Near its apex, the diaphragm is perforated by the urethra approximately 1 cm below the symphysis pubis. This diaphragm divides the urethra into two portions: the anterior portion below the urogenital diaphragm and the posterior urethra above.

The anterior urethra extends from the inferior aspect of the urogenital diaphragm to the external meatus. The anterior urethra is divided into two parts by the penoscrotal junction inferiorly and the suspensory ligament superiorly. The penile urethra lies anterior to the penoscrotal junction. Distally, the penile urethra is dilated to form the fossa navicularis. Proximal to the penoscrotal junction lies the bulbous urethra. The bulbous urethra dilates slightly in its most inferior aspect and proximally terminates in a symmetric cone shape (Fig. 3B.1). The glands of Littre lie along the anterior urethra (Fig. 3B.2). Cowper's glands empty into the dilated portion of the bulbous urethra. The corpus spongiosum surrounds the anterior urethra.

FIGURE 3B.1. Normal retrograde urethrogram, prior transurethral resection of the prostate (TURP). Contrast injected into the penile urethra shows excellent filling of

the penile *(arrowhead)* and bulbar urethra *(arrow).* The cone of the bulbous urethra is well depicted *(open arrow).* The prostatic urethra is dilated in this patient status post TURP. A small air bubble is seen in the penile urethra.

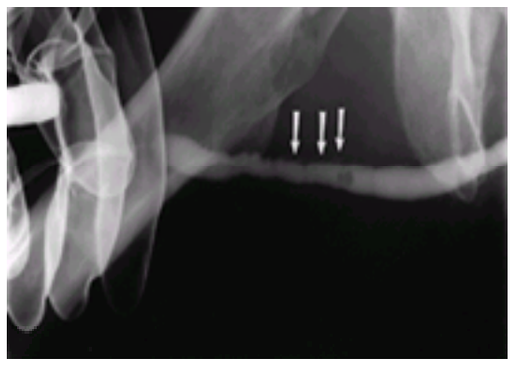

FIGURE 3B.2. Glands of Littre. Contrast has been injected into an Intracath placed in the penile meatus. Small contrast outpouchings are seen in the anterior urethra *(arrows).* These are the glands of Littre. Air bubbles are incidentally noted in the penile urethra.

The posterior urethra extends from the bladder neck to the urogenital diaphragm. The posterior urethra is composed of two parts: the membranous urethra and the prostatic urethra. The membranous urethra lies within the urogenital diaphragm and is 1 to 1.5 cm in length and 5 to 7 mm in caliber. The prostatic urethra extends through the prostate gland to the bladder neck. Anatomic features that may be noted when examining the posterior urethra include the verumontanum. This is a mound of smooth muscle on the posterior wall of the prostatic urethra. The superior aspect of the verumontanum lies above the middle of the prostatic urethra. The verumontanum extends inferiorly into the distal third of the prostatic urethra, tapering distal to form the urethral crest. There are three small orifices in the verumontanum. The superior opening is the prostatic utricle. Below and to the side of the prostatic utricle are the orifices of the ejaculatory ducts. On the side of the verumontanum is the prostatic sinus into which the prostatic ducts drain.

To understand urethrography, one must appreciate the presence of the urinary sphincters. The internal sphincter, which is composed of smooth muscle, surrounds the proximal portion of the prostatic urethra at the bladder neck. The intrinsic sphincter is also composed of smooth muscle and lies below the verumontanum. The external sphincter is composed of striated muscle and lies at the level of the membranous urethra. The internal sphincter of the bladder neck maintains passive continence. This internal sphincter is a circular band of smooth muscle, which is sympathetically controlled; it relaxes when bladder contraction occurs. Damage may occur in cases of traumatic pelvic injury or postsurgical obliteration, as can occur after a transurethral prostatic resection (TURP). The intrinsic sphincter consists of a 5-mm band of circular smooth muscle encircling the membranous urethra and extending proximally to surround the distal prostatic urethra. If damage occurs to the internal sphincter, passive continence may be maintained by the intrinsic sphincter. The intrinsic sphincter serves to empty the posterior urethra back into the bladder at the end of micturition. The external sphincter surrounds both the intrinsic sphincter and the membranous urethra. This sphincter is voluntarily controlled and is composed of striated muscle. Active continence is maintained by the external sphincter (22,23).

Technique

Although the technique of retrograde urethrography varies, the aim is to achieve consistent visualization of the urethra after the installation of contrast. Films must be exposed during the retrograde injection of contrast to adequately visualize the posterior urethra. The milking action of the intrinsic sphincter rarely allows opacification of the posterior urethra if contrast is not actively flowing through this portion of the urethra.

The initial film before a urethrogram is a coned film of the pelvis taken in a right posterior oblique position. The supervising physician reviews this film for abnormalities related to the pelvis, pelvic soft tissues, or bony structures. The patient is interviewed regarding possible heart murmurs, valve replacement, or the presence of a joint replacement. If any of these conditions exist, these patients are started on prophylactic antibiotics before the placement of a catheter and the injection of contrast. A 60-mL syringe is then filled with Reno-30 (diatrizoate meglumine 30%, Bracco Diagnostic Inc., Princeton, New Jersey). One standard technique requires the placement of a Foley catheter approximately 1 inch into the penis. A small amount of saline is injected into the balloon of a Foley catheter, with the dilated balloon fixed in the fossa navicularis. Films are obtained during the retrograde injection of contrast material. Typically, a 14- or 16-Fr Foley catheter is used for this study. Contrast material should be preinjected through the Foley catheter to purge air from the lumen. Patients are placed in a 45-degree right posterior oblique position so that the shaft of the penis is draped over the soft tissues of the thigh. After an initial volume is injected, resistance may be encountered due to spasm of the external sphincter. If there is spasm of the external sphincter, there will often be leakage of contrast from the meatus. In an attempt to overcome spasm of the external sphincter, patients are asked to attempt to void. Simultaneous to this action, contrast is injected in the hopes of filling the posterior urethra. Gentle pressure on the plunger of the syringe typically overcomes this resistance. There will be a noticeable decrease in effort when contrast begins to flow into the posterior urethra and bladder. This examination does not require fluoroscopic imaging (34).

Currently, we inject contrast into a syringe connected to a 19-by- $^{7}/_{8}$ butterfly needle apparatus from which the needle has been removed. This tubing is placed into the urethral meatus. Traction is placed on the penis, and manual compression is made close to the glans penis. Using this technique and appropriate penile traction, the hands of the individual injecting contrast will be outside the collimated beam. Alternatively, radiation-reduction gloves can be worn. The postinjection film is evaluated for adequate filling of all urethral segments. If necessary, additional images can be performed after repeat injection(s).

Other techniques are available for the performance of urethrography, including the use of a Brodney clamp (Fig. 3B.3) (11). This apparatus is no longer available at our institution. Nonetheless, practitioners have aimed to improve the diagnostic quality of retrograde urethrography using alternative techniques, including the use of an external compression “device.” One such technique includes the placement of a 20-Fr Foley catheter with a 30-mL balloon placed under the penis. A bandage, 3 to 4 cm wide and approximately 60 cm long, is cut from the edge of a sterile disposable polythene drape; this is then wound around the penis and the catheter. The balloon of the external Foley catheter is inflated with air to produce firm pressure on the urethra. This technique aims to achieve external compression and serve as a penile clamp for retrograde urethrography (15).

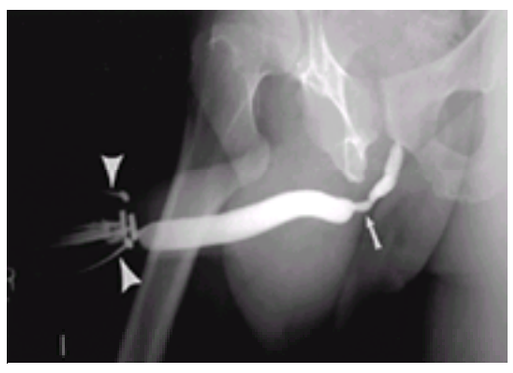

FIGURE 3B.3. Brodney clamp. A Brodney clamp *(arrowheads)* is seen positioned over the glans of the penis. Contrast has been injected in a retrograde fashion, and a bulbar urethral stricture *(arrow)* is demonstrated.

Other imaging techniques include pericatheter retrograde urethrography. This can be accomplished by placing an Intra-Cath alongside an indwelling Foley catheter,

permitting the injection of contrast adjacent to an indwelling Foley catheter. Compression distally should prevent spillage of contrast. The use of a pericatheter device can also serve the same purpose. A pericatheter device either 1 or 0.5 cm wide may be advanced along an indwelling catheter, through the meatus, and into the urethra until the injection arm of the device reaches the penile meatus. The standard device is 7 cm long; a smaller version is 4 cm long (18). The use of a disposable retrograde urethrogram catheter (“golf tee” catheter) made of soft blended plastic polymer has also been described. This catheter is 9 cm in overall length and has a 14-Fr outer diameter. The proximal end is flared and fits over a Toomey (standard catheter tip) syringe. The catheter is advanced to the level of the proximal flare, effectively occluding the penile meatus. Gentle pressure is applied around the base of the glans penis to prevent leakage of contrast. Mild traction is applied to stretch the urethra (24).

Although not our standard practice, a technique of double-contrast urethrography has also been described. Contrast coating of a urethral lesion has been described using 10 mL of iodized oil (Lipiodol) emulsion into the urethra, followed by 20 mL of air (43). A “choke” voiding urethrogram may be obtained by leaving a catheter in place and allowing the patient to void against pressure. This can be performed after the bladder is filled for a cystogram or after an intravenous urogram is performed. Meatal compression voiding urethrography (MCVU) using a Zipser clamp is described as a simple and accurate alternative to retrograde and noncompression voiding urethrography. Bladder filling with contrast either via a urethral catheter or as a result of an excretory urogram is first accomplished. The patient places the Zipser clamp behind the corona of his penis and signals the technologist when he begins to void. A radiograph is exposed, and the patient is told to stop voiding. If adequate urethral visualization is accomplished in full distention, the examination is concluded (8,13).

A recently described technique for retrograde urethrography includes the use of an appropriate-sized Bommelaer vacuum uterine cannula. This cannula is applied to the penile glans by increasing the negative pressure of the vacuum to a maximum of 25 mm Hg. After correct coupling of the cannula to the glans, contrast material is injected and spot films obtained. This technique permits better visualization of the distal tip of the anterior urethra, an area typically obscured by the presence of a Foley catheter. Patients experience less discomfort with this procedure compared with the Foley technique because the inflation of the balloon in the fossa navicularis is avoided. Opacification of the posterior urethra was reported to occur at a similar rate to that seen when using a Foley balloon method (3,27).

Urethrography of the Male Urethra

Radiographic landmarks seen during the performance of retrograde urethrography include the cone shape of the proximal bulbous urethra, the verumontanum within the prostatic urethra, and the bladder neck. Between the tip of the cone of the bulbous urethra and the inferior aspect of the verumontanum lies the membranous urethra. The penile urethra extends from the external meatus to the penoscrotal junction. The bulbous urethra lies between the inferior aspect of the urogenital diaphragm, where it exhibits a symmetric cone shape; it extends to the penoscrotal junction. The verumontanum is visualized as a smooth oblong-filling defect in the posterior wall of the prostatic urethra. Occasionally, a Cowper's duct or utricle may fill with contrast. Cowper's ducts are seen as faint lines of contrast adjacent of the proximal portion of the bulbous urethra. Cowper's ducts are posterior and lateral to the membranous urethra and extend from Cowper's glands to enter the cavernous portion of the bulbous urethra (41). The opacified utricle appears as a small tear drop–shaped cavity protruding posteriorly from region of the verumontanum. The glands of Littre appear as small linear collections of contrast material parallel to the superior margin of the anterior urethra. This is often associated with chronic infection or urethral stricture disease. Strictures may also account for opacification of Cowper's ducts and glands (Fig. 3B.4).

FIGURE 3B.4. Glands of Littre/Cowper's duct. There is a diffuse beaded appearance of the anterior urethra consistent with a long anterior urethral stricture. The bulbous urethra is dilated. A small amount of contrast is seen in Cowper's duct *(single arrow).* Small contrast collections on the ventral surface of the urethra are consistent with the glands of Littre *(multiple arrows).*

Rupture of the urethra during retrograde urethrography, although rare, can produce opacification of the corpus spongiosum, the paired corpora cavernosa, and the draining veins of the penis. Rupture may be secondary to a tight external sphincter or stricture, both processes causing increased intraurethral pressure during the injection of contrast material and an iatrogenic urethral tear. Corporal filling and venous filling may also be produced by trauma (whether caused by a Foley catheter or Brodney clap), previous urethral instrumentation, or external trauma (2) (Fig. 3B.5).

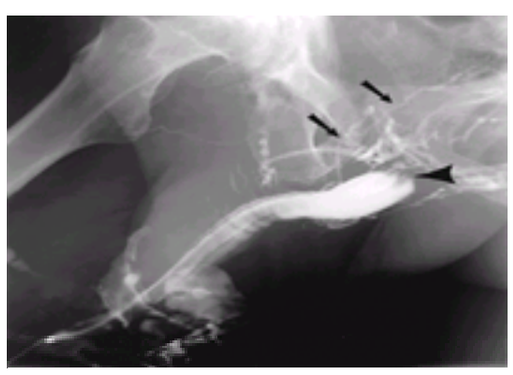

FIGURE 3B.5. Urethral extravasation. Contrast has been injected along side an indwelling Foley catheter. There is gross extravasation of contrast in the region of the membranous urethra *(arrowhead).* Filling is seen of the periurethral soft tissues, with widespread filling of pelvic veins *(arrows).*

Urethrography of the Female Urethra

The female urethra is approximately 4 cm long and extends from the internal to the external urethral orifice. It courses in an oblique and downward fashion and is slightly curved. The urethral meatus is anterior to the vaginal opening; contrast material does not usually enter the vagina during voiding.

Standard voiding cystourethrography in females includes preliminary films of the pelvis to establish a baseline reference. The bladder is then partially filled, and supine views can be obtained to evaluate for potential reflux. After the bladder is completely filled, patients are placed in a standing position. Lateral, anteroposterior, and oblique fluoroscopic images can be obtained during the voiding and postvoid stages. These procedures can be videotaped. Films are scrutinized for the presence of a urethral diverticulum, evidence of urethral prolapse or hypermobility, and stress incontinence (29).

Double-balloon urethrography is described as a more sensitive diagnostic test for diagnosing a female urethral diverticulum (12). This technique requires the placement of a Bardex Davis model catheter (Bard Urological Division). The catheter is inserted into the bladder, and the balloon is inflated to 30 mL and pulled back until it is seated in the trigone. A sliding balloon is then pushed against the external meatus and inflated to 20 mL to produce a seal. Contrast is injected into the central lumen of the catheter. If leakage is seen into the bladder around the proximal balloon, the pressure and/or position of the balloon must be adjusted to reestablish the seal. In a recently reported study, double-balloon urethrography had a greater sensitivity (100%) than voiding cystourethrography (44%) relative to a

confirmed surgical diagnosis (16) (Fig. 3B.6). Other authors have suggested that although the voiding cystourethrogram is not as sensitive as the double-balloon technique, it can still be used as a screening test. If the results of voiding cystourethrography are inconclusive and clinical suspicion persists, a double-balloon examination or MRI can be performed (28,33,40). Transrectal sonography has also been described in the diagnosis of urethral diverticula in women (39).

FIGURE 3B.6. A, B: Multiple urethral diverticula. Double-balloon retrograde urethrography reveals multiple diverticular outpouchings *(arrows).* This patient previously had a normal voiding cystourethrogram.

A variation in the double-balloon technique has been described. Dilute contrast may be used to inflate the intravesical and external balloons of the double-balloon catheter. The proximal balloon is inflated with 25% concentration contrast medium (Renografin 60, Conray 60, or Hypaque 50 diluted with saline) and then drawn snugly down to the internal urethral meatus. The external balloon is inflated with 50% contrast medium. Nondilute contrast medium is injected into the main lumen of the catheter. This is performed on the radiologic examination table, which facilitates fluoroscopic and spot films and provides suitable positioning of the patient during the injection of contrast material. The variation in concentration of contrast between the proximal and distal balloons and the full-strength contrast in the diverticulum permit more precise delineation of the relationship of the diverticulum to the bladder base, the internal sphincter, and the external urinary meatus (19).

An alternative examination in the investigation of potential female urethral diverticula simply requires obtaining a postvoid film after cystography. Comparison between a preliminary coned film of the pelvis and the postvoid film may show accumulation of contrast in an expected periurethral location (Fig. 3B.7). This is an easy technique to use and does not require a double-balloon catheter.

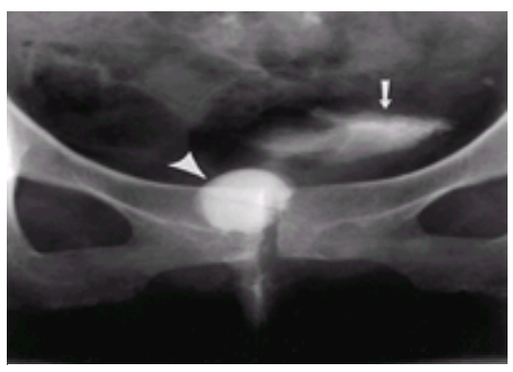

FIGURE 3B.7. Female urethral diverticulum. A rounded contrast collection is seen overlying the right public symphysis *(arrowhead).* This is separate from the small residual contrast in the bladder *(arrow).* Filling of this urethral diverticulum is demonstrated on the postvoid film from a cystogram.

Also described is the use of an Allis clamp to grasp the vaginal mucosa while a rubber olive-tip Brodney device is applied snugly to the urethral meatus. This maneuver is stated to result in elongation of the urethra, preventing compression and accordion-like shortening of the urethra (38). In our experience, patients who are suspected of having diverticular disease are best imaged with either a double-balloon technique or MRI.

Urethrography: Findings

Lesions that can be diagnosed on urethrography include traumatic injuries, congenital anomalies, obstructions, strictures, acquired diverticula, and neoplastic lesions. Congenital anomalies include hypospadias, posterior and anterior urethral valves, and urethral duplications. These anomalies, when severe, are usually treated surgically during childhood. Congenital duplication of the urethra is rare. Most duplications are incomplete and asymptomatic, requiring no treatment. A less common but clinically important entity is a complete patent duplication. These patients are symptomatic, with a double stream being the most common symptom. In all cases, the ventral channel proves to be the more normal urethral channel. These lesions have been classified into type I (blind and complete urethral duplication), type IIA (complete patent duplication with two meatus), type IIA1 (two noncommunicating urethras arising independently from the bladder), type IIA2 (a second channel arising from the first and coursing independently to a second meatus), type IIB [complete patent urethral duplication with one meatus (two urethras arising from the bladder or posterior urethra reuniting to form a common distal channel)], and type III (urethral duplication as a component of partial or complete caudal duplication) (32). Cysts of Cowper's duct may be congenital in children but are typically acquired in adults secondary to urethral infection. A localized collection at the floor of the bulbous urethra is the typical appearance (9,35).

The presence of a double-density sign points to the diagnosis of a male urethral diverticulum. The double-density sign in the bulbous urethra is confirmed as a posterior urethral diverticulum after obtaining an oblique view accounting for the creation of this double density (31) (Fig. 3B.8).

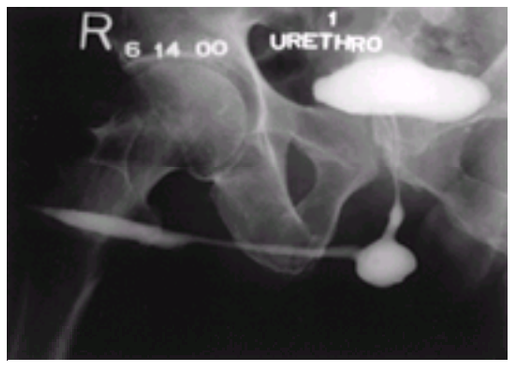

FIGURE 3B.8. Urethral diverticulum. Contrast is seen filling a bulbar urethral diverticulum. The distal bulbar urethra and proximal penile urethra are diffusely strictured.

Congenital saccular anterior urethral diverticula are uncommon. Congenital diverticula are termed *saccular* or *diffuse* on the basis of their anatomic configuration. A localized protrusion from the lumen into the ventral wall of the anterior urethra is a saccular-type diverticula. A generalized dilation of the entire anterior urethra, also

termed *megalourethra* or *urethral ectasia,* is characterized as a diffuse type. Saccular-type diverticula may produce anterior urethral obstruction via a valvelike mechanism. The radiographic appearance of a saccular diverticulum is characteristic. Contrast will fill an oval outpouching on the ventral aspect of the anterior urethra. The diverticulum involves the midportion of the penile urethra but can involve the bulbous urethra as well. There is a broad communication between the urethral lumen and the diverticulum. Primary differential considerations when detecting this entity are anterior urethral valves and a dilated Cowper's gland duct (17). Female urethral congenital anomalies are extremely rare. An ectopic ureter may insert into the female urethra and fill during voiding. An ectopic ureter may masquerade as a urethral diverticulum (6).

Urethral stricture disease is common as a result of infection, instrumentation, or trauma. Gonorrheal infection may lead to fibrous scar formation. Inflammatory strictures are found most commonly in the bulbar urethra. The glands of Littre are more abundant in this portion of the urethra and presumably harbor infectious bacteria. Urethritis may also be secondary to conditions such as tuberculosis and schistosomiasis, causing abscesses in the periurethral tissues and perineal fistula formation. The “watering-can” perineum describes the presence of urethral cutaneous fistulae in patients with longstanding strictures (36). Often, these strictures are the result of postgonococcal disease.

Acquired female urethral diverticula occur posterior to the midurethra, although rarely they may occur anteriorly. These originate from infected periurethral glands, which may form an abscess that ultimately ruptures into the urethra. Filling defects within a urethral diverticulum may be secondary to debris, the presence of calculus disease, or rarely, a tumor (10).

Primary carcinomas of the urethra are uncommon but are seen more commonly in women than in men. Most tumors are squamous cell carcinomas; a smaller percentage are transitional cell carcinomas or adenocarcinomas. In men, carcinomas are often associated with an anterior urethral stricture (42).

A well-known artifact in urethrography is the pseudostricture of the urethra. This is caused by pressure on the under surface of the penis by a collecting vessel. This should not be mistaken for a stricture. A short proximal stricture can appear to be long on a voiding study if flow through the narrowed area is not forceful enough to distend the urethra. A smooth uniform narrowing of the entire anterior urethra distal to the penoscrotal junction causes this characteristic pseudostricture. If doubt remains, a retrograde examination or repeat voiding urethrography should be performed (20).

CYSTOGRAPHY

Technique

The first film exposed during the performance of a cystogram is a scout kidney, ureter, bladder (KUB). This is typically exposed using 65 kV and 900 mA at 60 ms. This plain film is evaluated for the presence of abnormal calcifications; abnormal gas collections; and any potential abnormalities related to the kidneys, ureters, or pelvis. Before a Foley catheter is placed, patients are interviewed regarding their history of cardiac valvular disease and the presence of any joint replacement. Patients who have either a heart murmur (mitral or aortic prolapse/regurgitation), a prosthetic heart value, or an orthopedic joint replacement are placed on prophylactic antibiotics before the placement of the Foley catheter for the cystogram.

Typically, a 14-Fr, 16-inch Dover Rob-Nel catheter (Sherwood Medical, St. Louis, Missouri) is placed into the bladder. A bottle of Cystografin (diatrizoate meglumine 18%, Bracco Diagnostics Inc., Princeton, New Jersey) is infused into the Rob-Nel catheter. Contrast is infused until the patient complains of fullness. At this point, a supine KUB is exposed in addition to a left posterior oblique film. The supervising physician checks these films. The catheter is then removed, and a voiding film is obtained in a right posterior oblique. If the patient is unable to void for this film, an oblique film is exposed with the patient straining. The supervising physician reviews this film. Subsequent to this, the patient is allowed to void completely and a postvoid film is obtained in a frontal supine position. When cystography is performed, every effort should be made to administer as much contrast as the patient can comfortably retain. In the posttrauma setting, this is particularly important to avoid missing bladder extravasation. Ideally, 300 to 500 mL of contrast is administered.

Normal Anatomy

The bladder is oval shaped, with its greatest dimension in the vertical or horizontal position (especially in women). The bladder wall appears smooth when there is full distention and the bladder is normal (Fig. 3B.9). Continence is maintained at the level of the bladder neck. Filling of the posterior urethra may occur in patients who have had a prostatectomy or in patients who have an incompetent internal sphincter. A small amount of air may be seen within the bladder when air is introduced during instrumentation. The bladder base is flat in a supine position and cone shaped when the patient is erect. Voiding occurs when the smooth muscles of the bladder detrusor contract. There are three layers of muscle in the bladder: outer and inner longitudinal muscle and middle circular muscle. Pelvic floor musculature will relax during micturition, and the bladder will descend and change its appearance.

FIGURE 3B.9. Normal cystogram. Contrast (275 mL) fills this normal bladder as part of a pretransplant evaluation. There is no reflux. Calcification is seen in the iliac arteries bilaterally.

Films are evaluated for the presence of reflux, diverticula, possible mural lesions, and extravasation. If voiding films are desired, these are typically obtained with the patient in an upright position. A receptacle, which is radiolucent, is given to the patient. Filming is performed in an oblique position (Fig. 3B.10). As described previously, this technique can be modified by having the patient void against resistance. This can be accomplished by pinching the distal aspect of the penis or by using a penile clamp such as a Zipser clamp.

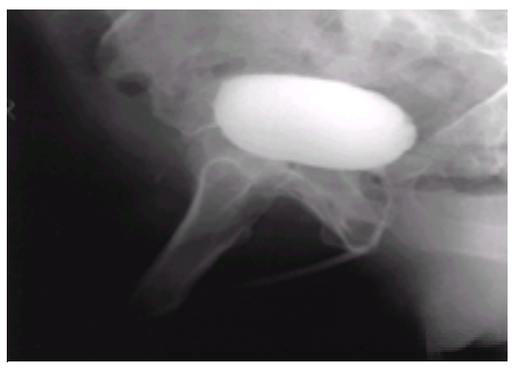

FIGURE 3B.10. Voiding film, normal voiding cystourethrogram. Contrast fills a normal-appearing bladder. There is no evidence of reflux. Filling is seen of a normal-appearing urethra.

Indications

Cystoscopy remains the gold standard for the urologic evaluation of the bladder; radiographic investigation is performed in a number of settings, including the evaluation of possible vesicoureteral reflux, evaluation of bladder diverticular disease, investigation of a potential bladder injury in a trauma patient, and common in our practice, documenting the bladder appearance in patients before a renal transplant.

The vast majority of cystograms are performed in the posttrauma setting; cystography may also be performed in postsurgical patients who have had radical retropubic prostatectomies. Reconstructive techniques of the vesicourethral anastomosis after radical retropubic prostatectomy involve placement of a urethral catheter for stenting the anastomosis and drainage of the bladder. Traditionally, this catheterization period is approximately 2 to 3 weeks. Cystographic evaluation in these postoperative patients permits evaluation of postoperative extravasation, allowing extension of the catheterization period. An abnormal appearance of the bladder contour in cystography suggests the presence of an intrapelvic fluid collection such as a hematoma or lymphocele. Ultrasound or computed tomography (CT) may be performed to diagnose these fluid collections as well as guide potential drainage (4,21).

Posttrauma cystograms should include standard frontal, oblique, and occasionally lateral views. In severely immobile patients, oblique views are often omitted. Postdrainage films in these patients assume added importance. Small amounts of extravasation should be readily identified on the postdrainage film (37). Recently, more attention has been paid to the diagnosis of bladder injury using CT because most posttrauma patients will have CT scans to exclude intraabdominal injuries. These studies should be evaluated closely for the presence of a bladder injury. CT cystography in the detection of bladder rupture has a reported overall sensitivity and specificity of 95% and 100%, respectively (7). Other authors have addressed the radiographic and clinical predictors of bladder rupture and compared CT cystography with conventional cystography in the evaluation of bladder injuries. These results show that CT cystography is clearly an accurate method for evaluating bladder injuries (14,26,30).

FUNDAMENTALS OF COMPUTED TOMOGRAPHY IMAGING

Computed tomography (CT) plays a crucial role in the diagnosis, management, and follow-up of many urologic disorders. A detailed discussion of the physical principles involved in the production of a CT image is beyond the scope of this chapter. However, a basic understanding of the physics of CT and its recent technologic advances is helpful to the ordering clinician to ensure appropriate patient referral and optimal scanning protocols.

CT is similar to conventional radiographic tomography in that a single slice or section of a patient is imaged. However, an important difference is that the x-ray beam passes only through the area of interest and not through adjacent structures, thus eliminating degradation of the image by superimposition of structures outside the slice. The entire urinary tract is directly shown in cross section, so overlying gas or bony structures do not obscure the areas of interest, as can occur with intravenous urography (IVU) or ultrasonography. Compared with magnetic resonance imaging (MRI), CT has better spatial resolution, is more widely available, usually has shorter scanning time, and is of lower cost. However, when an apparent renal mass is indeterminate in imaging features on CT, the greater contrast sensitivity of MRI may allow better detection of intratumoral enhancement. CT and MRI may therefore be complementary for such lesions. Anatomic regions such as the retroperitoneal structures, which are only indirectly imaged by conventional means, are directly visualized by cross-sectional techniques such as CT.

The creation of an image by CT relies on the inherently different attenuation characteristics of the various tissues in the body. CT has much higher contrast sensitivity than conventional radiographs and thus allows the differentiation of tissues with much smaller density differences than is possible with plain radiographs. Thus calculi that are nonopaque on abdominal films (e.g., uric acid stones) are seen as dense structures on CT scans.

Basically, a CT image is a two-dimensional representation of the distribution of different x-ray attenuation coefficients, or densities, of the various tissues within a narrow cross section of the subject's anatomy. The x-ray tube circles around the patient, emitting narrowly collimated x-ray beams from multiple different angular projections that pass through the subject and are sensed on the opposite side by a series of x-ray detectors. By reconstruction, an image is produced that is comprised of quantified grayscale values, known as *pixels,* that assign density values to individual points within the section. Each pixel value is directly related to the linear attenuation coefficient of the corresponding volume element of the slice, called a *voxel.* The density measurements are then standardized using the Hounsfield scale, named after Sir Godfrey Hounsfield, the inventor of the first clinically viable CT scanner (4,12,34). This scale assigns water a CT number, or Hounsfield Unit (HU), of zero and assigns all other tissue values ranging from -1,000 to approximately +2,000, depending on their attentions relative to water. Using this scale, air is -1,000 HU, fat is approximately -50 to -100 HU, fluid is 0 to +20 HU, soft tissue is between +40 and +60 HU, and cortical bone is between +1,000 and +2,000 HU. CT numbers may vary slightly between manufacturers and are a function of scanner kV (4,12).

The attenuation value of a specific tissue is measured by placing a cursor over the region of interest (ROI) on the workstation and instructing the computer to give the average CT number for that region. The number actually represents the average attenuation of the voxels within the cursor. Therefore measurements are most accurate if the ROI cursor is smaller than the structure being measured, if the cursor is placed well within its boundaries, and if the structure fills the entire slice width of the voxel. Measurements are subject to partial-volume artifact if the structure being measured is smaller than the slice width (4). For example, if the slice thickness is 10 mm and the ROI cursor is placed over a 5-mm renal cyst within the slice, the attenuation measurement will be erroneously high, representing the average of the cyst fluid and the adjacent 5 mm of renal parenchyma. Partial-volume artifact also occurs if an object extends only partially into a CT slice or if two different structures extend into the same slice; it is also exacerbated by patient motion and differences in respiration between slices, leading to respiratory misregistration. Partial-volume artifact is diminished when shorter scan times, thin-section collimation, and single breath-hold scanning techniques are used (4).

Following reconstruction, a CT image is processed to make certain anatomy or pathology more conspicuous by changing the window level and window width. The dynamic range of CT scanners is 4,096 different grayscale values. However, because a maximum of 256 gray levels can be displayed in a typical image, a small subset of the entire grayscale range must be chosen to optimize contrast within specific tissue types (12). The window level controls the image brightness. A midgray level in the center of the display range is selected. The window width defines the range of densities, from black to white, around the midgray level that will be displayed in the image. For example, the typical window level for soft tissue imaging within the abdomen and pelvis is 50 HU with a window width of 200 HU. Therefore only tissues with CT numbers of -50 to +150 HU will be displayed. Those with numbers less than -50 HU will be black, and those values greater than +150 will be white (12). Selecting a narrower window width will enhance contrast, as well as noise, but may be helpful in identifying subtle mass lesions, particularly those in the liver. In contrast, imaging the lung parenchyma requires a lower window level of approximately -700 HU and a wider width of 2,000 HU to enable display of a larger range of densities, including air-filled lung and soft tissue (12). A CT scan of the abdomen and pelvis is routinely reviewed in soft tissue, liver, bone, and lung windows. A liver window or similar narrow window is often helpful in improving lesion conspicuity within the kidneys, particularly when there is intense contrast enhancement of the renal parenchyma.

CT scanning geometry has evolved from first- to fourth-generation scanners. Rapid scan times and optimal spatial resolution require a large number of x-ray detectors, an integral feature of third- and fourth-generation scanners. First-generation scanners had a single x-ray tube and detector. Most modern scanners use third-generation geometry, in which the x-ray tube and a large number of detectors (referred to as a *detector array*) are rigidly fixed opposite one another and rotate together around the patient as the detector samples the fan of divergent rays. In fourth-generation scanners, the detector array forms a complete 360-degree outer ring that samples x-ray beams from the inner x-ray tube and generator as they rotate around the patient. The major advantage of the later-generation models is a faster scan time of 1 second or less and improved spatial resolution (4,12).

Helical computed tomography (HCT), or spiral CT imaging, became commercially available in the early 1990s (4,36,37). In conventional CT scanning, the x-ray tube

focal spot lies within a single plane, the table and patient are stationary as data are collected from each slice of anatomy, and the table is moved incrementally between each slice acquisition until the entire area of interest is imaged. During HCT, the table and patient are not stationary during image acquisition, but rather move at a predetermined constant speed while the x-ray tube, and usually the detector array, rotate 360 degrees around the patient. Therefore the x-ray tube focal spot forms a continuous helix around the patient, rather than multiple contiguous circular planes, enabling rapid acquisition of a volumetric data set. Whereas conventional CT images are typically reconstructed from the entire 360-degree angular view set, HCT images are reconstructed from half (180 degrees) of the available view set (4). Because the acquired views do not lie in a plane, the view set is not comprised of actual projections of the slice, but rather is interpolated from the adjacent volumetric data to create the image slice. For this reason, HCT is subject to increased volume averaging artifact. However, the benefits of diminished motion and respiratory misregistration outweigh the mild increase in partial-volume averaging. One of the greatest advantages of HCT is the ability to improve z-axis resolution by retrospectively selecting a narrower collimation using overlapping reconstruction. This feature is important when attempting to characterize small lesions based on attenuation measurements (4,26).

The development of HCT has enabled imaging of large anatomic regions in a single breath hold, which helps eliminate problems of respiratory misregistration between adjacent slices and helps improve lesion characterization. HCT also enables imaging during the optimal phase, or multiple phases, of enhancement following bolus injection of iodinated intravenous contrast media. In addition, identical image levels are more consistently achieved before and after intravenous contrast media for assessment of lesion enhancement characteristics (26). The risk of imaging during suboptimal phases of contrast enhancement, common in conventional CT imaging, is much reduced with HCT. The three-dimensional data set acquired during HCT imaging has also been critical in the development of three-dimensional CT reconstruction and CT angiography (CTA) (66). The more recent development of multidetector-row HCT (MDCT), also known as *multislice HCT,* and subsecond gantry rotation times, has further revolutionized CT imaging. Much more rapid scan times, improved longitudinal resolution, greater longitudinal coverage, and diminished radiation doses and intravenous contrast load are now possible (66).

COMPUTED TOMOGRAPHY OF THE KIDNEYS

Technique

Complete evaluation of the kidneys requires precontrast and postcontrast imaging. Thus, in patients with a suspected or known renal mass, or those with hematuria, both precontrast and postcontrast scanning should be performed. However, for some indications, such as evaluation of a patient with suspected acute renal colic, unenhanced (noncontrast) scanning alone is generally sufficient to answer the clinical question. Although many renal abnormalities may be detectable on postcontrast images, definitive evaluation of renal masses requires assessment of enhancement in the mass, for which thin-section images through the kidneys both before and after the administration of intravenous contrast media are necessary. It is imperative to use identical scanning parameters before and after contrast administration to ensure that attenuation measurements are obtained from exactly the same location within a lesion and that any change in attenuation can be attributed to lesion enhancement.

The dose of intravenous contrast depends on patient size but generally is between 100 and 150 mL (20 to 50 g of iodine). Oral contrast is given to all patients except those being evaluated for acute renal colic.

The kidneys can be imaged in three distinct phases after contrast administration: the corticomedullary phase (CMP), the nephrographic phase (NP), and the excretory phase (EP) (Fig. 3C.1). The CMP occurs between 25 and 80 seconds after initiation of the contrast bolus, when much of the contrast remains in the renal cortical capillaries, proximal tubules, and peritubal spaces (8,41,86). Because the medullary pyramids are lower in attenuation compared with the cortex, there is an increased chance of either missing a central low-attenuation mass or mistaking a normal pyramid for a mass (Fig. 3C.2 and Fig. 3C.3). More rarely, the enhancing renal cortex may obscure an intensely enhancing vascular cortical neoplasm (86). The NP occurs between 85 and 130 seconds after the initiation of contrast administration as contrast filters through the glomeruli, loops of Henle, and collecting ducts, creating homogeneous parenchymal enhancement. EP images are obtained 3 to 5 minutes after intravenous contrast administration. At this point, the renal parenchyma remains homogeneous but is diminished in attenuation compared with the NP (86). EP images are typically recommended if a urothelial tumor is suspected because contrast in the collecting system increases the conspicuity of a low-attenuation mass. They are also often helpful in distinguishing central renal cell carcinomas (RCCs) from transitional cell tumors located within a calyx or renal pelvis (81). Delayed images obtained after 15 minutes may be helpful in characterizing incidentally identified renal masses when preliminary unenhanced images were not obtained. It has been shown that the attenuation of renal neoplasms diminishes with time as the contrast “washes-out,” whereas the density of high-attenuation cysts does not change with time (54,86).

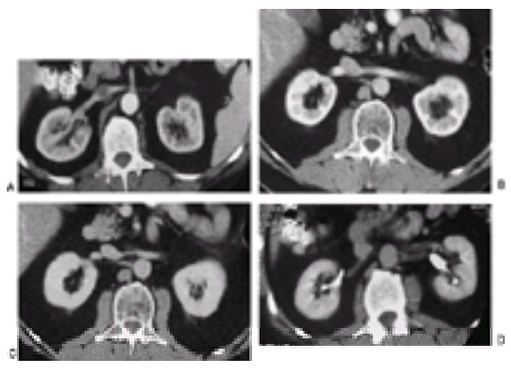

FIGURE 3C.1. Phases of renal contrast enhancement. In corticomedullary phase **(A, B),** the renal cortex and medulla are very distinct. Note flow artifact in cava on **A** and course of renal vessels. In nephrographic and excretory phases **(C, D),** the parenchymal enhancement is homogeneous, making it easier to detect renal masses.

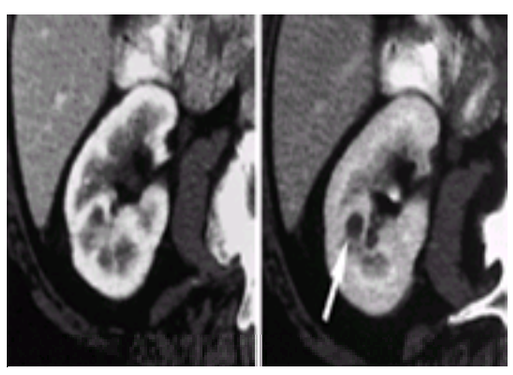

FIGURE 3C.2. Renal cyst obscured on corticomedullary phase (CMP) of enhancement. Image on right in nephrographic phase (NP) demonstrates a small cyst *(arrow),* which is a much more subtle finding on the CMP image on the left.

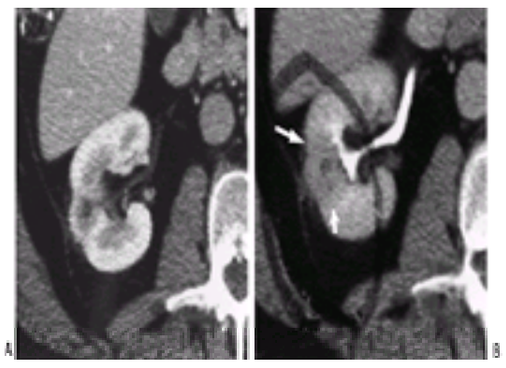

FIGURE 3C.3. Small renal cell carcinoma, poorly seen on corticomedullary phase (CMP) imaging. On CMP image **A,** there is an irregular bulge in the renal contour. The different enhancement of this lesion is much more obvious *(arrows)* on the excretory phase imaging **(B).** (Artifact on image circling area of interest).

Recognition of these phases of normal renal enhancement and the effect on renal mass detection, conspicuity, and characterization is very important. Masses may be difficult to recognize and characterize if imaging is performed during the CMP alone (Fig. 3C.2 and Fig. 3C.3). Of all renal lesions detected in the NP, only 67% to 72% are also detected in the CMP of imaging (8,18,78). In one study (18), the addition of NP imaging to CMP imaging resulted in a 4.4-fold increase in detection of medullary lesions, and a 1.2-fold increase in the detection of cortical lesions. False-positive results are also more common in the CMP of imaging (5,18,78). However, renal venous involvement is best seen during the CMP of enhancement (45).

Current scanning protocols for renal mass characterization are performed as follows. During HCT, unenhanced (precontrast) images are obtained through the kidneys at 5-mm increments. Intravenous contrast is then administered using a mechanical power injector at a rate of 2 or 3 mL per second. Following initiation of the contrast bolus, contiguous 5-mm scans are obtained through the kidneys. CMP images are acquired after a delay of 30 to 40 seconds, and NP images acquired after a delay of 100 seconds. If indicated, EP images are acquired 3 to 5 minutes after contrast bolus (18,45,78,86,88). It has been shown that the timing of the NP is variable and depends on multiple factors, such as the patient's cardiac output and renal function and the dose and rate of injection of the contrast media. Therefore it may be helpful to use a bolus-tracking device such as Smart-Prep (GE Medical Systems, Milwaukee, Wisconsin), which triggers the onset of HCT at the completion of the CMP (7) and ensures true NP imaging. As stated, postcontrast series should use scanning parameters identical to those used during the initial unenhanced series. If the entire abdomen is to be imaged, it is possible to scan the remainder of the abdomen and pelvis between the CMP and NP images (86).

Vascular-phase imaging, or CTA, is recommended in patients who are undergoing preoperative planning for nephron-sparing surgery, repair of ureteropelvic junction obstruction, or donor nephrectomy (32). Specific techniques for CTA are considered in Chapter 3F. With the advent of MDCT, it is now possible to perform high-quality CTA of the renal arteries and aorta and high-resolution imaging of the kidneys for lesion detection in a single examination. In the past, renal lesions were often suboptimally evaluated during the CMP of enhancement obtained during CTA.

Anatomic Considerations

The perinephric fat outlines the surface of the kidney; the renal capsule cannot be distinguished from the renal parenchyma. The fat in the renal sinus is of low attenuation and outlines the collecting system and the blood vessels, which course anteromedially. The perirenal fascia and the septa extending from the kidney to the anterior or posterior renal fascia are visible as linear soft tissue densities (48). The anterior renal fascia is usually seen on the left, less commonly on the right, and it separates the structures in the anterior pararenal space, such as the pancreas, retroperitoneal duodenum, and the ascending and descending colon, from the kidneys. The posterior renal fascia is commonly seen posterior to both kidneys.

The right adrenal gland is superior to the upper pole of the kidney, just dorsal to the inferior vena cava (IVC). The left adrenal gland is more anteriorly and medially located, with the splenic vein just anterior to it as a consistent landmark (30).

The renal parenchyma is of homogeneous soft tissue density on noncontrast images with attenuation values of 30 to 60 HU. The renal pelvis and proximal infundibula may be seen as water-density structures, particularly if the renal pelvis is extrarenal. The calyces are not identifiable without contrast excretion. After intravenous contrast administration, the renal vessels and cortex enhance brightly. In the first 60 seconds after contrast administration (the CMP), there is sharp distinction between the cortex and the medulla (Fig. 3C.1A and Fig. 3C.1B), but the medulla also soon enhances brightly (the NP) (Fig. 3C.1C). On delayed images, dense urine is seen in the collecting system in patients with normal renal function (Fig. 3C.1D). The ureter courses anteroinferiorly over the psoas muscle.

The renal veins lie ventral to the arteries, with the longer left renal vein (Fig. 3C.1B) coursing between the aorta and the superior mesenteric artery to the IVC (which may be oval or slitlike at this level). The right renal vein is shorter and, with a more oblique course into the cava, and may not always be well imaged on CT scans. The right renal artery crosses behind the cava to enter the kidney (Fig. 3C.1B) while the left courses directly to the kidney (Fig. 3C.1C and Fig. 3C.1D).

Normal Variants and Congenital Anomalies

Pseudotumors, named variously as the column of Bertin, dromedary hump, or hilar lip, may occur in the kidneys due to variations in the pattern of lobar fusion and may simulate renal masses on IVU and sonography. Compensatory hypertrophy due to focal scarring can also simulate a mass. All pseudotumors are isointense to the renal parenchyma on precontrast and postcontrast imaging and are readily distinguished from true renal masses.

Anomalies such as retroaortic renal vein; retrocaval ureter (Fig. 3C.5); circumaortic renal vein; and persistent, duplicated, or left-sided IVC can be recognized on CT, as can renal agenesis (Fig. 3C.6), malpositioned or ectopic kidneys, and fusion anomalies such as horseshoe kidneys or cross-fused ectopy. With renal agenesis, it is imperative to look for genital anomalies as well (Fig. 3C.6). CT is very accurate at distinguishing true renal agenesis from atrophic, nonfunctioning kidneys. Ectopic ureteral insertions, whether associated with duplication anomalies or not, can also be demonstrated.

FIGURE 3C.4. Course of renal vessels. Note that the right renal artery courses behind the cava. The renal sinus fat surrounds the vessels.

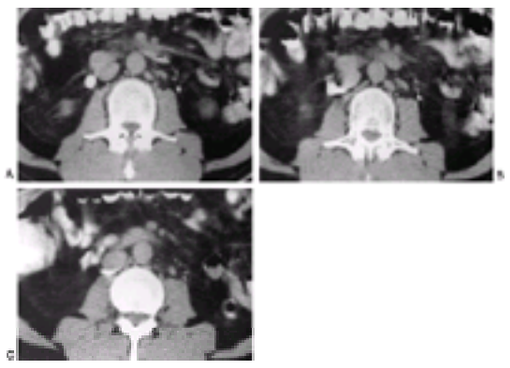

FIGURE 3C.5. Retrocaval course of mildly dilated right ureter is well seen. **A–C** tracks slices from superior to inferior.

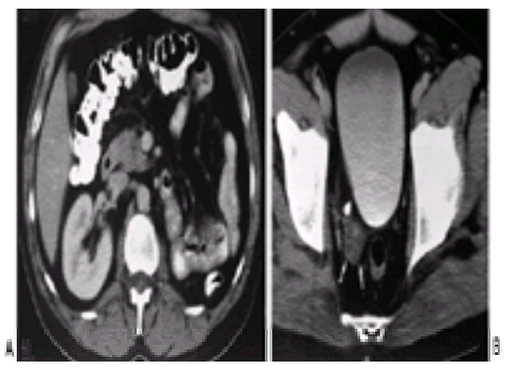

FIGURE 3C.6. A 30-year-old man with left renal agenesis and absent left seminal vesicle. There appears to be cystic change in the right seminal vesicle also *(arrows).*

Renal Masses

Renal Cell Carcinoma

The burgeoning use of CT in modern-day clinical practice is making the incidental discovery of RCCs an increasingly familiar scenario. Such masses may be detected during a CT scan being performed for symptoms referable to organ systems other than the urinary tract or for the workup of vague signs and symptoms. In a Japanese survey (3), incidentally discovered renal cell cancers increased from 20 in 1980 to 338 in 1988. Increasingly, more RCCs are detected at a smaller size (less than 3 cm in diameter) (1,19); in one study, 25% of incidentally discovered cancers were found to be smaller than 3 cm as compared with only 5% in the pre-CT era (71) (Fig. 3C.7). Contrast-enhanced CT is more sensitive than either sonography or IVU in detecting renal masses smaller than 3 cm (94% versus 79% and 67%, respectively) (1,84).

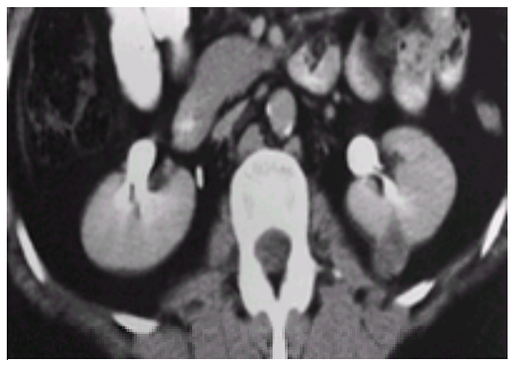

FIGURE 3C.7. Small left renal cell carcinoma discovered incidentally in a 42-year-old woman being evaluated for right abdominal pain. The mass is exophytic and enhances less than the normal renal parenchyma, expected findings with renal carcinoma.

CT is the recommended investigative modality when a renal mass is indeterminate in its characteristics on sonography, if a patient has a malignancy that metastasizes to the kidneys, or if there is a palpable flank mass. It is also the imaging modality of choice for evaluating a suspected renal mass and for staging a known neoplasm.

Imaging Features of Renal Cell Carcinoma

1. Distortion or bulge of the renal contour can occur. Because RCCs arise from the cortex, 95% of these lesions are exophytic (87) (Fig. 3C.8).

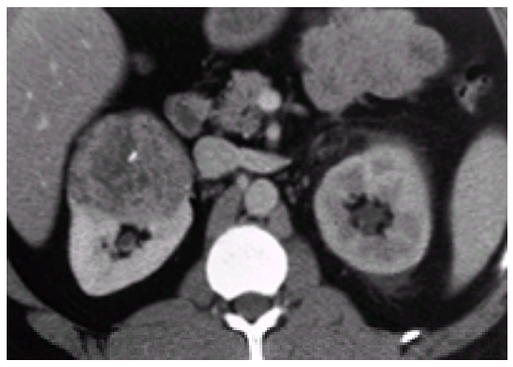

FIGURE 3C.8. Exophytic right renal cell carcinoma with a focus of calcification. On this contrast-enhanced scan, the mass is enhancing heterogeneously.

2. On unenhanced images, small lesions are homogeneous and isodense to the kidneys. Large masses vary from being nearly isodense to the kidneys (Fig. 3C.9) and slightly heterogeneous to being hypodense with necrotic areas (Fig. 3C.10A) or hyperdense due to hemorrhage (85). Calcification is seen in approximately 30% of cases when the tumors are larger than 3 cm (Fig. 3C.8, Fig. 3C.9, and 3C.10); smaller lesions are calcified about 3 % of the time (85,87).

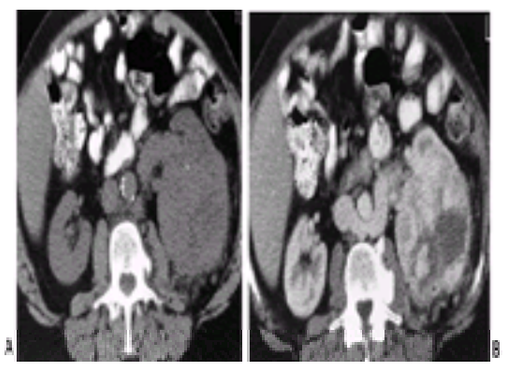

FIGURE 3C.9. Large left renal cell carcinoma. **A:** Unenhanced image demonstrates a small amount of calcification in the mass. **B:** Following contrast enhancement, there is irregular enhancement and a shaggy border to the mass, more likely due to perinephric collateral vessels than to perinephric extension. Note that the left renal vein is retroaortic.

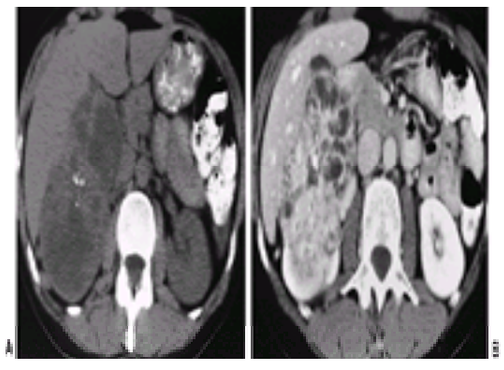

FIGURE 3C.10. Large, necrotic renal cell carcinoma. **A:** Unenhanced image shows calcification and low-attenuation areas in the mass, representing areas of cystic necrosis. **B:** There is avid, heterogeneous enhancement after contrast administration. The areas of cystic necrosis do not enhance.

3. After contrast administration, all RCCs enhance, but less so than the normal renal parenchyma. Most small tumors tend to have homogeneous enhancement, whereas larger tumors may show heterogeneity in enhancement (Fig. 3C.9B and Fig. 3C.10B), particularly if there is central necrosis. Papillary RCCs tend to demonstrate central cystic or necrotic degeneration and calcification, and they enhance less than the non–papillary cell types.

Staging of Renal Cell Carcinoma

The classification schemes for staging RCC are not reiterated here.

Stage I disease (confined within renal capsule) is difficult to distinguish from stage II disease (extension into perinephric fat but contained within Gerota's fascia) by CT scanning. Thickening of the renal fascia and the bridging septa (Fig. 3C.9) is more often the result of vascular engorgement and enlargement and edema in the perinephric region than the result of tumor extension (35). This shortcoming of CT is not usually a clinically significant issue because both stage I and II tumors are surgically respectable.

CT has a sensitivity of greater than 95% for the detection of regional lymph node metastases to the renal hilum or retroperitoneum (stage III disease) (Fig. 3C.11). Nodes larger than 1 cm in short axis diameter are considered to be enlarged by CT criteria. Lymphadenopathy can be caused by metastatic disease or reactive hyperplasia; these conditions are indistinguishable on CT imaging (76). Cystic necrosis may be seen in the nodes that are often hypervascular (Fig. 3C.11).

FIGURE 3C.11. Lymph node metastasis with left renal cell carcinoma. Contrast-enhanced scan shows nonenhancing areas of cystic necrosis with a large paraaortic node, which also appears to be necrotic *(arrows).* There were multiple other enlarged nodes on other cuts (not shown). The renal vein is compressed by the nodal enlargement, which is likely the cause of the decreased nephrogram in the left kidney.

Tumor extension into the renal vein or IVC is well evaluated with contrast-enhanced CT (Fig. 3C.12), with reported sensitivity and specificity rates in the range of 80% and 96% (35,38). A good bolus of contrast within the vascular structures facilitates evaluation of the venous structures—the tumor thrombus is seen as a filling defect in the brightly enhanced blood within the vessel. It is important not to misdiagnose streaming artifact in the IVC (from unopacified blood returning from the lower extremities or the renal veins) as tumor thrombus (Fig. 3C.1A). Enlargement of the renal vein may suggest the presence of tumor thrombus but can also be related merely to increased flow from a hypervascular neoplasm. Tumor thrombus is easier to detect in the left renal vein than in the right renal vein.

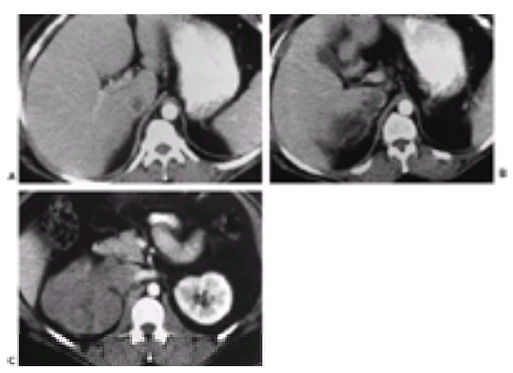

FIGURE 3C.12. Renal cell carcinoma with caval extension. There is a filling defect in the intrahepatic cava **(A),** subhepatic cava **(B),** and the right renal mass is seen extending into the renal vein and the inferior vena cava **(C).**

Adrenal involvement, whether due to direct extension in large tumors or to contralateral hematogenous metastasis, is well evaluated with CT (29).

Direct tumor spread to contiguous organs is detectable on CT as loss of the expected tissue planes between the kidneys and the adjacent organs such as the liver, spleen, psoas muscle, or pancreas. However, imaging in the axial plane alone (as with routine CT scanning) has the disadvantage that volume averaging of oblique tissue interfaces makes it difficult to determine whether a renal lesion merely abuts an adjacent organ such as the liver or actually invades it (Fig. 3C.10B). In such cases, MRI is often useful for further evaluation because imaging can be performed in the appropriate plane to answer the question.

CT or MRI scanning of the abdomen combined with CT scanning of the chest is the current recommendation for assessment of distant metastatic disease in patients with RCC Chest CT is highly sensitive for detecting metastatic disease, but its low specificity is a drawback because abnormalities related to granulomatous disease may be indistinguishable from metastatic disease (55). Radionuclide bone scanning is not recommended as a routine procedure and is indicated in patients with symptoms worrisome for metastatic disease. Because 5% of RCCs are bilateral, careful attention must be paid to the contralateral kidney in every case.

Accuracy of CT in Diagnosis of RCC

Contrast-enhanced CT scanning has an overall accuracy in the 95% range for the diagnosis of RCC, with the diagnosis of small renal masses proving the most difficult. False-positive diagnosis of RCC can be as high as 17% (67), even with contemporaneous imaging techniques. When a renal mass is indeterminate in nature on CT imaging, MRI can sometimes be helpful in demonstrating enhancement within the lesion, therefore better characterizing it. Alternatively, follow-up scans may demonstrate growth of the lesion. RCCs grow at a mean rate of 0.5 cm per year, a rate much faster than seen with benign lesions (6).

Postoperative Findings

Recurrence in the operative bed, liver, remaining kidney, adrenal glands, and the retroperitoneum can be assessed on follow-up CT examinations. The migration of normal structures into the operative bed, such as bowel, may simulate a recurrent tumor. Baseline scans are therefore of value in serial follow-up, particularly in patients who have undergone nephron-sparing surgery, so that the postoperative alterations in the appearance of the kidney are not misdiagnosed as tumor recurrence (39). Wedge-shaped or concave defects may be seen at the site of resection, and there may also be fat pads placed at the resection site.

Urothelial Tumors

Urothelial tumors are the second most common primary malignancies of the kidney, with transitional cell carcinoma (TCC) accounting for the vast majority (approximately 85% to 90%). Squamous cell carcinomas (SCCs) are the next most common, accounting for 6% to 7% of primary renal pelvic tumors. Other rarer urothelial tumors are not considered here.

CT Imaging Features of Urothelial Neoplasms (14,57,81,82)

Although most cases of TCC are diagnosed on IVU or retrograde pyelography, an occasional case may be picked up serendipitously on CT.

1. An intraluminal soft tissue mass in the pyelocalyceal system or ureter, which is isodense on precontrast images (31 to 48 HU), may be seen (57). TCC enhances less than the adjacent parenchyma after contrast administration (attenuation values of 43 to 82 HU) (Fig. 3C.13). In the EP, the mass may be outlined by the excreted contrast (Fig. 3C.14). With contemporaneous imaging techniques, TCC lesions larger than 1 cm can be visualized (81).

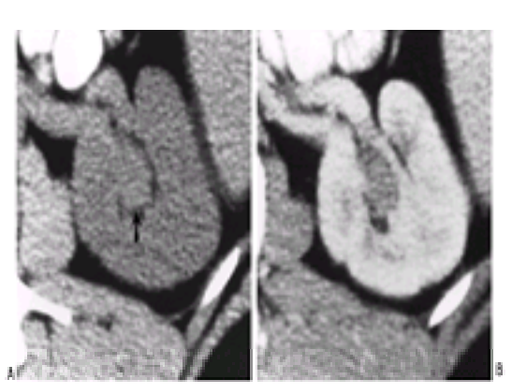

FIGURE 3C.13. Transitional cell carcinoma in the left renal pelvis. There is a soft tissue mass in the left renal sinus *(arrow)* on the unenhanced image **(A),** which enhances slightly after contrast **(B).** The sinus fat does not appear to be invaded.

FIGURE 3C.14. Transitional cell carcinoma in the left renal pelvis is seen as a filling defect *(arrowheads).*

2. Stippled calcification may be seen on the surface of the mass.
3. Rather than a well-defined mass, there may be concentric or eccentric thickening of the wall of the renal pelvis or ureter. Early flat or plaquelike lesions that would not be identifiable on IVU can often be detected on CT.
4. There may be hydronephrosis proximal to the lesion in the collecting system. An obstructive lesion will cause alterations in the nephrogram, which may be delayed, dense, striated, or persistent (Fig. 3C.15).

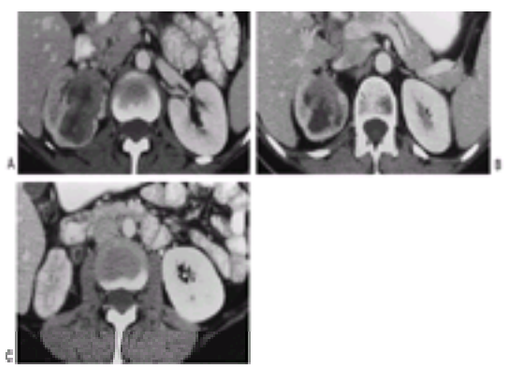

FIGURE 3C.15. Transitional cell carcinoma of the right renal pelvis, which is partially obstructing. Contrast-enhanced images demonstrate a mass in the right renal pelvis and lower pole collecting system **(A, B).** Because of the obstruction, the right nephrogram is delayed compared with the left kidney **(C).**

5. The reniform shape of the kidney is maintained even with large TCCs that infiltrate the renal sinus and the renal parenchyma.
6. Venous involvement (renal vein or the IVC), lymph node involvement, or distant metastases may be seen with stage IV tumors.

Utility of CT in Patient with TCC

CT is highly accurate in distinguishing stage III and IV disease from stage I and II disease because parenchymal invasion, tumor extension through the wall of the renal pelvis or ureter, lymphadenopathy, and other metastatic spread are well demonstrated. CT imaging can therefore be crucial in staging such patients if conservative management is being contemplated. Furthermore, in patients with high-grade obstruction in whom IVU is nondiagnostic, the level of obstruction can be demonstrated on CT and the obstructing ureteral lesion easily distinguished from obstruction due to a stone or other periureteral pathology (42).

The distinction between stage I disease (limited to mucosa) and stage II disease (invasion of muscle) is not possible with CT.

CT is extremely useful in the characterization of a radiolucent filling defect seen on urography and in distinguishing radiolucent calculus from a urothelial tumor or blood clots (57). On nonenhanced CT, all renal calculi have densities greater than 200 HU (as compared with mean density of 39 HU for TCC lesions), whereas blood clots are often denser than normal parenchyma (50 to 90 HU). Following administration of a bolus of contrast, TCC lesions show slight enhancement, but blood clots do not enhance.

Squamous Cell Carcinomas

SCCs are aggressive and tend to present late in their course, usually as an infiltrating renal mass rather than as an intraluminal or mucosal lesion. The kidney is usually enlarged and not functioning. Staghorn renal calculi are often associated, and in fact, calculi have been reported in 4 of 5 patients with renal SCC on CT. There may be infiltration of adjacent organs at presentation (56).

Angiomyolipoma

Angiomyolipomas (AMLs) are benign renal neoplasms that contain varying proportions of mature adipose tissue, smooth muscle, and blood vessels; one or two of these elements may predominate. The radiographic appearance can therefore range the spectrum from being nearly completely fatty to nearly all soft tissue (10,50,83). The detection of regions of fat within a lesion is confirmatory of the diagnosis of an AML; the density measurements in the fatty areas range from -10 to -50 HU. Calcification is usually not present, and if hemorrhage has occurred, it too will be evident (Fig. 3C.16, Fig. 3C.17, and Fig. 3C.18).

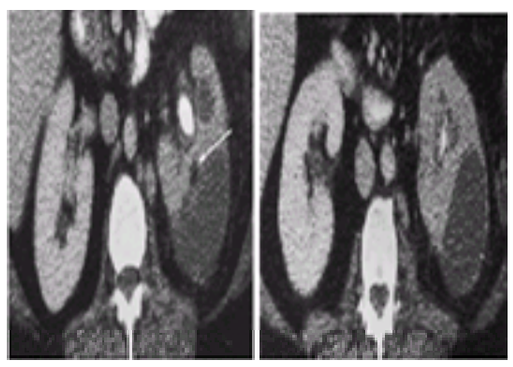

FIGURE 3C.16. Tiny angiomyolipoma *(arrow)* in the left kidney, which has caused a subcapsular hematoma. Note the compression of the renal contour. Patient also has a calculus in the renal pelvis.

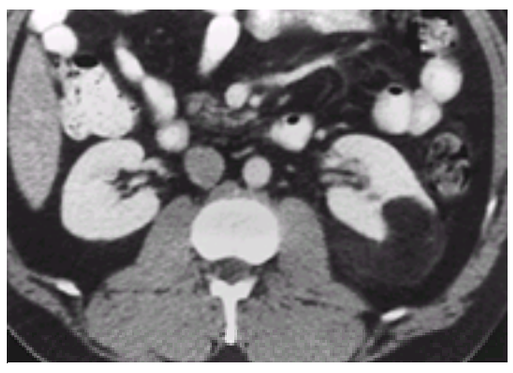

FIGURE 3C.17. Angiomyolipoma in the left kidney with a predominantly fatty composition. Note that the density of the lesion is similar to the retroperitoneal fat. Soft tissue strands are also seen within the mass, representing the other components.

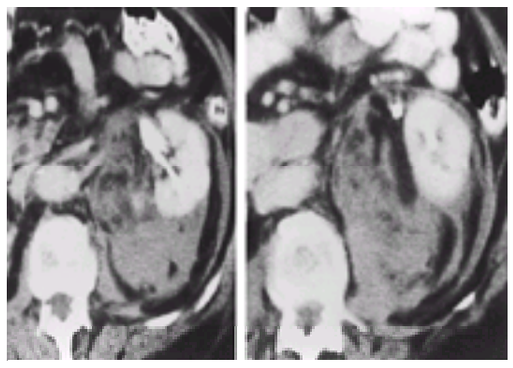

FIGURE 3C.18. Angiomyolipoma that has bled. Note the high-density blood that has accumulated in the perinephric space. Fat within the angiomyolipoma (AML) is also visible as dark patches. The kidney is displaced by the hemorrhage.

Most AMLs are asymptomatic and found incidentally on imaging. Lesions larger than 4 to 5 cm, being more prone to hemorrhage, may become clinically apparent because of hematuria or symptoms associated with perinephric or retroperitoneal hemorrhage. There may also be mass effect caused by displacement of adjacent organs. AMLs can increase in size over time, particularly lesions that are larger than 4 cm; thus follow-up is warranted for such lesions (74).

Typically, AML is a unilateral lesion in a middle-aged woman. Numerous bilateral AMLs should raise the suspicion of tuberous sclerosis (TS) because 80% of patients with TS have AMLs; 30% also have renal cysts. Sporadic occurrence of bilateral AMLs in patients without TS can also occur.

Fat within a renal mass is indicative of an AML. However, there are reports of RCCs that may appear to have fat within them because the tumor has engulfed renal sinus fat or undergone osteoid metaplasia with resultant fat and marrow deposition within the tumor (31).

Other Renal Tumors

Oncocytoma is an uncommon solid renal neoplasm with a distinctive histologic appearance. The CT features of this lesion are largely indistinguishable from those of an RCC (22).

Renal sarcomas are similar in radiographic appearance to RCCs. Leiomyosarcomas are the most common primary renal sarcoma, and they can arise from the renal capsule or the walls of renal veins or the IVC.

Lymphomatous involvement of the kidney is usually due to hematogenous or direct spread from an extrarenal source. Primary renal lymphoma is very rare because there is no lymphomatous tissue within the kidney. Non-Hodgkin's disease involves the kidneys far more frequently than Hodgkin's disease (92% versus 8%). The CT appearance is variable (65). There may be multiple discrete masses (31% cases), a solitary mass (23%), or tumor infiltration in the perirenal space (40%) (Fig. 3C.19).

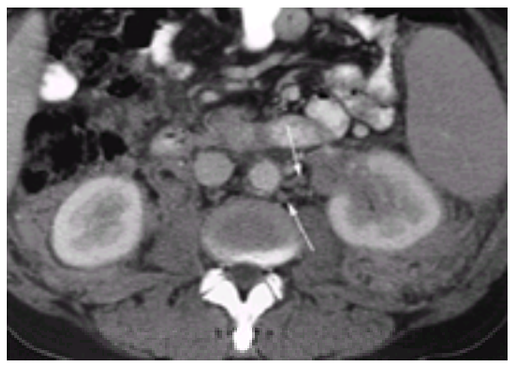

FIGURE 3C.19. Lymphoma presenting as a rind of soft tissue in the perinephric region bilaterally. There are also several small retroperitoneal lymph nodes *(arrows).*

Renal metastases are seen in association with metastatic disease elsewhere in a patient with a known primary malignancy. They are usually multiple and bilateral and are smaller than a 1 cm (33). An individual lesion may be indistinguishable from RCC, and percutaneous biopsy may be necessary to establish the diagnosis, if required.

Renal medullary carcinoma is a highly aggressive tumor that arises in the medulla near the renal papilla and then invades the parenchyma. It has been described in young patients, commonly but not exclusively African Americans, with sickle cell trait or hemoglobin SC disease. The central infiltrative pattern of tumor growth and extensive necrosis in a young patient should suggest the diagnosis. Mean survival from first symptoms to death is about 15 weeks (21).

Renal Cystic Masses

Simple Renal Cysts

Simple renal cysts are ubiquitous lesions that increase in number and size with age (20). Cysts should be of homogeneous water density (less than 20 HU) with thin or imperceptible walls, have a sharp interface with the renal parenchyma, and demonstrate no enhancement after contrast administration (Fig. 3C.20). No follow-up is necessary for lesions that meet these criteria.

FIGURE 3C.20. Simple renal cyst. The walls are thin, and there is no enhancement within the lesion.

Complicated Cysts

Cysts that are complicated by hemorrhage or infection will have an alteration in their imaging characteristics and may be confused with cystic renal neoplasms such as cystic RCCs or Wilms' tumor. The Bosniak classification system for renal cysts was devised to help categorize complicated renal cysts and predict the risk of malignancy (11). A *type I* lesion meets all of the aforementioned criteria for a simple cyst. A *type II* cyst (Fig. 3C.21, Fig. 3C.22, and Fig. 3C.23) is minimally complicated and demonstrates thin septations or minimal calcification on septa or the walls or is of high density (40 to 90 HU before contrast administration). These lesions have minimal risk for malignancy. *Type III* lesions may have one or more features suggestive of malignancy but no definite sign of malignancy. Such lesions exhibit thick or nodular walls or septations, thick or irregular calcification, and heterogeneous density but no enhancement of the walls or the septa in the lesion. Approximately 50% of these lesions will prove to be malignant, and surgical treatment or close follow-up is required for these lesions. *Type IV* lesions demonstrate unquestionable enhancement of a component of the lesion and are considered cystic tumors (Fig. 3C.24 and Fig. 3C.25).

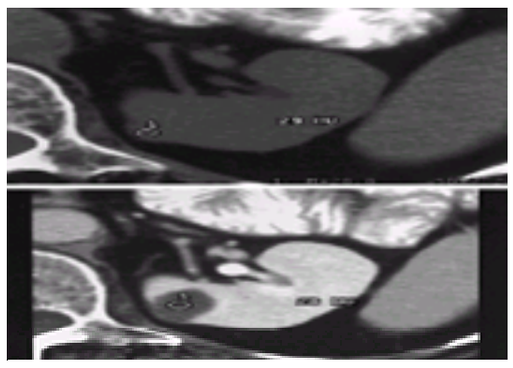

FIGURE 3C.21. High-density cyst. Bosniak II lesion. The lesion is of higher density (29 HU) than expected for a simple cyst (0 to 20 HU). However, there is no enhancement after contrast administration. The increased density is related to the presence of hemorrhage or proteinaceous material within the lesion.

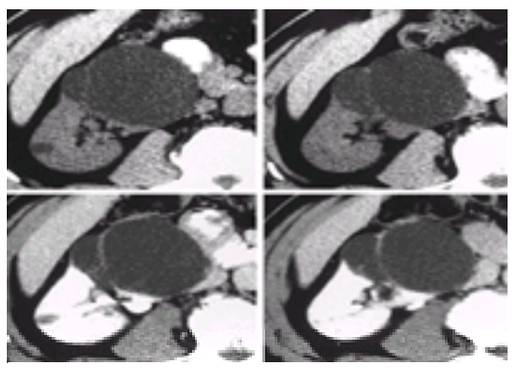

FIGURE 3C.22. Septated cyst. Bosniak II lesion. Nonenhaced images *(top row)* and enhanced images *(bottom row)* demonstrate thin septations within the cystic lesion.

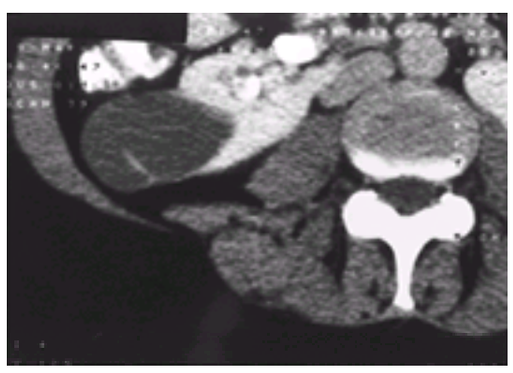

FIGURE 3C.23. Bosniak II cyst. Short thin septation in right renal cyst.

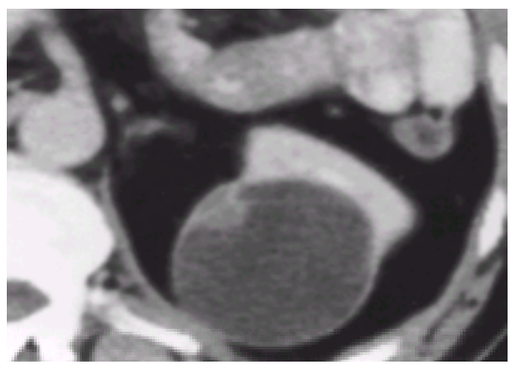

FIGURE 3C.24. Cystic renal cell carcinoma. Bosniak IV lesion. There is an enhancing nodule within the lesion that is predominantly cystic.

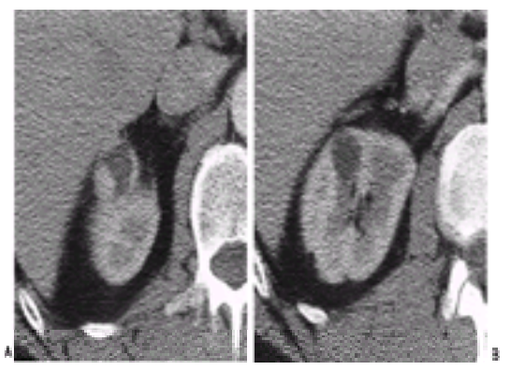

FIGURE 3C.25. Cystic renal cell carcinoma. Small right renal lesion has a thick irregular wall superiorly **(A)** and a relatively cystic appearance in its inferior aspect **(B).** However, nodular thickening in any portion of the lesion makes it a category IV lesion.

Multilocular Cystic Nephroma

A localized cystic disease of unknown etiology with no known hereditary pattern of inheritance, multilocular cystic nephroma (MCN) is a benign neoplasm. Multiple epithelial-lined cysts are separated by fibrous septa of varying thicknesses; a minority of lesions may have microscopic foci of nephroblastoma or sarcoma in the septa. The septations often enhance on contrast-enhanced CT, making it difficult to reliably exclude cystic RCC or Wilms' tumor, even when MCN is strongly suspected by imaging. Surgery is therefore indicated for these lesions (15).

Parapelvic Cysts

Parapelvic cysts occur in the renal sinus and may simulate hydronephrosis on noncontrast scans. Images in the EP of the CT scan will demonstrate mass effect on the collecting system.

Cystic Renal Diseases

Autosomal-dominant polycystic kidney disease (ADPKD) causes cyst formation in the kidneys, liver, pancreas, and spleen (Fig. 3C.26). The kidneys are often greatly enlarged, and multiple cysts of varying sizes are seen throughout the parenchyma. Cysts may show hemorrhage (and therefore be hyperdense) and calcification in the walls. Calculi are also common (51).

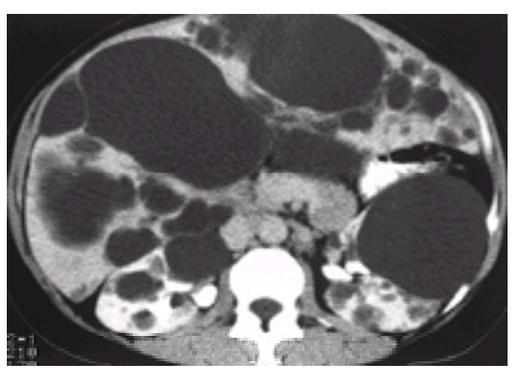

FIGURE 3C.26. Autosomal-dominant polycystic kidney disease. Innumerable large cysts in the kidneys and liver are pathognomonic of the disease.

Multiple bilateral simple renal cysts in an individual patient may be difficult to differentiate from ADPKD. The absence of a family history, normal renal function, lack of cysts in other organs (e.g., the liver), and normal renal size favor the diagnosis of multiple simple cysts.

Acquired Cystic Kidney Disease

Patients with chronic renal failure, particularly those receiving chronic dialysis, can develop numerous cysts in the kidneys; 90% of patients may demonstrate renal cysts after 5 to 10 years of dialysis therapy (52). There is also an increased incidence of RCC, which is three to six times greater than the annual incidence of renal carcinoma in the general population (62). Early in the course, the kidneys are small in size but increase in volume with time. The appearance may be indistinguishable from ADPKD, but no cysts occur in organs other than the kidneys.

Syndromes Associated with Renal Cysts

Many syndromes are associated with renal cysts; such diseases are also referred to as *pluricystic kidney disease* (64) and are not discussed here.

Two syndromes in which renal cysts occur in association with neoplasms are of particular importance to urologists. *TS* is associated with AMLs in 40% to 80% of patients, and renal cysts are seen in approximately 15% of patients. There may also be a slight increased incidence of RCC (9,16).

von Hippel–Lindau disease is an autosomal-dominant hereditary disease associated with renal cysts and cancers, pancreatic cysts, pheochromocytomas, and retinal and central nervous system hemangioblastomas (17). Approximately 60% of patients will have renal cysts, and 29% of patients develop clear cell renal carcinomas. As many as 600 microscopic tumorlets may be present in the parenchyma of each kidney.

Renal Inflammatory Processes

In patients with clinically suspected *acute pyelonephritis,* CT is used not for its diagnosis, but rather to detect complications when the clinical response to appropriate therapy is not satisfactory. CT is the best imaging method to delineate the extent of the renal inflammatory process and also evaluate for extrarenal extension of the disease (72,73).

The CT findings in acute pyelonephritis (40) are as follows: (a) The most common finding is the presence of one or more round or wedge-shaped areas of decreased attenuation, seen only on contrast-enhanced scans. These areas enhance less than the normal parenchyma (Fig. 3C.27). Delayed scans may show increased density in these same areas due to eventual filling of tubules that are obstructed by the surrounding edema (Fig. 3C.28 and Fig. 3C.29). This is likely the CT equivalent of a focal, delayed obstructive nephrogram. These zones of acute pyelonephritis have straight borders rather than rounded contours and extend from the renal collecting system to the capsule. (b) Striated bands of alternating low and high density may be seen within the wedge-shaped areas (striated nephrogram), representing slow flow of contrast-opacified urine through tubules that are obstructed by adjacent bands of interstitial edema. (c) Thickening of the renal fasciae and perinephric septa may occur as a result of edema. (d) Global or focal enlargement of the kidney may be seen. (e) Severe infections may lead to focal or global scarring and atrophy, detected on follow-up scans.

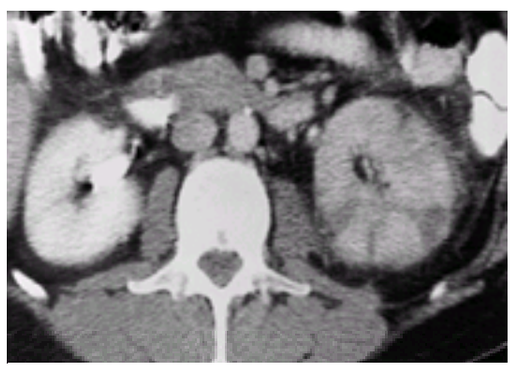

FIGURE 3C.27. Acute pyelonephritis of left kidney. Contrast-enhanced computed tomography scan. Note perinephric fascial thickening due to edema and wedge-shaped defects in the parenchyma that extend from the collecting system to the capsule. The nephrogram is delayed overall compared with the right kidney.

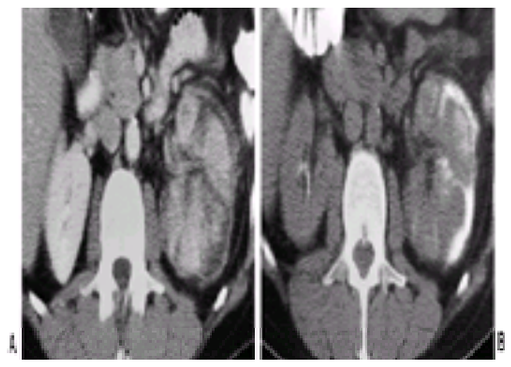

FIGURE 3C.28. Acute pyelonephritis. Contrast-enhanced scans. **A:** Early images demonstrate wedge-shaped filling defects in the parenchyma. **B:** Delayed images demonstrate a striated nephrogram with persistent opacification of some regions, likely obstructed tubules.

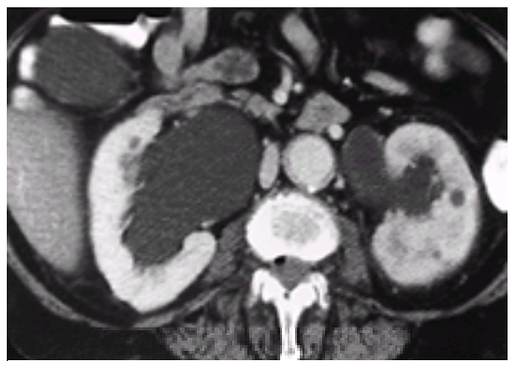

FIGURE 3C.29. Acute pyelonephritis of the left kidney in a patient with bilateral hydronephrosis due to bladder outlet obstruction. Note the patchy and irregular nephrogram in the left kidney. This appearance cannot be separated radiographically from changes due to acute obstruction. There is also a small cyst in the left kidney.

Emphysematous pyelonephritis (EPN) is a severe gas-forming infection in which gas is seen within the renal parenchyma itself. Identification of this entity requires aggressive treatment. Emphysematous pyelitis, on the other hand, is a gas-forming infection limited to the collecting system; it does not portend the same grave prognosis as does EPN.

The most common abnormality in *renal abscess* is an area of low attenuation on noncontrast images, which represents the liquefied center of the abscess cavity. Following contrast administration, a thick and irregular rind of enhancement is seen surrounding the abscess cavity (Fig. 3C.30). The remainder of the kidney may range from being normal in appearance to showing signs of acute pyelonephritis (72).

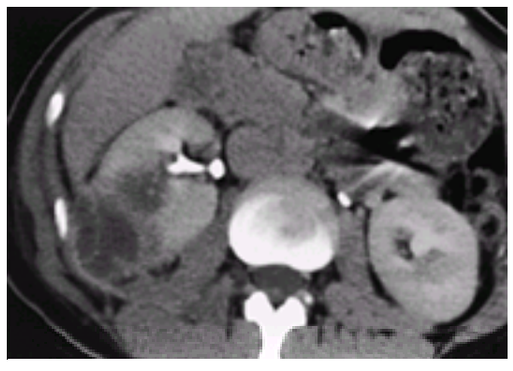

FIGURE 3C.30. Renal abscess. Irregular abscess cavities in the right kidney. Patient has right renal calculi (not shown). Note the asymmetric right perinephric fascial thickening.

Xanthogranulomatous pyelonephritis is an uncommon chronic infection associated with calculi and obstruction. The kidney is enlarged, and calculi, often staghorn, are present. The kidney is usually nonfunctioning. Perinephric extension is seen in 14% of patients, and fistulae may also occur (77).

Renal Trauma

CT is very accurate in the categorization of renal injuries, and it is the imaging modality of choice when significant renal injuries are suspected (25,61). Both oral and intravenous contrast should be used in such patients; delayed imaging is often required to detect contrast extravasation (Fig. 3C.31), which indicates laceration of the collecting system.

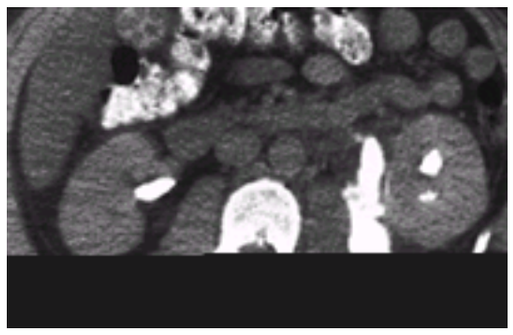

FIGURE 3C.31. Contrast extravasation in a patient who sustained blunt trauma. Delayed images demonstrate contrast tracking along the left perinephric space. The patient had extravasation from the collecting system in the left kidney (not shown).

The grading system of renal injuries by the American Association for the Surgery of Trauma (AAST) cannot be addressed here. However, there is a close relationship between the grading system and CT abnormalities seen in this setting.

normal and hyperplastic glands in that many patients with clinical evidence of hyperplasia may have normal-appearing adrenal glands. Bilateral enlargement is indicative of hyperplasia.

Adrenal Carcinomas

Adrenal carcinomas tend to be large, undergo central necrosis, and invade adjacent organs. If the mass is very large, the organ of origin may be difficult to determine, particularly if the adjacent organs are invaded and the normal adrenal gland is obliterated by the tumor. An adrenal carcinoma may be difficult to distinguish from a renal adenocarcinoma on CT. Calcification is seen in one-third of cases (28); venous extension, liver metastases, and lymphadenopathy may also be seen.

Incidental Adrenal Mass

Most incidentally discovered adrenal masses are benign. However, an adrenal mass in a patient with a known primary mass raises the question of adrenal metastases. If the mass is of low density, as described earlier, it is most likely is a benign adenoma. In one series, mean attenuation values were 2.2 HU for adenomas and 29.8 HU for metastases (49). If the threshold for nonenhanced CT density is set at 10 HU, the sensitivity-to-specificity ratio for diagnosis of an adenoma is 74%:96%. If the adenoma is lipid poor, the density will be higher and it may be difficult to distinguish it from a metastasis by CT. MRI may be warranted in such a case for further characterization.

Pheochromocytoma

Pheochromocytomas are hypervascular neoplasms with a tendency for hemorrhagic necrosis, even when benign. Heterogeneous enhancement of the mass is seen with contrast, an appearance that may be indistinguishable from that of an adrenal carcinoma. Thus correlation with biochemical tests is crucial for the diagnosis. Approximately 90% of pheochromocytomas arise from the adrenal glands, whereas 10% are extraadrenal.

If the patient has known hypertensive episodes, adequate pharmacologic adrenergic blockade should be in place before contrast administration so that a hypertensive crisis is not precipitated (intravenous injection of contrast can raise plasma catecholamine levels) (23,63).

Myelolipoma

Myelolipoma is a benign, nonfunctioning neoplasm of the adrenal gland containing variable amounts of fat and myeloid elements. Calcification may also be seen in the lesion (Fig. 3C.39). Large lesions may hemorrhage, although this is uncommon. The presence of foci of fat within an adrenal lesion is diagnostic of a myelolipoma (43).

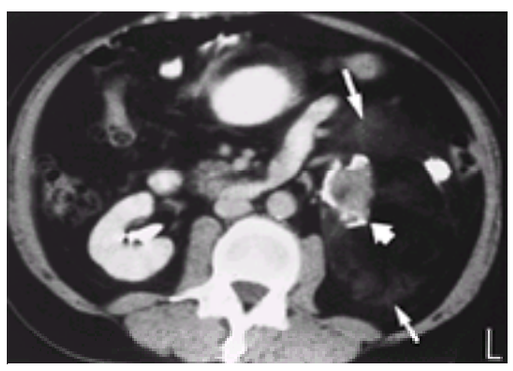

FIGURE 3C.39. Large left adrenal myelolipoma. The entire adrenal gland is replaced with low-density fatty tissue *(long arrows).* Note the large calcification within the lesion *(short arrow).*

Retroperitoneum

Lymphadenopathy

With CT, size alone is used to diagnose abnormalities in lymph nodes because intranodal architecture is not depicted on CT. Retroperitoneal and pelvic lymph nodes that are greater than 10 mm in short axis diameter are considered abnormal, although multiple smaller (6 to 8 mm) nodes are also cause for suspicion. Massively enlarged retrocaval and retroaortic nodes can displace these vascular structures.

CT is the preferred imaging method for staging patients with testicular neoplasms (Fig. 3C.40). Residual retroperitoneal masses that remain visible on CT scans after treatment can represent posttreatment fibrosis or teratoma, but they cannot be reliably differentiated from residual viable tumor (75).

FIGURE 3C.40. Retroperitoneal lymphadenopathy in a patient with testicular cancer. There is a small amount of calcification in the nodes, likely the result of therapy. The vascular structures are not identifiable on this unenhanced scan.

Primary Retroperitoneal Tumors

Retroperitoneal tumors are well depicted on CT, and their effect on the urinary tract is also elegantly demonstrated. Most solid retroperitoneal tumors are of soft tissue attenuation and cannot be distinguished on CT.

Retroperitoneal Fibrosis

Fibrous tissue proliferation around the aorta and the IVC is the hallmark of retroperitoneal fibrosis (RPF). A soft tissue density that obscures the contours of the IVC and the aorta is seen (Fig. 3C.41). The process may extend into the pelvis, and there may be vascular or ureteral encasement. On noncontrast CT, the density of the soft tissue is similar to that of muscle. Following contrast administration, variable enhancement is seen. Malignant forms of RPF cannot be distinguished from the

benign ones (2).

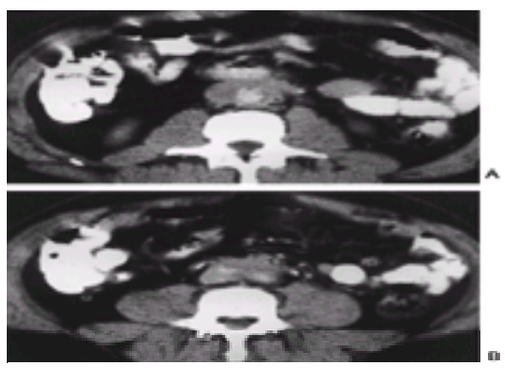

FIGURE 3C.41. Retroperitoneal fibrosis. **A:** There is soft tissue encasement of the aorta and the cava, obscuring the tissue planes that lie between them. **B:** The process extends caudally to encase the common iliac vessels also.

COMPUTED TOMOGRAPHY OF THE PELVIS

The entire abdomen and pelvis is imaged so rapidly with current scanners that on the initial scans through the pelvis, the urinary bladder is often not opacified with contrast excreted by the kidneys. Delayed images through the pelvis are required if assessment of the bladder wall is necessary, as in patients with bladder cancer. Pelvic lymph nodes larger than 1 cm in short axis diameter are considered abnormally enlarged. Normal-sized nodes may be difficult to differentiate from adjacent vessels and nerves without intravenous contrast.

Urinary Bladder

Tumors

CT scanning cannot reliably assess the presence or depth of muscle invasion of bladder tumors. However, gross invasion of perivesical structures can be ascertained, as can lymphadenopathy.

Bladder tumors are seen as sessile or pedunculated masses that project into the lumen or as focal or diffuse wall thickening (Fig. 3C.42). Perivesical extension causes blurring of the soft tissue planes; in more advanced cases, a soft tissue mass projecting into the adjacent tissues will be seen (Fig. 3C.43). The overall accuracy for detecting perivesical extension is 65% to 85%, and the accuracy for detecting lymph node involvement is 70% to 90% (44).

FIGURE 3C.42. Bladder cancer at the right ureteral orifice. There is ureteral dilation, which may be partially mechanical. No definite perivesical extension is seen.

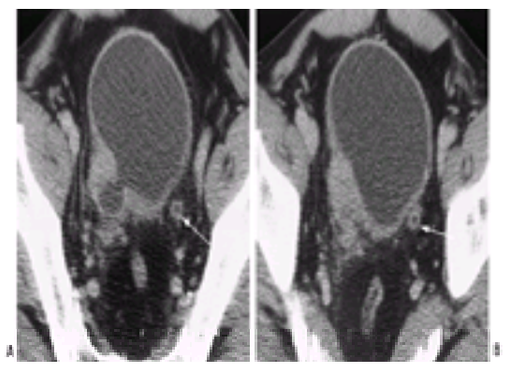

FIGURE 3C.43. Bladder cancer involving a right posterior bladder diverticulum. Note the soft tissue mass within the diverticulum **(A)** and perivesical extension of the mass **(B).** The left distal ureter is thickened *(arrow)* **(A, B),** raising the possibility of tumor involvement.

Trauma

Because CT is often the initial study performed in patients with blunt abdominal or pelvic trauma, CT cystography is a convenient way to assess for bladder injury. It is important to adequately distend the bladder actively and not rely on passive filling of the bladder with excreted contrast (Fig. 3C.44). With these caveats in mind, the sensitivity of CT cystography is comparable to that of conventional cystography for diagnosing bladder injuries (53).

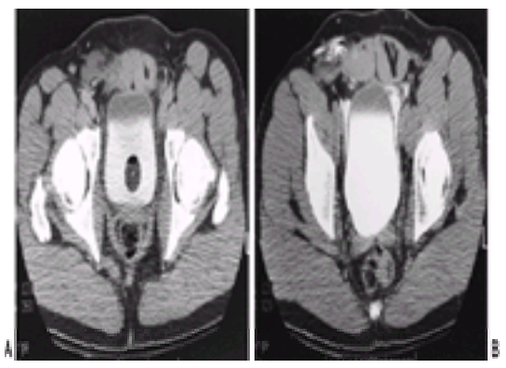

FIGURE 3C.44. Extraperitoneal bladder rupture. Patient in a motor vehicle accident. **A:** Images with passive bladder filling demonstrate no extravesical contrast. **B:**

When bladder is filled till there is a detrusor contraction, contrast extravasation from urinary bladder becomes obvious.

Prostate

The main utility of CT in patients with prostate cancer is in the detection of lymphadenopathy (Fig. 3C.45). The sensitivity for the detection of intraprostatic tumor, transcapsular extension, and seminal vesicle involvement is low (24,60).

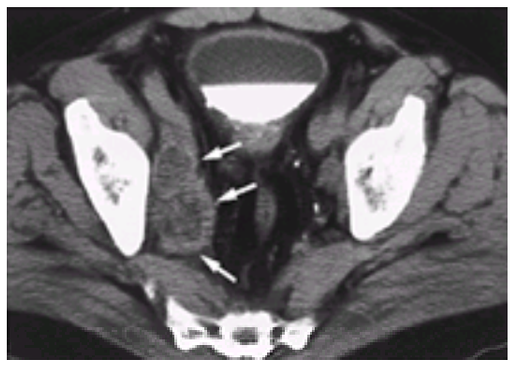

FIGURE 3C.45. Large, necrotic obturator lymph nodes *(arrows)* in a patient with prostate cancer.

In postoperative patients being evaluated for local recurrence, artifact emanating from metal clips can obscure the surgical bed.

Chapter References

The development of ultrasound instrumentation effective in the evaluation and treatment of many medical conditions dates back to the 1940s, when Firestone first described a technique using ultrasonic waves to detect flaws in metal castings (71). During World War II, the principles of ultrasound were used to develop sonar (sound navigation ranging), a tracking technique useful in identifying submerged enemy submarines. The first medical use of ultrasound was reported by an Austrian psychiatrist, Karl Dussik (29), who attempted to locate brain tumors with the use of two opposing ultrasound transducers. In the early 1950s, Howry and Bliss (46) used discarded naval equipment and studied and recorded the echo patterns obtained from a variety of soft tissue structures. They initially used water immersion techniques, and it was not until the early 1960s that they began experimenting with handheld scanners applied directly to the body surface. Since the early 1970s, with the development of real-time capability, grayscale imaging, high-frequency transducers, color-flow Doppler, and power Doppler, ultrasound has gained an important role in the clinical evaluation of many urologic abnormalities. The emerging use of ultrasound contrast agents promises to enhance and expand many of these applications.

BASIC PRINCIPLES OF ULTRASOUND

Ultrasound consists of sound waves of frequencies beyond the audible range of the human ear [greater than 20,000 Hz (cycles per second)]. For medical purposes, diagnostic ultrasound equipment uses sound waves between 2 million and 10 million MHz. Sound travels in a wave form that is dependent on the medium in which it travels and has a multitude of variables, including density, pressure, temperature, and particle motion (54). Sound waves are described in terms of frequency, period, amplitude intensity (determined by the source), propagation speed (determined by the medium), and wavelength (determined by the source and medium) (Fig. 3D.1).

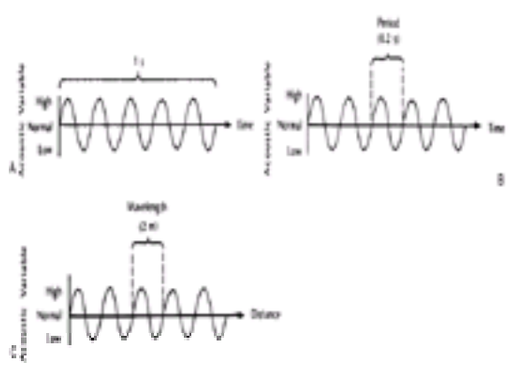

FIGURE 3D.1. A: Frequency. The number of complete variations (cycles) that an acoustic variable goes through in 1 second. In this diagram, five cycles occur in 1 second. One hertz is 1 cps. One megahertz is 1 million cps. **B:** Period. The time for one complete cycle. The period in this diagram is 0.2 seconds. **C:** Wavelength. The distance over which one cycle occurs. In this diagram each cycle is 2 m. (Adapted with permission from Kremkau FW. *Diagnostic ultrasound principles, instruments and exercises,* ed 3. Philadelphia: Saunders, 1989.)

The source of the ultrasound beam is a transducer consisting of a piezoelectric transmitter and receiver (Fig. 3D.2A). The piezoelectric crystal generates a wave at a frequency that is dependent on the strength of the current applied to it and the size of the crystal. Sound waves are produced by the deformation of the crystal associated with electrical excitation. Short impulses, approximately 10 ms each, of alternating current are applied to the crystal, and the ultrasound beam thus generated is focused by the transducer into a beam several millimeters in width. The thickness of the crystal determines the frequency of the generated sound waves. The sound waves are focused with an acoustic lens that produces a narrow beam only a few millimeters in diameter with good lateral resolution.

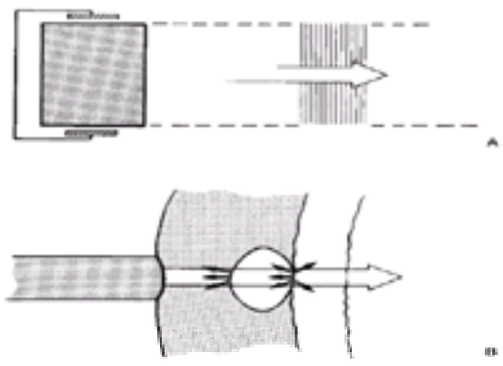

FIGURE 3D.2. A: High-frequency sound waves are transmitted after excitation of a piezoelectric crystal. **B:** Transmitter sound waves are reflected at tissue interfaces where there is a change in acoustic impedance. Reflected sound waves obey laws of optics—the angle of incidence is equal to the angle of reflection.

The body and its contents are the molecular medium that propagates the generated sound waves. In the presence of a homogeneous fluid medium (e.g., renal cyst, full urinary bladder), the sound waves are propagated in an uninterrupted manner. No sound waves are reflected back to the transducer, and therefore this area appears without echoes *(anechoic).* If the sound waves encounter a different density of tissue, a portion is reflected back to the source and that area is imaged. If the area or structure has a greater number of reflected waves than surrounding regions, it is termed *hyperechoic,* and if the echoes are less, the region appears *hypoechoic* (Fig. 3D.2B). The reflecting boundary is called an acoustic interface, and it exists because of the differing acoustic impedances between the two media. *Acoustic impedance* is the product of a medium density and the speed of sound in the medium. The greater the difference in acoustic impedance between the two media, the greater the amount of sound reflected back from the interface. Typically less than 1% of incident energy is reflected.

Whether the sound waves are reflected also depends on the relative size of the interface and the frequency of the generated wavelength. Sound waves of higher frequencies are generally reflected by smaller surface interfaces but have less depth of penetration, thereby giving better spatial resolution at the expense of decreased sound wave penetration. The use of lower-frequency sound waves sacrifices spatial resolution but makes it possible to image deeper structures. Appropriate transducer selection is critical for the success of the evaluation, and it is generally best to select the highest frequency that permits adequate tissue penetration and visualization of the desired structures. For example, higher-frequency transducers (7 MHz) are used for transrectal prostate imaging and lower-frequency ones (3.5 MHz) are used to view the kidneys.

During the course of the examination, the ultrasound transducer functions not only as a source of the sound waves but also as a receiver of the sound waves that have been reflected from the different tissue interfaces (Fig. 3D.3). The sound waves' energy is converted in the transducer by the piezoelectric crystal to electrical energy, which is then processed and displayed as a dot on a cathode ray tube (oscilloscope). The sound waves reflected back to the transducer are highly dependent on the angle of the reflector (Fig. 3D.4 and fig. 3D.5). Amplitude, or A-mode, records reflect echoes as spikes arising from a horizontal baseline and represent one of the earliest displays used in medical ultrasound (Fig. 3D.6). The main application of this mode is to measure the distances from the margins of a mass to the skin surface or to determine the internal architecture of the mass, but with the development of two-dimensional and real-time imaging this mode is rarely used. The brightness modulated display, or B-mode, is a two-dimensional image obtained while the transducer is moved along a given arc; the resultant display is of a cross-sectional image of the examined area. With the development of scan converters and real-time imaging, images are now displayed in varying shades of gray (grayscale imaging). Gray-scale imaging offers a significant improvement in the quality of images compared with those obtained with early B scanners. Use of Doppler, in particular color-flow and power Doppler, has allowed measurement of flow and detection of flow in vascular structures.

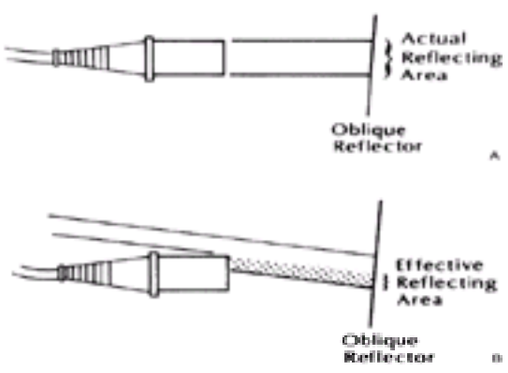

FIGURE 3D.5. Oblique reflector. **A:** Propagated sound waves. **B:** Reflected sound waves reached by transducer in shaded area. The remaining sound waves miss the

transducer. (Adapted with permission from Kremkau FW. *Diagnostic ultrasound principles, instruments and exercise,* ed 3. Philadelphia: Saunders, 1989.)

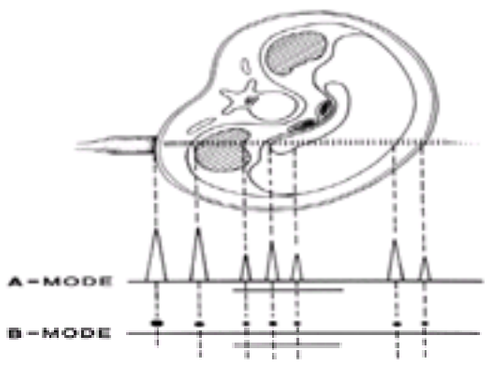

FIGURE 3D.6. Amplitude mode (A-mode) delineates reflected echoes as spikes arising from a horizontal baseline. The echo amplitude is plotted against distance between transducer and reflecting tissue interface. Brightness modulated display (B-mode) is a composite two-dimensional image obtained while transducer is moved along a given arc. Echoes are shown as multiple dots or points on the oscilloscope screen, the brightness of which is dependent on the intensity of the echo.

The transducer and its mechanism of action (mechanical sector and radial; array-linear, curved, and phased) are other important components of the instrumentation. In both forms of imaging, the sound waves sweep repeatedly through the tissue and structures to be imaged. Mechanical scanners use a variety of principles and can be composed of rotating transducers or groups of transducers, oscillating transducers, and the combination of oscillating transducers and reflectors (Fig. 3D.7). In most instances, the oscillating or rotating component is surrounded by a cup of liquid that is incorporated within the transducer assembly. Various ingenious techniques have been devised (54). Array transducers operate by the application of voltage pulses to single elements or groups of elements in succession (Fig. 3D.8). In the linear-array scanner, many small elements are aligned side by side much like the teeth of a comb, and the plane of the structure to be imaged is determined by the orientation of the scanner. In most instances, the scanner provides a real-time image. Phased-array and curved-array systems operate by applying voltages to all elements in the assembly. By allowing small time differences that can be controlled electronically, the pulsed sound waves can be shaped and steered in an infinite number of directions (Fig. 3D.9). With the linear-array system, real-time images are obtained. By orienting the transducer differently, a variety of scanned planes can be realized. Much work will continue to enhance the quality and resolution of the image received.

Doppler instrumentation is based on the principle of a change in reflected frequency caused by reflector motion. Differences between incident and reflected frequencies are related to the speed of the reflector or media boundary—the greater the speed, the greater the difference. *Doppler shift* refers to the difference between the incident frequency and the reflected frequency, and the Doppler equation provides a quantitative relationship between the flow speed and frequency change. The development of color-flow techniques and power Doppler has permitted assessment of the direction of blood flow in arteries and veins, which has been

useful in evaluation of a variety of benign and malignant urologic disorders.

Doppler instruments provide either continuous or pulsed voltages to the transducer. Continuous-wave instruments detect flow that occurs anywhere along the transmitted beam, but recently, pulsed-wave instruments have been introduced that provide information at a specific depth. Echoes can be received from different depths, depending on the receiver length and location, which can be controlled by the operator. Combination instruments are now available with the development of real-time cross-sectional ultrasound imaging in association with pulsed Doppler instrumentation (Fig. 3D.10). These instruments have allowed for the measurement of blood flow within specific blood vessels with the advent of color-flow technique and have been used in the assessment of blood flow within the kidney, testes, and penis. Power Doppler has greater sensitivity than conventional color Doppler, and it is particularly of value for assessing small vessels with low flow velocity (38). Echo-contrast development consisting of microbubble technology continues and offers much potential in clinical practice (15,107).

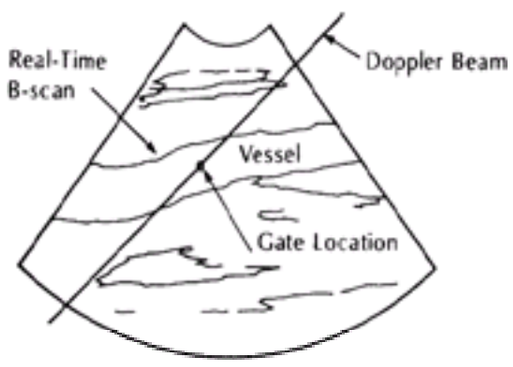

FIGURE 3D.10. Combination of real-time imaging and pulsed Doppler instrument. Blood flow measurement can be obtained within specific blood vessels. (Adapted with permission from Kremkau FW. *Diagnostic ultrasound principles, instruments and exercise,* ed 3. Philadelphia: Saunders, 1989.)

The images available for interpretation with most diagnostic ultrasound instruments are grayscale views; stop-action views can be obtained from a real-time examination. Real-time ultrasonography offers the advantage of dynamic imaging similar to that obtained with fluoroscopy. The obtained images are representations of a spectrum of echoes arising from the surface and substance of the given structure in two dimensions. With current scanners, a complete cross section of a structure is formed one line at a time. After one line is drawn, the transducer is moved slightly and pulsed again to draw another line. Typically 10,000 lines per second are drawn, enabling a complete image of the structure to be obtained. A permanent record of the scan can be recorded on Polaroid film, radiographic film, videotape, computer floppy disks, laser disks, and thermal paper.

Newer, less expensive equipment is making ultrasound examination of the urinary tract practical in the office setting. In addition, the equipment can be used for vascular flow studies, which is useful in the evaluation of men with erectile dysfunction and for assessing blood flow to a testicle when torsion of the spermatic cord is suspected. It can also be used in conjunction with urodynamic studies to image the bladder, bladder neck, and proximal urethra. Ultrasound examinations performed at the time of an office visit can speed diagnosis and treatment and reduce the cost of patient care.

RENAL ULTRASOUND

When ultrasound images of the kidneys are obtained, patients can be scanned in the supine, decubitus, or prone positions and images are obtained in the transverse and longitudinal planes (Fig. 3D.11). In the past, the kidneys were usually examined with the patient in the prone position; however, the frequent location of the upper poles beneath the rib cage often led to incomplete or unsatisfactory studies. Currently, the right kidney is best examined with the patient in the supine position, using the liver as an acoustic window. The best images of the left kidney are usually obtained with the patient in the right lateral decubitus position, with the spleen as an acoustic window. When indicated, different views can also be obtained in the oblique plane by moving the transducer through different arcs relative to the longitudinal and transverse planes.

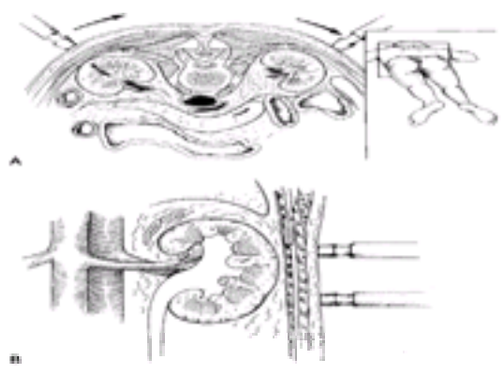

FIGURE 3D.11. Image planes of a transverse renal scan **(A)** and a longitudinal renal scan **(B).**

Renal Anatomy

The adult kidneys are paired, retroperitoneal structures lying between the twelfth thoracic and second lumbar vertebrae. Each kidney is approximately 10 cm long, 5 cm wide, and 2 to 5 cm thick. The right kidney is typically lower than the left. Ultrasonography continues to be an excellent modality to determine renal size. The upper pole of the right kidney is in contact with the adrenal superomedially and the duodenum anteromedially, and the posterior aspect of the right lobe of the liver overlies its anterior surface. Overlying the lower pole of the right kidney is the hepatic flexure of the colon and loops of small bowel. The anterior surface of the left kidney is in contact with the spleen, left adrenal, stomach, pancreas, descending colon, and small bowel. Posteriorly, the kidneys are in contact with the twelfth rib, diaphragm, transversus abdominis muscle, quadratus lumborum muscle, and psoas major muscle.

Each kidney is surrounded by a closely adherent, dense, fibrous capsule, which is surrounded by perinephric fat and enclosed in Gerota's fascia. On ultrasound examination, the renal outline is determined by the acoustic interface formed by the renal capsule and surrounding fat. Transverse scans show the kidney to be round or bean-shaped, whereas longitudinal images reveal an elliptic configuration (Fig. 3D.12). The renal parenchyma is relatively homogeneous, with the cortex appearing more echogenic than the medulla. Located in the center of the longitudinal renal scan is a dense echo complex consisting primarily of peripelvic fat, renal vessels, lymphatic vessels, and normal collecting system. The renal medullary pyramids appear somewhat less echogenic (more sonolucent) than the renal cortex and are often identified abutting on the dense sinus fat. The arcuate arteries separate the cortex from the renal medulla and, when visualized, allow for an accurate assessment of the renal cortical thickness. The renal vascular pedicle often can be identified with real-time scanning techniques. Doppler instrumentation has permitted assessment of blood flow in the main renal artery, and its branches have been used to evaluate patients with suspected renal vascular lesions and to assess for renal viability in the presence of severe hydronephrosis (13,65). Color-flow and power Doppler studies have provided detailed images of both the extrarenal and renal vasculature and are being increasingly used in patient evaluations (38,79,81).

Indications for Renal Ultrasound

Renal Mass

The question of a renal mass is usually raised by an abnormality found on excretory urography. In the adult, simple renal cysts are the most commonly diagnosed renal mass lesion. They are rarely seen in children. They occur with increasing frequency beyond age 30 years, and in an autopsy series, approximately 50% of all patients older than 50 years had at least one renal cyst (53). Ultrasound can identify cystic masses as small as a few millimeters in diameter. Solid mass lesions 1 to 2 cm wide also are routinely identified. The ability to identify a renal mass lesion depends on the depth of the lesion beneath the skin and the patient's body habitus.

Ultrasound has been extremely valuable in differentiating a simple renal cyst from other renal masses and is therefore the first study obtained in the evaluation of a suspected renal mass. On ultrasound, a renal cyst is typically spherical or slightly ovoid, demonstrates no internal echoes, has a clearly identifiable thin wall separate from the surrounding renal parenchyma, and allows enhancement of ultrasound transmission beyond the cyst (Fig. 3D.13). When these criteria are strictly adhered to, diagnostic accuracy rates approaching 100% have been reported (93). If a renal mass meets all of these criteria and the patient is asymptomatic, no further evaluation is required. If, however, the patient is symptomatic (pain or hematuria), cyst aspiration under ultrasound guidance can be performed to confirm the diagnosis. Aspirated fluid is routinely sent for cytologic study, lactate dehydrogenase, culture, and cholesterol determinations. While cyst puncture is performed, contrast material and air may be injected into the cyst to better define the cyst's margins and contours of the wall. Typically, computed tomography (CT) with and without injection of intravenous contrast agent is useful in assessing these symptomatic patients, thus avoiding the need for cyst aspirations. CT can also be used to help delineate a complex mass initially imaged with ultrasound, but occasionally, these studies are unable to exclude the presence of a renal malignancy, and often renal biopsy or surgical exploration is required to establish the correct diagnosis.

FIGURE 3D.13. A: Longitudinal renal scan showing characteristic findings of a simple renal cyst *(arrows). B:* Cyst *(C)* demonstrated on computed tomography scan.

The finding on ultrasound of a solid or indeterminate (complex) renal mass raises the possibility of the presence of a renal malignancy and dictates that additional evaluation be performed. Ultrasound characteristics of a solid renal mass include the presence of internal echoes, poor delineation of the posterior wall, and the lack of enhancement on through transmission (Fig. 3D.14).

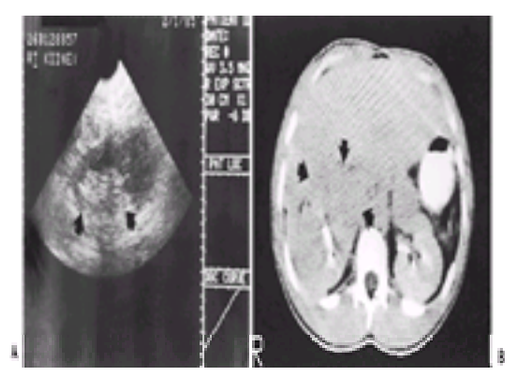

FIGURE 3D.14. Longitudinal renal ultrasound **(A)** and computed tomography scan **(B)** demonstrating findings of a hypernephroma *(arrows).*

The ultrasonic diagnosis of solid lesions is not as accurate as that of cystic lesions, and a false-negative rate has been reported to be as high as 14% (110). Therefore the diagnosis of a solid lesion requires further evaluation and possibly exploration. Color-flow and power Doppler studies have been used to differentiate solid renal masses (e.g., renal cell carcinoma versus renal lymphoma), and they have also been used to detect intravascular extension of invasive renal malignancies (37,55).

Angiomyolipoma, a benign tumor, seems to be the only solid renal mass with typical ultrasonographic features that allow presumptive diagnosis and safe differentiation from other solid mass lesions (62). If the lesion contains a high concentration of fat, it will be extremely echogenic, even more so than a solid renal mass. Hyperechogenicity coupled with the CT findings of fat lucency allows the diagnosis to be made with certainty (92) (Fig. 3D.15). Computer-aided tissue echo quantification has permitted the differentiation of small hyperechoic renal cell carcinomas from angiomyolipoma (111).

FIGURE 3D.15. Sagittal ultrasound of the right kidney shows a hyperechoic lesion at the superior aspect of the kidney. Computed tomography examination demonstrated fat within the tumor, indicative of an angiomyolipoma. (Permission granted by Urologic Multimedia, Inc.)

In the presence of a complex cystic lesion, the most likely diagnosis is necrotic tumor, hematoma, or abscess. The clinical course coupled with the findings on angiography or CT allows an accurate, certain diagnosis. When the diagnosis remains obscure, aspiration biopsy or exploration is often required.

A relatively new application is the use of ultrasound intraoperatively to monitor the cryoablation of small renal masses (126). Ultrasound has also been reported to be of value in the evaluation of the patient with acute renal trauma by determining the presence of urinary extravasation, perirenal hematoma, and renal fracture.

Collecting System Masses

Renal ultrasound has been extremely helpful in evaluating a noncalcified mass of the collecting system detected on excretory urography. A noncalcified or poorly calcified renal calculus (uric acid) demonstrates classic ultrasound findings. Typically, these calculi demonstrate increased echogenicity with acoustic shadowing (Fig. 3D.16). Other common soft tissue masses of the collecting system include tumors primarily of transitional cell origin, blood clots, and sloughed renal papilla (Fig. 3D.17). These abnormalities, although usually easily distinguishable from a nonopaque stone, often require urologic studies (e.g., ureteroscopy, biopsy) to arrive at the correct diagnosis. Intraluminal ultrasonography has allowed assessment of the ureter and collecting system, which has been of value when other imaging studies have failed (118).

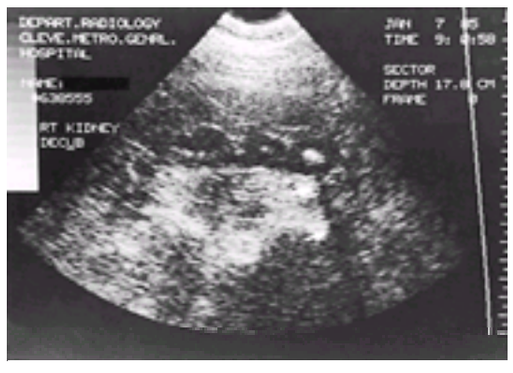

FIGURE 3D.16. Longitudinal scan demonstrating stone in the lower pole calyx. Stone is highly echogenic. Note area of acoustic shadowing *(arrows).*

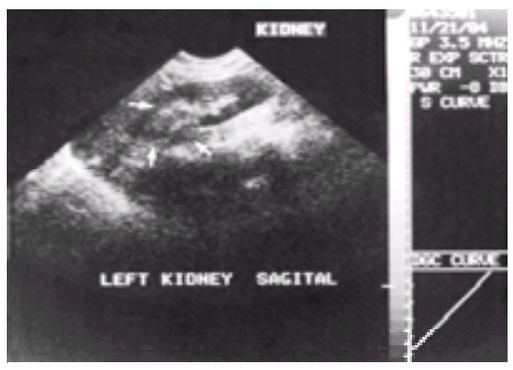

FIGURE 3D.17. Longitudinal renal scan demonstrating upper pole mass *(arrows).* Surgical exploration revealed transitional cell carcinoma.

Renal Failure and Hydronephrosis

Although accounting for only 5% of all cases of renal failure, ureteral obstruction is potentially reversible and is usually accompanied by hydronephrosis. As a screening study to rule out obstruction as the cause of renal failure, ultrasound has a sensitivity approaching 100% (49,116). Patients with renal failure resulting from parenchymal disease characteristically have small kidneys with diffuse increases in echogenicity. Doppler studies also have been useful in monitoring the renal vasculature in both critically ill patients and those with renovascular disease (40,91). Color-flow studies with measurement of resistive index (RI) have been used to assess parenchymal viability in an attempt to differentiate those kidneys that are worth repairing from those with minimal chance of recovery that should be removed (13).

Studies also have indicated that minimum hydronephrosis can be substantial when there is a clinical question of the presence of renal obstruction (51). The renal sinus that normally appears as a region of intense echogenicity because of many dense interfaces becomes interspaced with hypoechoic regions with the development of hydronephrosis. These hypoechoic regions represent the dilated calyces and infundibula (Fig. 3D.18). As the dilation of the collecting system becomes more pronounced, this central echogenic region may be unidentifiable altogether (Fig. 3D.19). This finding aids in the diagnosis of longstanding hydronephrosis and parenchymal thinning. The dilated intrarenal collecting system can be imaged with longitudinal scans to reveal a dilated renal pelvis and, at times, upper ureter (Fig. 3D.20). Lesions that may be misinterpreted as hydronephrosis include congenital megacalycosis, calyceal diverticulum, pelvic cysts, and a prominent extrarenal pelvis. False-positive studies can also be secondary to instances of high urinary output.

FIGURE 3D.18. A: Longitudinal scan demonstrating hydronephrosis secondary to ureteropelvic junction obstruction *(large arrow).* Note dilated calyces *(small arrows).* **B:** Computed tomography scan of same patient showing hydronephrotic kidney.

FIGURE 3D.19. Longitudinal scan demonstrating severe hydronephrosis with thinning of the renal parenchyma.

FIGURE 3D.20. Longitudinal scan demonstrating dilation of renal pelvis and upper ureter.

The assessment of the presence or absence of hydronephrosis has many implications in urologic practice. Although important in the evaluation of patients with impaired renal function, its assessment has application in evaluations made before and after treatment of many patients. Ultrasonography has been useful in the follow-up of patients after extracorporeal shock wave lithotripsy for the detection of hydronephrosis. Although abdominal radiographs are helpful in determining the presence of residual stone fragments, particularly in the ureter, ultrasound is a valuable adjunct in evaluating for the presence of hydronephrosis.

In addition, the technique is useful in follow-up of patients who have ureteral stones that are being observed and allowed to pass. The development or resolution of hydronephrosis can be easily assessed with this technique. False-negative studies can occur when urinary output is low or in instances when collecting system dilation is prevented by the presence of severe perineal and ureteral disease (e.g., inflammation, tumor).

Experience has indicated that Doppler studies are also useful in the evaluation of patients with acute renal obstruction. Changes in flow patterns and resistive indices are proving to be of increasing value to the clinician evaluating these patients (90,91,104). Other useful applications of ultrasonography relate to the postoperative follow-up of patients. Individuals undergoing urinary diversion or other surgical procedures on the urinary tract (e.g., pyeloplasty, ureteroneocystostomy) can be evaluated during the postoperative period to also assess for the development of resolution of preexisting hydronephrosis. Finally, the routine follow-up of patients with a variety of urologic disorders is improved with ultrasound assessment. Those with neurogenic bladders (e.g., spinal cord injury, myelomeningocele) can be assessed with this technique, as can those with malignancies (e.g., prostate carcinoma) and long-term postoperative patients (urinary diversion). Further evaluation and treatment can then be undertaken if hydronephrosis is detected.

RENAL TRANSPLANTATION

Because of its superficial position in the pelvis, the transplanted kidney is particularly well suited for ultrasound evaluation, which has also proved to be useful in evaluating posttransplant diminishing urine output. The short-term changes in renal volume associated with refection can usually be differentiated from an obstructive cause. It is also possible to detect the presence of perirenal hematomas, lymphoceles, and urinomas that may occur in the transplant patient.

Power Doppler and color-flow studies have been used to detect the presence of acute rejection. These studies have been helpful not only in the detection of acute rejection but also for the differentiation of acute rejection from the various other causes of renal failure (e.g., obstruction) (90,95,100,102,120).

PERIRENAL EVALUATION

Ultrasonography is useful in the evaluation of the perirenal space. Perirenal fluid collections may represent hematoma or urinoma, which usually are associated with an antecedent history of trauma or prior renal surgery (Fig. 3D.21). Urinomas tend to be cystic, whereas hematomas may be solid, cystic, or a combination of both, depending on the stage of clot breakdown. Ultrasound offers an accurate, noninvasive, radiation-free means of following the presence and course of perinephric hematomas resulting from blunt trauma.

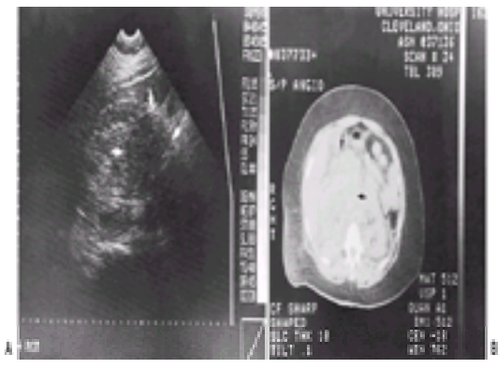

FIGURE 3D.21. A: Large perirenal hematoma after blunt abdominal trauma *(arrows).* **B:** Computed tomography scan of same patient.

The presence of a perinephric abscess is usually suggested by a febrile course unresponsive to the usual antibiotic regimen. Sonographically, the perinephric collection appears as a complex mass with the internal architecture dependent on the amount and type of pus and the presence or absence of gas within the abscess (Fig. 3D.22). Ultra-sound can be used to assist in percutaneous drainage of these collections, which in many instances has supplanted the need for open surgical procedures.

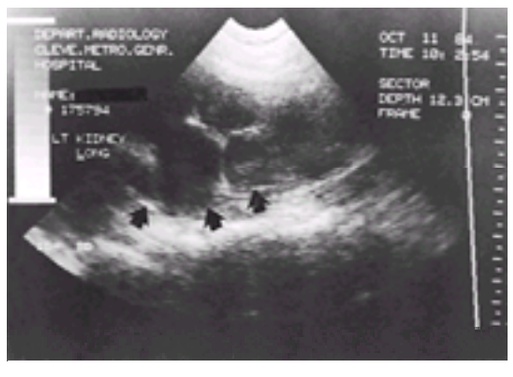

FIGURE 3D.22. Transverse scan showing complex perirenal mass, proved to be multiloculated perinephric abscess. Note multiple loculations *(arrows).*

SCREENING PROCEDURES

Renal ultrasonography has a role in the evaluation of suspected adult polycystic renal disease. The sonographic appearance is that of enlarged kidneys with randomly distributed cysts (Fig. 3D.23). Early cystic renal changes are ultrasonically visualized before any other signs or symptoms are apparent in affected individuals.

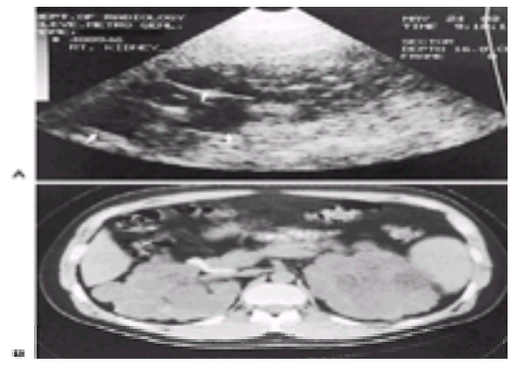

FIGURE 3D.23. A: Transverse scan showing multiple cysts *(arrows)* in an enlarged kidney. Changes typical of adult polycystic kidney disease. **B:** Computed tomography scan of same patient.

FETAL RENAL ULTRASOUND

Obstetric ultrasonography is often performed during the course of pregnancy and is useful in the evaluation of fetal size, gestational age, fetal lie, and placental position. Recent advances in ultrasound technology have improved the visualization of fetal anatomy and have led to increased identification of unsuspected congenital anomalies. Between 15 and 17 weeks of gestation, it is possible to identify the fetal kidneys by ultrasound approximately 50% of the time (58). By 20 weeks of gestation, it is unusual not to be able to identify the kidneys accurately. It is therefore currently possible to diagnose accurately the presence of in utero hydronephrosis; however, in most instances, it is impossible to differentiate its many etiologies: posterior urethral valves, primary megaureter (Fig. 3D.24), ureteropelvic junction obstruction, multicystic kidney (Fig. 3D.25), duplication anomalies with or without ureteroceles (Fig. 3D.26), vesicoureteral reflux, or prune-belly syndrome (22,28,50,127). The diagnosis of fetal hydronephrosis best serves to alert the primary physician to the need for additional urologic evaluation in the early neonatal period. When indicated, appropriate surgical intervention may be expeditiously performed.

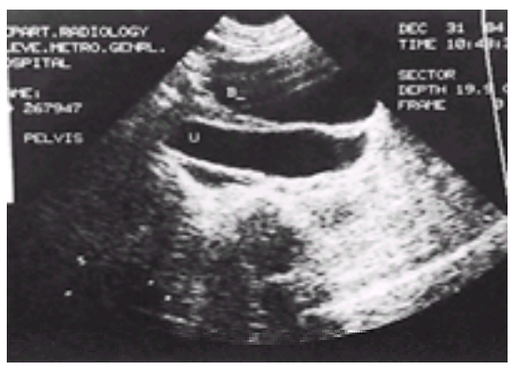

FIGURE 3D.24. Longitudinal pelvic scan showing dilated megaureter. B, bladder; U, ureter.

FIGURE 3D.25. Ultrasonic changes of multicystic kidney. Note multiple cysts *(arrows).*

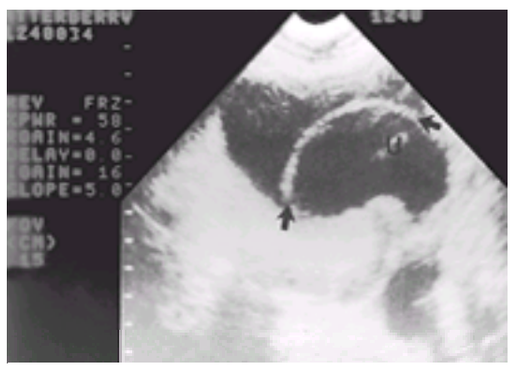

FIGURE 3D.26. Longitudinal scan of bladder demonstrating presence of ureterocele *(U).* Note thin wall of ureterocele *(arrows).*

RETROPERITONEAL SCANNING

The retroperitoneal space is a difficult area to examine with conventional radiographic methods, but it is well suited for sonographic studies. It is possible to identify lymph node enlargement, primary retroperitoneal tumors, and aortic aneurysms with a considerable degree of accuracy (Fig. 3D.27). Ultrasound may be helpful in determining the cause of ureteral deviation in patients with obstruction detected on excretory urography. In patients with retroperitoneal nodal metastases (e.g., testicular tumor), ultrasound remains an excellent way to follow up the response to chemotherapeutic regimens without the risk of repeated radiation exposure. More commonly, CT studies are used to assess the retroperitoneum and in most instances are the primary studies used. When indicated, ultrasound-guided biopsies can be performed of suspicious structures. Ultrasound examination of the retroperitoneum also has been used to identify and locate accurately the undescended testicle. The study is helpful in identifying the inguinal testis, but it is less accurate in localizing the intraabdominal testis.

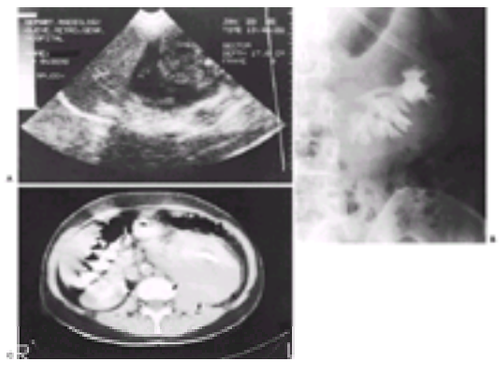

FIGURE 3D.27. A: Longitudinal scan of retroperitoneum demonstrating left perirenal mass. KID, kidney; M, mass; SPL, spleen. Surgical exploration revealed lymphoma. Intravenous urogram **(B)** and computed tomography **(C)** from same patient.

ULTRASONOGRAPHY OF THE ADRENAL GLAND

Because of their small size and protected location beneath the rib cage, it is often difficult to study the normal adrenal glands sonographically (9). Similarly, the evaluation of adrenal masses smaller than 3 cm is probably best performed with other radiographic techniques (e.g., CT, magnetic resonance imaging). Radionuclide and serum studies may also prove invaluable.

SCROTAL ULTRASONOGRAPHY

The superficial location and the maneuverability of the intrascrotal contents make the anatomic area well suited for sonographic evaluation. The primary use for scrotal ultrasound is in differentiating intratesticular lesions (tumors) from abnormalities arising from the paratesticular tissues. With the currently available high-frequency “small-parts” transducers, grayscale real-time techniques, and color-flow and power Doppler availability, a complete scrotal examination can be performed in minutes while providing excellent tissue resolution. The procedure is usually performed by first immobilizing the testicle with the free hand and then placing the transducer directly in contact with the scrotal skin. Mineral oil or acoustic gel is routinely used as a coupling agent to help reduce artifact (27).

Normal Ultrasonic Scrotal Anatomy

Sonographically, the scrotal wall appears as a hyperechoic strip 3 to 4 mm thick. Between the scrotal wall and the testicle is an anechoic area, usually no more than a few millimeters in width, which represents a small amount of fluid normally present between the visceral and parietal layers of the tunica vaginalis. The normal testicle measures about 4 by 3 by 3 cm and is characterized by a homogeneous, fine granular echo pattern (Fig. 3D.28). The tunica albuginea appears as a thin hyperechoic layer surrounding the testicle. Posteriorly, the tunica albuginea reflects into the testicle to form the mediastinum testis, a structure that usually is seen only with the newer small-parts transducers. The epididymis runs along the posterolateral aspect of the testicle. The head, or globus major, is seen above the superior pole of the testicle and, when normal, appears to be either hyperechoic or of the same echogenicity as the testicle. The body and tail of the epididymis sonographically appear as a coarser echo pattern than the testicle. The vas deferens, when visualized, appears as a circular hyperechoic area on transverse scans. Doppler and color-flow studies allow for assessing testicular perfusion, thus detecting vascular abnormalities associated with the spermatic cord. These studies have also been of value in the evaluation of patients with testicular trauma and intratesticular masses.

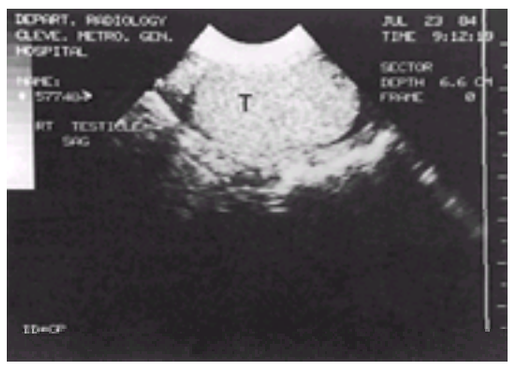

FIGURE 3D.28. Scrotal ultrasound showing sonographic appearance of normal testicle *(T).*

Applications of Scrotal Ultrasound

Patients with scrotal swelling and pain represent a diagnostic challenge and require prompt evaluation. Scrotal ultrasound has been helpful in differentiating the presence of inflammatory lesions (orchitis or epididymitis) from spermatic cord torsion, traumatic testicular disruption, and testicular or paratesticular tumors. Sonographically, epididymitis appears as a hypoechoic enlargement (inflammatory edema), usually involving the globus major. A reactive hydrocele may also be present (Fig. 3D.29). In the presence of epididymo-orchitis, the testicle adjacent to the involved epididymis may demonstrate areas. Individuals with presumed epididymo-orchitis who fail to respond to antibiotic therapy may demonstrate a testicular or scrotal abscess on ultrasound examination. When acute scrotal swelling occurs as a result of trauma, ultrasound has been helpful in differentiating testicular rupture from a normal testicle surrounded by hematoma (Fig. 3D.30). Acutely, the ischemic testicle is enlarged, with decreased echogenicity compared with the normal testicle. Color-flow studies can assess testicular perfusion and are invaluable in evaluating children with an acutely painful testicle (8,14,86,114). When properly performed, these studies are as reliable as radionuclide imaging and approach an accuracy of 98%.

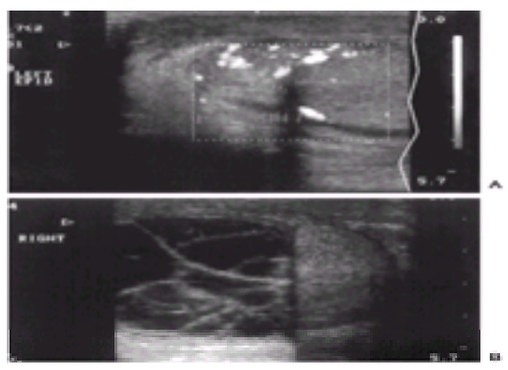

FIGURE 3D.29. A: Scrotal examination using power Doppler shows marked hyperemia involving a swollen left epididymis. These are typical features with acute epididymitis. **B:** Ultrasound of a different patient demonstrates a reactive hydrocele related to acute epididymitis. This shows a weblike pattern with multiple thick septations. (Permission granted by Urologic Multimedia, Inc.)

FIGURE 3D.30. Scrotal ultrasound demonstrating large hematoma *(arrows)* surrounding normal testicle *(T).*

A *hydrocele* is a fluid collection that occurs between the visceral and parietal layers of the tunica vaginalis, making accurate testicular examination difficult to perform on physical examination. Scrotal ultrasound has been helpful in identifying hydroceles secondary to a malignant process. In the presence of a hydrocele, the quality of the testicular sonogram may be improved because of the fluid, which acts as a biologic water bath. Typically, a simple hydrocele appears as an anechoic area surrounding the testes anterolaterally (Fig. 3D.31). The presence of a hypoechoic inhomogeneous mass in the testicle is suggestive of a malignancy and warrants surgical exploration (Fig. 3D.32). Unlike embryonal cell carcinoma, seminoma sonographically has a more homogeneous pattern (Fig. 3D.33). Nonseminomatous testicular tumors often demonstrate increased flow on Doppler studies. Individuals with repeated bouts of epididymal infection may also have scrotal pain and swelling. Ultrasonically, a diagnosis of chronic epididymitis is suggested by an enlarged hyperechoic epididymis (Fig. 3D.34).

Scrotal ultrasound, particularly when combined with Doppler studies, has been helpful in identifying the subfertile male patient with a nonpalpable or subclinical varicocele (30,88). The clinical significance of the subclinical or nonpalpable varicocele continues to be debated. Testicular microlithiasis is usually bilateral and has been found to be associated with testicular malignancies and infertility (2,77). The disorder is usually identified incidentally and, when found without clinical evidence of malignancy, is followed with periodic ultrasound examinations. Ultrasound studies have also been used to assess postpubertal testicles having undergone prepubertal orchidopexy (121) and in following the remaining testes after unilateral orchiectomy for testicular germ cell tumors (63). Ultrasonography has also been used to assess not only the location of undescended testes, but their histologic characteristics as well (6).

TRANSRECTAL ULTRASONOGRAPHY OF THE PROSTATE

Since its inception in the 1960s, abdominal and scrotal ultrasound has gained an important role in the evaluation of many urologic disorders. However, because of the relatively inaccessible pelvic location of the prostate, ultrasonic evaluation of this structure with conventional techniques has not been as widely accepted. In the late 1950s, Wild and Reid were the first to develop and test a transrectal ultrasonic probe (43). Although their initial experience with the transrectal approach resulted in visualizing only the rectal wall, the possible usefulness of this technique as a means to evaluate the lower urinary tract and particularly the prostate was clearly demonstrated. In 1964, Takahashi and Ouchi (115) used a transrectal probe equipped with a radial scanning device and obtained poor-quality tomographic pictures of the prostate, which had no clinical value. It was not until 1967 that Watanabe and associates (122,123) obtained the first clinically useful transrectal ultrasonic tomograms of the prostate. Since then, additional advances in instrumentation and technique have allowed for more reliable ultrasonic visualization of this pelvic organ. Today, the use of transrectal ultrasonography is helpful in the assessment of both benign and malignant disorders of the prostate and has been particularly valuable in biopsy and assessment of treatment of patients with carcinoma of the prostate.

Instrumentation

The transducer and its mechanism of action (mechanical sector and radial, array-linear, and phase) are important components of the current instrumentation used in this technology. Most transducers used for imaging the prostate vary in frequency from 6.0 to 7.5 MHz. This allows for excellent visualization of the posterior prostate, but because of the limited penetration of high-frequency sound, visualization of the anterior prostate is limited, especially when associated with significant enlargement. There is increasing interest in the role of color-flow Doppler studies; however, the utility of these studies continues to be debated (12,47,68,82,105). Different types of transducers are available, but most are typically biplanar and use radial or sector transducers. This allows imaging of the prostate in the transverse and sagittal planes. The transducer of the radial scanner rotates 360 degrees and propagates sound waves perpendicular to the long axis of the transrectal probe. Within the human body and with respect to the prostate gland, the sound waves are directed perpendicular to the long axis of the body and prostate. The direction is called *transaxial* or *axial,* and it is similar to the transverse plane of a CT image. Linear-array and mechanical sector scanners have eliminated the need for the rectal balloon, and the probe is placed in direct contact with the rectal wall. A decided advantage of these instruments is that transrectal prostate core biopsies and aspirations can be performed under ultrasonic guidance. In the phased-array scanner, many small transducers are aligned side by side, and when the scanner is oriented parallel to the long axis of the body, the sonographic images obtained are in the longitudinal or sagittal plane. Mechanical sector and phased-array scanners can provide images in either plane, and new biplanar probes incorporate both types of transducers in one unit.

Transverse images yield more information about the lateral margins and symmetry of the prostate, whereas longitudinal images delineate the apex and base of the gland more clearly. The longitudinal orientation appears to be more ideal for ultrasound guidance of prostate biopsy, even though the technique was first demonstrated with a radial scanner. Use of axial and longitudinal projections provides increased sensitivity in the examination of the prostate, and probes with both capabilities have been developed and will likely continue to be the standard.

Technique of Examination and Prostatic Biopsy

Technically, transrectal ultrasonography is minimally invasive and easy to perform. The entire examination takes 15 to 20 minutes and can be performed in the office on an outpatient basis without the need for anesthetics. Before beginning the examination, the clinician should perform a rectal examination to exclude the presence

of anal or rectal abnormalities that may contraindicate transrectal probe insertion. In addition, a careful digital examination of the prostate should be undertaken. The examination may be performed with the patient in the lithotomy, lateral decubitus, knee-chest, or sitting position. Before performing the study a cleansing enema can be administered, but this is not necessarily done routinely. The transrectal probe is then inserted approximately 8 to 9 cm above the anal verge, and serial sonograms are obtained. It is important to perform the study systematically. When transverse images are obtained, sonograms are typically obtained at increments of 5 mm beginning at the bladder and seminal vesicles and progressing toward the apex. When a longitudinal scanner is used, images are obtained at increments of 5 degrees right and left of center. All images should be appropriately marked and hard copies obtained so that they may be referred to at a later date. Permanent records can be obtained with Polaroid film, multiple format cameras, thermal printers, videotape, laser disks, and computer floppy disks.

Applications

Over the past 10 years, significant advances have been made in the technology and methodology associated with transrectal ultrasonographically guided biopsies of the prostate. Although initial reports used the transperineal route (43), more recent experience has been with transrectal approaches (60). In addition, data are being obtained on the relative merits of both core and aspiration techniques (60). Spring-loaded devices also have been used in association with ultrasound-guided systematic or sextant core biopsies, and they have resulted in sampling of the prostate with a reduction in the pain associated with the procedure (117). Technologic improvements in ultrasound instrumentation have resulted in the development of transducers that permit viewing of the prostate in a variety of planes, which also has increased the accuracy of biopsy techniques (32,60).

Transperineal biopsies have generally been performed with the aid of radial or linear-array scanners (Fig. 3D.35 and fig. 3D.36), but since the development of transrectal techniques, these procedures are performed rarely. The biopsy is performed under sterile conditions, and the perineum is cleansed and draped in the standard manner. Biopsies can be performed with the patient in either the lithotomy or lateral decubitus position, depending on the examiner's preference. When the radial scanner is used, often a grid with multiple holes is placed against the perineum and the site of needle entry corresponds to the grid that appears on the viewing screen (97). When an area of interest is imaged, the biopsy needle is inserted in the appropriate site on the grid and the movement of the needle is monitored on the viewing screen. One of the disadvantages of this system is that the needle cannot be tracked or followed continuously during the entire biopsy. If care is not exercised, tissue may be obtained that is cephalad or caudad to the particular area to be sampled. This disadvantage can be overcome with the use of a linear-array transducer. It is of interest that the techniques developed for biopsy have recently been used for interstitial radiation of the prostate. The approach allows for accurate seed implantation, which is a treatment modality for carcinoma of the prostate that is being used with increasing frequency.

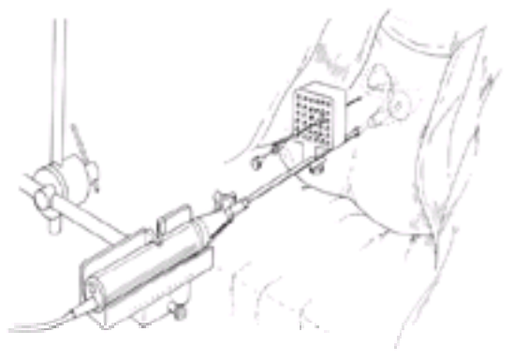

FIGURE 3D.35. Diagram demonstrating transperineal biopsy with radial transducer.

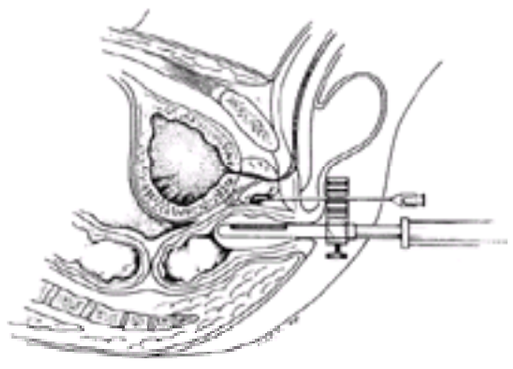

FIGURE 3D.36. Diagram demonstrating transperineal biopsy with linear-array transducer.

Transrectal biopsies are performed most commonly with a biplanar probe (Fig. 3D.37). Before performing the transrectal biopsy, many clinicians prefer to administer broad-spectrum oral antibiotics 1 hour before the procedure and to give the patient a cleansing enema. As with the transperineal biopsy, the procedure can be performed with the patient in either the lateral decubitus or the lithotomy position, based on the examiner's preference. Some clinicians use the knee-chest position because they believe the drainage of blood from the gland and associated collapse of prostatic and periprostatic veins improves the ultrasound image. Most of the newer instruments have markers that appear on the viewing screen when the transducer is in the biopsy mode, and these correspond to the path of the needle. Aligning the area from which a biopsy specimen is to be taken with these markers ensures that reliable biopsies can be obtained (Fig. 3D.38). Devices also have been developed for obtaining either aspiration or core biopsy. Although higher than with the perineal biopsy, the risk of sepsis remains low (less than 1%).

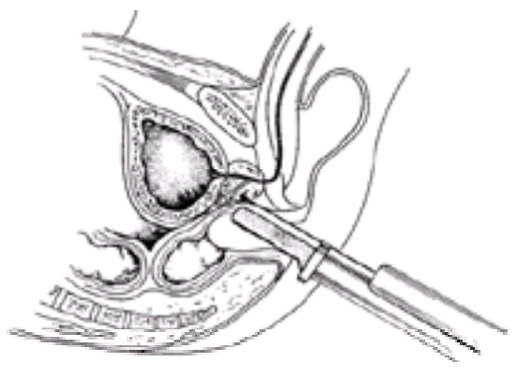

FIGURE 3D.37. Diagram demonstrating transrectal biopsy with end-fire multiplane probe.

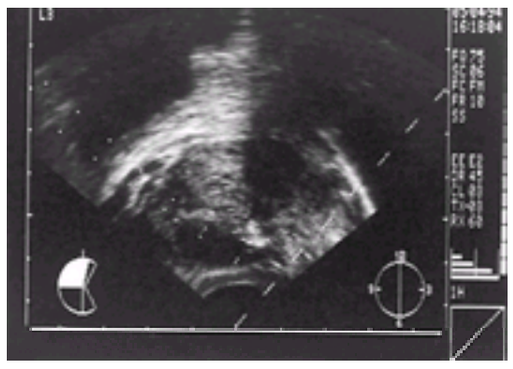

FIGURE 3D.38. Sagittal scan with markers indicating path of biopsy needle.

The normal prostate is viewed as a symmetric triangular ellipsoid structure that is delineated circumferentially by the continuous prostatic capsule (Fig. 3D.39). The capsule or margin is usually well defined, highly echogenic, continuous, and free of distortion. The anteroposterior diameter appears shorter than the transverse diameter because the posterior portion of the prostate becomes concave as a result of compression by the probe during the examination. The internal sonographic structure of the prostate is composed of multiple fine diffuse homogeneous echoes that probably represent acoustic interfaces created by numerous glands that are present. The posterior peripheral zone can usually be delineated from the more anterior, fibromuscular stroma and the central and transition zones.

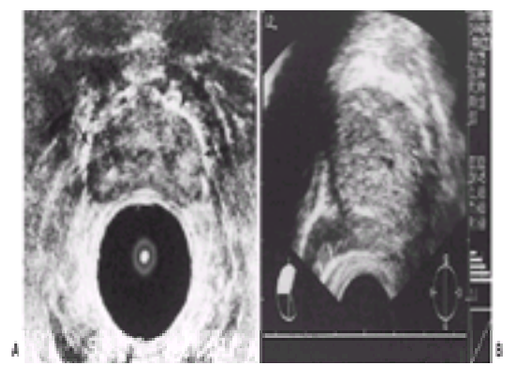

FIGURE 3D.39. A: Transverse image of normal prostate. **B:** Sagittal image of normal prostate. Note relationship of seminal vesicles *(arrows)* to prostate. Urinary bladder is to the left.

Benign prostatic hyperplasia is limited to the transition zone and appears as diffuse enlargement, with the greatest increase in size occurring in the anteroposterior diameter. The prostate margin remains well defined but thicker than is found in the normal gland. The hyperplastic portion of the gland consists of multiple fine homogeneous echoes believed to represent small adenomas located in fibrous tissue between glandular elements and multiple microcysts created by dilated prostatic ducts containing secretions, corpora amylacea, and microcalculi (Fig. 3D.40). Often, the transition zone that gives rise to benign prostatic hyperplasia can be differentiated from the more echogenic peripheral zone from which 70% of carcinomas arise. It is often difficult to distinguish the transition zone from the central zone in the presence of significant hyperplasia. Prostatic calculi, often present at the interface of the peripheral and transition zones, commonly can be identified by their marked echogenicity in association with typical “shadowing” (Fig. 3D.41).

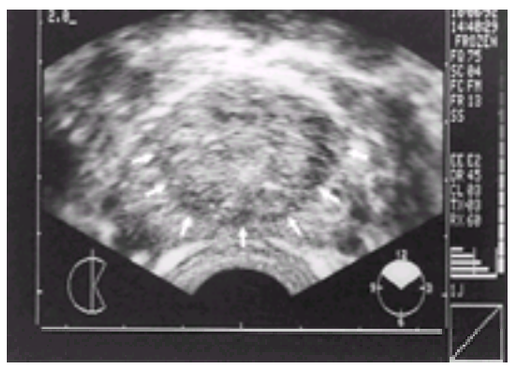

FIGURE 3D.40. Transverse image demonstrating typical appearance of benign prostatic hyperplasia. *Arrows* indicate transition zone border.

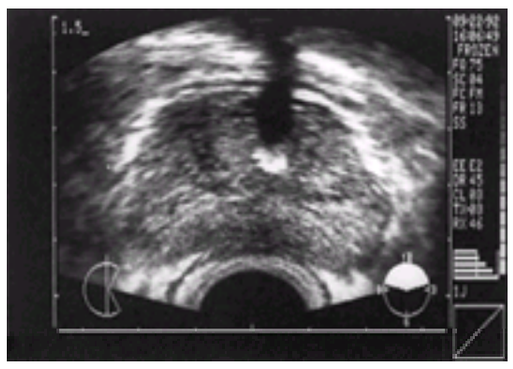

FIGURE 3D.41. Transverse image demonstrating hyperechogenicity and shadowing associated with prostatic calculi.

Unlike the usual homogeneous sonographic appearance of the normal hyperplastic prostate, the ultrasonic characteristics of carcinoma of the prostate are varied. Early studies with B-mode and initial gray-scale imaging reported that prostate cancers appeared as echo-dense or hyperechoic areas (52). With improvement in instrumentation and the use of higher-frequency transducers, the appearance of tumors changed. Some investigators began to demonstrate that prostatic malignancies, particularly when they are small and localized, appear as hypoechoic areas located in the peripheral zone (Fig. 3D.42), but others demonstrated that tumors can be hyperechoic, hypoechoic, isoechoic, or of mixed echogenicity (24,59,98). There does not appear to be a reliable correlation between histologic grade and ultrasonic pattern other than the fact that small tumors that tend to be well differentiated often appear hypoechoic and larger, and high-grade tumors tend to have a mixed pattern. Isoechoic tumors tend to have a mixed pattern. Isoechoic tumors tend to be better differentiated. Newer, high-resolution equipment visualizes a prostate tumor as an echopenic focus before it obtains a more echogenic appearance. A desmoplastic reaction and associated calcification are often associated with tumor growth and invasion. These changes may contribute to the mixed pattern observed with advanced tumors (99).

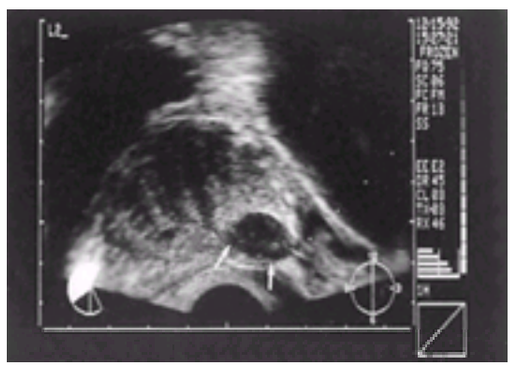

FIGURE 3D.42. Transverse image demonstrating appearance of peripheral zone hypoechoic carcinoma *(arrows).*

Unfortunately, many structures and benign processes within the prostate can have ultrasonic characteristics similar to the hypoechoic appearance of small prostate malignancies, including small nodules of hyperplasia, cysts, infarcts, inflammatory processes, cystic atrophy, blood vessels, and muscle tissue. Many carcinomas are isoechoic and cannot be imaged with this technique. In addition, anterior tumors often cannot be distinguished reliably from the normally hypoechogenic appearance of this region of the gland.

Improvements in technology have resulted in the development of newer devices that may improve the ability of ultrasonography to detect and stage prostate malignancies. Color Doppler, power Doppler, ultrasound contrast agents, and three-dimensional studies have all been used, but unfortunately, none has been able to locally determine the extent of disease once the diagnosis of carcinoma has been established (26,33,68,82,105).

Clinical Applications

Although transrectal prostatic ultrasonography has had its greatest use in the assessment of patients with carcinoma of the prostate, other applications include the evaluation of patients with both acute and chronic prostatitis and men with infertility (48). Experiences indicate that the technique is useful in the assessment and the detection of seminal vesicle abnormalities that may be associated with infertility, and ductal obstruction also has been confirmed with this technique.

Sekine and associates (108) have developed a transrectal electronic linear-array scanner that allows one to obtain longitudinal sonograms of the lower urinary tract. With real-time imaging, dynamic studies obtained while the patient is voiding may provide valuable diagnostic information on voiding dysfunction (87,109).

Staging

Transrectal ultrasonography has been useful in the evaluation of patients already diagnosed as having carcinoma of the prostate. The technique is valuable in assessing prostatic size and in detecting unrecognized invasive disease. Early reports show that the stage of prostatic carcinomas, as determined by transrectal ultrasonography, corresponded with the stage diagnosed pathologically on radical prostatectomy specimens (Fig. 3D.43). Pontes and associates (94) demonstrated a sensitivity of 89% and 100% for preoperative ultrasonic detection of capsular and seminal vesicle involvement, respectively. The specificity of detecting capsular penetration and seminal vesicle involvement was only 50% and 28%, respectively, because of the inability of the study to detect microscopic disease. Fujino and Scardino (34) reported the ability of ultrasound to detect invasive disease in 8 of 18 patients who had no extension of the disease by rectal examination. Lee and colleagues (61) introduced the concept of obtaining biopsy specimens from areas with a high probability of invasion, such as the apex and point at which the seminal vesicles enter the central zone. Areas of microscopic invasion that were not evident on digital rectal or routine ultrasound examination have been detected. More recent experience has indicated that ultrasound staging is limited, and its value in clinical decision making remains questionable (4,66,101,112). Others have attempted to characterize specific components of the tumor to assist in ultrasound staging, but the value of this methodology is limited (119).

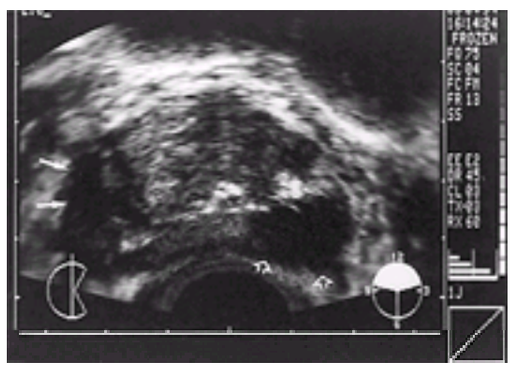

FIGURE 3D.43. Transverse image demonstrating distortion of border of prostate *(arrows)* associated with invasive carcinoma. Note hyperechogenicity of tumor.

Measurement of Prostate Gland Size

Transrectal ultrasonography is useful in documenting prostate gland volume, and it is accurate within 5% in determining true prostatic weight (39). This ability allows ultrasound to provide information regarding the response of the tumor to therapy. These determinations are based largely on total gland volume and not tumor volume. Prostate ultrasonography has documented reduction in prostate size after administration of endocrine therapy when used as treatment for patients with disseminated cancer. Within 3 to 6 months after either orchiectomy or estrogen therapy, a sonographically detectable 20% to 30% decrease in prostate volume occurs (17,96). Changes with estrogen therapy are slightly slower to occur than those with surgical castration.

Further usefulness of ultrasound has been demonstrated in the evaluation of prostate cancer patients treated with radiotherapy and chemotherapy. Studies have indicated that the maximum reduction in the size of the prostate occurs usually by 9 months after radiotherapy and 3 months after chemotherapy (34). As a response to therapy, in addition to decrease in size, the prostate resumed a more symmetric shape, the margin reformed and thickened, the degree of extracapsular extension diminished, and the seminal vesicles became normal in appearance. These techniques also have been used to measure prostatic size to document response to endocrine agents (e.g., 5a-reductase inhibitors) in the treatment of benign prostatic hyperplasia. A similar reduction in prostate size has been recognized.

Ultrasound-guided Biopsy, Interstitial Radiation Therapy, and Cryotherapy

As noted, transrectal prostatic ultrasonography is useful as an aid in the placement of the biopsy needle within a specific suspicious area of the prostate. Transrectal ultrasonically guided biopsies are widely used (Fig. 3D.44), and new aspiration and core biopsy needles with spring-load guns continue to be developed. Problems exist because not all tumors can be visualized ultrasonically, and more studies are required to correlate the area of the ultrasound biopsy with the physical findings. Hodge and colleagues (42) used ultrasound-guided biopsy to ensure accurate placement of the biopsy needle in the peripheral zone of the prostate. Multiple “systematic” biopsies are performed, and with this approach, more than 50% of patients with palpable abnormalities (e.g., firm areas, nodules) have been diagnosed as having carcinoma. It has also been recognized that the larger the prostate, the lower the yield in establishing a diagnosis of carcinoma (64). Ultrasound-guided biopsies have a role in the evaluation of patients with or suspected of having prostate cancer [e.g., abnormal digital rectal examination, elevated or change in prostate-specific antigen (PSA)]. Repeat ultrasound-guided biopsies after a negative digitally directed biopsy are thought to be worthwhile in patients with suspicious palpable abnormalities. In patients with nonpalpable but suspected prostate malignancy (e.g., elevated PSA), ultrasound-directed biopsy of sonographically suspicious areas or when performed in a sextant manner has been shown to assist in establishing the diagnosis of prostate cancer. Experience indicates that the

diagnosis of cancer can be increased by obtaining a greater number of cores (e.g., more than six) and by performing biopsies on more lateral aspects of the prostate to enhance sampling of the peripheral zone. In addition, the technique has a role in the evaluation of patients treated with definitive radiation therapy who have no palpable abnormalities, but suspicion of recurrence based on change in serum PSA.

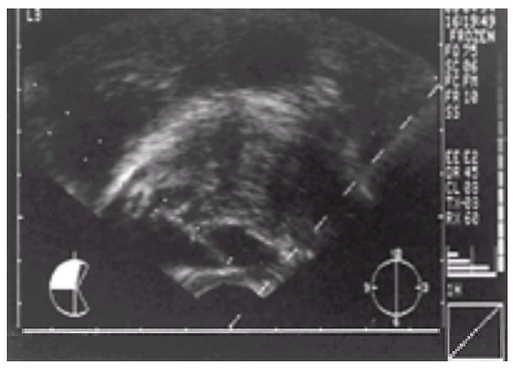

FIGURE 3D.44. Sagittal image with biopsy guide with visualization of hyperechoic needle demonstrating the use of ultrasound guidance to assist in a biopsy.

As noted earlier, ultrasound can also be used to direct radioactive seed implantation into the prostate when using this treatment modality (44). Permanent implantation of radioactive seeds offers some advantages over external beam radiation, and the implantation technique is less time-consuming for the patient and staff than a full course of external beam therapy. In addition, a higher concentration of seeds can be placed in and around the area of malignancy. The disadvantage of this technique is that extracapsular tumors with ill-defined margins may not be irradiated adequately and that regional lymphatic vessels are not treated appropriately. These problems may be overcome by combining interstitial therapy with external beam or endocrine therapy. Studies are in progress to assess these alternatives. Ultrasound has also been used to monitor the “ice ball” during cryoablation for treating prostatic malignancies. The monitoring not only ensures adequate treatment of the malignancy but also helps protect the rectum from injury.

Its important to recognize that ultrasound is unable to visualize a significant number of tumors located within both the peripheral and transition zones. In addition, the presence of these tumors may only be suggested by the finding of an elevated PSA with a prostate that may be free of palpable abnormalities. Ultrasound may be useful in assisting in biopsy, but ultrasound should not be used as a discriminator as to who should or should not be biopsied. This decision should be made on the basis of clinical indications (i.e., abnormal digital rectal examination or elevated serum PSA).

ULTRASONOGRAPHY OF THE URINARY BLADDER

The urinary bladder is an extraperitoneal musculomembranous sac that functions primarily as a urinary storage reservoir. In children younger than 6 years of age, the bladder is predominantly an intraabdominal organ lying beneath the anterior abdominal wall. In adults, it is a pelvic organ lying, when empty, beneath the symphysis pubis. When distended, the bladder assumes a globular shape and is easily studied with the transabdominal approach. Recently, transrectal and transurethral approaches have been used to study and define subtle bladder abnormalities.

Transabdominal Scanning

Transabdominal ultrasound imaging of the bladder is usually performed with the patient in the supine position and the bladder distended. Although it is not necessary to have a Foley catheter in place, its presence is helpful in identifying the bladder neck (Fig. 3D.45). Usually, a 3.5-MHz transducer is used to obtain transverse and longitudinal images.

FIGURE 3D.45. Longitudinal abdominal scan showing urinary bladder and enlarged prostate *(arrows).* Note Foley catheter balloon at the bladder neck.

Transrectal Scanning

Transrectal ultrasonic imaging of the bladder is performed with the same equipment and technique as previously described (Fig. 3D.46).

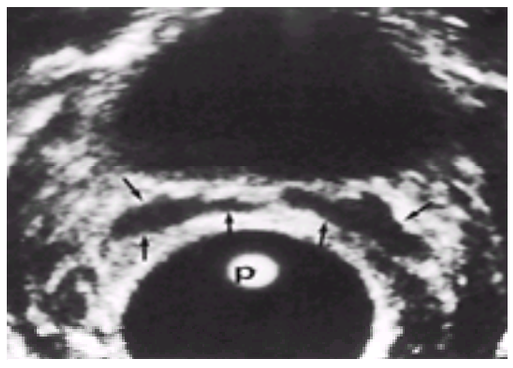

FIGURE 3D.46. Transrectal scan of normal bladder and seminal vesicles *(arrows).* Rectal probe *(p)* is in place.

Transurethral Scanning

Although both transabdominal and transrectal approaches have been helpful in evaluating bladder abnormalities, subtle changes in the bladder wall (e.g., muscular invasion by tumors) are often not discernible. Experience by Gammelgaard and Holm and others suggests that the bladder may be best studied with the transurethral

approach (80).

The scanner for transurethral ultrasonography consists of a motor that rotates a long rod, which is connected at the opposite end to an interchangeable transducer. The scanner fits within a standard resectoscope sheath and is interchangeable with the usual optical system. Two 5.5-MHz transducers are available. One emits the ultrasonic beam at 90 degrees to the instrument, whereas the other emits the beams at 135 degrees to the probe in retrograde fashion and is useful in studying the bladder neck region. With these two transducers, complete visualization of the entire bladder is possible. Probes with multiple and variable angulations are also available. During routing cystoscopy, when further evaluation of a detected bladder lesion is desired, the telescope is removed from the sheath and is replaced with the sterilized scanner. Dynamic scans using the transducers are obtained. The entire bladder wall can be rapidly scanned in a matter of minutes.

Normal Bladder

Ultrasonically, the normal bladder appears as a globular structure, the shape of which varies depending on the patient's position and degree of distention. The bladder wall is hyperechoic and appears as a symmetric, smooth surface. When distended, the fluid-filled bladder is anechoic (Fig. 3D.47).

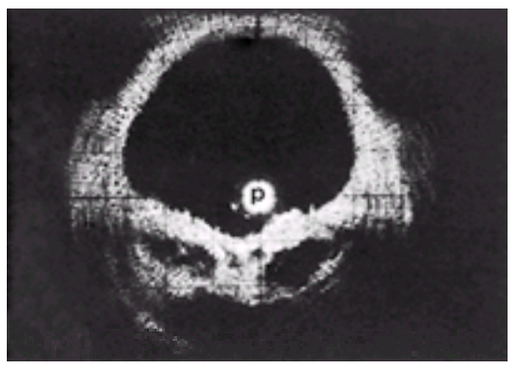

FIGURE 3D.47. Transurethral scan of normal urinary bladder. Note seminal vesicles posterior to the bladder. p, transurethral probe.

Clinical Application

Bladder tumors are a common urologic problem, the treatment of which depends on an accurate assessment of the grade of the primary tumor. With currently available staging modalities, errors may occur in nearly 50% of cases (10). Large, exophytic tumors appear ultrasonically as echogenic masses projecting into the lumen of the echo-free bladder (Fig. 3D.48). These areas are fixed to the wall; unlike blood clots or stones, they do not move as the patient changes position. Ureteroceles, although fixed to the bladder wall, are easily recognized by their thin echogenic wall surrounding a relatively anechoic center. Bladder stones readily move about with changes in intravesical volume and patient position, and like renal stones, they appear as dense hyperechoic areas associated with sonic shadowing.

FIGURE 3D.48. Transurethral bladder scan demonstrating large, exophytic bladder.

Superficial bladder tumors or minimally infiltrative tumors (stage T_1 or T_2) do not cause distortion or fixation of the bladder wall, and they demonstrate a well-defined base (Fig. 3D.49 and fig. 3D.50). Multiple scans obtained during bladder filling demonstrate free movement of the bladder wall.

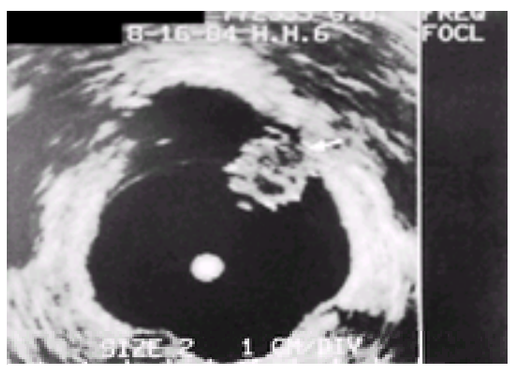

FIGURE 3D.49. Transurethral bladder scan demonstrating superficial bladder tumor. Note lack of bladder wall invasion *(arrow).*

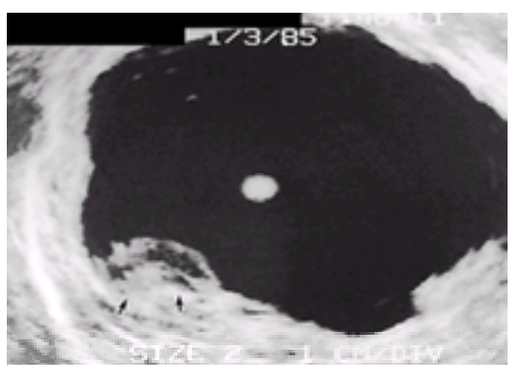

FIGURE 3D.50. Transurethral bladder scan demonstrating minimally invasive tumor *(arrows).*

Infiltrative tumors tend to be broad based, and the bladder wall may be fixed and distorted. Stage T_3 tumors that have completely extended through the bladder wall are visualized as an extravesical mass (Fig. 3D.51).

FIGURE 3D.51. Transurethral bladder scan demonstrating tumor invasion beyond bladder wall *(arrows).*

Probably the most common use of bladder ultrasonography has been in the estimation of residual urine in patients with voiding disorders. The study is helpful in estimating total bladder capacity and postvoid residual urine when urethral instrumentation is not desired or is contraindicated (16,79,103). The most commonly used formula is that of a prostate ellipse:

$$\text{Volume} = 0.5 \times \text{Diameter}_1 \times \text{Diameter}_2 \times \text{Diameter}_3$$

where $diameter_1$ is width, $diameter_2$ is height, and $diameter_3$ is length.

When these measurements are used, the correlation between catheterized and estimated residual volume has been reported to be as high as 98%. A three-dimensional device was recently described for this purpose (70).

Other applications include assessment of patients for vesicoureteral reflux (23,36,124) and increasingly assessment of abnormalities in bladder structure and function. Although limited, perineal and transvaginal ultrasonography has been reported to be of assistance in identifying the presence of vesicovaginal fistula (1,125). The technique of “video urodynamics” has been used with Doppler sonography (84,85), and urethral abnormalities have also been identified in assessing patients with stress urinary incontinence and other urethral disorders (7,31,56,57). It is likely that with continued technologic improvements these studies will be expanded because of their availability and cost-to-benefit ratio.

PENILE ULTRASONOGRAPHY

Ultrasonography of the penis has been used primarily in three clinical areas: assessment of Peyronie's disease, evaluation of urethral strictures, and assessment of impotence. This latter category is discussed in detail in the chapter related to the assessment of men with erectile dysfunction.

Peyronie's disease is an uncommon problem that is related to the excessive deposition of collagen and associated calcium in the tunica albuginea of the corpus cavernosum. Patients usually have pain and deformity of the penis associated with erection, and on physical examination a palpable area of “plaque” is often evident. Ultrasound has been used to visualize the area of fibrosis, and shadowing often can be noted secondary to the areas of calcification. Correlation has also been noted with xeroradiography (3,21). The ultrasound studies may have a role in the diagnosis of the condition but possibly may have a more important one in documenting progression or regression of the areas of abnormality.

Another interesting application of penile ultrasonography relates to the assessment of the distal male urethra. Experience has indicated that this technology is useful in the assessment of patients for urethral strictures, and excellent correlative data have been obtained with standard radiographic urethrography. An advantage of this technique is that the periurethral tissue can be seen clearly, and it is believed that this method of imaging may allow for a more informative decision regarding the most appropriate treatment of urethral stricture (19,20,35,76). Other interesting applications relate to imaging of urethral calculi (113).

Doppler ultrasound studies are widely used in the assessment of men with erectile dysfunction. Both inflow and outflow abnormalities can be readily identified. The penile arteries can be readily identified with current technology and changes in flow identified following intracorporeal injection with vasoactive agent. Recent experience also indicates these studies may be of value in determining the role of oral agents in treating patients with erectile dysfunction (20,25,41,73,78,83,106).

INTRAOPERATIVE ULTRASONOGRAPHY

Intraoperative real-time renal scanning displays a cross section of renal tissue and, using multiple images, allows accurate, three-dimensional stone localization. Most intraoperatively used portable ultrasound units use a frequency of 7 to 10 MHz and are modifications of the small ophthalmic ultrasound probe. The study is of value when performing open stone surgery. After adequately mobilizing the kidney, it is scanned in multiple planes until the stone is identified by its characteristic dense echo pattern and the presence of acoustic shadowing (Fig. 3D.52). Fine-needle probes are then passed to the stone and a nephrotomy made directly over the stone. With this technique, an experienced ultrasonographer can identify stones 2 mm or more in diameter.

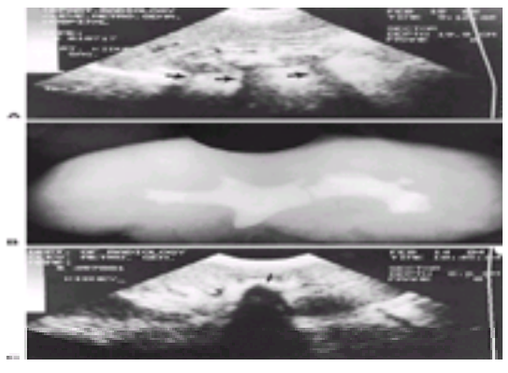

FIGURE 3D.52. A: Preoperative renal scan of large staghorn calculus. Note multiple areas of acoustic shadowing *(arrows).* **B:** Intraoperative radiograph before nephrotomy. **C:** Intraoperative ultrasound localizing small retained stone fragment *(arrow).*

Ultrasound probably has greater application at time of partial nephrectomy when removing small renal malignancies. Assimos and associates (5) reported the role of intraoperative ultrasonography in assisting in partial nephrectomy in patients with small renal tumors. The study is helpful in delineating the location and extent of these lesions. An additional application used intraoperative ultrasound to assess tumor involvement of the renal vein in patients with adrenal malignancy (67). More recently, ultrasonography has been used in association with laparoscopic cryoablation of renal malignancies. Ultrasound can monitor the formation of the “ice ball,”

thus ensuring adequate treatment (126).

Magnetic resonance imaging (MRI) is an important method of imaging the urinary tract. Not only has image quality and speed improved, but there are now many new applications for MRI in urology. With the advent of surface coils, contrast agents, and faster pulse sequences, the scope of information that can be derived from MRI has greatly expanded. This chapter reviews the basic principles underlying MRI, describes advances in magnetic resonance (MR) technology, and summarizes the current role of MRI in the genitourinary tract.

BASIC PRINCIPLES

More than half of the human body is composed of water, and each molecule of water contains two hydrogen protons. Hydrogen protons are ubiquitous and can be found not only in water but also attached to the aliphatic chains of fatty acids. Regardless of their chemical environment, each hydrogen proton, when it is placed in a magnetic field, will align either with or against the direction of the applied magnetic field. A slight preponderance of the protons will align in the same direction as the field because this is a lower-energy state. This small excess of protons aligned with the field as opposed to against the field is responsible for the MR signal.

Not only do the protons align with (or against) the externally applied magnetic field, but they also precess or rotate around the axis of the main magnetic field. This precession occurs at a precise frequency that is dependent on the strength of the externally applied magnetic field and is known as the *resonant,* or *Larmor, frequency.*

If a radio frequency (RF) pulse, tuned precisely to the resonant frequency, is applied to protons, they will absorb this energy and begin to deviate from alignment with the external magnetic field. Commonly, these RF pulses are left on long enough to deviate the protons 90 or 180 degrees with respect to the main magnetic axis, although any angle can be obtained. When the RF pulse is completed, however, the protons will quickly relax to their resting state; that is, they realign with the magnetic field. This relaxation process has two components. First, the axis of each proton returns to alignment with the main magnetic field. This process is termed T_1 *relaxation.* Also, protons dephase with respect to each other; that is, they start aligned, or “in phase,” with each other but end up randomly distributed. An analogy has been drawn with runners who begin a race at the same starting line but later may be spread around the track depending on their speed and endurance. Similarly, protons are initially aligned during exposure to an RF pulse but will separate from each other with time. This process is termed T_2 *relaxation.* T_1 and T_2 relaxation occur simultaneously, and neither process can be isolated from the other. Thus a T_1-weighted scan means that most of the effects are due to T_1 relaxation but T_2 relaxation also influences the image. Similarly, T_2-weighted images are influenced by T_1 differences among tissues.

Each tissue has its own properties with regard to T_1 and T_2. These are summarized in Table 3E.1. Fat, for instance, has the most rapid T_1 (relaxes quickly to equilibrium), whereas urine has a very long T_1 (relaxes slowly to equilibrium). On T_1-weighted images, fat is bright and urine is dark. The T_2 of urine is longer than that of fat, so on T_2-weighted images, urine is brighter than surrounding pelvic fat.

Tissue	T_1*	T_2
Fat	High	Less high
Muscle	Low	Low
Liver	Medium	Medium
Adrenal	Medium	Medium
Cyst	Low	High
Pheochromocytoma	Medium	Very high
Kidney		
Cortex	Medium	High
Medulla	Medium (less than cortex)	High
Cyst	Low	High
Hemorrhagic cyst	High	High
Tumor	Medium	Higher (variable)
Urine	Low	High
Bladder wall	Low	Low
Prostate		
Transition zone (TZ)	Medium	Low
Peripheral zone (PZ)	Medium (higher than TZ)	High
Tumor	Medium	Lower than PZ
Seminal vesicles	Low	High
Cortical bone	Low	Low
Marrow	Very high	High
Metastases	Medium	Low
Blood		
Fast flow	Low	Low
Slow flow	Medium to high	High
Tumor thrombus	Medium	Medium
Lymph nodes	Medium	Medium

*Liver, blood, meniscus, gray matter, testes.

TABLE 3E.1. SIGNAL INTENSITIES in T_1- and T_2-WEIGHTED IMAGES

T_1 and T_2 weighting is achieved by varying the timing of the pulse sequences applied to the resting protons. In a typical T_1-weighted image, a 90-degree RF pulse (a pulse that deviates protons 90 degrees) is followed by a 180-degree RF pulse. This second pulse is used to refocus the dephased protons. This is analogous to interrupting the race described previously and having the runners turn around and run back to the starting line. The slower runners have a head start over the faster runners, so all the runners reach the starting line at approximately the same time. For protons, this signal, or “echo,” can be measured at the time the protons become rephased (i.e., arrive at the “finish line”). The 90- and 180-degree sequence is repeated at short intervals until enough sequences have been acquired to form an image. By keeping the repetition time (TR) or time between repeated sequences to a minimum and also by minimizing the echo time between the 90- and 180-degree RF pulses (TE/2), T_1 weighting is achieved. Conversely, by lengthening the TR and TE, T_2 weighting is achieved. Typical values for a T_1-weighted spin echo scan are TR = 500 ms and TE = 15 ms, and typical values for a T_2-weighted spin echo scan are TR = 2000 ms and TE = 100 ms, although these numbers vary depending on manufacturer and model and the particular imaging requirements.

Other factors besides T_1 and T_2 influence an image. Flowing blood can cause an increased or decreased signal in vessels, depending on the imaging technique. Iron and other metals can induce strong local magnetic field gradients that degrade the image due to “susceptibility effects.” The proton concentration and physical state can also affect the signal: cortical bone and calcifications in the urinary tract have few free protons and thus yield very low signal intensities on all pulse sequences.

Paramagnetic contrast agents can be also used to modify the T_1 relaxation process in tissues. Gadolinium ion is *paramagnetic;* that is, it becomes “magnetic” when placed in a magnetic field. Gadolinium shortens the T_1 value of protons that come nearby, thus leading to enhancement of blood and vascular tissues. Because unchelated gadolinium ion is highly toxic, it must be tightly chelated to a harmless carrier that speeds its removal from the body by glomerular filtration. Gadolinium chelate enhancement on MRI is analogous to iodinated contrast media enhancement on computed tomography (CT); tumors are enhanced but less so than renal parenchyma, and the collecting system and bladder become opacified while cystic ischemic or necrotic areas are not enhanced. Paradoxically, at very high

concentrations of gadolinium, there is a darkening of signal as a result of shortening of T_2.

The magnet that supplies the external magnetic field in which the patient lies can be a permanent magnet, a resistive electromagnet, or a superconducting electromagnet. The advantages of the permanent magnet are that it does not require a large power source and it can have a more open architecture than other types of magnets. This is desirable for claustrophobic patients, pediatric patients, or interventional procedures requiring MR guidance. Resistive electromagnets are relatively energy inefficient, requiring large amounts of electric current. The advantage of the supercooled magnet is that it can generate a much higher magnetic field because the coil windings become superconducting at liquid helium temperatures. Higher field strength means higher signal for a given period of scanning, and this allows for faster imaging or higher-resolution images (or both). Field strength is measured in units of Tesla (T) (1 Tesla = 10,000 gauss). For reference, the earth's magnetic field varies from 0.5 to 2 gauss. Magnetic field strengths for MRI units currently on the market vary from 0.02 to 3 T.

There have been several recent technical improvements in MRI. One innovation is called *fast spin-echo* or *turbo spin-echo imaging.* This technique produces T_2-weighted scans in much less time than conventional T_2-weighted scans. This time reduction results in fewer artifacts resulting from motion. Fast spin-echo acquires groups of phase encodings during each excitation, greatly improving the efficiency of scanning.

Another innovation is the suppression of the fat signal in MRI. Fat is ubiquitous in the abdomen and pelvis. Because the protons in fat are in a different molecular milieu than the protons of water, they have a slightly different resonant frequency. With the application of an RF pulse that selectively suppresses the signal from fat but not water, the image is “fat suppressed.” By removing the fat from an image, the dynamic range of the image (gray scale) is changed, and the scan becomes more sensitive to slight increases in signal intensity due to enhancement. Instead of fat representing the brightest signal, the contrast-enhancing structure becomes the brightest signal and is easier to see. Fat-suppressed scans show greater enhancement for a given dose of gadolinium chelate and thus are more sensitive for detecting disease.

Another type of fat suppression is known as *chemical shift imaging.* Because protons in fat and water resonate at different frequencies, there are times when the protons in fat and water are in phase and times when they are completely opposed to each other. It is possible to time the imaging to “catch” the protons when they are either in phase or out of phase with each other. If one compares fat–water in-phase and fat–water out-of-phase images and detects a loss of signal for the latter, one can infer that the tissue in question contains some lipid. This is particularly useful in detecting adrenal adenomas, angiomyolipomas, and dermoids, as is described later. Because in-phase and out-of-phase images must be obtained with different pulse sequences, it is often helpful to normalize the signal intensity of the adrenal adenoma to another organ, such as the liver, muscle, or the spleen.

One of the main criticisms of MRI has been that it is too slow and thus motion artifacts degrade the image. It is now possible to obtain MR images during a single breath hold by using a type of scan known as *gradient echo imaging.* Instead of applying a second 180-degree RF pulse after the initial 90-degree RF pulse, magnetic gradients are used to refocus the MR signal. It is now routinely possible to obtain MR images at a rate of 50 to 100 ms per image. This is useful for following a contrast bolus within a renal lesion or in assessing contrast enhancement within a bladder lesion. Even faster imaging may become routinely available with echo planar imaging, or “snapshot” MRI.

Another development in MRI technology is magnetic resonance angiography (MRA). MRA can be used to image the abdominal vasculature, including the aorta and renal arteries and veins. An intravenous bolus of gadolinium chelate is administered and a three-dimensional (3D) acquisition is obtained through the abdomen during a single breath hold (10 to 20 seconds). These images can be reconstructed as projection images much like a conventional angiogram.

Surface coils have enabled high-resolution images to be obtained from targeted areas. The advantage of surface coils is that the signal is unattenuated by distance. Meanwhile, because the signal is collected only from the area of interest and not from the rest of the body, which often acts as an antenna for extraneous RF, signal to noise is further improved. This enhances the signal-to-noise ratio, which in turn can be used to obtain higher-resolution or faster images. Surface coils can be thought of as magnifying lenses for MRI. Endorectal surface coils for prostate imaging are one example of surface coils, but other noncavitary types of surface coils are commonly used for pelvic and renal imaging. Phased-array surface coils are combinations of coils that take advantage of the gain in signal-to-noise ratio afforded by multiple surface coils but allow a wider field of view to be scanned.

It is important to be aware of contraindications to MRI. Patients with pacemakers, implanted infusion pumps, cochlear implants, or any other implanted electronic devices should not be scanned with the device in place because it may be ruined or cause aberrant function. Patients with cerebral aneurysm surgical clips should generally not undergo MRI because these clips can become magnetic and torque. Newer aneurysm clips are MR compatible. Most other surgical clips, heart valves (with the exception of early Starr-Edwards valves), and orthopedic pins and screws are made of nonmagnetic stainless steel and are not contraindications for MRI. Patients with shrapnel imbedded in their bodies may experience movement of the fragment or pain during MRI. A metal worker who has chips of metal lodged in the eye may develop intraocular hemorrhage and blindness and should be evaluated with orbital radiographs before MRI if there is any question of an ocular metallic foreign body. In general, consultation with a radiologist is recommended if there is any doubt about the safety of a device. Claustrophobia is a relative contraindication for MRI but usually can be ameliorated by mild, oral anxiolytics. Because young children (younger than 5 years) usually cannot hold still long enough for an MRI, they must be sedated if adequate studies are to be obtained. There are no contraindications to gadolinium chelate administration except for severe renal dysfunction (creatinine clearance less than 20 mL per minute), in which case dialysis is recommended after use of the contrast. Gadolinium chelates have been used as a substitute for iodinated contrast in conventional x-ray angiography in patients with poor renal function, but there are reports of nephrotoxicity using this direct intraarterial method.

Limitations of MRI include the inability to detect calcification, susceptibility to flow and other motion artifact, and lack of a good oral contrast agent with which to differentiate normal bowel from pathology.

The cost of MRI not only has made it less attractive but also has made it a high-profile target for regulators. With increasing competition in the medical marketplace, MRI has become less expensive. This is achieved by efficiencies in throughput and overhead. Manufacturers are also offering smaller, less expensive MRI units. As a result, one of the barriers to the use of MRI, its cost, is becoming less of an issue.

ROLE OF MAGNETIC RESONANCE IMAGING IN THE GENITOURINARY TRACT

Kidney

When it was introduced, MRI was not generally considered helpful in the management of most renal masses compared with CT and ultrasound because of severe motion artifacts and nonspecificity (14). However, U.S. Food and Drug Administration (FDA) approval of contrast agents with gadolinium has made MRI more clinically applicable (16). MRI with gadolinium chelate enhancement is directly analogous to CT with iodinated contrast. However, because CT is less expensive and more available, it is still the preferred technique for evaluating parenchymal abnormalities of the kidney. MRI can be substituted for CT when there is a severe iodinated contrast allergy or renal dysfunction (39,91) (Fig. 3E.1, Fig. 3E.2, and Fig. 3E.3). The original gadolinium chelate introduced in 1988 was gadopentetate dimeglumine (GD-DTPA) (Magnevist, Berlex Laboratories); since 1993, two other compounds, gadoteridol (Gd-D03A) (ProHance, Squibb) and gadodiamide (Gd-DTPA-BMA) (Omniscan, Winthrop), have become available in the United States. All of these contrast agents are thought to have the same enhancement properties and offer a very high safety profile. Allergic reactions requiring treatment occur in less than 1% of the population. Gadolinium chelates do not cross-react with iodinated contrast agents, and they are not thought to have the same nephrotoxic potential as iodinated contrast agents, although allergies to both agents can be seen (32). Any patient with a strong history of multiple allergies should be considered at increased risk of reacting to a gadolinium chelate.

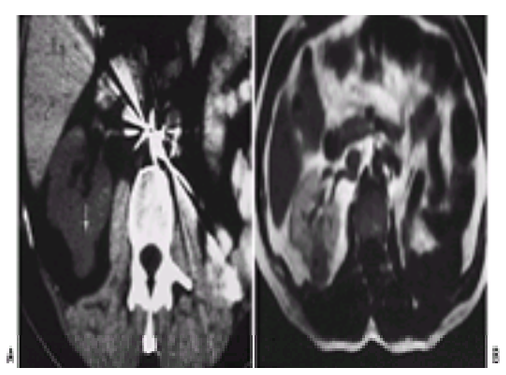

FIGURE 3E.1. A 47-year-old patient with prior nephrectomy for renal cell carcinoma and a severe contrast allergy. **A:** Noncontrast computed tomography (CT) scan 2 years after nephrectomy demonstrated a nonspecific bulge in the posterior kidney *(arrow).* Because intravenous iodinated contrast media could not be given, a magnetic resonance imaging (MRI) scan was performed with gadolinium. **B:** An enhancing mass corresponding to the lesion seen on CT that proved to be a recurrent renal cell carcinoma.

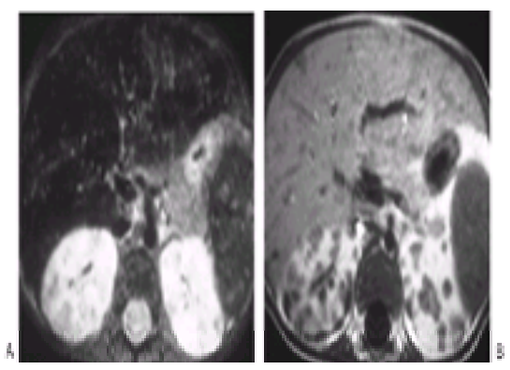

FIGURE 3E.2. Use of gadolinium-enhanced MRI in the presence of renal failure. This patient had been treated for acute myelogenous leukemia and developed fevers. Renal function was significantly diminished (serum creatinine = 2.9 mg/dL). **A:** Noncontrast T_2-weighted scan demonstrates nonspecific heterogeneous signal within the renal parenchyma. **B:** Postgadolinium-enhanced MRI demonstrates multiple distinct filling defects in the kidney and liver. These proved to be fungal *(Candida)* abscesses.

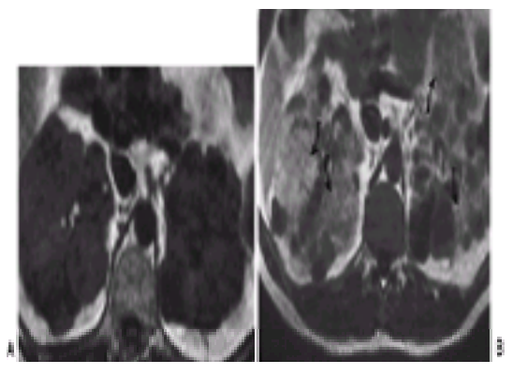

FIGURE 3E.3. Use of gadolinium-enhanced magnetic resonance imaging (MRI) scan for detecting renal masses in renal failure. This 38-year-old patient was thought to have autosomal-dominant polycystic kidney disease. When a family member was discovered to have symptoms of von Hippel Lindau disease, he was reevaluated. Because of his renal failure, gadolinium-enhanced MRI was performed. **A:** Precontrast T_1-weighted image demonstrates enlarged kidneys with a typical appearance of autosomal dominant polycystic kidney disease. **B:** Contrast-enhanced MRI, however, demonstrates multiple areas of enhancement consistent with renal cell carcinomas *(arrows).* This was confirmed surgically by bilateral nephrectomy and subsequent transplant.

Gadolinium chelates have been proposed as alternatives to iodinated contrast or conventional angiograms in patients with renal dysfunction. Because gadolinium is a heavy metal, it attenuates x-rays sufficiently to be a potential substitute for iodinated contrast. However, this approach should be viewed with caution because renal failure may occur after intraarterial gadolinium chelate administration.

Occasionally, contrast-enhanced CT and ultrasound results are indeterminate or contradictory regarding the type of renal lesion present. A common example is the hemorrhagic cyst, which may be hyperdense on CT and thus difficult to evaluate for enhancement, whereas the ultrasound may demonstrate echogenic debris within the lesion (Fig. 3E.4). MR has better sensitivity for enhancement within some masses than does CT and can detect small mural neoplasm (Fig. 3E.5). In such cases, contrast-enhanced MRI may be useful as a “tie breaker” study to help guide proper management. The multiplanar capabilities of MRI may also be useful in certain instances when CT and ultrasound may be limited by patient size (Fig. 3E.6).

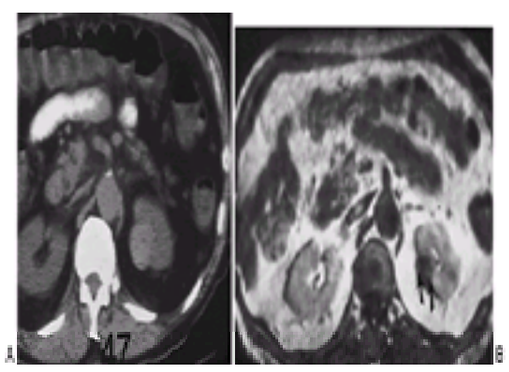

FIGURE 3E.4. Magnetic resonance in the evaluation of indeterminate renal masses. **A:** This hemorrhagic cystic lesion in the left kidney measured 47 HU on computed tomography. Postcontrast scan showed no enhancement. **B:** Postcontrast gadolinium study demonstrates two small nodules of enhancement in the wall *(arrows)* of the lesion, which were foci of low-grade renal carcinoma.

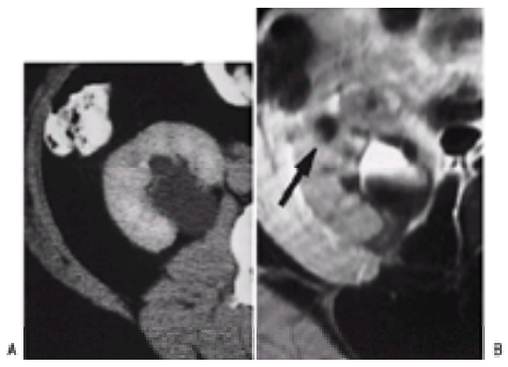

FIGURE 3E.5. The value of magnetic resonance imaging (MRI) in indeterminate renal masses. **A:** Contrast-enhanced computed tomography (CT) scan shows an inhomogeneous renal parenchyma but no definite focal masses. **B:** Postcontrast T_1-weighted image demonstrates a cystic mass in the right kidney with a small mural nodule *(arrow),* as well as several additional smaller lesions in the parenchyma. The patient had a ureteropelvic junction stenosis, accounting for the dilated renal

pelvis. The fluid level in the renal pelvis on the MRI is due to the more concentrated gadolinium layering below the less concentrated (bright), more dilute urine.

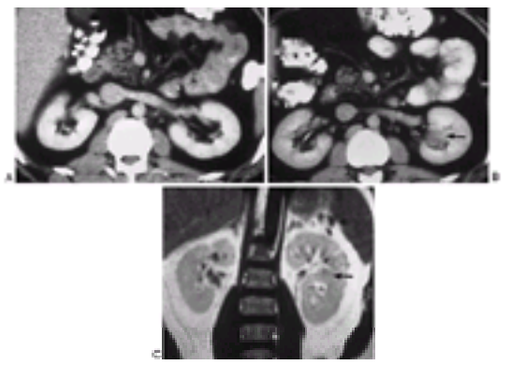

FIGURE 3E.6. Value of the multiplanar capabilities of magnetic resonance imaging (MRI) for renal imaging. **A:** Baseline computed tomography (CT) scan showed normal kidneys. **B:** A follow-up CT scan with intravenous contrast showed what appeared to be a mass in the renal pelvis *(arrow).* This could not be confirmed with ultrasound. **C:** Coronal MRI of the kidneys with gadolinium enhancement demonstrates a septa of Bertin *(arrow),* which most likely accounts for findings on this CT scan. No renal mass is identified with MRI.

When an MRI of the kidney is performed for renal masses, a torso-phased array coil should be used to boost signal. It is important that thin-section (5 to 7 mm) T_1-weighted MRI be performed before and after contrast media. This allows the direct measurement of lesion enhancement. The same parameters must be used before and after contrast to enable comparison of signal intensity. Unlike CT density measurements, MR signal intensity units are arbitrary and thus "rules" have not been generated regarding abnormal enhancement. If possible, fat-suppressed T_1-weighted images should be used because of the augmented sensitivity to contrast enhancement with this technique (72,79,80). However, conventional T_1 weighting should not be discarded because fat-saturated scans can hide vascular neoplasms (Fig. 3E.7). Cysts will not enhance and will remain very low in signal intensity, whereas solid lesions, such as renal cancers, will increase in signal intensity after contrast medium administration. Careful attention to the wall of the cyst may reveal a small mural cancer (Fig. 3E.7 and Fig. 3E.8). T_2-weighted MRI should also be performed to detect cysts, which will be very high in signal intensity, but tumors will also tend to be high in signal intensity except for rare cases of tumor or hemorrhage (Fig. 3E.9). MRI cannot differentiate benign oncocytomas and malignant renal cell carcinomas (23). Some authors advocate that serial scanning be performed during breath holding and contrast enhancement to demonstrate the enhancement pattern (22,49), but this is generally not necessary.

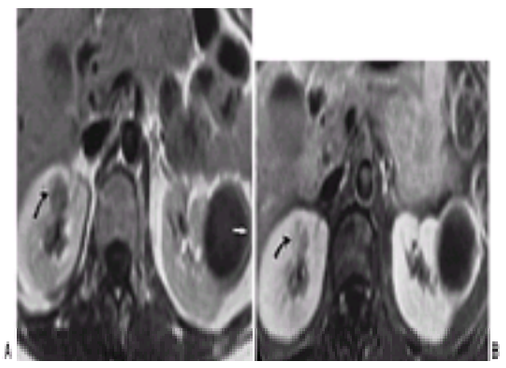

FIGURE 3E.7. The advantage of fat-suppressed T_1-weighted images for detecting enhancement in renal masses. **A:** Conventional contrast-enhanced T_1-weighted image demonstrates a thickened wall of a cystic left kidney *(white arrow),* but definite enhancement is not seen. A right-sided mass *(curved arrow)* is readily seen in the right kidney. **B:** Fat-suppressed T_1-weighted image after intravenous contrast demonstrates markedly enhanced wall of the cystic mass, which proved to be a renal cell carcinoma. The contralateral solid mass *(curved arrow)* is harder to identify on the fat-suppressed image.

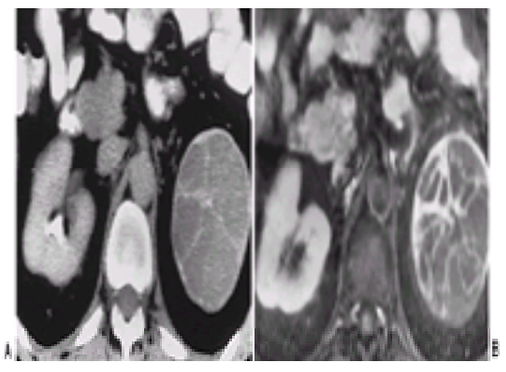

FIGURE 3E.8. The value of fat-suppressed T_1-weighted enhanced magnetic resonance imaging (MRI) for detecting mural enhancement. **A:** Contrast-enhanced computed tomography (CT) scan demonstrates a large cystic mass in the left kidney. It is not evident how much enhancement there is in the wall of the mass. **B:** Fat-suppressed T_1-weighted image after gadolinium enhancement demonstrates markedly enhanced irregular walls of the cystic mass, suggesting a malignancy. This lesion proved to be a cystic renal cell carcinoma.

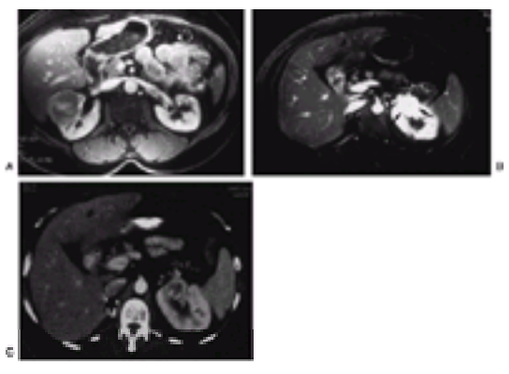

FIGURE 3E.9. Gadolinium-enhanced magnetic resonance imaging (MRI) contrasting a hypovascular and a hypervascular tumor. **A:** Hypovascular solid renal mass is easily seen on this fat-suppressed gadolinium-enhanced MRI. **B:** Hypervascular mass *(arrows)* in another patient is more difficult to see on this dynamic enhanced fat-suppressed MRI. **C:** The computed tomography (CT) scan of the lesion in **B** readily depicts the lesion. Lesions tend to enhance more on MRI than on CT.

Another application of renal MRI is in staging renal cancers for venous invasion. Enhanced CT can be equivocal with respect to caval thrombus due to streaming of contrast media in the inferior vena cava (IVC) during a bolus of iodinated contrast media. MRI can be used to detect thrombi within the renal veins and IVC when the CT is equivocal (56). MRI has proven to have a 90% to 100% positive predictive value for tumor thrombus in the IVC (Fig. 3E.10, Fig. 3E.11, and Fig. 3E.12) (1,27,29,37,61,78). MRI often cannot differentiate stage I from stage II renal cancers, although this is not a clinical problem. Extrinsic compression of the IVC due to bulky adenopathy may make assessment of thrombus difficult (36). Depending on the imaging technique, either the normal-flowing blood can have a low signal intensity with the tumor thrombus intermediate in signal or the normal-flowing blood can be high in signal intensity with tumor thrombus appearing as a low-signal defect (Fig. 3E.10). Scans should be obtained in all three planes to ensure that the IVC is fully evaluated; flow artifacts can cause false-positive results if only one plane is used. MRI can be used for nonneoplastic causes of renal vein thrombosis, such as with glomerulonephritis or lupus nephritis. MRI is also useful in identifying potential adjacent organ invasion, including the liver, pancreas, and spleen. The bones should always be evaluated on the sagittal image because MRI may be more sensitive than bone scan for detecting early bone metastases in the spine (40).

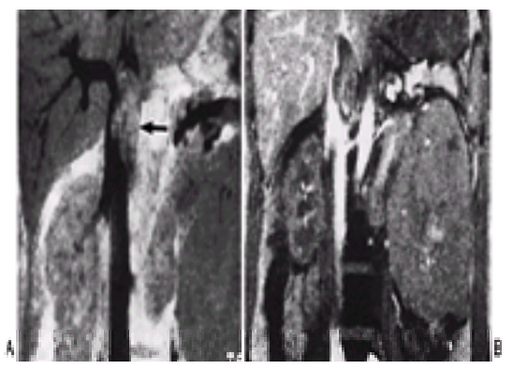

FIGURE 3E.10. Two techniques for identifying tumor thrombus within the inferior vena cava. **A:** There is a large left-sided renal mass. A tumor thrombus *(arrow)* is identified within the inferior vena cava. Because of the spin-echo technique used, the flowing blood appears dark and the tumor thrombus is relatively higher in signal intensity. **B:** When a gradient-echo technique is used, the flowing blood becomes bright in signal intensity, whereas the tumor thrombus is dark. Either technique can be used for detecting a thrombus within the inferior vena cava.

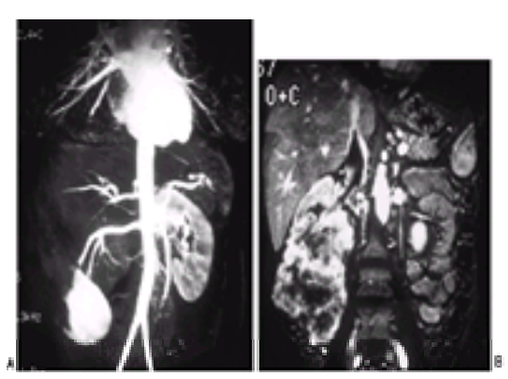

FIGURE 3E.11. New methods of staging renal cancers with magnetic resonance imaging (MRI). **A:** Magnetic resonance angiogram (MRA) of a patient with a large right renal cancer demonstrates the elongation of the right renal artery and extrarenal branching of this vessel. **B:** Delayed MRA from another case demonstrates filling defect in the inferior vena cava arising from the right renal cancer. The absence of enhancement within the thrombus distally (bland thrombus) contrasts with the more proximal portion of the thrombus that shows enhancement.

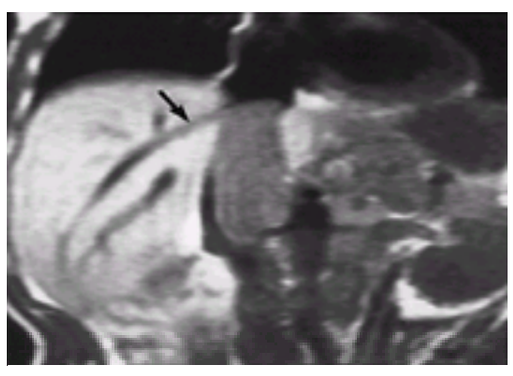

FIGURE 3E.12. Inferior vena caval thrombus caused by large left-sided renal cell carcinoma. T_1 coronal magnetic resonance imaging demonstrates a large thrombus within the inferior vena cava with extension of the thrombus into the right hepatic vein *(arrow).*

MRI is useful in detecting fat within angiomyolipomas (AMLs). CT demonstrates fat within an AML, which is diagnostic, but occasionally the fat may be obscured by previous hemorrhage or may not be visible. T_1-weighted images obtained before and after fat suppression will confirm that the mass is an angiomyolipoma if it contains fat, but neither CT nor MRI can differentiate a nonfatty AML from a renal cancer.

Renal lymphoma is often a multifocal process and can result in renal insufficiency (39). Noncontrast CT and ultrasound can be insufficient to identify renal lymphoma; however, MRI with gadolinium chelate enhancement will readily demonstrate the multiple masses within the renal parenchyma typical of renal lymphoma (Fig. 3E.2). In fact, this technique is readily applied to any patient with a parenchymal defect caused by renal infection, hemorrhage, or infarct (44) (Fig. 3E.13).

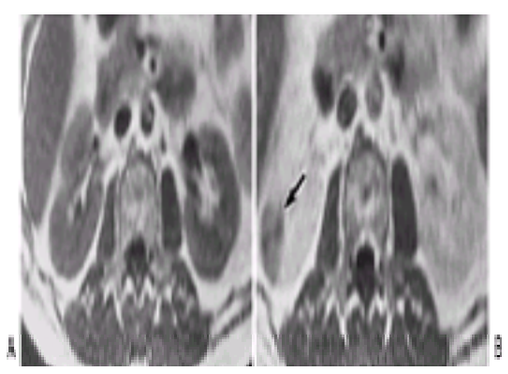

FIGURE 3E.13. Role of magnetic resonance imaging (MRI) in detecting renal infection in an immunocompromised patient. This patient was immunocompromised as a result of aplastic anemia. Previous exposure to nephrotoxic antibiotics had impaired his renal function. **A:** Precontrast T_1-weighted image shows no detectable

abnormality. **B:** Postcontrast T_1-weighted image demonstrates a focal defect in the periphery of the right kidney *(arrow).* Subsequent percutaneous biopsy demonstrated cryptococcus.

The evaluation of renal arteries by MRA is an important application of MRI. Sensitivity for renal artery stenosis varies from 90% to 100% overall to 90% for proximal renal artery and 82% for branch renal artery stenosis. Several studies have shown MRA to be a highly accurate method of detecting main renal artery stenosis (6,25,28,59). Although this technique is sensitive, it may overestimate the degree of stenosis because of flow-related artifacts (Fig. 3E.14). Because renal MRA is noninvasive, it is the preferred method of diagnosing renal artery stenosis and is more reliable than Doppler ultrasound. It is now possible to measure renal arterial velocity directly from an MR angiogram using phase-contrast MRA (6,52,76).

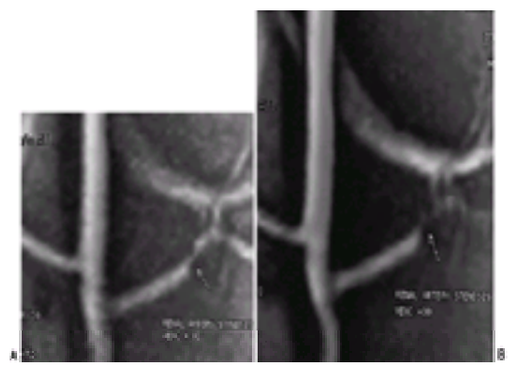

FIGURE 3E.14. Renal artery stenosis *(arrows)* detected with magnetic resonance angiography (MRA). **A:** This stenosis is demonstrated by MRA using appropriate parameters (VENC-80). **B:** Using other parameters (VENC-30), the stenosis appears more severe than it actually is.

One particularly useful application of MRA is in the renal transplant recipient, in whom renal arterial anastomotic stenosis is common (54,63). MRA is particularly well suited for these patients because surface coils can be used, which increase the available signal, thus permitting high-resolution images. Moreover, the use of iodinated contrast media is often contraindicated in patients with poorly functioning renal transplants. MRI can provide information about the integrity of the renal transplant parenchyma, obstruction of the ureter, and perinephric collections (31,33). Gadolinium chelate–enhanced imaging is useful in this setting to document renal infarctions and focal lesions such as tumors and infections. MRA can also be used to evaluate potential living related donors for vascular or parenchymal abnormalities before transplantation (3,64).

Adrenal

CT is the best method of evaluating the adrenals based on its sensitivity and availability (49). Often, however, CT findings are nonspecific, and MRI can then be used to characterize the features of an adrenal mass to determine if it is malignant (26). MRI of the adrenal gland may be particularly useful in confirming the presence of pheochromocytomas and in differentiating adrenal adenomas from metastatic disease.

Pheochromocytomas are often cystic and contain large amounts of free water. This is easily recognized as a high-signal-intensity mass on T_2-weighted images (55,95) (Fig. 3E.15). Naturally, not all pheochromocytomas are very high in signal intensity; hemorrhage within the tumor can cause lower signal intensity on T_2-weighted images (51). Nevertheless, the high-signal appearance of most pheochromocytomas and paragangliomas makes MRI useful for quickly identifying adrenal and ectopic sites of pheochromocytoma. Metaiodobenzyl guanidine (MIBG) studies are often more difficult to obtain and interpret. Other sites of paragangliomas, such as the organ of Zuckerkandl, the retroperitoneum, the bladder, the carotid bulb, and the jugular foramen, are also well suited to the multiplanar capabilities of MRI. Thus most pheochromocytomas, regardless of location, can be identified by MRI. Many other pathologic processes can have high signal intensity on T_2-weighted MRI, including metastases and cysts; however, these can usually be distinguished by the clinical setting (Fig. 3E.16). If bilateral or ectopic pheochromocytomas are discovered, a hereditary cause such as multiple endocrine neoplasia (MEN) II, MEN III (MEN IIb), von Hippel Lindau, or neurofibromatosis must be considered (66) (Fig. 3E.17). Neumann and co-workers (66) have shown that hereditary forms of pheochromocytoma occur more frequently than previously thought among patients with apparently sporadic pheochromocytomas. MRI can be helpful when retroperitoneal surgical clips obscure evaluation on CT (Fig. 3E.18).

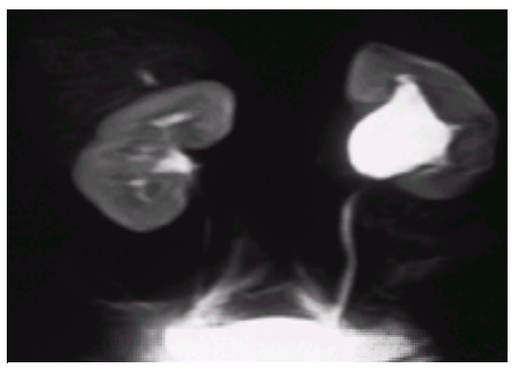

FIGURE 3E.15. A magnetic resonance urogram demonstrating a left ureteropelvic junction narrowing and hydronephrosis. This image was acquired using a fast T_2-weighted breath-hold scan.

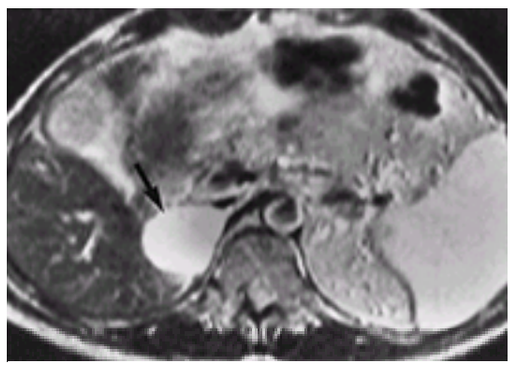

FIGURE 3E.16. High-signal-intensity adrenal mass not representing a pheochromocytoma. This T_2-weighted image demonstrates a very-high-signal-intensity lesion in the right adrenal gland. There is no clinical or chemical evidence of a pheochromocytoma. This patient had melanoma with metastases to the right adrenal gland.

FIGURE 3E.17. Bilateral pheochromocytomas in a patient with MEN IIb syndrome. This young woman experienced hypertensive crisis during childbirth. Subsequent workup revealed bilateral pheochromocytomas *(arrows)* on T_2-weighted magnetic resonance imaging. Bilateral pheochromocytomas are usually associated with hereditary forms of pheochromocytoma.

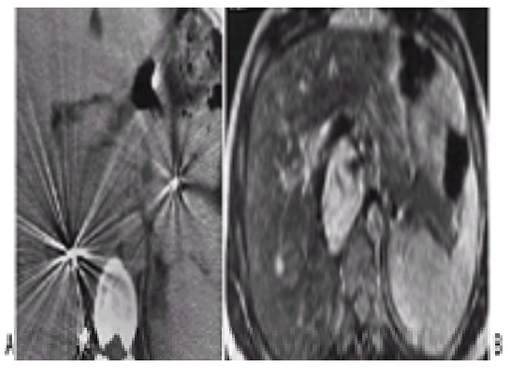

FIGURE 3E.18. The advantage of magnetic resonance imaging (MRI) in detecting retroperitoneal lesions when multiple surgical clips are present. This patient had resection of adrenal carcinoma several years before. **A:** Multiple clips obscure the retroperitoneum on this precontrast computed tomography (CT) scan. **B:** T_2-weighted image demonstrates a recurrence adjacent to the inferior vena cava. The MRI is less influenced by surgical clip artifact than is the CT.

Adrenal adenomas and adrenal metastases are common findings on CT, yet it is difficult to separate one from the other on the basis of CT alone. One important parameter is lesion size. Lesions smaller than 2 cm are more likely to be benign, but size alone is not sufficient to predict behavior (57). The adrenal adenoma contains intracellular lipid because it is composed of cortical tissue, which produces and stores steroid-based hormones. Thus low-density (less than 10 Hounsfield units [HU]) measurements on CT within a small (less than 2 cm) mass are virtually diagnostic of an adenoma (49,50,94). Very-low-density measurements (less than -10 HU) suggest a myelolipoma. However, many adenomas are greater than 15 HU in density. Metastatic lesions to the adrenals usually do not contain lipid but are generally high in extracellular water due to the leakiness of neoplastic vessels. The differences in histology and physiology can be exploited with several different strategies, each of which focuses on signal intensity differences between the tightly packed lipid-containing cells of adenomas and the loosely packed cells with a relatively large amount of extracellular water of metastases. The original attempts to differentiate these two entities with MRI included the ratio of signal intensity of the mass to that of the liver or fat on T_2-weighted images (12,70). Adenomas tend to have a low adrenal mass-to-liver signal ratio, whereas metastases tend to have a higher ratio. However, considerable overlap exists using these techniques (9,94). Another technique is to use dynamic enhanced MRI during rapid contrast media infusion (48). Metastases enhance at a much faster rate and attain higher-signal-intensity changes than adenomas. Although this technique appeared to be successful in one study, dynamic enhancement has not been widely applied (48,85).

Mitchell and associates (60) showed that reliable differentiation of adrenal adenomas and metastases could be achieved using chemical shift MRI. In this technique, fat- and water-bound protons are imaged with in-phase and out-of-phase scans. If the signal intensity of the adrenal mass decreases on the out-of-phase image relative to the in-phase image, the lesion contains lipid and therefore represents an adenoma (Fig. 3E.19). Lesions that show either no change or an increase in signal within the mass on the out-of-phase image do not contain lipid and therefore are more likely to be malignant. Initially, this technique was reportedly almost 100% accurate (60,93); however, subsequent data have shown some overlap between adenomas and metastases (15,47,70,85). Nevertheless, the chemical shift technique appears to be the most successful strategy for separating adenomas and metastases by MRI (82). Lesions deemed to be adenomas by MRI deserve follow-up until this technique is more established. Advocates of MRI argue that MRI is at least as effective as percutaneous adrenal biopsy and does not carry with it the 2% to 10% complication rate of adrenal biopsy (11,81,82,92). Of course, additional functional assessment for a chemically active adenoma is useful in identifying benign but functional lesions that should be removed (18).

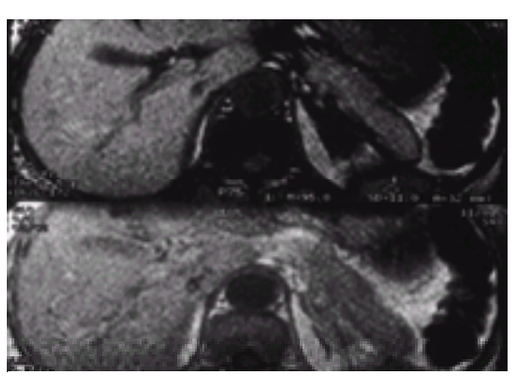

FIGURE 3E.19. Chemical shift magnetic resonance imaging to determine that an adrenal mass is benign. *Top image* is an out-of-phase T_1-weighted scan that demonstrates a low-signal left adrenal mass. *Bottom image* shows an increase in signal in the same lesion when scanned with an in-phase T_1-weighted scan. The decrease in signal within the left adrenal mass is highly suggestive of a benign process such as an adrenal adenoma or hyperplasia.

Ureter and Bladder

MRI of the ureter is now possible, although it does not yet have the resolution of plain film radiography. In MR urography, strongly T_2-weighted scans are obtained through the ureters in the coronal plane (4). Alternatively, T_1-weighted scans are obtained after low-dose administration of gadolinium chelates with a small dose of furosemide (Lasix) to enlarge the ureter (67). Stenoses, obstructions, and filling defects caused by stones or tumors can be seen with these techniques. They are especially useful in pediatric and pregnant patients, in whom exposure to ionizing radiation is undesirable (7). MR urography provides a noninvasive method of surveying the ureters for causes of hematuria.

A routine role for MRI in bladder disease has not been established. MRI is clearly not as good as cystoscopy for diagnosing bladder tumors or evaluating hematuria. MRI has been used to document tumors within diverticula, to characterize suspected intravesical pheochromocytomas, and to aid in the identification of urachal tumors.

MRI has been suggested as a method for staging bladder cancer invasion of the bladder wall (10). Assessment of tumor invasion is currently limited by sampling error and accuracy, especially in the assessment of extravesical extension. It has only recently become pragmatic even to consider bladder cancer staging by MRI because the spherical nature of the bladder means that there are an infinite number of planes perpendicular to the bladder wall. To obtain truly perpendicular sections at all points in the bladder requires 3D imaging, which has now become feasible (5). One of the major improvements in bladder MRI was the use of pelvic phased-array coils, which boost the available signal significantly. With a 3D data set, the bladder wall can be “sectioned” in any plane perpendicular to the bladder wall at the tumor site (Fig. 3E.20). Thus the depth of muscle invasion becomes possible to measure. Fat-suppression techniques have also proven useful in identifying invasion of the perivesical fat.

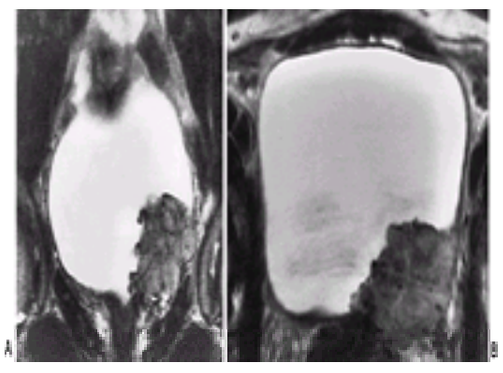

FIGURE 3E.20. Transmural invasion of bladder tumor using phased-array surface coils. **A:** A coronal T_1-weighted magnetic resonance imaging (MRI) demonstrates a papillary mass within the base of the bladder with extension outside the bladder wall. **B:** Axial T_1-weighted MRI demonstrates the extent of the mass through the wall in another plane.

Several different methods of assessing the bladder wall for tumor invasion have been suggested. Highly T_2-weighted images of the bladder wall demonstrate a trilayer appearance to the bladder wall corresponding to the mucosa, submucosa-lamina propria, and muscularis layers. The degree of disruption of these bands can be used to indicate the depth of tumor invasion and is accurate in 73% of patients (5). The other method of assessing bladder wall invasion is with dynamic enhanced MRI, which is performed after a bolus injection of a gadolinium chelate contrast agent. Normally, after contrast administration, an enhancing trilayer appearance is seen corresponding to the three layers seen with T_2 weighting. The layers are disrupted to varying degrees by the invading tumor (5,62,83,86,89). This technique has achieved greater than 90% accuracy in some centers (5) (Fig. 3E.21).

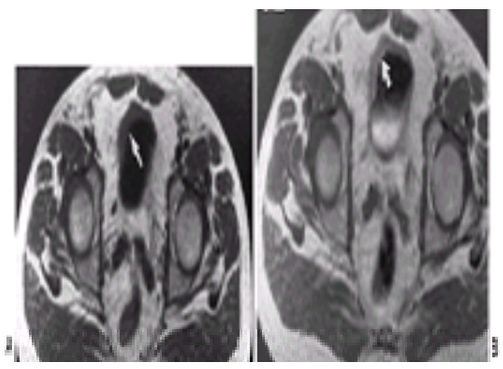

FIGURE 3E.21. The use of gadolinium enhancement to detect bladder wall tumors. **A:** Precontrast T_1-weighted magnetic resonance imaging scan demonstrates a thick rind of bladder tumor against the anterior lateral wall *(arrow).* **B:** Postcontrast enhancement demonstrates enhancement of the tumor with small projections into the perivesical fat. The mucosal surface of the tumor is enhanced to a greater extent than the transmural component of the tumor.

The major limitation of MRI for local staging is that microscopic disease cannot be detected. The clinical importance of this is uncertain, but it lessens the accuracy of MRI staging. Also, tumors at the bladder outlet can be difficult to evaluate because the anatomy of the layers of the bladder wall is somewhat different at this site. Nevertheless, overall, extravesical extension is detected with a sensitivity of approximately 93% (65,86). Endorectal surface coils and phased-array surface coils placed on the low pelvis have been used to improve the signal-to-noise ratio and hence the resolution of the images. Conventional body coil MRI is used to detect lymphadenopathy; however, MRI is no more accurate than CT for assessing adenopathy because both modalities depend on changes in size as the criterion for positivity. As is well known from CT, nodes may be enlarged by hyperplastic changes, and small nodes may be infiltrated with tumor.

A recent development in MRI has been the dynamic assessment of pelvic floor relaxation. In this study, a rapid T_2-weighted image is obtained sagittally through the bladder base, uterus, and rectum at rest and then again during a straining maneuver (97). Cystoceles, uterine prolapse, rectal prolapse, and enteroceles are surprisingly well seen without having to resort to cystoproctolography, which is an uncomfortable and embarrassing procedure (53,96). The MR procedure is equally applied in men and in women, although it is usually a greater clinical issue in women because it is associated with incontinence (17,30,58).

Prostate

MRI of the prostate offers the possibility of accurate local staging of prostate cancers. With sufficient resolution, it is possible to visualize the neurovascular bundle and prostatic capsule with reliability. Results with whole body coil imaging, however, were disappointing, and it became clear that endorectal coils were needed for accurate staging (43,71). With the advent of endorectal surface coils, prostate MRI became a feasible method of staging local spread of prostate cancer. The endorectal coil allows a significant gain in signal-to-noise ratio, which permits high-resolution images. Thus fine detail of the prostatic surface and internal anatomy can be obtained (Fig. 3E.22, Fig. 3E.23, and Fig. 3E.24). Initial reports demonstrated a very high sensitivity for extracapsular disease versus localized disease (75); however, a subsequent multiinstitutional trial has had difficulty reproducing these results (69,90). As more experience has been gained it has become clear that MRI is useful in specific instances in which the risk of extracapsular disease is high based on prostate-specific antigen (PSA) and tumor grade (46).

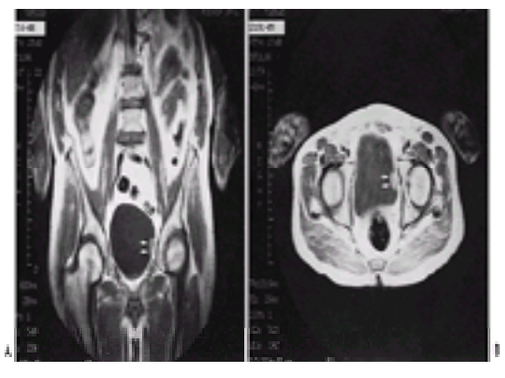

FIGURE 3E.22. Superficial bladder cancer on T_1-weighted magnetic resonance imaging. The small tumor *(double arrows)* is seen in the coronal **(A)** and axial **(B)** planes. Note that the bladder wall is undisturbed and there is no evidence of transmural invasion. No adenopathy is present. The natural contrast between the tumor

and the urine in the bladder allows the tumor to be delineated.

FIGURE 3E.23. Coronal T_1-weighted magnetic resonance imaging scan of large muscle invasive bladder cancer *(short arrows)* and tumorous pelvic lymph node *(long arrows).*

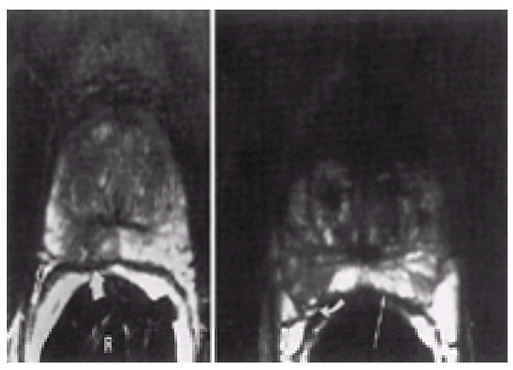

FIGURE 3E.24. Endorectal coil magnetic resonance imaging scan showing stage B prostate cancer. A transverse section demonstrates the thick Denonvilliers' fascia *(white arrows).* The tumor, which is low in signal intensity, can be seen in the background of the high-signal-intensity peripheral zone. The neurovascular bundle *(black arrow)* is spared. R, rectum. (Courtesy of Dr. Ronald M. Summers, NIH.)

To be successful, prostate MRI must be performed with an endorectal surface coil, which is inflated in the rectum with 60 to 100 mL of air and with a phased-array pelvic coil placed anteriorly on the pelvis (42). Glucagon (1 mg intramuscularly) is administered to reduce bowel motion. T_2-weighted images must be obtained with the highest resolution (3 to 4 mm thick with the smallest possible field of view). Field of view must be limited, and a large matrix size must be used. Axial and oblique coronal views through the prostate long axis should be obtained. Contrast enhancement, especially when applied dynamically, is useful in some instances (84,88).

T_2-weighted axial endorectal coil images and oblique coronal T_2-weighted images allow the apex to be evaluated more fully. Scanning should be extended through the seminal vesicles on both planes. T_1-weighted body coil images should be obtained through the pelvis to detect lymphadenopathy. As with bladder cancer, the criterion for lymph node involvement on MRI is increased size, which has well-known limitations.

The normal T_2-weighted image of the prostate demonstrates a high-signal peripheral zone with a central hypointense region corresponding to the central gland (central and transitional zones). The urethra is often high in signal intensity because of the presence of small amounts of urine and glandular tissue in the prostatic urethra. The central gland is surrounded by a hyperintense peripheral zone, which is the site of most prostate cancers. The posterior median raphe in the peripheral zone is often hypointense. Surrounding the peripheral zone on all but the posterior wall is the high-signal periprostatic venous plexus (Santorini's plexus), which serves as a marker for the margin of the prostate. The neurovascular bundles are seen at approximately the 5 and 7 o'clock positions on the axial views. Denonvilliers' fascia is seen as a thick low-signal band between the prostate and rectum (Fig. 3E.24). The seminal vesicles appear as multiple locules of high signal intensity above the prostate. The vas deferens are thick-walled structures medial to thin-walled seminal vesicles.

Prostate cancers appear as areas of relative hypointensity compared with the peripheral zone (68) (Fig. 3E.25). Of course, this appearance is not universal. Several hyperintense prostate cancers (mucinous adenocarcinoma) have been reported; moreover, hypointense lesions can represent biopsy artifact, hyperplasia, infarction, and other nonneoplastic disorders. To avoid a potentially misleading biopsy artifact, MRI should not be performed within 3 weeks of a biopsy.

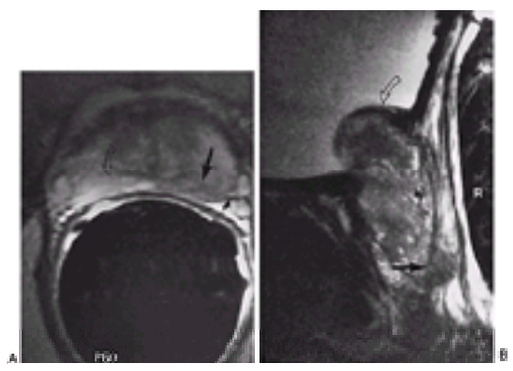

FIGURE 3E.25. Endorectal coil magnetic resonance imaging scan showing T_3 prostate cancer. **A:** The transverse image demonstrates the hypointense tumor *(black arrow)* involving the left prostatic hemisphere. The tumor abuts and involves the neurovascular bundle. *Curved arrow* demonstrates normal peripheral zone. **B:** Sagittal view demonstrates the bulging of the capsule *(straight arrow)* from the tumor. Prostatic hyperplastic nodules are seen within the bladder base *(curved arrow).*

The seminal vesicles, normally high in signal intensity, become focally hypointense when involved with tumor on T_2-weighted images. However, this can be mimicked by epithelial hyperplasia of the glandular lining of the seminal vesicle or by atrophy. Thus hypointense seminal vesicles are suspicious but not absolutely diagnostic of extracapsular extension. Contrast-enhanced MRI may show areas of tumor, which should enhance while benign entities remain low in signal intensity (84).

The reported accuracy of endorectal coil imaging varies from 51% to 82% depending on patient mix and experience (69,90). Overall, the staging accuracy is approximately 68% to 70% in most studies (13,69). Most staging errors with MRI occur from understaging, which will not deny patients potentially curative surgery. False-positive studies are unusual but are more problematic because they would deny potentially curative surgery. Another issue is that intraobserver disagreement occurs with some frequency using endorectal coil MRI, and proper training is essential before these studies begin to yield clinically useful data (35,73). However, with improvements in MRI technique it is expected that image interpretation will become more uniform and reliable. For instance, accuracy can be greatly improved by using a computer-based algorithm that considers both MR and clinical features of the patient. MR has also been proposed as a method of guiding placement of

brachytherapy seeds (19). MR spectroscopy (MRS) has recently been proposed as a diagnostic technique. There is a growing recognition that extracapsular disease per se is not necessarily a contraindication to radical prostatectomy (46,74). Better methods of determining inherent biologic aggressiveness of tumors are being sought. One method, MRS, is based on the metabolic signature of cancers relative to the rest of the prostate. Using ^{1}H spectroscopy, the normal prostate is unusually rich in citrate and choline. Cancers are lower in citrate, resulting in abnormal choline-to-citrate ratios. Data indicate that the magnitude of substrate ratios such as choline to citrate reflects the biologic aggressiveness independent of other factors such as PSA and Gleason score.

Testicle

MRI does not currently have a routine role in the evaluation of testicular disease. This is because of the combined success of physical examination and testicular sonography for diagnosing the most testicular diseases. There is experimental evidence that MRI may be useful in the evaluation of testicular torsion and neoplasia. However, it is unlikely that MRI will be a mainstream test for these indications.

The testicles are normally very bright on T_2-weighted images. Testicular MRI must be performed with surface coils to achieve high-resolution images. Tumors are even more hyperintense but often are heterogeneous in signal intensity. Cysts and dilated rete testis will be uniformly hyperintense on T_2-weighted images. Therefore MR is useful when the differential consideration of a testicular ultrasound is dilated rete testis versus a neoplasm. Testicular tumors enhance significantly with intravenous contrast media, but the appearance on MRI is nonspecific regarding histology (21). MRI may be valuable in local staging of the scrotum because small disruptions of the tunica albuginea may be missed on ultrasound and physical examination. However, MRI does not contribute sufficient information to be justified routinely.

Dynamic enhanced testicular MRI has been used to evaluate testicular ischemia in animals. Enhancement is very delayed or absent on the torqued side, and time activity curves analogous to the radionuclide scan can be obtained (20). Delayed washout of the contrast medium may be related to venous compression. Better anatomic detail is possible with MRI than with sonography, and the torqued spermatic cord can be directly visualized. Advantages of MRI are that it does not require radiation, it can provide a semiquantitative assessment of perfusion, and it may provide more information about the viability of the testicle than either nuclear medicine or color-flow Doppler studies. Disadvantages include its cost, limited availability on an emergency basis, and requirement for intravenous contrast.

Penis

The anatomy of the penis is readily depicted on MRI (38). On T_1-weighted images, the corpora are relatively low in signal. The corpora are high in signal intensity on T_2-weighted imaging. The urethra is not seen unless a Foley catheter is in place (Fig. 3E.26). Absence of a high signal within the corpora can be seen in thrombosis associated with priapism (45,77) (Fig. 3E.27). The plaques of Peyronie's disease can also be detected with MRI and can be used to guide and monitor treatment (34,87). Fractures of the penis, in the setting of pelvic crush injuries, can be evaluated for surgical repair using MRI (2,8,24).

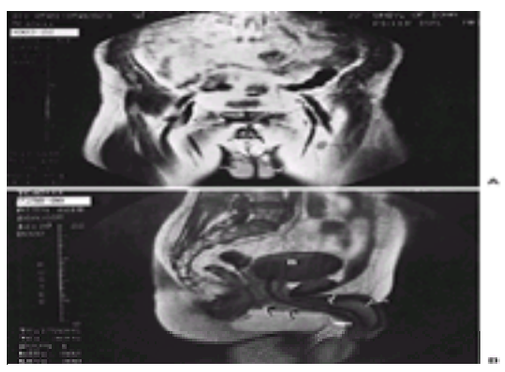

FIGURE 3E.26. A: Coronal T_1-weighted magnetic resonance imaging (MRI) scan of normal pelvis showing corpus spongiosum *(curved arrow),* corpora cavernosa *(straight arrows),* and testicles *(open arrows).* **B:** Sagittal T_1-weighted MRI of normal pelvis showing corpus cavernosum *(straight arrow)* and bulbocavernosus muscle *(curved arrows).* There is a catheter in the bladder **(B).**

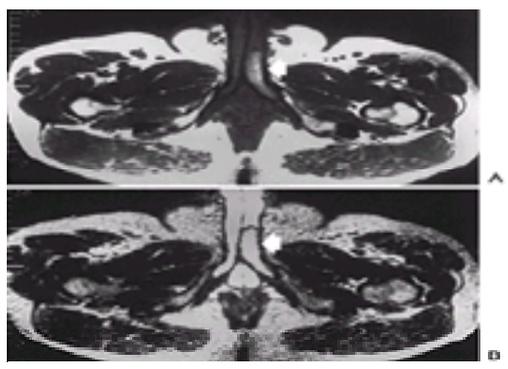

FIGURE 3E.27. Partial penile thrombus with priapism. **A:** T_1-weighted image demonstrates a high-signal-intensity thrombus *(arrow)* within the left corpora cavernosa. **B:** T_2-weighted image demonstrates a high-signal-intensity rim. (Reprinted with permission from Kimball DA, Yuh WTC, Farmer RM. MR diagnosis of penile thrombus. *J Comput Tomogr* 1988;12:604.)

Investigators have evaluated the potential of dynamic enhanced MRI for determining the cause of erectile dysfunction (41). They have found delayed enhancement of corpora in patients with arterial insufficiency. Valvular disease results in a rapid washinn and washout of contrast media (41). The future of penile MRI for erectile dysfunction will depend on the success of procedures to correct erectile dysfunction.

MAGNETIC RESONANCE IMAGING IN THE FUTURE

There are several exciting trends in MRI. MR technology continues to improve in total imaging time, spatial resolution, and flexibility. Recently, determination of the functional status of organs has become possible with dynamic enhancement or changes in perfusion. Focus is now directed at the brain because it is the most straightforward organ to assess, but functional studies may soon be directed at other organs, including the kidneys and testicles. This may affect the assessment of renal function and primary testicular infertility. MRS may also prove to be a useful diagnostic tool.

Open-bore magnets that decrease patient anxiety but also allow for invasive procedures under MRI are widespread. These may permit biopsy or even operative procedures to be performed with real-time MR guidance. The quality of open-bore magnets has greatly improved, although the flexibility of such units remains limited.

New contrast agents are being developed to improve the tissue specificity of MRI. Such agents may be able to distinguish malignant and benign nodes noninvasively. Ultrasmall iron dextran particles already have shown promise in this area in animals. Tissue-specific antibody imaging may also be possible. The goal of this research is to improve the tissue specificity of MRI and allow noninvasive “MR biopsies” to be reliably performed, and this continues to be an active area of research.

Acknowledgments

The author wishes to thank Barbara McCoy for her secretarial assistance and Ronald M. Summers, MD, PhD, for valuable advice.

The dramatic advances that have occurred in radiologic imaging techniques over the last 20 years make it difficult for editors of textbooks to decide what is worthy of inclusion and what should be discarded. The solution in this chapter was to give different imaging modalities used for urologic investigations their own section. This works fine until one addresses imaging of urology conditions that have a predominantly vascular basis. The current state of imaging in regard to vascular disease can at times require the use of any or all of the different modalities. Angiography, still the gold standard for visualization of vascular issues, is being rapidly supplemented by computed tomographic angiography (CTA), magnetic resonance angiography (MRA), color Doppler ultrasound, and nuclear medicine. With the current emphasis on cost containment, efficient workups, and clinical pathways, trying to determine when and where to use each of these modalities can be perplexing. This chapter attempts to define the strengths and weaknesses of each imaging technique by approaching the subject from a clinical question standpoint. Technical descriptions of the different modalities, except for angiography, are covered in other chapters.

TECHNIQUE OF ANGIOGRAPHY

The basics of angiography have not changed since Seldinger (22) described his technique for percutaneous puncture of the common femoral artery in 1953. However, the tools have undergone significant improvements, with a resultant increase in success rates and decrease in complications. Although angiography is still an invasive procedure compared with ultrasound or computed tomography (CT), this fact alone should not prevent a patient from having an angiogram if indicated. Most series quote the incidence of serious complications from angiography in the range of 0.5% to 2.5% (14,23,24); however, these studies were all done before 1980, when catheters were larger and stiffer, fluoroscopic visualization was inferior to that available today, and digital subtraction angiography had not been developed. In addition, nonionic contrast was not available at that time. No large series of complications from angiography have been published recently, but it is reasonable to assume that the basic procedure is safer than it was 25 years ago.

The most important aspect of preprocedure evaluation of the patient is assessment of renal function. The amount of contrast material used for a study is usually not an issue in otherwise healthy individuals, but diabetic patients and patients with impaired renal function are more susceptible to acute renal failure (4,5,10,17). A baseline creatinine level should always be obtained and any recent trends noted. The risk of acute renal failure is greater in someone with a creatinine of 2.5 mg/dL that has been rising over the last week than in a patient who has been stable at that level. There is no clear consensus on whether bleeding parameters should be checked, although the majority still check prothrombin time, partial thromboplastin time, and platelets. Anyone with a history of bleeding tendencies should have appropriate laboratory studies. Most angiographers require an international normalized ratio of less than 1.5 before proceeding with angiography.

In the past, most patients were admitted to the hospital the night before a procedure. This is no longer true unless the patient happens to already be an inpatient. Therefore particular attention must be paid to adequate hydration before the study (7). Outpatient angiography is now common. Outpatients usually arrive early in the morning, are evaluated, receive an intravenous catheter and groin preparation, and are then taken to the angiography suite.

The procedure is usually performed using conscious sedation such as midazolam and fentanyl, as well as local anesthesia at the arterial puncture site. Sterile preparation and drape is observed. Access is obtained through either common femoral artery. If the femoral arteries are unavailable for any reason, angiography can be performed from an axillary artery approach. Translumbar aortography is no longer performed. Nonionic contrast material is nearly always used in angiography. The risk of contrast reaction is much less. There is currently debate over whether nonionic contrast carries a lower risk of nephrotoxicity. This is covered in more detail in other chapters. Carbon dioxide and gadolinium are sometimes used as contrast agents in patients with severely compromised renal function (2,12,26). Procedures are most often performed using a 5-Fr catheter. For many interventions, microcatheters, which can be placed through a 5-Fr catheter, are used.

After the procedure is completed, the catheter is removed from the groin and pressure is held for approximately 15 minutes. Historically, patients had to lie flat with their legs straight for 6 hours after the procedure, but many sites now allow patients to ambulate earlier. Also, a number of percutaneous closure devices have recently become available. These devices act by using either a suture or a collagen plug to obtain immediate hemostasis. As more experience is gained with these devices, the recovery period will continue to shorten.

As mentioned earlier, many imaging techniques can be used to aid in the diagnosis and treatment of vascular-related problems. The remainder of this chapter provides guidance on the appropriate use of various imaging modalities in a number of common clinical problems. This is not meant to be a thorough discussion of each entity because these are covered in later chapters.

RENOVASCULAR HYPERTENSION

It is fair to say that this is one area where the treatment of the disease has progressed more rapidly than the diagnosis. Angioplasty and metal stents have significantly simplified the treatment of renovascular hypertension over the last 15 years (Fig. 3F.1), but our ability to accurately detect the presence of the disease has changed little. It is also fair to say that there is more variability from institution to institution in the diagnostic techniques used than in any other of the clinical situations discussed here.

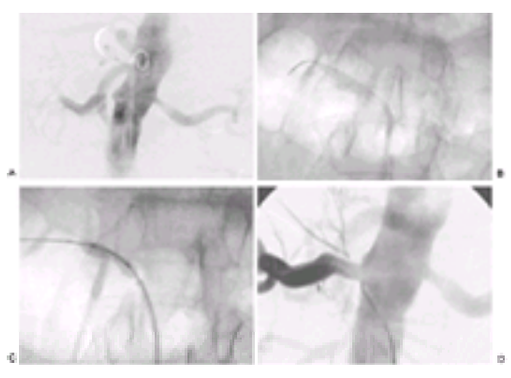

FIGURE 3F.1. Patient with difficult to control hypertension on four medications. Creatinine elevated at 1.7 mg/dL. **A:** Digital subtraction angiography demonstrates a 99% stenosis in the right renal artery and a less severe stenosis on the left. **B:** A balloon-on-a-wire low-profile system is used to dilate the lesion. **C:** Because of a residual 40% stenosis, a balloon-expandable stent is placed. **D:** Stent in place and no residual stenosis.

All the imaging techniques are aimed at identifying a renal artery stenosis. This must then be correlated with other clinical data to determine the likelihood that the stenosis is related to the hypertension. Venography with renal vein sampling for renin is the one exception. Lateralization of elevated renin to one kidney is presumptive evidence of renovascular hypertension. Angiography can be done at the same time to determine the presence or absence of a stenosis. Unfortunately, it takes a number of days to get the renin assay results back, so if this approach is taken, angioplasty/stent placement must be postponed until the results are available. In practice, renal vein sampling for renin is not usually performed at most institutions except in questionable cases or when it is unclear how to proceed. One example is the case in which no arterial stenosis is found but peripheral renins are clearly elevated. Renal vein sampling may indicate which kidney is the culprit. Another example is the case in which a stenosis is found but does not appear significant. Obtaining renal vein renins can then be used to determine whether to bring the patient back for treatment of the questionable stenosis.

As far as imaging of a stenosis is concerned, angiography is still the gold standard; however, CTA (18) and MRA (8) have both made dramatic improvements over the last 10 years. The success of these two modalities is highly dependent on the experience and interest of the radiologists at a given institution. At medical centers with little experience in either CTA or MRA, their reliability is variable. Many centers have begun using these as a standard screening examination, and in experienced hands, the accuracy exceeds 85%. More important, the negative predictive value can be greater than 95% (18). Angiography is still performed at the time of treatment, but using CTA or MRA can greatly reduce the number of negative angiograms. CTA and MRA have the advantage of being noninvasive, but they both require intravenous contrast material. Gadolinium is now used for almost all MRA, and CTA requires rapid intravenous contrast injection. Computerized three-dimensional (3D) reconstruction techniques show promise of replacing standard two-dimensional imaging in the near future. This allows examination of the artery in 360 degrees and increases the sensitivity of the examination.

Nuclear medicine renal scans, with or without captopril, can be useful in cases of unilateral stenosis (6). Interpretation becomes more difficult if both sides show symmetric function. At institutions where CTA and MRA have not been pursued, renal scans remain the primary screening tool for renal artery stenosis.

The use of ultrasound in the evaluation of arterial stenoses has become common. In fact, many vascular surgeons perform carotid endarterectomy based on ultrasound findings alone in some cases. Unfortunately, the renal arteries lie deep within the body, making ultrasound examination difficult and, in some cases, impossible. Although there have been technologic improvements in ultrasound transducers, this method remains the most operator dependent of all imaging methods. Some operators have obtained a high success rate using this as a screening examination, but they are in the minority.

In summary, many options are now available for imaging renal artery stenoses, but only angiography maintains a high accuracy rate from institution to institution. The best approach is to discuss this issue with the radiologists at a given medical center and ask them which technique they prefer for screening. In cases with a strong clinical impression of renovascular hypertension, it may be quickest and most cost-effective to proceed directly to angiography.

RENAL TUMOR DIAGNOSIS

Imaging of tumors is covered in other sections, but there is a vascular-related topic worth mentioning: determination of renal vein and inferior vena cava (IVC) invasion by tumor.

Invasion of the IVC by renal cell carcinoma was a diagnosis made by venography up until the advent of ultrasound. Now CT and magnetic resonance imaging (MRI) also have that capability. Interestingly, this is one area where angiography (venography) may not represent the gold standard. CT and MR are both capable of detecting a thrombus in the IVC. Both modalities have pitfalls, as does venography, primarily related to flow phenomena (21). Ultrasound, on the other hand, is limited only if the IVC cannot be well visualized. Ultrasound also has the advantages of requiring no contrast and being the least expensive. Comparisons of the different modalities consistently show that ultrasound should be the first choice. Venography can be reserved for those cases in which the IVC is not well seen. Although ultrasound is the best examination, if a CT or MRI has already been obtained and the question of caval invasion is answered in an unequivocal manner, there is no need to pursue additional studies.

RENAL TUMOR EMBOLIZATION

There are usually no specific arterial questions that must be answered when working up renal tumors, and CT and MRI have done away with the old technique of intraarterial epinephrine in the diagnosis of small lesions. However, percutaneous arterial embolization should be kept in mind for very large tumors or when there are other reasons to make extra efforts to decrease blood loss, such as when operating on a patient who will not accept blood transfusions. In these instances, preoperative embolization can be helpful (Fig. 3F.2). Angiography is performed in the standard manner, and the number of renal arteries is defined. Transcatheter embolization is then performed with alcohol (13), Gelfoam, or another embolic material. Embolization of renal cell carcinomas is one of the older applications of this technique, and therefore much experience has been gained. The procedure should be straightforward for any fellowship-trained interventional radiologist. The patient should proceed to surgery within the next 48 hours because parasitization of vessels by the tumor occurs rapidly.

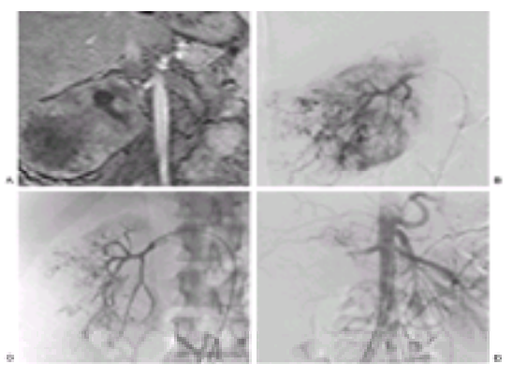

FIGURE 3F.2. This patient is a 56-year-old man with right flank mass and hematuria. **A:** Magnetic resonance imaging scan demonstrates renal cell carcinoma fed by enlarged renal artery. **B:** Digital subtraction angiography confirms single renal artery. **C:** Absolute alcohol is used to embolize tumor preoperatively. Occlusion balloon is in place to prevent reflux. **D:** Follow-up angiogram shows no flow through renal artery.

OCCULT HEMATURIA

Occasionally, a patient with hematuria undergoes the standard battery of tests and no cause can be found. In this context, if bleeding is seen coming out of a ureter during cystoscopy, angiography should be the next step. An arteriovenous malformation becomes a possibility, and the other imaging modalities will not reliably demonstrate these lesions. Angiography, on the other hand, will not only make the diagnosis, but embolization can be undertaken (3), often at the same sitting.

Modern angiographic catheters and embolic materials make this procedure very simple. A standard renal arteriogram is done in multiple projections. If an arteriovenous malformation or arteriovenous fistula is found, embolization can be undertaken at the same sitting. If a 5-Fr catheter can easily be advanced selectively into the branch vessel that is the culprit, embolization can be performed with no additional maneuvers. If not, microcatheters can be used that almost always allow catheterization of third-, fourth-, or even fifth-order branches (Fig. 3F.3). Coils are used for embolization with Gelfoam occasionally needed as an adjunct. This is clearly the best modality for making the diagnosis, and the fact that a minimally invasive treatment is available at the same time is a plus.

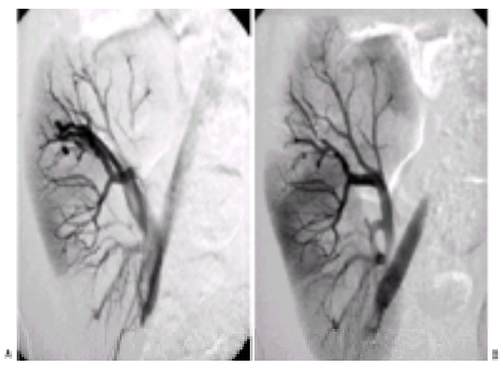

FIGURE 3F.3. Renal transplant patient with persistent hematuria following biopsy. **A:** Renal artery injection shows small pseudoaneurysm and early draining vein emptying into iliac vein. **B:** Following placement of two microcoils, fistula is occluded with minimal loss of parenchyma.

LIVING RENAL DONOR WORKUP

In recent years, CTA has become the procedure of choice (25). CT is less invasive than angiography, gives functional information not available on MRA, and is probably less expensive. In comparison with ultrasound and MRA, CT has been shown to be superior in depicting accessory renal arteries (9,19) (Fig. 3F.4). Standard CT examinations for this indication require three parts. An initial noncontrast scan should be obtained to exclude any calcifications in the kidneys. This is followed by a true CTA examination. Our protocol uses 3-mm-thick slices 1 mm apart from the celiac axis to the bifurcation. We inject 3.8 mL of 150 mL of Omnipaque 350 per second, with a 12-second delay. A delayed scan is then performed to evaluate the kidney and ureters.

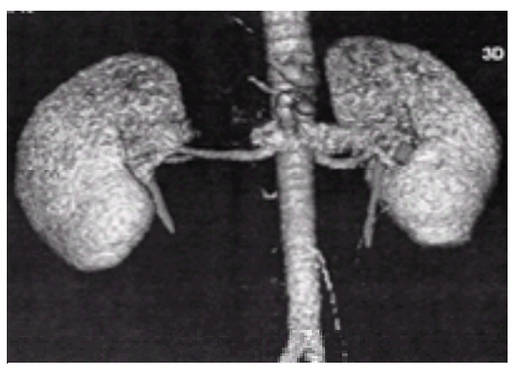

FIGURE 3F.4. Living renal donor computed tomography angiogram shows single arteries to each kidney and left renal vein passing anterior to the aorta. Different color schemes can be used depending on the preference of the viewing physicians. See also Color Figure 3F.4.

The standard axial images are reviewed along with 3D reconstructions. The fact that 3D images can be rotated 360 degrees (Fig. 3F.5) can be a major advantage in determining the number and location of renal arteries. Using a posterior view can be helpful in visualizing the left renal artery where it lies behind the vein. When both sets of images are used, it is only in rare cases that angiography is still needed. An additional advantage to the 3D reconstructions at our institution is that the surgeons prefer those images to take to the operating room.

FIGURE 3F.5. Living renal donor. Image can be viewed in 360 degrees to better evaluate each artery and other structures. **A:** Anteroposterior view showing single arteries to each kidney. **B:** Right oblique showing no stenosis in the right renal artery. **C:** Left oblique showing left renal vein passing anterior to aorta.

MRA with gadolinium has become a good method of visualizing the renal arteries at institutions with experience in this technique; however, it does not have the advantages of CT in picking up calcifications or in demonstrating function by contrast material in the collecting system.

URETEROPELVIC JUNCTION OBSTRUCTION

Preoperative assessment for treatment of ureteropelvic junction obstruction includes defining the location and number of crossing vessels. Until recently, this has been one of the few situations in which there has been no substitute for angiography. CTA is now proving to be of value for this condition (20). Adding 3D reconstructions has the potential to give minimally invasive surgeons even more information. Because this is a relatively new application of CT, it may be helpful to do a comparison with angiography until sufficient experience is gained to be sure the findings of CTA are reliable.

TRAUMA

Angiography remains the gold standard for trauma to the kidney where vascular injury is suspect. CT is the best overall screening tool, but doing a true CT angiogram in this situation is difficult and unreliable. If either occlusion of the renal artery is suspected or if the patient is actively bleeding from the kidney, emergency angiography should be undertaken immediately.

Occlusion of the renal artery or avulsion of the renal pedicle, once diagnosed by angiogram, should be taken immediately to the operating room. There is no minimally invasive technique at this time that can be used to treat this condition.

Bleeding from the kidney can be treated with transcatheter embolization. Angiography will demonstrate the bleeding site, and then a standard embolization technique, such as that mentioned in the occult hematuria section, can be used. This is one instance in which the embolization technique is not only less invasive but is probably easier to perform than trying to control bleeding from a branch vessel surgically.

TRANSPLANT KIDNEYS

The fact that a transplanted kidney is in a different location has important ramifications for vascular imaging. Because of the superficial location, ultrasound is very accurate in determining the presence or absence of a stenosis. The main difficulty lies in separating the transplant artery from the internal iliac artery and its branches. If ultrasound finds high velocities suggestive of renal artery stenosis, angiography can be undertaken for confirmation and to treat with angioplasty or stent placement. Nuclear medicine studies can be undertaken to evaluate renal blood flow and excretion, but they are not as helpful in renal artery stenosis because there is no “other” kidney for comparison.

Ultrasound can also be useful in evaluating any other vascular abnormalities that might occur. Because these kidneys often undergo biopsy, there is the potential for pseudoaneurysm or arteriovenous fistula formation. Ultrasound can often detect either one of these conditions. Angiography again is reserved for confirmation and treatment. Three-dimensional CT has recently been suggested to be of value in the vascular evaluation of transplant kidneys (11). Although this work is relatively recent, with the current explosion in fast CT techniques, it can be expected that the application of CT in the transplant setting will increase.

There is an additional attribute of transplant kidneys that makes a difference in angiography. Because angiography is often undertaken in the setting of a rising creatinine, it is helpful to limit iodinated contrast material or even exclude it completely. Carbon dioxide can be used as a very good contrast material, particularly with latest-generation digital equipment. Transplant kidneys are particularly well suited to this because the kidney lies anterior to the feeding vessel. Carbon dioxide contrast, being lighter than blood, will tend to fill anterior structures better. Unfortunately, because of the same reasoning, native kidneys do not visualize as well with carbon dioxide contrast material. Special maneuvers such as turning the patient onto his or her side must be performed. Some institutions have also begun using gadolinium, a non–iodine-based contrast material, to evaluate the kidneys.

IMPOTENCE AND PRIAPISM

Impotence is increasingly being recognized as a more common problem than previously believed. With this recognition has come greater emphasis on diagnostic arterial studies. Ultrasound with Doppler (16) can be helpful, but angiography remains the most sophisticated study (1). Internal pudendal arteriography can be performed from a femoral artery puncture. Intraarterial vasodilators and pharmacologic erection are necessary for a complete evaluation. Although the techniques are straightforward, this is not a procedure routinely used at all medical centers. Therefore the experience of any individual should be considered before requesting these studies.

Priapism is a rare but exceptionally painful condition. Imaging studies are not usually required, but Doppler ultrasound is being increasingly used when necessary. When the veins do not appear to be the problem, investigation of the arterial system with angiography can be helpful. Catheterization of the hypogastric arteries is required. Microcatheters can then be used to selectively catheterize the internal pudendal arteries. If high-flow priapism is thought to exist and other treatment methods have failed, embolization has been successful (27).

MRA and CTA, although becoming increasingly used in place of angiography, have not yet been shown to be of benefit in either of these two conditions.

VARICOCELE

Varicocele is another condition that rarely needs any imaging technique; however, venography may be used to evaluate the venous drainage in cases in which there is a recurrent varicocele or where embolotherapy is requested. CTA and MRA with 3D reconstructions can both show enlarged gonadal veins, but because embolotherapy is undertaken at the same time as venography, there is usually no reason to obtain cross-sectional imaging studies. Venography is usually performed from a femoral vein approach with catheterization of the left renal vein. The gonadal vein is then catheterized, and contrast material is injected with the table tilted in reverse Trendelenburg position. The main vein and any collateral channels are identified, and embolization can be performed. This procedure is particularly helpful in patients with anatomic variants of venous drainage (15).

A wide variety of embolic materials have now been used for this indication. Initially, detachable balloons were most common, but sclerotherapy agents and injection of boiling contrast material have subsequently been used. The introduction of microcatheters with the resultant decrease in spasm of the veins has led to increased use of metal coils. In Europe, sclerotherapeutic agents are used more commonly (15).

Radioactive tracers have been used for more than 30 years to measure renal function and to image the urinary tract. Because of the kidneys' rich vascularity, unique function, and high metabolic rate, a number of radiopharmaceuticals have been used to study this organ system. The anatomic placement of the urinary tract is favorable for external counting and imaging, except that the bladder is anterior and the kidneys are posterior. Nuclear medicine has made unique and valuable contributions to the study of the genitourinary tract, but it cannot compete with other modalities such as radiography and sonography for high-resolution anatomic imaging. On the other hand, none of the other imaging modalities has the ability of nuclear medicine for functional imaging or quantitation.

This chapter outlines the pharmaceuticals used in genitourinary evaluation, radiation dose from nuclear procedures in relation to radiographic procedures, instrumentation, and clinical applications. Nuclear medicine procedures applicable to patients with genitourinary disease that are not specific to the genitourinary system are not discussed in any detail. Included among the latter techniques are procedures for imaging infection (gallium citrate Ga-67 scans and indium In-111 oxine-labeled or technetium-99m [^{99m}Tc] HMPAO-labeled white blood cell [WBC] scans), bone imaging (e.g., ^{99m}Tc methylene diphosphonate), lung scanning (^{99m}Tc macroaggregated albumin and xenon-127 gas or xenon-133 gas), and cardiovascular studies (thallium-201 images of myocardial perfusion or ^{99m}Tc-tagged red blood cells [RBCs] for evaluation of cardiac function). These and other nuclear procedures are beyond the scope and intent of this chapter.

RENAL RADIOPHARMACY

Pharmaceuticals

Chemical Structures

The chemical structures for the various compounds in use in nuclear medicine renal work range from the simple to the complex. The compounds themselves vary in their pharmacology from the general to the specific.

Xenon-127 and xenon-133 are the simplest compounds in use; they are also nonspecific. Xenon is a monatomic gas, belonging to the noble, or “inert,” gas group. It is sparingly soluble in water or isotonic saline and quite soluble in fat. Xenon-127 has the better half-life for storage, the better energy for imaging, and confers the smaller radiation dose, but xenon-133 has been the more available and cheaper isotope.

The radioactive nuclide most used in nuclear medicine is ^{99m}Tc, which has a 6-hour half-life and a 140-keV gamma ray energy. It is ideal for examinations taking less than 1 day using the Anger camera, the most common nuclear medical imaging instrument today. The radionuclide is obtained in the pertechnetate form, TcO_4^-, from a “generator.” A new generator is delivered to most laboratories weekly. There is a supply of sterile, pyrogen-free ^{99m}Tc in most nuclear medicine laboratories at all times. The pertechnetate form may itself be used in studying renal blood flow and cystograms. Other technetium radiopharmaceuticals are compounded from purchased kits and available pertechnetate.

Most of the compounds in use have been chosen because of specific interaction with the kidneys. For example, ethylenediamine tetraacetic acid (EDTA) is a chelating compound with the ability to bond a positive metal ion; the nitrogens provide electrons for the covalent bonds, as do the oxygens of the acetic acids. The compound in routine use in nuclear medicine is diethylenetriamine pentaacetic acid (DTPA). It bonds its three nitrogens and five acidic oxygens to positively charged metal ions. EDTA and DTPA are shown schematically in Fig. 3G.1. The method for naming these compounds has been to assume that biomedical people could not remember the chemical names and that the initials were not sonorous enough, so parts of the chemical names or initials have been turned into the simpler names *edetate* and *pentetate.*

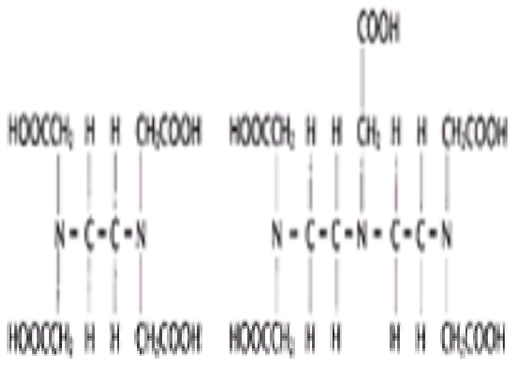

FIGURE 3G.1. Chemical structures of *(left)* ethylenediamine tetraacetic acid (EDTA) and *(right)* diethylene triamine pentaacetic acid (DTPA).

Commercial kits are available for compounding ^{99m}Tc DTPA, ^{99m}Tc glucoheptonate (GH) (Fig. 3G.2), and ^{99m}Tc meso-2,3-dimercaptosuccinic acid (DMSA) (Fig. 3G.3). All three kits contain stannous chloride as a reducing agent, so Tc $^{4+}$ will be the positive ion species chelated by the organic compound. The package inserts should be consulted for special instructions in using the radiopharmaceuticals.

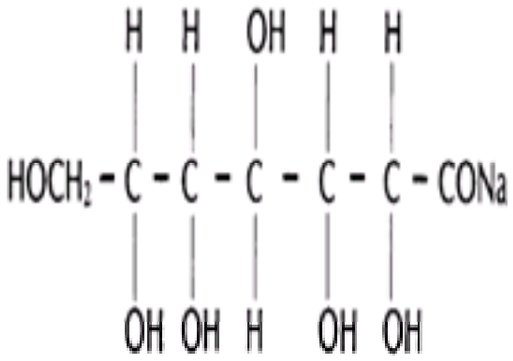

FIGURE 3G.2. Chemical structure of sodium glucoheptonate (GH).

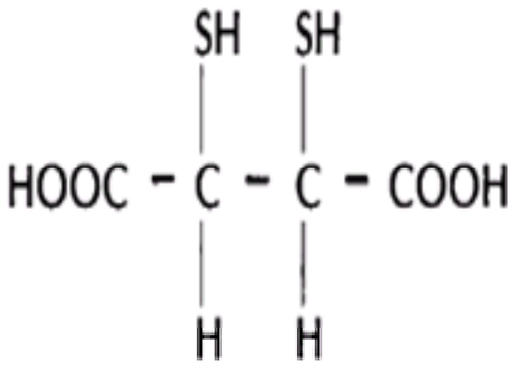

FIGURE 3G.3. Chemical structure of dimercaptosuccinic acid (DMSA).

More recently, ^{99m}Tc mercaptoacetyltriglycine (MAG_3) (Fig. 3G.4) has been introduced for renal tubular function studies (51). It has the advantages of ^{99m}Tc and kit formulation using stannous ion. It has been approved by the U.S. Food and Drug Administration (FDA) for renal imaging and for studying renal function.

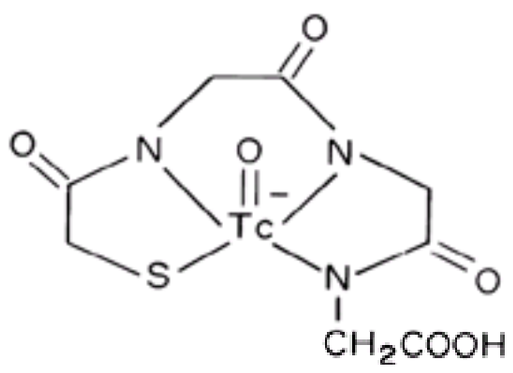

FIGURE 3G.4. Chemical structure of ^{99m}Tc MAG_3.

The chromium isotope, ^{51}Cr, has been chelated to EDTA for renal work. The half-life of ^{51}Cr is 27.8 days, and although the chemical characteristics of ^{51}Cr EDTA are favorable (5), the yield of radioactive decay products available for counting is low. Therefore ^{51}Cr EDTA is used for examinations requiring blood sampling but not those requiring imaging.

The iodine isotopes, ^{123}I and ^{131}I, have been attached to the ortho position of hippuric acid to create compounds for renal tubular function studies. The structure is given in Fig. 3G.5. Because ^{123}I has a 13.2-hour half-life, ^{123}I hippurate (Hippuran) must be made on site with recently purchased ^{123}I or must be purchased for the studies for that day. The ^{131}I hippurate, with an 8-day half-life, may be kept on hand at all times if demand for its use is sufficient.

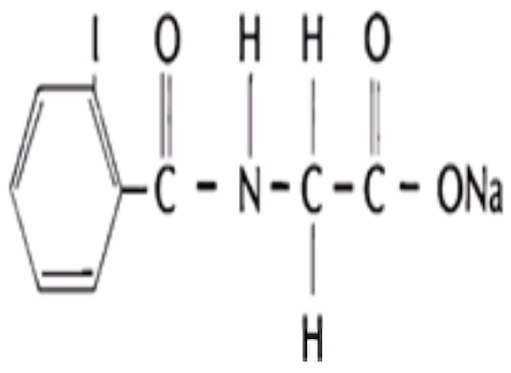

FIGURE 3G.5. Chemical structure of sodium *o*-iodohippurate (OIH).

BIOLOGIC BEHAVIOR

Xenon is more soluble in fat than in blood. If the patient is caused to rebreathe from a closed system containing radioactive xenon mixed with air or oxygen, the patient becomes more and more radioactive, with fat accumulating the major part of the activity. If the patient is then caused to breathe air alone, the washout of the xenon from the tissues can be observed with nuclear medical instruments. The rate of washout correlates with the blood flow to the organ or area. This technique has been used in many organs in the body.

The specific behavior of ^{99m}Tc DTPA and ^{51}Cr EDTA is considered later in this chapter in the discussion of glomerular filtration rate (GFR). A variable amount (10% or less) of injected ^{99m}Tc DTPA is bound to protein.

^{99m}Tc GH is injected intravenously (IV). The material is found in the plasma, and blood clearance is rapid (1,4), similar to DTPA. The GH clears by both tubular secretion and glomerular filtration. Approximately 70% of the material is excreted in the urine of normal subjects. Approximately 6% of the dose is retained in each kidney, largely in the cortex, permitting imaging of the cortex 3 to 4 hours after injection. A normal variation is clearance by the liver into the gallbladder and intestines.

^{99m}Tc DMSA is slowly injected IV. It is distributed in the plasma, loosely bound to plasma proteins. The activity clears from the plasma with a half-time of 60 minutes and concentrates in the renal cortex. Approximately 16% of the activity is excreted within 2 hours, increasing to 25% by 6 hours. At 2 hours, 15% is concentrated in each kidney; this increases to 20% by 6 hours (1). Imaging is best performed 3 hours or more after injection.

Iodinated hippurate has been used extensively in the examination of renal function; there is a voluminous literature on the use of this compound. The biologic behavior of iodinated hippurate is discussed in the section on effective renal plasma flow. Most of the hippurate is actively secreted by renal tubules. In a normal person, 70% of the compound is excreted in the urine in 30 minutes.

^{99m}Tc MAG_3, also known as *mertiatide,* is another renal tubular agent; it is confined to the plasma, having less RBC binding than sodium iodohippurate (OIH) (35). The plasma protein binding of MAG_3 is approximately twice as great as that of OIH. MAG_3 has a plasma clearance of approximately half that of OIH, probably as a result of decreased glomerular filtration and lower tubular secretion.

Dosimetry

Both nuclear studies and radiographic procedures result in patient exposure to ionizing radiation. The major difference between the two procedures is that radioactive pharmaceuticals produce patient exposure from internal sources, whereas that from a radiographic diagnostic procedure results from external irradiation. Exposure from radiographic procedures can be accurately determined if the unit is accurately calibrated and the exposure factors are known. In nuclear procedures, the patient dosage is determined by the biologic handling of the pharmaceutical, the physical behavior of the radionuclide, and patient dosage. Alterations in patient physiology, as for example in renal failure, affect the absorbed dose of radiation markedly if the radiopharmaceutical behavior is altered by the disease process. In recent years, patient exposure has been reduced in both areas by improvements in radiopharmaceuticals, nuclear instrumentation, radiographic and fluoroscopic equipment, and film and screen sensitivity. The patient exposures listed in Table 3G.1 and Table 3G.2 are considered average exposures and may not be accurate for a given patient or a particular institution. There are inaccuracies in published radiation dose calculations for a number of these materials (55). Personnel exposures should be low with both types of procedures if appropriate protective measures such as syringe shields and equipment shielding are used. The procedure potentially resulting in the highest exposure is fluoroscopy because a typical fluoroscope exposes the patient and personnel to as much as 10 rad per minute.

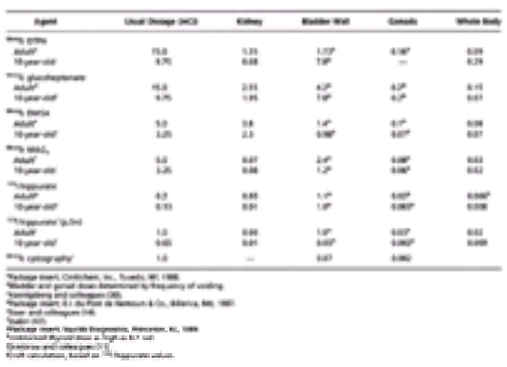

TABLE 3G.1. TYPICAL ABSORBED DOSES (RAD) FROM COMMON RADIONUCLIDE STUDIES

Procedure	Dose
Intravenous urograms	
(No. of films/examinations)	(5.31)
Mean exposure/examination	3.133 R
Mean marrow dose/examination	0.103 rad
Mean male gonadal dose/examination	0.207 rad
Mean female gonadal dose/examination	0.588 rad
Mean dose to total body/examination	0.278 rad
Fluoroscopy	
Exposure/min	2–10 rad

TABLE 3G.2. ADULT DOSES FROM RADIOGRAPHIC PROCEDURES

Certain terms must be defined to understand exposure to ionizing radiation. The patient dose of a radiopharmaceutical is measured by the number of atoms disintegrating per second. The term most commonly used in nuclear medicine is *millicurie (mCi),* defined as 3.7×10^7 disintegrations per second. A *microcurie (mCi)* is

3.7×10^4 disintegrations per second.

The Système Internationale (SI) units are coming into more common use; the SI unit for radioactive decay is the becquerel (Bq), which is 1 disintegration per second. Because many disintegrations occur per second, reference is often made to megabecquerels (MBq), 10^6 disintegrations per second, and to gigabecquerels (GBq), 10^9 disintegrations per second. Therefore 1 mCi is equal to 37 MBq, 37×10^6 Bq. Obviously, a radionuclide with a long half-life in the patient will usually expose the patient to more ionizing radiation than another radiopharmaceutical with a shorter effective half-life. The effective half-life is influenced both by the physical decay rate of the nuclide and by the biologic turnover of the pharmaceutical.

Two terms are commonly used as measures of x-ray and patient exposure. The *roentgen* (R) is a measure of ionization of air by x-rays or gamma rays. There is no physical difference between an x-ray and a gamma ray. An x-ray originates from atomic electrons, and a gamma ray originates in the nucleus of an atom. One R results in 2.082×10^9 ion pairs in 1 mL of air at standard atmospheric pressure. The term *roentgen* is usually used to express the output of an x-ray machine. The amount of energy absorbed by a patient's tissue is expressed in rad. The *rad* is defined as 100 ergs absorbed per gram of tissue. In most tissues, exposure to 1 R results in approximately 1 rad of absorbed energy. The two terms are used somewhat interchangeably, but it should be remembered that the roentgen is a measure of exposure, whereas the rad is a measure of energy absorbed by tissue.

The SI unit for exposure to ionizing radiation is the coulomb per kilogram, and for absorbed radiation is the gray (Gy), with 100 rad equal to 1 Gy. Table 3G.3 gives the conversion factors to SI units.

	Customary Units	SI Units
Radioactive materials	1 curie (Ci)	3.7×10^{10} becquerels (Bq)
	2.7×10^{-11} Ci	1 Bq
Absorbed dose	1 rad	0.01 gray (Gy)
	100 rad	1 Gy

TABLE 3G.3. CONVERSION FACTORS TO SI UNITS

Table 3G.1 lists typical absorbed doses in patients receiving the five most common radionuclide studies of the urinary tract. The bladder receives the highest exposure from most of these pharmaceuticals, but this dose can be reduced considerably by frequently emptying the bladder. Free iodine, present to some extent in ^{131}I hippurate, will result in exposure to the thyroid. The dose of the thyroid can be reduced by more than 90% by giving Lugol's solution, saturated solution of potassium iodide, or other blocking agents before the study.

The doses listed from radiographic procedures in Table 3G.2 are based on a survey performed by the Bureau of Radiologic Health between 1964 and 1970. The patient exposures can be reduced somewhat from the values listed by using better collimation of the x-ray beam, by using improved films and screens, and by reducing the number of films or fluoroscopic exposures.

INSTRUMENTATION

Two types of instruments are most often used to detect ionizing radiation in clinical applications. The oldest and simplest technique uses a gas detector. In this type of instrument, a charge is placed across electrodes in a chamber containing some type of gas. Gamma rays or x-rays cause the gas to ionize, thereby resulting in current flow across the electrodes. The amount of voltage between the electrodes determines the amount of current flow, the sensitivity of the detector, and the useful range of radiation that the instrument can accurately measure. The walls of the chambers can be altered to allow detection of very poorly penetrating radiation or highly penetrating radiation.

Two types of gas detectors are commonly used in nuclear medicine laboratories. A Geiger-Müller (GM) survey meter is usually used for detecting contamination in the nuclear medicine laboratory. This gas detector operates with a relatively high voltage, making the detector sensitive for small amounts of radiation. A typical range of usefulness is between 0 and 50 millirads per hour (1 rad = 1,000 mrad). The ionization chamber is usually attached to a rate meter and an electronic package by an electrical cord that allows survey of work areas. The probe is relatively nondirectional. The standard survey meter is intended for detection of x-rays and gamma rays and is not very suitable for low-energy beta ray detection.

The second type of gas detector usually found in the laboratory is a dose calibrator. At one time, most of the radiopharmaceuticals administered in nuclear medicine laboratories had relatively long half-lives and were purchased as needed from a pharmaceutical supplier in precalibrated doses. Patient doses were withdrawn from a precalibrated vial, and activity was calculated based on the known activity per cubic centimeter. As discussed previously, many of the radiopharmaceuticals carry the radioactive label ^{99m}Tc.

Technetium is eluted daily from a shielded ion exchange column containing molybdenum-99. The elution is unpredictable, and therefore the patient dose must be accurately measured in the laboratory. Highly accurate dose calibrators currently available allow the measurement of bulk quantities of individual patient doses of radiopharmaceuticals. The dose calibrators use a gas-filled ionization detector. Physically, the detector is a well chamber that allows the vial or syringe to be inserted for high-efficiency counting. These instruments are capable of accurately measuring over a wide range of activity, typically from approximately 1 mCi to more than 2,000 mCi. One millicurie equals 1,000 mCi. The dose calibrators are designed to give a digital readout of activity and are usually accurate to within 5%. The dose calibrators must be checked daily against known standard amounts of activity. These chambers operate with a relatively low voltage to allow measurements of high radiation intensities, and they are not accurate for measuring low-energy x-rays, low-energy gamma rays, or beta rays.

The other major category of detectors of ionizing radiation uses solid crystals. In most laboratories, the detector is sodium iodide, doped with an impurity such as thallium. Sodium iodide is hygroscopic, and therefore the crystal is completely enclosed in a barrier impervious to water, such as aluminum or glass. Ionizing radiation is absorbed by the crystal, converting the energy to visible light. Thus the sodium iodide crystal is called a scintillation crystal or scintillation detector. The light produced by each ionizing event is quite small and is detected by a nearby photomultiplier (PM) tube, which has a photocathode that converts light energy into a small electronic pulse. The electronic pulse is amplified more than 1 million times within the PM tube, making it large enough to be amplified and processed in standard electronic circuits. Thus an ionizing event in the crystal produces light that is converted into an electronic pulse. The magnitude of the pulse is related to the amount of energy contained in the ionizing event. The pulse can be analyzed to determine the energy of the x-ray or gamma ray that hit the crystal. Pulses can be integrated over a variable time to give counts per second or counts per minute. The count rate can be displayed on a meter or a digital printout, or it can be stored in a computer.

A single crystal detector is usually mounted in some type of lead or other heavy-metal shielding so that the crystal is sensitive to x-rays or gamma rays from a localized region (Fig. 3G.6). Typically, a single crystal–single PM tube system is used for measuring count rate from the thyroid for thyroid uptake determination or monitoring the count rate in the kidneys during a renogram. Under these circumstances, the probe and its collimator are positioned so that the crystal monitors the count rate in the organ and nearby tissues being surveyed. The successful use of this detector assumes that the organ can be accurately localized from anatomic landmarks.

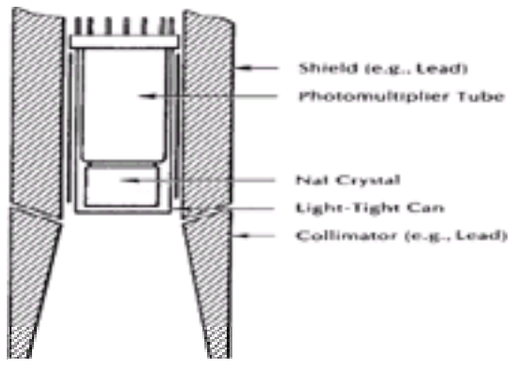

FIGURE 3G.6. Typical probe detector system. The sodium iodide (NaI) crystal and photomultiplier (PM) tube are shielded by lead to restrict the field of view to the desired anatomic region. The crystal is enclosed in a polished can to increase the reflection of light to the PM tube and protect the crystal from degradation by moisture.

A sodium iodide scintillation detector can be manufactured in the form of a “well counter.” This is used for counting in vitro samples. In effect, the sample is inserted into a hole in the protected crystal so that high counting efficiency is achieved. As with the scintillation probe, the activity can be counted over time to determine sample activity.

The imaging device used in most departments is the Anger camera. The camera contains a single crystal, measuring up to 50 cm in diameter, that is round, square, or rectangular in shape and 0.25 to 0.375 inches thick. Behind the crystal, there is a matrix of PM tubes, typically numbering anywhere from 37 to 91, which look at the intensity of light from each scintillation in the crystal (Fig. 3G.7). The light striking the multiple PM tubes is analyzed so that the location of the scintillation is determined, as well as the total energy from the x-ray or gamma ray. The front of the crystal is protected by a collimator. The multiple holes in the collimator determine the origin of the photons that hit the crystal. Ordinarily, most Anger cameras are used with a parallel-hole collimator that sees a field of view 25 to 50 cm in size depending on the size and shape of the system. The thickness of lead septa between holes is selected for the appropriate energy of the photons being imaged, that is, low energy (up to 160 keV) and medium energy (160 to 360 keV). The hole diameter and collimator thickness are selected for desired resolution and counting efficiency.

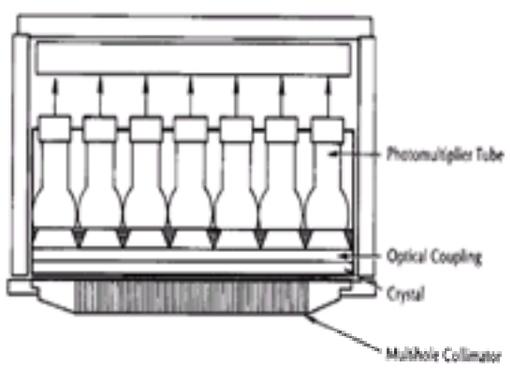

FIGURE 3G.7. Diagram of a cross section through a 37 photomultiplier (PM) tube gamma camera. The PM tubes are arranged in a hexagonal array, with three rings of tubes surrounding a central tube. Gamma rays or x-rays pass through the collimator and interact with the crystal, producing light. The location of the scintillation and the total energy absorbed are determined from the signal output by the PM tubes. The amplified signal is analyzed for energy levels and sent to the cathode ray tube or computer for recording.

The camera electronics include an energy discriminator (spectrometer) to be sure that only the appropriate energy is accepted. The crystal detects stray cosmic rays, scattered x-rays, and so forth, as well as the desirable photons emitted by the nuclide being imaged. The image quality will suffer unless the unwanted radiation is excluded by energy discrimination.

The final image that is viewed depends on where the signal is sent once it leaves the PM tubes and analyzers. It may enter a cathode ray tube (CRT) that puts a series of dots on the screen. By using time-lapse photography of the CRT, an image is generated on Polaroid film or transparency film. The same signals may be sent to a computer for storage and later manipulation.

Computers have been used in nuclear medicine for years to digitize and store the information from the scintillation probe or Anger camera for later manipulation. Over the years, the storage capacity and sophistication of programs have improved greatly. When using a computer to store and manipulate data, it is essential that the information be stored in an adequate format. If images are integrated for 1 minute each, for instance, the data cannot be later analyzed at 1-second intervals. Therefore the appropriate prescription for the storage must be determined before initiating the study. Most commercial computers now have several software programs that allow histogram displays of activity versus time. These curves can be stripped or analyzed to allow washin and washout rate determinations, fractionation of individual renal function, and analysis of blood clearance rates to determine GFR and effective renal plasma flow. In addition, computer manipulation is essential to enhance images from an Anger camera and perform specialized procedures such as single photon emission computed tomography (SPECT). SPECT creates tomographic images in much the same way as computed tomography (CT) scanning, by combining images from multiple positions as the camera rotates about the patient.

PROCEDURES

The following sections describe the range of procedures available in nuclear medicine to assist the renal diagnostician. For easy reference, the examinations, radiopharmaceuticals, and typical doses of radioactivity are outlined in Table 3G.4.

Examination	Agent	Dose of Activity
Renal blood flow imaging	^{99m}Tc compound	15 mCi
Effective renal plasma flow		
Imaging	^{131}I hippurate	200 μCi
Blood sampling only	^{131}I hippurate	30 μCi
Imaging	^{123}I hippurate	1.0 mCi
Imaging	^{99m}Tc MAG_3	10 mCi
Blood sampling only	^{99m}Tc MAG_3	300 μCi
Glomerular filtration rate		
Imaging	^{99m}Tc DTPA	15 mCi
Blood sampling only	^{99m}Tc DTPA	300 μCi
Blood sampling only	^{125}I iothalamate	100 μCi
Blood sampling only	^{51}Cr EDTA	100 μCi
Renal cortical imaging	^{99m}Tc DMSA	5 mCi
Cystography	^{99m}Tc pertechnetate	1 mCi
Testicular imaging	^{99m}Tc pertechnetate	15 mCi

TABLE 3G.4. RADIOPHARMACEUTICALS AND ACTIVITY DOSAGE FOR GENITOURINARY EXAMINATIONS

Renal Imaging

Renal images are typically performed with Anger cameras. The arrival of activity can be recorded in the form of renal vascular studies. This information can also be analyzed by computer to compare the washin rates for the two kidneys. Most of the technetium pharmaceuticals can be used for the vascular sequence, provided adequate amounts of activity (15 to 20 mCi) are injected, but the later static views show varying features depending on the pharmaceutical used. The vascular sequence is typically recorded on film and by the computer at one frame per 2 seconds, but the framing rate can be tailored to the patient's age and the injected dose. In general, faster sequences are desired for children. The limiting factor on the renal vascular sequences is generally the low information density due to a small number of counts per image, so higher imaging rates may actually cause deterioration of the images. Because of its ability to add frames together, the computer is often a more satisfactory method than film for recording and displaying this information.

The static images of the kidneys are collected immediately after the vascular sequence and up to several hours later. Static images may contain as many as 1 million counts and require up to several minutes' accumulation time. ^{99m}Tc DTPA is filtered and concentrated in the tubules and is then excreted through the collecting system. Activity in the calyces, renal pelvis, and ureters decreases after 5 to 10 minutes, and delayed views beyond 30 minutes have little value unless the patient has obstruction.

The ^{99m}Tc MAG_3 imaging sequence is very similar to DTPA; it is best used in a dynamic fashion for vascular imaging and the renogram referred to later.

^{99m}Tc GH and DMSA show progressive accumulation in the kidneys over several hours; delayed views will show better images of the renal cortex after the background and collecting system activity have decreased. Patient hydration will influence the washout rates from the kidneys just as with a renogram. This effect is used in the “furosemide (Lasix) renogram,” discussed under Hydronephrosis and Hydroureter later in this chapter.

Renograms

Initially, renograms were performed using multiple, single-crystal probes positioned over the patient's back. The probes were positioned by external anatomic landmarks, but this often did not locate the kidneys in the field of view of the probes. Later, workers positioned the probes by injecting a small amount of renal tracer (e.g., ^{203}Hg chlormerodrin) and finding the maximum count rate before injection of ^{131}I hippurate. More recently, most renograms have been performed with Anger cameras, even though the sensitivity of a camera is somewhat less than that of a probe. The versatility of data recorded from a camera more than offsets the disadvantage of the higher pharmaceutical dose required. A renogram may be performed using external probes with as little as 30 mCi of ^{131}I hippurate. Renograms performed on Anger cameras typically use 200 mCi of the same agent. With the camera, the accumulated information is usually stored by a computer for later analysis of individual kidney count rates and generation of renogram curves. The camera-generated data are acquired by the computer at intervals of 10 to 15 seconds for as long as 30 minutes to 1 hour.

The term *renogram* simply indicates that an activity versus time graph is being generated from the kidney activity. Classically, the renogram study was performed with ^{131}I hippurate, but other agents such as ^{99m}Tc DTPA or MAG_3 may be used. The shape of the renal curve is obviously affected by the pharmaceutical used. The shape is also affected by patient preparation and positioning. For instance, the classic renogram is performed with the patient mildly dehydrated and seated in front of the Anger camera. Drainage from the upper collecting system is more consistent in the upright position, but unfortunately, there is more tendency for the patient to move. Patients who cannot maintain this position comfortably and consistently may be imaged in the supine position. Follow-up patient studies should always be performed in the same position, if possible.

Hydration state affects the timing and shape of the renogram curves. Phase I (Fig. 3G.8), lasting approximately 30 seconds, represents the arrival of the IV-injected pharmaceutical in the blood pool of the kidney and adjacent tissues. There will be a phase I increase in count rate regardless of the status of the kidney because there is blood pool activity in all tissues. The activity during this phase is poorly related to renal blood flow. Phase II typically lasts 4 to 6 minutes and terminates when activity in the kidney reaches a maximum. As the kidney extracts the radiopharmaceutical from blood, the count rate gradually rises. Because the blood levels fall rapidly during the first few minutes, activity in the urine is maximum initially and gradually falls with time. When this most active urine leaves the region of interest being analyzed, the count rate will start to fall. Thus the rate of increase in count rate during phase II is directly related to the renal blood flow and renal function. The rate of increase of activity is not affected by hydration, but the duration of phase II is inversely related to the urine formation rate.

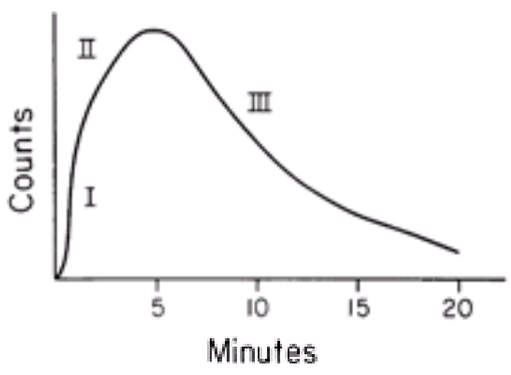

FIGURE 3G.8. Renogram curve showing count rate versus time. The shape is affected by the radiopharmaceutical injected intravenously. The idealized curve shown is typical of that following hippurate injection in a moderately hydrated patient, recording activity with a gamma camera and computer. Phase I is vascular content in kidney and background. As the kidney extracts the tracer, activity rises in phase II. When the collecting system starts emptying through the ureter, activity falls in phase III.

Phase III starts at the peak of renal activity and illustrates a gradual fall in count rate as the most concentrated activity is washed from the collecting system. The time that is required for the count rate to fall to half of the peak value is called the half-time for washout, and this time is affected by urine formation rate. Numerous other aspects of the shape and timing of the renogram curve have been analyzed, but none is specific for disease process. However, if hydration state and positioning are consistent, changes in the slope of phase II, the time to peak, and the half-time for washout do reflect changes in renal status.

Mathematical Model: Two-Component Model

To be able to quantitate the results of functional studies, a model is developed to describe the organ function. A connection is made between the numbers that are available from the noninvasive examination and the properties that it is desired to measure. In the case of the kidneys, the quantities to be measured include renal plasma flow, GFR, and individual kidney function. Whether renal plasma flow or GFR is measured depends on the pharmaceutical used in the measurement.

The estimation of renal blood flow and function can be computed by the Fick principle, which when applied to the kidney gives the following formula:

$$\text{Clearance} = U_V/(A - V)$$

where *U* is the concentration of the test substance in the urine, *V* is the volume of urine, *A* is the concentration of the substance in the renal artery, and *V* is the concentration of the substance in the renal vein. If the substance is completely removed by the kidney, the renal vein concentration can be assumed to be zero; the arterial concentration may be assumed to be equal to the peripheral venous concentration. Thus the formula is simplified as follows:

$$\text{Clearance} = U_V/A$$

To perform a clearance measurement using Fick's principle, blood is sampled and a total urine collection is made during continuous IV infusion of the agent for three

20-minute periods. The assumption is made that the body reaches a steady state in which the input of the measured substance is the same as the output. One can further assume that measurements of the quantity of the substance in the infusion and the peripheral venous concentration are sufficient. If the separate function of each kidney is desired, catheters must be placed in each ureter.

It was discovered by Sapirstein and co-workers (42) that a single injection of the test substance could be substituted for continuous infusion with no compromise in the total functional information.

In a renal function examination using a radiopharmaceutical, the numbers that are available are the relative concentration in the kidneys as attenuated by tissue and the amount of activity per unit volume in the blood during the examination. The relative concentration in the urine in the bladder during the examination may be compared with the absolute concentration in voided urine at the end of the examination, especially in transplant patients whose kidney and bladder are close enough together for imaging at the same time. Note that unless complex techniques are resorted to, only samples removed from the patient can be quantitated in an absolute way.

It has been observed that the radioactivity per unit volume of plasma of radiopharmaceuticals injected for renal examination decreases according to a biexponential curve as a function of time. This means that the curve of plasma activity as a function of time shown in Fig. 3G.9 can be decomposed into two straight lines (on a semilogarithmic scale as shown in Fig. 3G.10). Each of these lines is described by its intercept with the activity axis, which is its concentration at time equals zero, and its half-time, or the amount that disappears per unit time. Thus one curve yields four numbers.

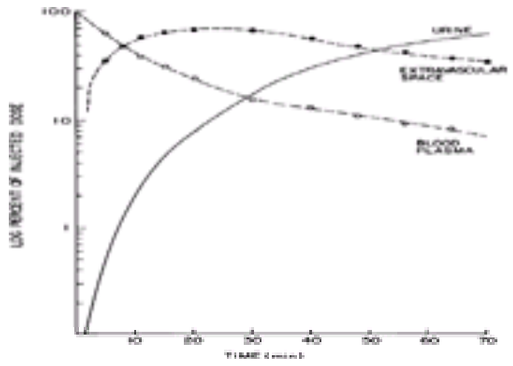

FIGURE 3G.9. The semilog graph of percent of injected dose versus time illustrates the amount of sodium *o*-iodohippurate in the blood, urine, and extravascular space.

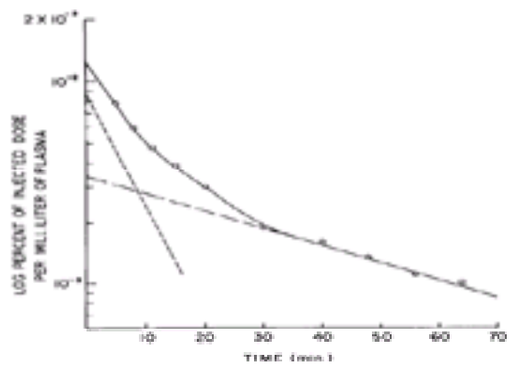

FIGURE 3G.10. The semilog graph of percent of injected dose per milliliter of plasma versus time shows a biexponential functionality. The two exponential parts are shown.

If, in turn, we consider a model of renal function (Fig. 3G.11), it is possible to write differential equations describing the loss of material from one compartment and the gain of an equal amount by another, following the arrows of the model and using the language and symbolism of reaction-rate chemistry. The model pictured is called an *open two-compartment mammillary model* (33). Such differential equations can be solved to yield mathematical functions that describe the concentration in each compartment as a function of time. For this model, the function that describes the concentration in the vascular compartment as a function of time is a biexponential curve. Thus the kinetic variables in the model can be related to the numbers generated from patient plasma sampling. The renal clearance is a function of all four numbers, which come from both parts of the curve:

$$\text{Clearance} = \ln(2)(A_1 \times t_1 + A_2 \times t_2)$$

where A_1 and A_2 are the fractions of the injected dose per milliliter for each of the two parts of the curve at time zero, and t_1 and t_2 are the half-times for the two parts of the curve.

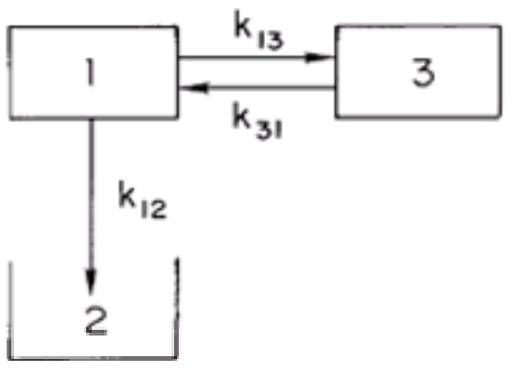

FIGURE 3G.11. The open two-compartment mammillary model. Compartment *1* is the plasma, compartment *3* is the extravascular space, and compartment *2* is the urine. There is kinetic equilibrium between compartments *1* and *3,* and there is no return from compartment *2. k* indicates the rate constant for transfer from compartment i to compartment j.

The measurements of the plasma disappearance curve may be made in several different ways. One method is to take plasma samples over a time suitable for defining the two parts of the curve; ten samples are sufficient to permit curve-fitting and the discrimination of poor samples. Some laboratories have simplified this method to taking one blood sample at a particular time with the subsequent calculation of renal clearance by a relationship connecting the clearance to the single-sample activity and several constants. A second method involves the measurement of a major blood pool in the body, such as the cranium or the heart, with a probe detector, combined with a blood sample that is compared with a standard to permit calibration of the plasma disappearance curve.

Clearly, using eight to ten blood samples to define the biexponential curve is the more accurate method, although simplification of the test procedure is necessary in

some instances. In such a case, a method that accurately defines the longer half-life part of the curve should be sufficient to eliminate the difficulties of a single sample. In this case, the clearance equation becomes as follows:

$$\text{Clearance} = \ln(2)(A \times t)$$

where *A* is the fraction of the injected dose per milliliter of plasma at time zero, and *t* is the half-time of the line.

It should be pointed out that the simplified methods may not allow the accurate comparison of one patient to an absolute scale but may permit the progress of that patient's disease to be observed with changes in the renal function value because a particular patient's measurement is reproducible.

Constant Infusion Methods

Constant infusion methods, in which there is an IV infusion of saline containing the radioactive material, seem simple and appealing. Once a steady state is reached, measurements of urine and blood concentrations and interval urine volumes are all that is required to perform a clearance measurement.

The apparent simplicity is not real. The patient must be given a priming dose of the material to ensure that the blood and extravascular space will come to equilibrium during the constant infusion period, and the patient must be well hydrated to be able to urinate on command at given intervals. Urinary retention, normally up to 100 mL, is greater than this in certain diseases, and highly variable. Bladder retention can be estimated with external detectors, but this complicates the examination.

Computer Processing for Fractionation

The fractionation of renal clearance into values for the individual kidneys is accomplished by reference to the images acquired by the Anger camera at 15-second intervals after injection of the tracer dose. Regions of interest are drawn around the kidneys; background-corrected activity versus time curves are generated. From this point, two different methods can be used to complete the calculation.

In the slope method, the slopes of the curves for the two kidneys between 60 and 150 seconds after injection are calculated using least-square methods. The two slope values are added together, and the fractional contribution of each kidney's slope to the total is calculated. This is the fractional contribution that each kidney makes to the clearance.

In the integrated count method, the counts for each kidney between 60 and 150 seconds after injection are found, after background correction; this is a relative measure of the activity multiplied by time in each kidney. The two integrated counts are added, and the fractional contribution of each kidney to the total is calculated. Once again, this is the fractional contribution that the kidney makes to the clearance.

Both of these methods give similar results for kidneys that function well. The results for poorly functioning kidneys are open to more uncertainty for several reasons: The selection of the background region becomes more critical; the difference between kidneys and background is small and shows great variability; and the statistical uncertainties of radioactive detection are more serious for lower counts, so all the calculations have greater uncertainty.

When percentages are used for comparisons, they must always add up to 100%. This means that if one kidney remains the same after some elapsed time but the other improves in clearance, the one that remains the same will appear to have lost function on a percentage basis. It is thus incumbent on the observer to look at both the percentages and the absolute clearance values.

Glomerular Filtration Rate

The glomeruli produce an ultrafiltrate of the plasma by means of a physical process, which is nonselective for substances of low molecular weight. The volume of this ultrafiltrate, expressed in milliliters per minute, is defined as the GFR. The formation of the filtrate is regulated by the hydrostatic pressure gradient, osmotic pressure, the filtration surface, and membrane porosity.

To measure GFR, the agent must have the following characteristics (45):

1. Be nontoxic, physiologically inert, and chemically stable
2. Be easily and accurately measured in blood and urine
3. Be fully filterable through the glomerular membrane
4. Not combine with plasma proteins
5. Not be resorbed, synthesized, destroyed, or excreted by tubules
6. Have a constant clearance with high or low urinary flow, and greater or lesser concentrations of the agent in the plasma
7. Have a clearance equal to that of other tracers already proved adequate for GFR measurement, such as inulin
8. Be eliminated exclusively by the kidneys

The standard for comparison for GFR measurements is inulin clearance in a protocol that includes continuous IV infusion and three 20-minute complete urine collections and three blood samples drawn during the urine sampling periods. The protocol is not practical for clinical use.

The use of radioactively labeled compounds has simplified GFR measurement by simplifying the measurement of the agent. Of the radioactively labeled materials, ^{99m}Tc DTPA comes closest to fulfilling the criteria for GFR measurement. It can also be used in combination with an imaging examination to visualize renal and ureteral anatomy and to quantitate the fraction of the GFR attributable to each kidney (fractionation). Inulin, labeled with the beta-minus emitter carbon-14, can also be used with the standard continuous infusion method or in a plasma sampling mode, as can sodium iothalamate and other radiographic contrast agents, labeled with ^{125}I or ^{131}I. DTPA and EDTA have also been used. The ready availability of ^{99m}Tc DTPA makes its use simpler than any of the other materials mentioned here.

The measuring process is described earlier in this chapter. Ten plasma samples obtained during 1.5 to 2 hours of blood sampling after a single IV injection should be sufficient to define the two parts of the biexponential curve. The single-sample technique uses a function of the form where *A, B,* and *C* are constants, and *S* is the fraction of the injected dose per milliliter of plasma in the 3-hour sample (7).

The radionuclide technique described by Gates (18) is an alternative method of measuring the GFR. The calculation is based on the renal uptake on Anger camera images during the 2- to 3-minute interval following tracer (^{99m}Tc DTPA) arrival in the kidneys. The GFR is computed by using the following formula:

$$\text{GFR} = A(L + R) - B$$

where *L* and *R* represent the depth-corrected percentages of renal uptake for the left and right kidneys and *A* and *B* are constants. The formula was derived from linear regression analysis comparing the renal uptake of ^{99m}Tc DTPA with 24-hour creatinine clearance in 51 adult studies.

The advantage of this method is that it allows rapid determination of split renal function, as well as total GFR, without blood samples. The accuracy of this method, however, has been called into question. Ginjaume and co-workers (19) compared four methods of measuring GFR and found that the effective volume technique using one blood sample taken at 2 hours was the best compromise between accuracy and convenience and that the Gates method presented practical problems due to uncertainty in background subtraction and kidney-depth approximation.

The mean value of GFR in the normal adult is approximately 130 mL per minute in men and 120 mL per minute in women, with an uncertainty of 10%. The GFR of the newborn is between 20% and 40% of the adult value and increases progressively until, at age 1 year, it becomes equal to adult values in relation to the standard surface area.

Effective Renal Plasma Flow

If the renal tubules can be assumed to remove a substance totally from the blood during perfusion, a study of the concentration of that substance could yield values of renal blood flow. Most of the substances used in such a measurement are concentrated in the plasma, so the measurement is of renal plasma flow (RPF).

The ideal substance for estimating RPF should have the following characteristics:

1. Be nontoxic, physiologically inert, and chemically stable
2. Be easily and accurately measured in blood and urine
3. Be fully secreted by renal tubules
4. Be readily dissociated from any plasma protein complex in its transit through the kidney
5. Not be resorbed, synthesized, or destroyed by tubules
6. Have a saturable clearance so that high concentrations have lesser clearance values
7. Have nearly total renal extraction
8. Be eliminated exclusively by the kidneys

Both because only a portion of renal blood flow is presented to renal secretory tissue as opposed to the small fraction that normally perfuses the nonsecretory tissue (perirenal fat, pelvis, and capsule) and because no substance perfusing the kidney will be totally extracted, the calculated clearance will be less than the total renal plasma flow, so it is termed *effective renal plasma flow* (ERPF). Extraction efficiency of the tubules may be decreased in disease, as may renal blood flow.

Para-aminohippurate (PAH) was found to meet the aforementioned criteria best. Sodium iodohippurate (OIH) was found to be similar in behavior to PAH; in addition, it can be labeled with radioactive isotopes of iodine, such as ^{131}I, ^{123}I, and ^{125}I, making detection of the material simpler than in the previously used chemical methods. ^{131}I and ^{123}I have the added advantage of ready imaging with the Anger camera.

Because ^{131}I OIH disappears from the blood according to a biexponential function, the open two-compartment mammillary system is appropriate for analysis. Again, the examination protocol may be combined with imaging so that the images and fractional ERPF for each kidney are obtained along with the total ERPF value. The protocol may be based on serial blood sampling between 5 and 70 minutes after IV injection of ^{131}I OIH, to define the biexponential curve, or a less accurate single-sampling method can be used. Tauxe and co-workers (49) performed an elaborate analysis, which suggested that it was feasible to use a single blood sample, at 44 minutes after injection, and a polynomial to calculate the ERPF:

$$ERPF = A + B/S + C/S$$

where *A, B,* and *C* are constants, and *S* is the fraction of the injected dose per milliliter of plasma.

Normal ERPF values lie above 600 mL per minute, with a 10% uncertainty. Approximately 50% of the function should be attributable to each kidney. Filtration fraction is the comparison of GFR and ERPF measurements. The normal value is approximately 0.2. Tauxe (48) documents ERPF values in normal patients and patients with unilateral nephrectomy.

Renal plasma flow can also be measured with ^{99m}Tc MAG_3 (40,41). As the agent becomes widely available and more controlled studies are performed, the ERPF ratio between MAG_3 and OIH will be better known. From the University of Alabama research, the 44-minute MAG_3 concentration is 0.563 times the OIH value (41).

Nuclear Cystography

Although cystograms may be performed after the bladder has filled following an IV injection of a radiopharmaceutical, the study is more accurate in detecting ureteral reflux if the tracer is placed directly in the urinary bladder. From $^3/_{10}$ to 1 mCi of ^{99m}Tc pertechnetate is mixed with 250 to 500 mL of sterile saline in an IV bottle. The IV bottle should not be more than 3 feet above the bladder. After the tubing is attached to the catheter, the bladder is slowly filled and the time and volume are recorded. At the same time, sequential images are recorded by the camera and computer. The patient is then instructed to void with the catheter in place; if voiding is impossible, the catheter is withdrawn.

The recording sequence varies somewhat among laboratories, but in general, frames are recorded on film and in the computer at 15- to 30-second intervals. Posterior projections are used. Images or computer curves may reveal reflux up the ureters. The severity of reflux is usually gauged by the volume of infused fluid required to produce significant reflux. Increasing volumes instilled before reflux occurs implies improvement.

Scrotal Imaging

Nuclear imaging to evaluate scrotal pathology has been used since 1973 with excellent accuracy reported. Its primary role is the differentiation of testicular torsion from epididymitis in patients with an “acute” scrotum. The standard radionuclide used is ^{99m}Tc pertechnetate.

In our procedure, the patient is given an oral dose of potassium perchlorate 30 minutes before radionuclide dose to block thyroid uptake. Potassium iodide can also be used. Positioning includes taping the penis to the abdominal wall and supporting the testicle on a tape sling to rest the testicle on a slightly higher plane than the thigh. A large-field-of-view camera is positioned anteriorly, and no shielding is used.

A bolus of 20 mCi of ^{99m}Tc pertechnetate is injected IV. A flow sequence of 3 seconds per frame at 70-mm image size is used, and then static images with a LEAP collimator are obtained immediately and at 5 and 10 minutes for 500,000 counts per view. The analysis is described in the following section.

CLINICAL APPLICATIONS

Acute Renal Failure

Acute renal failure may be caused by anatomic or physiologic abnormalities. Anatomic causes of renal failure include occlusion of renal arteries and veins and obstruction of the urinary tract at any level. Physiologic causes of acute renal failure include blood volume depletion (“prerenal”) and acute tubular necrosis (ATN). The first step in evaluation of acute renal failure is sonography to evaluate the status of the collecting system (3). Contrast studies are not recommended because of their potential adverse effect on renal function. If the sonogram shows no evidence of dilation of the collecting system, the next step is dynamic renal scintigraphy.

We recommend ^{99m}Tc DTPA or ^{99m}Tc MAG_3. The technetium compounds provide better anatomic detail than either ^{123}I hippurate or ^{131}I hippurate. An important part of this examination is the visual evaluation of renal blood flow. The flow portion of dynamic imaging is the essential part in the evaluation of renal arterial blood flow. Analysis is based on observing the symmetry and the intensity of kidney visualization. The peak of activity in the kidney should be no more than 3 seconds after the peak of activity in the aorta. The intensity of activity in a normal-sized kidney should equal or exceed the early activity in the spleen (16).

Unilateral delay or decrease in kidney visualization on the flow study signifies a vascular abnormality. The possible vascular abnormalities include renal artery occlusion secondary to embolism, thrombosis, or dissection of an aortic aneurysm; renal artery laceration secondary to trauma; renal artery stenosis; and renal vein thrombosis. Unilateral delay can also be caused by severe unilateral ureteral obstruction or damage from infection or other disease. The sonographic findings are helpful in this differential.

Bilateral delay or decrease in renal perfusion is less specific. This pattern could be due to bilateral vascular compromise, severe prerenal circulatory failure, severe renal causes of failure (including ATN), and severe bilateral ureteral obstruction (Fig. 3G.12). Obstruction is again excluded by the sonographic findings.

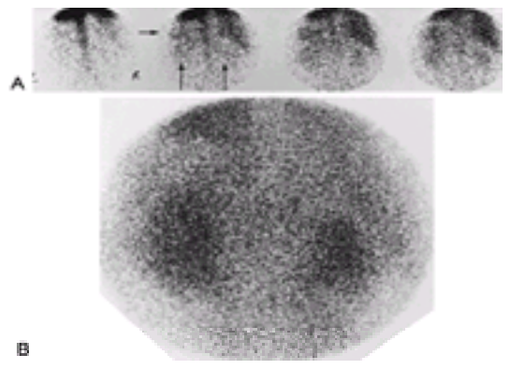

FIGURE 3G.12. Woman, 64 years old, with acute tubular necrosis following partial resection of her small bowel. **A:** ^{99m}Tc DTPA vascular sequence shows symmetrically poor renal blood flow. *Vertical arrows,* kidneys; *horizontal arrow,* spleen. **B:** Static image at 20 minutes demonstrates moderate bilateral uptake. No bladder activity was demonstrated.

The static images are analyzed for renal size and position along with symmetry, uniformity, and promptness of uptake bilaterally. In normal kidneys, the immediate postdynamic images demonstrate symmetric, homogeneous activity in the renal cortices. Within 5 minutes, background activity lessens and the collecting systems are well visualized.

Renal size and position can suggest the cause, as well as prognosis, of the disease process. Bilaterally, normal-sized kidneys suggest recent onset and potential reversibility. Small kidneys indicate chronic disease, congenital or acquired, and irreversibility. Large kidneys can be seen in polycystic disease, an infiltrating disease such as amyloidosis, or renal vein thrombosis (44).

Evaluation of symmetry and uniformity of uptake on the static views compared with the flow study can also suggest underlying causes. Asymmetry of uptake with a corresponding flow abnormality correlates with a vascular problem. Lack of uniformity of uptake is caused by localized parenchymal disease. Wedges or segments of decreased activity that correlate with vascular distributions imply vascular abnormalities. Mass lesions may also cause nonuniformity and are discussed later in this chapter.

Promptness of uptake is also an important indicator. Delay in uptake in the kidneys suggests poor renal function secondary to parenchymal compromise. Causes include prerenal circulatory failure; renal disease, such as ATN; and postrenal obstruction. When severe enough, this compromise can decrease the flow as described previously.

In the severely oliguric or anuric patient, renal function may be so severely compromised that ^{99m}Tc DTPA or ^{99m}Tc GH scans are inadequate. In that case, ^{131}I hippurate is recommended because renal concentration can occur with as little as 3% of normal function (38). ^{99m}Tc MAG_3 provides results that are comparable to those with hippurate in patients with impaired renal function (50).

Chronic Renal Failure

In evaluating the azotemic patient, excretory urography becomes inadequate when the plasma creatinine level exceeds 5 mg per 100 mL. Large bolus doses of organic iodides may improve visualization radiographically but adversely affect already compromised renal function. ^{99m}Tc MAG_3 is the recommended agent for evaluation of chronic renal failure. Technetium compounds are chosen because flow studies can be performed. Additional experience with ^{99m}Tc MAG_3 shows that this compound is preferred to hippurate or DTPA. As in acute renal failure, the size, position, promptness, symmetry, and uniformity of renal uptake of the kidneys are important in guiding investigation and narrowing the diagnostic possibilities (46).

Masses and Pseudomasses

In evaluating a renal mass, the purpose of noninvasive tests is to narrow the diagnostic possibilities and avoid intervention if the mass is benign. The current resolution of scintigraphy is not as good as that of radiography. Lesions as small as 1 cm have been detected on phantoms, but a larger lesion centrally placed in the kidney may not be detected by scintigram. On the other hand, peripheral lesions or those obscured by fat or bowel gas may be better visualized. Therefore radiologic and radionuclide techniques are complementary in evaluation of renal masses.

Ultrasound is generally the recommended first procedure for initial characterization of a renal mass. If lobulation is noted, a normal variant, or “pseudomass,” of the kidney may be present, such as a hypertrophied column of Bertin, splenic impression, dromedary hump, or fetal lobulation. The next step is nuclear imaging with ^{99m}Tc DMSA, used because of its concentration in the parenchyma. If the lobulation is secondary to a pseudomass, the static images will demonstrate normally functioning parenchyma. In some cases, the pseudomass may actually be more intense because of the increased thickness of the parenchyma (37).

If lobulation is not seen sonographically and the mass is atypically cystic, complex, or solid, CT or angiography is recommended. In determining whether a mass is vascular or nonvascular, radionuclide vascular flow studies are 80% to 85% accurate, a rate lower than the other two modalities.

Whether the mass is neoplasm, infarction, abscess, cyst, or localized pyelonephritis, the renal study will be abnormal due to replacement of normal parenchyma that concentrates radionuclide. A typical cyst or infarct will demonstrate no activity on blood flow or on early and delayed images. A typical renal carcinoma will demonstrate activity on blood flow and early images but a photon-deficient area on delayed images (Fig. 3G.13). An abscess or localized pyelonephritis may be similar to a cyst or tumor, depending on the size and amount of hyperemia.

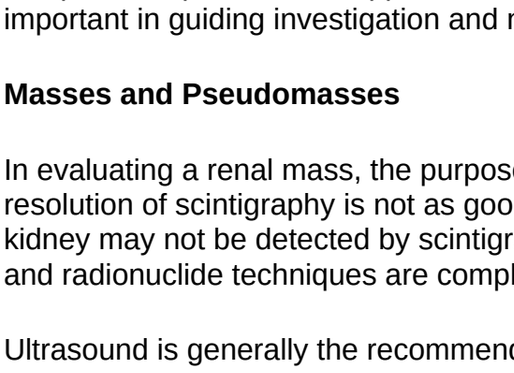

FIGURE 3G.13. Woman, 38 years old, with right hypernephroma. ^{99m}Tc glucoheptonate study showed initial delay of flow to right kidney (0 to 30 seconds). **A:** View at 40 seconds shows definite vascularity of tumor *(arrows).* **B:** Histogram of blood flow to abdominal organs demonstrates initial delay in blood flow to tumor, then increased activity compared with left kidney. Normal delay in flow to liver is seen, corresponding to portal venous supply. **C:** Static views at 5 minutes show minimal function of right kidney, particularly in the upper pole. **D:** Computed tomography scan shows large right renal mass *(arrows)* with crescentic area of functioning renal tissue present along anteromedial aspect. Bowel loops in the left abdomen are opacified with oral contrast agent.

Hydronephrosis and Hydroureter

One of the most important applications of renal scintigraphy is in the evaluation of urinary tract obstruction. Renal imaging can help in the diagnosis, determination of timing for surgical intervention, and evaluation of therapy. It is also valuable in assessing renal function, which cannot be evaluated reliably by intravenous pyelography (IVP). In the setting of acute obstruction, any renal function implies salvageability, whereas in chronic obstruction, poor function suggests permanent damage.

When the ultrasound examination shows urinary tract dilation, the next question is whether obstruction is present. Conventional urography and radionuclide scanning are unreliable in differentiating obstructive from nonobstructive hydronephrosis.

Perfusion studies introduced by Whitaker (54) obtaining pressure–flow relationships have provided a more functional approach. The procedure requires placing a catheter into the renal pelvis to obtain pressure readings. This is an invasive procedure that can involve a significant radiation dose when done fluoroscopically.

Using parenteral diuretics allows radionuclide renography to be modified to obtain similar information by noninvasive methods. Published reports indicate a high degree of accuracy in distinguishing the dilated obstructed system from the nonobstructed (53).

The success of diuretic renography is directly dependent on strictly following the procedure. First, the patient must be well hydrated either by oral or IV methods. The patient needs to void just before injection or have a Foley catheter inserted for constant drainage. We prefer ^{99m}Tc DTPA because of its excellent visualization of the collecting system and inject 15 mCi (or the appropriate pediatric dose). MAG_3 is used in newborns or where renal function is poor. Images are taken every 5 minutes and continuously on computer until the *entire* collecting system is filled with radionuclide. (If this takes longer than 1 hour, the study decreases in reliability.) The patient then voids and is injected with furosemide, 1 mg/kg, up to 40 mg IV. Images are taken every 5 minutes for the next 30 minutes.

Computer analysis of the renal collecting system activity is performed, resulting in computer curves of the counts. Three curve patterns are possible. A definite decrease in counts with time after furosemide administration represents a nonobstructive pattern (Fig. 3G.14), whereas a definite increase is obstructive (Fig. 3G.15). A plateau signifies an indeterminate pattern, which could be secondary to poor renal function and poor response to furosemide, or a very large atonic hydronephrotic sac. Providing the renal function is good, $T_{1/2}$ (half-time for washout) of less than 10 minutes is normal; greater than 20 minutes indicates obstruction; and 10 to 20 minutes is indeterminate. These numbers are not absolute, and the volume of the affected collecting system is related to the half-time of washout. A distended bladder can also delay the washout, and catheterization of the bladder is often necessary. Efforts have been made to develop consistent methods for performing diuretic renograms for better consistency among institutions (9).

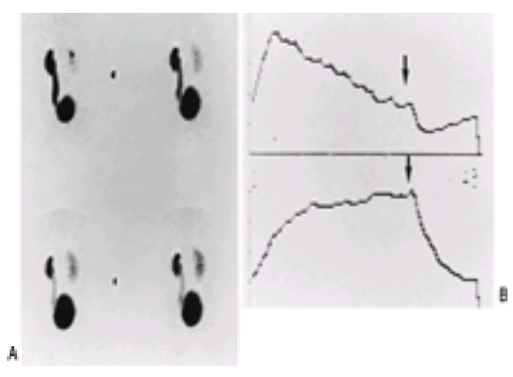

FIGURE 3G.14. Boy, 2 years old, following left ureteral reimplantation. ^{99m}Tc DTPA study. **A:** Posterior images demonstrate left hydronephrosis and hydroureter and a normal right kidney. The top left image was taken 30 minutes after radionuclide injection, at time of furosemide administration. Subsequent images were taken at 5-minute intervals showing radionuclide excretion. **B:** The right kidney *(top curve)* has excreted most of the radionuclide before furosemide administration. The *bottom curve* shows decreasing counts in the left kidney only after furosemide *(arrow)* signifying no evidence of obstruction.

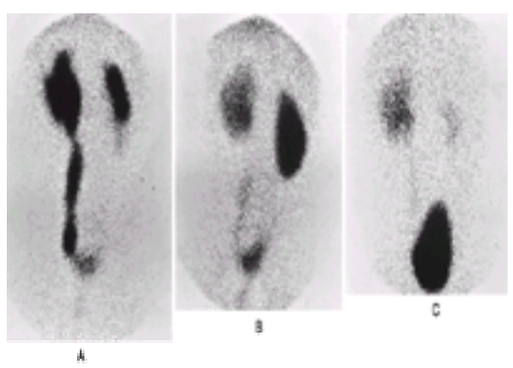

FIGURE 3G.15. Boy, 5 years old, with dilated, nonobstructed collecting system on the left and a dilated, obstructed collecting system on the right. Furosemide ^{99m}Tc DTPA study. **A:** Posterior image taken at 30 minutes after radionuclide injection, at time of furosemide administration. **B:** Twenty minutes after furosemide administration, the nonobstructed left system has emptied and the obstructed right side has accumulated more. **C:** Postoperative image at 25 minutes after furosemide administration shows resolution of obstructed right system.

Vesicoureteral Reflux

Reflux nephropathy is a recognized problem in the pediatric population, and it is evaluated in the workup of urinary tract infection. It is also recognized in some adults as a cause of hypertension, proteinuria, and renal failure. The traditional study is a voiding cystourethrogram, which can deliver a radiation dose of several hundred millirads to several rads. The retrograde radionuclide cystogram gives a fraction of this radiation dose depending on several factors, including the amount of material instilled and the time the solution remains in the bladder before voiding (8).

The traditional voiding cystourethrogram can categorize reflux into grades of severity by visualizing the morphology of the urinary tracts. The radionuclide grading is determined by the volume in the bladder when reflux occurs and the amount of reflux. The anatomy of the collecting system, as well as the base of the bladder and urethra, cannot be assessed (Fig. 3G.16). However, the residual volume after voiding can be accurately determined.

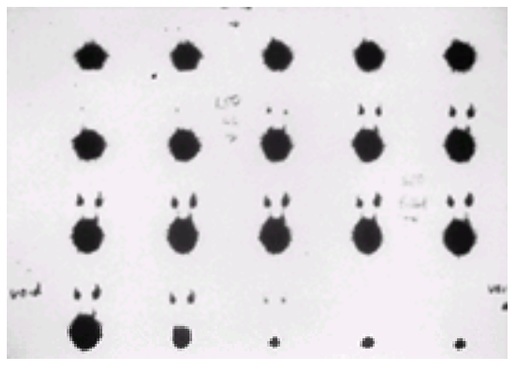

FIGURE 3G.16. Retrograde ^{99m}Tc pertechnetate voiding cystoureterogram demonstrates activity in both ureters and kidneys. The left side refluxes first as the bladder fills, indicating worse reflux. After voiding, activity cleared from the upper tracts.

The quantity of reflux that is significant in a single study is not yet defined. Serial studies can be of value for comparison to determine whether improvement has occurred. Accurate records of the volumes of solution instilled resulting in reflux are important, as is quantitation of reflux by visual and computer analysis. An increased volume instilled before reflux implies improvement (32). More recently, grading of reflux by radionuclide cystography has been correlated with the criteria for grading established by the International Reflux Study Committee (56). Despite the emphasis in the international study on calyceal detail (26), the correlation is stated to be 80% to 100%.

Studies have now shown that kidney infection, associated with reflux, often causes sufficient damage to result in scarring, proteinuria, or hypertension. Sonography and contrast urograms are relatively insensitive for detection of initial damage (13,43). Renal scans and SPECT with ^{99m}Tc DMSA significantly increase the detection rate and are the recommended screening procedures (Fig. 3G.17).

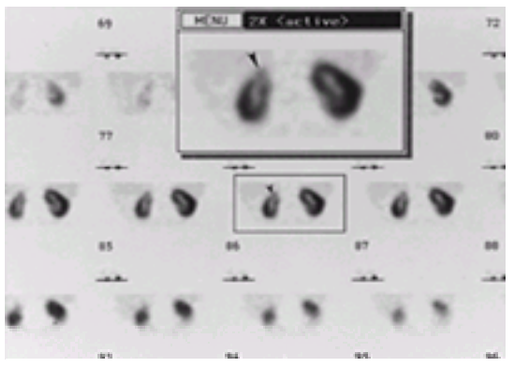

FIGURE 3G.17. Boy, 8 years old, with chronic renal insufficiency and recurrent urinary tract infections. ^{99m}Tc DMSA coronal SPECT images show the right kidney to be smaller than the left kidney with a significant scar in the upper pole *(arrowheads).* The selected image is magnified. This size defect is often difficult to demonstrate on planar views.

Renovascular Abnormalities

Renal artery stenosis not only plays a role in hypertension but also is a potentially treatable cause of renal failure. In most patients, renal damage has already occurred. Damage can cause abnormalities on the renal images that resemble other diseases, making the results nonspecific. However, this test can still be valuable in following patients with documented renal artery stenosis.

As with renal artery embolism, dynamic radioisotope scanning with technetium compounds is preferred (Fig. 3G.18). On the initial flow images, decreased perfusion of the affected kidney is noted along with reduced concentration followed by a prolonged parenchymal transit time. The sensitivity is 60% to 85%. Serial studies can guide in timing for intervention and evaluation of open surgical or angioplastic treatment.

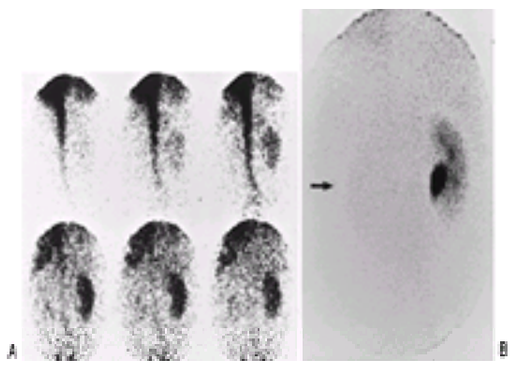

FIGURE 3G.18. Man, 65 years old, with sudden onset of left flank pain and hematuria. **A:** ^{99m}Tc glucoheptonate flow study shows good flow to the right kidney and minimal flow to the left. **B:** Delayed view demonstrates minimal left renal uptake *(arrow);* the right kidney appears normal. The combination of significantly decreased flow to the entire left kidney and delayed uptake is compatible with left renal artery embolus.

Some centers prefer hippurate scanning to evaluate unilateral renovascular disease. Emphasis is on observing differences in the time interval between injection and peak activity (transit time) and on the symmetry of the downslope of the third phase on the renogram curve. The affected kidney will show a prolonged transit time and a slower decline in the excretory phase. A difference of 20% or more in these parameters is generally considered the criterion for positive diagnosis. Accuracy from 87% to 96% has been claimed (34). Analysis of ERPF and fractionation of renal function allow measurement of individual renal flow (Fig. 3G.19).

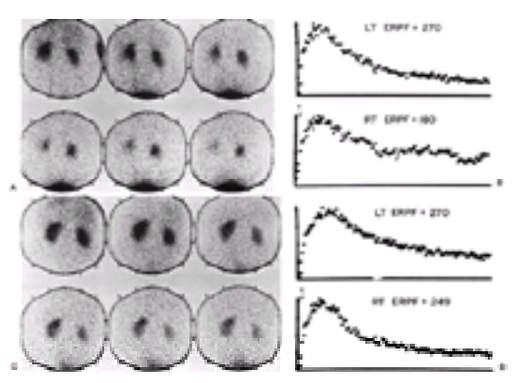

FIGURE 3G.19. Angioplasty of renal artery. **A, B:** Preangioplasty for right renal artery stenosis. ^{131}I hippurate scan shows delayed clearance of the right kidney on the static views and the renogram curve. The effective renal plasma flow (ERPF) was diminished on the right (180 mL per minute) compared with the left. **C, D:** Postangioplasty there was improvement in clearance of the right kidney and the ERPF on the right increased to 249 mL per minute.

Recent studies have shown that the specific effects of angiotensin-converting enzyme inhibitors (captopril) on renal function add both sensitivity and specificity to the

radiorenogram. Various authors have advocated using ^{99m}Tc DTPA, ^{99m}Tc MAG_3, or ^{131}I hippurate. Although success has been obtained with all three tracers, the theoretical reasons for using an enzyme inhibitor would seem to favor the use of DTPA. In part, the lack of optimal sensitivity of radiorenograms is due to the intrarenal compensation for a decrease in renal perfusion pressure distal to a stenotic renal artery. It has been demonstrated that the release of renin and subsequent formation of angiotensin II cause a selective vasoconstriction in the efferent renal arterioles, thus maintaining glomerular filtration pressure. Only when the renal artery stenosis becomes more severe is this compensation inadequate to maintain renal function. Recent studies have shown that comparing renal excretion of ^{99m}Tc DTPA, ^{99m}Tc MAG_3, or ^{131}I hippurate before and after oral administration of 25 to 50 mg of captopril improves the sensitivity of the renogram from 60% to more than 90% (Fig. 3G.20). In addition, there is increased specificity because a lack of response indicates that the compensation mechanism is inoperative (17). Although blockage of the converting enzyme affects the renograms performed with hippurate, MAG_3, and DTPA, the use of the latter agent would seem to be preferred because it is excreted by only glomerular filtration, the physiologic process most affected when compensatory efferent arteriolar vasoconstriction is blocked. However, studies have shown excellent results with MAG_3 (12,15,36).

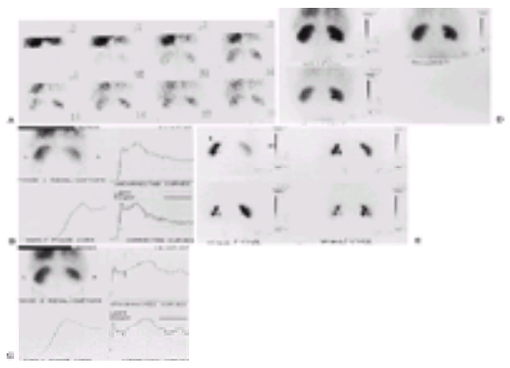

FIGURE 3G.20. Boy, 17 years old, with recent-onset hypertension. Angiographic studies later confirmed 90% stenosis of right renal artery. The vascular sequence **(A)** showed flow reduced somewhat on the right (57% left, 43% right). Baseline ^{99m}Tc DTPA images showed 60% of glomerular filtration rate on the left and 40% on the right. The images suggest slower emptying of the calyces and pelvis on the right **(B).** Renogram curves show the right curve (dark) smaller than the left (light) on both uncorrected and background-corrected graphs **(C).** However, the reduced flow and function could be caused by a small kidney, not necessarily renal artery stenosis. The repeat DTPA study after 25 mg captopril orally **(D, E)** shows further decrease in function on the right (36%) with delayed washout of activity. This adverse response to the converting enzyme is highly suggestive that arterial stenosis with renin release is a causative factor in the hypertension.

Renal vein thrombosis is an uncommon entity that can be imaged with radionuclides. Technetium compounds are preferable because flow studies and detailed static views can be obtained. Typically, in renal vein thrombosis, the involved kidney is enlarged, with decreased flow and poor, delayed uptake (Fig. 3G.21).

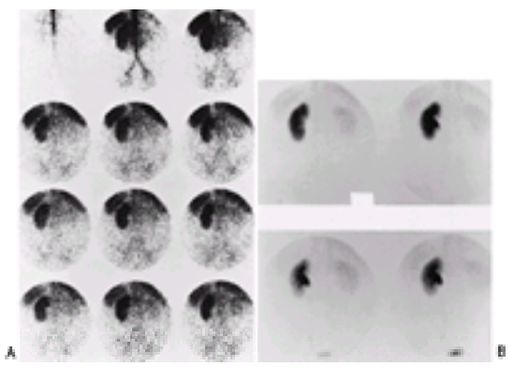

FIGURE 3G.21. Man, 27 years old, developed hematuria after retroperitoneal resection for testicular cancer. ^{99m} Tc glucoheptonate study. **A:** Renal flow study shows poor flow to right kidney. **B:** Static images at 5-minute intervals postinjection show poor right renal uptake. The combination of asymmetric poor flow along with poor function implies renal vein thrombosis. However, usually the involved kidney is also enlarged.

Transplant Evaluation

Radionuclide imaging is a routine part of the assessment of renal function following renal transplant. Our technique involves injection of the patient with ^{99m}Tc MAG_3. Routine images are taken in the anterior position as previously described because of the kidney's position. Computer analysis produces the renogram curves. We look at the total transplant counts, shape of the renogram curve, bladder-to-kidney count ratio at 30 minutes, and static views. Total transplant counts are helpful to compare in serial studies; we have no absolute value for determination of function based on one individual scan. Estimation of renal function with the Gates technique is more quantitative (18).

The bladder-to-kidney ratio is determined by drawing regions of interest around the kidney and the bladder and obtaining total counts at a specific time (23). The normal ratio at 30 minutes is 3:1 to 5:1 with hippurate, but it can be up to 10:1 or more with MAG_3. For this parameter to be useful, the Foley catheter must be clamped, which cannot usually be done until after the first week. Also, native kidneys may still have some function and falsely imply good transplant function.

In the early postoperative period (up to 4 weeks), serial radionuclide scanning and sonography are helpful in following renal function and determining the cause of oliguria or anuria. Total absence of flow and function, along with a photopenic area on the static images, can be caused by renal artery or vein thrombosis, hyperacute rejection, or severe urinary obstruction. Obstruction can usually be diagnosed by ultrasound; however, nonobstructed dilation of the collecting system can occasionally occur after transplantation. Diuretic renography may be helpful in differentiating obstruction from nonobstruction if adequate function is present.

Diminished early radionuclide uptake with progressively increasing activity in later views and poor excretion can be seen with ATN, acute rejection, and urinary obstruction. This pattern implies preserved blood flow but decreased concentrating and excreting capability. A kidney with ATN typically can extract hippurate or MAG_3 from the blood but has difficulty transporting it into the tubular lumen (“tubular block”). Cadaver transplants virtually always show an element of ATN in the early postoperative period. Postoperative ATN will resolve without therapy, after 1 day to several weeks.

As the kidney improves after ATN, the total excreted counts will increase and the bladder-to-kidney ratio will improve (Fig. 3G.22). The shape of the curve may not change initially but contains more counts; after further improvement, the curve will start peaking in the first 10 minutes. Any reversal of this sequence or failure of improvement implies rejection. However, other processes, such as infection or renal artery stenosis, also cause a deterioration in renal function. Considerable confusion has been added to this evaluation in recent years because of the toxicity of the immunosuppressive agent cyclosporine. Unfortunately, by usual techniques it is not possible to differentiate between cyclosporine toxicity and rejection. After 6 months, a renogram is of little value unless serial studies are maintained; serial laboratory values (creatinine and blood urea nitrogen [BUN]) are more pertinent and economical.

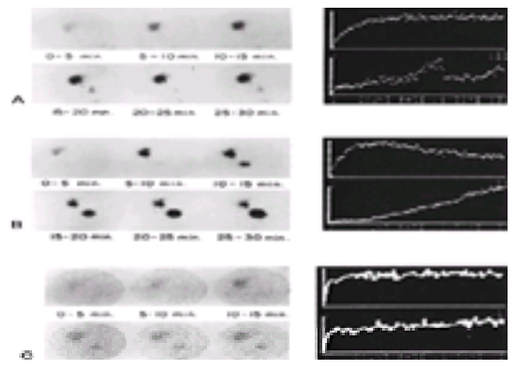

FIGURE 3G.22. Man, 54 years old, with end-stage renal disease who received a cadaver transplant kidney in the right iliac fossa. A series of renograms was performed using 200 mCi of ^{131}I hippurate. **A:** Baseline study 24 hours after transplantation. Sequential camera images *(left)* show progressive accumulation of activity in kidney with transport to urinary bladder. The renogram curves *(right)* reflect progressive kidney accumulation, the plateau occurring after approximately 10 minutes as the tracer emptied into the urinary bladder. The lower curve, from the urinary bladder, shows intermittent emptying because the Foley catheter was not clamped. **B:** The transplant function gradually improved as the acute tubular necrosis cleared. On this study performed 6 weeks after transplantation, the renogram curve *(above)* shows a peak at approximately 8 minutes with a gradual fall in count rate during phase III. Tracer gradually accumulated in the bladder, with a bladder-to-kidney ratio of 2.8:1 at 30 minutes. **C:** Repeat study at 3 months after transplantation. Serum creatinine levels were increased with significant deterioration in renal function. Note the very flat renogram curve *(above)* and minimal accumulation of activity in the urinary bladder. Not only has the bladder-to-kidney ratio deteriorated to 0.6:1, but the total excreted activity in the kidney and bladder fell to approximately 25% of prior values. The patient underwent therapy for rejection with a subsequent improvement in renal function.

Leaks may develop at the ureterovesical anastomosis, at the cystotomy site, or from a renal biopsy site (Fig. 3G.23). These can be well demonstrated by collection of the radionuclide outside of the urinary tract. Hematomas or lymphoceles (Fig. 3G.24) appear as photondeficient areas around the kidney or between the kidney and bladder.

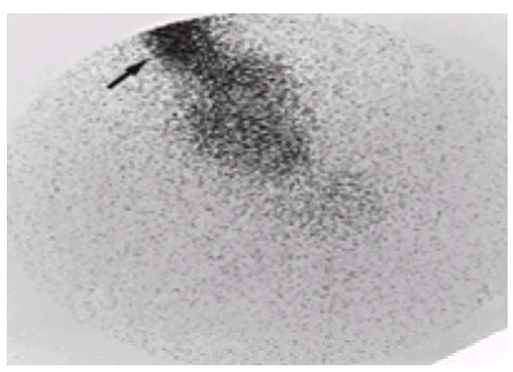

FIGURE 3G.23. Man, 24 years old, 3 weeks after a cadaver transplant. ^{131}I hippurate study shows extravasation of radionuclide at the superior margin of the transplant *(arrow)* representing a urinary anastomotic leak.

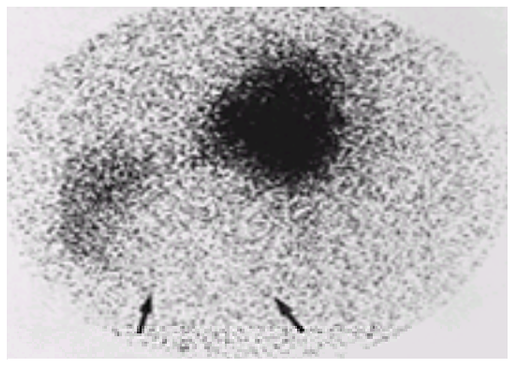

FIGURE 3G.24. Man, 42 years old, developed nephrotic syndrome after transplant. ^{131}I hippurate study shows large photopenic area *(arrows)* compressing the left lateral aspect of the bladder, which proved to be a lymphocele obstructing urinary excretion.

Some centers use technetium compounds to evaluate renal transplants, including evaluation of renal blood flow dynamically. In the normally perfused transplant, activity on the flow or dynamic images should do the following:

1. Appear in the graft within 6 seconds of its appearance in the adjacent iliac artery
2. Obtain maximum activity per unit area equal to or greater than that in the adjacent artery
3. Clearly fall after the peak

Renal blood flow is usually preserved in ATN but deteriorates in rejection. The evaluation of the static views is similar to that of the hippurate images. We have found the MAG_3 renogram to be better than that from hippurate or DTPA alone.

Other agents used include ^{99m}Tc sulfur colloid, gallium citrate Ga-67, and labeled platelets. Although such studies may be useful, they are not routine and are beyond the scope of this chapter.

Congenital Anomalies

Congenital anomalies such as horseshoe kidney (Fig. 3G.25), crossed fused ectopia, and ectopic kidneys are easily demonstrated by radionuclide scanning. ^{99m}Tc DTPA and MAG_3 are the agents of choice.

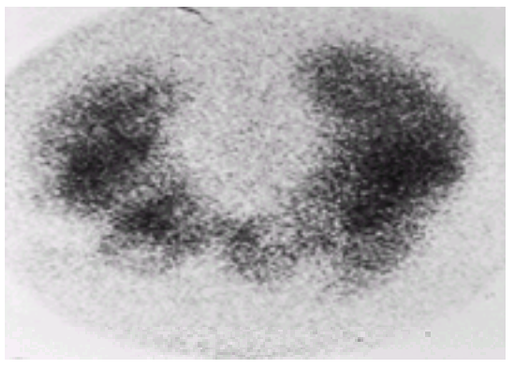

FIGURE 3G.25. Boy, 8 years old, with recurrent urinary tract infections. ^{99m}Tc iron hydroxide DTPA study demonstrates a horseshoe kidney. This anterior view shows the bridging tissue better than a posterior view.

A renal mass in the infant or child should first be evaluated by ultrasound. A solid mass should then be studied by CT. A cystic mass can be either a multicystic dysplastic kidney or hydronephrosis, which can sometimes be difficult to differentiate sonographically. A MAG $_3$ scan is the next recommended study. Nonvisualization of the corresponding kidney on early and delayed views confirms dysplasia (Fig. 3G.26). However, delayed films may show some activity secondary to a small amount of residual functioning tissue, which is usually irregularly located in a photopenic mass. A more uniform cortical rim sign with gradual filling of the central collecting system is typical of hydronephrosis. The time of appearance of these features during the scanning period depends on the severity of obstruction.

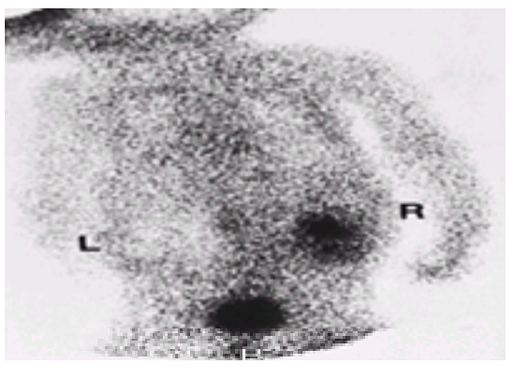

FIGURE 3G.26. Boy, 3 days old, with cystic left kidney on ultrasound. ^{99m}Tc glucoheptonate study demonstrates a normal right kidney and a photon-deficient area in the region of the left kidney that remained photopenic, compatible with a multicystic kidney. Bladder activity *(B)* was evident on this delayed static image.

TRAUMA

The excretory urogram and CT are the traditional modes of initial evaluation of the kidneys in the trauma setting. Many reports have shown the sensitivity of radionuclide image for detection of extent of damage and the evaluation of renal function. However, we advocate CT scanning for initial evaluation because other organs and the retroperitoneum can be evaluated simultaneously. Nuclear imaging can be valuable in following renal function after trauma.

The agent of choice is ^{99m}Tc MAG$_3$ or DTPA, because blood flow to the kidneys can be rapidly evaluated. If there is no immediate blood flow to either kidney on the flow study or initial static images, immediate angiography or surgical exploration may be necessary. Extravasation and obstruction can also be detected by scanning.

Scrotal Imaging

Scrotal imaging provides an accurate means of distinguishing between the most common causes of “acute” scrotum: epididymitis and testicular torsion. Less common causes include hydroceles and testicular tumors.

In classic acute epididymitis, hyperemia occurs in the head, body, and tail of the epididymis. The radionuclide angiogram shows significantly increased perfusion through the spermatic cord vessels. On the static views, increased tracer activity usually extends laterally, corresponding to the location of the epididymis (Fig. 3G.27).

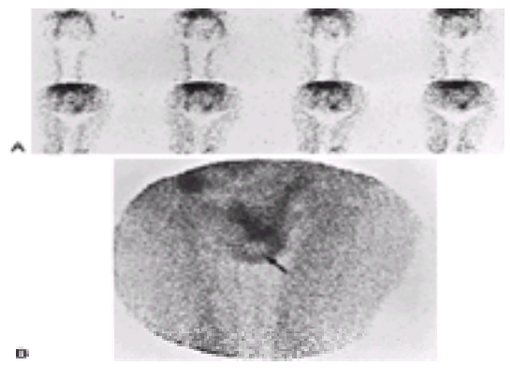

FIGURE 3G.27. Boy, 11 years old, with left testicular swelling. **A:** ^{99m}Tc pertechnetate flow study shows increased blood flow to the left epididymis. **B:** Increased activity along the lateral aspect of the left scrotum on the static views is present, compatible with epididymitis. The right scrotum *(arrow)* contained a hydrocele, causing the photopenic appearance. The differentiation between a photopenic and ischemic testicle and a hydrocele is easy after physical examination and transillumination.

If the inflammatory process spreads to the testis, it is termed *epididymo-orchitis.* The radionuclide activity then extends also medially to involve the testis. Extensive scrotal swelling or rotation of the scrotum in positioning may produce medial activity in the absence of testicular involvement.

If the inflammation is confined to a small area of the epididymis, focal hyperemia occurs only in the infected part, and the radionuclide angiogram may often show “normal,” barely perceptible activity. Later images may show a focal “spot” of increased activity.

Torsion of the spermatic cord has been described as displaying four radionuclide patterns (25). The first is seen if spontaneous detorsion occurs within 4 hours after torsion, which usually results in a normal scan. Occasionally, mild hyperemia is present throughout the entire hemiscrotum.

In early testicular torsion of less than 7 hours' duration, the testicle is often viable. The radionuclide angiogram shows no increase of perfusion through the vessels or to the scrotum. The scrotal scans demonstrate a cold area in the location of the testicle. In this second pattern, minimal, if any, activity is seen in the dartos, making

the cold area often difficult to see.

Midphase testicular torsion occurs approximately 7 to 24 hours after torsion, when the testicle may still be viable. A reactive edema and erythema are present, resulting in increased activity in the scrotal region. This results in a halo of activity around the cold testicle (Fig. 3G.28), the third pattern.

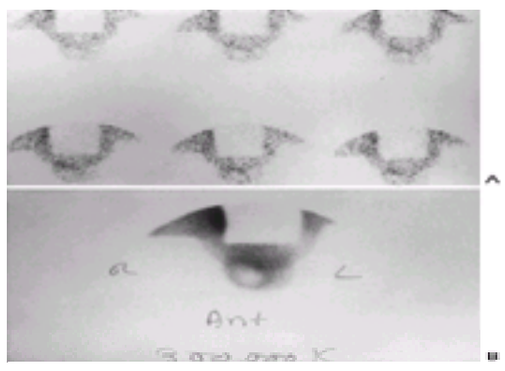

FIGURE 3G.28. Midphase testicular torsion. **A:** Flow study shows no hypervascularity but a developing focal area of increased uptake along the superior aspect of the right testis on later views. **B:** Delayed view shows photopenic area of right testis with surrounding increased uptake along all borders. Because the shield obscured the spermatic vessels, we no longer advocate its use.

The final pattern of “missed testicular torsion” occurs usually more than 24 hours after torsion. The testicle may still be viable if the twist is less than 360 degrees. The radionuclide angiogram will often show dartos perfusion. An intense halo of activity with a cold center is present and occasionally increased activity in the region of the spermatic cord. A testicular abscess can have a similar pattern. This symmetric halo should not be confused with the asymmetric curvilinear activity in epididymitis.

A hydrocele is a collection of fluid between the layers of the tunica vaginalis. It may be primary or secondary to epididymitis, testicular torsion, tumor, trauma, or posthernia repair. On the radionuclide angiogram, the perfusion is normal or a reflection of the underlying cause. The scrotal scan demonstrates a lucency around the central nidus of testicular tissue.

Radionuclide scanning of testicular tumors is usually performed to exclude other causes of the pain and swelling. The radionuclide angiogram may show normal or moderately increased perfusion. If increased, the scrotal perfusion is diffuse rather than linear or halolike. A cool area may represent a focal area of central necrosis or relative tissue avascularity (25).

EVALUATION OF PROSTATE CANCER

Adenocarcinoma of the prostate is the most commonly diagnosed malignancy in men. As in the case of all malignancies, appropriate therapeutic intervention requires accurate staging. Clinical examination, serum prostate-specific antigen (PSA) level, Gleason score, and imaging modalities such as bone scintigraphy, CT, and magnetic resonance imaging (MRI) are used for staging prostate carcinoma. However, the sensitivity of CT and MRI is poor in detecting lymph node metastases (52). A monoclonal antibody (Capromab pendetide) that reacts with prostate-specific membrane antigen (PSMA) has been commercially available for imaging prostate carcinoma for several years. PSMA is a glycoprotein produced by both the benign and malignant epithelial cells of the prostate gland. Capromab pendetide is a murine immunoglobulin (IgG_1) that is radiolabeled with indium-111 and reacts with more than 95% of prostate carcinomas (21). It is available for injection in a kit form (10). In-111 chloride is used for radiolabeling. After IV injection, Capromab pendetide is slowly cleared from the bloodstream. It is eliminated via the kidneys and by the gastrointestinal tract.

The incidence of adverse events following the antibody infusion is low (4%). The incidence of human antimurine antibody (HAMA) titers greater than 8 ng/mL after a single IV injection is reported to be 8%. The FDA has approved it for single injection. The incidence of HAMA levels greater than 8 ng/mL after repeated injections is reported to be 19%, but the incidence of adverse reactions is only 5%, with altered biodistribution present in 7% (21,31).

Anterior and posterior imaging of the chest, abdomen, and pelvis is performed at 72 to 96 hours. On a normal scintiscan, activity is seen in the liver, kidneys, bone marrow, urinary bladder, and bowel. Occasionally, significant bowel activity can cause interference with image interpretation, and a laxative 24 hours before imaging is routinely used. Sometimes, additional delayed imaging at 96 to 120 hours is necessary. Planar imaging is followed by SPECT imaging of the pelvis and abdomen (Fig. 3G.29). We recommend simultaneous blood pool imaging with ^{99m}Tc-labeled RBCs at 72 to 96 hours to provide an outline of the blood vessels and improve the specificity (29). Image coregistration with pelvic CT using blood vessels as anatomic landmarks is technically feasible and improves specificity (20). Some authors use a subtraction analysis software that subtracts the ^{99m}Tc-RBC data set from the In-111 data set to allow easier identification of the metastatic sites (39).

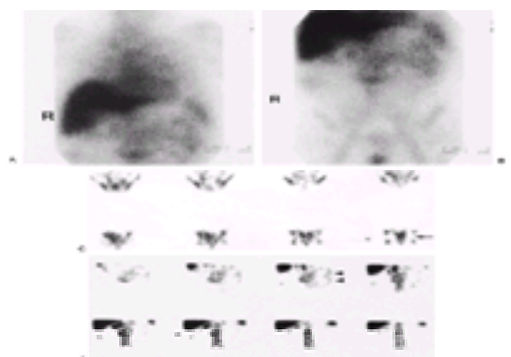

FIGURE 3G.29. Man, 65 years old, with newly diagnosed prostate cancer. **A:** Anterior planar image of the chest and abdomen was obtained 96 hours after the injection of In-111 Capromab pendetide. Uptake is seen in the blood pool of the heart, liver, and bowel. **B:** Anterior planar image of the abdomen and pelvis shows uptake in the iliac vessels, bowel, and bone marrow. **C:** Transverse SPECT images of the pelvis show uptake in the prostate *(arrow),* consistent with carcinoma. **D:** Coronal SPECT images of the abdomen (day 5) show uptake in the bowel *(arrowheads),* as well as focal uptake in the midline suggestive of periaortic lymph nodes.

Altered biodistribution manifested by intense liver, bone marrow, and urinary bladder uptake is sometimes seen. The etiology for this phenomenon is unknown, but it decreases the sensitivity of the test. Accumulation of the antibody is seen in areas of inflammation such as arthritis, fractures, surgical incision sites, and reactive lymph nodes. Accumulation in Paget's disease of the bone and necrotic tumors has also been reported (21).

Since the availability of this antibody, many clinical studies have been performed. It is useful in patients with new diagnosis of prostate carcinoma who are at high risk for metastatic disease and in patients with elevated PSA after radical prostatectomy.

Hinkle and colleagues (24), in a multicenter trial, studied 51 patients with prostate carcinoma at high risk for metastases with the antibody scan. All of the patients underwent prostatectomy and open pelvic lymphadenectomy. They reported the sensitivity and specificity for detecting extraprostatic disease as 75% and 86%, respectively. The accuracy and positive predictive value was 81% and 79%, respectively. A study by Burgers and co-workers (6) also compared the imaging findings on the antibody scan with CT or MRI and surgery. They reported an accuracy of 92% for detecting prostate cancer and 81% for extraprostatic lesions with the

antibody imaging compared with an accuracy of 53% and 48% with other imaging modalities such as CT or MRI. They also reported “skip metastases” in two patients at the level of aortic bifurcation. These patients had negative pelvic lymph nodes at surgery (6). Although these statistics are better than CT or MRI, the results vary considerably. Babaian and colleagues (2) reported a sensitivity and specificity of 44% and 86%, respectively, in a study of 19 patients undergoing pelvic lymph node dissection. However, all of these studies were reported before the use of ^{99m}Tc-RBC blood pool imaging.

In 181 patients with recurrent prostate cancer after radical prostatectomy and rising PSA, antibody imaging was performed to evaluate local recurrence and distant metastases (27). All patients had prostatic fossa biopsied. Immunoscintigraphy showed disease in 60% of patients, with localization more frequently to the prostatic fossa (34%). Extraprostatic localization was seen in 42%. Abdominal lymph nodes showed localization in 23% and pelvic lymph nodes in 22% of the patients. Only 50% of the patients with positive scans in the prostatic fossa had the finding confirmed by biopsy. The overall sensitivity was 49%, specificity 71%, positive predictive value 50%, and negative predictive value 70%. The investigators concluded that single biopsy of the prostatic fossa is insensitive because of the sampling error involved. The accuracy for detecting distant metastases was not evaluated by this study because the extraprostatic sites of antibody localization were not confirmed by other conventional imaging modalities or biopsies in this study (27).

Thirty-two patients with failed radical prostatectomy were evaluated with the antibody scan (28). After pelvic radiotherapy, these patients were followed for 13 months. Seventy percent of patients with antibody localization only to the prostate bed had a durable complete response; 22% had a positive extraprostatic and extrapelvic localization (28).

Haseman and colleagues (22) imaged 14 patients with elevated PSA with Capromab pendetide imaging and F-18 fluorodeoxyglucose (FDG) positron emission tomography (PET) imaging. All patients had biopsies of the prostatic fossa. In the limited number of patients studied, antibody scan was superior to PET imaging in the detection of both local recurrence and lymph node metastases (22). However, more studies are needed to confirm this finding.

Antibody imaging with Capromab pendetide is used for patients with a new diagnosis of prostate cancer and high risk of metastatic disease and in patients with failed radical prostatectomy. Capromab pendetide imaging is challenging, and experience, along with dual isotope imaging with ^{99m}Tc-RBC labeling, is of great help.

Urinary tract infections are common, affect men and women of all ages, and vary dramatically in their presentation and sequelae. Although the urinary tract is normally free of bacterial growth, bacteria that generally ascend from the rectal reservoir may cause urinary tract infections. When bacterial virulence increases or host defense mechanisms decrease, bacterial inoculation, colonization, and infection of the urinary tract occur. Clinical manifestations can vary from asymptomatic bacterial colonization of the bladder to irritative voiding symptoms associated with bacterial infection, upper tract infections associated with fever and chills, and bacteremia associated with severe morbidity, including sepsis and death. The clinical challenges are (a) to identify patients at risk; (b) to prevent or minimize infections by reducing factors that increase the risk of infection; (c) to accurately and efficiently diagnose infections; and (d) to provide prompt, effective, and safe therapy in a cost-effective manner. This chapter defines various types of infection and reviews the epidemiology and bacterial and host factors instrumental in urinary tract infections. The clinical manifestations and diagnostic techniques used to identify the site and severity of infection are then discussed. Pertinent antimicrobial agents and their use are reviewed. Common clinical scenarios are discussed, beginning with the clinical and laboratory findings, the differential diagnoses, and sequential management steps necessary to achieve satisfactory results.

DEFINITIONS

Urinary tract infection is an inflammatory response of the urothelium to bacterial invasion. *Bacteriuria* is a commonly used term that means bacteria in the urine. It has been assumed to be a valid indicator of either bacterial colonization or bacterial infection of the urinary tract. Although this is usually true, studies in animals (153,232) and humans (75) have indicated that bacteria may colonize the urothelium without causing bacteriuria. *Pyuria,* the presence of white blood cells (WBCs) in the urine, is generally indicative of infection and a significant inflammatory response of the urothelium to the bacterium. Bacteriuria in the absence of pyuria is generally indicative of bacterial colonization without infection of the urinary tract. Alternatively, bacteriuria may represent bacterial contamination of an abacteriuric specimen during collection. The possibility of contamination increases as the reliability of the collection technique decreases from suprapubic aspiration, to catheterization, to voided specimens. The term *significant bacteriuria* has a clinical connotation and is used to describe the number of bacteria in a suprapubically aspirated, catheterized, or voided specimen that exceeds the number usually caused by bacterial contamination from the skin, the urethra, or the prepuce or introitus, respectively. Hence, it represents a urinary tract infection.

Infections are often defined by their presumed site of origin. *Cystitis* describes a clinical syndrome associated with dysuria, frequency, urgency, and occasionally suprapubic pain. These symptoms, although generally indicative of cystitis, may also be associated with infection of the urethra or vagina or noninfectious conditions such as interstitial cystitis, bladder carcinoma, or calculi. Conversely, patients may be asymptomatic and have infection of the bladder and possibly the upper urinary tract.

The term *bacterial nephritis* should be reserved for interstitial renal inflammation primarily caused by the immediate or late effects of bacterial infection in the renal parenchyma. *Pyelonephritis* refers to bacterial nephritis involving the renal parenchyma and collecting system. *Acute pyelonephritis* refers to a clinical symptom complex or pathologic lesion characterized by fever, chills, and flank pain, or tenderness that is always associated with urinary tract infection. It may, however, have no morphologic or functional components detectable by routine clinical modalities. *Chronic pyelonephritis* describes a shrunken, scarred kidney that can only be

diagnosed when there is postinfectious morphologic, radiologic, or functional evidence of renal disease. However, it need not be associated with urinary tract infection at the time of study.

Acute prostatitis is a febrile urinary tract infection associated with prostate tenderness and swelling and irritative voiding symptoms. *Chronic bacterial prostatitis* is a subtle condition characterized by recurrent relapsing urinary tract infections caused by persistence of the pathogen in the prostatic secretory system between courses of antimicrobial therapy. *Nonbacterial prostatitis* refers to an inflamed prostate without bacterial infection.

Urinary tract infections may also be described in terms of the anatomic or functional status of the urinary tract and the health of the host. Infections occurring in a functionally and anatomically normal urinary tract and a healthy host are considered *uncomplicated* infections. A *complicated* infection is associated with factors that increase the chance for acquiring bacteria and decrease the efficacy of therapy (Table 4.1). The urinary tract is functionally or anatomically abnormal, the host is compromised, or the bacteria have increased virulence. Renal diseases that reduce the concentrating ability of the kidney or neurologic conditions that alter bladder-emptying capabilities are commonly encountered functional abnormalities. Examples of common anatomic abnormalities include obstruction associated with calculi or enlargement of the prostate or congenital or acquired sites of residual urine, such as calyceal or bladder diverticula.

- Functional or anatomic abnormality of urinary tract
- Male gender
- Pregnancy
- Elderly
- Diabetes
- Immunosuppression
- Childhood urinary tract infection
- Recent antimicrobial use
- Indwelling urinary catheter
- Urinary tract instrumentation
- Hospital-acquired infection
- Symptoms for greater than 7 days at presentation

TABLE 4.1. FACTORS THAT SUGGEST COMPLICATED URINARY TRACT INFECTION

Infections may be defined by their relationship to other urinary tract infections. A *first* or *isolated infection* is one that occurs in an individual who has never had a urinary tract infection or has one remote from a previous urinary tract infection. An *unresolved infection* is one that has not responded to antimicrobial therapy. A *recurrent infection* is one that occurs after documented, successful resolution of an antecedent infection. If the infection is a new event associated with reintroduction of bacteria into the urinary tract from outside, the term *reinfection* is appropriate. If the recurrent infection is due to bacteria reemerging from a focus within the urinary tract, the term *bacterial persistence* or *bacterial relapse* is used. These definitions require careful clinical and bacteriologic assessment and are important because they influence the type and extent of the patient's evaluation and therapy.

The presumed source of bacteria that causes the infection can be used to further define infections. *Domiciliary infections,* or *outpatient-acquired infections,* occur in individuals who are not institutionalized at the time they incur the infection. *Nosocomial infections,* or *health care–associated infections,* occur in individuals who are hospitalized or institutionalized and, often, in those who are catheterized (i.e., catheter-associated nosocomial urinary tract infections). Domiciliary infections are usually caused by common fecal bacteria (i.e., Enterobacteriaceae) and are generally susceptible to most antimicrobial therapy, whereas nosocomial infections are frequently caused by *Pseudomonas* and other more antimicrobial-resistant strains.

EPIDEMIOLOGY

Urinary tract infections are among the most common infectious diseases acquired by humans, affecting more than 7 million people annually in the United States and accounting for substantial morbidity (140). Urinary tract infections affect approximately 30% of women between the ages of 20 and 40, a prevalence 30 times more than in men, and at least half of all women will experience one or more infections during their lifetime (140,190). However, with increasing age, the ratio of women to men with bacteriuria progressively decreases. At least 20% of women and 10% of men older than 65 years of age have bacteriuria (23). Many adults previously had urinary tract infections as children (104). Once a patient has an infection, he or she is likely to develop subsequent infections. Longitudinal studies in young women with symptomatic recurrent infections have shown an overall attack rate of 0.2 infections per month (182). Infections tended to occur in clusters that were followed by remission-free intervals that averaged approximately 1 year. However, most remissions were followed by recurrent urinary tract infection, thus underscoring the importance of genetic factors in the pathogenesis of recurrent urinary tract infections in women.

Risk factors can be compounded. The prevalence of bacteriuria increases with institutionalization or hospitalization and concurrent disease. In a study of women and men older than 68 years of age, Boscia and Kaye (23) found that 24% of functionally impaired nursing home residents had bacteriuria compared with 12% of healthy domiciliary subjects (24). It is well established that in the presence of obstruction, infection stones, or diabetes mellitus, urinary tract infections in adults can lead to progressive renal damage (96). In the absence of these complicating factors, it is difficult to implicate infection in the pathogenesis of severe renal disease in adults.

PATHOGENESIS

Successful invasion of the urinary tract is determined in part by the virulence characteristics of the bacteria, the inoculum size, and the inadequacy of host defense mechanisms. These factors also play a role in determining the ultimate level of colonization and damage to the urinary tract.

Routes of Infection

Ascending Route

Most bacteria enter the urinary tract from the fecal reservoir via ascent through the urethra into the bladder. This route is enhanced in individuals with significant soilage of the perineum with feces, women using spermicidal agents (142), and patients with intermittent or indwelling catheters.

The weight of clinical and experimental evidence strongly suggests that most episodes of pyelonephritis are caused by retrograde ascent of bacteria from the bladder through the ureter to the renal pelvis and parenchyma. Although cystitis is often restricted to the bladder, in approximately 50% of instances, there is further extension of the infection into the upper urinary tract (32). Although reflux of urine is probably not required for ascending infections, edema associated with cystitis may cause sufficient changes in the ureterovesical junction to permit reflux. Once the bacteria are introduced into the ureter, they may ascend to the kidney unaided. However, this ascent would be greatly increased by any process that interferes with the normal ureteral peristaltic function. Gram-negative bacteria and their endotoxins, as well as pregnancy and ureteral obstruction, have a significant antiperistaltic effect.

Bacteria that reach the renal pelvis can enter the renal parenchyma by means of the collecting ducts at the papillary tips and then ascend upward within the collecting tubules. This process is hastened and exacerbated by increased intrapelvic pressure from ureteral obstruction or vesicoureteral reflux, particularly when it is associated with intrarenal reflux.

Hematogenous Route

Infection of the kidney by the hematogenous route is uncommon in normal individuals. However, the kidney is occasionally secondarily infected in patients with *Staphylococcus aureus* bacteremia from oral sites or with *Candida fungemia.* Experimental data indicate that infection is enhanced when the kidney is obstructed (322).

Lymphatic Route

Direct extension of bacteria from the adjacent organs via lymphatics may occur in unusual circumstances, such as a severe bowel infection or retroperitoneal abscesses. There is little evidence that lymphatic routes play a significant role in the vast majority of urinary tract infections.

Urinary Pathogens

Most urinary tract infections are caused by facultative anaerobes usually originating in the bowel flora. Uropathogens such as *Staphylococcus epidermidis* and *Candida albicans* originate in the flora of the vagina or perineal skin.

Escherichia coli is by far the most common cause of urinary tract infections, accounting for 85% of community-acquired and 50% of hospital-acquired infections. Other Gram-negative Enterobacteriaceae, including *Proteus* and *Klebsiella,* and Gram-positive *Enterococcus faecalis* and *Staphylococcus saprophyticus* are responsible for the remainder of most community-acquired infections. Nosocomial infections are caused by *E. coli, Klebsiella, Enterobacter, Citrobacter, Serratia, Pseudomonas aeruginosa, Providencia, Enterococcus faecalis,* and *S. epidermidis* (175). Less common organisms such as *Gardnerella vaginalis, Mycoplasma* species, and *Ureaplasma urealyticum* may infect patients with intermittent or indwelling catheters (81,167).

The prevalence of infecting organisms is influenced by the patient's age. For example, *S. saprophyticus* is now recognized as causing approximately 10% of symptomatic lower urinary tract infections in young, sexually active females (192), whereas it rarely causes infection in males and elderly individuals. A seasonal variation with a late summer to fall peak has been reported (148).

Virulence characteristics play a role in both selecting the organism that will invade the urinary tract and determining its level of infection within the urinary tract. It is generally believed that uropathogenic strains, such as *E. coli,* are selected from fecal flora not by chance but rather by the presence of virulence factors that enable them to adhere to and colonize the perineum and urethra and migrate to the urinary tract where they establish an inflammatory response in the urothelium (298,399). Subsequently, other virulence factors that play a role in the persistence and expansion of infection include resistance to serum bactericidal activity (21), hemolysin (150), and aerobactin (164). Half of all second urinary tract infections are caused by the same strain that causes the first and has identical virulence factors (94).

Bacterial Adherence in the Pathogenesis of Urinary Tract Infections

It is well established that bacterial adherence to epithelial cells is an essential early step in the initiation of urinary tract infections. This interaction is influenced by the adhesive characteristics of the bacteria, the receptive characteristics of the epithelial surface, and the fluid bathing both surfaces. Bacterial adherence is a specific interaction that plays a role in selecting the organism, the host, and the site of infection. Portions of this section on bacterial adherence have been published (298).

Bacterial Adhesins

The bacterial cell structures that seem to be most important in binding the bacteria to epithelial cells are long filamentous protein appendages called pili, or fimbriae (Fig. 4.1). Bacteria may produce a number of antigenically and functionally different pili on the same cell; others produce a single type; and in some, no pili are seen (179). A typical piliated cell may contain 100 to 400 pili. These supramolecular structures are usually 5 to 10 nm in diameter, up to 2 μm long, and appear to be composed primarily of subunits known as pilin, which have molecular weights of 17 to 27 kDa, depending on the type of pili (179). *Pili* are defined functionally by their ability to mediate hemagglutination (HA) of specific types of erythrocytes. The most well-described pili are type 1 and P pili. Type 1 pili are commonly expressed on both nonpathogenic and pathogenic *E. coli* and appear to facilitate bacterial colonization of the vaginal mucosa and bladder. These pili mediate HA of guinea pig erythrocytes (67). The reaction is inhibited by the addition of mannose; thus type 1 pili are termed *mannose-sensitive HA* (MSHA) (275,357). P pili have receptors that adhere to a-D-Galp-(1-4)b-D-Galp belonging to the globoseries of glycolipids (168,196), which are found on P blood group antigens and in uroepithelium (356). Adherence of P-piliated strains to human red blood cells is not inhibited by mannose; hence, P pili are termed *mannose-resistant HA* (MRHA) (169,275,357).

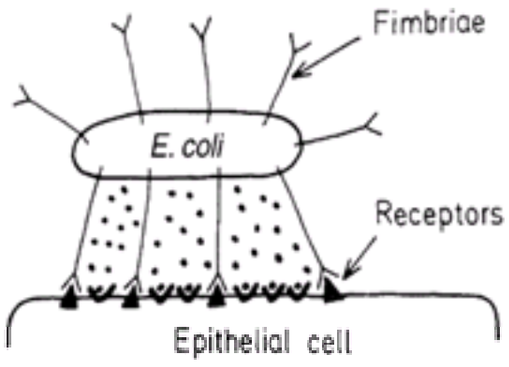

FIGURE 4.1. Bacterial adherence. Adhesins on pili mediate attachment to specific epithelial cell receptors. (Reprinted with permission from Schaeffer AJ. The role of bacterial adherence in urinary tract infection. *AUA Update Series* 1989;8:18.)

Bacterial pili are subject to rapid phase variation *in vitro* and *in vivo* wherein bacteria revert between states of expression and nonexpression of pili. For example, some bacteria grown in a broth medium express pili, whereas the same strain grown on the same medium in a solid state will cease production of pili. Occurrence of phase variation may contribute to the pathogenesis of infections (72,154).

Evidence for the role of type 1 and P pili in urinary tract infection has been established by *in vitro* and *in vivo* studies. Svanborg Eden and associates (355) were the first to report a correlation between bacterial adherence *in vitro* and severity of urinary tract infections. They showed that *E. coli* strains from girls with acute pyelonephritis had high adhesive ability, whereas strains from girls with asymptomatic bacteriuria or normal feces had low bacterial adherence. Between 70% and 80% of the pyelonephrogenic strains had adhesive capacity, but only 10% of the fecal isolates adhered. This association is not observed in individuals with abnormal urinary tracts. Lomberg and colleagues (200), for example, showed that in girls, recurrent pyelonephritis with gross reflux (in which most of the scarring historically occurs) was minimally associated with P-piliated *E. coli* strains.

Type 1 pili consist of a helical rod composed of repeating Fim A subunits joined to a 3-nm wide distal tip structure containing the adhesin Fim H (165). Binding of the Fim H adhesin to mannosylated host receptors present on the urothelium is critical to the ability of *E. coli* to colonize the bladder and cause cystitis (52,190,360). Animal studies showed that *E. coli* expressing type 1 pili, but not those not expressing pili, can cause urinary tract infections (159). Furthermore, anti–type 1 pili antibodies and competitive inhibitors protected animals from experimental urinary tract infections (7,153).

An animal model of ascending urinary tract infections and studies of isolates from different sites in patients with urinary tract infection provide evidence that phase variation can occur during *E. coli* urinary tract infection *in vivo.* Type 1 piliated *E. coli* that were capable of phase variation were introduced into the mouse bladder in the piliated phase, and the bacteria recovered from the bladder and urine 24 or more hours after inoculation were tested for piliation. All of the animals had bladder colonization, and 78% of the bacteria recovered showed type 1 piliation. The bacteriologic state of the urine often differed from that of the bladder. The urine was sterile in 59% of the animals with bladder colonization, and the bacteria recovered from the urine were often nonpiliated. Phase variation also occurred over time. When bladder and kidney cultures were examined 1, 3, and 5 days after intravesical inoculation of piliated bacteria, organisms recovered from the bladder remained piliated, whereas organisms recovered from the kidney and urine showed significantly less piliation (297a) (Fig. 4.2).

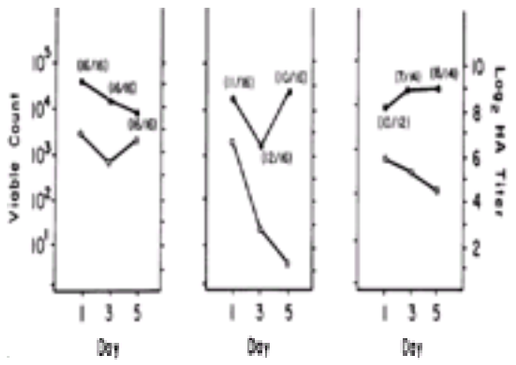

FIGURE 4.2. Time study after intravesical inoculation with strain I-149 that compared the mean viable-bacteria count *(open circle)* and HA titer *(closed circle)* for bladders **(A),** kidneys **(B),** and urine specimens **(C)** from the same animals. Each point is the mean of all the animals tested. The numbers in parentheses show the proportion of animals inoculated that gave positive cultures. The HA titers were tested after 18 hours of growth on agar. The HA titer of bacteria recovered from the kidney decreased significantly by day 5 (P <.001). (Reprinted with permission from Schaeffer AJ, Amundsen SK, Schmidt LN. Adherence of *E. coli* to human urinary tract epithelial cells. *Infect Immun* 1979;24:753.)

Studies in humans using indirect immunofluorescence of fresh urine bacteria have confirmed *in vivo* expression and phase variation of pili. Kisielius and associates (178) analyzed the urine of adults with lower urinary tract infection and detected type 1 pili in 31 of 41 specimens and P pili in 6 of 18 specimens. The piliation status of the bacterial population in the urine was heterogeneous, varying from predominantly piliated to a mixture of piliated and nonpiliated cells (Fig. 4.3). Strains isolated from different sites in the urogenital tract showed variation in the state of piliation. These results demonstrate that *E. coli* type 1 and P pili are expressed and subject to phase variation *in vivo* during acute urinary tract infections.

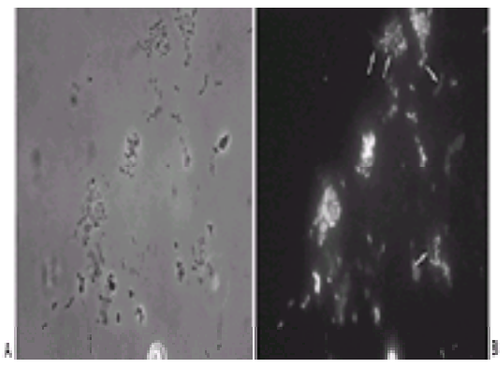

FIGURE 4.3. Phase-contrast micrograph **(A)** and immunofluorescence **(B)** stained with antiserum to type 1 pili of strain I-149 and with fluorescein-5-isothiocyanate (FITC)-conjugated second antibody of nonadherent *E. coli* in the urine of a patient with acute urinary tract infection showing a mixture of piliated and nonpiliated *(arrows)* cells. (Reprinted with permission from Kisielius PV, Schwan WR, Amundsen SK, et al. *In vivo* expression and phase variation of type-1 and P pili by *Escherichia coli* in the urine of adults with acute urinary tract infections. *Infect Immun* 1989;57:1656.)

This process of phase variation has obvious biologic and clinical implications. For example, the presence of type 1 pili may be advantageous to the bacteria for initially adhering to and colonizing the bladder mucosa. Subsequently, type 1 pili may be unnecessary for strains in suspension in urine, and in fact detrimental because they enhance apoptosis, phagocytosis, and killing by neutrophils (232,318). In the kidney, P pili may then take over as the primary mediator of bacterial attachment via their binding to the glycolipid receptors (348).

Epithelial Cell Receptivity

The significance of epithelial cell receptivity in the pathogenesis of ascending urinary tract infection has been studied initially by examining adherence of *E. coli* to vaginal epithelial cells and uroepithelial cells collected from voided urine specimens. Fowler and Stamey (92) established that certain indigenous microorganisms (e.g., lactobacilli, *S. epidermidis*) avidly attached themselves to washed epithelial cells in large numbers. When vaginal epithelial cells were collected from patients susceptible to reinfection and compared with such cells obtained from controls resistant to urinary tract infection, the *E. coli* strains that cause cystitis adhered much more avidly to the epithelial cells from the susceptible women. These studies established increased adherence of pathogenic bacteria to vaginal epithelial cells as the first demonstrable biologic difference that could be shown in women susceptible to urinary tract infection.

Subsequently, Schaeffer and colleagues (298) confirmed these vaginal differences in women, but in addition, they observed that the increased adherence was also characteristic of buccal epithelial cells. As can be seen in Fig. 4.4, there is a striking similarity in the ability of both cell types to bind the same *E. coli* strain. In addition, there was a significant relationship between vaginal cell and buccal cell receptivity. Seventy-seven different *E. coli* strains were tested for their ability to bind to vaginal and buccal epithelial cells. A direct nonlinear relationship between buccal and vaginal adherence in controls and patients was confirmed for urinary, vaginal, and anal isolates. Thus high vaginal cell receptivity was associated with high buccal cell receptivity.

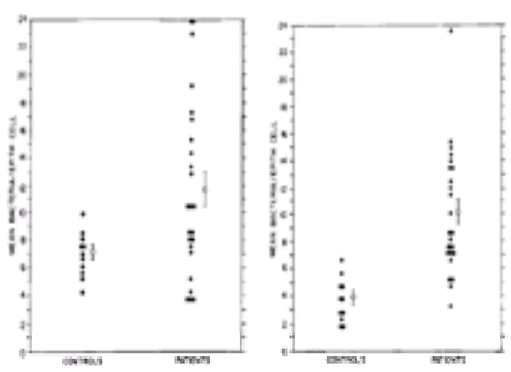

FIGURE 4.4. *In vitro* adherence of *E. coli* to vaginal **(A)** and buccal **(B)** cells from healthy controls and patients with recurrent urinary tract infections. Values represent an average of 14 **(A)** and 11 **(B)** determinations in each individual. The *open circles* and *bars* represent the means plus standard error. (Reprinted with permission from Schaeffer AJ et al. Association of *in vitro Escherichia coli* adherence to vaginal and buccal epithelial cells with susceptibility of women to recurrent urinary-tract infections. *N Engl J Med* 1981;304:1062.)

These observations emphasize that the increase in receptor sites for *E. coli* on epithelial cells from women with recurrent urinary tract infections is not limited to the vagina and thus suggest that a genotypic trait for epithelial cell receptivity may be a major susceptibility factor in urinary tract infections. This concept was extended by examining the human leukocyte antigens (HLAs), which are the major histocompatibility complex in humans and have been associated statistically with many diseases (299). The A3 antigen was identified in 12 (34%) of the patients, a frequency significantly higher than the 8% frequency observed in healthy controls. Thus HLA-A3

may be associated with increased risk of recurrent urinary tract infections.

Bladder urothelial cells deposit on their apical surfaces a quasi-crystalline array of hexagonal complexes made up of four integral membrane glycoproteins known as *uroplakins* (132,353). *In vitro* binding assays have shown that two of the uroplakins, UPIa and UPIb, bind *E. coli* expressing type 1 pili (397). Blood group antigens, carbohydrate structures bound to membrane lipids or proteins, also constitute an important part of the uroepithelial cell membrane. The presence or absence of blood group determinants on the surface of uroepithelial cells may influence an individual's susceptibility to a urinary tract infection. Sheinfeld and associates (313) determined the blood group phenotypes in women with recurrent urinary tract infection and compared them to age-matched women controls. Women with Lewis Le(a-b-) and Le(a+b-) phenotypes had a significantly higher incidence of recurrent urinary tract infections than women with Le(a-b+) phenotypes. There was no significant difference in the distribution of ABO or P blood group phenotypes. The Lewis antigen controls fucosylation. The protective effect in women with the Le(a-b+) phenotype may be due to fucosylated structures at the vaginal cell surface or in the overlying mucus, which decreases availability of putative receptors for *E. coli* (238). In addition, Stapleton and co-workers (349) have shown that unique *E. coli*–binding glycerides are found in vaginal epithelial cells from nonsecretors but not from secretors. These studies individually and collectively support the concept that there is an increased epithelial receptivity for *E. coli* on the introital, urethral, and buccal mucosa that is characteristic of women susceptible to recurrent urinary tract infections and may be a genotypic trait.

Variation in Receptivity

A small variation in both vaginal cell and buccal cell receptivity may be observed from day to day in healthy controls. Adherence ranges from 1 to 17 bacteria per cell and appears to be both cyclic and repetitive. When adherence was correlated with the days of a woman's menstrual cycle, higher values were noted in the early phase, diminishing shortly after the time of expected ovulation (day 14) (Fig. 4.5). The number of bacteria per epithelial cell often correlated with the value obtained on the same day of the menstrual cycle 1 or 2 months previously. Premenopausal women are particularly susceptible to attachment of uropathogenic *E. coli* and nonpathogenic lactobacilli at certain times during the menstrual cycle and to *E. coli* during the early stages of pregnancy. The importance of such hormones as estrogens in the pathogenesis of urinary tract infection is therefore a matter of great interest, especially because the clinical urologist may see women who have recurrent cystitis at regular intervals, possibly in response to these hormonal changes.

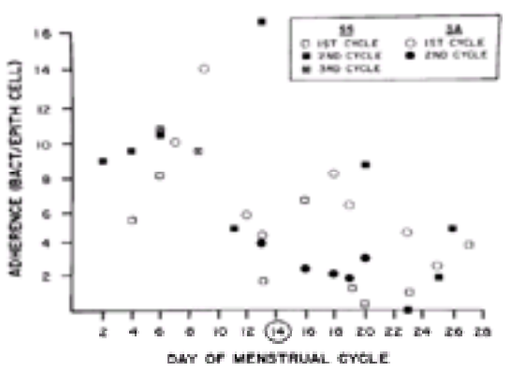

FIGURE 4.5. Relationship between the adherence of *E. coli* and the day of the menstrual cycle on which uroepithelial cells were obtained from two women with no history of urinary tract infections. Adherence was measured on the same day that the cells were collected. (Reprinted with permission from Schaeffer AJ, Amundsen SK, Schmidt LN. Adherence of *E. coli* to human urinary tract epithelial cells. *Infect Immun* 1979;24:753.)

Reid and Sobel (275) found that uropathogens attached in larger numbers to uroepithelial cells from women older than 65 years of age than to cells from premenopausal women 18 to 40 years of age. Raz and Stamm (274) noted that susceptibility to recurrent urinary tract infection was increased by the lowered estrogen levels found in the postmenopausal women and that estrogen replacement decreased uropathogenic bacterial colonization and the incidence of urinary tract infection.

The possibility that vaginal mucus might influence bacterial receptivity was investigated by Schaeffer and colleagues (302). Type 1 piliated *E. coli* bound to all of the vaginal fluid specimens (372). The binding capacity of vaginal fluid from women colonized with *E. coli in vivo* was greater than that from noncolonized women (293). The importance of vaginal fluid in bacteria–epithelial cell interactions was investigated in an *in vitro* model that measured the effect of vaginal fluid on the binding of bacteria to an epithelial cell line (100). Vaginal fluid from colonized women enhanced binding of bacteria to epithelial cells. Conversely, vaginal fluid from noncolonized women inhibited adherence. Thus the vaginal fluid appears to influence adherence to cells and presumably vaginal mucosal colonization. Subsequent studies demonstrated that secretory immunoglobulin A (IgA) is the primary glycoprotein responsible for vaginal fluid receptivity (272).

Natural Defenses of the Urinary Tract

Periurethral and Urethral Region

The normal flora of the vaginal introitus, the periurethral area, and the urethra usually contain microorganisms such as lactobacilli, coagulase-negative staphylococci, corynebacteria, and streptococci that form a barrier against uropathogenic colonization (79,211,263). Changes in the vaginal environment related to estrogen and pH may alter the ability of these bacteria to colonize. More commonly, however, acute changes in colonization have been associated with use of antimicrobial agents and spermicidal agents that alter the normal flora and increase the receptivity of the epithelium for uropathogens. The importance of vaginal colonization with uropathogens is supported by the classic longitudinal observations of Stamey and associates (337) on women who were prone to recurrent urinary tract infections. Episodes of bacteriuria were often preceded by uropathogenic colonization of the vaginal introitus and periurethral areas with bacteria from the fecal flora that subsequently infected the bladder. Between episodes of bacteriuria, women with recurrent urinary tract infections showed a higher prevalence and a greater density of perineal colonization with urinary pathogens than did healthy control subjects (300,330). Other studies have shown reduced titers of cervical IgA (339) and low vaginal pH (336) associated with increased susceptibility to urinary tract infections.

Little is known about the factors that predispose patients to urethral colonization with uropathogens. The proximity of the urethral meatus to the vulvar and perianal areas suggests that contamination occurs frequently. The nature of urethral defense mechanisms other than flow of urine is largely unknown. Bacterial multiplication in the normal urethra may be inhibited by the indigenous flora (42). Although colonization of the periurethral and urethral regions is prerequisite to most infections, the ability of the organisms to overcome the normal defense mechanisms of the urine and the bladder is clearly pivotal.

Urine

In general, fastidious organisms that normally colonize the urethra will not multiply in urine and rarely cause urinary tract infections (40). In contrast, urine will usually support the growth of nonfastidious bacteria (8). Urine from normal individuals may be inhibitory, especially when the inoculum is small (173). The most inhibitory factors are the osmolality, urea concentration, organic acid concentration, and pH. Bacterial growth is inhibited by either very dilute urine or a high osmolality when associated with a low pH. Much of the antibacterial activity of urine is related to a high urea and organic acid content (324). From a clinical perspective, however, these conditions do not appear to significantly distinguish between patients who are susceptible or resistant to infection.

The presence of glucose in the urine may increase infections. This is consistent with the increased frequency and severity of infection in diabetes (8). Urine obtained from pregnant women exhibits a more suitable pH for growth of *E. coli* in all stages of gestation (9). Uromodulin (Tamm-Horsfall protein), a kidney-derived mannosylated protein that is present in an extraordinarily high concentration in the urine (greater than 100 mg/mL), may play a defensive role by saturating all the mannose-binding sites of the type 1 pili, thus potentially blocking bacterial binding to the uroplakin receptors of the urothelium (68,188).

Bladder

Bacteria presumably make their way into the bladder fairly often. Whether small inocula of bacteria persist, multiply, and infect the host depends in part on the ability of the bladder to empty (58). Additional factors responsible for defense include antiadherence mechanisms and antibacterial properties of the bladder mucosa.

Alterations in any or all of these defense mechanisms presumably enhance the ability of bacteria to colonize and infect. The mucopolysaccharides that coat the surface of the uroepithelial cells may modulate receptivity and prevent bacterial attachment. However, damage to the bladder mucus may allow bacteria to gain access to the urothelium.

One consequence of bacterial colonization of the bladder is the exfoliation and excretion of infected and damaged superficial cells. Mulvey and colleagues (232) demonstrated that this process is mediated by type 1 piliated bacteria that induce programmed cell death. However, some bacteria can resist this innate host defense mechanism by invading into deeper tissue. The possibility that these factors may be modified to reduce susceptibility to infection has been explored primarily through immunization in animal and human systems. For example, in a monkey model, vaccination with P fimbria has been shown to reduce adherence of P-fimbriated *E. coli* to uroepithelial cells and prevent acute pyelonephritis (280). Similarly, vaccination of mice with Fim H adhesin prevents cystitis in mice (191). Vaccination in women may reduce colonization of the vaginal introitus and subsequent ascending bacteria (369).

Kidney

The renal medulla and renal papilla have been identified as highly susceptible to infection because of high osmolality, low pH, low blood flow, and a high concentration of ammonia, which is thought to inactivate complement (17). Hyperosmolality of the renal medulla also favors the conversion of bacteria to a cell-wall–deficient state that is resistant to cell-wall–active antimicrobials and may lead to persistent infection despite therapy (118). The cortex, on the other hand, is much more resistant to infection. No natural barrier or defense mechanism against bacterial adherence has been identified in the kidney. Tamm-Horsfall protein may bind bacteria and prevent or diminish adherence and colonization, but its role requires further study.

During pyelonephritis and cystitis, an acute inflammatory response occurs. This response is aimed at limiting bacterial spread and persistence within the kidney. However, the infiltrating phagocytic cells drawn to the infection may also contribute to local tissue damage and result in renal scarring (281).

Immune Mechanisms

The urinary tract is part of the secretory immune system. Most of the human and experimental animal studies have focused on the immune response to bacterial infections of the upper tract and colonization of the vaginal introitus. Kidney infections are accompanied by both serum and local kidney immunoglobulin synthesis and the appearance of type-specific antibodies in the urine. Antibodies in serum against the O antigen and, to a lesser extent, the K antigen of the infecting *E. coli* strain have been found (289). Serum antibodies directed at type 1 and P pili have also been identified after acute pyelonephritis (65,277). In pyelonephritis, IgG and SIgA also appear in the urine and may become evident before antibodies are detected in the serum. These antibodies are synthesized locally within the kidney and may enhance bacterial opsonization and ingestion of the invading microorganisms by local phagocytic cells. These antibodies may have further protective function. Svanborg Eden and Svennerholm (354) showed that IgG and SIgA derived from the urine of patients with acute pyelonephritis reduced *in vitro* adherence of the same strain of *E. coli* to uroepithelial cells. Similarly, immunization with *E. coli* P pili resulted in immunoglobulin production in experimental animals that prevented ascending pyelonephritis by reducing the adhesive capacity of the invading autologous uropathogenic *E. coli* (249,280).

The role of urinary immunoglobulins in preventing infection of the bladder is less clear. IgA-producing lymphocytes have been demonstrated in the submucosa of infected rat bladders (133). Infection of the lower urinary tract is usually associated with a reduced or undetectable serologic response, reflecting the superficial nature of this type of cystitis. However, Uehling and Wolf (368) showed that bladder immunization of rats with bacterial antigens decreases *in vivo* adherence of *E. coli* to bladder mucosa and that bladder immunization with killed bacteria may also protect rats against pyelonephritis (367). The protective function of urinary immunoglobulins was also emphasized by the observations of Riedasch and associates (278) that lower urinary levels of SIgA were associated with an increased risk of urinary tract infection in humans.

Uehling and colleagues (369) have also demonstrated that vaginal immunization with mixtures of *E. coli* may prevent or reduce uropathogenic colonization of the introitus and reduce subsequent urinary tract infections. This line of research may lead to the development of vaccines to reduce the incidence of recurrent infection.

Evidence supports a protective role of cell-mediated immunity in urinary infections. Profound depression of or even absent T-cell function has not been associated with increased frequency of urinary tract infection or altered course of infection. The innate immune system response to an infection in the bladder or kidneys is primarily of local inflammation, which is followed by an adaptive response characterized in part by an antibody response to the infecting bacteria. Neutrophils from the urinary tract appear to be essential for bacterial clearance, and their recruitment plays a pivotal role in resistance to urinary tract infections (122). In mice, a urinary tract infection will spontaneously resolve in most cases; however, in mice with specific genetic backgrounds, a urinary tract infection can persist. This suggests that the presence or absence of specific host genes may determine how effectively a urinary tract infection will be resolved (145). The role of immune deficiencies in human susceptibility to urinary tract infections warrants investigation.

Alterations in Host Defense Mechanisms

Obstruction

Obstruction to urine flow at all anatomic levels is a key factor in increasing host susceptibility to urinary tract infection. Obstruction inhibits the normal flow of urine, and the resulting stasis compromises bladder and renal defense mechanisms. Stasis also contributes to the growth of bacteria in the urine and their ability to adhere to the urothelial cells. In the animal model of experimental hematogenous pyelonephritis, the kidney is relatively resistant to infection unless a ureter is ligated. Under these circumstances, only the obstructed kidney becomes infected (119). Clinical observations support the role of obstruction in pathogenesis of urinary tract infection and in increasing severity of infection. Mild episodes of cystitis or pyelonephritis can become life-threatening when obstruction to urine flow becomes present. Although obstruction clearly increases the severity of infection, it need not be a predisposing factor. For example, men with large residual urine may remain uninfected for years. However, if they are catheterized, even small inocula may lead to severe infections that are difficult to eradicate.

Vesicoureteral Reflux

Hodson and Edwards (136) first described the association of vesicoureteral reflux, urinary tract infection, and renal clubbing and scarring. Children with gross reflux and urinary tract infections usually develop progressive renal damage manifested by renal scarring, proteinuria, and renal failure. Those with a lesser degree of reflux usually improve or completely recover spontaneously or after treatment of the urinary tract infection. In adults, the presence of reflux does not appear to decrease renal function unless there is stasis and concurrent urinary tract infections.

Underlying Disease

There is a high incidence of renal scarring in patients with underlying conditions that cause chronic interstitial nephritis, virtually all of which produce primary renal papillary damage. These conditions include diabetes mellitus, sickle cell disorders, adult nephrocalcinosis, hyperphosphatemia, hypokalemia, analgesic abuse, sulfonamide nephropathy, gout, heavy-metal poisoning, and aging (97). An increased incidence of clinical overt urinary tract infections appears to occur in women with diabetes mellitus, but there is no substantial increase among diabetic men (90,250,371). Autopsy studies have shown the incidence of pyelonephritis to be fourfold to fivefold higher in diabetic than in nondiabetic individuals (279). However, such studies may be misleading because it is difficult to distinguish renal parenchymal changes resulting from pyelonephritis from the interstitial inflammatory changes of diabetic nephropathy.

Although most urinary tract infections in diabetic patients are asymptomatic, diabetes appears to predispose the patient to more severe infections. One study using antibody-coated bacteria techniques to localize the site of infection showed the upper urinary tract to be involved in nearly 80% of diabetic patients with urinary tract infections (90). This evidence of increasing immunologic response in diabetic patients who acquire bacteriuria suggests renal parenchymal involvement and a potential increase in morbidity. Once established, upper urinary tract infections are often complicated by emphysematous pyelonephritis, papillary necrosis, perinephric abscess, or metastatic infection (384).

Other conditions that may increase the susceptibility of the kidney to infection include hypertension and vascular obstruction (97). Association of renal infection with several other renal diseases, including glomerulonephritis, atherosclerosis, and tubular necrosis, which are not associated with papillary necrosis, does not lead to pyelonephritis and scarring.

Pregnancy

The prevalence of bacteriuria in pregnant women varies from 4% to 7%, and the incidence of acute clinical pyelonephritis ranges from 25% to 35% in untreated bacteriuric women (331). This is probably the result of dilation of the ureters and pelvis of the kidney secondary to pregnancy-related hormonal alterations. It is not surprising that untreated bacteriuria in the first trimester is accompanied by a substantial incidence of acute pyelonephritis, because Fairley and associates (82) documented that half of these women have upper tract bacteriuria. Untreated bacteriuria involving these dilated upper tracts would be expected to produce a significant number of abnormalities that should be radiologically apparent. Kincaid-Smith and Bullen (177) performed a culture on 4,000 women at their first antenatal visit. Of 240 bacteriuric women, 148 returned for intravenous urography 6 weeks after delivery. Approximately 40% of these patients had radiologic abnormalities consistent with pyelonephritis or analgesic nephritis. Brumfitt and colleagues (28) showed that the incidence of radiologic abnormalities in bacteriuria of pregnancy was proportional to the difficulty in clearing the infection. Patients who responded promptly to a single course of therapy had a 23% incidence of radiologic abnormalities, but those who remained bacteriuric despite repeated therapeutic efforts had a 65% incidence of radiologic changes. Thus prolonged bacteriuria and pyelonephritis of pregnancy appear to be associated with significant radiologic abnormalities. However, there is little evidence to suggest that bacteriuria of pregnancy or acute pyelonephritis of pregnancy causes these renal radiologic abnormalities.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Pyelonephritis is classically associated with fever, chills, and flank pain. Nausea and vomiting are commonly present. Cystitis is usually associated with dysuria, frequency, urgency, suprapubic pain, and hematuria. Lower tract symptoms are commonly present and usually predate the appearance of upper tract symptoms by several days. Renal or perirenal abscess may cause indolent fever and flank mass and tenderness. In the elderly, the symptoms may be much more subtle (e.g., epigastric or abdominal discomfort), or the patient may be asymptomatic (282). Patients with indwelling catheters often have asymptomatic bacteriuria, but fever associated with bacteremia may occur rapidly and become life-threatening.

Diagnosis

Presumptive diagnosis of urinary tract infection is made by direct or indirect analysis of the urine and is confirmed by urine culture. Assessment of the urine provides clinical information about the status of the urinary tract. The urine and the urinary tract are normally free of bacteria and inflammation. False-negative urinalysis and culture can occur in the presence of urinary tract infection, particularly early in an infection when the numbers of bacteria and WBCs are low or diluted by increased fluid intake and subsequent diuresis. Occasionally, the urine may be free of bacteria and WBCs despite bacterial colonization and inflammation of the uroepithelium (75,153). False-positive urinalysis and culture are caused by contamination of the urine specimen with bacteria and WBCs during collection. This is most likely to occur in voided specimens but can also occur during urethral catheterization. Suprapubic aspiration of bladder urine is least likely to cause contamination of the specimen; therefore it provides the most accurate assessment of the status of bladder urine.

Urine Collection

In circumcised men, voided specimens require no preparation. For men who are not circumcised, the foreskin should be retracted and the glans penis washed with soap and then rinsed with water before specimen collection. The first 10 mL of urine (representative of the urethra) and a midstream specimen (representative of the bladder) should be obtained. Prostatic fluid is obtained by performing digital prostatic massage and collecting the expressed prostatic fluid on a glass slide. In addition, collection of the first 10 mL of voided urine after massage will reflect the prostatic fluid added to the urethral specimen. Catheterization of a male patient for urine culture is not indicated unless the patient cannot urinate.

In women, contamination of a midstream urine specimen with introital bacteria and WBCs is common, particularly when the woman has difficulty spreading and maintaining separation of the labia. Therefore the female should be instructed to spread the labia, wash and cleanse the periurethral area with a moist gauze, and then collect a midstream urine specimen. Cleansing with antiseptics is not recommended because they may contaminate the voided specimen and provide a false-negative urine culture. If the voided specimen shows evidence of contamination as indicated by vaginal epithelial cells and lactobacilli on urinalysis, catheterization should be performed and a midcatheterized specimen collected. Suprapubic aspiration is highly accurate, but because it carries some morbidity, there is limited clinical usefulness except for a patient who cannot urinate on command, such as patients with spinal cord injuries.

Urinalysis

Urinalysis provides rapid identification of bacteria and white cells and presumptive diagnosis of urinary tract infection. Usually, the sediment from an approximately 5- to 10-mL specimen obtained by centrifugation for 5 minutes at 2,000 rpm is analyzed. Microscopic bacteriuria is found in more than 90% of infections with counts of 10^5 colony-forming units (CFU) per milliliter of urine or greater and is a highly specific finding (161,340). However, bacteria are usually not detectable microscopically with lower colony count infections (10^2 to 10^4/mL). Significant pyuria can be determined simply and reliably with a microscope by accurately examining the centrifuged sediment or by using a hemocytometer to count the number of WBCs in the unspun urine. Approximately 1 to 2 WBCs per high-power field (HPF) in sediment from a centrifuged specimen represents about 10 WBCs/mm^3 in an unspun specimen. More than 2 WBCs per HPF in a centrifuged specimen or 10 WBCs/mm^3 of urine correlates well with the presence of bacteriuria and is rarely seen in nonbacteriuric patients (344). In clinical studies, determination of pyuria in voided urine specimens has a reported sensitivity of 80% to 95% and a specificity of 50% to 76% for urinary tract infection (depending on the definition of infection, the patient population, and the method used to evaluate for pyuria) (308,340,386,393).

Microscopic hematuria is found in 40% to 60% of cases of acute cystitis and is uncommon in other dysuric syndromes (343,386). Thus microscopic bacteriuria and hematuria lack sensitivity but are highly specific for urinary tract infections.

Urine Culture

Confirmation of urinary tract infection requires documentation of bacteria by culture. Urine should be cultured immediately or refrigerated at 40°C. Direct surface plating is the traditional quantitative culture technique used by most microbiology laboratories. A known amount of urine is streaked on split agar plates. Half of the plate contains a nonselective medium, such as blood agar, for growth of any bacteria, and the other half contains a selective medium, such as MacConkey, which is specific for Gram-negative bacteria. Each bacterial rod or cluster of cocci will form a single colony after overnight growth in an incubator. Dip-slide culture is a simpler, less expensive, and somewhat less accurate technique. An agar-coated slide is dipped in the urine and replaced into its sterile container. An approximate colony count is determined after overnight incubation at room temperature by comparing the appearance of the slide with a series of pictures provided by the manufacturer.

The definition of significant bacteriuria as greater than 10^5 CFU/mL was originally published by Kass and Finland (171) to differentiate infected from contaminated urine in voided specimens from women with asymptomatic bacteriuria. Most bacteria, when allowed to incubate for several hours, will reach colony counts to this level. However, this cutoff has limitations because about one-third of women with acute symptomatic cystitis caused by *E. coli, S. saprophyticus,* and *Proteus* have colony counts in midstream urine specimens between 10^2 and 10^4 CFU/mL (329,345). Thus, in dysuric women, the appropriate threshold value for defining significant bacteriuria is 100 CFU/mL or greater (345).

In a clinical setting, false-positive urine cultures are problematic. Women susceptible to infections often carry large numbers of pathogenic bacteria on the perineum that could contaminate a voided urine specimen. Contaminated cultures often show more than one organism and include indigenous bacteria such as lactobacilli. Diagnostic accuracy of voided specimens in women can be optimized by detailed history, proper collection techniques, and carefully performed urinalysis.

Midstream urine specimens in men or catheterized specimens in women are less likely to be contaminated, and hence counts of 10^2 CFU/mL are usually diagnostic of significant bacteriuria. Any uropathogen identified in a urine specimen obtained by suprapubic aspiration should be considered significant.

Rapid Screen Methods

Biochemical and enzymatic tests have been devised to detect bacteriuria and pyuria (261). The Griess test detects the presence of nitrite in urine that is formed when

bacteria reduce the nitrate normally present in urine. Tests for detecting pyuria by determining leukocyte esterase activity have also been developed (46). In a study comparing traditional urine culture with these indirect tests, the combination of nitrite and leukocyte esterase tests (either test positive) had a sensitivity of 71% and a specificity of 83% when compared with 10^3 CFU/mL or greater of urine cultures (262). However, several investigators (155,258) noted substantial variability in the sensitivity and specificity results, which could be markedly influenced by the types of patients and infections chosen to evaluate the tests. This concept of spectrum bias was illustrated by a study that reported differences in the sensitivity of reagent strip testing, ranging from 56% to 92%, by changing only the groups of patients included in the analysis. Although false-positives are relatively uncommon, the borderline sensitivity of these tests, especially among patients with less characteristic symptoms of urinary tract infections, does not allow these inexpensive tests to replace careful microscopic urinalysis in symptomatic patients (311). Their main role is in screening asymptomatic patients (261).

IMAGING

Imaging studies are not required in most cases of urinary tract infections because clinical and laboratory findings alone are sufficient for correct diagnosis and adequate management of most patients. However, febrile infections, infection in an otherwise healthy male, signs or symptoms of urinary tract obstruction, failure to respond to appropriate therapy, and a pattern of recurrent infections suggesting bacterial persistence within the urinary tract warrant imaging for identification of underlying abnormalities that require modification of medical management or percutaneous or surgical intervention.

Excretory urography has traditionally provided excellent anatomic assessment of the urinary tract and remains the best examination for detection of lesions of the collecting system and ureter. Ultrasonography and computed tomography (CT) scans have gained considerable acceptance. Ultrasonography serves as a rapid, noninvasive means of evaluating the renal collecting system, parenchyma, and surrounding retroperitoneum for evidence of infection, and it is particularly useful for identifying hydronephrosis, calculi, and abscess. A single radiograph for calculi should accompany ultrasonography. Ultrasonography examination is also useful for diagnosing postvoid residual urine. CT clearly is the modality of choice for identifying inflammatory processes that involve the renal, perirenal, and pararenal spaces and radiolucent calculi. Magnetic resonance imaging may provide some advantages in delineating the extent of inflammation.

Although gallium-67 scanning has been reported to be useful in the diagnosis of pyelonephritis and renal abscess, it is uncommonly required and may be positive in noninfectious entities. Indium-111–labeled WBC studies have limited efficacy in establishing the presence of an inflammatory focus, particularly when the patient's clinical presentation does not suggest an infectious process.

ANTIMICROBIAL THERAPY

Therapy for urinary tract infections must ultimately eliminate bacterial growth in the urinary tract. This can occur within hours if the proper antimicrobial agent is used. Efficacy of the antimicrobial therapy is critically dependent on the antimicrobial levels in the urine and the duration that this level remains above the minimum inhibitory concentration of the infecting organism (141). Hence, resolution of infection is closely associated with the susceptibility of the bacteria to the concentration of the antimicrobial agent achieved in the urine (215,333,338). Inhibitory concentrations in urine are achieved after oral administration of all commonly used antimicrobial agents, except for the macrolides (erythromycin). The concentration of the antimicrobial agent achieved in blood is not important in treatment of uncomplicated urinary tract infections. Blood levels are critical in patients with bacteremia and febrile urinary infections consistent with parenchymal involvement of the kidney and prostate.

In patients with renal insufficiency, dosage modifications are necessary for agents that are cleared primarily by the kidneys and cannot be cleared by another mechanism. In renal failure, the kidneys may not be able to concentrate an antimicrobial agent in the urine; hence, difficulty in eradicating bacteria may occur. Urinary tract obstruction may also reduce concentration of antimicrobials within the urine.

The antimicrobial selection and the duration of therapy must consider the spectrum of activity of the drug against the known pathogen or the most probable pathogens based on the presumed source of acquisition of infection, whether the infection is judged to be uncomplicated or complicated, potential adverse effects, and cost. An often underemphasized but important characteristic is the drug's impact on the fecal and vaginal flora and the hospital bacterial environment. Bacterial susceptibility will vary dramatically in patients exposed to antimicrobials and in individuals in inpatient and outpatient settings. It is imperative that each clinician keep abreast of changes that affect antimicrobial use patterns.

Bacterial Resistance

In the last several years, the frequency and spectrum of antimicrobial-resistant urinary tract infections have increased in both the hospital and community. The increasing frequency of drug resistance has been attributed to combinations of microbial characteristics, bacterial selection pressure due to antimicrobial use, and societal and technologic changes that enhance the transmission of drug resistance (50). Bacterial resistance may occur because of natural (inherited) chromosomal-based resistance or by acquired chromosomal- or extrachromosomal (plasmid)-mediated resistance due to exposure of an organism to antimicrobials. Inherited resistance exists in a bacterial species because of the absence of the proper mechanism on which the antimicrobial agent can act. For example, *Proteus* and *Pseudomonas* species are always resistant to nitrofurantoin. Chromosomal-mediated resistance can be acquired by urinary bacteria during therapy for urinary tract infections. Before antimicrobial therapy, relatively resistant mutants of a bacterial strain may be present in the urine at very low concentrations. The remainder of the bacteria, which are susceptible to the administered antimicrobial agent, will be eradicated by therapy, but within 24 to 48 hours, a repeat urine culture will show high bacterial counts of the resistant mutant. In essence, the antimicrobial therapy has selected out the resistant mutant. This phenomenon is most likely to occur when the antimicrobial level in the urine is close to or below the minimum inhibitory concentration of the drug. Underdosing and noncompliance, as well as diuresis induced by increased fluid intake, can contribute to this process.

Resistance may also be acquired and transferable via extrachromosomal plasmids, which contain the genetic material for the resistance. This so-called R-factor resistance occurs in the fecal flora and is much more common than selection of preexisting mutants in the urinary tract. All antimicrobial classes are capable of causing plasmid-mediated resistance with the exception of the fluoroquinolones and nitrofurantoin. Hence, patients previously exposed to b-lactams, aminoglycoside, sulfonamide, trimethoprim (TMP), and tetracycline will often have R-factor resistance to both the antimicrobial to which the bacteria were exposed and also to other antimicrobials. In addition, the plasmids carrying the resistant genetic material are transferable both within species and across genuses. Thus, for example, a patient receiving tetracycline may harbor several fecal strains that are resistant to tetracycline, ampicillin, sulfonamides, and TMP. Because the fecal flora is the major reservoir for bacteria that ultimately colonize the urinary tract, infections that occur after antimicrobial therapy and that can cause plasmid-mediated resistance are commonly caused by organisms with multidrug resistance.

Antimicrobial resistance is also influenced by the duration and amount of antimicrobial used. For example, documented increased use of fluoroquinolones in the hospital setting has been directly associated with increased resistance of bacteria (particularly *Pseudomonas*) to the fluoroquinolones. Resistance tends to increase the longer the antimicrobial is used. Conversely, reduction in duration of therapy and in the amount of the drug use can lead to reemergence of more susceptible strains.

Most studies reporting antimicrobial resistance have been based on surveys of laboratory isolates, generally without correlation with clinical or epidemiologic factors (e.g., the presence and nature of symptoms, age, sex, and whether the infection was complicated). Gupta and colleagues (117) determined the prevalence of and trends in antimicrobial resistance among uropathogens isolated from a large, well-defined population of women with acute uncomplicated cystitis. Over a 5-year period, the prevalence of resistance to trimethoprim/sulfamethoxazole, ampicillin, and cephalothin increased significantly, whereas resistance to nitrofurantoin and ciprofloxacin remained uncommon. However, fluoroquinolone resistance of *E. coli* has increased from less than 1% to 7% in hospitalized patients. Previous use of fluoroquinolones and the presence of underlying urologic diseases were the strongest determinants for urinary tract infections caused by resistant strains (76).

Antimicrobial Formulary

Trimethoprim/sulfamethoxazole

The combination of trimethoprim/sulfamethoxazole (TMP-SMX) has been the most widely used antimicrobial for the treatment of acute urinary tract infections. TMP alone is as effective as the combination for most uncomplicated infections and may be associated with fewer side effects (163); however, the addition of SMX contributes to efficacy in the treatment of upper tract infection via a synergistic bactericidal effect and may diminish the emergence of resistance (31). TMP alone or in combination with SMX was effective against most common uropathogens, with the notable exception of *Enterococcus* and *Pseudomonas* species. TMP and TMP-SMX are inexpensive and have minimal adverse effects on the fecal flora. Disadvantages are relatively common adverse effects, consisting primarily of skin rashes and

gastrointestinal complaints (49).

Nitrofurantoin

Nitrofurantoin is effective against common uropathogens, but it is not effective against *Pseudomonas* and *Proteus* species (157). It is rapidly excreted from the urine but does not obtain therapeutic levels in most body tissues, including the gastrointestinal tract. Therefore it is not useful for upper tract and complicated infections (387). It has minimal effects on the resident fecal and vaginal flora and has been used effectively in prophylactic regimens for more than 30 years. Acquired bacterial resistance to this drug is exceedingly low.

Cephalosporins

All three generations of cephalosporins have been used for the treatment of acute urinary tract infections (387). In general, as a group, activity is high against Enterobacteriaceae and poor against enterococci. First-generation cephalosporins have greater activity against Gram-positive organisms, whereas second-generation cephalosporins have activity against anaerobes. Third-generation cephalosporins are more reliably active against community-acquired and nosocomial Gram-negative organisms than other b-lactam antibiotics. Their cost should limit their use to complicated infections and situations where parenteral therapy is required and resistance to standard antibiotics is likely. Cephalosporins produce less resistance among fecal bacteria than the aminopenicillins, but the incidence of *Candida* vaginitis is nearly the same (157).

Aminopenicillins

Ampicillin and amoxicillin have been used often in the past for the treatment of urinary tract infections, but the emergence of resistance in up to 30% of common urinary isolates has lessened the usefulness of these drugs (141). The effects of these agents on the normal fecal and vaginal flora can predispose patients to reinfection with resistant strains and often lead to *Candida* vaginitis (157). The addition of the b-lactamase inhibitor clavulanate to amoxicillin greatly improves activity against b-lactamase–producing bacteria resistant to amoxicillin alone. However, its high cost and frequent gastrointestinal side effects limit its usefulness. The extended-spectrum penicillin derivatives (e.g., piperacillin, mezlocillin, azlocillin) retain ampicillin's activity against enterococci and offer activity against many ampicillin-resistant Gram-negative bacilli. This makes them attractive agents for use in patients with nosocomially acquired urinary tract infections and as the initial parenteral treatment of acute uncomplicated pyelonephritis acquired outside of the hospital, although less expensive agents are equally effective.

Aminoglycosides

When combined with TMP-SMX or ampicillin, aminoglycosides are the first drugs of choice for febrile urinary tract infections. Their nephrotoxicity and autotoxicity are well recognized; hence, careful monitoring of patients for renal and auditory impairment associated with infection is indicated. Once-daily aminoglycoside regimens have been instituted to maximize bacterial killing by optimizing the peak concentration-to-minimum inhibitory concentration ratio and reduce potential for toxicity (239). Administering an aminoglycoside as a single daily dose can take advantage not only of its concentration-dependent killing ability but also of two other important characteristics: time-dependent toxicity and a more prolonged postantibiotic effect (103,401). The regimen consists of a fixed 7-mg/kg dose of either gentamicin or tobramycin. Subsequent interval adjustments are made by using a single concentration in serum and a nomogram designed for monitoring of once-daily aminoglycoside therapy (Fig. 4.6). This regimen is clinically effective, reduces the incidence of nephrotoxicity, and provides a cost-effective method for administering aminoglycosides by reducing ancillary service times and serum aminoglycoside determinations.

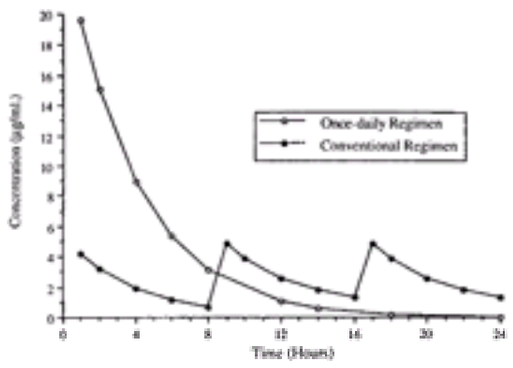

FIGURE 4.6. Simulated concentration-versus-time profile of once-daily (7 mg/kg every 24 hours) and conventional (1.5 mg/kg every 8 hours) regimens for patients with normal renal function.

Aztreonam

Aztreonam has a similar spectrum of activity as the aminoglycosides, and as with all b-lactams, it is not nephrotoxic. However, its spectrum of activity is less broad than the third-generation cephalosporins. It should be used primarily in patients who have penicillin allergies.

Fluoroquinolones

Fluoroquinolones share a common predecessor in nalidixic acid and inhibit DNA gyrase, a bacterial enzyme integral to replication. The fluoroquinolones have a broad spectrum of activity that makes them ideal for the empiric treatment of urinary tract infections. They are highly effective against Enterobacteriaceae, as well as *Pseudomonas aeruginosa.* Activity is also high against *S. aureus* and *S. saprophyticus,* but in general, antistreptococcal coverage is marginal. Most anaerobic bacteria are resistant to these drugs; therefore the normal vaginal and fecal flora are not altered (396). Bacterial resistance initially appeared to be uncommon, but it is being reported at an increasing rate because of indiscriminate use of these agents (374,396).

These drugs are not nephrotoxic, but renal insufficiency prolongs the serum half-life, requiring adjusted dosing in patients with creatinine clearances of less than 30 mL per minute. Adverse reactions are uncommon; gastrointestinal disturbances are more common. Hypersensitivity, skin reactions, mild central and peripheral nervous system reactions, and even acute renal failure have been reported (138). Administration of the fluoroquinolones to immature animals has caused damage to the developing cartilage; therefore they are currently contraindicated in children, adolescents, and pregnant or nursing women (47). There are important drug interactions associated with the fluoroquinolones. Antacids containing magnesium or aluminum interfere with absorption of fluoroquinolones (63). Certain fluoroquinolones (enoxacin and ciprofloxacin) elevate plasma levels of theophylline and prolong its half-life (396). For most uncomplicated urinary tract infections, the fluoroquinolones have been only slightly more effective than TMP-SMX. However, as resistance to TMP-SMX increases, the fluoroquinolones have distinct advantages in empiric treatment of patients recently exposed to antimicrobials and in the outpatient treatment of complicated urinary tract infections (61,117). They may be considered as first-line agents in areas where a significant level of resistance (greater than 20%) exists (in common bacteria) to agents such as ampicillin and TMP-SMX.

BLADDER INFECTIONS

Uncomplicated Cystitis

Most cases of uncomplicated cystitis occur in women. Approximately 25% to 30% of women 20 to 40 years of age have a history of urinary tract infections (190). Although it is much less common, young men may also experience acute cystitis without underlying structural or functional abnormalities of the urinary tract (185). Risk factors include sexual intercourse and use of spermicides (93,139). Sexual transmission of uropathogens has been suggested by demonstrating identical *E. coli* in the fecal and urinary flora of sex partners.

The presenting symptoms of cystitis are variable but usually include dysuria, frequency or urgency, and suprapubic pain. Because acute cystitis, by definition, is a superficial infection of bladder mucosa, fever, chills, and other signs of dissemination are not present. Some patients may experience suprapubic tenderness, but most have no diagnostic physical findings. In women, physical examination should include the possibility of vaginitis, herpes, and urethral pathology, such as a diverticulum.

E. coli is the causative organism in approximately 75% to 80% of cases of acute cystitis in young women (192). *S. saprophyticus,* a commensal organism of the skin, is the second most common cause of acute cystitis in young women, accounting for 10% to 20% of these infections (166). Other organisms less commonly involved include *Klebsiella* and *Proteus* species and *Enterococcus.* In men, *E. coli* and other Enterobacteriaceae are the most commonly identified organisms.

Laboratory Diagnosis

The presumptive laboratory diagnosis of acute cystitis is based on microscopic urinalysis, which indicates microscopic bacteriuria, pyuria, and hematuria. Indirect dipstick tests for bacteria (nitrite) or pyuria (leukocyte esterase) may also be informative but are less sensitive than microscopic examination of the urine. Urine culture remains the definitive test, and in symptomatic patients, the presence of 10^2 CFU/mL or more of urine usually indicates infection (345).

Routine urine cultures are often not necessary. It is generally more cost-effective to manage many patients who have symptoms and urinalysis findings characteristic of uncomplicated cystitis without an initial urine culture because treatment decisions are usually made and therapy is often completed before culture results are known (181). This position was supported by a cost-effectiveness study (38) in which it was estimated that the routine use of pretherapy urine cultures for lower urinary tract infection increases costs by 40% but decreases the overall duration of symptoms by only 10%.

Thus, in patients with symptoms and signs suggesting acute cystitis and in whom no complicating factors are present, a urinalysis that is positive for pyuria, hematuria, or bacteriuria, or a combination, should provide sufficient documentation of urinary tract infection and a urine culture may be omitted. A urine culture should be obtained for patients in whom symptoms and urine examination findings leave the diagnosis of cystitis in doubt, however. Pretherapy cultures and susceptibility tests are also essential in the management of patients with recent antimicrobial therapy or urinary tract infection. In these situations, various pathogens may be present and antimicrobial therapy is less predictable and must be tailored to the individual organism (341).

Differential Diagnosis

Cystitis must be differentiated from other inflammatory infectious conditions in which dysuria may be the most prominent symptom, including vaginitis, urethral infections caused by sexually transmitted pathogens, and miscellaneous noninflammatory causes of urethral discomfort (180). Characteristic features of the history, physical examination, and voided urine or other specimens allow patients with dysuria to be assigned to one of these diagnostic categories. Vaginitis is characterized by irritative voiding associated with vaginal irritation and is subacute in onset. A history of vaginal discharge or odor and multiple or new sexual partners is common. Frequency, urgency, hematuria, and suprapubic pain are not present. Physical examination reveals a vaginal discharge, and examination of vaginal fluid demonstrates inflammatory cells. Differential diagnosis includes herpes simplex virus, gonorrhea, *Chlamydia,* trichomoniasis, yeast, and bacterial vaginosis. Urethritis causes dysuria that is usually subacute in onset and is associated with a history of discharge and new or multiple sexual partners. Frequency and urgency of urination may be present but are less pronounced than in patients with cystitis, and fever and chills are absent. Urethral discharge with inflammatory cells or initial pyuria in the male is characteristic. The common causes of urethritis include gonorrhea, *Chlamydia,* herpes simplex virus, and trichomoniasis. Appropriate cultures and immunologic tests are indicated. Urethral injury associated with sexual intercourse, chemical irritants, or allergy may also cause dysuria. A history of trauma or exposure to irritants and a lack of discharge or pyuria are characteristic.

Management

Antimicrobial Selection

Oral antimicrobial agents for treatment of acute uncomplicated cystitis are listed in Table 4.2. TMP and TMP-SMX are effective and inexpensive agents for empiric therapy. They are recommended in areas where the prevalence of resistance to these drugs among *E. coli* strains causing cystitis is less than 20% (377). When used alone, TMP is as efficacious as TMP-SMX and is associated with fewer side effects, presumably because of the absence of the sulfa component (123). Nitrofurantoin has maintained an excellent level of activity over three decades and is well tolerated, but it is more expensive than TMP-SMX. It is not associated with plasmid-mediated resistance, however, so it is an excellent choice for patients with recent exposure to most other antimicrobials. The high *in vitro* resistance to ampicillin and sulfonamide and the high cost of amoxicillin/clavulanate and the cephalosporins limit their usefulness. The fluoroquinolones offer excellent activity, and they are well tolerated. Their use for uncomplicated cystitis should be limited to patients with allergy to less costly drugs, to patients with previous exposure to antibiotics causing bacterial resistance, and to areas where the prevalence of resistance to TMP or TMP-SMX is 20% or greater (377).

Drug	Dosage	Cost Per Day*
TMP-SMX	1 double-strength tablet b.i.d. (160/800 mg)	$0.28
Trimethoprim	100 mg b.i.d.	$0.38
Sulfisoxazole	1 g, followed by 500 mg q.i.d.	$0.32
Ciprofloxacin	500 mg b.i.d.	$8.36
Enoxacin	400 mg b.i.d.	$6.84
Levofloxacin	500 mg q.i.d.	$8.58
Nitrofurantoin	100 mg q.i.d.	$3.24
Amoxicillin	250 mg t.i.d.	$0.68
Cephalexin	500 mg q.i.d.	$4.52

*Prices in dollars reflect the average wholesale price to the pharmacist as of February 2000. When products were available from multiple sources, the least expensive generic supply prices were used. The price to the patient is dependent on the pharmacist's professional fee structure.

TABLE 4.2. ORAL ANTIMICROBIAL AGENTS FOR UNCOMPLICATED CYSTITIS

Duration of Therapy

The traditional approach of 7 to 14 days of therapy for acute uncomplicated cystitis overtreats most patients, is more costly, and is associated with more side effects than shorter-term therapy (312). As an alternative, investigators initially proposed single-dose therapy wherein patients were given 1 to 2 days of conventional therapy in one dose. Although single-dose therapy was nearly as effective as 7-day therapy in healthy women with cystitis (85,266), resolution of symptoms was sometimes slower. Furthermore, it proved less effective in the presence of recent urinary tract infections, with the use of spermicides, and when more than 10^5 CFU/mL of urine was present (85).

Three-day therapy now appears to be the preferred regimen in uncomplicated cystitis in women (244,377). In an excellent review of more than 300 separate clinical trials of single-dose, 3-day or 7-day treatment with TMP, TMP-SMX, fluoroquinolones, and b-lactam antimicrobial therapies, it was concluded that, irrespective of the antimicrobial used, single-dose therapy is not as effective as 3-day therapy. Three-day therapy is as effective as a 7- to 10-day course of treatment (377). Three-day therapy with TMP-SMX, TMP, amoxicillin, or cloxacillin has been associated with cure rates similar to longer courses of therapy and an incidence of adverse effects as low as that seen with single-dose therapy and lower than seen with longer courses of therapy (3,44,189,218). Seven-day therapy often causes more adverse effects and therefore is recommended only for women with symptoms of 1 week or more, men, and individuals with possible complicating factors. Other options include nitrofurantoin, perhaps as 7-day therapy, and fosfomycin single-dose therapy; each of these requires further study. b-Lactams as a group are less effective in treatment of cystitis than TMP, TMP-SMX, and the fluoroquinolones.

Cost of Therapy

The cost of treating a urinary tract infection involves not only the initial evaluation and cost of the drug but what occurs subsequently. The most important prediction of

high cost-effectiveness is high efficacy against the most common urinary pathogen—*E. coli*. The lower the effectiveness against this bacterium, the greater the number of revisits, cases of progression to pyelonephritis, and follow-up costs. Antimicrobial cost is a poor prediction of cost-effectiveness as illustrated by the finding that the most expensive and least expensive drugs, the fluoroquinolones and TMP-SMX, are approximately equally cost-effective (283). Both of these drugs are more cost-effective than nitrofurantoin and amoxicillin.

UNRESOLVED URINARY TRACT INFECTIONS

Unresolved infection indicates that initial therapy has been inadequate in eliminating bacterial growth in the urinary tract. If the symptoms of urinary tract infection do not resolve by the end of treatment or if symptoms recur shortly after therapy, urinalysis and urine culture with susceptibility testing should be obtained. If the patient's symptoms are significant, empiric therapy with a fluoroquinolone is appropriate pending results of the culture and susceptibility testing.

The causes of unresolved bacteriuria during antimicrobial therapy are shown in Table 4.3. Most commonly, the bacteria are resistant to the antimicrobial agent selected to treat the infection. Typically, the patient has received the antimicrobial therapy in the recent past and developed fecal colonization with resistant bacteria. b-Lactams, tetracycline, and sulfonamides are notorious for causing plasmid-mediated R factors that simultaneously carry resistance to multiple antimicrobial agents. The second most common cause is development of resistance in a previously susceptible population of bacteria during the course of treatment of urinary tract infections. This problem occurs in approximately 5% of the patients receiving antimicrobial therapy. It is easy to recognize clinically because culture on therapy shows that the previous susceptible population has been replaced by resistant bacteria of the same species. It can be shown that resistant organisms were actually present before contact with the initial antimicrobial agent, but they were present in such low numbers that it was impossible to detect by *in vitro* susceptibility studies before therapy. When the antimicrobial concentration in the urine is insufficient to kill all the bacteria present, the more resistant forms will emerge. This characteristically is seen in patients who are underdosed or who are poorly compliant and hence have inadequate dose regimens. The third cause is the presence of an unsuspected, second pathogen that was present initially and is resistant to the antimicrobial therapy chosen. Treatment of the dominant organism unmasks the presence of the second strain. The fourth cause is rapid reintroduction of a new resistant species while the patient is undergoing initial therapy. Rapid reinfection that mimics unresolved bacteriuria should alert the clinician to the possibility of an enterovesical fistula. If the culture obtained on therapy shows that the initial species is still present and susceptible to the antimicrobial chosen to treat the infection, the unresolved infection must be caused by either inability to deliver an adequate concentration of antimicrobial agents into the urinary tract or an excessive number of bacteria that “override” the antimicrobial activity. In patients with azotemia, a determination of urinary antimicrobial concentrations usually shows that the level of the drug is below the minimal inhibitory concentration of the infecting organism.

1. Bacteria resistance to the initial drug selected for treatment*
2. Development of resistance from initially susceptible bacteria
3. Bacteriuria caused by two different bacterial species with mutually exclusive susceptibilities
4. Rapid reinfection from a new, resistant species during initial therapy for the original susceptible organism
5. Azotemia
6. Staghorn calculi in which the "critical mass" of the susceptible bacteria is too great for antimicrobial inhibition
7. Papillary necrosis from analgesic abuse

*The first four causes are characterized by identification of bacteria resistant to the antimicrobial agent the patient is receiving.
Modified with permission from Stamey TA. *Pathogenesis and treatment of urinary tract infections*. Baltimore: Williams & Wilkins, 1989.

TABLE 4.3. CAUSES OF UNRESOLVED BACTERIURIA IN DESCENDING ORDER OF IMPORTANCE

In patients with papillary necrosis, severe defects in the medullary concentrating ability dilutes the antimicrobial agent. A large mass of bacteria within the urinary tract is most commonly associated with a giant staghorn calculus. Even though adequate urinary levels of bactericidal drugs are present, the concentration is inadequate to sterilize the urine. This occurs because even susceptible bacteria cannot be inhibited once they reach a certain critical density, particularly if attached to a foreign body.

RECURRENT URINARY TRACT INFECTIONS

Recurrent urinary tract infections are caused by either reemergence of bacteria from a site within the urinary tract *(bacterial persistence)* or new infections from bacteria outside the urinary tract *(reinfection).* Clinical identification of these two types of recurrence is based on the pattern of recurrent infections. Bacterial persistence must be caused by the same organism in each instance, and infections that occur at close intervals are characteristic. Conversely, reinfections usually occur at varying and sometimes long intervals and often are caused by different species. The distinction between bacterial persistence and reinfection is important in management because patients with bacterial persistence can usually be cured of the recurrent infections by identification and surgical removal or correction of the focus of infection. Conversely, women with reinfection usually do not have an alterable urologic abnormality and usually require long-term medical management. Reinfections in men are uncommon and may be associated with an underlying abnormality, such as urethral stricture; therefore, at a minimum, endoscopic evaluation is indicated.

Bacterial Persistence

Although patients with bacterial persistence are relatively uncommon, their identification is important because they represent the only surgically curable cause of recurrent urinary tract infections. A systematic radiologic and endoscopic evaluation of the urinary tract is mandatory. Excretory urography and cystoscopy provide the initial screening. Urea-splitting organisms, such as *P. mirabilis,* cause infection stones that are relatively radiolucent. If such a stone is suspected, plain film tomograms and, if necessary, computed tomographic scans without contrast should be obtained (114). Retrograde urography may be required in selected patients to delineate abnormalities, such as diverticulum or nonrefluxing ureteral stump.

The infection that ultimately leads to an infection stone commonly begins inconspicuously as inadequately treated cystitis. Underlying urinary tract abnormalities are not a prerequisite for this type of infection. However, patients with indwelling catheters, urinary diversions, or other urinary tract abnormalities are particularly susceptible to these infections. Medical management with continued suppressive antimicrobial therapy and acidification temporarily relieves symptoms and retards deterioration of renal function in some patients. Complete removal of the calculus is generally required for bacteriologic cure and to prevent renal damage due to obstruction (319). Percutaneous nephrolithotomy and extracorporeal shock wave lithotripsy (ESWL) are now the preferred treatment for most renal and upper ureteral calculi. Follow-up radiographs are essential to ensure that all the stone fragments are removed, and cultures must demonstrate that the urease-splitting bacteria are eradicated. Most of the other congenital or acquired abnormalities listed in Table 4.4 require surgical removal for eradication of the source of bacterial persistence. Chronic bacterial prostatitis is treated initially with long-term antimicrobial therapy and, in select cases, by radical transurethral resection (222).

1. Infection renal stone
2. Chronic bacterial prostatitis
3. Infected perikalyceal diverticulum
4. Infected nonrefluxing ureteral stump following nephrectomy
5. Atrophic, infected kidney
6. Medullary sponge kidney
7. Infected urachal cyst
8. Infected necrotic papilla from papillary necrosis

*Although patients with bacterial persistence are relatively uncommon, these circumstances are important because they represent the only surgically curable causes of recurrent urinary tract infections.
Modified with permission from Stamey TA. *Pathogenesis and treatment of urinary tract infections*. Baltimore: Williams & Wilkins, 1980.

TABLE 4.4. CAUSES OF BACTERIAL PERSISTENCE OF URINARY TRACT INFECTIONS[a]

In patients in whom the focus of infection cannot be eradicated, long-term, low-dose antimicrobial suppression is necessary to prevent symptoms of infection. The antimicrobial drugs used for low-dose prophylaxis will also be effective for bacterial suppression if the persistent strain is susceptible. These include nitrofurantoin, TMP-SMX, cephalexin, and the fluoroquinolones.

Reinfections

Patients with recurrent infections caused by different species or occurring at long intervals almost invariably have reinfections. These reinfections most often occur in women and girls and are associated with ascending colonization from the fecal flora. Reinfections in men are often associated with a urinary tract abnormality. The possibility of a vesicoenteric or vesicovaginal fistula should be considered when the patient has any history of pneumaturia, fecaluria, diverticulitis, obstipation, previous pelvic surgery, or radiation therapy. Evaluation of the patient with presumed reinfections must be individualized.

Failure to recognize and correct abnormalities that reduce formation, transmission, and elimination of urine by the urinary tract increases the incidence of reinfection in susceptible patients and reduces the effectiveness of antimicrobial therapy. Abnormalities should be corrected and urinary tract function restored by medical, pharmacologic, or surgical management. A thorough urologic evaluation is essential in all men and in women with evidence of upper tract infections (fevers, chills, flank pain, hemorrhagic cystitis, or other risk factors, such as history of unexplained hematuria, obstructive symptoms, neurogenic bladder dysfunction, renal calculi, fistula, analgesic abuse, or severe disease such as diabetes mellitus). In women, diaphragm-spermicide use has been associated with an increased risk of urinary tract infection and vaginal colonization with *E. coli* (143). Spermicides containing the active ingredient nonoxynol-9 may provide a selective advantage in colonizing the vagina, perhaps by a reduction in vaginal lactobacilli and through enhancement of adherence of *E. coli* to epithelial cells (116,144). Thus spermicidals should be discontinued in women with recurrent urinary tract infection, and other forms of contraception should be used. In postmenopausal women, the risk of infection is reduced by estrogen replacement (274).

Excretory urography will demonstrate the anatomy of the urinary tract and provide reasonable assessment of its functional status. In healthy women, upper tract abnormalities associated with reinfections are very rare; therefore routine excretory urography is not indicated. Cystoscopy should be performed in men or women who have frequent reinfections and symptoms suggestive of obstruction, bladder dysfunction, and fistula. Dilation of a stenotic urethra to a normal caliber would appear appropriate. There is little evidence, however, that repeated urethral dilation is indicated in the routine management of most women.

Antimicrobial management in women who have had two or more symptomatic urinary tract infections over a 6-month period or three or more episodes within a 12-month period involves one of three regimens: low-dose continuous prophylaxis, self-start intermittent therapy, or postintercourse prophylaxis.

Low-dose Continuous Prophylaxis

Low-dose continuous prophylaxis is indicated when the urine culture shows no growth (usually when a patient has completed antimicrobial therapy). Nightly therapy is then begun with one of the following drugs: (a) nitrofurantoin 50 to 100 mg half-strength (HS) (332), (b) TMP-SMX, 40 to 200 mg (346), (c) TMP 50 mg (346), or (d) Keflex 250 mg (213). Patients will have less than one urinary tract infection per year while taking these regimens. Every-other-night therapy is also effective and is probably practiced by most patients. When breakthrough infections occur, they are not necessarily accompanied by symptoms; therefore we advocate monitoring for infections every 1 to 3 months, even in asymptomatic patients. Breakthrough infections usually respond to full-dose therapy with the drug used for prophylaxis. However, cultures and susceptibility tests may indicate that another drug is indicated. After the infection is cured, prophylaxis may be reinstituted. Low-dose prophylaxis is usually discontinued after about 6 months, and the patient is monitored for reinfection. Approximately 30% of women will have spontaneous remissions that last up to 6 months (183). Unfortunately, many of the remissions are followed by reinfections, and low-dose prophylaxis must be reinstituted. At this point, many patients prefer an alternative form of management.

Self-start Intermittent Therapy

With self-start intermittent therapy, the patient is given a dip-slide device to culture the urine and is instructed to perform a urine culture when symptoms of urinary tract infection occur (294). The patient is also provided a 3-day course of empiric, full-dose antimicrobial therapy to be started immediately after performing the culture. It is important that the antimicrobial agent selected for self-start therapy have a broad spectrum of activity and achieve high urine levels to minimize development of resistant mutants. In addition, there should be minimal or no side effects on the fecal flora. Fluoroquinolones are ideal for self-start therapy because they have a spectrum of activity broader than any of the other oral agents and are superior to many parenteral antimicrobials, including aminoglycosides. Nitrofurantoin and TMP-SMX are acceptable alternatives, although they are somewhat less effective. Antimicrobial agents such as tetracycline, ampicillin, SMX, and cephalexin in full doses should be avoided because they can give rise to resistant bacteria (395).

The culture is brought to the office as soon as possible. If the culture is positive and the patient is asymptomatic, a culture is performed 7 to 10 days after therapy to determine efficacy. In most cases, the therapy is limited to two inexpensive dip-slide cultures and a short course of antimicrobial therapy. If the patient has symptoms that do not respond to initial antimicrobial therapy, a repeat culture and susceptibility testing of the initial culture specimen are performed and therapy adjusted accordingly. If symptoms of infection are not associated with positive cultures, urologic evaluation should be performed to rule out other causes of irritative bladder symptoms, including carcinoma in situ, interstitial cystitis, and neurogenic bladder dysfunction. Our experience with this technique has been very favorable, and we find that it is particularly attractive to patients who have less frequent infections and are willing to play an active role in their diagnosis and management.

Postintercourse Prophylaxis

Antimicrobial management through postintercourse prophylaxis is based on research establishing that sexual intercourse can be an important risk factor for acute cystitis in women (241). Diaphragm users have a significantly greater risk of urinary tract infection than do women who use other contraceptive methods (86). Postintercourse therapy with antimicrobials, such as nitrofurantoin, cephalexin, TMP-SMX, or a fluoroquinolone taken as a single dose, will effectively reduce the incidence of reinfection (224,265).

RENAL INFECTION (BACTERIAL NEPHRITIS)

Although renal infection is less prevalent than bladder infection, it often is a more difficult problem for the patient and his or her physician because of its often varied and morbid presentation and course, the difficulty in establishing a firm microbiologic and pathologic diagnosis, and its potential for significantly impairing renal function. Although the classic symptoms of acute onset of fever, chills, and flank pain are usually indicative of renal infection, some patients with these symptoms do not have renal infection. Conversely, significant renal infection may be associated with an insidious onset of nonspecific local or systemic symptoms, or it may be entirely asymptomatic. Therefore a high clinical index of suspicion and appropriate radiologic and laboratory studies are required to establish the diagnosis of renal infection.

Unfortunately, the relationship between laboratory findings and the presence of renal infection often is poor. Bacteriuria and pyuria, the hallmarks of urinary tract infection, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Interstitial renal inflammation, once thought to be caused predominantly by bacterial infection, is now recognized as a nonspecific histopathologic change associated with a variety of immunologic, congenital, or chemical lesions that usually develop in the absence of bacterial infection. Infectious granulomatous diseases of the kidney often have either radiologic or pathologic characteristics that mimic renal cystic disease, neoplasia, or other renal inflammatory disease.

The effect of renal infection on renal function is varied. Acute or chronic pyelonephritis may transiently or permanently alter renal function, but nonobstructive pyelonephritis is no longer recognized as a major cause of renal failure. However, pyelonephritis, when associated with urinary tract obstruction or granulomatous renal infection, may lead rapidly to significant inflammatory complications, renal failure, or even death.

If urinary tract infection is associated with fever, chills, and flank pain, the infection is judged to be more severe and usually involves the kidneys. Bacterial nephritis,

whether isolated or recurrent, may cause acute or chronic renal parenchymal damage and act as the source for recurrent episodes of renal or lower urinary tract infection (13,95).

Interstitial renal inflammation is a nonspecific cellular response of the renal interstitium that may or may not be complicated by fibrosis and varying degrees of tubular or glomerular damage. It generally has been believed that bacterial infection of the kidney, such as pyelonephritis, was the most common cause of interstitial renal inflammation and subsequent development of serious renal disease. More recently, however, the nonspecific nature of the histopathologic changes of interstitial renal inflammation has been appreciated. As a result of urologic evaluations of patients with chronic preexisting interstitial renal inflammation, it is now recognized that interstitial renal inflammation is associated with immunologic reactions, congenital lesions, or papillary damage in the absence of bacterial infection and that bacterial infection is often a secondary event. Thus histologic evidence alone is too often assumed indicative of bacterial nephritis and is not sufficient to establish whether interstitial changes in the kidney are either primary or secondary to bacterial infection or of noninfectious causes.

Pathology

The opportunity for pathologic confirmation of acute bacterial nephritis is rare. The kidney may be edematous. Focal acute suppurative bacterial nephritis caused by hematogenous dissemination of bacteria to the renal cortex is characterized by multiple focal areas of suppuration on the surface of the kidney (Fig. 4.7). Histologic examination of the renal cortex shows focal suppurative destruction of glomeruli and tubules. Adjacent cortical structures and the medulla are not involved in the inflammatory reaction. Acute ascending pyelonephritis is characterized by linear bands of inflammation extending from the medulla to the renal capsule (Fig. 4.8). Histologic examination usually reveals a focal wedge-shaped area of acute interstitial inflammation with the apex of the wedge in the renal medulla. Polymorphonuclear leukocytes or a predominantly lymphocytic and plasma cell response are seen. Bacteria also may be present.

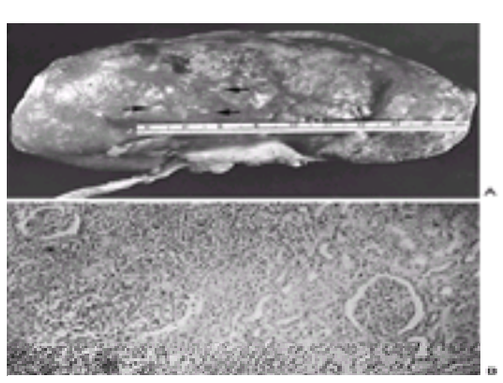

FIGURE 4.7. Acute focal suppurative bacterial nephritis. **A:** Surface of kidney. *Arrows* indicate focal areas of suppuration. **B:** Renal cortex showing focal suppuration destruction of glomeruli and tubules.

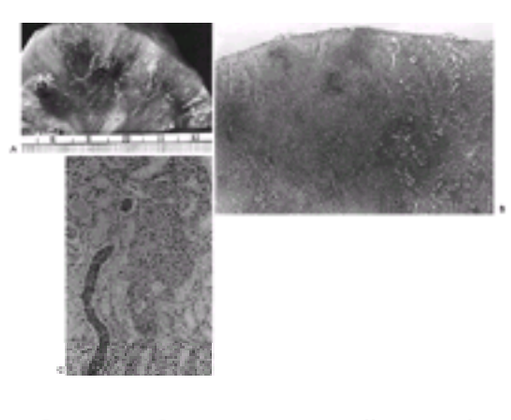

FIGURE 4.8. Acute ascending pyelonephritis. **A:** Cortical structures, tubules, and collecting ducts diffusely infiltrated with inflammatory cells. **B:** Section of the renal cortex showing wedge-shaped destruction of renocortical structures as a result of ascending infiltration with inflammatory cells. **C:** Thickened and inflamed tissue surrounding the collecting ducts in the medulla. A polymorphonuclear cast of segmented neutrophils is clearly visible.

The changes that appear to be most specific for chronic pyelonephritis are evident on careful gross examination of the kidney and consist of a cortical scar associated with retraction of the corresponding renal papilla (97,131,135,137). The kidney shows evidence of patchy involvement with numerous chronic inflammatory foci mainly confined to the cortex but also involving the medulla (Fig. 4.9). The scars may be separated by intervening zones of normal parenchyma, causing a grossly irregular renal outline. The microscopic appearance, as with most chronic interstitial disease, includes the presence of lymphocytes and plasma cells. Although glomeruli within scars may be surrounded by a cuff of fibrosis or be partially or completely hyalinized, glomeruli outside these severely scarred zones are relatively normal. Vascular involvement is variable, but in patients with hypertension, nephrosclerosis may be found. Papillary abnormalities include deformity, sclerosis, and sometimes necrosis. Studies in animals have clearly indicated the critical role of the papilla in the initiation of pyelonephritis (98). However, these changes are not necessarily specific for bacterial infection and may occur in the absence of infection as a result of other disorders such as analgesic abuse, diabetes, and sickle cell disease.

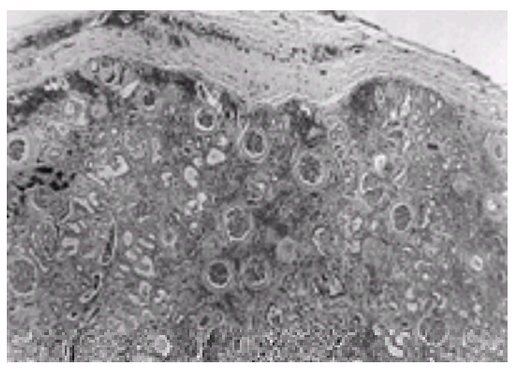

FIGURE 4.9. Chronic pyelonephritis. The renal cortex shows thickened fibrous capsule and focal retracted scar on surface of kidney. Focal destruction of tubules in center of picture is accompanied by periglomerular fibrosis and scarring.

The classic pathologic description of chronic pyelonephritis has traditionally been that of Weiss and Parker (382); however, their autopsy studies included late stages of the disease, which are often complicated by hypertension and vascular changes and are best referred to as *end-stage kidneys.* They repeatedly emphasized that patients with this form of renal disease did not always have clinical evidence of bacterial infections of the urinary tract sufficient to explain the severe loss of renal tissue. Stamey and Pfau (334) presented a case of pure symptomatic pyelonephritis, incurable with drug therapy and uncomplicated by vascular hypertension. The microscopic sections together with Heptinstall's comments represent an unusual opportunity to study the pathologic characteristics of this disease in its purest form.

Acute Pyelonephritis

Clinical Findings

The onset of acute pyelonephritis is usually abrupt. The classic clinical features are chills, fever (100°F or greater), and costovertebral angle or flank pain accompanied by symptoms of cystitis.

Although some authors regard loin pain and fever in combination with significant bacteriuria as diagnostic of acute pyelonephritis, it is clear from localization studies using ureteral catheterization (335) or the bladder wash-out technique (83) that clinical symptoms correlate poorly with the site of infection (77,80,321,333). In a large study of 201 women and 12 male patients with recurrent urinary tract infection, Busch and Huland (32) showed that fever and flank pain are no more diagnostic of pyelonephritis than they are of cystitis. Of patients with flank pain, fever, or both, more than 50% had lower tract bacteriuria. Patients with bladder symptoms or no symptoms frequently had upper tract bacteriuria. Approximately 75% of patients give a history of previous lower urinary tract infections.

On physical examination, there often is tenderness to deep palpation in the costovertebral angle. Variations of this clinical presentation have been recognized. Acute pyelonephritis may also simulate gastrointestinal tract abnormalities with abdominal pain, nausea, vomiting, and diarrhea. Asymptomatic progression of acute pyelonephritis to chronic pyelonephritis, particularly in compromised hosts, may occur in the absence of overt symptoms.

Laboratory Findings

The patient may have leukocytosis with predominance of neutrophils. Urinalysis usually reveals numerous WBCs, often in clumps, and bacteria. Leukocytes exhibiting brownian motion in the cytoplasm (glitter cells) may be present if the urine is hypotonic, but they are not in themselves diagnostic of pyelonephritis. The presence of large amounts of granular or leukocyte casts in the urinary sediment is suggestive of acute pyelonephritis. A specific type of urinary cast characterized by the presence of bacteria in its matrix has been demonstrated in the urine of patients who have had acute pyelonephritis (Fig. 4.10) (199). Bacteria in the casts were not easily distinguished by simple bright-field microscopy without special staining of the sediment. Staining the sediment with a basic dye such as dilute toluidine blue or KOVA (I.C.L. Scientific, Fountain Valley, California) stain demonstrated the bacteria in casts without difficulty. Urine cultures are invariably positive. Most often, the causative microorganism is *E. coli.* However, more resistant species, such as *Proteus, Klebsiella, Pseudomonas,* or *Serratia,* should be suspected in patients who have recurrent urinary tract infections, are hospitalized, or have indwelling catheters, as well as in those who required recent urinary tract instrumentation. Except for *Enterococcus faecalis* and *S. epidermidis,* Gram-positive bacteria rarely cause pyelonephritis. Blood cultures should be obtained in patients with severe toxicity because bacteremia and sepsis are common.

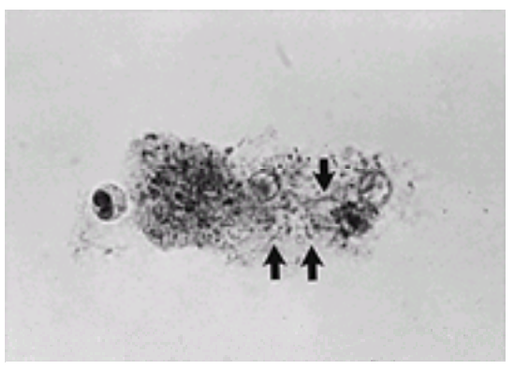

FIGURE 4.10. Bright-field micrograph of a mixed bacterial leukocyte cast from patient with acute pyelonephritis. Only the bacteria and the nucleus of a leukocyte stain strongly. *Arrows* show some bacteria. Many more are clearly demonstrated by through-focusing (toluidine blue O stain, magnification ×640). Differential Diagnosis

Acute appendicitis, diverticulitis, and pancreatitis can cause a similar degree of pain, but the location of the pain often is different. Results of the urine examination are usually normal. Herpes zoster can cause superficial pain in the region of the kidney but is not associated with symptoms of urinary tract infection; the diagnosis will be apparent when shingles appear.

Initial Management

Hospitalization, initially with complete bed rest, intravenous fluids, and antipyretics, is required for patients with significant toxicity. Patients with less severe disease may be managed as outpatients. Bladder outlet obstruction and associated urinary retention should be relieved by an indwelling urethral or suprapubic catheter. Upper tract obstruction, if suspected, should be ruled out by ultrasonography or intravenous urogram. An obstructed kidney has difficulty concentrating and excreting antimicrobial agents. In addition, obstruction in effect creates a potential abscess, pyonephrosis, which can rapidly destroy the renal parenchyma and endanger the patient's life. Any substantial obstruction must be relieved expediently by the safest and simplest means.

Until the results of the culture and susceptibilities are available, broad-spectrum antimicrobial therapy should be instituted. A Gram stain of the urine sediment is helpful to guide the selection of the initial empiric antimicrobial therapy. Outpatient, single-drug oral therapy with a fluoroquinolone is more effective than TMP-SMX for patients with domiciliary infections (359). Many physicians administer a single parenteral dose of an antimicrobial (ceftriaxone, gentamicin, or a fluoroquinolone) before initiating oral therapy (158,267). If a Gram-positive organism is suspected, amoxicillin or amoxicillin / clavulanic acid is recommended (377). If a patient is sufficiently ill to require hospitalization (high fever, high WBC count, vomiting, dehydration, or evidence of sepsis) or fails to improve during the initial outpatient treatment period, the patient should be admitted and treated with intravenous antimicrobials. A parenteral fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside is recommended (377). If Gram-positive cocci are causative, ampicillin/sulbactam with or without an aminoglycoside is recommended.

Subsequent Management

Even though the urine usually becomes sterile within a few hours of starting antimicrobial therapy, patients with acute pyelonephritis may continue to have fever, chills, and flank pain for several more days (18). Ambulatory patients should be treated with a fluoroquinolone for 7 days (359). Alterations in antimicrobial therapy may be made depending on the patient's clinical response and the results of the culture and susceptibility tests. Susceptibility tests should also be used to replace potentially toxic drugs, such as aminoglycosides, with less toxic drugs, such as the fluoroquinolones, aztreonam, and cephalosporins. For women with uncomplicated pyelonephritis, 7-day fluoroquinolone therapy is associated with greater bacteriologic and clinical cure rates than 14-day TMP-SMX therapy (359). In hospitalized patients with bacteremia, parenteral therapy should be continued for 7 days. If results of the blood cultures are negative, parenteral therapy can be discontinued after several days. In either case, an appropriate oral antimicrobial drug (fluoroquinolone; TMP, TMP-SMX, or amoxicillin or amoxicillin/clavulanic acid for Gram-positive organisms) should be continued in full dosage for an additional 10 to 14 days.

Excretory urography is usually performed after institution of adequate therapy and resolution of the patient's symptoms; therefore it is not surprising that most patients with pyelonephritis have a normal excretory urogram (317,385). However, if obtained during acute pyelonephritis, the most common radiologic abnormality is renal enlargement, which occurs from generalized renal edema as a consequence of the inflammatory process (Fig. 4.11A). An overall length of 15 cm or a length 1.5 cm greater than the unaffected side has been established as criteria for the diagnosis of renal enlargement in acute pyelonephritis (56,317,385). The inflammatory response may also cause cortical vasoconstriction, which is presumably responsible for the diminished nephrogram and delayed appearance of the pyelogram, as well as compression of the collecting structures, so that the calyces have an attenuated or spidery appearance. In addition to these abnormalities, calyceal and ureteral dilation have occasionally been reported (124). This finding has been commonly attributed to a decrease in ureteral peristalsis caused by bacterial endotoxin. Although ureteral dilation may occur with infection, this diagnosis should not be made until obstruction, either past or present, has been excluded.

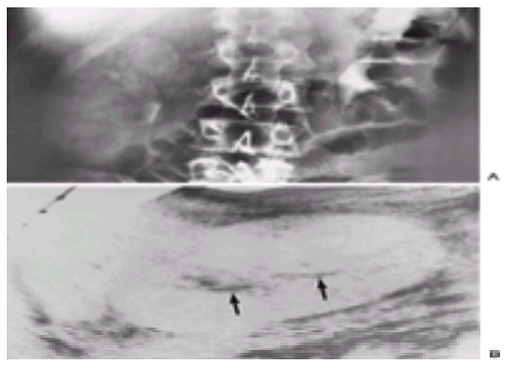

FIGURE 4.11. Acute pyelonephritis. **A:** Excretory urogram. Ten-minute film demonstrates enlarged right kidney with minimum function. Findings are consistent with edema. **B:** Ultrasound of the right kidney demonstrates renal enlargement, hypoechoic parenchyma, and compressed central collecting complex *(arrows).*

Ultrasound (Fig. 4.11B) and CT show renal enlargement, hypoechoic or attenuated parenchyma, and a compressed collecting system. In patients with fever greater than 72 hours, these studies are most helpful for ruling out obstruction and identifying complicated renal and perirenal infections (327).

Unfavorable Response to Therapy

When the response to therapy is slow or the urine continues to show infection, an immediate reevaluation is mandatory. Urine and blood cultures must be repeated and appropriate alterations in antimicrobial therapy made on the basis of susceptibility testing. Radiologic investigation is indicated to attempt to identify unsuspected obstructive uropathy, urolithiasis, or underlying anatomic abnormalities that may have predisposed the patient to infection, prevented a rapid therapeutic response, or caused complications of the infectious process, such as renal or perinephric abscess. Radionuclide imaging may be useful to demonstrate functional changes associated with acute pyelonephritis (decrease in renal blood flow, delay in peak function, and delay in excretion of the radionuclide) (87) and cortical defects associated with vesicoureteral reflux.

Follow-up

Repeat urine cultures should be performed on the fifth to seventh day of therapy and 10 to 14 days and 4 to 6 weeks after discontinuing antimicrobial therapy to ensure that the urinary tract remains free of infections. For the few patients who have recurrent infections that presumably represent “relapse,” re-treatment for 6 weeks has been recommended (162).

Depending on the clinical presentation and response and initial urologic evaluation, some patients may require additional evaluation (e.g., voiding cystourethrogram, cystoscopy, bacterial localization studies) and correction of an underlying abnormality of the urinary tract.

Acute Focal or Multifocal Bacterial Nephritis

Acute focal or multifocal bacterial nephritis is an uncommon, severe form of acute renal infection in which a heavy leukocyte infiltrate is confined to a single renal lobe (focal) or multiple lobes (multifocal).

Clinical Findings

The clinical presentation of patients with acute bacterial nephritis is similar to that of patients with acute pyelonephritis but usually is more severe. About half of the patients are diabetic, and sepsis is common. Generally, leukocytosis and urinary tract infection resulting from Gram-negative organisms are found; more than 50% of the patients are bacteremic (385).

Radiologic Findings

The diagnosis must be made by radiologic examination. The urographic findings are those of a mass, most commonly poorly marginated and suggestive of renal abscess or tumor (Fig. 4.12A). The mass has slightly less nephrographic density than the surrounding normal renal parenchyma.

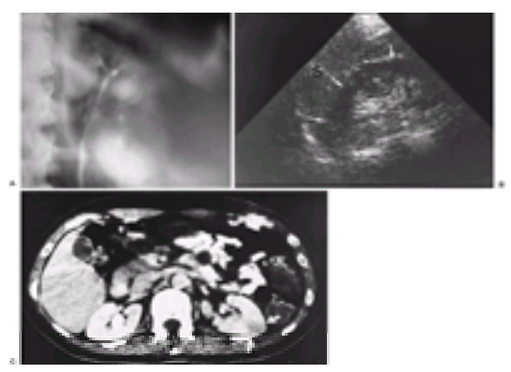

FIGURE 4.12. Acute focal bacterial nephritis. **A:** Excretory urogram. Five-minute tomogram demonstrates normally functioning upper and lower poles and a poorly marginated midrenal mass with poor function and absent collecting system visualization. **B:** Ultrasound; longitudinal view of the left kidney demonstrates spleen *(S)* and left kidney *(arrows).* Note irregular midpole mass *(M)* of slightly higher echo texture than surrounding normal renal parenchyma. **C:** Contrast-enhanced computed tomography scan demonstrates a wedge-shaped area of low density *(arrows)* in the middle portion of the left kidney. The findings resolved after antibiotic therapy.

Ultrasonography and CT aid in establishing the diagnosis. On ultrasonography, the lesion is typically poorly marginated and relatively sonolucent with occasional low-amplitude echoes that disrupt the cortical medullary junction (56) (Fig. 4.12B). Contrast enhancement is necessary with CT studies because the lesion is difficult to visualize on the unenhanced study (Fig. 4.12C). Wedge-shaped areas of decreased enhancement are seen. No definite wall is evident, and frank liquefaction is absent. Conversely, abscesses tend to have liquid centers, are usually round, and are present both before and after contrast enhancement. More chronic abscesses may also show a ring-shaped area of increased enhancement surrounding the lesion (56). Gallium scanning reveals uptake that is in the region of and larger than the previously demonstrated mass (284). In patients with multifocal disease, the findings are similar, but multiple lobes are involved.

Management

Acute bacterial nephritis probably represents a relatively early phase of frank abscess formation. In a series of cases reported by Lee and co-workers (195), a patient with acute focal bacterial nephritis progressed to abscess formation. Treatment includes hydration and intravenous antimicrobials for at least 7 days, followed by 7 days of oral antimicrobial therapy. Patients with bacterial nephritis typically respond to medical therapy, and follow-up studies will show resolution of the wedge-shaped zones of diminished attenuation. Failure to respond to antimicrobial therapy is an indication for appropriate studies to rule out obstructive uropathy, renal or perirenal abscess, renal carcinoma, or acute renal vein thrombosis. Long-term follow-up studies performed in a few patients with multifocal disease have

demonstrated a decrease in renal size and focal calyceal deformities suggestive of papillary necrosis (62).

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is an acute necrotizing parenchymal and perirenal infection caused by gas-forming uropathogens. The pathogenesis is poorly understood. Because the condition usually occurs in diabetic patients, it has been postulated that the high tissue glucose levels provide the substrate for microorganisms such as *E. coli,* which are able to produce carbon dioxide by the fermentation of sugar (303). Although glucose fermentation may be a factor, the explanation does not account for the rarity of emphysematous pyelonephritis despite the high frequency of Gram-negative urinary tract infection in diabetic patients, nor does it explain the rare occurrence of the condition in nondiabetic patients.

In addition to diabetes, many patients have urinary tract obstruction associated with urinary calculi or papillary necrosis and significant renal functional impairment. It seems more reasonable to postulate that impaired host response caused by local factors, such as obstruction, or a systemic condition, such as diabetes, allows organisms with the capability of producing carbon dioxide to use necrotic tissue as a substrate to generate gas *in vivo.* Thus emphysematous pyelonephritis should be considered a complication of severe pyelonephritis rather than a distinct entity.

Clinical Findings

All of the documented cases of emphysematous pyelonephritis have occurred in adults (130). Juvenile diabetic patients do not appear to be at risk. Women are affected more often than men.

The usual clinical presentation is severe, acute pyelonephritis, although in some instances, a chronic infection precedes the acute attack. Almost all patients display the classic triad of fever, vomiting, and flank pain (303). Pneumaturia is absent unless the infection involves the collecting system. Results of urine cultures are invariably positive. *E. coli* is most commonly identified. *Klebsiella* and *Proteus* are less common.

Radiologic Findings

The diagnosis is established radiographically. Tissue gas that is distributed in the parenchyma may appear on abdominal x-ray films as mottled gas shadows over the involved kidney (Fig. 4.13). This finding is often mistaken for bowel gas. A crescentic collection of gas over the upper pole of the kidney is more distinctive. As the infection progresses, gas extends to the perinephric space and retroperitoneum. This distribution of gas should not be confused with cases of emphysematous pyelitis in which air is in the collecting system of the kidney. Emphysematous pyelitis is secondary to a gas-forming bacterial urinary tract infection, often occurs in nondiabetic patients, is less serious, and usually responds to antimicrobial therapy.

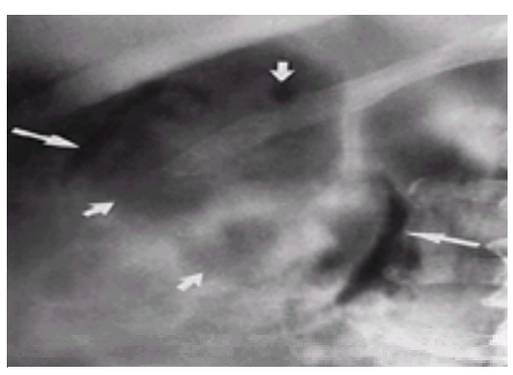

FIGURE 4.13. Emphysematous pyelonephritis; plain film. Extensive perinephric *(long arrows)* and intraparenchymal *(short arrows)* gas secondary to acute bacterial pyelonephritis.

Excretory urography is rarely of value in emphysematous pyelonephritis because the affected kidney usually is nonfunctioning or poorly functioning. Because of the significant risk of contrast nephropathy in critically ill, dehydrated diabetic patients with abnormal renal function, retrograde pyelography rather than excretory urography is advisable to demonstrate obstruction. Obstruction is demonstrated in approximately 25% of the cases. Ultrasonography usually demonstrates strong focal echoes suggesting the presence of intraparenchymal gas (27,53). CT is the imaging procedure of choice in defining the extent of the emphysematous process and guiding management (Fig. 4.14). An absence of fluid in CT images or the presence of streaky or mottled gas with or without bubbly and loculated gas appears to be associated with rapid destruction of renal parenchyma and a 50% to 60% mortality rate (19,376). The presence of renal or perirenal fluid, the presence of bubbly or loculated gas or gas in the collecting system, and the absence of streaky or mottled gas patterns is associated with a less than 20% mortality rate. A nuclear renal scan should be performed to assess the degree of renal function impairment in the involved kidney and the status of the contralateral kidney.

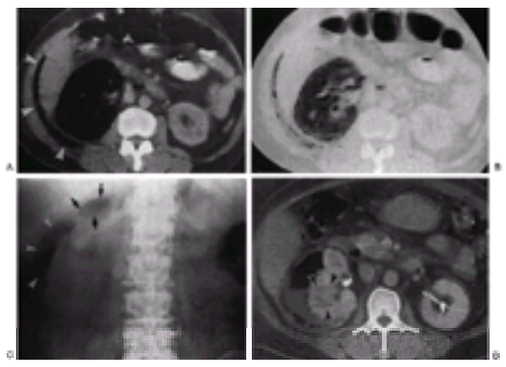

FIGURE 4.14. A, B: Type I emphysematous pyelonephritis (EPN) with complete renal destruction in a 49-year-old woman. **A:** Computed tomography (CT) scan of the right kidney shows complete destruction with gas *(arrowheads)* extending beyond the renal fascia. **B:** CT scan with a modified lung window display shows the characteristic streaky gas in the completely destroyed kidney. The patient died on arrival in the emergency department before nephrectomy was attempted. **C, D:** Type II EPN in a 57-year-old woman. **C:** Radiograph shows crescent-shaped *(arrowheads)* and loculated *(arrows)* gas in the right renal area. **D:** CT image obtained after administration of contrast material shows a low-attenuation area *(arrowheads)* in the right kidney due to acute pyelonephritis as well as a subcapsular abscess with fluid, bubbly, and loculated gas. The patient survived after percutaneous drainage was performed.

Management

Emphysematous pyelonephritis is a surgical emergency. Most patients are septic, and fluid resuscitation and broad-spectrum antimicrobial therapy are essential. If the kidney is functioning, medical therapy can be considered (19,376). Nephrectomy is recommended for patients who do not improve after a few days of therapy (73). If the affected kidney is nonfunctioning and not obstructed, nephrectomy should be performed because medical treatment alone is usually lethal. If a kidney is obstructed, catheter drainage must be instituted. If the patient's condition improves, nephrectomy may be deferred pending a complete urologic evaluation. Although there are isolated case reports of retention of renal function after medical therapy combined with relief of obstruction, most patients require nephrectomy (149).

Renal Abscess

Renal abscess or carbuncle is a collection of purulent material confined to the renal parenchyma. Before the antimicrobial era, 80% of renal abscesses were attributed to hematogenous seeding by staphylococci (36). Although experimental and clinical data document the facility for abscess formation in normal kidneys after hematogenous inoculation with staphylococci, widespread use of antimicrobials in the past 25 years appears to have diminished the propensity for Gram-positive abscess formation (57,64).

During the past two decades, Gram-negative organisms have been implicated in many adults with renal abscesses. Hematogenous renal seeding by Gram-negative organisms may occur, but this is not likely to be the primary pathway for Gram-negative abscess formation. Clinically, there is no evidence that Gram-negative septicemia antedates most lesions. Furthermore, Gram-negative hematogenous pyelonephritis is virtually impossible to produce in animals unless the kidney is traumatized or completely obstructed (57,362). The partially obstructed kidney rejects blood-borne Gram-negative inocula, as does a normal kidney. Thus ascending infection associated with tubular obstruction from prior infections or calculi appears to be the primary pathway for establishment of Gram-negative abscesses. Two-thirds of Gram-negative abscesses in adults are associated with renal calculi or damaged kidneys (290) (Fig. 4.15). Although the association of pyelonephritis with vesicoureteral reflux is well established, the association of renal abscess with vesicoureteral reflux has rarely been noted in the past (310). However, it has been observed that reflux often is associated with renal abscesses and persists long after sterilization of the urinary tract (362).

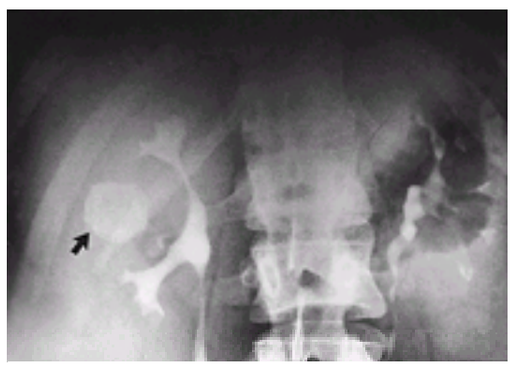

FIGURE 4.15. Renal abscess associated with infection stone. Excretory urogram. Twenty-minute film demonstrates a large, right midpole calculus *(arrow).* Abscess associated with this infection stone causes displacement of adjacent collecting system.

Clinical Findings

The patient's symptoms may include fever, chills, abdominal or flank pain, and occasionally, weight loss and malaise. Lower urinary tract infections, including cystitis, also usually occur. Occasionally, these symptoms may be vague and delay diagnosis until surgical exploration or, in more severe cases, at autopsy (5). A thorough history may reveal a Gram-positive source of infection 1 to 8 weeks before the onset of urinary tract symptoms. The infection may have occurred in any area of the body. Multiple skin carbuncles and intravenous drug abuse introduce Gram-positive organisms into the bloodstream. Other common sites are the mouth, lungs, and bladder (205). Complicated urinary tract infections associated with stasis, calculi, pregnancy, neurogenic bladder, and diabetes mellitus also appear to predispose the patient to abscess formation (5).

Laboratory Findings

The patient typically has marked leukocytosis. The blood cultures are usually positive. Pyuria and bacteriuria may not be evident unless the abscess communicates with the collecting system. Because Gram-positive organisms are most commonly blood borne, urine cultures in these cases will typically show no growth or a microorganism different from that isolated from the abscess. When the abscess contains Gram-negative organisms, the urine culture usually demonstrates the same organism isolated from the abscess.

Radiologic Findings

The urographic findings depend on both the nature and the duration of the infection. In patients in whom abscess formation has progressed from an episode of acute bacterial nephritis or those in whom the kidney has been seeded by an outside infection, radiologic examination may demonstrate generalized renal enlargement with distortion of the renal contour on the affected side. There also may be renal fixation evident on inspiratory and expiratory films and obliteration of the corresponding psoas shadow. Scoliosis is often present, with a concavity of the curve facing the affected kidney. If renal involvement is diffuse, the nephrogram will be delayed or even absent. When an abscess is more localized, the findings may be similar to those of acute focal bacterial nephritis.

In a more chronic abscess, the predominant urographic abnormalities are those of a renal mass lesion (Fig 4.15). The calyceal system may be poorly defined or show distortion or even amputation. Nephrotomography usually reveals a relative radiolucency in the involved area. Occasionally, the excretory urogram will appear normal despite the presence of a renal abscess, particularly if the abscess involves the anterior or posterior portion of the kidney without impinging on the parenchyma or collecting system.

CT appears to be the diagnostic procedure of choice for renal abscesses because it provides excellent delineation of the tissue. On CT, abscesses are characteristically well defined both before and after contrast enhancement. Initially, CT shows renal enlargement and focal, rounded areas of decreased attenuation (Fig 4.16A). After several days of the onset of the infection, a thick, fibrotic wall begins to form around the abscess. CT of a chronic abscess shows obliteration of adjacent tissue planes, thickening of Gerota's fascia, and a round or oval parenchymal mass of low attenuation that forms a ring when the scan is enhanced with contrast material (Fig 4.17A). The ring sign is caused by the increased vascularity of the abscess wall.

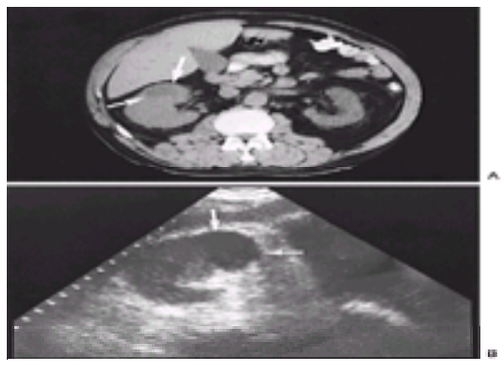

FIGURE 4.16. Acute renal abscess. **A:** Nonenhanced computed tomography scan through the midpole of the right kidney demonstrates right renal enlargement and an area of decreased attenuation *(arrows).* After antimicrobial therapy, follow-up scan showed complete regression of these findings. **B:** Ultrasound. Transverse scan of the right kidney demonstrates a poorly marginated rounded focal hypoechoic mass *(arrows)* in the anterior portion of the kidney.

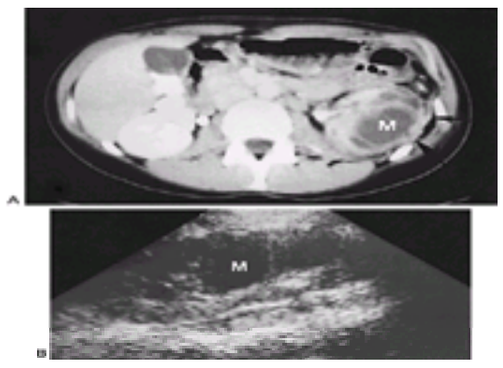

FIGURE 4.17. Chronic renal abscess. **A:** Enhanced computed tomography scan shows irregular septated low-density mass *(M)* extensively involving the left kidney. Note thickening of perinephric fascia *(arrows)* and extensive compression of the renal collecting system. Findings are typical of renal abscess. **B:** Ultrasound. Longitudinal scan demonstrates septated hypoechoic mass *(M)* occupying much of the renal parenchymal volume.

Ultrasonography is the quickest and least expensive method to demonstrate a renal abscess. An echo-free or low-echo-density space-occupying lesion with increased transmission is found on the sonogram. The margins of an abscess are indistinguishable in the acute phase, but the structure contains a few echoes, and the surrounding renal parenchyma is edematous (Fig 4.16B). Subsequently, the appearance tends to be that of a well-defined mass. However, the internal appearance may vary from a virtually solid lucent mass to one with large numbers of low-level internal echoes (Fig 4.17B). The number of echoes depends on the amount of cellular debris within the abscess. Presence of air results in a strong echo with a shadow. Differentiation between an abscess and a chronic tumor is impossible in many cases. Arteriography is used occasionally to demonstrate abscesses. The center of the mass tends to be hypovascular or avascular, with increased vascularity at the cortical margins and lack of vascular displacement and neovascularity.

Radionucleotide imaging with gallium or indium is sometimes useful in evaluating patients with renal abscesses. The exact mode of gallium-67 localization in tissues is not clear. Suggested possible mechanisms include concentration within labeled polymorphonuclear leukocytes, leakage of protein-bound gallium through capillaries, and increased vascularity of the lesion. Delayed imaging is often necessary. Gallium is a nonspecific method of identifying an inflammatory lesion; more important, it lacks anatomic detail. In addition, gallium is excreted into the colon and sequestered in postsurgical beds, inflammatory sites, and tumors; therefore the interpretation of gallium scans can be extremely difficult.

Indium-111–labeled leukocyte scanning is a clinically effective method for detecting inflammatory diseases and abscesses. Indium-111–labeled leukocytes accumulate only in sites of inflammation and not in normal kidneys or in tumors. Thus their presence appears highly specific for inflammation. However, the indium scan has limitations. Hyperalimentation and hyperglycemia can prevent the accumulation at the site of inflammation, and the distribution of leukocytes is altered in patients who have had splenectomy or bone marrow radiation. The necessity of high doses of radiation with indium scanning may make it unsuitable for pediatric patients (107).

Ultrasonography and CT identify more than 90% of abscesses (91,316). Ultrasonography demonstrates a hypoechoic mass with irregular walls and acoustic shadowing if gas is present. CT scan findings depend in part on the age and severity of the abscess (16).

Management

Although the classic treatment for an abscess has been incision and drainage, there has been good evidence that the use of intravenous antimicrobials and careful observation of a small abscess less than 3 cm in diameter, if begun early enough in the course of the process, may obviate surgical procedures (198).

When hematogenous dissemination is suspected, the pathogenic organism most commonly is penicillin-resistant *Staphylococcus,* and the antibiotic of choice therefore is a penicillinase-resistant penicillin (305). If a history of penicillin hypersensitivity is present, the recommended drug is either cephalosporin or vancomycin. Cortical abscesses that occur in the abnormal urinary tract are associated with more typical Gram-negative pathogens and should be treated empirically with intravenous third-generation cephalosporins, antipseudomonal penicillins, or aminoglycosides until specific therapy can be instituted. These individuals can have follow-up with ultrasonography or CT until the abscess resolves. A clinical course contrary to this should lead to the suspicion of misdiagnosis or an uncontrolled infection with development of perinephric abscess or infection with an organism resistant to the antimicrobials used in therapy. In these instances, drainage is usually necessary.

CT- or ultrasound-guided needle aspiration may be necessary to differentiate a small abscess from a hypovascular tumor. Aspirated material can be cultured and appropriate antimicrobial therapy instituted on the basis of the findings. Abscesses larger than 3 cm and smaller abscesses in immunocompromised hosts or those that do not respond to antimicrobial therapy should be drained percutaneously (91,316). However, surgical drainage currently remains the procedure of choice for most renal abscesses greater than 5 cm in diameter.

Infected Hydronephrosis and Pyonephrosis

If bacterial infection occurs in a hydronephrotic kidney, a purulent exudate will collect in the renal collecting system. Pyonephrosis refers to infected hydronephrosis associated with suppurative destruction of the parenchyma of the kidney, with total or near-total loss of renal function (Fig. 4.18). The point at which infected hydronephrosis ends and pyonephrosis begins is difficult to determine.

FIGURE 4.18. Pyonephrosis; gross specimen. Kidney shows marked thinning of renal cortex and medulla, suppurative destruction of the parenchyma *(arrows),* and distention of the pelvis and calyces. Previous incision released large quantity of purulent material. Ureter showed obstruction distal to the point of section.

Clinical Findings

The clinical presentation is variable, ranging from no complaints to urosepsis. However, many patients will be ill with fever, chills, and flank pain and tenderness. A history of urinary tract calculi, infection, or surgery is common. Bacteriuria may not be present if the ureter is completely obstructed. Wu and colleagues (398) observed significantly higher erythrocyte sedimentation rates and C-reactive protein levels in patients with infected hydronephrosis or pyonephroses compared with those with simple hydronephrosis. A cutoff of erythrocyte sedimentation rate greater than 100 mm per hour and C-reactive protein of 3 mg/dL yielded a specificity and sensitivity of 89% and 100%, respectively, and a diagnostic accuracy of 97%. Changes in these parameters can be used to evaluate the effectiveness of antimicrobial

therapy.

Radiologic Findings

The ultrasonographic diagnosis of infected hydronephrosis depends on demonstration of internal echoes within the dependent portion of a dilated pyelocalyceal system. CT scan is nonspecific but may show thickening of the renal pelvis, stranding of the perirenal fat, and a striated nephrogram. The urographic findings are those of urinary tract obstruction and depend on the degree and duration of obstruction. Typically, the obstruction is longstanding, and excretory urography shows a poorly functioning or nonfunctioning hydronephrotic kidney. Ultrasound demonstrates hydronephrosis and fluid debris levels within the dilated collecting system (56) (Fig 4.19A). The diagnosis of pyonephrosis is suggested if focal areas of decreased echogenicity are seen within the hydronephrotic parenchyma.

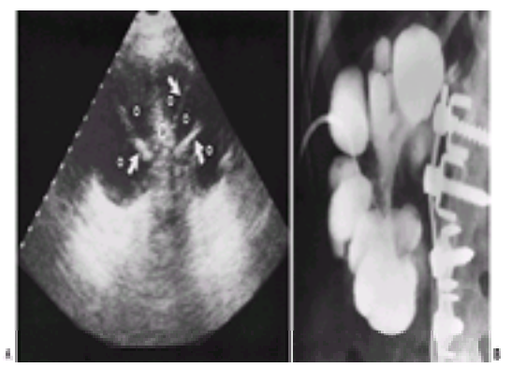

FIGURE 4.19. Pyonephrosis. **A:** Ultrasound. Longitudinal scan of the right kidney demonstrates echogenic central collecting complex *(C)* with radiating echogenic septae *(arrows)* and thinned hypoechoic parenchyma. Multiple dilated calyces *(o)* with diffuse low-level echoes are seen. **B:** Antegrade pyelogram performed through a percutaneous nephrostomy catheter correlates well with the ultrasound image. Dilated pus-filled calyces are demonstrated. The renal pelvis is obliterated by chronic scarring and stone disease. The kidney did not regain function.

Management

Appropriate intravenous antimicrobial therapy is important, but immediate drainage of the kidney is mandatory. Percutaneous nephrostomy (Fig. 4.19B) or retrograde ureteral catheterization (or, if necessary, open nephrostomy) must be performed. When the patient's condition has stabilized, appropriate corrective surgery or nephrectomy can be performed depending on the patient's age, the cause and type of obstruction, and the degree of renal function impairment.

Perinephric Abscess

Perinephric abscess (PNA) usually results from rupture of an acute cortical abscess into the perinephric space. Patients with pyonephrosis, particularly when a calculus is present in the kidney, are susceptible to perinephric abscess formation. Diabetes mellitus is present in approximately one-third of patients with perinephric abscess (70,361). In about one-third of the cases, perinephric abscess is caused by hematogenous spread, usually from sites of skin infection. A perirenal hematoma can become secondarily infected by the hematogenous route or by direct extension of a primary renal infection. Rarely, perinephric or psoas abscess may be the result of bowel perforation, Crohn's disease, or spread of osteomyelitis from the thoracolumbar spine. *E. coli, Proteus,* and *S. aureus* account for most infections.

Clinical Findings

The onset of symptoms is typically insidious. Symptoms have been present for more than 5 days in most patients with perinephric abscess compared with only about 10% of patients with pyelonephritis. The clinical presentation may be similar to that of pyelonephritis; however, more than one-third of patients may be afebrile. An abdominal or flank mass can be felt in about half of the cases. Psoas abscess should be suspected if the patient has a limp and flexion and external rotation of the ipsilateral hip. Laboratory features include leukocytosis, elevated levels of serum creatinine, and pyuria in more than 75% of cases. Edelstein and McCabe (70) showed that results of urine cultures predicted PNA isolates in only 37% of cases; a blood culture, particularly with multiple organisms, was often indicative of perinephric abscess, but identified all organisms in only 42% of cases. Therefore therapy based on the results of urine and blood cultures often may be inadequate. Pyelonephritis usually responds within 4 to 5 days of appropriate antibiotic therapy; perinephritic abscess does not. Thus perinephric abscess should be suspected in a patient with urinary tract infection and abdominal or flank mass or persistent fever after 4 days of antimicrobial therapy.

Radiologic Findings

Excretory urography is abnormal in 80% of cases. However, the abnormalities are not specific. Classically, the radiographic features of perinephric abscess have been the absence of psoas shadow, a mass in the perirenal area often associated with indistinct renal outlines, and an elevated or immobile diaphragm. With large abscesses, the soft tissue density may extend to the pelvis following the renal fascia. In patients with perinephric abscess secondary to gas-forming organisms, bubbled collections of extraluminal gas are seen surrounding the kidney (203). CT is particularly valuable for demonstrating the primary abscess. In some cases, the abscess is confined to the perinephric space; however, extension to the flank or psoas muscle may occur (Fig. 4.20). CT is able to show with exquisite anatomic detail the route of spread of infection into the surrounding tissues. This information may be helpful in planning the approach for surgical drainage. Ultrasound demonstrates a diverse sonographic appearance ranging from a nearly anechoic mass displacing the kidney to an echogenic collection that tends to blend with normally echogenic fat within Gerota's fascia (56).

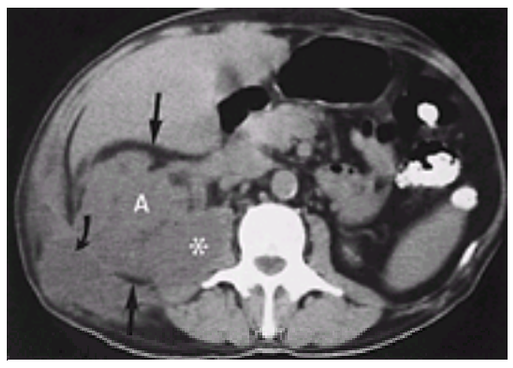

FIGURE 4.20. Extensive perinephric abscess. Nonenhanced computed tomography scan through the lower pole of the right kidney (previous left nephrectomy). Extensive abscess *(A)* distorts and enlarges renal contour, infiltrates perinephric fat *(arrows),* and also extends into the psoas muscle *(asterisk)* and the soft tissues of the flank *(curved arrow).* Also note that normal renal collecting system fat has been obliterated by the process.

Occasionally, a retroperitoneal or subdiaphragmatic infection may spread to the paranephric fat that is outside Gerota's fascia. The clinical symptoms of insidious onset of fever, flank mass, and tenderness are indistinguishable from those associated with perinephric abscess. Urinary tract infection, however, is absent. Ultrasonography and CT can usually delineate the abscess outside Gerota's fascia (Fig. 4.21).

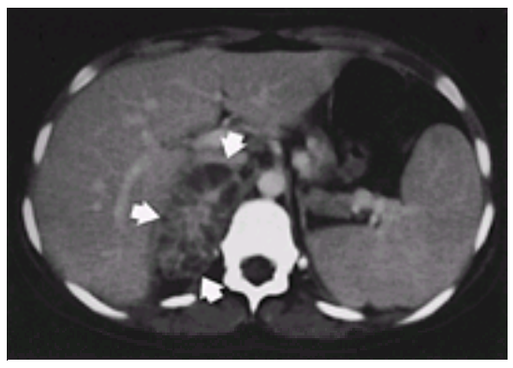

FIGURE 4.21. Perinephric abscess involving the right adrenal gland. Computed tomography scan. Large right pararenal mass *(arrows)* with multiple low-density areas within. At surgery, a large pararenal abscess with extensive involvement of the right adrenal was found.

Management

Once the diagnosis of perinephric or paranephric abscess is established, the primary treatment is surgical drainage. Gram stain identifies the pathogenesis and guides antimicrobial therapy. An aminoglycoside together with an antistaphylococcal agent, such as methicillin or oxacillin, should be started immediately. If the patient has a penicillin hypersensitivity, cephalothin or vancomycin may be used.

Once the perinephric abscess has been drained, the underlying problem must be dealt with. Some conditions, such as renal cortical abscess or enteric communication, require prompt attention. Nephrectomy for pyonephrosis may be performed concurrent with drainage of the perinephric abscess if the patient's condition is good. In other instances, it is best to drain the perinephric abscess first and correct the underlying problem or perform a nephrectomy when the patient's condition has improved.

Chronic Pyelonephritis

In patients without underlying renal or urinary tract disease, chronic pyelonephritis secondary to urinary tract infection is a rare disease and an even more rare cause of chronic renal failure. In patients with underlying functional or structural urinary tract abnormalities, however, chronic renal infection can cause significant renal impairment. Hence, it is essential that appropriate studies be used to diagnose, localize, and treat chronic renal infection.

The prevalence of chronic pyelonephritis has also been assessed in patients undergoing dialysis for end-stage renal disease. Despite a 2% to 5% prevalence of bacteriuria in women, only 1,000 to 2,000 women have end-stage renal disease as a result of pyelonephritis. Schechter and colleagues (304) analyzed the cause for renal failure in 170 patients referred to them for dialysis. Chronic pyelonephritis was the primary cause of end-stage renal disease in 22 (13%) but was usually associated with an underlying structural defect. Unequivocal nonobstructive chronic pyelonephritis was not found. The authors also observed that symptomatic infections tended to occur before the onset of azotemia in most patients with chronic pyelonephritis. Similarly, Huland and Busch (151) evaluated 161 patients with end-stage renal disease and found that 42 had chronic pyelonephritis. However, in addition to a history of urinary tract infections, these 42 patients had complicating defects, such as vesicoureteral reflux, analgesic abuse, nephrolithiasis, or obstruction. Nonobstructive uncomplicated urinary tract infection alone was never found to be the cause of renal insufficiency. Thus, using end-stage renal disease seen at autopsy or at the dialysis clinic as an indicator, the prevalence of uncomplicated chronic bacterial pyelonephritis is rare.

In addition, the role of bacterial infection in development of chronic renal disease can be assessed in patients with renal interstitial and tubular damage similar to that which has classically been called *chronic pyelonephritis.* The frequency with which various potential causes of interstitial damage are operative in patients with interstitial nephritis was assessed by Murray and Goldberg (234). These investigators not only concluded that urinary tract infection is rarely the sole cause of chronic renal disease in the adult, but they also observed that 89% of their azotemic patients had a readily identifiable primary cause of their interstitial nephritis. Thus, when patients with a clinical diagnosis of chronic interstitial nephritis are selected as the starting point, it is easy to associate many factors with this disease, but urinary tract infection does not seem to be one of them.

Clinical Findings

There are no symptoms of chronic pyelonephritis until it produces renal insufficiency, and then the symptoms are similar to those of any other form of chronic renal failure. If a patient's chronic pyelonephritis is thought to be an end result of many episodes of acute pyelonephritis, a history of intermittent symptoms of fever, flank pain, and dysuria may be elicited. Similarly, urinary findings and the presence of renal infection correlate poorly. Bacteriuria and pyuria, the hallmarks of urinary tract infection, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Asscher (7a) has tabulated eight long-term follow-up studies from the literature on kidneys of adults with urinary tract infections. The data from these reports on 901 patients show that bacteriuria present in otherwise healthy adults for long periods may be associated with nonexistent or extremely minimum evidence of kidney damage. Conversely, patients who have chronic pyelonephritis may have negative urine cultures.

Radiologic Findings

The diagnosis of chronic pyelonephritis can be made with the greatest confidence on the basis of pyelographic findings. The essential features are asymmetry and irregularity of the kidney outlines, blunting and dilation of one or more calyces, and cortical scars at the corresponding site (Fig. 4.22). In the absence of stones, obstruction, and tuberculosis, and with the single exception of analgesic nephritis with papillary necrosis (which can be readily excluded by history), chronic pyelonephritis is virtually the only disease that produces a localized scar over a deformed calyx (331). In advanced pyelonephritis, calyceal distortion and irregularity together with cortical scars complete the picture. Hodson (135) pointed out that renal infarction, an extremely rare condition, may closely resemble pyelonephritic scars but that the renal pyramid remains with renal infarction in contradistinction to pyelonephritis.

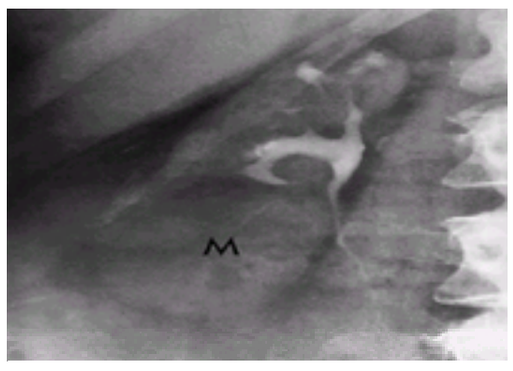

FIGURE 4.22. Chronic pyelonephritis. Excretory urogram. Ten-minute film demonstrates irregular renal outline with upper pole parenchymal atrophy. Note significant loss of renal cortical thickness over blunted and dilated calyces. Lower pole mass *(M)* is a simple cyst.

Management

Management of radiographic evidence of pyelonephritis should be directed at treating infection, if present; preventing future infections; and monitoring and preserving renal function. The treatment of existing infection must be based on careful antimicrobial susceptibility tests and selection of drugs that can achieve bactericidal concentrations in the urine and yet are not nephrotoxic. Achievement of acceptable bactericidal levels of a drug in the urine of a patient with chronic pyelonephritis may be difficult because the diminished concentrating ability of pyelonephritis may impair excretion and concentration of the antimicrobial agent. The duration of antimicrobial therapy is often prolonged to maximize the chance of cure. With patients in whom renal damage develops or progresses in the presence of urinary tract infection, the working hypothesis should be that there is an underlying renal, usually papillary, lesion or underlying urologic condition, such as obstruction or calculus, that has increased susceptibility to renal damage. Appropriate nephrologic and urologic evaluation should be undertaken to identify and, if possible, correct these abnormalities.

Bacterial "Relapse" from a Normal Kidney

The concept that bacteria persist in the renal parenchyma between bacteriuric episodes and cause "relapsing" urinary tract infections was based on a study by Turck and colleagues (366) that suggested that bacterial persistence could be recognized by simply identifying two consecutive recurrent infections with the same organism. Unfortunately, this study did not indicate whether the urine was cultured during therapy to ensure that the original infection had actually been eradicated. It is possible that some of these so-called relapses were in fact unresolved initial infections and that ureteral edema associated with catheterization may have impeded clearance of the initial infecting strain.

Subsequent studies summarized by Stamey (331) and Forland and associates (90) have shown that in a normal urinary tract recurrent infections are not caused by relapse from bacterial persistence in the kidney. With ureteral catheterization techniques, Cattell and associates (39) localized the site of bacteriuria in 42 patients who had follow-up for 6 months after therapy. They analyzed the response to antimicrobial therapy of 2 weeks' duration. Of the 26 patients who were cured of their initial infection, 16 had recurrence with the same organism; 8 had upper tract infections, and 8 had bladder bacteriuria.

If bacterial persistence in the kidney is a major problem after therapy, one would expect that patients who have more recurrent infections would also have more relapses than those who have less frequent recurrences. Mabeck (206) analyzed this, however, and found that with an increasing number of recurrences, the relationship among treatment failure, relapse, and reinfection remained unchanged. Thus bacteria do not persist in normal kidneys between recurrent urinary tract infections (331), and recurrences with the same strain are not caused by "relapse" from the kidney.

INFECTIOUS GRANULOMATOUS NEPHRITIS

Renal Tuberculosis

Tuberculosis is an acute or chronic infectious disease that in the United States is usually caused by *Mycobacterium tuberculosis. Mycobacterium bovis, Mycobacterium kansasii,* and *Mycobacterium intracellulare* are rare causes of tuberculosis.

Mycobacteria customarily gain access to the human body by inhalation, although the bovine organisms may be acquired by ingestion of unpasteurized milk. After initiation of the tuberculous infection, a primary pathologic focus develops, which usually heals spontaneously. In addition, the primary infection often results in an initial silent bacillemia that is responsible for systemic spread of *Mycobacterium* with latent infection of many organs. These latent foci of tuberculous infection may break down and result in overt tuberculosis of the kidney or other organs many years later. Bacillemia and seeding of the kidneys or other organs may also occur from a focus of progressive primary or reactivation tuberculosis in the lung or from clinically evident secondary tuberculosis in other organs. Therefore any individual who has previously been infected with tuberculosis is at risk for developing renal involvement.

Renal infection is among the most common sites for extrapulmonary tuberculosis. Approximately 5% of the estimated 250,000 patients with active tuberculosis in the United States have cavitary tuberculosis of the genitourinary tract (236,323,381). Thirty percent to 50% of patients with renal tuberculosis have had previous tuberculous pulmonary disease documented by history or implied from chest roentgenograms (320). However, it is uncommon for pulmonary tuberculosis to be active at the time of diagnosis of renal tuberculosis. Although effective chemotherapy has resulted in a significant decrease in the prevalence of pulmonary tuberculosis, the frequency of renal tuberculosis has not declined significantly in recent decades (197,236).

Pathology and Pathogenesis

In the hematogenous phase that takes place after the primary infection, both kidneys are seeded with tubercle bacilli in 90% of cases. However, clinically apparent renal tuberculosis is usually unilateral. The initial lesions involve the renal cortex with multiple small granulomas in the glomeruli and in the juxtaglomerular regions. With patients in whom acquired cellular immunity develops, there is inhibition of bacterial multiplication and containment of the disease process to the renal cortex. Microscopic examination reveals central caseation necrosis surrounded by pink staining epithelial histiocytes, Langhans' giant cells, and more peripherally, lymphocytes and plasma cells (125). Most patients are asymptomatic and have normal findings on radiologic examination. The asymptomatic cortical disease may be stable for many years and an incidental finding at nephrectomy or autopsy. These early lesions may resolve completely either spontaneously or as a result of treatment.

In untreated patients who fail to heal spontaneously, the lesions may progress slowly and remain asymptomatic for variable periods. In most individuals, the latent period between initial exposure and reactivation of renal disease is 10 to 40 years (320) and may be increased by appropriate therapy (236). The cortical areas of infection may seed the glomerular filtrate, creating lesions in the tubules and Henle's loop, resulting in additional foci in the renal pyramid. As the lesions progress, they produce areas of caseous necrosis, chronic interstitial nephritis with papillary necrosis, and parenchymal cavitation (Fig. 4.23). Large, tumorlike parenchymal lesions or tuberculomas often have a fibrous wall and can resemble a solid mass lesion. Their content may vary from caseous to calcified material (125). Larger blood vessels may show obliterative arteritis.

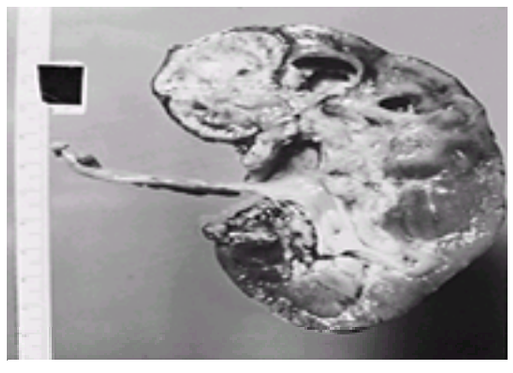

FIGURE 4.23. Tuberculoma, gross specimen. A destructive necrotic mass is present in the upper pole. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

Once cavities form, spontaneous healing is rare and destructive lesions result. With necrotizing papillitis, there is spread of the infection to the renal pelvis, ureter, and bladder. The inflammation and edema produce obstruction of the infundibula and ureter, leading to caliectasis, calyceal clubbing, and ureteral strictures, with consequent pelvic and ureteral dilation. Extensive peripelvic fibrosis may cause a substantial decrease in the pelvic capacity (Fig. 4.24). With extensive renal tuberculosis, parenchymal calcification is often present, varying from faint punctate foci to a complete cast of the kidney. Total destruction of the kidney may occur, resulting in autonephrectomy (Fig. 4.25).

FIGURE 4.24. Tuberculosis with pelvic fibrosis. Gross specimen shows several large necrotic cavities. The peripelvic fibrosis has caused marked diminution in the pelvic volume. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

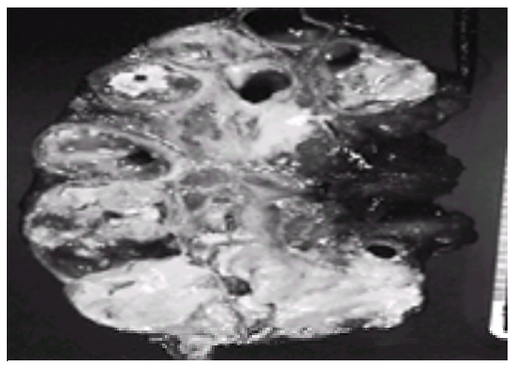

FIGURE 4.25. Tuberculosis, autonephrectomy. Gross specimen shows complete parenchymal destruction by extensive caseous necrosis. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

Seeding of the urine may also result in involvement of the bladder and male genital organs. Tuberculous inflammation in the bladder produces necrosis, ulceration, and fibrosis, which result in a thick-walled sac of small capacity.

Clinical Findings

Renal tuberculosis is predominantly a disease of young to middle-aged adults. Approximately 50% of the patients are 20 to 40 years of age, and approximately 75% are younger than 50 years of age (247,381).

Because of the slow progression and variable course of the disease, there is no classic presentation. Approximately 20% of patients subsequently found to have tuberculosis will be symptom free. Tuberculous nephropathy is an insidious process that often goes unrecognized for long periods. Up to 70% of patients with even advanced cavitary tuberculosis of the kidney may have few diagnostic renal symptoms (22,193). Gross hematuria; dull, vague flank discomfort; and ureteral colic secondary to passage of clots, debris, or calculi are the most common renal symptoms. Constitutional complaints such as fevers, chills, night sweats, weight loss, and malaise are uncommon. It is only when the bladder is involved that the patients become severely symptomatic. Frequency is the most common presenting symptom and is often progressive and occurs during the day and at night. Pain, urgency, and dysuria are also common with bladder involvement.

The physical examination is usually not helpful diagnostically. A chronic draining fistula tract from previous renal surgery or palpably enlarged, firm seminal vesicles on rectal examination should arouse suspicion. Patients with chronic epididymitis unresponsive to therapy should also be evaluated for tuberculosis.

Patients may also have complications of renal tuberculosis, including draining sinus, hypertension, renal failure, secondary amyloidosis, and adenocarcinoma of the renal pelvis (20,88,187,352,383,392). A draining sinus or abscess cavity can occur many years after completion of chemotherapy even in the presence of sterile organs. Pyelocutaneous fistula is often associated with calculus obstruction of the ureteropelvic junction.

Hypertension is present in approximately 5% to 10% of patients with renal tuberculosis; the incidence in patients with unilateral nonfunctioning or poorly functioning kidneys is approximately 25%. Although some of these individuals have evidence of renal ischemia as determined by renal vein renin studies and normalization of blood pressure after nephrectomy, most patients appear to have hypertension that is not mediated by the renin-angiotensin system and is not cured by nephrectomy (246).

Laboratory Findings

The urinalysis is abnormal in 90% of the patients. The most common finding is sterile, acid pyuria, often accompanied by hematuria and proteinuria. Pyuria in the absence of a positive culture for the usual uropathogens should always warrant consideration of diagnosis of renal tuberculosis. Acid-fast smears of urinary concentrates are usually negative and are not totally reliable if positive because the saprophytic organism *Mycobacterium smegmatis* may contaminate the urine and is morphologically indistinguishable from *M. tuberculosis* on acid-fast smear.

The most important laboratory test is urine culture for *M. tuberculosis.* Cultures are positive in approximately 90% of affected individuals (55). First-morning urine specimens are more reliable than 24-hour collections because they are easier to collect and there is much less chance of bacterial contamination. Because discharge of *M. tuberculosis* into the urine may be intermittent, it is advisable to collect morning urine specimens on a total of at least 3 separate days (236). Cultures should be obtained regardless of whether pus is present in the urine because positive cultures have been found in otherwise normal specimens (156). Susceptibility testing should be performed on isolated organisms.

Although the classic finding of renal tuberculosis is sterile pyuria, many patients have a concurrent positive culture for uropathogenic organisms at initial presentation. This finding should not preclude consideration of diagnosis of renal tuberculosis in the proper clinical setting. Such patients continue to demonstrate pyuria after the uropathogenic organism is eradicated by appropriate antimicrobial therapy.

The sealing off of cavitary lesions in chronic infections may in rare cases result in persistently negative findings on urine culture for tuberculosis and may mean that the disease in some patients remains undiagnosed despite repeated cultures (204). The tuberculin test, although not diagnostic, is of value only if positive.

Tuberculosis depresses renal function, but the damage has to be widespread before the serum creatinine level is elevated. Biochemical evidence of renal functional impairment is seen in less than 10% of patients with renal tuberculosis. Renal failure may be accentuated by obstructive uropathy that results from ureteral stricture or by secondary amyloidosis (210). Estimations of renal function are essential to preliminary assessment of patients with renal tuberculosis and determining the dose levels of antituberculous drugs. Wisnia and colleagues (392) showed that 58% of patients with renal tuberculosis had chronic renal failure at the time of diagnosis; 43% had subclinical impairment of creatinine clearance, 10% had compensated renal failure, and 5% had uremia.

It is apparent that the clinical presentation may be subtle, and therefore a high index of suspicion of renal tuberculosis is indicated in patients with a history of past or present tuberculosis, with chronic cystitis that fails to respond to adequate antimicrobial therapy, or with sterile pyuria accompanied by gross or microscopic

hematuria.

Radiologic Findings

Approximately 90% of patients with renal tuberculosis will have abnormal excretory urograms. The roentgenographic findings vary according to the severity of the destructive process and the duration of the disease. Early changes in the radiologic appearance of the tuberculous kidney may be subtle and difficult to find; hence, a normal excretory urogram does not rule out renal tuberculosis.

The most suggestive urographic features of renal parenchymal tuberculosis are the presence of cavities that communicate with the collecting system and fill with contrast medium and dilation of part or all of the calyceal system (125,236). Initially, the cavities are small; appear as a slight irregularity of a minor calyx; and show a moth-eaten, feathery, irregular appearance (Fig. 4.26A). Fibrous stenosis may cause amputation of one or more calyces (Fig. 4.26B). As the calyceal system becomes eroded, the parenchyma is destroyed by cavitation and the picture may closely resemble pyelonephritis (Fig. 4.27). The kidney will be either enlarged if caseous sacs are present or atrophic if there is longstanding infection. Parenchymal curvilinear or confluent calcifications in areas of caseous necrosis are common (Fig. 4.28). Autonephrectomy with complete nonvisualization of kidney may result from complete parenchymal destruction or hydronephrosis caused by stenosis of the renal pelvis or ureter (Fig. 4.29).

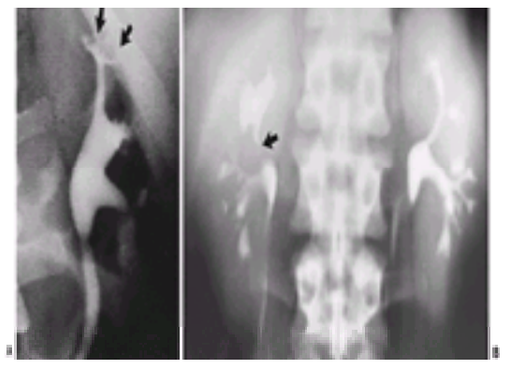

FIGURE 4.26. Tuberculosis. Early disease. Excretory urograms. **A:** Calyceal surface is irregular with linear rays of contrast material extending into the medulla(arrows). **B:** Tomogram demonstrates upper pole infundibular stenosis *(arrow).* No ureteral involvement is seen. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

FIGURE 4.27. Tuberculosis, advanced disease. Excretory urogram shows a large cavity communicating with the calyx in the middle portion of the kidney. Note the irregularity and narrowing of the remainder of the collecting system. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

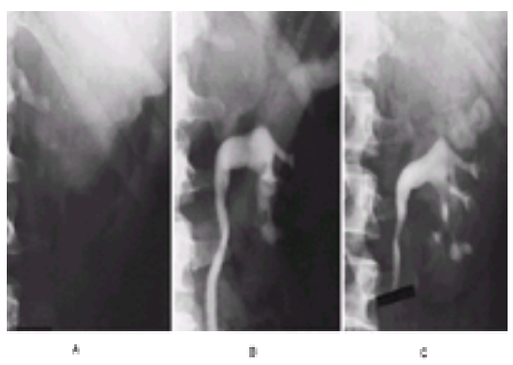

FIGURE 4.28. Tuberculoma. **A:** Faint calcification over the renal fossa. **B:** Fifteen-minute film from an excretory urogram shows “amputation” of the upper pole calyx in the region of calcification. **C:** Delayed film reveals contrast material filling the mass, indicating its communication with the collecting system. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

FIGURE 4.29. Tuberculosis, autonephrectomy. Extensive confluent calcifications in the renal fossa. The excretory urogram indicated no function. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

Fibrosis may cause the volume of the renal pelvis to be markedly reduced (Fig. 4.30). Tuberculous ureteritis is common and results in rigidity and a beading or corkscrew appearance (Fig. 4.31). Ureterovesical junction obstruction is caused by tuberculous cystitis or strictures of the distal third of the ureter. Although not

common, mural calcification in the wall of the calyces, pelvis, ureter, or bladder is extremely suggestive of renal tuberculosis (125).

FIGURE 4.30. Tuberculosis with pelvic fibrosis. Retrograde pyelogram shows significant calyceal irregularity. The calyces come together and empty into the proximal ureter. (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

FIGURE 4.31. Tuberculosis, advanced disease. Retrograde pyelogram shows extensive ureteral changes including irregularity and rigidity, giving “pipestem” appearance. Note extensive distortion, irregularity, and amputation of the upper pole calyx.

Retrograde urography should be used in cases of nonvisualized or poorly functioning kidneys. A voiding cystogram may show a severely contracted bladder with vesicoureteral reflux in one or both sides.

Sonographic examination has limited diagnostic value. CT has several advantages; it can be used in nonfunctioning kidneys and is very sensitive for detecting calcifications and perinephric extension or perinephric hemorrhage that may complicate renal tuberculosis. CT is also the best technique for demonstrating pelvic and ureteral mural thickening. Angiography has limited usefulness in diagnosing renal tuberculosis. Arterial fibrosis results in narrowing or amputation of the small intrarenal arteries (101,125).

Differential Diagnosis

If all of the radiographic findings are typical of renal tuberculosis, the diagnosis is straightforward. However, all of the classic findings are often absent, and the radiographs may suggest medullary sponge kidney, papillary necrosis, invasive transitional cell carcinoma, chronic pyelonephritis, or schistosomiasis. The pertinent radiologic discriminators have been summarized by Hartman (125).

Medullary sponge kidney and papillary necrosis demonstrate extracaliceal accumulations of contrast material and medullary nephrocalcinosis, but cortical calcification and parenchymal masses are rare. Ring calcification near a necrotic or sloughed papilla is extremely suggestive of papillary necrosis. Chronic urinary tract infection and pyelonephritis show distortion of the renal cortex and collecting system similar to tuberculosis, but calyceal, pelvic, and ureteral strictures are not commonly associated with typical urinary tract infections. Invasive transitional cell carcinoma may show infundibular narrowing or calyceal amputation and may be difficult to differentiate radiographically from tuberculosis. Transitional cell carcinoma is not associated with communicating cavities or parenchymal calcification. Infundibular narrowing and submucosal calcifications are seen in amyloidosis of the kidney, but amyloidosis is not associated with destructive communicating cavities or parenchymal calcification. *Schistosoma haematobium* infection of the urinary tract may cause ureteral and bladder calcifications. However, schistosomiasis does not involve the renal parenchyma primarily and is not associated with renal calcification. Schistosomiasis affects only the distal ureter, whereas tuberculosis often involves the entire ureteral length.

Cystoscopy

In early cases of tuberculosis, the bladder is diffusely red and extremely sensitive. Bladder wall ulcerations, severe contracture of the bladder, and golf-hole ureteral orifices are seen in more advanced disease. Ulcerated areas in the bladder strongly suggest tuberculosis. Tuberculous ulcers are irregular and shallow with undermined edges, often well circumscribed from adjoining normal-appearing mucosa. Neoplasms may have a similar appearance and must be differentiated by biopsy.

Management

Appropriate management must be based on an accurate bacteriologic diagnosis and initial assessment of the extent of the disease, the level of renal function, and the nature and severity of ureteric obstruction. Renal tuberculosis in the absence of active pulmonary tuberculosis does not represent a significant infectious risk; therefore isolation is not required. Management always includes appropriate chemotherapy and surgery when indicated. With close and long-term follow-up, the overall mortality rate for renal tuberculosis has dropped from approximately 50% to 2%.

Table 4.5 gives an overview of agents available for treatment of tuberculosis. There is no uniformly recommended chemotherapeutic program. Patients with positive urine cultures but negative findings on urinalysis and normal urograms usually are treated with isoniazid and rifampin for 1 year. Patients with clinically manifest renal tuberculosis are usually treated with three antituberculous drugs such as isoniazid, ethambutol, and rifampin for 2 years (381). If the patient's initial urinary isolate is *M. tuberculosis* resistant to isoniazid or is one of the nontuberculous (atypical) mycobacteria, isoniazid therapy should be stopped and two other drugs chosen on the basis of *in vitro* susceptibilities. A short-term regimen of only 4 months' duration has been recommended by Gow (110) and is summarized in Table 4.6. The initial results with this regimen appear promising, but longer follow-up is required.

Drug	Usual Dose	Route	Frequency	Adverse Effects
Isoniazid	300 mg/day	p.o.	Once daily	Hepatotoxicity, peripheral neuropathy, asymptomatic transaminase rise
Ethambutol	25 mg/kg/day 15 mg/kg/day	p.o. p.o.	Once daily for 60 days Once daily for remainder of treatment period	Optic neuritis seen at 25 mg/kg dose, less frequent at 15 mg/kg dose; usually reversible if drug is stopped immediately
Rifampin	600 mg/day	p.o.	Once daily	Hepatotoxicity, thrombocytopenia
Pyrazinamide	25 mg/kg/day	p.o.	Once daily	Hepatotoxicity; dose and duration related; hyperuricemia
Ethionamide	750–1,000 mg/day	p.o.	Divided doses, 250 mg each	Nausea, vomiting, anorexia, abdominal pain
Cycloserine	750–1,000 mg/day	p.o.	Divided doses, 250 mg each	Neurotoxicity: headache, drowsiness, somnolence, psychotic disturbance, peripheral neuropathy
Para-aminosalicylic acid	200 mg/kg/day	p.o.	2 divided doses	Gastrointestinal irritation, rash, and fever; hemolysis in glucose-6-phosphate dehydrogenase deficiency
Streptomycin	750–1,000 mg/day	i.m.	Once daily for 60–90 days and twice weekly thereafter	Ototoxicity, especially in older persons; rash and fever, nausea
Capreomycin	750–1,000 mg/day	i.m.	Once daily	Renal toxicity and ototoxicity, especially in older persons

TABLE 4.6. GOW'S SHORT-COURSE REGIMEN FOR TREATMENT OF RENAL TUBERCULOSIS

Usually, tuberculous bacilli disappear from urine immediately after initiating chemotherapy, but to monitor the drug's effect, repeated cultures should be done every 3 to 4 months. All of the antituberculous drugs have toxic effects when used continuously. Renal and hepatic function should be monitored during the treatment. Rifampin and isoniazid appear to be the safest drugs in the presence of impaired renal function (276).

Surgery was once commonly used in the treatment of renal tuberculosis, but since the advent of effective antituberculous chemotherapy, it is reserved primarily for management of local complications, such as ureteral stricture or for treatment of nonfunctioning kidneys. If surgery is warranted, it is wise to precede the operation with at least 3 weeks and preferably 3 months of triple-drug chemotherapy.

The incidence of ureteral strictures has been reported to be as high as 10% in centers that treat large numbers of patients with urinary tuberculosis (248). The stricture may be present at the time of diagnosis of renal tuberculosis, but it often develops or progresses during otherwise effective treatment with chemotherapeutic agents (48). Recommended treatment of strictures includes ureteroneocystostomy, construction of a Boari flap, or transluminal balloon ureteral dilation (10,233,375). Success rates with these procedures have been reported at 60% to 90%.

Horne and Tulloch (146) added prednisolone 5 mg four times a day to the standard chemotherapy regimen in all patients with renal tuberculosis who had evidence of stricture formation at presentation or in whom it developed during treatment. No important side effects were noted. Of 29 patients so treated, 72% were relieved of obstruction and only 2 (7%) patients showed recurrence after withdrawal of steroids; both individuals responded to further courses of steroids. Success with steroid therapy has not been universal, however (48).

Removal of a nonfunctioning kidney is usually indicated for advanced unilateral disease complicated by sepsis, hemorrhage, intractable pain, newly developed severe hypertension, suspicion of malignancy, inability to sterilize the urine with drugs alone, abscess formation with development of fistula, or inability to have appropriate follow-up (194,201,236). Prophylactic removal of a nonfunctioning kidney to prevent complications, remove a potential source of viable organisms, and shorten the duration of convalescence and requirement for chemotherapy is advocated by some authors (88,252,394).

Others who have followed up a large series of patients treated with medical therapy alone have concluded that because the frequency of late complications is only 6%, routine nephrectomy should not be performed for every nonfunctioning kidney (194,380). These authors treated patients for 2 years. The merits of short-term therapy and prophylactic nephrectomy versus long-term, 2-year chemotherapy and selected nephrectomy warrant further study.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a chronic inflammatory disease characterized by accumulation of lipid-laden foamy macrophages. It begins within the pelvis and calyces and subsequently extends into and destroys renal parenchymal and adjacent tissues. In most cases, xanthogranulomatous pyelonephritis is unilateral and results in a nonfunctioning, enlarged kidney associated with obstructive nephropathy secondary to nephrolithiasis. It has been known to imitate virtually every other inflammatory disease of the kidney, as well as renal cell carcinoma, on radiographic examination. In addition, the microscopic appearance of xanthogranulomatous pyelonephritis has been confused with clear cell adenocarcinoma of the kidney on frozen section and has led to radical nephrectomy (33).

Pathology and Pathogenesis

The kidney is usually massively enlarged and has a normal contour. Xanthogranulomatous pyelonephritis may be diffuse, as in approximately 80% of the patients, or segmental. In the diffuse form of the disease, the entire kidney is involved, whereas in segmental xanthogranulomatous pyelonephritis, only the parenchyma surrounding one or more calyces or one pole of a duplicated collecting system is involved. On sectioning, the kidney usually demonstrates nephrolithiasis and peripelvic fibrosis. The calyces are dilated and filled with purulent material, but fibrosis surrounding the pelvis usually prevents dilation. The papillae are often destroyed by papillary necrosis (109). In advanced stages of the disease, multiple parenchymal abscesses are filled with viscous pus and lined by yellowish tissue (Fig. 4.32A). The cortex is often thin and is often replaced by xanthogranulomatous tissue. The capsule is often thickened, and extension of the inflammatory process into the perinephric or paranephric space is common (109,115,219).

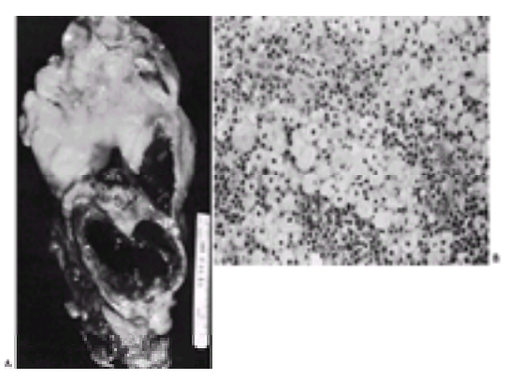

FIGURE 4.32. Xanthogranulomatous pyelonephritis. **A:** Gross specimen. Kidney is massively enlarged, measures 23 by 12 cm; the normal architecture is replaced by a shaggy yellow upper pole mass corresponding to xanthogranulomatous inflammation and numerous distorted and dilated calyces. **B:** Microscopically, the shaggy

yellow tissue is composed primarily of lipid-laden histiocytes mixed with other inflammatory cells.

On microscopic examination, the yellowish nodules that line the calyces and surround the parenchymal abscesses contain dark sheets of lipid-laden macrophages (foamy histiocytes with small, dark nuclei and clear cytoplasm) intermixed with lymphocytes, giant cells, and plasma cells (Fig. 4.32B). Xanthogranulomatous cells are not specific to xanthogranulomatous pyelonephritis but may be present anywhere inflammation or obstruction coexists. The origin of the fatty substance is disputed. Cholesterol esters that make up a part of the lipid might be derived from lysis of erythrocytes after hemorrhage (286).

The primary factors involved in the pathogenesis of xanthogranulomatous pyelonephritis are nephrolithiasis, obstruction, and infection (115). Nephrolithiasis has been noted in as many as 83% of the patients in various series; approximately half of the renal stones have been of the staghorn type (45,237,255). It has been proposed clinically and demonstrated experimentally that primary obstruction followed by infection with *E. coli* can lead to tissue destruction and collections of lipid material by histiocytes (271). The bacteria appear to be of low virulence because spontaneous bacteremia has rarely been described. Other possible interrelated factors include venous occlusion and hemorrhage, abnormal lipid metabolism, lymphatic blockage, failure of antimicrobial therapy in urinary tract infection, altered immunologic competence, and renal ischemia (99,109,219,226,363). The concept that xanthogranulomatous pyelonephritis is related to incomplete bacterial degradation and altered host response has received mixed support (176,254). Thus it appears that there is probably no single factor that is instrumental in the pathogenesis of this disease. Rather there is an inadequate host acute inflammatory response within an obstructed, ischemic, or necrotic kidney.

Clinical Findings

Xanthogranulomatous pyelonephritis should be suspected in patients with urinary tract infections and a unilateral enlarged nonfunctioning or poorly functioning kidney with a stone or a mass lesion indistinguishable from malignant tumor. Although it may occur at any age, the peak incidence of xanthogranulomatous pyelonephritis is in the fifth to the seventh decade. Women are more commonly affected than men. There is no predilection for either kidney.

Most patients have multiple, chronic symptoms that are variable and nonspecific. Patients usually have flank pain, fever or chills, malaise, weight loss, symptoms of cystitis, calculi or palpable mass, and a history of recurrent urinary tract infection. Many patients are admitted to the hospital for urosepsis. Less commonly, hypertension, hematuria, or hepatomegaly is the presenting complaint. The medical history is often positive for urinary tract infections and urologic instrumentation (69,89,109,111,209,237,260,400).

Laboratory Findings

Hematologic evaluation commonly shows anemia and leukocytosis. Diabetes mellitus is present in approximately 15% of the patients. Urinalysis reveals proteinuria and pyuria in nearly all cases. Urine cultures are positive in approximately 70% of patients. Although earlier reports indicated that *P. mirabilis* was the primary pathogen, in recent studies, *E. coli* was cultured in 40% of specimens, and *P. mirabilis* was cultured in approximately 30%. Other pathogens include *Klebsiella, Pseudomonas,* and *Bacteroides* (73). Anaerobes, most often bacteroids, have been isolated in a small number of patients (45,69,111). Approximately 10% of the patients will have mixed cultures. It is noteworthy that about one-third of the patients have sterile urine, probably because many patients receive long-term antimicrobial therapy or are taking antimicrobials when the culture is obtained. The infecting organism may be revealed only by tissue cultures obtained during surgery.

Ballesteros and associates (14) reported accurate preoperative diagnosis of xanthogranulomatous pyelonephritis by serial urinary cytology in 80% of their cases. Subsequent investigators have sought but not found xanthogranuloma cells in the urine (45,69). Thus the diagnostic value of urine cytologic testing remains unclear.

Xanthogranulomatous pyelonephritis is usually unilateral; therefore azotemia or frank renal failure is uncommon (109,115). Reversible hepatic dysfunction has been observed in 20% to 40% of patients with diffuse xanthogranulomatous pyelonephritis (209,363). Liver enzymes return to normal after nephrectomy.

Radiologic Findings

Approximately 50% to 80% of patients show the classic triad of unilateral renal enlargement with little or no function and a large calculus in the renal pelvis (73). At times, the enlargement may be localized and resemble a renal mass. Less commonly, excretory urography demonstrates delayed function and hydronephrosis, which may be massive. Smaller calcifications within the mass are not uncommon but are much less specific (Fig. 4.33A). Although there is abundant intracellular fat, the plane almost never demonstrates significant lucency (126). Retrograde pyelography may show the point of obstruction and dilation of the renal pelvis and calyces. If there is extensive parenchymal damage, contrast studies may demonstrate an ulcerated pyelocalyceal system with multiple irregular filling defects.

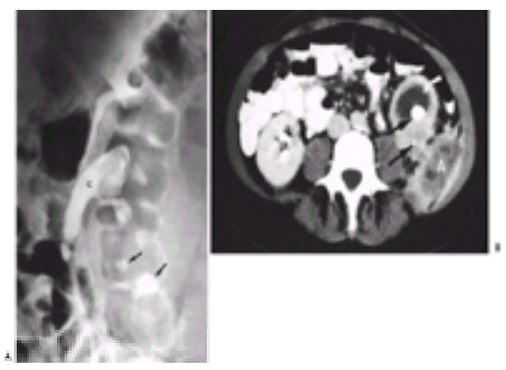

FIGURE 4.33. Xanthogranulomatous pyelonephritis. Excretory urogram. **A:** Ten-minute film shows lower-pole enlargement and nonfunction. Note a large pelvic calculus *(C)* and several smaller parenchymal calculi *(arrows).* The upper pole of the bifid collecting system functions normally. **B:** Enhanced computed tomography scan shows collecting system and parenchymal calculi *(arrows)* with lower pole pyonephrosis *(curved arrow)* and an irregular, predominantly low-density perinephric abscess *(A)* extending into the soft tissues of the flank.

Sonography usually demonstrates global enlargement of the kidney (225). The normal renal architecture is replaced by multiple hypoechoic fluid-filled masses that correspond to debris-filled, dilated calyces or foci of parenchymal destruction (78,127). With focal involvement, a solid mass involving a segment of the kidney is demonstrated with an associated calculus in the collecting system or ureter. Renal cell carcinoma and other solid renal lesions must be considered in the differential diagnosis (73).

CT is probably the most useful radiologic technique in evaluating patients with xanthogranulomatous pyelonephritis. CT usually demonstrates a large, reniform mass with the renal pelvis tightly surrounding a central calcification without pelvic dilation (69,108,126,326) (Fig. 4.33B). Renal parenchyma is replaced by multiple water density masses representing dilated calyces and abscess cavities filled with varying amounts of pus and debris. On enhanced scans, the walls of these cavities demonstrate a prominent blush resulting from the abundant vascularity within the granulation tissue. However, the cavities fail to enhance, whereas tumors and other inflammatory lesions usually do. The findings of focal xanthogranulomatous pyelonephritis often mimic neoplasm. The CT scan is particularly helpful in demonstrating the extent of renal involvement and may indicate whether adjacent organs or the abdominal wall is involved (69,170).

Radionuclide renal scanning using ^{99}Te dimercaptosuccinic acid (DMSA) is used to confirm and quantify the differential lack of function in the involved kidney (115). Magnetic resonance imaging has not yet superseded CT in the evaluation of renal inflammation, but it provides some advantages in delineating extrarenal extension of inflammation (325). Lesions of xanthogranulomatous pyelonephritis may appear as cystic foci of intermediate intensity signal on T_1-weighted images and hyperintensity on T_2-weighted images. Angiography is seldom required for diagnosing xanthogranulomatous pyelonephritis. Most commonly, there is stretching and

attenuation of vessels around avascular masses with an irregular nephrogram (73). Benign neovascularity, absence of irregular vessels, and arterial- venous shunting are also characteristic.

Differential Diagnosis

Diagnosis of segmental xanthogranulomatous pyelonephritis without calculi may be difficult. Xanthogranulomatous pyelonephritis in association with massive pelvic dilation cannot be distinguished from pyonephrosis. When xanthogranulomatous pyelonephritis occurs within a small contracted kidney, the radiographic findings are nonspecific and nondiagnostic. Renal parenchymal malakoplakia may show renal enlargement and multiple inflammatory masses replacing the normal renal parenchyma, but calculi are usually not present. Renal lymphoma may be associated with multiple hypoechoic masses surrounding the contracted, nondilated pelvis, but lymphoma is usually clinically obvious, and renal involvement is usually bilateral and not associated with calculi (126).

Management

The management of xanthogranulomatous pyelonephritis is usually surgical. Antimicrobial therapy may be necessary to stabilize the patient preoperatively; occasionally, long-term antimicrobial therapy will eradicate the infection and restore renal function (230). Nephrectomy is required for diffuse xanthogranulomatous pyelonephritis. Partial nephrectomy is the preferred treatment for focal xanthogranulomatous pyelonephritis if the diagnosis can be established preoperatively or, if necessary, by frozen section at the time of surgery (251,259). However, the lipid-laden macrophages associated with xanthogranulomatous pyelonephritis closely resemble clear cell adenocarcinoma and may be difficult to distinguish solely on the basis of frozen section. Furthermore, xanthogranulomatous pyelonephritis has been associated with renal cell carcinoma, papillary transitional cell carcinoma of the pelvis or bladder, and infiltrating squamous cell carcinoma of the pelvis (268,307,363). Therefore, if malignant renal tumor cannot be excluded, nephrectomy should be performed.

It is important to remove the entire inflammatory mass because in nearly 75% of patients, xanthogranulomatous tissue is infected. If incision and drainage alone are performed rather than nephrectomy, the patient may continue to suffer from protracted debilitating illness and may develop a renocutaneous fistula, and an even more difficult nephrectomy will be necessary (73). Extensive xanthogranulomatous pyelonephritis may make surgical dissection and ligation of the friable vascular pedicle particularly difficult. Extension of the inflammatory reaction to adjacent bowel, diaphragm, and aorta requires tedious dissection and at times resection of the involved tissues.

Renal Parenchymal Malakoplakia

Malakoplakia, from the Greek words meaning “soft plaque,” is an uncommon inflammatory lesion described originally by Michaelis and Gutmann (227). It was characterized by Von Hansemann (373) as soft, yellow-brown plaques with granulomatous lesions in which the histiocytes contain distinct basophilic inclusions or Michaelis-Gutmann bodies. Although its exact pathogenesis is unknown, malakoplakia probably results from abnormal macrophage function in response to a bacterial infection, which is most often *E. coli.* The inclusions probably represent calcification around incompletely digested bacteria (1,217).

The disease usually affects the lower urinary tract; only about 50 patients with renal parenchymal malakoplakia have been reported (216). Clinically, radiologically, and at surgery, malakoplakia often mimics a neoplastic growth. The mortality rate can exceed 50%, and morbidity can be substantial (347). Extension of renal parenchymal malakoplakia into the perirenal space is uncommon (6). Renal parenchymal malakoplakia may also be complicated by renal vein thrombosis and inferior vena cava thrombosis (128,216).

Concomitant nonrenal foci of malakoplakia are seen occasionally in patients with renal parenchymal malakoplakia (347). The most common locations of other foci are the bladder and ureter. Less common sites that have been reported include the retroperitoneum, abdominal wall, colon, testis and epididymis, lungs, scrotum, prostate, adrenal gland, lymph nodes, and diaphragm (216).

Pathology and Pathogenesis

Two basic patterns of renal parenchymal malakoplakia have been described: multifocal and unifocal. The multifocal pattern accounts for 75% of the reported cases and is bilateral in about half of the patients (128). The kidney is usually enlarged and contains multiple masses varying from several millimeters to several centimeters. They are usually yellow, are well demarcated, and may have a focus of hemorrhage or suppuration (Fig. 4.34A and Fig. 4.34B). The masses often coalesce to form larger nodules. These nodules often project beyond the cortical margin, resulting in an irregular contour. Less commonly, the nodules are limited to the papilla or the medulla and occasionally mimic necrotizing papillitis, in which cases the renal contour is normal (26,66,125).

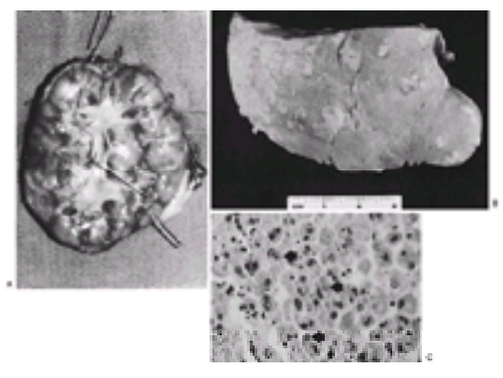

FIGURE 4.34. Renal parenchymal malakoplakia. **A:** Cut surface demonstrates extensive cortical and upper medullary replacement by multifocal, confluent, tumorlike masses. **B:** Cortical surface exhibits multiple, firm, plaquelike lesions. **C:** Hallmark of malakoplakia is demonstration of the Michaelis-Gutmann body *(arrows),* which represents incompletely destroyed bacteria surrounded by lipoprotein membrane (hematoxylin-eosin stain). (**A, B:** Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. I and II. *Monogr Urol* 1985;6:3.)

Unifocal disease usually appears as a large yellow-gray mass, 2.5 to 8 cm in diameter (128). The mass is usually smooth and well marginated, and central necrosis or cyst formation may be present. Calcification of the mass is unusual (309).

Microscopically, malakoplakia is characterized by the Von Hansemann histiocyte, a large polygonal cell with foamy eosinophilic cytoplasm and compact, dark nucleus admixed with intracellular and extracellular Michaelis-Gutmann bodies. The latter contain precipitated calcium phosphate crystals and iron so that both periodic acid–Schiff and von Kossa calcium stains and iron stains are useful in demonstrating the inclusions (202). They are slightly smaller than a red blood cell and are recognized by concentric laminations that impart a targetoid or owl's-eye appearance (102) (Fig. 4.34C). Histochemical and ultrastructural studies have shown that these Michaelis-Gutmann bodies represent incompletely destroyed bacteria surrounded by concentric lipoprotein membranes. Extracytoplasmic Michaelis-Gutmann bodies probably represent debris released from dead cells (216).

It has been shown that macrophages in malakoplakia involving the kidney and bladder contain large amounts of immunoreactive a-antitrypsin (35). The amount of a-antitrypsin remains unchanged during the morphogenetic stages of the pathologic process. Macrophages from other pathologic processes, closely resembling malakoplakia but without Michaelis-Gutmann bodies, do not contain a-antitrypsin except for a few macrophages in tuberculosis and xanthogranulomatous pyelonephritis. Therefore immunohistochemical staining for a-antitrypsin may be a useful test for an early and accurate differential diagnosis of malakoplakia.

Megalocytic interstitial nephritis shows histologic changes that are similar to those of renal parenchymal malakoplakia, but the lesions are usually confined to the renal cortex and Michaelis-Gutmann bodies are less prevalent. Some authors believe that megalocytic interstitial nephritis and renal parenchymal malakoplakia represent two ends of the spectrum of a similar process (102,125,273).

The pathogenesis of malakoplakia is unknown. Almost all reported cases are associated with Gram-negative urinary tract infections, and one of the most popular

theories is that malakoplakia results from incomplete resolution of the bacterial infection. Hematogenous dissemination of *E. coli* and subsequent foci of renal parenchymal malakoplakia may explain the finding of lesions limited to the cortex and medulla without renal-pelvic or lower tract disease. Patients with renal malakoplakia limited to the renal papilla or associated with contiguous renal pelvic involvement or obstructive uropathy probably have had an ascending infection (125).

The demonstration of bacteria within phagocytic vacuoles of histiocytes suggests an inability of the histiocyte to digest the bacteria. It is not clear, however, why a histiocyte response is found instead of the usual polymorphonuclear leukocyte response. The association of malakoplakia with debilitating diseases such as sarcoidosis, diabetes mellitus, and tuberculosis suggests an immunologic defect as a prerequisite for its development. Defective monocyte function has been demonstrated in one patient with malakoplakia (1). In this case phagocytosis was normal, but complete degradation of the bacteria was impossible because of low levels of cyclic guanine monophosphate, which may have resulted in decreased lysosomal degradation and inability of the cell to release the lysosomal enzymes. This defect appears to be reversible by cholinergic agonists that cause accumulation of cyclic guanine monophosphate in monocytes and enhance chemotaxis, but this finding has yet to be confirmed. At present, malakoplakia should be considered an unusual inflammatory lesion resulting from altered host macrophage or histiocytic response.

Clinical Findings

The diagnosis of renal parenchymal malakoplakia is difficult but should be suspected if there is substantial enlargement of the kidney in the presence of urinary tract infection. Renal parenchymal malakoplakia usually affects middle-aged women with recurrent urinary tract infections. The most common signs and symptoms are fever, flank pain, or a palpable flank mass (125,347). The most common pathogen is *E. coli,* which accounts for approximately 75% of the cases. *Aerobacter aerogenes, Klebsiella pneumoniae,* and *Proteus* are cultured less commonly (102,216). In addition, *E. coli* cultures have been obtained from the resected kidney, perinephric abscess, or blood or cerebrospinal fluid of affected patients. Renal failure without evidence of obstruction is not uncommon when malakoplakia is bilateral or occurs in a solitary kidney.

The association of some cases of malakoplakia with altered immune states, such as transplantation, sarcoidosis, hemolytic uremic syndrome, tuberculosis, steroid therapy, lymphoma, leukemia, alcoholism, or emaciation, is common (34,125). Nevertheless, many patients in whom malakoplakia occurs have no recognized defects.

Radiologic Findings

Multifocal malakoplakia on excretory urography typically manifests as enlarged kidneys with multiple filling defects (Fig. 4.35A). Renal calcification, lithiasis, and hydronephrosis are absent. The multifocal nature is best appreciated with ultrasonography, CT, or arteriography. Sonographic examination may demonstrate renal enlargement and distortion of the central echo complex. The masses are often confluent, resulting in an overall increase in the echogenicity of the renal parenchyma (128). CT often shows masses or enlargement of the kidneys. On CT, the foci of malakoplakia are less dense than the surrounding enhanced parenchyma (125). Arteriography typically reveals a hypovascular mass with peripheral neovascularity (Fig. 4.35B and Fig. 4.35C) (41,364).

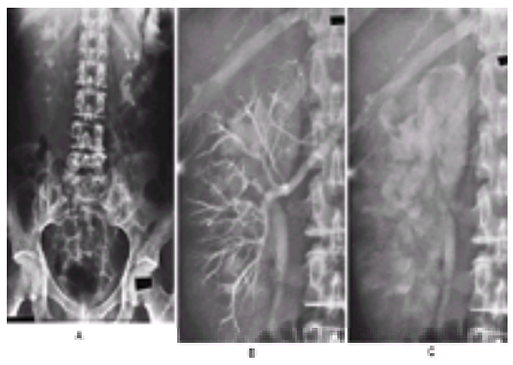

FIGURE 4.35. Multifocal renal parenchymal malakoplakia. **A:** Excretory urogram. The right kidney is enlarged (16.5 cm) with dilation of the upper pole calyces and poor filling of the renal pelvis. **B:** Early angiogram. Separation of the intrarenal vessels without neovascularity. **C:** Angiographic nephrogram. Multiple irregular filling defects located primarily within the cortex. (Courtesy of Charles E. Bickham Jr., MD, Bethesda, MD. Reprinted with permission from Hartman DS, Davis CJ, Lichtenstein JE, et al. Renal parenchymal malakoplakia. *Radiology* 1980;136:33.)

Intense renal uptake of gallium-67 in the clinical setting of fever, progressive renal failure, and nephromegaly strongly supports a diagnosis of renal parenchyma malakoplakia (147). Unifocal malakoplakia on intravenous urography manifests as a noncalcified mass that is indistinguishable from other inflammatory or neoplastic lesions. Ultrasound and CT may demonstrate a solid or cystic structure depending on the degree of internal necrosis. Angiography may demonstrate neovascularity (364). Extension beyond the kidney, which can occur with either multifocal or unifocal malakoplakia, is best demonstrated by CT.

Differential Diagnosis

The differential diagnosis includes renal cystic disease, neoplasia, and renal inflammatory disease (125). Malakoplakia should be considered when one or more renal masses are observed, particularly in female patients with recurrent urinary tract infections with *E. coli,* altered immune response syndromes, or cystoscopic evidence of malakoplakia or filling defects in the collecting system (43). Malakoplakia should also be suspected when these radiographic findings occur in a renal transplant patient who has persistent urinary tract infection despite appropriate antimicrobial therapy. Cystic disease generally can be excluded by careful sonographic and CT evaluations. Renal involvement with metastatic disease or lymphomas usually occurs late in the course of the disease, which is well established. Multifocal renal cell carcinoma is most often seen in the context of von Hippel–Lindau disease with its other clinical manifestations. Patients with xanthogranulomatous pyelonephritis usually have signs and symptoms of urinary tract infection. As with malakoplakia, the involved kidney is enlarged, but renal calculi and obstruction are common. Multiple renal abscesses are often associated with hematogenous dissemination resulting from cardiac disease.

Management

Initial management is directed at controlling the urinary tract infection, correcting the immunologic defect, and improving renal function if necessary (125). Nephrectomy is usually performed for unilateral disease.

Long-term antimicrobial therapy, such as rifampin, TMP-SMX, and doxycycline, has been used successfully in approximately 10% to 15% of patients with renal parenchymal malakoplakia established by biopsy (347). Dramatic improvement has also been reported in patients with intraabdominal malakoplakia treated with cholinergic agents and ascorbic acid (1).

The long-term prognosis appears to be related most directly with the extent of disease. When parenchymal renal malakoplakia is bilateral or occurs in the transplanted kidney, death usually occurs within 6 months (26,66,134). Patients with unilateral disease usually have a long-term survival after nephrectomy.

Renal Echinococcosis

Echinococcosis is a parasitic infection caused by the larval stage of the tapeworm *Echinococcus granulosus.* The disease is prevalent in dogs, sheep, cattle, and humans in South Africa, Australia, New Zealand, Mediterranean countries (especially Greece), and some parts of the former Soviet Union. In the United States, the disease is rare; however, it is found in immigrants from Eastern Europe or other foreign endemic areas or as an indigenous infection among Native Americans in the southwest and Eskimos (269).

Pathology and Pathogenesis

Echinococcosis is produced by the larval form of the tapeworm, which in its adult form resides in the intestine of the dog, the definitive host. The adult worm is 3 to 9 mm long. The ova in the feces of the dog contaminate grass and farmlands and are ingested by sheep, pigs, or humans, the intermediate hosts. Larvae hatch, penetrate venules in the wall of the duodenum, and are carried by the bloodstream to the liver. Those larvae that escape the liver are next filtered by the lungs. Approximately 3% of the organisms that escape entrapment in the liver and lungs may then enter the systemic circulation and infect the kidneys. The larvae undergo vesiculation, and the resultant hydatid cyst gradually develops at a rate of about 1 cm per year. Thus the cyst may take 5 to 10 years to reach pathologic size.

Echinococcosis cysts of the kidney are usually single and located in the cortex (235). The wall of the hydatid cyst has three zones: (a) a peripheral zone of fibroblasts derived from tissues of the host becomes the adventitia and may calcify, (b) an intermediate laminated layer that becomes hyalinized, and (c) a single inner layer that is composed of nucleated epithelium (called the *germinal layer*). The germinal layer gives rise to brood capsules that increase in number, become vacuolated, and remain attached to the germinal membrane by a pedicle. New larvae (scoleces) develop in large numbers from the germinal layer within the brood capsule (Fig. 4.36). The hydatid cyst is also filled with fluid. When brood capsules detach, they enlarge and move freely in the fluid and are then called daughter cysts. Hydatid sand is composed of free larvae and daughter cysts.

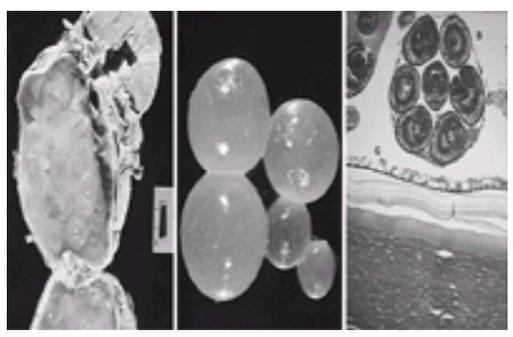

FIGURE 4.36. Echinococcosis. **A:** Gross specimen. A cystic mass 7 by 11 cm in lower pole. Smaller daughter cysts are identified within the larger cystic mass. **B:** Gross specimen. Daughter cysts represent brood capsules that have detached and move freely. **C:** Photomicrograph. Brood capsules *(B)* arising from the germinal layer *(G)* contain viable and degenerating scoleces *(S).* (Reprinted with permission from Hartman DS. Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney. III and IV. *Monogr Urol* 1985;6:26.)

Clinical Findings

The symptoms of echinococcosis are those of a slowly growing tumor. Most patients are asymptomatic or have flank mass, dull pain, or hematuria (105,235). Because the cyst is focal, it rarely affects renal function. Rarely, the cyst ruptures into the collecting system, and the patient may experience severe colic and passage of debris resembling grape skins in the urine (hydatiduria). The cyst may also rupture into an adjacent viscus or the peritoneal cavity. The fluid is extremely antigenic (126).

Laboratory Findings

If cyst rupture occurs, the definitive diagnosis can be established by identifying daughter cysts in the urine or by identifying the laminated wall of the cyst (328).

Fewer than half of the patients have eosinophilia. The most reliable diagnostic test uses partially purified hydatid arc 5 antigens in a double diffusion test (51). Complement fixation, hemagglutination, and the Casoni intradermal skin tests are less reliable but, when combined, are positive in approximately 90% of patients (328).

Radiologic Findings

Excretory urography typically shows a thick-walled cystic mass, occasionally calcified (29). If the cyst ruptures into the collecting system, daughter cysts may be outlined in the pelvis as an irregular mass or as multiple solitary lesions (105). Occasionally, direct filling of the cyst with contrast medium occurs.

Ultrasonography and CT are useful in characterizing the mass; CT is more sensitive (314). Ultrasonography usually demonstrates a multicystic or multiloculated mass. A sudden change in position may demonstrate bright falling echoes corresponding to hydatid sand, which can be observed during real-time evaluation of a hydatid cyst (287).

On CT, several patterns of renal echinococcosis may be recognized. The most specific is a cystic mass with discrete round daughter cysts and a well-defined enhancing member (214). The less specific pattern is that of a thick-walled multiloculated cystic mass (105). The presence of daughter cysts within the mother cyst differentiates the lesion from simple renal cyst and from renal abscesses, infected cysts, and necrotic neoplasm.

Both CT and ultrasound are useful in evaluating the liver. Angiography is seldom required. Diagnostic aspiration carries a high risk of rupture and spillage of the highly antigenic cyst contents and risk of fatal anaphylaxis (285). Nevertheless, Baijal and colleagues (11) described a percutaneous management of renal hydatidosis as a minimally invasive diagnostic and therapeutic option.

Management

The prognosis of echinococcosis is good but depends on the site and size of the cysts. Although there have been preliminary reports on the use of mebendazole in the treatment of hydatid disease, the results have been less than satisfactory (71).

Surgery remains the mainstay of treatment of renal echinococcosis (270). The cyst should be removed without rupture to reduce the chance of seeding and recurrence. If the cyst wall is calcified, the larvae are probably dead and the risk of seeding is low, although a daughter cyst may be viable. If the cyst ruptures or cannot be removed and marsupialization is required, the cyst contents initially should be aspirated and the cyst filled with a scolecoidal agent such as 30% sodium chloride, 0.5% silver nitrate, 2% formalin, or 1% iodine for approximately 5 minutes to kill the germinal portions (235,315,328).

BACTERIURIA IN PREGNANCY

Asymptomatic bacteriuria is one of the most common infectious complications of pregnancy. The overall prevalence of bacteriuria in pregnancy ranges from 2% to 7%, and the risk of acquiring bacteriuria during pregnancy increases with duration of pregnancy (37,243,351). Spontaneous resolution of bacteriuria in pregnant women is unlikely unless treated. Nonpregnant patients often clear their asymptomatic bacteriuria, but pregnant women become symptomatic more frequently and tend to remain bacteriuric (74). Pyelonephritis develops in 1% to 4% of all pregnant women (358) and in 20% to 40% of pregnant women with untreated bacteriuria (257,401). Treatment of asymptomatic bacteriuria found early in pregnancy has been shown to decrease the prevalence of subsequent acute pyelonephritis from 28% to less than 3% (358).

Pathogenesis

The anatomic and physiologic changes induced by the gravid state significantly alter the natural history of bacteriuria (256). The significant physiologic changes in pregnancy, which may develop as early as the first trimester, lead to urinary stasis and mild hydroureteronephrosis and contribute to development of pyelonephritis. Recent studies of *E. coli* adhesins and their respective specific tissue receptors have established an adhesin-based mechanism of pyelonephritis-induced preterm births and low birth weights in mice (172). There is a higher incidence of *E. coli* bearing Dr adhesins during the third trimester of pregnancy in women with gestational

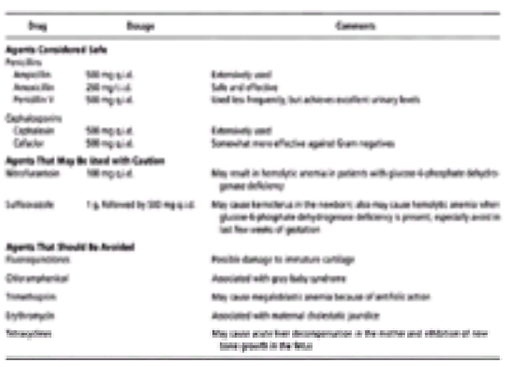
pyelonephritis (245) and an upregulation of Dr adhesin in the kidney, endometrium, and placenta during the third trimester of pregnancy (212). When infected intravesically with *E. coli*–bearing Dr adhesin, nearly 90% of mice that were hyporesponsive to bacterial lipopolysaccharide and had a deficient immune response delivered preterm, compared with 10% of mice infected with *E. coli* without Dr. Also, there was a significant reduction in fetal birth weight in the Dr-infected group. Bacterial tissue culture showed systemic spread of the Dr *E. coli* to the placentae and fetuses.

Management

In the preantibiotic era, pregnant women with symptomatic urinary tract infections and bacterial pyelonephritis were reported to have a high incidence of prematurity, low birth weight, and death (106). The relationship between asymptomatic bacteriuria and prematurity is less clear. Gilstrap and colleagues (106) found no difference in pregnancy among patients treated for asymptomatic bacteriuria as compared with nonbacteriuric controls. However, because women with asymptomatic bacteriuria are at higher risk for developing a symptomatic urinary tract infection that results in adverse fetal sequelae, all women with asymptomatic bacteriuria should be treated. The pathogens are similar to those seen in nonpregnant women (207).

An initial screening culture should be performed in all pregnant women during the first trimester (351). If the culture shows no growth, repeat cultures are generally unnecessary because patients who have no growth in their urine early in their pregnancy are unlikely to develop bacteriuria later (220,243). Pregnant women with a history of recurrent urinary tract infection or vesicoureteral reflux may benefit from antimicrobial prophylaxis (30).

If the culture is positive, special consideration must be given to the selection of antimicrobial agents chosen to treat infection to prevent fetal toxicity. Table 4.7 lists the antimicrobial agents and dosing for use in pregnancy. The aminopenicillins and cephalosporins are considered safe and generally effective throughout pregnancy. In patients with penicillin allergy, nitrofurantoin is a reasonable alternative. It may be used safely during the first two trimesters in patients without glucose-6-phosphate dehydrogenase deficiency. Given the low efficacy of short-course b-lactam therapy in nonpregnant women, it is prudent to describe a full 7-day course of therapy in pregnant women. Follow-up cultures should be obtained to document absence of infection. Pregnant women with acute pyelonephritis should be hospitalized and treated initially with parenteral antimicrobials. More than 95% of these patients respond within 24 hours using ampicillin and an aminoglycoside (59) or cephalosporins (291). Appropriate oral agents should then be given for at least 14 days (84). After the treatment course is completed, low-dose prophylaxis with nitrofurantoin, amoxicillin, or cephalexin has been shown to be effective in preventing reinfection (292,370). The efficacy of postcoital prophylaxis with either cephalexin (250 mg) or nitrofurantoin (50 mg) has been reported (264).



Drug	Dosage	Comments
Agents Considered Safe		
Penicillins		
Ampicillin	500 mg q.i.d.	Extensively used
Amoxicillin	250 mg t.i.d.	Safe and effective
Penicillin V	500 mg q.i.d.	Used less frequently, but achieves excellent urinary levels
Cephalosporins		
Cephalexin	500 mg q.i.d.	Extensively used
Cefaclor	500 mg q.i.d.	Somewhat more effective against Gram negatives
Agents That May Be Used with Caution		
Nitrofurantoin	100 mg q.i.d.	May result in hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency
Sulfisoxazole	1 g, followed by 500 mg q.i.d.	May cause kernicterus in the newborn; also may cause hemolytic anemia when glucose-6-phosphate dehydrogenase deficiency is present; especially avoid in last few weeks of gestation
Agents That Should Be Avoided		
Fluoroquinolones		Possible damage to immature cartilage
Chloramphenicol		Associated with gray baby syndrome
Trimethoprim		May cause megaloblastic anemia because of antifolic action
Erythromycin		Associated with maternal cholestatic jaundice
Tetracyclines		May cause acute liver decompensation in the mother and inhibition of new tissue growth in the fetus

TABLE 4.7. ORAL ANTIMICROBIAL AGENTS USED IN PREGNANCY

Drugs that are relatively contraindicated during pregnancy include the fluoroquinolones, TMP, chloramphenicol, erythromycin, tetracycline, sulfonamides, and nitrofurantoin. Fluoroquinolones are contraindicated because of their effects on immature cartilage. TMP may have teratogenic effects and should be avoided, especially in the first trimester. The “gray-baby syndrome” is a toxic effect of chloramphenicol on neonates resulting from the inability of the infant to metabolize or excrete the drug. Erythromycin may cause cholestatic jaundice in the mother. Tetracycline may cause fetal malformations and maternal liver decompensation. Sulfonamides may cause kernicterus and neonatal hyperbilirubinemia and should be avoided in the third trimester. Nitrofurantoin can cause hemolytic anemia in both mother and child when glucose-6-phosphate dehydrogenase deficiency is present.

BACTERIURIA IN THE ELDERLY

Urinary tract infections in the elderly are a common and expanding health problem (174). The prevalence of bacteriuria increases with age, institutionalization, and concurrent diseases and may exceed 50% in selective groups (23,297). Longitudinal studies have clarified the dynamic aspect of bacteriuria in the elderly with frequent, spontaneous alteration between positive and negative urine cultures (231). The incidence of asymptomatic bacteriuria is much more common than is apparent from a single survey, implying that most elderly will eventually have episodes of bacteriuria (24).

Pathogenesis

The pathophysiology of increased susceptibility is multifactorial and poorly understood. Age-related changes include decline in cell-mediated immunity, neurogenic bladder dysfunction, increased perineal soiling as a result of fecal and urinary incontinence, increased incidence of urethral catheter placement, and in women, changes in the vaginal environment associated with estrogen depletion (274,297). Bacteriologic characteristics of infection in the elderly differ from those in younger patients (12). *E. coli* remains the most common uropathogen, but there is a significant increase in the incidence of *Proteus, Klebsiella, Enterobacter, Serratia,* and *Pseudomonas* species, as well as enterococci. *S. saprophyticus* is not seen in this population. Polymicrobial bacteriuria is more common among the elderly (240).

Diagnosis

Diagnosis of urinary tract infections in the elderly can be difficult. Urinary tract symptoms are often absent, and concomitant disease can mask or mimic urinary tract infection. Even severe upper tract infections may not be associated with fever or leukocytosis (12). Therefore a high index of suspicion is warranted, and diagnosis should rely on the results of a carefully obtained urinalysis and culture. The presence of greater than 10^5 CFU/mL of urine remains the standard for diagnosis in these patients. Pyuria alone is not a good predictor of bacteriuria in this population (253). Boscia and associates (25) reported that more than 60% of women with pyuria of 10 WBCs/mm^3 or greater (noted in midstream specimens) did not have a concurrent bacteriuria. However, the absence of pyuria was a good predictor of the absence of bacteriuria. Because urinary tract abnormalities can often predispose and complicate bacteriuria in the elderly, a thorough urologic evaluation is warranted. Commonly used studies include plain radiographs of the abdomen, renal and bladder ultrasonography, excretory urography, and cytoscopy.

Significance of Screening Bacteriuria

The significance of asymptomatic bacteriuria in the elderly is unclear (297). There is no documented relationship between asymptomatic bacteriuria and uncomplicated urinary tract infections and worsening renal function in this population. The treatment of asymptomatic bacteriuria to improve incontinence has not been justified (12). Although studies have demonstrated decreased survival in bacteriuric patients compared with nonbacteriuric control subjects, it is unclear whether increased mortality rates and bacteriuria are causally related (2,12). Nicolle and associates (240) randomized institutionalized women with bacteriuria to treatment or observation and followed these patients for more than 1 year. Treatment did not result in improved survival and was associated with a number of adverse effects.

Management

The exceedingly high prevalence of recurrent bacteriuria in this population, concern over the adverse actions of drugs, and the emergence of resistance associated with antimicrobial use make a universal recommendation to treat asymptomatic bacteriuria in the elderly unwarranted. However, asymptomatic patients with an alkaline pH and cultures indicating that urea-splitting organisms are present should be treated to prevent development of infection stones. When symptomatic infections are being treated, antimicrobial selections should take into account the potential for impaired metabolism and excretion of these drugs, as well as the

greater likelihood of drug interactions in this population.

CATHETER-ASSOCIATED BACTERIURIA

Catheter-associated bacteriuria is the most common hospital-acquired infection, with an incidence of more than 1 million per year (121,342). The development of bacteriuria in the presence of an indwelling catheter is inevitable and occurs at an incidence of approximately 10% per day of catheterization. Intermittent catheterization has been associated with rates of bacteriuria of less than 1% in healthy individuals and 15% in elderly hospitalized patients (365). The most important risk factors associated with increased likelihood of developing catheter-associated bacteriuria are duration of catheterization, female gender, absence of systemic antimicrobials, and catheter-care violations (342). Most catheter-associated urinary tract infections are asymptomatic. In patients with short-term catheter placement, only 10% to 30% of bacteriuric episodes produce typical symptoms of acute infection (120,129). Similarly, although patients with long-term catheters are bacteriuric, the incidence of febrile episodes occurs at a rate of only 1 per 100 days of catheterization (378).

Pathogenesis

Bacteria enter the urinary tract of a catheterized patient by several routes. Bacteria can be introduced at the time of initial catheter placement by either mechanical inoculation of urethral bacteria or contamination from poor technique. Subsequently, the bacteria most commonly gain access via a periurethral or intraluminal route (342). In women, periurethral entry is the most prevalent. Daifuku and Stamm (60) found that among 18 women who developed catheter-associated bacteriuria, 12 had antecedent urethral colonization with the infecting strain. Bacteria may also enter the drainage bag and follow the intraluminal route to the bladder. This route is particularly common in patients who are clustered among other patients with indwelling catheters (208).

The urinary catheter system provides a unique environment that allows for two distinct populations of bacteria: those that grow within the urine and another population that grows on the catheter surface. A biofilm represents a microbial environment of bacteria embedded in an extracellular matrix of bacterial products and host proteins that often lead to catheter encrustation (342). Certain bacteria, particularly of the *Pseudomonas* and *Proteus* species, are adept at biofilm growth, which may explain their higher incidence in this clinical setting (229). The uropathogens isolated from the catheterized urinary tract often differ from those found in noncatheterized ambulatory patients. *E. coli* is still the most common organism isolated, but *Pseudomonas, Proteus,* and *Enterococcus* species are very prevalent (378). In patients with long-term catheterization of more than 30 days, the bacteriuria is usually polymicrobial and the presence of four or five pathogens is not uncommon (379). Although certain species may persist for long periods, the bacterial populations in these patients tend to be dynamic.

Significant bacteriuria in patients with catheters is present when greater than 100 CFU/mL is present because even this low level progresses to greater than 10^5 CFU/mL in almost all patients (208,350). Pyuria is not a discriminate indicator of infection in this population.

Management

Careful aseptic insertion of the catheter and maintenance of a closed dependent drainage system are essential to minimize development of bacteriuria. The catheter–meatal junction should be cleaned daily with water, but antimicrobials should be avoided because they lead to colonization with resistant pathogens, such as *Pseudomonas.*

Incorporation of silver oxide (301) or silver alloy (288) into the catheter and hydrogen peroxide into the drainage bag has been reported to decrease the incidence of bacteriuria in some studies (301), but not in other populations (342). Concurrent administration of systemic antimicrobials transiently decreases the incidence of bacteriuria associated with short-term catheterization, but after 3 to 4 days, the incidence of bacteriuria is similar to the rate in catheterized patients not taking systemic antimicrobials, and the prevalence of resistant bacteria and side effects is substantial. The concept of instilling nonvirulent bacteria into the bladder to completely block colonization and infection by pathogens has been tested in patients with spinal cord injuries (152). Patients successfully colonized with the nonvirulent strain had reduced symptomatic urinary tract infection and a subjective improvement in quality of life.

In patients with indwelling catheters, urine cultures should be performed if they become febrile and require antimicrobial therapy. The antimicrobial should be discontinued within 48 hours of resolution of the infection. If the catheter has been indwelling for several weeks, encrustation may shelter bacteria from the antimicrobial; therefore the catheter should be changed.

When a catheter is to be removed and there is a high probability of bacteriuria, a culture should be obtained 24 hours before removal. The patient should be started on empiric antimicrobial therapy such as TMP-SMX just before decatheterization and maintained on therapy for 2 days. A posttherapy culture should be obtained 7 to 10 days later to confirm the eradication of the bacteriuria.

FUNGURIA

Funguria is usually associated with predisposing factors, including indwelling catheters, antimicrobial therapy, diabetes mellitus, hospitalization, and immunosuppressed states (184).

Clinical Findings

Fungi may invade the kidneys as the result of hematogenous spread from other sources of infection or the gastrointestinal tract. *Candida albicans* accounts for approximately 50% of positive fungal cultures. *Candida glabrata* is the second most common fungus, representing approximately 10% to 15% of positive fungal cultures (228). *C. glabrata* is a normal commensal organism of the gastrointestinal tract and vagina and probably colonizes the urinary tract by ascending infection.

Asymptomatic funguria, implying urinary colonization rather than infection, is common. Invasive infection is suggested by the presence of irritative voiding symptoms and pyuria. Renal or perinephric abscesses and fungus balls (also known as bezoars) may result from funguria. These patients may demonstrate symptoms suggestive of pyelonephritis with flank pain and fever. However, fungal balls may develop in the collecting system of asymptomatic patients.

Diagnosis

The criteria for diagnosis are unclear. Particularly in women, vaginal or perineal colonization may contaminate urine specimens. Microscopic examination can reveal fungi budding forms or pseudohyphae. The presence of pyuria does not correlate well with the presence of symptoms or the degree of funguria. Cultures of 10,000 to 15,000 CFU/mL have been suggested as cutoff points for infection (182). Regardless of the count, a positive culture requires evaluation.

Management

A treatment algorithm for genitourinary fungal infection has been presented by Wise (388) (Fig. 4.37). Before antifungal therapy, predisposing factors to funguria should be eliminated. Unnecessary indwelling catheters should be removed and the nutritional status should be optimized. Discontinuation of broad-spectrum antimicrobial agents reduces fungal colonization. If, after removal of the catheter, fungal infection persists, amphotericin B may be instilled intravesically for up to 1 week. Fifty milligrams of amphotericin B dissolved in 1 L of sterile water is introduced into the bladder via a three-way catheter over a 24-hour period (390). Alternatively, 200 to 300 mL of irrigant may be instilled for 1 to 2 hours with clamping of the catheter. Miconazole (50 mg per liter per day) has also been shown to be effective as a bladder irrigant (391). Amphotericin B may also be instilled via nephrostomy tube for upper tract fungal infection. Oral fluconazole has been shown to be as effective and safe as amphotericin B bladder irrigation for treatment of older adults with funguria (160).

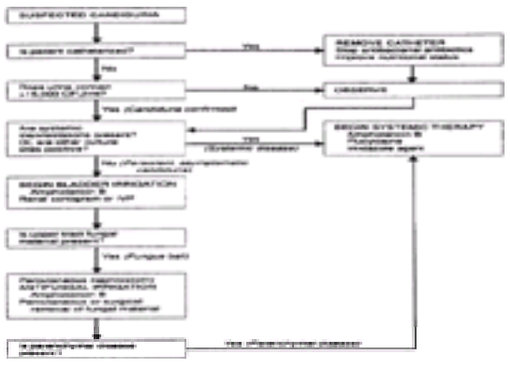


FIGURE 4.37. Treatment algorithm for management of suspected candiduria. IVP, intravenous pyelogram. (Reprinted with permission from Wise GJ. Amphotericin B in urologic practice. *J Urol* 1990;144:215.)

Funguria also may be treated effectively with oral agents. Flucytosine is readily absorbed from the gastrointestinal tract and is primarily excreted renally. A dosage of 100 to 200 mg/kg per day in four divided doses for 2 to 3 weeks is recommended. Dosing adjustments should be made for patients with renal insufficiency. Wise and associates (389) reported success (as defined by a decrease in colony counts or clinical improvement) in 212 of 225 patients treated for 21 to 28 days. Fungal resistance was reported in 14 of the patients. Flucytosine may be used in combination with amphotericin B bladder irrigation. Side effects include an elevation in liver function tests, diarrhea, and agranulocytosis.

Fluconazole is a triazole antifungal agent that is readily absorbed from the gastrointestinal tract and is excreted predominantly in unchanged form in the urine. Dosing is typically 200 mg for the first day followed by 100 mg daily for 10 to 14 days. Success rates of greater than 75% to 80% have been reported in studies treating *Candida* species with limited numbers of patients (15,221,242). The most common side effects present in 60% of patients include nausea, headache, skin rash, abdominal pain, vomiting, and diarrhea (113).

Patients with renal candidiasis and disseminated infection are usually treated with intravenous amphotericin B. Amphotericin B acts in a fungicidal fashion by binding to the fungal-cell membranes, eventually resulting in disruption of the internal cellular components. Fungal resistance is uncommon. Because excretion is primarily biliary, amphotericin B may be administered to patients with renal insufficiency with caution because of its nephrotoxic effects, but without need for dosing adjustment. Side effects of significance with amphotericin B include chills, rigors, fevers, phlebitis, bone marrow toxicity, and potassium and magnesium depletion. After an initial dose of 1 mg, the dose may be increased gradually in daily increments of 5 mg to a maintenance dose of 0.3 to 1.2 mg/kg. Daily dosing should not exceed 50 mg. Although strict guidelines for duration of total amount of therapy do not exist, most renal infections require between 500 mg and 1.5 to 2 g over a 6- to 12-week period (223). Fluconazole has not been used extensively for upper tract infections, but when given intravenously, it has been shown to be effective in treating systemic candidiasis in critically ill patients (4,54,112,186).

The presence of fungal balls and accompanying obstruction should be assessed in patients with suspected upper tract funguria. Fungal balls typically involve *Candida* species because of their propensity to develop pseudohyphae. Patients with upper tract obstruction are especially prone to fungemia. The patients often require the placement of percutaneous nephrostomy tubes to relieve the obstruction. This tube may then be used to instill antifungal irrigant or to provide a tract for access for percutaneous endourologic removal of the fungal ball.

Chapter References

The urinary tract in pregnancy is of interest to the urologist because of the interesting physiologic changes that pose challenges in the management of its problems. In caring for patients during pregnancy, the urologist must always consider the effects of treatment on both the mother and the fetus. In this chapter, the marked changes in urinary tract anatomy and function during pregnancy are presented, as well as the clinical problems of urolithiasis, infection, hydronephrosis, coexistent renal diseases, and lower urinary tract dysfunction.

Physiologic changes during pregnancy include (a) an increase in renal blood flow of 60% to 80%; (b) increased glomerular filtration of 40% to 50%, with subsequent lowering of mean serum creatinine to less than 0.5 mg/dL; and (c) increases in cardiac output of 30% to 50%, associated with decreased peripheral resistance and increased stroke volume. Hydronephrosis of pregnancy is caused by both hormonal and mechanical factors. During pregnancy, there is net retention of sodium, potassium, and calcium. Urolithiasis has a similar incidence and causes as for nonpregnant patients, but it creates problems in the last trimester because one cannot safely operate or use shock wave lithotripsy on lower ureteral stones. Hypertension, renal insufficiency, and bacteriuria are major risk factors in fetal outcome. Pregnancy does not affect most renal diseases, and renal function usually increases temporarily in the diseased kidney during pregnancy. Acute renal failure of pregnancy, acute cortical necrosis, and idiopathic postpartum acute renal failure are problems seen in pregnancy. Pregnancy can be a success during dialysis or after renal transplantation. Excellent reviews have been published by Loughlin (148), Dafnis and Sabatini (51), Jungers and co-workers (118), and Weiss and Hanno (269).

RENAL PHYSIOLOGY IN PREGNANCY

Several changes in renal function normally occur owing to the gravid state; the one most relevant to urologists is dilation of the ureters, pelves, and calyces (146). Hydronephrosis of pregnancy may be attributed to a combination of factors, principally hormonal and mechanical. There is evidence that circulating estrogenic and progestational compounds produced by placentas in animals surgically lacking fetuses result in ureterectasis in the absence of mechanical obstruction (208,257,258). Prostaglandin E_2 has smooth muscle–relaxing properties that also contribute to hormonally induced hydronephrosis (217). Probably a greater contributing factor in physiologic hydronephrosis of pregnancy is stasis induced by the dextrorotating and enlarging uterus at midterm, explaining the proclivity for such obstruction to occur on the right. Experimental evidence for what otherwise may be taken as obvious is that differential pressure measurements in the ureter, above and below the pelvic brim, reveal a gradient at the level of the uterus in erect patients that resolves in the knee-chest position (165,219).

During pregnancy, cardiac output is increased. This is associated with decreased peripheral resistance and increased stroke volume. Initially, blood pressure decreases; later in pregnancy, the heart rate increases and stroke volume returns toward normal. Plasma volume increases 40%, and red blood cell volume increases 25% (141). Changes in the respiratory system include a 20% reduction in functional residual capacity by the fifth month of pregnancy (204). This is accompanied by a 15% increase in oxygen consumption, putting the mother at risk for developing hypoxemia during periods of hypoventilation.

There are gestational increases in both glomerular filtration rate (GFR) of 40% to 50% and renal plasma flow (RPF) of 60% to 80% (67). These changes occur in patients with either a solitary (native or transplant) kidney or two functioning kidneys (54,55). Increases in GFR and RPF also occur in the diseased kidney. An explanation for these hemodynamic and physiologic changes likely derives from increased cardiac output and decreased renal vascular resistance (133), as well as increased serum levels of aldosterone, deoxycorticosterone, progesterone, placental lactogen, and chorionic gonadotropin (146). A practical consequence of increased GFR is that plasma creatinine levels are reduced to a mean of 0.46 mg/dL during pregnancy because creatinine production is unchanged. Thus plasma creatinine concentrations that are normal for the general population are abnormally high in gravid patients and should signal a nephrologic evaluation for possible renal functional impairment (146,253). A corollary of increased RPF and glomerular filtration during pregnancy is the increase in urinary excretion of protein, glucose, amino acids, and vitamins (22,146,275).

An increase in renal volume as much as 30% is observed in pregnant patients in the absence of hydronephrosis. This is thought to be due to hemodynamic and hormonal factors, specifically increases in RPF and increased glomerular filtration surface area caused by a growth hormone–like effect of prolactin (38).

It has long been known that pregnancy is associated with hypercalciuria (129), a phenomenon attributed to increased GFR (163), increased calcium filtration (105), and excess intestinal calcium absorption secondary to high plasma levels of calcitriol (83). However, overwhelming evidence suggests that stone formation is not enhanced by pregnancy, and stone-formers who become pregnant do not incur a higher incidence of urolithiasis (103). Thus it may be assumed that pregnancy also occurs within a milieu of factors that mitigate the stone-forming effect of hypercalciuria, such as increased excretion of stone inhibitors (citrate, magnesium, and glycosaminoglycans) (20,80,179,180).

Pregnancy is associated with diminished plasma osmolality (60). A maximum decrease in osmolality of 10 mOsm/kg can be expected from week 10 of gestation until parturition. Although it is tempting to explain this finding in terms of altered vasopressin metabolism, no such evidence exists and the cause for the altered osmoregulation of pregnancy is obscure (56,58,59). On the other hand, renal handling of sodium during pregnancy is better understood.

A small quantity of sodium (950 mEq) is accumulated during pregnancy. Thus there must be factors accounting for this maintenance of sodium homeostasis in that the increase in GFR that normally accompanies pregnancy in and of itself would cause a loss of 5,000 to 10,000 mEq sodium daily as an additional filtered load (146). Tubular reabsorption accounts for preservation of the majority of this increased filtered sodium load (13). However, other factors, including hormonal and physical changes, result in sodium maintenance. Aldosterone production and excretion are known to increase to high levels as an offset to natriuresis during pregnancy (27). Deoxycorticosterone, another potent mineralocorticoid, likewise increases in pregnancy, especially during the third trimester (28,187,272). Further enhancing sodium retention are high levels of circulating estrogens in pregnancy (145,271). The antinatriuretic effect of estrogens is also enhanced by their induction of 21-hydroxylation of progesterone (a salt-wasting hormone), yielding salt-retaining deoxycorticosterone (155). Other potentially salt-retaining hormones of pregnancy include adrenocorticotropic hormone, cortisol, prolactin, growth hormone, and placental lactogen (146). Although circulating catecholamines may result in natriuresis via direct renal effects or indirectly through renal sympathetic innervation, levels of these compounds are variably and only slightly changed; thus their effects on sodium metabolism appear to be minimal (12). Renin and angiotensin II levels are distinctly elevated during gestation (15,106). The influence of the renin-angiotensin axis on sodium homeostasis is indirect, to the extent of its relation to aldosterone metabolism and volume status. It is currently theorized that gestational renin levels may be affected by increases in prostaglandin E_2 and prostacyclin produced by the uterus, resulting in general vasodilation, decreased blood pressure, and augmented

vascular volume during pregnancy (75,79).

The physical factors influencing sodium metabolism in pregnancy are increased ureteral pressure and increased uterine blood supply with its arteriovenous shunting characteristics (35,208). These physical factors are greatly influenced by position and levels of ambulation and generally are believed to result in sodium retention in the pregnant subject.

In summary, the tremendous potential for gestational salt loss owing to increased GFR is offset in multiple ways that are both hormonal and physical. These factors combine to the net observation that sodium is retained slightly during pregnancy.

UROLOGIC SYMPTOMS IN PREGNANCY

The most common urologic symptom in pregnancy is frequency of voiding (nearly universal at term in primigravidas), followed by stress incontinence, 35% at term (237). Other symptoms often found include urgency, urge incontinence, poor stream, and incomplete emptying, although these are not typically found to be severe enough to warrant investigation with micturitional studies (49).

Hematuria may occur as a normal concomitant of pregnancy because of microanatomic changes in such (enlarged) kidneys that exhibit renal venous fragility in the collecting tubules or pelvis (264). Recurrent unilateral gross hematuria occurring during consecutive pregnancies has been reported to be related to renal varicosities owing to mechanical (uterine compressive) and hormonal factors causing pelvic venous congestion (52). Another common urologic gestational symptom is flank pain, which can be attributed to multiple underlying processes, such as hydronephrosis, pyelonephritis, urinary calculi, spontaneous renal rupture, or tumors.

USE OF MEDICATIONS DURING PREGNANCY

Urologists often are asked to treat pregnant patients for conditions that require prescriptions, such as pain relievers, antimicrobials, antipyretics, anesthetics, and anticholinergics. The potential for pharmaceutical teratogenicity behooves a detailed knowledge of medications safe for use in pregnancy.

Antibiotics (Table 5.1) and analgesics are the most commonly prescribed medications by urologists for pregnant women. Antimicrobials that are considered safe without reservation (barring allergies) include penicillins, cephalosporins, and erythromycin (133,182,276). Nitrofurantoin is regarded as safe in pregnancy because of low blood levels, although the rare complication of idiosyncratic pulmonopathy should be kept in mind with long-term administration (6,198). The safety of this drug during pregnancy should not be confused with its association with hemolytic anemia in breastfed infants with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Aminoglycosides may be safely administered during pregnancy (44) when used with the usual judicious attention to monitoring of renal function and serum peak and trough levels. Sulfonamides are safe until 28 weeks, after which time there is a risk of fetal kernicterus and hemolysis in patients with G6PD deficiency (113,133). Trimethoprim/sulfamethoxazole is contraindicated because of possible teratogenicity and fetal folate antagonism (211). Tetracycline should be assiduously avoided to prevent dysgenesis of fetal limbs (weeks 0 to 12) and teeth, which results from competition with calcium for access into sites of bone development (87,113). Chloramphenicol is contraindicated near term because of potential bone marrow depression and fetal gray syndrome (113,267), although it may be used safely throughout most of gestation. Isoniazid may cause a number of congenital defects, such as infant encephalopathy; metronidazole must be used with caution during the second and third trimesters (37) in that rat lung adenomas and increased bacterial mutation rates have been found experimentally (113). Erythromycin and amoxicillin/clavulanic acid are considered safe in pregnancy, although formal human studies of the latter combination are lacking (2,113). Although ketoconazole as an antifungal has not been documented to cause fetal malformation, it is not recommended during pregnancy because of its association with teratogenicity in rats and an inhibitory effect on androgen and corticosteroid synthesis (168). Angiotensin-converting enzyme inhibitors cause neonatal renal failure and hypotension and should thus not be used.

Antibiotic	Safety Margin (Barring Allergy)
Penicillins	Safe
Cephalosporins	Safe
Erythromycin	Safe
Nitrofurantoin	Safe (hemolytic anemia in breastfed infants with G6PD deficiency)
Aminoglycosides	Potential CNS toxicity, ototoxicity (monitor serum levels, renal function)
Sulfonamides	Safe until 28 weeks (thereafter risk hemolysis, kernicterus if G6PD deficiency)
Trimethoprim/sulfamethoxazole	Contraindicated (teratogenic, fetal folate antagonist)
Tetracyclines	Contraindicated (fetal limb, dental dysgenesis)
Chloramphenicol	Contraindicated near term (fetal bone marrow depression, "gray syndrome")
Isoniazid	May cause congenital defects (e.g., infant encephalopathy)
Metronidazole	Use with caution in second and third trimesters only (possibly mutagenic)
Amoxicillin/clavulanic acid	Formal studies lacking, safety unknown
Quinolones	Bone growth retardation
Ketoconazole	Contraindicated (teratogenic in vivo, inhibits steroid synthesis)

CNS, central nervous system; G6PD, glucose-6-phosphate dehydrogenase.

TABLE 5.1. ANTIBIOTIC USE IN PREGNANCY

Fortunately, a variety of analgesics may be used with a wide safety margin during pregnancy. Whereas acetaminophen is safe in pregnancy, aspirin is contraindicated, particularly during the third trimester, because of a propensity for causing newborn intracranial (subchoroidal) hemorrhage (41,220,231). However, prospective studies have failed to demonstrate an increased risk of aspirin-induced fetal malformations (231). From the maternal standpoint, aspirin may cause anemia, peripartum uterine hemorrhage, prolonged gestation, or labor (119). Although theoretically nonsteroidal antiinflammatory drugs may be thought to carry the same caveats as aspirin, they should be avoided, especially during the third trimester, to prevent premature closure of the ductus arteriosus, a prostaglandin-dependent phenomenon (144). For more severe pain, narcotic analgesics are considered safe without reservation when used short term before parturition (107). Under these circumstances, the urologist may prescribe appropriate dosages of morphine, meperidine, or oxycodone.

Although an exhaustive discussion of all pharmaceuticals is beyond the scope of this chapter, two specific substances deserve special mention. As surgeons, urologists will often need to use topical sterilizing agents. When administered near term, povidone-iodine may be absorbed vaginally or perineally to the extent that neonatal hypothyroidism and goiter may result (26,134). Hexachlorophene, another common topical antiseptic, is also of concern because of its association with neurotoxicity and white matter vacuolar degeneration (270). These substances should be used judiciously during pregnancy and should be rinsed thoroughly with sterile water where applied.

DECISION MAKING FOR GESTATIONAL URINARY TRACT IMAGING

Paramount in the mind of the physician caring for a pregnant patient in need of roentgenographic imaging studies is radiation-dosage tolerance. Significant pelvic radiation dosages (5 to 15 cGy) during the first trimester increase the risk of teratogenicity from 1% to 3% (244). Putting this into perspective, a standard urogram renders 1.5 cGy to the fetus; however, prudence dictates the standard that limited exposure to two or three “shots” should be taken during a gestational urogram. These images include the plain film, a 30-minute exposure, and a 2- or 3-hour exposure if the diagnosis of obstruction remains in doubt. Because each plain abdominal film yields 0.2 cGy to the fetus, the two- or three-shot urogram is considered safe even during the first trimester (66,103,159). On the other hand, data exist to cause concern with even low doses of roentgen ray exposure to the fetus. Specifically, an average of 1 rad of fetal exposure has been correlated with a net 2.4-fold increase in the incidence of all childhood malignancies (99). However, it is not clear during which trimesters radiation exposure occurred. Although ultrasound is safe under all circumstances of pregnancy, its use in diagnosing obstruction is of limited value because of its suboptimal view of the ureter and presence of hydroureteronephrosis as a physiologic concomitant of pregnancy. Thus, because urography is found to have diagnostic value greatly in excess of sonography during pregnancy (103), it is recommended in the following situations: (a) persistent fever, (b) massive or increasing hydronephrosis as seen during serial urosonography, and (c) pain or emesis refractory to conservative therapy.

The theoretic risk of development of childhood cancer (not necessarily teratogenicity) should at all times be kept in mind when subjecting the fetus to roentgen ray exposure (156,177). In particular, there is no evidence that fetal radiation exposure below 5 rad causes congenital malformation, spontaneous abortion, or growth retardation (25). However, the relative risk of childhood leukemia occasioned by fetal exposure of 1 to 2 rad is increased from 1 in 3,000 (general population) to 1 in 2,000 (229). Put into perspective, the risk of leukemia for a sibling of a leukemic child is 1 in 700 (25).

In view of these data, it is useful to discuss radiation dosages received by the uterus owing to specific imaging studies. For example, cerebral angiography causes less than 10 mrad exposure to the uterus, a negligible dosage, due to the maximum distance of the collimated beam from the brain to the pelvis (262). In contrast, double-vessel coronary angioplasty provides 90 mrad uterine exposure (76,86), and barium enema causes 2 to 4 rad fetal exposure due to proximity of the study to the uterus (16). Other roentgen ray studies may be ordered during pregnancy. Computed tomography causes maximum radiation exposure at the skin level, with a progressive decrease toward the body interior. Correspondingly, radiation dosage to the fetus diminishes with enlargement of the pregnancy and its investing tissues (48). Specifically, a ten-slice abdominal study causes 2.6 rad fetal exposure at weeks 0 to 14, whereas the same study provides only 1.7 rad to the conceptus at weeks 35 to 42 (48,207,228). Likewise, administration of radiopharmaceuticals may be safely done during pregnancy. Nuclear medicine studies of the brain, biliary system, skeleton, lungs, kidneys, abscesses, and heart may all be accomplished with fetal exposures varying from 40 to 1,100 mrad (48). In general, because radioactive iodine readily crosses the blood-placental barrier, isotopic iodine administration should be avoided during pregnancy (261). Magnetic imaging is thought to be safe during pregnancy because studies of static, gradient, and radiofrequency magnetic fields at strengths lower than 2 tesla have thus far failed to demonstrate mutagenic or other deleterious effects on the fetus (48,81,225,262).

In summary, it is useful to keep in mind the American College of Obstetricians and Gynecologists' guidelines for diagnostic imaging during pregnancy (5):

X-ray exposure under 5 rad has not been associated with increased fetal anomaly or spontaneous abortion.
Maternal health should not be compromised by irrational fears of the dangers of ionizing radiation to the fetus. However, alternative imaging procedures such as ultrasonography and magnetic resonance imaging (MRI) should be used instead of x-rays when applicable.
Although ultrasonography and MRI are unassociated with known adverse fetal effects, MRI to date is not recommended for use in the first trimester.
Radiologic consultation is advisable if it is deemed necessary to estimate fetal dose when roentgenologic procedures are performed during pregnancy.
Therapeutic radioactive iodine isotopes are contraindicated during pregnancy.

Ultrasound is the most common modality used in diagnosis of calculous disease in pregnancy. However, because most symptomatic gestational calculi will be in the ureter and hydronephrosis is a normal finding in pregnancy, in most cases, ultrasound and its suboptimal view of the ureter will fail to be diagnostic in this setting. Horowitz and Schmidt (103) performed 11 ultrasound examinations in six gravid patients with calculi and found this modality to be diagnostic only once. In comparison, excretory urography was diagnostic in six of ten pregnant patients. These authors use a two-shot urogram consisting of a plain film and 3-hour postcontrast film with the idea that clearance of contrast from the symptomatic side excludes significant obstruction. They specifically outline the following situations in which urography is indicated: (a) persistent pyrexia or positive urine culture despite 48 hours of intravenous antibiotics, (b) declining renal function, (c) massive hydronephrosis detected by sonography, and (d) unrelenting pain or vomiting. In conclusion, sonography is most useful in evaluating gravid patients thought to have acute symptomatic stone disease requiring further investigation with roentgenographic imaging studies (269).

Renal sonography can be used in serial fashion without concern of radiation-induced fetal injury in the pregnant patient. Muller-Suur and Tyden (178) found that 31 of 35 patients with flank pain had hydronephrosis. In this study, the upper limit of normal pelvic diameter was determined to be 17 mm. In asymptomatic patients, normal renal pelvic diameters during the first, second, and third trimesters were 5 ± 1 mm, 10 ± 3 mm, and 12 ± 2 mm, respectively, on the right side, and 3 ± 1 mm, 4 ± 1 mm, and 5 ± 1 mm, respectively, on the left. These parameters constitute a guide to selection of patients having ureteral colic for further study. Whereas neither parity nor a history of urinary tract problems is found to be related to the degree of dilation, the incidence of hydronephrosis as determined by ultrasound investigation is 90% on the right side and 67% on the left (197). When hydronephrosis is found sonographically during pregnancy, a question may arise as to whether it is caused by obstruction or normal physiologic changes of the gravid state. Such a distinction may be made by determination of internal vascular resistivity indices by use of renal Doppler duplex ultrasound. Statistically significant relation is made between elevation of resistivity index and pathologic upper tract dilation in symptomatic pregnant patients (101). In this fashion, duplex renal ultrasound may be used to attribute hydronephrosis caused by calculus as opposed to nonobstructive physiologic phenomena.

HYDRONEPHROSIS OF PREGNANCY

Obstructive changes in the upper tracts during pregnancy are attributable to evolution of a physiologic process. Stadfeldt (236) reported right hydroureteronephrosis caused by uterine compression of the ureter at the level of the iliac vessels as long ago as 1861. Although their subject matter was autopsies of women dying in late pregnancy, Harrow and colleagues (98) were able to draw the same conclusion 103 years later using data compiled from excretory urography. Further support for the direct compression theory derives from the observation that hydronephrosis tends not to occur in gravid women with either ectopic ureters or those placed ectopically as in patients with urinary diversion; in neither of these two cases do the ureters become compressed between the uterus and iliac great vessels (247). Clark (39) reported an alternative explanation for hydronephrosis of pregnancy; namely, ureteral compression is caused by a dilated right ovarian vein that crosses over the ureter on its way toward the vena cava, as opposed to the left ovarian vein that runs a more parallel course with its ureteral mate. Although both he and others (68) performed resection of the offending ovarian veins plus ureterolysis with good results, this experience largely has not been found to be reproducible (214).

Hydroureterectasis in pregnancy first occurs as a simple consequence of ureteral compression above the pelvic brim by the enlarging, dextrorotating uterus at about midterm (70,269). Such rotation explains why hydronephrosis of pregnancy is usually found on the right. Hormonal factors may also contribute to this “physiologic” hydronephrosis. The elegant experiments in rhesus monkeys of Van Wagenen and Jenkins (257) and Van Wagenen and Newton (258) permitted the conclusion that in these animals, hormonal changes by a functioning placenta lacking a (surgically removed) conceptus induce ureterectasis. Whereas in the past these changes have been thought to be normal concomitants of pregnancy and not necessarily pathologic, current literature is replete with reports of obstructive uropathy in gravid women causing acute renal failure and polyhydramnios (71,102), acute pain (206), hypertension (138), and spontaneous renal rupture (88).

When symptoms of pain or infection are refractory to conventional nonoperative therapy with analgesics or antimicrobials, invasive manipulation of the hydronephrosis of pregnancy is indicated. The most commonly used method of temporary relief of this type of obstruction is placement of a ureteral stent or drainage catheter (19,71,112,138,151,184,240). Alternatively, for example, when ureteral tortuosity late in pregnancy precludes retrograde stent passage, percutaneous nephrostomy under either fluoroscopic (206) or sonographic (24,31,124,256) guidance may resolve symptomatic hydronephrosis. Indeed, for the tortuous ureter late in pregnancy, the straightening technique described by Pryor and Gillenwater (205) can be helpful in negotiating an otherwise unnavigable channel in stent passage. These authors suggest preliminary passage of a floppy-tip guidewire through a dual-channel cystoscope bridge to straighten the ureter in anticipation of catheter placement through the second channel. Stent passage also can be facilitated without the need for roentgenographic imaging through the use of endoluminal ultrasound (273). Goldfarb and associates (85) caution that pregnant stone-formers are at additional risk for development of concretions on indwelling stents. Thus increased fluid intake should accompany care of hydronephrosis of pregnancy treated with stenting.

Aside from the drainage procedures described previously, other solutions to the symptomatic hydronephrosis of pregnancy include epidural block (209) and delivery of the fetus at or near term, either by labor induction through amniotomy (192) or cesarean section (61). Bed rest in the contralateral position cannot be overemphasized to prevent complications of severe hydronephrosis of pregnancy, especially in patients with a solitary kidney (102).

An uncommon but potentially life-threatening complication of hydronephrosis of pregnancy is spontaneous renal rupture. The pathogenesis of this entity stems from increased hydrostatic pressure within the collecting structures that exceeds the holding capacity of the calyceal– renal capsular junctions resulting in extravasation (172). Kidneys with prior damage through infection, trauma, or surgery are particularly prone to rupture because of increased intracavitary pressure against noncompliant, scarred renal parenchyma. Symptoms occur between 18 weeks of gestation (172,258,278) and 1 day postpartum (61,121,172). Flank pain, hematuria, flank mass, and hypotension are harbingers of spontaneous renal rupture of pregnancy. Specific diagnosis may be carried out using sonography, limited excretory urography, and retrograde ureteropyelography. In addition, arteriography may be used to identify the source of hemorrhage in ruptured kidneys that have bled and caused hemodynamic instability (114). This technique may prove therapeutic with the addition of angioembolization, although radiation dosage for such a procedure is such that it cannot be recommended during the first trimester. Although most patients with hemorrhagic spontaneous renal rupture of pregnancy have required nephrectomy (172), timely use of rest in the contralateral decubitus position, ureteral stenting, or percutaneous nephrostomy may be expected to prevent this disastrous complication (64,132,162,189).

It should be noted that retroperitoneal hemorrhage may have origins in other than hydronephrosis of pregnancy as evidenced by the report of Plaus (202); he found hemorrhagic necrosis of metastatic renal choriocarcinoma related to a prior pregnancy in a patient with a positive pregnancy test and normal pelvic examination who was clearly not pregnant. A related problem is the rare spontaneous rupture of the ureter in pregnancy due to impacted proximal ureteral calculus (69).

URINARY CALCULOUS DISEASE IN PREGNANCY

Although symptomatic urinary calculi of pregnancy are vexing and pose problems that challenge all who treat them, they are neither more nor less common than their counterparts in the general population (103). This is accounted for in that the many determinants that tend to increase stone formation in pregnancy are offset by opposing factors. Hydronephrosis, decreased ureteral peristalsis, infection, and calcium supersaturation (159) all augment the stone-forming tendency of pregnancy, whereas increased excretion of stone inhibitors (magnesium, citrate, and glycosaminoglycans) works in the reverse (80). Although most researchers have found that calculi of pregnancy tend to occur in multiparas (9,47,170,191,227,235,241), a more recent study found primiparas to be more commonly afflicted (191).

Diagnosis of calculi in the pregnant patient begins with symptoms of flank or abdominal pain, urinary urgency, nausea, and vomiting. Because any of these symptoms are compatible with normal pregnancy, imaging studies must be done for confirmation. Ultrasound may reveal hydronephrosis, but as discussed earlier, this finding is entirely consistent with physiologic dilation and may lack diagnostic capability. Even demonstration of the presence of a calculus in the renal collecting system may not be definitive because most symptomatic calculi during pregnancy are located in the ureter (269). A diligent sonographer may occasionally demonstrate a calculus in the ureter adjacent to a filled bladder; however, the unreliability of sonography in this setting leads to the conclusion that roentgenography is necessary to diagnose most symptomatic urinary calculi requiring intervention by the urologist, as discussed previously.

Because most symptomatic stones during pregnancy will pass spontaneously, the treatment of these stones is primarily expectant (62,100,103,240). This conservative posture is feasible because most calculi become asymptomatic after the first trimester (137,240), so stones that remain in the urinary tract but become asymptomatic can be “nursed along” until intervention may be undertaken without concerns for fetal health following parturition.

Similar to treatment for symptomatic hydronephrosis of pregnancy, intervention most commonly assumes the form of stent placement (66,103,150,158). It has been suggested that stents be changed monthly to prevent rapid encrustation in patients with chronic recurrent stone disease or in those with persistent infection (216). We consider it axiomatic that asymptomatic stone disease in women of childbearing age be treated prophylactically to preempt the dilemma of diagnosis and treatment of stones during pregnancy. Rittenberg and Bagley (213) recommend flexible ureteroscopy for both diagnosis and extraction of symptomatic calculi in pregnancy; however, narrow-caliber, semirigid fiberoptic telescopes have been useful in our experience, especially because most of these calculi are below the iliac crossover. Ureteroscopy is further facilitated during pregnancy by ureterectasis, both physiologic and obstructive in nature.

Alternative management options of calculi include placement of percutaneous nephrostomy tubes and open lithotomy (47,66,96), both considered safe in pregnancy. However, the position of extracorporeal shock wave lithotripsy (ESWL) in pregnant patients is less clear. Although female fertility is believed to be unaffected by ESWL (259), there is a dearth of information as to the safety of shock waves administered in the vicinity of a fetus. Ultrasound-guided shock waves during early pregnancy in Sprague-Dawley rats were not found to be harmful (232a). Certainly, the small but significant radiation dosage received by many patients from fluoroscopic imaging during ESWL would support the use of devices using ultrasound coupling to the shock wave energy source. Suffice it to say that the lack of mitigating data at present places pregnancy as a relative contraindication to ESWL.

Open surgery can be safely performed for stones in the kidney or upper ureter. Open surgery is *contraindicated* in the last half of pregnancy for lower ureteral stones. There is not enough room in the pelvis to operate, and it would be difficult to correct any surgical complications. In the past, some urologists approached lower ureteral stones through a small vaginal incision.

To continue medications for prophylaxis of stone disease during pregnancy is questionable. Gregory and Mansell (90) reported experience with 46 pregnancies in cystinuric patients. D-Penicillamine was continued during gestation (with the exception of weeks 6 through 20 to prevent mutagenicity) with no congenital defects identified. Sodium bicarbonate and potassium citrate were also continued throughout pregnancy with no ill effects on the fetus. However, thiazides are known to cross the placental barrier, causing fetal or neonatal jaundice and thrombocytopenia, thus creating a relative contraindication for pregnancy (93,269). Calcium-binding agents and low-calcium diets should be replaced with liberal fluid intake alone to prevent nutritional deficiencies in the evolving conceptus.

URINARY INFECTION IN PREGNANCY

Asymptomatic bacteruria is present in 4% to 7% of pregnancies, similar to the incidence in menstruating women generally (127,133,188,246). Thus, although pregnancy does not in and of itself cause bacteruria, the latter's association with pyelonephritis results indirectly in prematurity, low birth weight, and growth retardation (133,135,277,278). Kass (121,123) demonstrated that 20% to 40% of pregnant women with first trimester bacteruria acquire pyelonephritis in the third trimester. Conversely, successful treatment of bacteruria significantly lessens the progression to pyelonephritis of pregnancy and associated low birth weight, growth retardation, and premature labor (42,122). This is especially true in diabetic patients (176). It is therefore considered axiomatic that bacteruria of pregnancy be both screened for and treated. In a study of 3,254 patients screened for bacteruria of pregnancy (238), it was found that the risk of acquiring bacteruria increased with the duration of pregnancy, from 0.8% at the end of the first trimester to 1.93% at term. Because the risk of onset of bacteruria is highest between weeks 9 and 17 of gestation, it was suggested that week 16 is the optimal time for screening if considerations of economy dictate a single specimen be selected for this purpose. A meticulous, clean-catch midstream urine culture growing greater than 100,000 colony-forming units (CFU)/mm is considered significant for purposes of treatment and antimicrobial prophylaxis during pregnancy (196).

Offending microorganisms in the genesis of urinary tract infections during pregnancy are those causing infection in the general adult female population, primarily Gram-negative rods. *Escherichia coli* is the most common, followed by *Klebsiella, Enterobacter, Proteus,* Gram-positive cocci, and enterococci (in order of frequency) (7,154). Stenqvist and colleagues (239) demonstrated that pregnancy does not diminish the virulence of *E. coli* strains that cause pyelonephritis compared with those causing only asymptomatic bacteruria, suggesting that pregnancy does not enhance host factors for resistance to upper urinary tract infection. Matorras and associates (164) found 20% of pregnant diabetic patients (twice as many as nondiabetic patients) to be colonized rectovaginally with group B streptococcus. However, group B streptococci did not cause more frequent urinary infection in diabetic than in nondiabetic patients. Urethritis caused by *Chlamydia trachomatis* occurs in 50% of women with dysuria, pyuria, and urinary frequency (266). In addition, chlamydial cervicitis was found in 21% of 11,544 women at their first prenatal visit; when untreated, it was associated with premature rupture of membranes, as well as low birth weight and decreased survival (221). Neonatal complications of chlamydial infection included nasopharyngitis, pneumonitis, and conjunctivitis. Thus *Chlamydia* is not “normal flora” and should be treated when discovered during pregnancy with erythromycin 500 mg four times daily for 7 to 10 days (266).

Once urinary tract infection is established in the pregnant patient, it becomes necessary to select both initial treatment and subsequent prophylaxis. Krieger (133) recommends full-dose antibiotic therapy for 7 to 10 days in treatment of gestational bacteruria. In addition, treatment for acute cystitis is the same as for asymptomatic bacteruria of pregnancy (169). However, regimens for initial treatment vary from single-dose to 3-day courses using amoxicillin (82,115), nitrofurantoin (97), and cephalexin (115,167). Angel and co-workers (8) found that in the absence of bacteremia, oral antibiotic therapy was as safe and effective as intravenous treatment for acute pyelonephritis during pregnancy.

Prophylaxis against recurrence of bacteruria for the remainder of pregnancy once the initial positive culture has been treated may be given as a daily or periodic dose of a suppressive antimicrobial agent. Van Dorsten and colleagues (254) used nitrofurantoin 50 mg three times daily as uroprophylaxis unless the initial posttreatment urine culture grew an organism resistant to that drug. Alternatively, Pfau and Sacks (201) use postcoital prophylaxis in the form of either cephalexin (250 mg) or nitrofurantoin (50 mg), similar to the case in nonpregnant patients. An intermediate prophylaxis regimen would be an equivalent dose of any antibiotics known to be safe and effective in pregnancy and for the particular microorganism in question as a nightly dose for the duration of the remainder of gestation (142,196,254). Close bacteriologic follow-up (e.g., semiweekly or monthly urine cultures) should follow initial treatment and be used to determine when additional bursts of full-course antibiotics should be prescribed.

Demonstration of persistent bacteruria during pregnancy is associated with structural urinary tract defects warranting thorough urologic evaluation postpartum (65). Austenfeld and Snow (10) found increased rates of urinary tract infection and miscarriage in women having undergone prior ureteroneocystostomy for childhood vesicoureteral reflux. Evaluation with early and repetitive urine cultures accompanied by prompt intervention with antimicrobials as described previously is appropriate in pregnant patients with any preexisting anatomic urinary anomaly.

RENAL FAILURE IN PREGNANCY

Chronic renal failure can be exacerbated by pregnancy, and acute renal failure (ARF) can be caused by pregnancy. Pregnancy is further complicated by end-stage renal disease (ESRD) treated either by dialysis or transplantation. These parallel management problems and counseling for women with renal disease facing pregnancy are now considered.

Renal failure resulting from pregnancy is classified into three etiologic categories: prerenal, renal, and postrenal. Prerenal states are caused principally by hypovolemia attributable to hyperemesis gravidarum and uterine bleeding (131). Hemorrhage in turn has three primary etiologies: abortion, placenta previa, and abruptio placentae. Unchecked by appropriate replacement of lost fluids, prerenal azotemia deteriorates into acute tubular necrosis (ATN), the most common cause of ARF in pregnancy (55). ATN and its counterpart, renal cortical necrosis (RCN), are the chief causes of ARF of pregnancy (Table 5.2). ATN and RCN are distinguished from one another in that ATN occurs in a setting of preeclampsia (hypertension, proteinuria, and edema), eclampsia (preeclampsia plus seizure and coma), sepsis, and hemorrhage (215). In contrast, RCN follows disseminated intravascular coagulation (caused by amniotic fluid embolism, intrauterine fetal demise, or abruptio placentae), transfusion reactions, and sepsis (caused by chorioamnionitis, septic abortion, and pyelonephritis) (92,131). Clinically, ATN may be distinguished from RCN in that, whereas ATN rarely causes anuria and is usually reversible, RCN is manifested by anuria followed by irreversible renal damage accompanied by renal cortical calcification (269). RCN may occur during the puerperium as the syndrome of idiopathic postpartum renal failure. This rare syndrome is clinically characterized by oligoanuric acute renal failure following an otherwise uneventful pregnancy, which often progresses to RCN. [Three of five cases in a series of 57 cases of ARF in pregnancy were reported by Grunfeld and Pertuiset (92).] Although ARF occurs with an incidence of 1 in 2,000 to 5,000 pregnancies, more than 20% of cases of ARF in women are seen during pregnancy (92,131). Fortunately, ARF in females is declining as a result of improved obstetric care in general, and it has nearly disappeared late in the first trimester because of eradication of septic abortion (269).

Acute Renal Failure Etiology	Acute Tubular Necrosis	Renal Cortical Necrosis
Predisposing factors	Prerenal azotemia (hyperemesis gravidarum, uterine hemorrhage), preeclampsia, eclampsia, sepsis	Disseminated intravascular coagulation (amniotic fluid embolism, abruptio, intrauterine fetal demise), transfusion reactions, sepsis (chorioamnionitis, septic abortion, pyelonephritis)
Clinical manifestations	Nonoliguric renal failure	Oliguric renal failure, may occur as idiopathic postpartum renal failure
Outcome	Resolution of renal insufficiency	Chronic renal failure, renal cortical calcification

TABLE 5.2. ACUTE RENAL FAILURE IN PREGNANCY: ACUTE TUBULAR NECROSIS AND RENAL CORTICAL NECROSIS COMPARED

Whereas pregnancy may be a cause of acute renal disease, it may exacerbate preexisting renal disorders. Imbasciati and associates (109) reported 18 patients with serum creatinines more than 1.6 mg/dL underwent 19 pregnancies resulting in 13 live births, of which 50% were premature. Of the 18 patients, 14 were followed postnatally; 5 of 14 (36%) developed rapidly progressive renal insufficiency. Abe and colleagues (1) described renal deterioration in 25% of women with chronic renal disease in the midst of or following pregnancy. Others have recommended termination of pregnancy if the pregnancy causes progressive decline in renal function (152). Pregnancy does not seem to permanently influence kidneys with diabetic nephropathy, glomerulonephritis, renal transplants, or polycystic kidneys (136). However, manifestations of cystic renal disease, such as hypertension, infection, hematuria, and calculi, may cause management problems in pregnant patients with autosomal-dominant polycystic kidney disease (APCKD). In contrast, reflux nephropathy entails significant risk for acceleration of renal dysfunction during and after pregnancy. Becker and co-workers (14) reviewed 20 patients during a 10-year span and found 4 (20%) developing ESRD within 2 years of parturition, while 4 others who aborted went on to develop hypertension and ESRD. They conclude that patients with a history of reflux nephropathy incur a 50% risk of progression to end-stage renal failure. Patients with renal failure or hypertension are at greater risk for impairing renal function during pregnancy.

Although pregnancy might accelerate the progression of chronic renal disease toward the end stage, pregnancy remains a possibility for the patient with established ESRD. The first term pregnancy in a hemodialysis patient was reported in 1971 (43). A more recent series (210) describes nine births resulting from 14 pregnancies in 13 patients enrolled in dialysis programs (8 patients receiving chronic ambulatory peritoneal dialysis and 6 receiving hemodialysis). Although no congenital anomalies were identified, pregnancies tended to be complicated by exacerbation of hypertension and worsening residual renal function; babies were small for gestational age. These data support the general recommendation for allowing attempt of conception in the dialysis population with close medical surveillance.

If ESRD presents a set of risks to patients contemplating or facing pregnancy, renal transplantation becomes a “double-edged sword” in (to the positive) eliminating the azotemic state and (to the negative) causing fetal exposure to immunosuppressive drugs (63). It is now known that successful renal transplantation improves the likelihood of pregnancy from 1 in 200 (pretransplantation) to 1 in 50 (34). Conversely, pregnancy is unlikely to harm an adequately functioning renal graft (54). Specifically, only 15% of renal transplants will deteriorate as a result of pregnancy (226). However, in those few transplant patients experiencing increasing azotemia during pregnancy, termination has been recommended to prevent irreversible transplant damage (226). An interesting window of opportunity has been observed in transplant patients who become pregnant. That is, pregnancy occurring more than 5 years after transplantation causes permanent renal injury in 75% of cases (57). On the other hand, the outcome of pregnancy itself is superior at least 2 years after transplantation (34). These combined observations yield the conclusion that renal transplant patients should plan their pregnancies between 2 and 5 years after transplantation.

Pregnancy further affects renal transplant function in that the immunologically privileged state of gestation diminishes the incidence of transplant rejection (195). A corollary of this phenomenon is the occasional “rebound” of transplant rejection occurring postpartum. Immunosuppressive drugs (e.g., steroids, azathioprine, cyclosporine), although teratogenic at high dosages, are usually safe at moderate dosages during pregnancy (63,139,186). Although renal transplant patients must be monitored closely throughout pregnancy for development of hypertension, urinary infection, prematurity, and preeclampsia, transplant function is only minimally jeopardized during gestation (30,190).

UROLOGIC CONSIDERATIONS IN THE PREGNANT PATIENT WITH A SPINAL INJURY

Approximately 2,000 women of childbearing age sustain spinal cord injury annually in the United States alone (46). As a result of vastly improved rehabilitative measures, pregnancy has become a real possibility in such patients. Cross and associates (46) reported 25 pregnancies in 16 women with cervical (7 patients) or thoracic (9 patients) spinal injuries. Twenty-two babies, four of whom were delivered via cesarean section, and three abortions resulted from these pregnancies. Eleven patients had symptomatic urinary tract infections, one had removal of a bladder calculus, and seven had autonomic dysreflexia (see also reference 265) related to a number of stimuli, such as a full bladder, enema, bowel movement, Foley catheter change (143), or uterine contraction. Greenspoon and Paul (89) recommend maintenance of a clean perineum to prevent ascent of bacteria from skin to bladder. The usual means of bladder drainage (e.g., intermittent clean catheterization, suprapubic catheterization, Credé maneuver) should be continued intrapartum. All spinal injury patients should be monitored closely and are at increased risk for asymptomatic bacteruria of pregnancy. Because most are managed with some type of catheterization, bacteruria is the rule in pregnant patients with a spinal injury; consequently, most will require antibiotic prophylaxis during pregnancy to reduce attendant complications, such as prematurity or low birth weight.

In the past, many patients with spinal injury or those with congenital spinal anomalies have been managed with extensive urologic surgical procedures to relieve obstruction or stasis in the upper or lower tracts. Such patients requiring delivery via cesarean section especially should be treated with great care, preferably with a team of operating gynecologic and urologic surgeons to avoid injury to bladder, ureter, or diversionary intestinal segment (212).

LOWER URINARY TRACT DYSFUNCTION IN PREGNANCY

Whereas urinary stress incontinence and frequency are common lower tract symptoms during pregnancy, gestational urinary retention is distinctly uncommon (237). The latter is thought to occur as a result of uterine retroversion during early pregnancy, a situation that tends to spontaneously reverse in the second trimester (95). That is, urethral obstruction caused by first trimester uterine retroversion resolves with backward cervical movement and fundal anteversion occurring at week 14 or 15 (84). Thus this form of urinary retention may be resolved by either temporary placement of a pessary or manual repositioning of the fundus (84,183,230). The problem may be circumvented by intermittent catheterization and voiding in the prone position (203).

Urinary retention may occur as a consequence of epidural block preceding delivery by cesarean section. This complication may be avoided by preoperative placement of a Foley catheter that is indwelling for several days postpartum. The incidence of urinary retention in this cohort is thereby reduced from 40% to zero (126). In patients with neurogenic urinary retention treated with indwelling bladder stimulator devices, there have been no adverse effects on the pregnancy or fetus

(157,181).

Urinary stress incontinence occurs commonly both during and after pregnancy. The genesis of pregnancy-related stress incontinence remains controversial. It seems likely that myogenic or neurogenic damage to the urethral sphincter may occur after difficult vaginal delivery or that facilitated by application of forceps (245). On the other hand, Van Geelen and associates (255) found that neither functional urethral length nor urethral closure pressure changed significantly during pregnancy, nor was there a notable influence by either the duration of labor or the presence of an episiotomy on postpartum urethral pressure profiles. In the same study of 43 asymptomatic primigravidas, urethral closure response to stress maneuvers did not change during the course of pregnancy, nor did birth weight influence urethral pressure or length parameters postpartum in patients undergoing vaginal delivery. The conclusion was that inherent weakness in the sphincter mechanism rather than pregnancy itself caused stress incontinence.

In contrast, Iosif (110) found that only 4.9% of 1,411 patients developed permanent pregnancy-related stress incontinence, and of this 4.9%, most developed incontinence during their first pregnancy. Moreover, the incidence of stress incontinence in parous patients' mothers was greater by fivefold in incontinent patients as compared with that of controls. It was inferred that pregnancy itself rather than birth trauma was responsible for stress incontinence. The same author has studied stress-incontinent women urodynamically during and after pregnancy and has found that urethral closure pressure progressively diminishes during the course of gestation, as opposed to continent women, who exhibit an increase in both urethral length and urethral closure pressure as pregnancy proceeds (111). This finding supports the concept that physiologic changes in urethral function (or the lack thereof), as opposed to direct trauma to urethral smooth muscle or innervation during parturition, lead to stress incontinence. Petros and Ulmsten (200) propose an effect of relaxin, produced by the corpus luteum of pregnancy, on urethral collagen (depolymerization and resulting tissue softening) as causing reversible stress incontinence in a pregnant patient having had an intravaginal sling operation. Further studies will be necessary to confirm whether relaxin or other hormonal phenomena are responsible for temporary or permanent changes in urethral function during and after pregnancy.

UROLOGIC COMPLICATIONS OF CESAREAN SECTION AND VAGINAL DELIVERY

The incidence of overall injuries to the urinary tract during caesarean section is less than 1%, although it is much higher if associated with cesarean hysterectomy (147). Ureteral injury during cesarean section occurs 0.1% of the time (148). Such injuries are most often repaired using ureteroneocystostomy facilitated by psoas hitch (148). Injury to the urinary bladder is the most commonly reported acute urologic obstetric injury and is often caused by an opening in the bladder dome created during cesarean section (11,72,173). Repair is straightforward owing to the lack of involvement of the trigonal structures. However, low-segment cesarean section may injure the bladder base or ureters, risking vesicovaginal (0.7% incidence) or, more rarely, ureterovaginal fistula (4,104,147). Multilayer closure and omental interposition during repair is prudent in prevention of such complications. Rare urologic obstetric complications include urethral diverticula that may obstruct labor (174), atraumatic bladder or urethral rupture, necrosis of the anterior vaginal wall leading to vesicovaginal fistula secondary to obstructed labor (147), vesicouterine fistula following repeat cesarean section (250), loss of pelvic floor muscle tone after episiotomy and high forceps delivery (94,128,243,249), and trans-serosal invasion of the bladder by placenta percreta (222,232). Recent data suggest that repeat cesarean section has now become the principle cause of vesicouterine fistula due to altered vascularization of the supravaginal septum and distortion of bladder anatomy after primary section (116).

Vesical neck support and mobility are affected by both vaginal delivery and cesarean section, more so with the latter. Forceps delivery in particular may have profound effects on ability of women to contract their pelvic floor musculature. In addition, forceps delivery causes prolonged pudendal nerve terminal latencies as compared with vaginal delivery without forceps. Multiparity with or without forceps delivery results in pudendal nerve dysfunction similar to forceps delivery in primigravidas or in women having had a prolonged second stage of labor or high birth weight (3,233,242). Such pudendal nerve dysfunction may persist and worsen over the years following delivery (234). Cesarean delivery seems to preserve pudendal nerve function and, by extension, pelvic floor muscle tone. Similarly, noninstrumented vaginal delivery leads to transient but reversible pudendal nerve dysfunction (248). Thus it is clear that preservation of pelvic floor neuromuscular integrity is directly related to efforts to minimize the use of forceps and episiotomy in facilitating vaginal delivery, as well as limiting prolongation of the second stage of labor, prevention of third- and fourth-degree lacerations, and judicious application of cesarean delivery (94,250).

URINARY TRACT RECONSTRUCTION AND PREGNANCY

Pregnancy is possible in patients having undergone prior urinary tract reconstruction, whether for neurogenic bladder, tumor, or voiding dysfunction. Fenn and colleagues (74) described 19 pregnancies in 18 women ages 21 to 36 years having undergone clam enterocystoplasty for intractable detrusor instability. Pajor and colleagues (193) advocate lower urinary reconstruction with an ileocecal as opposed to ileal bowel segment to avoid uterine-induced mesenteric compromise during the course of pregnancy. Kennedy and co-workers (125) reported on successful pregnancies in four women with exstrophy having had flap vaginoplasty and creation of subsequent continent right colonic urinary reservoir with an orthotopic perineal stoma (Indiana pouch). The authors performed cesarean section and close monitoring for maternal or fetal distress in all cases. Creagh and colleagues (45) reported 34 pregnancies in 27 women with reconstructed lower urinary tracts who underwent either vaginal or cesarean delivery, indicated by specific obstetric considerations. Most of their patients (28 of 34) underwent successful vaginal delivery. Thus patients having undergone lower urinary reconstruction may safely deliver either vaginally or via cesarean section; attendance of the urologist is essential in all cases.

URINARY TRACT TUMORS DISCOVERED DURING PREGNANCY

Despite pregnancy being an immunologically impaired state, the incidence of malignancy is similar to that in the general population (185). A wide variety of urologic tumors have been reported to occur during pregnancy (149). Specifically, renal cell carcinoma is the most common renal neoplasm of pregnancy; because the latter is a condition of the young, angiomyolipoma occurs next in frequency (263). For the same reason, Wilms' tumor is known in pregnancy (23). Bladder cancer during pregnancy may take the form of adenocarcinoma (78), transitional cell carcinoma (18,19), or squamous cell lesions (120). Because electrical current may induce neighboring uterine contractions, obstetric treatment to diminish uterine smooth muscle reactivity may be helpful in reducing the possibility of premature labor from electroresection and cautery. Similarly, laser phototherapy is useful to treat bladder tumors of pregnancy while eschewing prematurity.

Adrenal tumors such as pseudocyst (251) and pheochromocytoma (29,224) are extant during pregnancy. Key issues in pheochromocytoma of pregnancy include diagnostic conundrum (symptoms and signs resemble those of preeclampsia, leading to mortality rate greater than 50% when undiagnosed), choice of a-blockade (prazosin, to avoid teratogenicity of phenoxybenzamine), means of imaging (MRI is especially useful for localizing pheochromocytoma and is free of ionizing radiation), timing of surgical resection (expeditiously), and route of delivery (vaginal preferred) (29,91,149,160,224,260).

TIMING OF ANESTHESIA DURING PREGNANCY

General anesthesia in and of itself does not entail a risk of adversity to pregnancy (48). This holds especially true when the (nonobstetric) procedure is complication free. A landmark study from Scandinavia evaluated 5,405 incidental surgical procedures performed during all three trimesters of pregnancy. Although the incidence of low birth weight and prematurity was greater in these patients as compared with a large cohort of pregnancies, there was no tendency toward congenital malformation in the operated group. It was concluded that there is an increased risk of prematurity following intragravid surgical procedures requiring general anesthesia, which may be attributed to the underlying condition rather than the procedure or anesthetic itself (40,166).

Other considerations involving anesthesia during pregnancy include timing of semiurgent procedures that may not be postponed until parturition. There is evidence that nonobstetric surgical procedures are most safely performed during the second trimester owing to the increased risk of spontaneous abortion during the first trimester and induction of premature labor when procedures take place near term (108).

A related issue is the diminished requirement for both local and general anesthetics during pregnancy (149). Thus dosages of inhalation anesthetics such as halothane and isoflurane should be reduced in pregnancy to compensate for the sedative effects of progesterone (153,171,194). Likewise, the requirement for local anesthetics is decreased during the first trimester because of increased cell membrane receptor sensitivity to these agents, again a progestational-mediated phenomenon (53,73).

CONCLUSION

Urologic problems during pregnancy are often undertreated because of unfounded fears of causing fetal harm. An understanding of pathophysiologic changes in the urinary tract, as well as appropriate use of antimicrobials, anesthetics, imaging studies, and invasive procedures, will lead to resolution of most such problems while

providing a margin of safety for both mother and child.

Chapter References

The usefulness of an individual surgical laser is predicated by the unique tissue effect generated by thermal transformation of light energy. Lasers can be used to coagulate, incise, or vaporize tissue and, under certain circumstances, provide a combination of these processes. Selective absorption of laser energy by the target tissue is possible, thereby increasing the efficiency of therapy and decreasing the risk of side effects. The transmission of laser energy by small, flexible optical fibers facilitates energy delivery either directly or through an endoscope. Adaptations allowing side firing and diffuser tip emission of laser energy have further expanded the therapeutic capabilities for surgical lasers.

This chapter reviews the pertinent aspects of laser history, physics, and tissue interaction. To safely use laser energy, the surgeon must have an adequate understanding of methods to manipulate and influence tissue effects. Specific urologic applications of laser surgery are discussed in detail. No written document can be all-inclusive; nevertheless, detailed recommendations are provided for individual urologic problems in an effort to be a practical reference for the clinical surgeon.

LASER PHYSICS

Although the concept of stimulated emission of radiation was hypothesized by Einstein in 1917, the first beam of laser light was not generated until 1960 (69). Mulvaney and Beck used ruby laser and carbon dioxide (CO_2) lasers in urology and found them to have minimal value in destroying kidney stones but projected possible use for tumor ablation (91). It was not until the development of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser and a suitable fiber delivery system that lasers began to play a role in urologic surgery.

To safely and effectively apply laser energy as a surgical tool, a basic understanding of laser physics and tissue effects is essential. The tissue-destructive properties of a laser beam can be therapeutically beneficial if properly used, but they can also produce unique complications if misdirected or applied with inadequate knowledge or experience.

The word *laser* is an acronym for “light amplification by stimulated emission of radiation.” White light from an incandescent bulb is a divergent mix of multiple wavelengths (colors). In contrast, laser light consists of nearly a single wavelength (monochromatic) that travels in a unidirectional manner (collimated) and can be deflected for projection onto tissue surfaces. In theory, the beam is nondivergent, although the angle of divergence from surgical laser fibers is at least 5 degrees and often much greater.

Surgical lasers are powered by electricity, which is used to ignite a flashlamp. Atoms of the active medium in the laser resonator are energized from the ground state to an excited state by photons produced by the flashlamp. When the atoms spontaneously decay to the ground state, a photon of specific wavelength is emitted (Fig. 6.1). The spontaneously emitted photon interacts with an excited-state atom, stimulating it to decay, and emits a second monochromatic photon. Because the original incident photon is also released, stimulated emission of radiation involves a factor of two energy gain with each atomic interaction (Fig. 6.2). A totally reflecting mirror at one end of the laser cavity and a partially reflecting mirror at the other preserve photons within the resonator. Photon reflection through the laser resonator substantially increases laser output because photons have greater opportunity to stimulate excited-state atoms to decay. Photons exit the resonator as a nearly nondivergent beam through the partially reflecting mirror at one end. The laser beam may pass directly from the laser or be coupled to a flexible, fused-silica glass optical fiber.

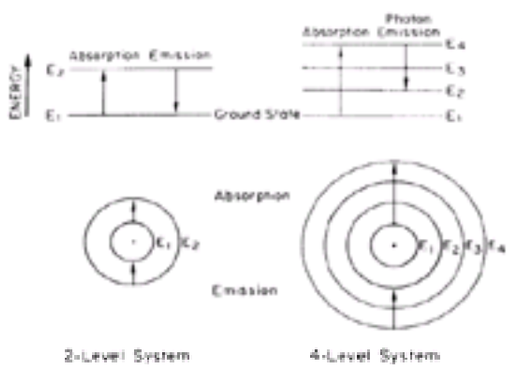

FIGURE 6.1. Diagram of energy states corresponding to electron energy levels. Laser wavelength is directly related to the energy released by electron decay from the excited to the ground state.

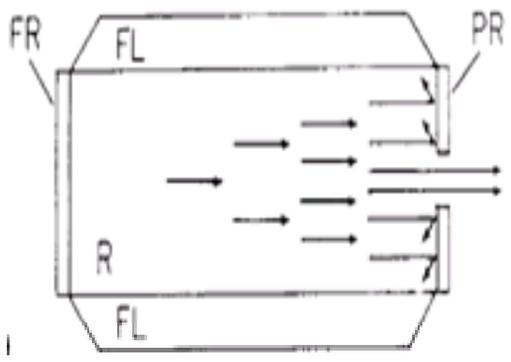

FIGURE 6.2. Laser design and energy gain. FL, flash lamp; FR, fully reflective mirror; PR, partially reflective mirror; R, laser resonator rod.

The active medium, that is, the source from which the photons are emitted, determines the wavelength of a particular laser. It may be a gas (CO_2, argon), a liquid (rhodamine-B, coumarin green), or a solid [neodymium, potassium titanyl phosphate (KTP)].

In general, minimum modifications are necessary to prepare an operating room or cystoscopic area for laser use. Electrical outlets [220 V (three-phase), 50 amp], ideally with isolated transformers, are required for argon and some older or high-energy Nd:YAG lasers. A 206-V (single-phase), 50-amp wall power source is optimal for most Nd:YAG, holmium, and KTP lasers. A few lower-power devices such as diode lasers, CO_2 lasers, and some newer Nd:YAG lasers require only a 110-V power source. When planning an operating room for laser surgery, one should have all three of the power outlets near each other in a convenient location. This includes a high-amperage 110-V power source; a three-phase 220-V, 50-amp power source; and a single-phase 206-V, 50-amp power source.

Lasers generate a large amount of waste heat that must be removed from the resonator cavity to prevent overheating. All currently available urologic lasers use an internal radiator and fan for cooling. Very-high-energy systems and older medical lasers may require cooling water obtained through a hose connected to a running water source. A wastewater drain is also required if external cooling water is used. Externally cooled systems are cumbersome and have limited portability.

Access to the operating room should be controlled to prevent accidental entry during laser use. Protective shades should cover all windows. As with any procedure using electrically powered equipment, the operating room floor should be kept as dry as possible. Deflection of the laser beam into the eye can produce retinal injury with the Nd:YAG, argon, and KTP lasers and a corneal burn with the CO_2 or holmium laser. Therefore eye protection is mandatory for all persons in the operating room during laser use. Typically, glasses or goggles with green-tinted lenses are used for the Nd:YAG laser, amber lenses for the argon and KTP lasers, and clear lenses for the CO_2 and holmium lasers. Newer, more expensive clear lenses are available to protect the eye from Nd:YAG and KTP laser energy. During endoscopic laser surgery, the use of either a solid-state CCD camera or a wavelength-specific lens cap over the eyepiece of the telescope may suffice once the fiber is inserted into the cystoscope or laparoscope. One should never underestimate the amount of laser light that can be reflected backward from the end of the fiber through the cystoscope toward the surgeon's eye.

TISSUE EFFECTS OF LASER ENERGY

Tissue Optical Properties

Tissue optical properties control the transformation of laser light energy into heat (124). Cellular destruction generally is not evident when tissue temperatures less than 60°C are maintained for only a few seconds. Above 60°C, protein denaturation ensues, although minimum volatilization and tissue vaporization occur below 100°C. Above 100°C, cellular water evaporates and charring and tissue vaporization are observed.

Several important factors influence the extent of thermal destruction that occurs when a laser beam is projected onto tissue surfaces. The most easily controlled factor is laser wavelength. Body tissues contain chromophores, such as hemoglobin, that preferentially absorb certain wavelengths of light. The absorption characteristics of a particular laser wavelength depend on the relative tissue absorption and can vary significantly from one wavelength to another.

Absorption and scattering of laser light are important in determining the extent of tissue injury during laser surgery. As tissue is irradiated, light traveling through the tissue is attenuated by absorption and scattering. The proportionality constant describing the amount of light attenuated by absorption is the absorption coefficient (μ_a). The constant describing the attenuation of light due to scattering away from the direction of propagation is the scattering coefficient (μ_s). A third parameter, the anisotropy coefficient (*g*), describes the fraction of light scattered into any given direction and is assumed to be the average cosine of the scattering angle. These three coefficients are referred to as the *optical properties.* The propagation of light in tissue depends on three dimensionless parameters, one of which has already been discussed (*g*); the other two are based on the absorption and scattering coefficients. These are the albedo (*a*) and the optical depth (t), defined as follows:

and

where *d* is the sample thickness.

Because the distribution of light in tissue depends on tissue optics, much research on measuring the optical properties of tissues has been conducted and several methods have been introduced (98,123,127,130). A study of the optical properties of rat prostate tumor revealed values of 0.05 mm^{-1}, 27.0 mm^{-1}, and 0.98 for μ_a, μ_s, and *g,* respectively (4). Scientific studies into the tissue effects of various laser treatments must consider these factors.

Energy Density

In addition to wavelength and angle of incidence, other parameters can be used to predict and, to some extent, control the tissue effects and depth of penetration of a particular laser, including energy density. Stated simply, energy density is the amount of energy delivered to a given area of tissue. It is determined by the following formula:

$$\textbf{Power (Watts)} \times \textbf{Duration (seconds)/Area}^2 \textbf{ (cm}^2\textbf{)}$$

The power output of a particular laser is controlled from the instrument panel. Duration can be modified by controlling the time length of a particular pulse or by varying the speed with which the beam is moved across the tissue surface.

An influential component of the formula for energy density is the size of the treatment area. Treatment area is a function of offset distance and divergence angle:

$$\textbf{Area} = p \times [\textbf{Offset distance} \times \tan(\textbf{Divergence angle}/2)]^2$$

Surgical laser fibers with a wide angle of divergence produce a lower energy density than nondivergent fibers by treating a larger surface area or spot size with the same amount of energy. The distance between the fiber tip and the tissue surface also influences the energy density by markedly changing the treated surface area.

Contact techniques increase energy density by limiting the treatment surface area.

The angle of divergence from the fiber tip is unique to each device. The end-fire probes used over the last decade have an angle of divergence of only 5 to 15 degrees. Tissue injury from short-duration (2 to 3 seconds), high-energy density exposure may extend for several centimeters. Widely divergent beams (up to 90 degrees) produce a much lower energy density. Long-duration (60 to 90 seconds), low-power (40 to 60 W) exposure with these fibers can coagulate a large volume of tissue with coagulation depths of over 1 cm.

Optical properties of tissue have been shown to be temperature dependent. This is of concern because an increase in the absorption or scattering coefficient prevents light from penetrating deeper into the tissue, thus compromising laser treatment. Chambettaz and colleagues (21) measured temperature-dependent changes in total reflectance and transmittance while irradiating excised arterial wall specimens at 383 W/cm ^{2} and 191 W/cm^2. They found that with the higher irradiance, transmittance decreases rapidly with increasing temperature up to 51.4°C, followed by a rapid increase in transmittance as temperatures continued to increase. Reflectance measurements showed inverse responses. When the tissues were irradiated at 191 W/cm ^{2}, changes in transmittance and reflectance occurred more slowly with their extrema occurring at 44.1°C. Another study reported a fourfold increase in the scattering coefficient (0.43 to 1.74 mm $^{-1}$) of porcine myocardium during coagulation, whereas the absorption coefficient remained relatively unchanged (0.04 to 0.05 mm $^{-1}$) (31). Splinter and colleagues (123) also demonstrated a twofold to threefold increase in the reduced scattering coefficient in canine and human coagulated myocardial tissue. Pickering and colleagues (99) found that the scattering coefficient of rat liver increased while the absorption and anisotropy coefficients decreased during tissue heating. They also noted that the rates of change in these properties were proportional to the amount of energy used to heat the samples.

Coagulation

When tissues are heated to less than 60°C for only a few seconds, tissue warming without irreversible damage is observed. Between 60° and 100°C, permanent protein denaturation occurs, causing tissue coagulation. Although this is irreversible and destructive, immediate tissue removal does not occur. The thermally injured tissue either sloughs or is reabsorbed by the body's inflammatory mechanism. Transurethral laser treatment of the prostate causes coagulation and delayed slough of tissue for 4 to 8 weeks (75). Tissue sloughed from the urinary tract is amorphous and does not cause urinary retention. Hemostasis both during and after treatment usually is excellent because the coagulation process extends to blood vessels within the volume of treated tissue. Poorly absorbed wavelengths, such as the 1,064-nm light produced by the Nd:YAG laser, primarily cause tissue coagulation. Coagulation rather than vaporization may be favored when using a given wavelength by lowering the energy density. In general, low-power, long-duration laser exposure through a large irradiated area such as that produced by diode lasers for interstitial laser prostatectomy increases the amount of coagulation and the depth of tissue injury compared with higher-power laser sources used for a short duration.

Vaporization

When high tissue temperatures (generally above 100°C) are achieved, immediate tissue vaporization ensues. Surface carbonization may be observed and a smoke plume generated. Some degree of coagulation accompanies carbonization, so hemostasis is usually adequate, although less than that observed with pure coagulation techniques. Carbonization significantly increases the tissue absorption coefficient, leading to further marked tissue heating in the small area of carbonized tissue. The total coagulation depth may actually be decreased by absorption of nearly all the laser light at the tissue surface.

Vaporization is more difficult to achieve under water than in an air environment. This is particularly pertinent for urologic endoscopic use because the irrigating fluid causes surface cooling. If desired, vaporization is facilitated by using highly absorbed wavelengths (CO_2 or holmium lasers), using a high laser power output, applying the energy pulse over a very brief period, or decreasing the treated surface area (as with contact tips).

Physics of Laser Prostatectomy

Side-firing Laser Prostatectomy

Side-firing laser coagulation prostatectomy involves disposition of laser light into tissue. The prostate, like other bodily tissues, is somewhat transparent to incident light. Photons of laser light experience three possible interactions during passage through tissue. Initially, photons pass through tissue in the original incident direction. This is termed *through transmission.* Interaction with tissue causes photons to be extensively scattered in directions other than the original incident direction. This process is wavelength dependent and causes the beam to form a plume with lateral width. Once a photon is *absorbed* by tissue, its energy is liberated as heat. Thermocoagulation will occur if enough laser energy is used to achieve tissue temperatures of 60° to 70°C for more than a few seconds.

Many factors affect tissue temperature distribution, including laser, optical, and thermal parameters. Laser parameters consist of wavelength, power, spot size, beam profile, and scanning velocity. The optical parameters of importance are surface reflection and the tissue absorption and scattering coefficients. Thermal parameters are the characteristics of the tissue, such as thermal conductivity, specific heat, tissue density, and convective heat transfer coefficient. Of these, thermal and optical properties depend on temperature and wavelength.

Tissue optical characteristics define the effect of a specific laser delivery system. Three parameters are most important: energy loss caused by urethral reflection, tissue absorption, and scattering coefficients. Loss caused by urethral reflection is largely unavoidable, although there is some evidence that incident beams normal to the tissue surface transmit a higher portion of their energy into tissue-oblique beams.

Tissue absorption for a given wavelength is estimated by the Lambert-Beers law: $I_x = I_0\, e^{-ax}$, where

I_0 = Incident beam intensity
I_x = Beam intensity at tissue depth × centimeters
a = Tissue absorption coefficient (μ_a)
x = Depth (cm)

The relatively low absorption coefficient at the 1,064-nm wavelength (Nd:YAG) permits deep tissue penetration and therefore deeper tissue heating and coagulation (Fig. 6.3). The greater absorption coefficient at the 532-nm (KTP) or the 633-nm wavelength (helium:neon) causes rapid tissue absorption. Absorption of most incident energy in a relatively small volume of tissue will cause rapid heating of superficial tissues. Several studies have demonstrated the wavelength dependency of the absorption coefficient in a typical biologic tissue (22,49). This is the principal mechanism causing differing tissue effects of lasers with different wavelengths. Rapid superficial vaporization seen with the CO_2 laser is a consequence of the tissue absorption coefficient being greater than 1,000 times that of the Nd:YAG laser operating at 1,064 nm.

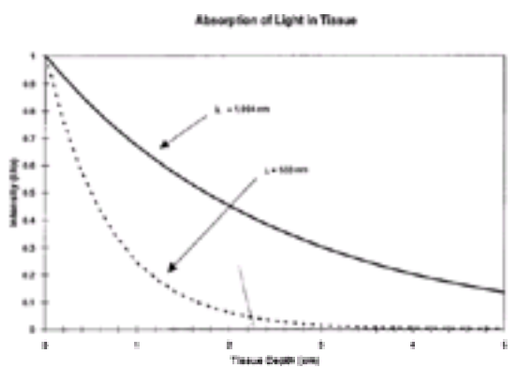

FIGURE 6.3. Relative intensity of light passing through tissue in canine prostatic tissue from two clinically important laser sources. Only the effect of the absorption coefficient (μ_a) is considered here.

Surface carbonization is one clinically important factor that markedly affects the tissue absorption coefficient. Carbon black is a near-perfect absorber of all visible and infrared wavelengths. Surface charring increases the absorption coefficient (μ_a) by several orders of magnitude. During Nd:YAG laser prostatectomy, surface char can alter the treatment session producing a superficial effect similar to the CO_2 laser. Surface charring should be avoided if possible during a side-firing coagulative treatment session. This has been theorized to be the causative mechanism of why, in one series, exposure at 40 W proved clinically superior to exposure at 60 W (54).

Tissue heating is also influenced by the light-scattering coefficient described previously (22,49,95). Scattering measures the propensity of the laser photons to reflect within tissue (Fig. 6.4). This process causes divergence from the original beam path and therefore increases the width of tissue injury from a given incident beam (100). Both laser wavelength and tissue temperature increase the scattering coefficient. The initial importance of light scattering at physiologic temperature during Nd:YAG lasing is limited. However, increasing tissue temperature during a treatment session greatly increases the scattering effect (94). Coagulated tissue volume is substantially increased because of tissue scatter when using the Nd:YAG laser.

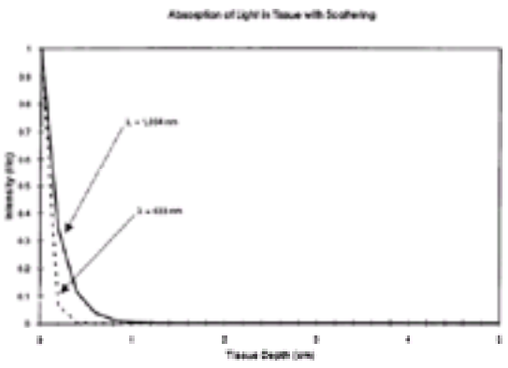

FIGURE 6.4. Laser scattering plays a critical role in depth-dependent attenuation of laser light. This figure describes light passage through canine prostatic tissue of two clinically important laser sources. Comparison with Fig. 6.3 clearly demonstrates the importance of light scattering.

Laser parameters, such as wavelength, power, spot size, beam profile, and scanning velocity, also substantially affect tissue treatment (102). The importance of wavelength is largely determined by tissue absorption and scattering coefficients as discussed earlier. Although near-infrared light from the Nd:YAG (1,064 nm) laser provides good results, other sources in the range of 800 to 1,000 nm may also be used. High-power (25 to 50 W) diode lasers are competitive alternatives to the continuous-wave Nd:YAG laser source. Although diode lasers may achieve results comparable to the volume of prostatic coagulation achieved using the Nd:YAG laser, exposure at these wavelengths may not achieve superior clinical or experimental results. Other commonly available medical laser sources (CO_2, holmium, alexandrite, KTP, and argon) are too strongly absorbed by tissue (high μ_a) to be useful for side-firing, noncontact coagulation prostatectomy.

Laser power is an important determinant of the extent of tissue injury. Coagulation prostatectomy requires tissue temperatures of 60° to 70°C for about 3 seconds to effect reliable protein denaturation. It is important to differentiate between temperature and heat. The relationship between heat, or enthalpy, and tissue temperature is described by the following equation:

DH = (Enthalpy) the amount of heat in tissue = (Cp)(DT)

where *Cp* is the tissue heat capacity and D*T* is the tissue temperature change. From this equation, one could conclude that increased power would yield increased tissue coagulation. Surface effects negate this relationship, however. Extreme surface heating, as seen in high-power applications, causes surface charring. In the presence of char, laser light transmission deep into tissue is limited because of surface absorption. To overcome this effect, laser power must be increased substantially.

The extent of surface heating at a given power is also a function of spot size. Indeed, power density (power divided by spot size) and the prostatic optical absorption coefficient are the critical determinants of surface tissue heating. Side-fire laser beam profile is often considered analogous to spot size. This is an oversimplification based on the assumption that laser power is uniformly spread throughout the incident spot (25). Data have shown marked variations in visible laser beam profile between different side-firing devices. These data are useful for determination of optimal exposure techniques. Narrow beam–profile devices require different exposure techniques than those with widely divergent beams.

The importance of movement of the laser beam during prostatectomy is only now being understood. Initial laser prostatectomy studies were performed with a static exposure technique using a divergent laser fiber (low power density) (33,54). This technique treated a large volume of tissue, minimized surface charring, and facilitated laser scattering. Static treatment is clearly not appropriate for many of the newer fibers with a narrow divergence angle and, consequently, smaller spot size.

Several devices with narrow divergence angles have less than a 3-mm spot size. Laser light scattering at 1,064 nm throughout prostate tissue is not sufficient to ensure thorough coverage of an entire prostate without probe movement. Analytic and finite element mathematical models for predicting optimum tissue exposure (94) predicted the volume of coagulated tissue (greater than 70°C) to be 36% to 109% greater with a laser scanning rate of 1 mm per second than an identically powered laser source where the beam is stationary for 60 seconds. Intuitively, the optimal scanning-rate speed would be as slow as possible without causing tissue charring.

In addition to a slow scan rate, optimal treatment depends on the initial static “dwell” period. During probe movement, tissue ahead of the probe is heated because of forward scatter of the laser light. Tissue treated at the beginning of a laser pass is not exposed to energy from prior forward scatter. Undertreatment of the initial region may occur unless the fiber is held static for 2 to 4 seconds before initiating movement. Mathematical modeling techniques have predicted the optimal dwell period (90). These data indicate that a dwell period of approximately 4 seconds is optimal. Intuitively, however, one should dwell for as long a period as possible without creating tissue carbonization.

Contact Vaporization Prostatectomy

Contact vaporization prostatectomy differs considerably from the coagulation procedures described previously and from techniques that use a holmium laser to resect the prostatic adenoma. During contact vaporization, ablation occurs in real time creating an open prostatic fossa similar to transurethral resection of the prostate (TURP). During vaporization prostatectomy, the structural components of tissue are carbonized and much of the water component is vaporized. Equipment unique to contact laser prostatectomy is required for the procedure.

Contact vaporization prostatectomy is most commonly performed using the Contact Laser system (SLT, Inc., Valley Forge, Pennsylvania). When using this system, a 7-mm diameter, round contact probe is threaded onto a 600-µm optical fiber (Fig. 6.5). A black, absorbent coating is deposited onto the probe surface during manufacture. This coating absorbs approximately 30% of the laser energy, causing intense probe heating. Contact between the hot probe and tissue produces tissue vaporization. Passage of laser energy through the probe into tissue further enhances vaporization and facilitates hemostasis because of subsurface tissue coagulation. The advantage of true tissue vaporization is not without cost. Contact prostatectomy requires considerably more time than coagulation techniques.

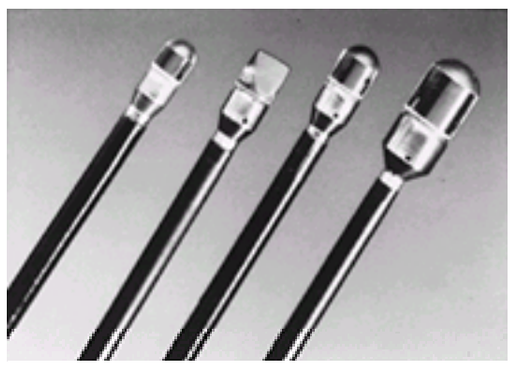

FIGURE 6.5. Contact laser prostatectomy devices. Reusable, fused-silica glass contact probes are threaded onto a semirigid, coaxial optical fiber. Several probe sizes are available; however, the larger probes produce more efficient tissue vaporization during contact laser prostatectomy.

Other Vaporization Techniques

Durable, side-firing laser fibers may also be used for tissue vaporization. Nonmetallic refractive fibers having a narrow divergence angle are used both in contact and slightly offset from tissue. Fournier and Narayan (35) have reported using the Ultraline fiber for contact and noncontact vaporization in the clinical and laboratory setting. These investigators reported superior vaporization when the fiber was used in contact with tissue because of the markedly increased power density during contact treatment. Fiber durability is an issue. The same authors reported consistent fiber tip etching at approximately 50,000 Joules (J) and recommended increasing laser output from 60 to 80 W to compensate for transmission loss at that point. Total device failure occurred after 150,000 J. Other nonmetallic fibers have not been tested as extensively in this application, but they may be useful. These data are particularly important in confirming the appropriateness of side-firing fibers for laser-vaporization prostatectomy. Physical laws involving the heat of vaporization of prostatic tissue apply to both the contact-probe and side-firing devices. Total energy requirements should be similar. Side-firing devices must be able to withstand at least 100,000 J to be useful for vaporization prostatectomy.

CHOICE OF LASER WAVELENGTH

Laser instruments differ primarily in the wavelength and pulse duration of the emitted light. Wavelength is a function of the chemical composition of the active medium in the resonator cavity, which may be a solid, liquid, or gas as described previously. In addition, a frequency-doubling crystal may be used to modify the wavelength of an existing laser source. An example of this is the KTP laser, which is a frequency-doubled Nd:YAG laser.

Argon Laser

Argon has several potential lasing lines between 488 and 514 nm. Light at this wavelength is poorly absorbed by water but strongly absorbed by body pigments, such as melanin and hemoglobin, and chromophores, such as hematoporphyrins. Consequently, tissue absorption is intermediate between that of the poorly absorbed Nd:YAG and the strongly absorbed CO_2 laser. The selective absorption of argon energy by hemoglobin has led to its use for treatment of hemangioma. Commercially available surgical argon lasers have a relatively limited power output and generally can only be used for small (less than 1 cm in size) lesions. Use of argon lasers has been largely abandoned for treatment of superficial transitional cell carcinoma of the bladder. Other devices such as continuous-wave Nd:YAG, KTP, and holmium lasers are better suited for this application.

Argon Dye Laser

Dye lasers can be used to produce coherent monochromatic laser light over a wide range of wavelengths depending on the type of dye used. The argon-pumped dye laser uses an argon laser instead of a flashlamp to power a dye laser. By selecting the proper wavelength (choosing the proper dye), one can selectively excite a tissue chromophore. Hematoporphyrin derivative has been used in several studies because of selective uptake by carcinoma *in situ* in the bladder (15,16 and 17,42,101). Hematoporphyrin derivative is activated by wavelength-specific (630-nm) argon-pumped dye laser light. The use of an inefficient laser to pump another inefficient laser causes tremendous energy loss. For this reason, energy output of the argon-pumped dye laser is limited to 5 to 10 W. Most treatment protocols require bladder illumination time to be 1 hour or more. Research into selective absorption of chromophores by tumor cells and preferential laser destruction of those cells continues; however, these techniques have yet to find widespread acceptance.

Carbon Dioxide Laser

The 10,600-nm wavelength of a carbon dioxide laser is strongly absorbed by water. Thus the energy is rapidly absorbed at the tissue surface, creating high-temperature vaporization. The depth of CO_2 laser light penetration is limited, less than 1 mm. High-intensity vaporization coupled with superficial penetration can produce a scalpel-like effect. Carbonization will occur if the energy is applied to a cutaneous surface for more than a few seconds. A smoke plume is produced, and a dedicated smoke evacuator should be used if infectious material such as condyloma is being treated.

The relatively long wavelength of the carbon dioxide laser creates problems for transmission via flexible fibers. Wavelengths in the far-infrared position of the electromagnetic spectrum are absorbed by optical and most fiberoptic glass. Attempts have been made to develop cystoscopes using a series of reflecting mirrors. So far, however, a practical CO_2 laser cystoscope has not been developed, although specific optical devices to redirect the CO_2 laser beam have been designed for otolaryngologic applications. In urologic applications, the beam is delivered to tissue via a series of articulating arms and reflecting mirrors. CO_2 lasers have proven useful for first-line therapy of various lesions of the external genitalia and with open surgical applications.

Diode Laser

Diode lasers operate differently than the previously described lasers that generate laser light by illuminating a resonator cavity with a flashlamp. Monochromatic coherent light can be generated directly by semiconducting laser diodes. Low-power diode lasers are commonly used to read information from computer and audio discs. Diode lasers designed for urologic applications produce greater power than those found in consumer applications; however, maximum power output is less than that produced by most other laser sources. Current urologic diode lasers weigh less than 20 pounds, fit in a briefcase, and require only a 110-V electrical source. The most commonly used urologic application of the diode laser is transurethral interstitial laser therapy of the prostate. In this application, the laser is coupled to a fused silica glass fiber that incorporates a diffuser tip onto the distal end.

Holmium:Yttrium-Aluminum-Garnet Laser

The holmium:YAG laser emits light in the midinfrared region of the electromagnetic spectrum (2,100 nm). Unlike the continuous-wave lasers described previously, energy emission occurs in a rapid pulse over a few milliseconds. Holmium:YAG laser light is highly absorbed by water and produces explosive vaporization and cutting.

Several companies produce holmium lasers. All have pulse repetition rates of about 5 to 20 Hz, 3 to 5 J per pulse, each of which is delivered over approximately 500 microseconds. The light, invisible to the human eye, is readily transmitted through a flexible optical fiber. All manufacturers provide a range of optical fibers from 200 to 1,000 microns. The smaller fibers are particularly useful for ureteroscopic applications.

Unlike an electrohydraulic lithotripsy probe, the holmium laser fiber tip should be held in close approximation to the stone or tissue surface being treated. Otherwise, rapid attenuation of the laser light will occur because of absorption by water. When treating ureteral or renal stones, the clinician must take care to keep the fiber tip away from urothelial tissue. Unlike coumarin green-pulse dye lasers that were widely used in the 1990s, holmium laser light will cut ureteral tissue as well as fragment stones.

The hemostatic abilities of the holmium laser are less than a continuous-wave Nd:YAG laser because there is more vaporization of tissue. One should keep this in mind because once started, bleeding may be difficult to stop without switching to electrocoagulation. The holmium:YAG laser has been extensively used for urinary tract stone fragmentation in addition to cutting and coagulation of soft tissue. Most urologists would agree that the holmium laser is the most used and most versatile laser for a wide range of urologic applications.

Potassium Titanyl Phosphate Laser

KTP lasers use a potassium titanyl phosphate crystal to double the frequency of Nd:YAG lasers, thereby producing 532-nm wavelength green light. Interaction of Nd:YAG light with the KTP crystal causes substantial energy loss. Therefore the energy output of the typical dual-wavelength laser in KTP mode is only approximately half that of the Nd:YAG mode. The 532-nm wavelength provides an intermediate level of vaporization and coagulation. The energy can be transmitted by the same standard optical fiber used for Nd:YAG treatment. Tissue effects are similar to those achieved with an argon laser, although greater power can be produced than with most surgical argon lasers. KTP lasers have been used for treatment of superficial transitional cell cancer in the bladder, ureter, and renal pelvis. In some circumstances, KTP lasers provide an increased safety margin compared with Nd:YAG lasers because of limited coagulation depth. However, treatment is slower than with Nd:YAG lasers, and treatment for large tumors may be more difficult. KTP lasers have also been used for treatment of external genital and urethral lesions.

Combined techniques for treatment of benign prostatic hyperplasia (BPH) using coagulating energy followed by vaporization of prostate tissue with a KTP laser have been described. Early studies clearly demonstrated the feasibility of this method; however, widespread acceptance of the technique did not occur because of the increased operative time and the need to use more than one modality. Higher-energy KTP lasers are now available that address these concerns.

Nd:YAG Laser

For many years since its introduction into clinical practice in 1979, the Nd:YAG laser was the most commonly used laser in urologic surgery. This continuous-wave laser produces an invisible 1,064-nm light that is nearly ideal for deep tissue coagulation. When used in a noncontact mode, tissue coagulation is complete and hemostasis is total. The Nd:YAG is the preferred laser source for coagulative destruction of vascular lesions of the urogenital tract. Because of this great utility, the Nd:YAG laser can be purchased coupled with a holmium laser source. Most urologic surgical laser applications can be performed using a single dual-wavelength Nd:YAG/holmium laser.

The active medium within the resonator cavity consists of neodymium atoms contained within a YAG lattice. The Nd:YAG laser emits invisible infrared 1,064-nm wavelength light. Light at this wavelength is poorly absorbed by water and body pigments. Because of poor absorption, the light penetrates deeper into tissue than other commonly used urologic lasers.

In a fluid environment, the poor absorption of the laser energy results in thermal coagulation of both surface and subsurface tissue. Structural and architectural integrity of the tissue is maintained. A certain percentage of the energy is transmitted through the target organ. Thus the thermal effects may extend to adjacent organs. After noncontact Nd:YAG laser treatment, hemostasis is usually total. The coagulated tissue takes on a white, fluffy appearance. The tissue sloughs secondarily over a several-week period, although complete healing may take up to 3 months (75).

CLINICAL APPLICATIONS OF LASER SURGERY

The thermal effects of laser energy have been used for the treatment of a variety of urologic lesions. In certain situations, lasers do not appear to be as effective as standard therapy or offer no particular advantages. In other circumstances, lasers provide substantial practical and therapeutic improvements over other treatment methods. The unique physics and tissue effects of laser energy have created new treatment opportunities for selected problems in urologic surgery. Table 6.1 indicates which lasers are used for various problems in urologic surgery.

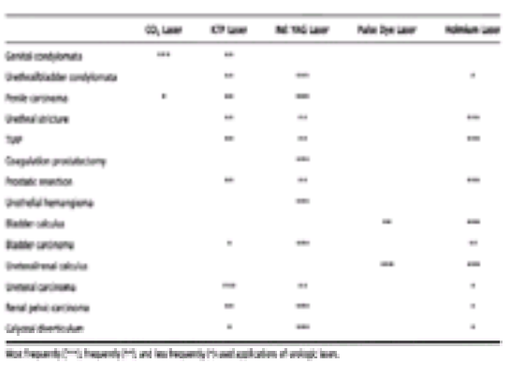

TABLE 6.1. UROLOGIC LASER APPLICATIONS

Urinary Tract Stones

Successful treatment of urinary tract stones is the single largest reason for the popularity of the holmium laser. The holmium laser improved on the previously available coumarin green-pulse dye laser by producing more rapid and complete stone fragmentation. The coumarin green laser had the important limitation of frequently not fragmenting the hardest calcium oxalate monohydrate stones. With the holmium laser, this limitation has been overcome.

One group of investigators examined the end products of stone fragmentation (129). These authors found that after holmium laser treatment, calcium oxylate monohydrate produced calcium carbonate, cystine yielded cysteine and free sulfur, calcium phosphate produced calcium pyrophosphate, magnesium ammonium phosphate produced ammonium carbonate and magnesium carbonate, and uric acid yielded cyanide. The same group later examined in detail the conversion of uric acid to cyanide (126). No reports of adverse health consequences of cyanide exposure have been reported to this date.

Tissue cutting in addition to stone fragmentation is the principle disadvantage of the holmium laser for work in the ureter. Ureteral injury is avoided by careful placement of the optical fiber tip onto the stone surface and away from the ureteral wall. Although laser energy settings for stone fragmentation are less than those used for transurethral incision of the prostate (TUIP) or most other cutting procedures, energy at these settings can do considerable damage to the ureteral wall if placed in direct contact. Laser energy settings for ureteral stone fragmentation typically range between 1 and 2 J with pulse repetition rates of between 5 and 15 Hz. Even the hardest stones fragment successfully with this amount of energy (65).

Some care should be taken to avoid head-on holmium laser exposure to ureteroscopic guidewires. Freiha and colleagues (36) demonstrated that it is possible to cut a guidewire with holmium laser energy. However, the authors found that the energy had to be applied directly and from a distance of less than 1 mm.

Renal and bladder stones are also effectively fragmented with the holmium laser. Given the larger size of those stones and the more open operative space, energy settings are often increased when treating renal and bladder stones. Treatment is more time efficient if peripheral stone tissue is treated first. One should avoid the temptation to break large stones into several pieces early in the treatment session. By staying on the periphery of a stone, one can continuously break off the superficial layers into dust or sand. Treatment continues until the stone has been completely ablated. Further details of stone management with the holmium laser are presented elsewhere in this text.

External Genitalia

Laser treatment of lesions of the external genitalia usually uses the CO_2, Nd:YAG, or KTP laser. Direct application of CO_2 laser energy to lesions of the external

genitalia is performed either with a hand piece and a series of articulating arms and mirrors or a coupling microscope. Fiber-conducted light from a KTP or Nd:YAG laser can be directed using a hand piece. The choice of laser is based on the desired depth of tissue destruction. CO_2 lasers produce only superficial vaporization, KTP lasers produce a moderate level of coagulation, and Nd:YAG lasers produce the greatest depth of coagulation for tumor treatment.

Condyloma Acuminatum

Lasers are well established as effective treatment for condyloma acuminatum. CO_2, Nd:YAG, argon, and KTP lasers can be used, although most clinical experience is with CO_2 and Nd:YAG lasers (37,47). With a CO_2 laser the lesion is vaporized, and large amounts of smoke are produced. Proper smoke evacuation equipment must be available to prevent inhalation of viral particles that may be in the smoke plume. Application of laser energy to the skin is painful, and local anesthetics are injected subcutaneously before treatment. For large or more extensive lesions, a penile block may be preferable. The skin is cleansed with an iodine-based or equivalent compound. The power output chosen is based to some extent on the size of the lesion, but the lowest output that successfully vaporizes the condyloma is desirable. Usually, 5 to 10 W of power will suffice. Rosemberg and colleagues (105) described a technique of vertical, horizontal, and oblique application of the beam to ensure complete removal. As successive portions of the condyloma are treated, the carbonized surface is removed by wiping with a saline-soaked sponge. Bleeding does not occur until the deeper layers of the dermis are reached. Care should be taken to avoid a full-thickness skin injury. The white dermal layer underlying the condyloma should be left intact. An antibacterial cream may be applied topically after treatment, but analgesics are usually unnecessary. Lesions of the urethral meatus can be treated satisfactorily with a CO_2 laser and nasal speculum, but the lack of a fiber delivery system has precluded treatment of more proximal urethral lesions.

Very large lesions should be treated in stages to prevent a large area of full-thickness burn. Bridges of either normal or pathologic tissue should remain intact between large treatment areas even if this commits the patient to a second treatment session. Untreated tissue bridges will hasten the healing process and lessen the chance that skin grafting of a large area will be required. In most patients, excellent cosmetic results can be anticipated.

Using the CO_2 laser, Lundquist and Lindstedt (68) treated more than 150 patients with condyloma resistant to podophyllin therapy. Ninety-five percent of patients were reported cured, although some required a second treatment. Similar results have been reported by Bellina (13). Rosemberg (103) found an 88% cure rate in 61 patients undergoing only a single treatment. More recently, others have used erbium and pulse dye lasers for condylomata (48). Tissue ablation with the erbium laser is extremely superficial, more so than the CO_2 laser. This laser offers a potential benefit relative to existing therapy. One other benefit is that the plume from erbium laser treatment apparently does not contain viable viral particles (48).

The Nd:YAG laser also has been shown to be effective in the treatment of condyloma acuminatum (72). Unlike after CO_2 laser treatment, the lesions do not undergo vaporization. Rather, they are coagulated and may be removed with forceps or allowed to slough secondarily. Treatment depth may be more difficult to control than with the CO_2 laser, but a treatment session proceeds more rapidly when large lesions are encountered.

Nd:YAG laser energy is applied with a power of 10 to 15 W until the lesion turns a pale white color. The epithelium surrounding the lesion should be treated for a distance of 2 to 3 mm to destroy the virus in adjacent areas. Care should be taken to avoid excessive energy density, which can result in third-degree thermal injury and full-thickness skin slough. One must also consider the location of the dorsal neurovascular bundles and underlying corporal bodies when using the Nd:YAG laser.

The oncogenic potential of certain subtypes of the human papillomavirus has been reported. Microscopic lesions can often be detected on the penis of sexual partners of women with carcinoma or carcinoma *in situ* of the cervix (6,8). Five percent acetic acid applied to the penis for 5 minutes on a soaked gauze wrap produces a white discoloration of small human papillomavirus lesions that can then be detected by examination with magnifying loupes (34). Carpiniello and associates (20) found a high recurrence rate of these lesions after CO_2 laser treatment despite the use of topical 5-fluorouracil cream after laser treatment. This and other studies have demonstrated that condylomata are difficult to eradicate. Previous studies probably overstated the cure rate by a substantial margin.

Carcinoma of the Penis

Laser treatment of selective carcinomas of the penis may avoid the need for partial penectomy in some patients. Although topical application of 5-fluorouracil cream seems to be the preferred initial treatment for erythroplasia of Queyrat, lasers have been effective in eliminating resistant lesions (70). Because this is a premalignant lesion that does not invade deeply into tissue, lasers with superficial penetration produce sufficient treatment. Good results have been achieved with the CO_2 laser.

For an invasive carcinoma, a greater depth of coagulation is advisable (Fig. 6.6). Appropriate patient selection is the key element determining success. Pretreatment biopsies of the lesion should be taken in order to assess tumor depth. In most situations, the Nd:YAG laser is preferable. Energy should be applied to the entire lesion, as well as the surrounding, more normal-appearing skin. Generally, 25 to 35 W of energy is used with the Nd:YAG laser. Iced saline applied to the surface of the lesion during treatment helps cool the superficial tissues and prevent carbonization. This avoids a smoke plume and increases the effective energy penetration because char at the tissue surface absorbs laser light. Treatment should continue until all areas of the lesion are coagulated. The tissue surface will remain intact.

FIGURE 6.6. A: Invasive squamous cell carcinoma of the penis. **B:** After Nd:YAG laser treatment, the lesion has a coagulation eschar that may take up to 6 weeks for complete healing.

After treatment with the Nd:YAG laser using these energy parameters, a third-degree thermal injury is created. The lesion is usually painless, but slough of necrotic tissue and drainage may persist for up to 2 months. Eventually, reepithelialization will occur unless residual cancer is present. The necrotic lesion may result in secondary adenopathy, making the assessment of the inguinal lymph nodes during the healing process more difficult. Cosmetic results are good considering the other options. Most patients are left with a shallow divot and normal epithelial covering.

Results of laser treatment of carcinoma of the penis indicate that treatment generally can be successful in properly selected patients. Malloy and colleagues (73) have treated 23 patients with the Nd:YAG laser for carcinoma of the penis. Six patients had T_{is} and no evidence of recurrent cancer an average of 34 months after treatment. Of 15 men with T_1 tumors, 12 were cancer free with a mean follow-up of 31 months. Two men with T_2 cancer had reduction of the tumor mass but were not cured. Hofstetter (44) treated 17 patients with T_1 and T_2 tumors. With follow-up of 3 to 6 years, only one patient had died from metastatic disease.

The obvious advantage of laser treatment of penile cancer is preservation of the phallus. Although efforts to avoid partial or total penectomy ultimately should not compromise the chances for cure, not all patients with squamous cell cancer require amputation. Laser therapy plays an important role in the management of properly selected patients with carcinoma of the penis.

Urethral Stricture Disease

Lasers have been extensively used for incision and coagulation of urethral scar tissue. The Nd:YAG laser has been used with or without contact tips. More recently,

the holmium laser has been extensively used for both incision and ablation of urethral stricture tissue.

Animal data suggest that tissue treated with Nd:YAG laser light heals with more elastic fibers and less collagen deposition than comparable electrosurgical injury. In addition, there is less bleeding into the tissues, with possibly less secondary scarring. These ideas have formed the basis for laser treatment of benign urethral strictures. There is no doubt that laser energy can cut urethral strictures, but delayed results have been mixed.

Holmium:YAG laser properties are nearly optimal for urethral stricture incision. Under direct vision, the fiber tip is placed immediately adjacent to the scar. One should not push the optical fiber tip into tissue because that maneuver may result in deep bleeding that cannot be stopped with further laser energy. Laser power is set at 1 to 3 J per pulse and the pulse rate at about 5 Hz. Absorption of holmium laser light by superficial scar tissue results in cellular disruption and cutting. Given appropriate power, tissue injury is limited to a 1- to 2-mm coagulation zone below the cleavage zone. Cutting proceeds until the appropriate depth is reached. Holmium laser urethrotomy produces less deep tissue injury than Nd:YAG laser urethrotomy.

Several techniques for Nd:YAG laser treatment of urethral strictures have been described. A metal guidewire is inserted through the urethral lumen to maintain orientation. Circumferential laser energy may be delivered to the entire stricture in anticipation of secondary slough of this tissue and normal healing (Fig. 6.7). With this technique and no postoperative Foley catheter, Smith and Dixon (120) reported a recurrence rate of 56% at 6 months and considered this method generally to offer no advantages over standard therapy. Shanberg and Tansey (113) described radial incisions through the stricture with direct contact between the fiber and the tissue. Results in five patients with bladder neck contractures were good. However, recurrences were noted in 58% of the patients with urethral strictures.

FIGURE 6.7. Urethral stricture after circumferential Nd:YAG laser application. The coagulated tissue sloughs secondarily.

Merkle (87) described short-duration (0.2-second) pulses of 25 W placed at multiple sites of the stricture. A catheter was left indwelling for 2 weeks. Successful results (no recurrence of the stricture) were reported in 90% of patients, but others have not reproduced this experience.

Tips for laser fibers may be designed for direct contact between the tissue and the fiber tip. These can be constructed of various materials in differing geometric configurations. By concentrating the energy density, they increase the cutting effect. Smith (118) conducted a prospective study with sapphire contact-tip Nd:YAG laser fibers in 20 men with benign urethral strictures. The cutting effect was unsatisfactory in half of the patients, and recurrence was seen in 13.

The argon laser has been used in other series (1). Rothauge and colleagues (107) treated 41 patients, but longterm results were not reported. The coagulative effects on the tissue would be similar to those obtained with a KTP laser (111,128), but the limited power output of an argon laser appears to make the procedure tedious and technically unsatisfactory for strictures with dense scar tissue.

On the basis of physics and tissue effects, a CO_2 laser is the most appealing laser for the treatment of urethral strictures. Theoretically, the scar could be vaporized with little effect on the underlying urethra. However, until a contact CO_2 laser fiber or cystoscope is perfected, treatment requires gaseous distention of the urethra, a setting in which fatal air embolus has been reported.

Benign Lesions of the Bladder

Lasers are the preferred treatment for patients with bladder hemangioma (121). Although this is an unusual lesion, it can be a particularly debilitating and difficult problem, especially in patients with various congenital venous anomalies such as the Klippel-Trenaunay-Weber syndrome. Nd:YAG laser treatment has been performed in these patients with excellent results, and there have been no reported instances of serious bleeding induced by the laser (Fig. 6.8).

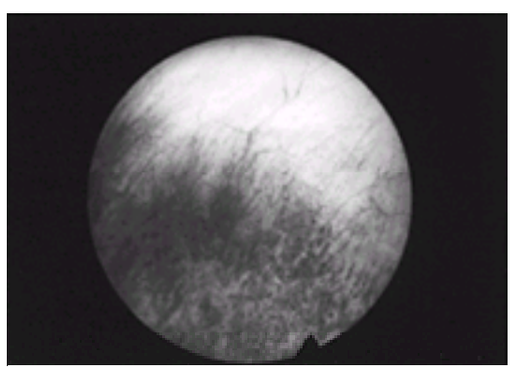

FIGURE 6.8. Hemangioma of the bladder 3 months after Nd:YAG laser application contrasting the treated area *(upper right)* with the nontreated region.

Laser treatment for control of chronic bleeding from radiation cystitis or Cytoxan-induced cystitis has been less successful. Nd:YAG lasers are capable of ablating focal areas of bleeding from cystitis, but the diffuse nature of these diseases is the primary limitation of therapy. Unlike hemangioma or arterial venous malformations, hemorrhagic cystitis is a diffuse condition that is not well treated by local methods.

The success that some have reported with Nd:YAG laser treatment of interstitial cystitis is intriguing but somewhat difficult to explain. In some series, 60% to 70% of patients experience significant pain relief and improvement in their irritative voiding symptoms after laser treatment of active Hunner's ulcers and areas of the bladder most intensely involved with the process (110). Virtually all patients treated had failed multiple alternative treatments. Symptomatic recurrence is common some 8 to 10 months after laser treatment, but successful results can be achieved with a second laser treatment. At this point, laser therapy for interstitial cystitis has not been shown to be more effective than more conventional therapy or placebo.

Bladder Cancer

Since they were first introduced into clinical practice almost 15 years ago, lasers have been used for ablation of transitional cell carcinoma of the bladder. Justification for the use of lasers as an alternative to standard methods of electrocautery resection has been based on theoretic therapeutic advantages, as well as an observed decrease in treatment-related morbidity. The development of new laser wavelengths and instrumentation has facilitated and expanded the use of lasers in a number of areas of urologic surgery, including treatment of bladder cancer.

Patient Selection

Although some investigators maintain that tumor recurrence rate is decreased after laser treatment compared with electrocautery resection (43), laser therapy of superficial bladder cancer is performed most often to decrease or eliminate the need for inpatient hospitalization. Commonly, patients with bladder cancer of low invasive potential undergoing laser treatment have previously undergone resection or biopsy of recurrent, low-grade papillary transitional cell carcinoma. When papillary tumors of low invasive potential are seen on routine surveillance cystoscopy, laser treatment can be an effective, low-morbidity treatment.

Laser vaporization or coagulation results in tumor destruction that does not allow retrieval of tissue for adequate histologic examination. Preoperative, cold-cup biopsies can partially address this issue and allow pathologic examination to determine tumor grade and give some staging information. In general, though, sessile-appearing tumors or those with broad stalks should be treated by electrocautery resection with biopsies of the underlying bladder muscle wall. Some investigators believe that first-time tumors should be treated by electrocautery resection rather than laser treatment so that adequate histologic material is available (116).

Tumor size is another consideration. Lesions greater than 1 to 2 cm in size are difficult to treat with laser alone and may require a debulking electrocautery resection before a laser treatment of the tumor base. However, this may obviate many of the practical advantages of laser if electrocautery resection is required anyway.

Tumor location is a relatively minor issue. Virtually all parts of the bladder are accessible for laser treatment. Extra caution is appropriate for tumors on the bladder dome where loops of small bowel may be adjacent. Small bowel thermal injury and perforation with intact bladder wall has occurred. Treatment of tumors overlying the ureteral orifice appears to be associated with a very low risk of stricture and ureteral obstruction.

Treatment Technique

A number of different treatment techniques have been described for laser destruction of bladder tumors. Differences exist depending on the laser wavelength. The amount and manner of energy delivery depend on the preoperative assessment of tumor stage.

Superficial Tumors of Low Invasive Potential

Laser treatment of superficial transitional cell carcinoma of the bladder (stages T_a to T_1) is usually performed on an outpatient or ambulatory surgery basis. When treatment is performed without anesthesia, the patient is able to perceive the laser energy and often describes it as a burning type of discomfort. However, treatment is tolerated better than electrocautery resection. The exact reason for this is uncertain. However, laser energy probably results in rapid heating and destruction of nerve fibers in a well-defined volume of tissue. Electrocautery resection is associated with more irregular propagation of the energy along nerve and muscle bundles. The decision to perform laser therapy with general or regional anesthesia is based primarily on the surgeon's experience; the patient's personality; and the size, number, and location of the tumors.

When a rigid cystoscope is used, the patient is placed in a standard lithotomy position. Most cystoscope instrument companies offer a laser bridge that adapts to the standard cystoscope with either a 19- or 21-Fr sheath. The laser insert allows stabilization of the fiber tip and a watertight entry port. The optical fiber is inserted through the channel, and the tip of the laser fiber is positioned just beyond the end of the visualizing telescope. Fiber tip placement is especially important when using the holmium:YAG laser because treatment energy may destroy the telescope lens if the two are in close proximity.

Nd:YAG and holmium lasers are the most commonly used lasers for treatment of bladder carcinoma. Both lasers can be used satisfactorily. One needs to know the relative merits of each laser, however. Noncontact treatment with the Nd:YAG laser results in tumor coagulation and preservation of the underlying bladder wall. As mentioned, underlying small bowel injury may occur, but the mechanical integrity of the bladder wall is almost always preserved. The holmium laser, on the other hand, produces tissue cutting at even moderate settings. Aggressive resection may result in bladder wall perforation.

For a noncontact technique with the Nd:YAG laser, a standard 400- or 600-micron end-fire optical fiber is used. The fiber tip is positioned 3 to 5 mm from the tumor surface with the aiming beam illuminating the region of intended treatment. With the Nd:YAG laser, 20 to 30 W of energy usually is sufficient for complete tumor coagulation. The duration of the treatment usually is controlled by the speed with which the aiming beam is moved across the tumor surface. The laser can be operated in a continuous mode whereby energy is emitted whenever the foot pedal is depressed. An aiming beam, either from a flashlamp or a helium neon laser, marks the point of impact (the Nd:YAG laser beam is invisible to the human eye). Sterile water, normal saline, or amino acid solutions can be used for irrigation. A continuous-flow system is not required; the irrigant usually can be turned off during treatment because bleeding is usually nonexistent.

Laser treatment is best performed as a dynamic process rather than a series of adjacent, static impulses. The beam is slowly moved across the surface of the tumor in a “painting” fashion. The tumor undergoes a white discoloration indicative of adequate thermal coagulation (Fig. 6.9). Care should be taken to avoid excessive laser energy application in any given area. Usually 2 to 3 seconds of duration is required in a given area for complete thermal coagulation to be evident. Techniques have been described wherein a ring of coagulated tissue is created around the tumor base to seal blood and lymphatic vessels. In practice, this is unnecessary because bleeding does not occur even if the energy is applied initially to the center of the exophytic portion of the tumor.

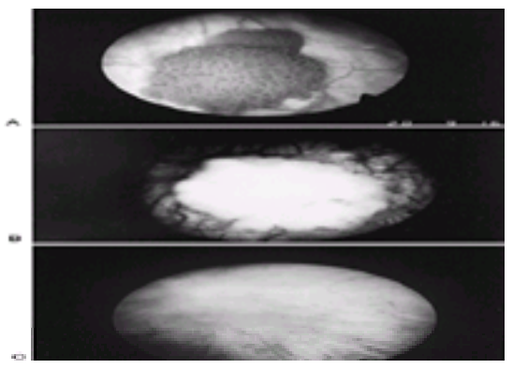

FIGURE 6.9. A: Papillary transitional cell carcinoma of the bladder. **B:** After Nd:YAG laser treatment, the lesion undergoes a white discoloration indicative of adequate thermal necrosis. **C:** Six weeks later, complete bladder healing is evident.

It is not necessary to treat the tumor base initially, but it is important to make certain that all aspects of the lesion have been thermally coagulated. After the papillary frondular tissue is coagulated, it usually can be dislodged with the tip of the fiber or the cystoscope to expose deeper portions and the tumor base. Treatment is best performed with the bladder as empty as possible to avoid excessive thinning of the bladder wall. This allows an added margin of safety for underlying small bowel. If the tumor is located in the air bubble, either the air can be evacuated or the patient can be tilted to remove the tumor from the air bubble. If this proves to be difficult, treatment can be performed through the air bubble itself, but there is usually some surface carbonization and smoke production. The temperature of the irrigating fluid does not seem to be a major factor in determining tissue or treatment effect.

Subsurface boiling may be observed during treatment, producing a popcornlike effect. These microexplosions, although sometimes dramatic, carry no particular significance. If the fiber tip inadvertently touches the bladder wall, there usually is some superficial carbonization and a cratering effect. The foot pedal is released and the fiber withdrawn from the tissue surface. If there is any tissue adherent to the fiber tip, it should be wiped away with a moist sponge before proceeding with therapy. If necessary, cleavage of the fiber tip and stripping of the outer sheath will restore the fiber to original condition.

The depth of coagulation cannot be monitored satisfactorily intraoperatively. In general, coagulation depth is predicted preoperatively based on known characteristics

of the wavelength, power, duration of laser output, and spot size. In most circumstances, 3 to 5 mm of complete tissue coagulation can be anticipated.

If a small amount of bleeding occurs, especially after a cold-cup biopsy, hemostasis usually is accomplished in the course of laser treatment. However, even a relatively small amount of blood undergoes rapid carbonization and can both obscure and prevent effective energy delivery to the tumor surface.

Superficial tumors in bladder diverticula can be treated satisfactorily with a laser. Even though, by definition, there is no muscular backing to a diverticulum, actual free perforation of the diverticulum and bladder wall is uncommon. Usually, there is some shriveling of the mucosa of the diverticulum as the coagulation process occurs. The iliac blood vessels and obturator nerve are often adjacent to diverticula, but if appropriate energy densities are used, direct injury is unlikely. The obturator nerve is not stimulated by laser energy. Obturator spasm and a leg jerk, as may be observed with electrocautery, do not occur.

Treatment of tumors directly overlying the ureteral orifices is performed in the same manner as if the tumor were located elsewhere in the bladder. Stents should be removed from the ureteral orifice before treatment is performed because the laser energy may melt the stent itself. Metal guidewires can be used alternatively. After an extensive treatment overlying the ureteral orifice, postoperative management with a stent may be advisable because of temporary edema. However, the long-term risk of ureteral stenosis appears to be low.

A postoperative Foley catheter is usually not necessary because of the lack of bleeding. The thermally coagulated tissue either sloughs as imperceptible particles or is resorbed. If the treatment is thought to be adequate, follow-up cystoscopy can be performed as per the routine for a particular patient depending on tumor grade, stage, and prior history.

Intravesical drugs can be used after laser treatment, and the indications for their use should be the same as after electrocautery resection. However, because raw surfaces of the bladder wall are not exposed after laser treatment, intravesical drugs, such as bacille Calmette-Guérin (BCG) or chemotherapy, can be introduced more rapidly after treatment with an apparent decreased risk of systemic absorption (24).

Muscle-invasive Tumors

The ability of Nd:YAG lasers to produce transmural coagulation without perforation has allowed laser treatment of some invasive bladder cancers. Even in a controlled setting, however, the treatment depth is variable (122). However, application of energy to both the inner and outer bladder wall through both a cystoscope and a laparoscope allows overlapping zones of thermal necrosis and complete transmural coagulation (108). When treated with this technique, the bladder wall maintains structural integrity because of rapid fibroblast infiltration and collagen deposition (108). The location of most invasive bladder tumors near the trigone makes laparoscopic visualization and energy application somewhat difficult.

Patients being considered for laser treatment of invasive bladder cancer should first undergo a standard transurethral electrocautery resection. This accomplishes two purposes. First, it allows accurate histologic examination for tumor staging. Second, resection debulks the surface of the tumor. Logically, if laser therapy is considered a method for extending the margin of resection, the electrocautery resection should extend deeply into the bladder muscle.

Under most circumstances, it is best to delay laser treatment for at least 3 to 5 days after an electrocautery resection. This allows any bleeding to cease and any overlying clot to lyse. Active bleeding or blood clot interferes with delivery of energy. General or regional anesthesia is required because relatively large amounts of laser energy are needed. The irregular appearance of the resection crater does not allow visual determination of treatment adequacy. Therefore systematic application of laser energy to the entire resection crater, as well as an adequate surrounding margin, should be performed.

Because the goal of treatment is transmural necrosis, energy output up to 45 or 50 W may be appropriate. When an end-fire fiber with a 5- to 15-degree angle of divergence is used, the energy is maintained in a given area for 2 to 3 seconds. If a laparoscope has been inserted, the small bowel can be displaced from the treatment area. After adequate energy has been applied through the cystoscope, the Nd:YAG laser fiber can be inserted through the laparoscope and energy can be applied to the intraperitoneal surface of the bladder in the same region, if visualization is adequate. Steaming or subtle coagulation of the intraperitoneal bladder surface behind the tumor can often be seen laparoscopically during cystoscopic Nd:YAG laser therapy. Otherwise, the intended treatment site may be difficult to determine.

The most appropriate patients for laser treatment of invasive bladder cancer are those with minimally invasive lesions (11,117). Lasers have been used to treat bulky, invasive bladder cancers. However, the surface effect that is obtained in this circumstance usually offers no demonstrable benefit compared with electrocautery debulking and cauterization of the tumor surface.

A catheter is not required postoperatively but may be used depending on the amount of the bladder surface area requiring treatment. Follow-up cystoscopy is performed after 1 month to assess healing and to detect any obvious residual tumor. Reepithelialization of the bladder surface overlying residual cancer is feasible, but most often, there is no residual tumor present when complete reepithelialization occurs within 2 to 3 months of treatment.

Complications of Bladder Treatment

Laser treatment of bladder cancer is used because of the observed decrease in patient morbidity and treatment-related complications. Usually, there is minimal discomfort after treatment. A distinct advantage is the almost complete lack of bleeding that occurs with coagulative procedures. Bleeding that may be present from a preoperative biopsy usually is coagulated adequately during the course of energy application. The coagulation that occurs from the laser energy itself causes virtually no bleeding either as an immediate or a delayed phenomenon.

The most feared complication of laser treatment of bladder cancer is perforation of an adjacent viscus. The small bowel or colon may lie in direct approximation with the peritoneal surface of the bladder. Thus the risk for bowel perforation is greatest with laser treatment on the posterior bladder wall or dome. Hofstetter and colleagues (43) treated more than 500 tumors and reported only two incidences of small bowel perforation, in at least one of which excessive energy levels were used inadvertently. Smith (116) has had no cases of small bowel perforation in over 150 laser treatments of superficial bladder tumors.

Most patients with bowel perforation develop signs and symptoms within 8 to 24 hours of treatment, but symptomatic presentation has been delayed for as long as 2 weeks. Abdominal pain, physical examination findings consistent with an acute abdomen, and free intraperitoneal air are all associated with bowel perforation from laser therapy. It is important to recognize that bowel perforation may occur in the absence of bladder perforation. A cystogram may be normal. The thicker muscle wall of the bladder makes it less prone to perforation, and forward scatter of the energy can place the bowel at risk.

Immediate laparotomy is indicated if small bowel or colon perforation is suspected. The site of laser energy is identified. The zone of tissue injury may be far greater than is visibly evident, so resection of the affected site is indicated.

Results

Initially, laser treatment of superficial bladder cancer was promoted as a means to decrease the recurrence rate (45,74). Indeed, both Nd:YAG and holmium laser treatments have low local recurrence rates at the site of prior resection. Modern thinking about urothelial field change disease has produced serious questions about whether any therapy directed toward specific lesions can affect the eventual rate of recurrence, however.

Both prospective and retrospective clinical series have, in general, failed to support a favorable effect of laser treatment on recurrence rate of bladder cancer (12,50). In most retrospective series, the patient population under study is one of the most influential factors in determining recurrence rate. This complicates comparisons of laser-treated patients to historical series of those undergoing electrocautery resection. Prospective studies have shown no apparent salutary effect of laser treatment on the overall recurrence of superficial bladder cancer.

On the other hand, there is good evidence attesting to the effectiveness of laser therapy in eradicating existing and visible superficial bladder tumors. Multiple series have shown a local recurrence rate of around 5% to 10%, a figure that compares favorably with electrocautery resection. In a randomized, prospective study, Beisland and Seland (12) found a local recurrence rate of 43% for stage T_1 transitional cell carcinoma treated with electrocautery resection alone compared with only 7% for

Nd:YAG laser treatment.

There are no studies comparing various laser fibers, wavelengths, or contact versus noncontact treatment of superficial bladder tumors. There have been published reports of holmium:YAG treatment of bladder tumors (50). If adequate vaporization or coagulation of the lesion occurs, good results can be anticipated in terms of local eradication of visible tumors with any of the laser wavelengths. Overall, though, the Nd:YAG laser has proven to be the most versatile and produces the most complete hemostasis. There is no evidence that other laser treatment techniques offer an increased margin of safety.

Laser therapy is firmly established as an effective treatment for superficial bladder cancer of low malignant potential. The ability to eradicate existing, visible tumors is comparable or, perhaps, superior to results obtained with electrocautery resection. Overall, though, there is no demonstrable favorable effect on tumor recurrence. Therefore the indications for adjuvant intravesical treatment with either BCG or cytotoxic drugs are unchanged after laser therapy compared with standard treatment recommendations.

Laser treatment of superficial bladder cancer has been associated with an observed decrease in treatment-related morbidity. Bleeding is almost nonexistent, and catheter drainage of the bladder is not required. Treatment can be performed on an ambulatory basis. A complication unique to laser therapy, perforation of an adjacent viscus, is unusual if appropriate treatment parameters are used. A number of laser wavelengths and fibers have been used successfully to treat superficial bladder cancer. One has not been proven to be inherently superior to another, although the Nd:YAG laser used in a noncontact manner produces optimum coagulation. Holmium laser energy may also be safely used to cut and coagulate bladder tumors. The primary limitations of laser treatment of superficial bladder cancer are the lack of tissue available for histologic examination and the difficulty in treating tumors that are larger than 2 cm with laser alone. Laser treatment of invasive bladder cancer is limited by difficulties and inaccuracies with clinical staging of invasive transitional cell carcinoma and by the inability to predict and control the depth of coagulation.

Benign Prostatic Hyperplasia

Lasers exert their therapeutic effects on tissue through transformation of light energy into heat. Contemporary BPH treatment methods rely on various modifications of laser parameters to produce a desired therapeutic effect. Modifications in instruments for delivery of energy have facilitated treatments that rely on coagulation (e.g., side-firing refractive, reflective free-beam techniques), vaporization (e.g., contact tips, holmium desiccation), or cutting (e.g., holmium laser resection of the prostate). Coagulation is associated with superb hemostasis but results in minimal immediate tissue removal. Obstructive voiding symptoms usually worsen for several days because of postoperative tissue edema. Irritative voiding symptoms also may be prolonged and problematic in some patients. Cystoscopy as long as 3 months after coagulation laser prostatectomy may show residual shaggy gray necrotic tissue (75). On the other hand, vaporization techniques with current instrumentation are slow, and hemostasis is less secure.

The techniques and results that have been reported for laser treatment of BPH are discussed next. Despite the considerable differences between some techniques, similar satisfactory results have been reported. Laser prostatectomy is a compromise procedure in which one attempts to achieve most of the benefits of TURP with decreased morbidity.

Historical Perspective

Early attempts at laser treatment of the prostate met with some anticipated limitations because of difficulty in energy delivery. We and others observed that noncontact laser coagulation of prostatic tissue using conventional end-fire probes resulted in unsatisfactory removal of prostatic tissue (83,119). There was no immediate relief of obstructive symptoms. In fact, some of the edema that occurred secondary to the laser treatment resulted in a temporary increase in symptoms and often urinary retention.

In 1982, McPhee and colleagues developed a modified cautery resectoscope that enabled the simultaneous availability of both electrical (cautery resection/coagulation) and Nd:YAG laser energy. Eleven patients (five with prostatic cancer and six with BPH) underwent transurethral resections using laser irradiation alone for hemostatic control. From 12 to 45 g of tissue was resected using 9,600 to 17,200 J of laser energy at dose ranges of 60 to 90 W for a duration of 1 to 3 seconds. All patients had a satisfactory postoperative voiding pattern, although one patient had bleeding on the third postoperative day, requiring a 3-unit transfusion. The technique was cumbersome, and difficulty was encountered in controlling bleeding of large vessels at the bladder neck when an exaggerated oblique angle of laser application was required (82).

When an end-fire probe is used, obtaining hemostasis on actively bleeding vessels often is difficult. Hemoglobin absorbs Nd:YAG laser energy and effectively diminishes penetration of the laser beam into the tissue. Direction of the beam to the end of the bleeding vessel can be problematic. Thus, although the Nd:YAG laser is an excellent device for coagulating tissue with virtually complete hemostasis during treatment, it is less useful as an instrument to stop active bleeding.

Littrup and colleagues (67) performed percutaneous ablation of the canine prostate using transrectal ultrasound guidance, ethanol injection, and Nd:YAG laser ablation. Transrectal ultrasound guidance was used to direct treatment. Ethanol injections produced an intraglandular hemorrhagic necrosis that extended in some animals to the external prostatic sphincter and the mucosa of the urethra and bladder. Ninety-two percent (11 of 12) of the laser ablations produced intraglandular foci of thermal tissue damage that had distinct margins of transition between necrotic and viable cells. Ultrasound visualized the areas of ablation well, and it was believed that ultrasound could be used as a real-time, intraoperative monitor of treatment effects. However, no follow-up clinical trials have been published.

Although limited success was reported in some of these series, historically laser treatment achieved a very minor role in the management of prostatic obstruction. End-fire probes created access difficulty, tissue coagulation and vaporization was suboptimal, and laser treatment was inferior to electrocautery in gaining hemostasis of actively bleeding vessels. The side-firing laser device altered significantly the methodology for laser treatment of the prostate and improved clinical results.

One of the earliest side-firing techniques to report the results of a controlled study was the transurethral laser-induced prostatectomy (TULIP) (IntraSonix, Burlington, Massachusetts) (106). The system combined a real-time ultrasound transducer and Nd:YAG laser delivery system contained within a 22-Fr urethral probe (5). The laser energy was delivered through a 600-micron, fused-silica fiber that, at the distal end, was coupled to a novel, right-angle microprism integrated into a probe. A 2.8-mm spot size was produced on the tissue surface when the probe was centered inside a 36-Fr balloon. The ultrasound scanner produced a 90-degree real-time sector scan using a 7.5-MHz transducer. Angular resolution was approximately 2 mm, and the depth of view could be set from 2 to 5 cm. A sweep rate of 2 Hz was used in initial studies. A polymer balloon transparent to Nd:YAG laser frequency light encloses the fiber tip and the deflecting prism. This allows the prism to be surrounded by pure degassed water and prevented fouling of the tip by contact with surrounding tissue. The procedure was performed by imaging the bladder neck with ultrasound and slowly withdrawing the laser beam from the bladder neck to the apex of the prostatic urethra using ultrasound guidance. Multiple passes are made depending on the size of the prostate. Laser power in the 20- to 40-W range at a pull rate of approximately 1 mm per second was used in most treatments (77).

Takahashi and colleagues (125) followed 30 patients after a TULIP procedure for symptomatic BPH. At 3 months, flow rate increased from 7.9 to 14.5 mL and remained at 14.7 mL at 1 year. Prostate volume was not significantly different than the pretreatment value when examined at 1 year. Using a modified Boyarsky Symptom Score, there was a mean decrease from 18.4 preoperatively to 7.6 at 3 months after treatment, 6.2 at 6 months, and 6.2 at 12 months. The changes at all three of these intervals are statistically significant (P <.05). Peak flow rates did not improve immediately, but they improved progressively over time. The mean peak flow rate increased from a preoperative level of 7.2 mL per second to 12.4 mL per second at 3 months, 13.1 mL per second at 6 months, and 11.1 mL per second at 12 months. Again, all of these changes are statistically significant (P <.05).

None of the patients undergoing the TULIP procedure in the clinical trial required a blood transfusion, although 1.5% required cystoscopy after treatment for irrigation of bladder clots (78). Urethral strictures were observed in 9.8% of patients and impotence in 4.6%. Only 5.2% of patients reported retrograde ejaculation. Persistent problems with incontinence have been observed in 4.6% of the patients undergoing the TULIP procedure. Most of these complications or adverse treatment effects are well within the ranges reported for series of patients undergoing electrosurgical transurethral prostatectomy. The mean blood loss of less than 16 mL for the procedure clearly is less than that observed after comparable patient groups undergoing transurethral prostatectomy.

The primary limitation of the TULIP procedure was the delayed time until optimal treatment results were achieved. In fact, most patients had aggravation of symptoms during the first several weeks after treatment until laser-induced edema and tissue effects resolved. Although the duration of hospitalization was short, most patients required bladder drainage via a urethral catheter or suprapubic tube for 1 to 2 weeks, and irritative voiding symptoms often persisted for 6 weeks or longer. The TULIP device never was marketed in the United States. Nevertheless, the clinical trial was one of the most carefully conducted multicenter trials of laser BPH therapy.

Contemporary Techniques

Technologic improvement and methodologic changes have altered significantly the manner in which laser treatment of the prostate is performed. The theoretic basis for treatment is more substantially founded than with the techniques described previously. Promising clinical results have emerged.

It is important to recognize that the term *laser prostatectomy* encompasses a wide variety of instruments, laser wavelengths, and techniques. Often, the described methodology bears little resemblance to alternative techniques. Therefore it is invalid to discard all methods of laser prostatectomy simply because one described technique may not achieve satisfactory clinical results. Likewise, promising results or advantages with one particular method of laser prostatectomy may not be applicable to other techniques.

Each of the various methods of laser prostatectomy is described categorically. Clinical techniques and postoperative results are discussed in detail. Laser prostatectomy methods are continuously evolving, and it is not possible to define the optimal method, if any, for laser treatment of the prostate.

Clinical and Laboratory Studies

Right-angle Delivery Systems

The Urolase fiber (C.R. Bard, Covington, Georgia) was the first side-firing optical fiber to experience widespread use for laser prostatectomy. Although it is no longer available, a large part of the total laser prostatectomy literature describes results using this device. This fiber originally was developed for use in gynecology to ablate the endometrium. However, Johnson and associates (52) performed laboratory dosimetry studies and canine experimentation for potential use in the prostate. They found no evidence of tissue penetration beyond the prostatic capsule in their initial study.

In a follow-up study, Johnson and associates (53) performed serial gross and histopathologic examinations of the prostate following transurethral laser prostatectomy in the canine model. Gross examination of the prostate immediately after treatment showed acute swelling of the prostate, causing an overall increase in size of 25% to 35%. The acute swelling regressed rapidly as evidenced by an increase in the size of the urethral lumen at 3 hours. A urethral catheter was left indwelling for 7 to 10 days following the laser treatment to prevent postoperative urinary retention. Within 24 hours, the well-demarcated sphere of thermal necrosis measuring 2.7 cm in diameter had begun liquefaction and cavitation. By the end of 1 week, a central cavity had been formed with a peripheral rim of viable tissue. Within 5 weeks, reepithelialization of the central cavity was observed. The findings were reproducible despite variability in the flow of irrigation and difficulty maintaining a consistent distance between the fiber tip and the prostatic urethral lumen.

Various methods are used to create angled or side-firing laser fibers. Many fibers have a wide angle of divergence, allowing noncontact coagulation of large volumes of prostate tissue. In general, low-power, prolonged-duration exposure generates deeper tissue coagulation than high-power, shorter-duration exposure (19). Using a Urolase fiber, Kabalin and Gill (55) found maximum tissue coagulation with 40 W applied for 90 seconds in both a canine model and an *in vivo* human prostate model. The mean depth of tissue ablation was 16 mm with a mean volume of tissue ablation of 5.5 mL. A plateau effect was observed wherein longer exposure or higher power did not appreciably extend the depth of injury.

Shanberg and associates (112) applied laser energy transurethrally before radical prostatectomy with a Prolase II fiber. Sixty Watts applied for 60 seconds had the greatest treatment depth, and coagulation necrosis extended a mean of 1.75 cm into tissue.

Most of the clinical and laboratory studies using side-firing lasers have involved noncontact application resulting in coagulation necrosis. When placed in direct contact with tissue, energy density is increased. Using high power output and tissue contact, Fournier and Narayan (35) evaporated canine prostate tissue with an Ultraline fiber (Hereaus, LaserSonics, Milpitas, California) (Fig. 6.10). This potentially allows bulk tissue removal for immediate voiding.

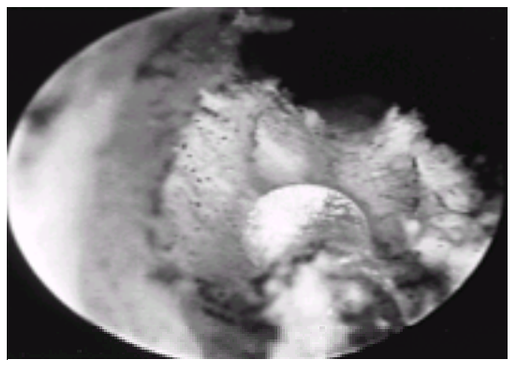

FIGURE 6.10. Side-firing refractive laser prostatectomy.

It is important to recognize that differences exist between various fibers, and the optimal energy parameters for one fiber may not apply to others. Furthermore, laser tissue effects in dog prostates are different and, usually, exaggerated compared with a human prostate. Differences in the stromal-to-epithelial ratio may account partly for the lack of direct comparability (32).

Costello and associates (26,27) initially published results of small, clinical series of patients undergoing laser prostatectomy with a Urolase fiber (visual laser ablation of the prostate [VLAP]). The patients underwent epidural anesthesia; a 23-Fr cystoscope with a deflecting mechanism was used. The fiber was positioned approximately 5 mm beyond the end of the telescope just proximal to the verumontanum. Either glycine or water was used for irrigation. The metal alloy tip of the laser delivery system was placed approximately 1 mm away from the prostatic urethra.

In the initial pilot study, energy was delivered at 60 W continuous wave for 1 minute in each of four quadrants, including the roof of the prostatic fossa, the floor, and both lateral lobes. However, subsequent improvements in the reflectivity of the fiber tip decreased the treatment time to 15 to 30 seconds in four quadrants (27). For patients with significant median lobe enlargement, laser energy was applied for approximately 30 seconds to the bladder neck. Treatment was continued until the circular fibers of the bladder neck were visually apparent. Visible vaporization of the lateral lobes was observed.

Subsequent clinical trials generally used longer treatment times than the 15 to 30 seconds reported in this study. An average of 18,000 J of laser energy was delivered per patient with a mean treatment time of 4.2 minutes. Six weeks after treatment, the mean symptom score fell from 15 to 4, and the mean peak flow increased from 5 to 9 mL per second. Of 12 patients treated, postoperative urinary retention developed in one patient; 2 subsequently required TURP because of persistent symptoms; and one underwent a bladder neck incision. A Foley catheter was left indwelling postoperatively for 2 to 3 days.

Norris and associates (97) reported results in 108 patients treated on an outpatient basis using a Urolase fiber with energy parameters of 60 W for 60 seconds. An average of 19,457 J of energy was applied. Preoperative American Urological Association (AUA) symptom score was a mean of 22.3 compared with 9.2 postoperatively. The peak flow rate increased from a mean of 7.56 to 12 mL per second. No blood transfusions were required, and none of the patients developed a urethral stricture. Seventeen percent of patients required reinsertion of a Foley catheter for urinary retention, and four subsequently required a TURP. Visually, the prostatic fossa eventually resembles a post-TURP appearance (75).

Kabalin (54) reported his initial experience using 40 W of power for 30 to 60 seconds. Total energy ranged from 7,200 to 19,200 J. In 25 patients, peak urine flow rates increased 120% and 141% at 3 and 6 months, respectively, and symptom scores decreased 66% and 78%, respectively. Treatment modifications occurred, and subsequent experience in more than 250 patients has shown no transfusion requirement. Re-treatment has been required in only 5 of the last 150 patients (3.3%). A power of 40 W for 90 seconds has been used with a total energy of a mean of 44,000 J. Peak flow increased from 6.7 mL per second preoperatively to a mean of 18.5

mL after 1 year of follow-up (55).

Dixon and colleagues (33) reported the initial results of a randomized, prospective double-blind study of TURP versus laser prostatectomy using a side-firing, noncontact technique. At 12 months, 16% of the laser group had failed and required an additional procedure compared with 4% for TURP. This re-treatment rate is higher than that reported in comparable series. Symptom score was decreased 30% for laser and 59% for TURP, whereas flow rate increased 82% in the laser group and 147% for TURP. The number of patients randomized at the time of the report (56) was too small for a meaningful comparison of side effects.

A common theme throughout these clinical series is objective and subjective treatment response that approaches that of TURP. However, laser-treated patients have a higher rate of recatheterization, prolonged voiding symptoms, and repeat procedures. In turn, bleeding is almost nonexistent with laser, the risk of urethral stricture is diminished because of the use of smaller instruments, and antegrade ejaculation is preserved in many patients. Coagulative side-firing laser prostatectomy can be performed safely in anticoagulated patients (18). Furthermore, the lack of bleeding facilitates performance of laser prostatectomy on an outpatient basis (66), although TURP also can be performed successfully without hospitalization (63).

Other Side-firing Devices

Numerous side-firing devices have been produced for laser prostatectomy. The number of such devices changes frequently and precludes complete listing. All major urologic laser manufacturers offer side-firing fibers that can be used for laser prostatectomy.

Most practitioners use a scanning technique. Probe movement occurs at the slowest possible rate while avoiding carbonization. A methodical, cylindric treatment pattern satisfactorily ensures thorough exposure of the entire prostate. Each pass through the prostate begins with a dwell period as long as possible while avoiding carbonization.

Other investigators have used high-power exposure. These techniques involve a combination of both coagulation and vaporization. Slow fiber movement allows surface heating sufficient to ablate superficial tissue. With sufficient energy input, the Nd:YAG laser may be used to bore cavities into the prostate. This technique requires far greater energy use and therefore longer treatment time than pure coagulation prostatectomy. Decreased postoperative obstruction is a potential benefit, however.

Clinical results from other side-firing devices are similar to those achieved with the Urolase device. Patients experience symptom score decreases similar to those of TURP, uroflow increases about two-thirds those of TURP, frequent urinary retention, and decreased procedure-related morbidity (23).

Contact Vaporization

Contact laser systems use a conventional fiberoptic waveguide with a fused-silica glass or synthetic-sapphire contact tip coupled to the fiber. Because energy density is inversely related to the square of the radius of the spot size, contact fibers greatly increase the energy delivered for a given volume of tissue. This facilitates tissue vaporization. The contact probes initially developed could tolerate only limited power output without melting. In addition, these devices proved to be relatively inefficient for incising or vaporizing large tissue volumes as is required for treatment of prostatic enlargement (118). Recent advances in contact-probe development have increased efficiency, however. Absorptive coatings added to the contact-probe surface increase direct thermal heating.

Similar to TURP, contact prostatectomy demands considerable understanding of the treatment procedure. The procedure begins using the Nd:YAG laser in continuous-wave mode at 40- to 80-W output. Under cystoscopic visualization, the hot contact probe is pushed into prostatic tissue. Knowledge of anatomic landmarks is critical for efficient tissue vaporization. For that reason, the procedure begins at the bladder neck (Fig. 6.11). Initial short passes are repeated over 360 degrees to open the bladder neck. Subsequent longer passes vaporize progressively more distal tissue (Fig. 6.12). The procedure is repeated until an open prostatic fossa is created to the verumontanum. Contact vaporization prostatectomy causes minimal bleeding but is not bloodless. It is important to vaporize tissue in a methodical fashion to maintain adequate visualization. As discussed previously, increased vaporization sometimes implies decreased coagulation and hemostasis. However, this has not been a practical problem with contact laser treatment of the prostate. Adequate hemostasis occurs during treatment. The primary limitation has been that, even with some of the design changes and improvements, vaporization of the prostate is relatively slow and tedious. Milam (88) has calculated that nearly 50,000 J of energy must be converted to heat and effectively transferred to the prostate in order to vaporize 20 g of tissue. Considering inefficiencies in the system that result in loss of nearly 50% to 90% of the energy before reaching the prostate, total laser outputs of over 100,000 J may be necessary to completely vaporize 20 g of prostatic tissue. Thus further improvements in energy delivery are necessary.

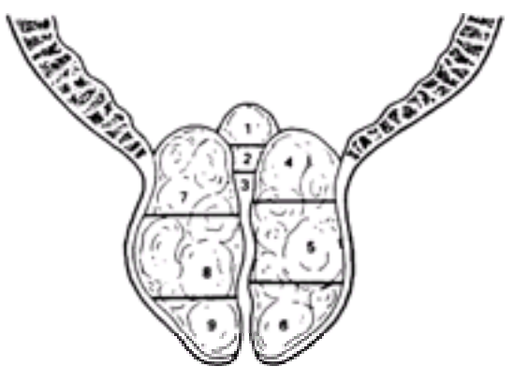

FIGURE 6.11. The sequence for contact laser vaporization of the prostate. Initial vaporization of the median lobe and bladder neck region facilitates improved visualization during the procedure. The procedure extends distally until the entire prostate is vaporized.

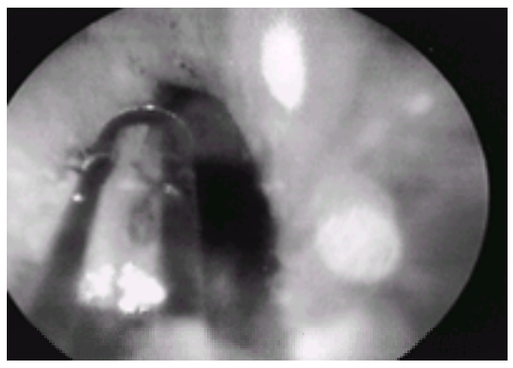

FIGURE 6.12. Contact vaporization of prostatic tissue.

Contact laser treatment of the prostate theoretically is appealing because the technique results in immediate tissue vaporization. Thus therapeutic results do not depend on secondary tissue slough. The immediate voiding problems experienced by some patients after noncontact laser treatment methods may be avoided with contact lasers. This, coupled with the excellent hemostasis observed during treatment, minimizes the need for postoperative Foley catheter drainage of the bladder. Most investigators routinely remove the catheter on the morning of the first postoperative day. Although hemostasis is good, the procedure is not bloodless. Unlike side-firing coagulation prostatectomy, contact prostatectomy should not be performed on anticoagulated patients.

Anson and associates (3) found earlier voiding in their patients compared with noncontact treatment. Aleida (2) used contact laser tips as an adjunct to electrocautery

and thought that the combination allowed earlier hospital discharge (29).

Narayan and co-workers (93) performed prostatectomy using direct contact with a side-firing Ultraline fiber. The fiber has a beam divergence of only 17 degrees. Tissue vaporization was achieved using 60 to 80 W of power and dragging the fiber tip through tissue. Mean total energy for glands 20 to 40 g in size was 42,024 J and 95,732 J for those more than 40 g. The prostatic fossa healed completely by 6 months with a decrease in ultrasound-measured prostate volume of 34%. Only 2 of 61 patients subsequently required a TURP, and no significant bleeding occurred. Peak flow was increased 164% at 12 months.

Interstitial Fiber Placement

It has been known for many years that application of low-power laser energy to a given location within a solid organ over several minutes will induce a 1- to 2-cm zone of coagulation necrosis. By using several fiber placements, nearly the entire prostate can be treated while preserving the urethral lining. This principle is used in interstitial laser coagulation (ILC) of the prostate.

ILC has become popular due to the technical ease of treatment, low morbidity, outpatient nature of therapy, and relatively low cost of equipment acquisition. Most described laser treatments of the prostate involve transurethral application of the laser energy. Just as with transurethral electrocautery resection of the prostate, laser injury to the urethral mucosa accounts for some of the treatment-related morbidity. A procedure that preserves the integrity of the prostatic urethra conceivably could decrease or eliminate any treatment-related bleeding, as well as postoperative, irritative voiding symptoms.

As discussed previously, Littrup and colleagues (67) performed interstitial treatment of the canine prostate using the Nd:YAG laser. Placement of the laser fiber was monitored by transurethral-ultrasound guidance. They observed pathologically a homogeneous zone of thermal necrosis and concluded that this technique may be useful for treatment of benign prostatic hypertrophy. However, no follow-up clinical studies have been reported.

McPhee and associates (85) performed studies on interstitial application of laser irradiation using hematoporphyrin-derivative photosensitized Dunning R-3327 prostate cancers. They showed a beneficial effect of treatment on tumors, with either arrest of tumor growth or a decrease in tumor size in most animals. However, the photosensitizers currently available are retained in malignant or dysplastic cells and require systemic administration. Therefore this technique would have no utility for treatment of benign prostatic hypertrophy. Nonetheless, there is at least the potential for the future development of photodynamic therapy of the benign prostate using locally administered photosensitizers.

Johnson and associates (51) placed a frosted Nd:YAG laser fiber interstitially in dog prostates and delivered 10 W of power for 5 minutes to each lobe. Coagulation necrosis followed by interstitial cysts 6 weeks later was observed. A subsequent study using a cylindrically diffusing tip and 25 W for 10 minutes showed large areas of liquefaction necrosis followed by cystic cavitation (28).

McNicholas and associates (81) used interstitial Nd:YAG laser fibers placed percutaneously with low-power (1 to 2 W), long-duration (400 to 1,500 seconds) exposure in dogs. Coagulation necrosis followed by liquefaction and cystic degeneration was observed. Muschter and colleagues (92) reported 15 patients with symptomatic BPH treated with interstitial Nd:YAG laser application and subsequently have accumulated a much larger experience. Five Watts of energy was applied for up to 10 minutes, creating tissue temperatures exceeding 100°C. By 2 months, prostate size measured by ultrasound had decreased from an average of 63 to 44 g and peak flow had increased from 6.6 to 15.2 mL per second. A follow-up report of 42 patients from the same group showed a 30% decrease in prostate size 3 months after treatment (92). The same authors went on to investigate diffuser tip probes coupled to a lightweight diode laser source. This device is now known as the Indigo Laser System (Johnson and Johnson, Superior, Colorado). Many practitioners have used this device with good results. One group found that symptom scores using the AUA symptom index fell from 20.2 to 9.8 at 9 months after treatment and that the uroflow rate increased from 4.4 to 6.2 mL per second over the same period (40). An indwelling catheter was used in all patients postoperatively and was removed between day 3 and day 7. Interstitial laser coagulation appears to produce results similar to those reported with noncontact techniques. One potential advantage is urethral preservation, although urinary retention remains a problem.

Holmium Laser Resection

Holmium laser resection of the prostate (HoLRP) differs substantially from the techniques described previously in this chapter. As noted, the holmium:YAG laser at greater than 1 J per pulse is an excellent cutting laser. HoLRP uses this property to cut and resect rather than coagulate or desiccate tissue. Much like TURP, there is a substantial learning curve. With experience, however, the urologist can learn to resect a volume of tissue similar to that removed during TURP (57,58,64). Unlike coagulation prostatectomy with a side-firing device, tissue is immediately removed, symptom scores drop rapidly, and postoperative urinary retention due to tissue edema is not a problem. Properly performed, HoLRP results in immediate tissue resection similar to TURP with improved hemostasis. Unlike coagulation techniques, though, HoLRP is not bloodless.

HoLRP has been compared with VLAP in a small multicenter study of experienced investigators (39). Forty-four men were randomized to either HoLRP or VLAP. There were no significant differences between the preoperative patient groups. Mean total operative time was longer with HoLRP than with VLAP, 52 versus 41 minutes, respectively. Catheterization time differed considerably, 1.4 days for HoLRP versus 11.6 days for VLAP. There were no significant differences in postrecovery AUA symptom score; however, PdetQmax and Schafer grade measurements at 3 months showed greater relief of obstruction in the HoLRP group. The Qmax did not differ statistically.

Matsuoka and associates (76) evaluated 103 patients treated with HoLRP. They used a high-power laser and a forward-firing 550-micron optical fiber. Symptom score, Qmax, and quality of life were significantly improved at the 1-week visit. Similar results were maintained for up to 36 months postoperatively.

Carcinoma of the Prostate

Laser therapy has never been proved effective for curative treatment of adenocarcinoma of the prostate and is not advocated. An investigative method for endoscopic laser treatment of carcinoma of the prostate has been described, and initial clinical results are available (9,10). An “extended” or “radical” transurethral resection with electrocautery was performed with the intent of removing all prostatic tissue (80). Six to ten weeks after the resection, laser treatment was performed with the Nd:YAG laser. A power output of up to 70 W was used and applied to the entire prostatic capsule. The laser fiber tip was positioned 1 to 2 mm from the tissue surface.

McNicholas (79) has treated 30 patients by this method. Ultrasound follow-up has shown a nearly 75% reduction in the overall volume of the prostate, but it is uncertain how much of the reduction in size is secondary to the transurethral resection as opposed to the laser therapy. Fifty-four percent of patients had an undetectable postoperative prostate-specific antigen (PSA) level, whereas 14% of patients had a PSA level outside the normal range. Undoubtedly, further follow-up will be necessary to assess the efficacy of this technique. The multifocal nature of prostatic adenocarcinoma makes one question whether this type of ablative therapy has promise.

Ureter

The small diameter and flexibility of laser fibers allow their use through either rigid or flexible ureteroscopes (115). Flexible 200- to 400-micron fibers are particularly suited for ureteroscopic application. Larger-diameter fibers may pass through the working ports of several small ureteroscopes, but the rigidity of a 400- to 600-micron fiber inhibits active deflection of the ureteroscope tip. Nd:YAG, KTP, and holmium lasers may all be used on the ureter for soft tissue ablation. KTP and holmium lasers have a theoretic advantage over the Nd:YAG laser for treatment in the thin-walled ureter. Both lasers produce more superficial zones of tissue injury than the Nd:YAG laser.

In highly selected patients with low-grade transitional cell carcinoma of the ureter, successful treatment can be achieved with endoscopic Nd:YAG, KTP, or holmium laser therapy (62,72) (Fig. 6.13). Several authors have reported extensive single-institution experience.

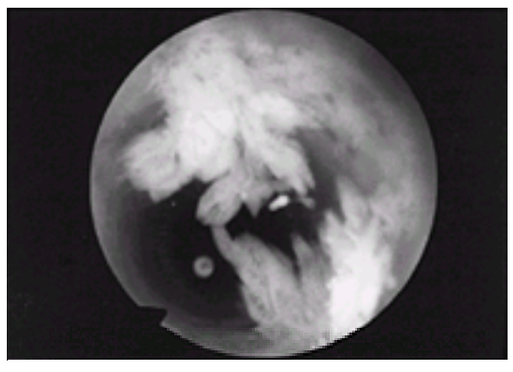

FIGURE 6.13. Papillary transitional cell carcinoma of the ureter. Nd:YAG laser energy can be applied via a small fiber inserted through either a flexible or rigid ureteroscope.

Schmeller (109) treated 18 patients using the Nd:YAG laser. Treatment was not feasible in three patients because of tumor size or location. Of the remaining 15 patients, 14 had no evidence of recurrence with a variable but generally adequate length of follow-up after laser treatment. Ureteral strictures developed in three patients in whom circumferential treatment was performed.

Kaufman and Carson (61) reported nine patients with ureteral tumors treated with the Nd:YAG laser. No patient had a recurrence, and no strictures were observed. Gaboardi and colleagues (38) treated 18 patients with biopsy-confirmed ureteral tumors with Nd:YAG laser energy applied through a ureteroscope (25 to 30 W for 3 seconds). Eight patients developed a recurrence that was subsequently treated with a repeat Nd:YAG laser application. Nephroureterectomy was required in one patient for tumor control.

Thirty-eight patients with upper tract transitional cell carcinoma were treated in one series using both Nd:YAG and holmium lasers (62). Patients underwent ureterorenoscopy every 6 to 12 weeks until they were proven to be tumor free. Seventy-five percent of recurrent tumors were not identified radiographically. Patients were treated with the Nd:YAG laser or later with the holmium laser. Median follow-up was 35.1 and 26 months, respectively. High tumor grade, size, and multifocality were associated with tumor persistence and recurrence. The authors concluded that endoscopic management of upper tract transitional cell carcinoma is reasonable in selected patients. No significant difference was noted between the Nd:YAG and holmium laser–treated groups.

Kidney

Lasers have not proven to be particularly beneficial for partial nephrectomy. The hemostasis achieved with the CO_2 laser is suboptimal (7,104). The Nd:YAG laser is a poor cutting instrument and is not useful for incising the renal parenchyma (14). When combined with an ultrasonic surgical aspirator, the Nd:YAG laser does appear to be capable of decreasing the blood loss associated with partial nephrectomy (86). However, this technique requires the combination of two cumbersome instruments, and the inconvenience may outweigh the benefits.

The Nd:YAG laser has been useful when the surgical margins are precarious after treatment of a renal cell carcinoma. After enucleation of a renal tumor or a compromised partial nephrectomy, Nd:YAG laser energy can be applied to further extend the margin some 5 mm and help gain hemostasis (71). Virtually no patient morbidity is involved in this technique, and it seems to be a potentially beneficial use of the Nd:YAG laser.

The Nd:YAG laser has been used for percutaneous thermoablation of inoperative renal tumors. The investigators treated three patients using real-time guidance in an open-access interventional magnetic resonance imaging (MRI) scanner (30). Ablation and necrosis of target tissue was confirmed by follow-up gadolinium-enhanced MRI. Whether this type of treatment affects patient outcome remains to be seen. Nevertheless, the authors have demonstrated the concept of percutaneous ablation of malignant renal tissue with the Nd:YAG laser.

Kidney cancer, prostate cancer, and bladder cancer affect more than 250,000 people annually in the United States, and nearly 56,000 die from these diseases each year. Significant and dramatic improvements have been made in the last decade in both the diagnosis and the treatment of these malignancies. However, despite these remarkable advances, most patients with advanced renal, prostate, or bladder cancer still die from these diseases. We have witnessed a dramatic biotechnologic revolution over the past two decades, which has provided significant opportunities for the development of better methods for diagnosis, prevention, and treatment of these genitourinary malignancies. Many scientists and clinicians believe that the key to the development of rational and effective forms of therapy for patients with advanced genitourinary malignancies lies in the understanding of the fundamental basis of these cancers, that is, in identification of the genes that cause these cancers and elucidation of the molecular genetic basis for their progression. Examples of molecular therapeutics have proven this principle, and it is the hope of scientists and clinicians that understanding the molecular genetic basis of genitourinary cancers and their molecular pathways will lead to even better methods for diagnosis, prevention, and treatment of these cancers.

RENAL CELL CARCINOMA: ETIOLOGY, NATURAL HISTORY, AND MOLECULAR GENETICS

Renal cell carcinoma is a historical term that has been applied to a number of renal parenchymal tumors of different histopathologic types. An attempt to classify renal cell carcinomas was begun by Grawitz (160) in 1883, when the origin of renal tumors was attributed to an ectopic adrenal rest and named “hypernephroma.” Understanding of the genetic abnormalities found in renal tumors has led to a recognition of distinctive histologic types of tumors. Kovacs (245) classified genetically similar renal cell tumors and divided them clinically into four groups: those with papillary growth or nonpapillary pattern, chromophobe renal cell carcinomas, and renal oncocytomas. Papillary renal cell carcinomas were defined by the presence of at least 75% of the tumor with a papillary pattern (245).

Recently, a division of renal cell tumors into benign and malignant categories has been proposed (462). Benign tumors were subclassified into oncocytoma, papillary renal adenoma, and metanephric adenoma. Malignant tumors were subclassified into conventional (clear-cell) renal carcinoma; papillary renal carcinoma; chromophobe renal carcinoma; collecting duct carcinoma; and renal cell carcinoma, unclassified.

Incidence and Time Trends

Malignant tumors of the kidney account for about 3% of cancer incidence in the United States. Approximately 30,800 new cases of renal cancer were estimated to occur in the United States in the year 2001, and 12,100 patients were predicted to die of their disease (163a). Generally, renal cancers occur at a median age of 65 years, and men are affected 1.5 times as frequently as women (163).

The incidence of renal cancer in the United States has been increasing over the last 65 years (69). The age-adjusted incidence rates for renal cancer over approximately the last 20 years have been 9.6 per 100,000 person-years for Caucasian men, 11.1 for African-American men, 4.4 for Caucasian women, and 4.9 for African-American women (69). Annual incidence rates in these groups have risen from 2.3% to 4.3% per year. Increases occurred in all stages, the largest occurring in patients with localized renal tumors (rising from 3.8% to 5.6% per year during the same period). The development of new imaging technologies has not accounted

for all of these changes (69). Trends in 5-year relative cancer survival rates have been increasing for both Caucasians and African-Americans (163).

Etiology

Environmental and hereditary genetic factors have been associated with the development of the renal cell carcinomas, although individual toxins have not been linked to specific histologies. Environmental factors thought to confer risk include cigarette smoking, petrochemicals, cadmium, and thorium dioxide. Other related factors include obesity and long-term renal dialysis for the treatment of end-stage renal disease. Hereditary forms of most of the histologic types of renal cell carcinoma have also been described.

The increasing incidence of renal cell carcinoma in the United States has been attributed to increased obesity and protein intake, rising incidence of hypertension in the increasing obese and elderly populations, and increasing exposure to toxic environmental agents. Smoking has been on the decline, and this may contribute to a smaller proportion of patients developing renal cancer in the future.

Cigarette Smoking

Case-control studies generally report an association between cigarette smoking and the development of renal cancer (relative risk of 1.35 to 2.2) (255,289,299,300,415,458,461) with risk related to duration of exposure (300,317). The risk attributed to cigarette smoking has been shown to increase with increasing number of cigarettes smoked per day (461). The dose-response relation observed further substantiates this association (48,255,289,300). The lack of association in some studies has been attributed to lack of power secondary to small sample size or biased samples with a high prevalence of smoking in the control group, such as hospital controls (413). With cessation of smoking, the risk of renal cell carcinoma decreases, as much as 30% to 50% at 10 to 25 years (299,461). Gender and presence of a filter on the cigarette have not been found to alter risk. It has been estimated that 24% of female and 30% of male renal cell carcinomas (24) to approximately 18% overall may be caused by cigarette smoking (300a).

In patients with renal cancer, it has been suggested that patients who smoke have more advanced disease at diagnosis and shorter survival than nonsmokers (411).

Obesity

The presence of obesity has been highly correlated with the development of renal cell carcinoma in case-control studies (317,415). The question of whether the risk of renal cell carcinoma is attributed to obesity alone or obesity-related food pattern remains to be answered. Obesity is linked to dietary intake. The incidence of renal cell carcinoma has been positively correlated with intake of fat-containing foods (fats, oil, meat, milk, sugar) and negatively correlated with cereals and vegetables (36,289).

Case-control studies and cohort studies have shown increased risk of developing renal cancer related to high caloric intake (relative risk of 1.7), high intake of fatty foods (relative risk of 1.90), and high protein intake (relative risk of 1.71) (11,36,289,456). Decreasing risk was seen with increasing intake of fruit (relative risk of 0.4 to 0.85) and vitamin C (relative risk of 0.62) (36,456). Studies controlling for caloric intake, body mass, and smoking show protein intake as an independent risk factor (11). It has been estimated that 21% of renal cell carcinoma in the general population is attributed to excess body weight (24).

Hypertension

Cohort studies have been performed to evaluate the association of hypertension and associated medical treatment with the development of renal cancer (186,373,415). Hypertension alone does not appear to be associated with such a risk (186). Although not entirely consistent, the accumulated data suggest that diuretics may increase the risk of renal cancer, especially among women. Increase usage or duration of use was associated with greater risk. The use of b-adrenergic blockers has also been suggested to be associated with the development of renal carcinoma (odds ratio of 1.5 to 3.0) (415). It has been estimated that 18% of renal cell carcinoma is attributable to hypertension (24).

Occupation

Case-control and cohort studies have shown that exposure to various chemicals is significantly linked to the development of renal cancer (294,301,433). Significant associations have been reported in the blast-furnace and coke-oven industries (odds ratio of 1.7 to 2.0); in the iron and steel industry (odds ratio of 1.6 to 2.5); among firefighters (odds ratio of 3.5), glassworkers (odds ratio of 3.5), chemical processors (odds ratio of 2.6), photographers (odds ratio of 2.1), and painters (odds ratio of 1.6); and for exposure to asbestos (odds ratio of 1.4 to 1.6), cadmium (odds ratio of 2.0), dry cleaning solvents (odds ratio of 1.4 to 1.5), gasoline (odds ratio of 1.6 to 2.1), petroleum products (odds ratio of 1.6), carbon tetrachloride (odds ratio of 2.5), and tetrachlorethene (odds ratio of 10.8) (98,294,301,433).

Carcinogenesis is thought to occur secondary to exposure to toxic metabolites of the environmental agents. A common mechanism of metabolism is enzymatic conjugation with glutathione, which facilitates further processing. Further conjugation with cysteine adducts allows acetylation to mercaptic acids, which are excreted in the urine, or cleavage by kidney tubular epithelium to highly reactive chlorinated thioketenes. *In vitro* and *in vivo* studies suggest that these metabolites are highly genotoxic (171,229).

End-stage Renal Disease

The development of cystic disease in kidneys of patients undergoing hemodialysis was first observed by Dunnill (108) in an autopsy study in 1977. Cystic disease has subsequently been found in patients with chronic renal failure and undergoing dialysis. Patients with end-stage renal disease maintained by dialysis have an 18% to 88% incidence of acquired renal cystic disease and a 1% to 7% incidence of renal cancer (187,348,364). Risk of cystic disease appears to increase with duration of dialysis (364,432). The renal cancer histology that is clinically apparent has most frequently been clear cell. Clinically inapparent cancers, that is, microscopic papillary renal cancers, have also been reported with some frequency (187,348).

Male patients may be more frequently affected (187,348). Patient survival appears to be related to tumor stage (348). Overall survival in patients reviewed in the literature was 70% at 1 year, 35% at 5 years, and 10% at 10 years (298).

Medical and Family History

A single first-degree relative affected with renal cancer is associated with an increased familial risk of developing renal cancer (relative risk of 1.6) (373). Thyroid disease was also associated with the development of renal cancer (relative risk of 1.6) (373). A significant trend in risk was reported with number of childbirths in women (272). Use of oral contraceptives has also been associated with a reduced risk of renal cancer in nonsmoking women (272). No association has been reported with estrogen replacement therapy in women (272).

Polymorphic Xenobiotic-metabolizing Enzymes

Environmental toxins may be directly toxic, or they may require metabolic activation by oxidative (phase I) enzymes, such as members of the cytochrome P450 family (CYP), to be transformed into toxic metabolites. Removal of most carcinogens starts with the conjugation action of phase II enzymes, such as the glutathione-S-transferase (GST) and arylamine *N*-acetyltransferases (NAT) families of enzymes.

A wide range of metabolizer enzyme activity in each gene family has been described, ranging from a polymophism associated with loss of the involved gene to a gene with full enzymatic activity. These naturally occurring genetic polymorphisms could infer great interindividual variation in susceptibility to develop cancer after exposure to environmental toxins. Polymorphisms of these types have been shown to be associated with development of bladder and head and neck cancers in patients who smoke (195,256).

The ability to metabolize environmental toxins may be protective for the development of renal cancer. Presence of the 1A1 allele of CYP has been associated with an increased risk of developing renal cancer (283). Presence of the CYP1A1allele with either the TT1 or TP1 alleles of GST or the NAT2 (slow acetylator) polymorphism has been reported to further increase this risk (283). Patients with loss of the Mu1 allele of GST (null polymorphism) and presence of p1 GST polymorphism have

even higher risk if the CYP1A1 or NAT2 (slow acetylator) is also present (283).

Hereditary Forms of Renal Cancer

Renal cell carcinoma can occur in an inherited form, similar to retinoblastoma, breast cancer, prostate cancer, and colon cancer. As many as 4% of renal cancers may be inherited (275). Inherited renal cancers are characterized by early age of onset of bilateral, multifocal renal tumors. Two forms of clear-cell renal cancer have been described. Von Hippel–Lindau disease (VHL) is an autosomal dominant inherited multiorgan tumor syndrome in which 40% to 45% of affected individuals develop clear-cell renal tumors (Fig. 7.1) (150,349). Its incidence has been estimated as 1:36,000 (291). Individual families have also been described with reciprocal germline chromosome 3 translocations that are associated with the development of clear-cell renal tumors (35,74,240,248,271,449).

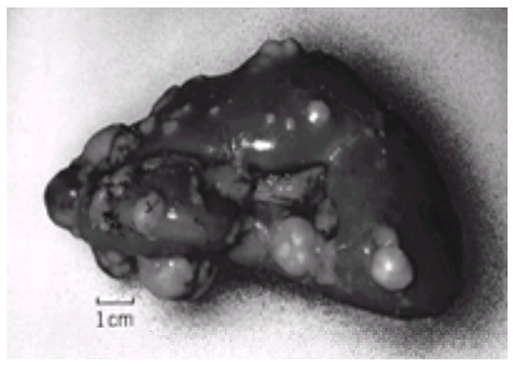

FIGURE 7.1. Von Hippel–Lindau (VHL) disease is characterized by the development of multiple bilateral clear-cell renal cancers and cysts over the course of the patient's life. A typical VHL kidney is shown here.

Hereditary basophilic papillary renal cell carcinoma (Fig. 7.2) (463,464) and hereditary renal oncocytoma (453) have also been described, both manifesting with autosomal dominant inheritance of bilateral, multifocal renal tumors.

FIGURE 7.2. Hereditary papillary renal cancer is characterized by the development of bilateral basophilic (type 1) papillary renal cell cancers over the course of the patient's life. Cystic disease does not occur as part of HPRC. A typical HPRC kidney is shown here (463).

Birt-Hogg-Dubé syndrome (BHD) is characterized by the clinical manifestations of skin fibrofolliculomas and pulmonary cysts leading to spontaneous pneumothorax. Recently, it has been observed that renal tumors of several histologic tumor types can develop in these patients. This syndrome is currently being characterized (428).

Natural History

Patient survival is strongly associated with tumor stage. Five-year disease-specific survival has been reported as 91%, 74%, 67%, and 32% for tumor, node, metastasis (TNM) stages I, II, III, and IV lesions (69,430). Tumor characteristics similarly correlated with a 5-year survival rate of 83% for stage T_1, 57% for stage T_2, 42% for stage T_3, and 28% for stage T_4 disease. Tumor grade is also associated with patient survival: 89% 5-year survival for grade 1, 65% for grade 2, and 46% for grades 3 and 4. Overall, TNM stage and tumor grade were the most important prognostic indicators, whereas the Eastern Cooperative Oncology Group (ECOG) performance status was a less significant predictor and tumor stage was not an independent predictor (209,216,316,430).

Evaluation of prognosis associated with different tumor histopathologies suggests that some renal cancer types may be more aggressive than others. In patients with similar size renal tumors, those with clear-cell renal cancer had metastases at the time of diagnosis more frequently than patients with papillary or chromophobe renal tumors (37% versus 16% versus 8%, p = .044 and .048, respectively) (280). Patients with papillary and chromophobe renal cancer also had longer survival.

Clinical parameters at initial presentation have also been correlated with survival. Symptomatic presentation and significant weight loss have been associated with decreased survival (144). Shortened survival has been associated with the laboratory findings of elevated serum lactate dehydrogenase, C-reactive protein, erythrocyte sedimentation rate, and alkaline phosphatase; low hemoglobin; and hypercalcemia (144,297,316).

Molecular Genetics

Renal carcinoma may occur in both inherited and noninherited forms. As many as 4% patients with renal carcinoma may carry an inherited factor (275). Inherited renal cancer gives special insight into the earliest genetic changes required for the different histologic types of renal cancer to develop. Clinically, patients with familial renal cancer are characterized by early age at presentation of multiple, bilateral renal tumors. New renal tumors can develop over the course of the patient's life.

The best-characterized hereditary renal cancer is VHL (151), in which as many as 45% of affected individuals develop clear-cell renal carcinoma (151,349). Individual families have also been described with hereditary clear-cell renal cancer associated with the reciprocal germline translocation of chromosome 3 to 8 (74,271,449), chromosome 3 to 6 (248), or chromosome 3 to 2 (35,240). Hereditary papillary renal cell carcinoma is a familial form with autosomal dominant transmission, but at a reduced penetrance in comparison with VHL and familial clear-cell cancer (463). Hereditary renal oncocytoma has been described in a number of families (453) BHD is a hereditary renal syndrome characterized by autosomal dominant inheritance of multiple bilateral chromophobe renal tumors, spontaneous pneumothorax, and characteristic cutaneous trichofolliculoma (34,362,428).

The study of inherited forms of renal tumors allows the use of the powerful tools of linkage analysis to localize and identify the initial genetic abnormality leading to a specific histologic subtype of renal cancer. Identification of these genes may be useful clinically in the diagnosis of renal tumors and their metastases.

HISTOPATHOLOGIC CLASSIFICATION OF RENAL TUMORS

Renal tumors have been classified based on cytomorphologic characteristics and presumed cellular origin. Thoenes and colleagues (422) developed one of the first modern classifications of benign and malignant renal tumors based on these features. Renal tumors were categorized as (a) clear cell, (b) chromophil, (c) chromophobe, (d) spindle shaped or pleomorphic, or (e) oncocytoma. The study of tumor genetics has led to the recognition of distinctive types of renal tumors:

carcinoma with papillary morphologic pattern, carcinoma with nonpapillary pattern, chromophobe renal cell carcinoma, and renal oncocytoma (245).

Storkel and colleagues (406) and Kovacs and colleagues (243) proposed a histopathologic classification of renal tumors based on the underlying genetic abnormalities of the different subtypes. Both classifications recognize benign and malignant renal neoplasms. Malignant tumors were classified into conventional or clear-cell, papillary, chromophobe, collecting duct, and unclassified renal cancer. Benign tumors were classified into metanephric adenoma and adenofibroma, papillary renal cell adenoma, and renal oncocytoma. A European and American joint working group adopted a similar histologic classification system in 1997 (Table 7.1) (406,462).

Malignant Neoplasms
1. Conventional (clear-cell) carcinoma
2. Papillary renal carcinoma
3. Chromophobe renal carcinoma
4. Collecting duct carcinoma
5. Renal cell carcinoma, unclassified
Benign Neoplasms
1. Oncocytoma
2. Papillary adenoma
3. Metanephric adenoma

Histologic classification of renal tumors by the Union Internationale Contre le Cancer (UICC) and the American Joint Committee on Cancer.

TABLE 7.1. UICC CLASSIFICATION OF RENAL TUMORS

GENETIC CLASSIFICATION OF RENAL NEOPLASMS

Hereditary Conventional Renal Cancer

Germline mutations in the VHL gene (chromosome 3p25) lead to conventional (clear-cell) renal cancer, the most common form of inherited renal cancer. Single families with reciprocal germline translocations involving chromosome 3 have also been described to develop a hereditary form of conventional renal cancer (35,74,240,248,271,449). Evaluation of tumors from these patients reveals both copies of the VHL gene to be inactivated. One copy of the gene has the germline mutation and the second copy has a somatic (acquired) mutation (35,154,271,377). Inactivation of both copies of a gene in this fashion is characteristic of a tumor-suppressor gene. These findings support mutation of the VHL gene as the initial genetic event in the development of clear-cell renal cancer.

Clear-cell Renal Carcinoma

Conventional, or clear-cell, renal carcinoma makes up 70% to 80% of renal tumors (462) and is the most studied renal tumor. Conventional renal carcinoma is believed to derive from proximal renal tubular epithelial cells (25,129). These tumors consist predominantly of cells with clear cytoplasm, although foci of cells with eosinophilic cytoplasm are common. Tumor architecture is usually solid and cystic, and tumors have a characteristic delicate branching vasculature. Approximately 5% of these tumors develop high-grade, sarcomatoid changes (406,462).

Sporadic Clear-cell Renal Cancer

Similar to inherited conventional (clear-cell) renal cancer, sporadic conventional renal cancer is thought to arise from loss of function of both copies of the VHL gene. In sporadic tumors, both mutations occur as somatic events. Ninety-eight localized and advanced conventional renal tumors analyzed by Gnarra and colleagues (154) had loss of one copy of the VHL gene [loss of heterozygosity (LOH)]. The second copy of the VHL gene was mutated in 57% of the tumors. These findings have been confirmed by other reports of chromosome 3p LOH and by cytogenetic studies (10,154,227).

An alternative mechanism of inactivation to LOH, hypermethylation, has also been described. Chromosomal regions rich in groups of CpG, termed *CpG islands,* are often found in the 5´ regulatory areas of genes, where hypermethylation could render the genes inactive (33). Hypermethylation of the VHL gene was reported in 11% (149) to 19% (191) of sporadic conventional renal tumors. Hypermethylation of the VHL gene has been associated with loss of expression of the VHL gene by Northern blot analysis (191).

These data show a very high degree of loss of one copy of the VHL gene by LOH, and at least 53% to 76% inactivation of the second copy, in conventional renal cancers (154,191,227,410). Inactivation of the VHL gene has been associated specifically with conventional renal cancers (154,227) and suggests the requirement of inactivation of both copies of the VHL gene for the development of conventional renal cancer.

Other Early Genetic Changes

Loss of function of the VHL tumor-suppressor gene has been associated with increased expression of transforming growth factor-a (TGF-a) (234). Northern blot mRNA expression of TGF-a and TGF-b_1 has been reported elevated in 60% of undefined sporadic renal cancers when compared with normal kidney (156). As many as 75% of undefined sporadic renal cancers have increased expression of the *myc* oncogene (232,452).

Late Events or Progression

Higher clinical stage, higher tumor grade, and poor prognosis have been associated with the expression of specific genetic abnormalities. The best-characterized changes have been in the p53 (chromosome 17p13) tumor-suppressor gene. P53 is the most commonly mutated gene in human cancer and is linked to control of cell cycling from G_1 to S phase. Oda and colleagues (329) studied both carcinomatous and high-grade sarcomatous portions of 14 sarcomatoid renal cancers by polymerase chain reaction, subcloning and sequencing the p53 gene. Sarcomatoid tumors had a high mutation rate for the p53 gene (78.6%), compared with a low p53 mutation rate (14.3%) in carcinomatous tumors. Immunohistochemical studies of p53 in these tumor types has demonstrated similar findings (196).

Thirty-seven percent of conventional renal cancers examined with dual-color fluorescence in situ hybridization had loss of chromosomes 14q (457). This loss was significantly correlated with higher stage, higher histologic grade, and worse patient outcome. Similar studies have shown loss of chromosome 14q correlated with higher nuclear grade and advanced tumor stage (379). Smaller studies have shown loss of genetic material on chromosome 2 (351) correlated with higher tumor stage and gain of chromosomes 12 and 20 (102) with higher nuclear grade. Increased expression of type IV collagenase in renal cancer cell lines from patients with metastatic renal cancer has correlated with shortened survival (445) Larger studies are required to corroborate these findings.

Loss and mutations of the VHL gene in all stages of conventional renal carcinoma, as well as in familial forms, indicates that the VHL gene is central to the origin of this tumor (154,259).

Papillary Renal Cell Carcinoma

The second most common cancer of the kidney is papillary renal cancer, accounting for 10% to 15% of renal neoplasms (245,422). Papillary renal cancer has distinct morphologic and cytogenetic features that distinguish it from conventional (clear-cell) and chromophobe renal cancer (99,245,422).

Papillary renal cancer is defined by the presence of at least 75% of the tumor composed of papillary or tubulopapillary architectural pattern (6,99,422). Papillary tumors are chromophilic, describing their characteristic uptake of dyes, and are subdivided into eosinophil, basophil, and duophil tumors (422). Basophilic tumors contain small cells with scanty amphophilic cytoplasm and small, low-grade nuclei (244,422). Eosinophilic tumors are characterized by large cells with abundant eosinophilic cytoplasm and large nuclei. Delahunt and Eble (99) proposed to classify papillary renal cancer into type I and type II, corresponding to

chromophil-basophilic and chromophil-eosinophilic tumors (422).

Papillary renal cancer occurs more often in men, with a 5:1 to 8:1 preponderance (245,247). Basophilic papillary renal cancer occurs about twice as frequently as the eosinophil variant (99). The incidence of eosinophil papillary renal cancer is higher in patients with end-stage renal disease than in the general population (203,250). Survival rates for patients with all types of papillary renal cancer are higher than those for patients with conventional renal cancer (6,172,358).

Hereditary Papillary Renal Cancer

A hereditary form of basophilic papillary (type I) renal cancer has been described, characterized by multiple bilateral renal tumors inherited in an autosomal dominant fashion (376). The hereditary papillary renal cell carcinoma gene is the protooncogene, *c-met,* located on chromosome 7q31.1-34 (374). Missense mutations in the tyrosine kinase domain of the *c-met* gene have been identified in the germline of affected family members.

Sporadic Papillary Renal Cancer

Approximately 80% of sporadic papillary renal cancers contain multiple copies of genes. Trisomy or tetrasomy of chromosome 7 and trisomy of chromosome 17 have been found in 45% to 100% and in 64% to 100% of papillary renal cancers, respectively (27,101,203,246,462). Sporadic papillary renal carcinomas have been shown to contain mutations of the *c-met* gene (374,375). Introduction of mutant *c-met* will transform cells *in vitro* and is tumorigenic in nude mice (217), findings typical of a tumor oncogene. The chromosome 7 mutations have been observed in all stage and grade tumors, suggesting that *c-met* oncogene expression is an initial event in the development of basophilic papillary renal cancer. Early molecular events in eosinophilic papillary renal cancers are not well described, although there has been an associated with the 1:X translocation (221,390,454).

Trisomy of chromosome 17 may occur as a later abnormality (27,101). No p53 mutations have been reported in these tumors, suggesting that other genes in this chromosome are involved in tumor progression (78,101). Other DNA losses described include LOH on chromosomes 9p, 11q, 14q, 21q, and 6p in 43%, 43%, 37%, 37%, and 33% of the tumors, respectively (425). In addition, Y chromosome loss has been observed in 80% to 90% of papillary renal cancers from males (101,202,252).

Mutations in the *c-met* oncogene differentiate papillary renal tumors from conventional tumors on a genetic basis. Chromosome 3p and VHL gene abnormalities are not important in the development of this neoplasm (10,132,425).

Chromophobe Renal Cell Carcinoma

Chromophobe renal cancer accounts for approximately 5% of renal neoplasms (90,422). Chromophobe renal cancer is characterized histologically by compact growth pattern of large polygonal cells with pale reticular cytoplasm and prominent cell membranes (423). Chromophobe cells often have numerous cytoplasmic vesicles by electron microscopic analysis (31,90). Compared with conventional renal cancer, these cells have low glycogen content. Another diagnostic finding in chromophobe renal cancer is lack of cytoplasmic staining with routine dyes. A diffuse, strong cytoplasmic staining with Hale's colloid iron stain has been suggested to be characteristic for chromophobe renal cancer (427). This tumor, however, may be composed of so-called eosinophilic chromophobe cells, which have a large number of mitochondria and few cytoplasmic vesicles (421). The presumed progenitor cells for chromophobe renal cancer are the intercalated cells of the collecting duct (337,420).

Five-year survival has been reported as 92% for chromophobe and 62% for conventional renal cancer of equal nuclear grade (423). Other studies, however, demonstrated similar 5-year survival rates between chromophobe and conventional renal cancers of nuclear grade II and Robson clinical stage I (85% and 84%, respectively), perhaps because most chromophobe renal cancers were stage I (86%) or were discovered incidentally (53%) (90).

Karyotypic changes in chromophobe renal cancers included monosomies of chromosomes 1, 2, 6, 10, 13, and 17 (211,242,251). Molecular genetic studies have confirmed these findings, with loss in 54% to 95% of tumors (50,382,398). Chromosome 3p loss of heterozygosity was observed in 25% of chromophobe tumors, with only rare mutations in the VHL gene (227,389).

Mutations in the p53 gene were identified in 30% of chromophobe renal cancers studied, whereas LOH on chromosome 17p was detected in 78% of tumors. The lack of correlation of p53 mutations with LOH suggested the presence of a second genetic abnormality on chromosome 17 (78).

No genetic change has been observed to occur in all tumor nuclear grades or clinical or pathologic stages, suggesting the initial genetic occurrence characteristic of this tumor type.

Collecting Duct Carcinoma (Bellini Duct Carcinoma)

Collecting duct carcinoma (CDC) makes up approximately 0.4% to 2.6% of renal cancers (243,406,462) and is thought to arise from the medullary collecting ducts (420). Collecting duct carcinomas are usually centrally located, arising in the renal medulla, are white-gray in color, and demonstrate a tubulopapillary growth pattern and a microcystic and solid pattern. Microscopic findings are high-grade cytologic atypia and stromal desmoplasia with dysplastic changes in the neighboring medullary renal tubules. Strong positivity for intracytoplasmic mucin is seen on appropriate stains (228). Collecting duct cancer may be more aggressive in clinical behavior than other renal cancers (14,103). Local invasion or lymph node metastases are common (228).

Few chromosomal studies have been performed on CDC. The most frequently described karyotypic abnormalities have been monosomy of chromosomes 18, 21, and Y (57,165). Other findings include gain of chromosomes 7, 12, 17, and 20. Loss of heterozygosity has been found on chromosome 1q in 57% to 69% of CDC, especially in the region of 1q32 (346,405). LOH has also been detected on chromosomes 8p (48%), 6p (45%), 21q (40%), and 13q (50%). Forty-five percent of tumors have amplification of the oncogene *c-erbB* (383). All patients with this finding died within 1 year, whereas half of patients without amplification were alive after a mean follow-up of 42 months (383).

Renal medullary carcinoma (RMC) may be a variant of CDC (243,406) first described by Davis and colleagues (93) in 1995. RMC has been reported only in African-American patients with sickle cell trait or hemoglobin–sickle cell disease (92,93). Karyotypic findings were loss of chromosome 11 in four of six tumors examined (13). This finding is noteworthy for the presence of the b-globin gene on chromosome 11p (97).

Renal medullary cancer manifests in the second or third decade of life, usually with metastatic disease (92,93). Mean patient survival has been reported as 3.5 months after diagnosis (135,194).

Mean tumor size at presentation has been 7 cm in diameter, located primarily in the renal medulla (92,93). There is a characteristic infiltrative growth pattern (92) with peripheral satellite tumors in the renal cortex and venous and lymphatic invasion. RMC demonstrated a reticular, yolk sac–like, or adenoid cystic appearance, frequently with poorly differentiated areas in a highly desmoplastic stroma.

Renal Oncocytoma

Renal oncocytomas make up 3% to 5% of renal tumors and are thought to originate from the distal renal tubule (7,420). Renal oncocytomas are predominantly composed of eosinophilic cells arranged in a characteristic nested or organoid fashion (7,341). Oncocytomas are usually well circumscribed, beige or mahogany brown tumors that lack areas of necrosis. A gross or microscopic central scar may be present. Renal oncocytomas have nuclei that are round with uniform contours. About half of tumors have prominent nucleoli. A high content of cytoplasmic mitochondria is characteristic of oncocytoma (115). Renal oncocytoma lack significant necrosis, mitosis, or conspicuous papillary formations (7). The eosinophilic (granular) cytoplasm of oncocytomas may appear similar to that found in other renal neoplasms such as chromophobe, conventional, and papillary renal cancer (341). Typical renal oncocytomas are considered a benign neoplasm (7,304,406).

Three types of genetic abnormalities of oncocytoma have been observed: (a) numerical anomalies, including loss of chromosomes Y and 1 (46,188,426); (b) translocations involving the breakpoint region 11q13 [t(5;11)(q35;q13) and t(9;11)(p23;q13)] (323,393); and (c) a variety of other genetic abnormalities, including chromosomal monosomies (164), trisomy 1, 7, 12, and 14 (434), and loss of heterozygosity of chromosomes 17p, 17q, 10q, and 3p (414). Genetic abnormalities in

patients with hereditary forms of renal oncocytoma have not been described (453) (Fig. 7.3).

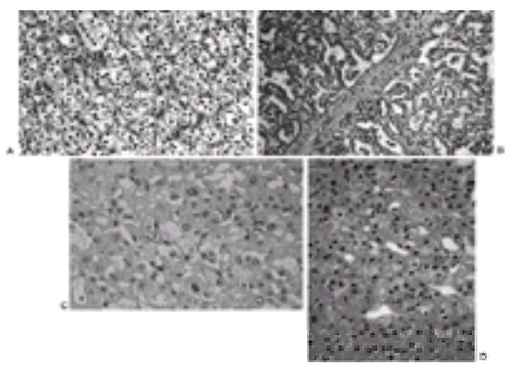

FIGURE 7.3. A: Clear-cell renal carcinoma (characterized by VHL gene mutation) (153,274). **B:** Papillary type 1 renal carcinoma (464) from patient with hereditary papillary renal carcinoma (374) characterized by *c-met* mutation (375). **C:** Chromophobe renal carcinoma. **D:** Oncocytoma, as seen in patients affected with Birt-Hogg-Dubé syndrome (428).

Papillary Adenoma

The most common renal neoplasm is papillary adenoma, occurring in as many as 20% of patients (166). Papillary adenomas are solid-tubular-papillary structures consisting of small “blue” cells (basophilic) or large eosinophilic cells, similar to low-grade papillary renal cancers. Papillary adenomas are usually less than 5 mm in diameter (246,406). There are no cytologic criteria to distinguish papillary adenomas from small papillary renal cancers, suggesting that papillary adenoma could represent early papillary renal cancer (45). Genetic findings are trisomy or tetrasomy 7, trisomy 17, and loss of the Y chromosome (246,249).

Metanephric Adenoma

Renal metanephric adenomas are rare, benign, well-circumscribed tumors that may represent the benign counterpart of Wilms' tumor (143,356). Histologically, metanephric adenomas are composed of uniformly small epithelial cells forming tubules or tubulopapillary structures. They are characterized by an unusual degree of cell maturation and differentiation. Rosette-like configurations with no evidence of necrosis or cellular atypia can be present. The cell nuclei are oval, smooth, and without mitosis. Only rare cytogenetic studies have been reported (143,356).

OVERVIEW

The initial genetic changes important for the development of each histologic tumor subtype appear to be unique to each tumor type and may be useful in molecular diagnosis of renal tumors or their metastases (Table 7.2). Characterization of these genetic anomalies will allow more accurate diagnosis and prognostic evaluation and may help in planning therapy. The identification of familial forms of these tumors is an important tool in the identification of hereditary forms of renal cancer. Identification of germline mutations in these families allows earlier diagnosis with an associated wider range of treatment options. The identification of secondary genetic markers, such as mutations of p53, duplication of chromosome 5q22, loss of chromosome 14q, and overexpression of collagenase type IV, will contribute to prognostic planning of individual patients' tumors in the future.

Pathologic Subtype Findings	Initial Findings	Later Findings
Conventional (clear-cell) carcinoma	3p LOH VHL gene mutation	+5q −8p, −9p, −14q p53 mutation C-erbB-1 oncogene expression
Papillary renal carcinoma	+7, +17 −Y Met gene mutation	+12, +16, +20 −9p, +11q, −14q, −17p, −21q PRCC-TFE3 gene fusion
Chromophobe renal carcinoma	−1	−1p, −2p, −6p, −13q, −21q, −Y p53 mutation
Collecting duct carcinoma	−1B, −Y	−1q, −6p, −8p, −11, −13q, −21q C-erbB-1 oncogene expression
Oncocytoma	−1, −Y, 11q rearrangement*	
Papillary adenoma	+7, +17 −Y	—

Genetic findings and pathologic subtypes of renal tumors. Common genetic abnormalities, or abnormalities not associated with stage, were assumed to occur early. Other abnormalities were assumed to occur later, possibly associated with progression. −, Loss of chromosomal segment; +, gain of chromosomal segment; LOH, loss of heterozygosity. Unclassified renal cell carcinoma and metanephric adenoma are not characterized sufficiently to identify common genetic abnormalities.
*Not enough data to assign abnormality as an early or late event.

TABLE 7.2. COMMON GENETIC FINDINGS IN PATHOLOGIC SUBTYPES OF RENAL TUMORS

CLINICAL MANAGEMENT OF HEREDITARY RENAL CANCER

Types of Hereditary Renal Cancer

The best-characterized form of hereditary renal cancer is von Hippel–Lindau disease (VHL). VHL is an autosomal dominant inherited disorder caused by a defect in the VHL gene, located on chromosome 3p25, resulting in the development of clear-cell tumors (259). Mutations in the VHL gene predispose patients to develop retinal angiomas, central nervous system hemangioblastomas, endolymphatic sac tumors, renal cysts and cancers, pancreatic cysts and islet cell tumors, pheochromocytomas, and epididymal cystadenomas (32,257,295,447). Patients with VHL demonstrate variable clinical penetrance of these tumors. From 24% to 45% of patients with VHL have been reported to develop renal cell carcinoma (64,257,292). However, of patients in the 60- to 70-year-old age group, 90% to 95% develop cystic or solid renal lesions (64). Affected patients with VHL usually develop multiple, bilateral clear-cell renal tumors and can develop new tumors over the course of their life. Patients develop VHL and renal cancer at a mean age of 39 years, 10 to 20 years younger than patients with sporadic renal cancer (151) (Fig. 7.4).

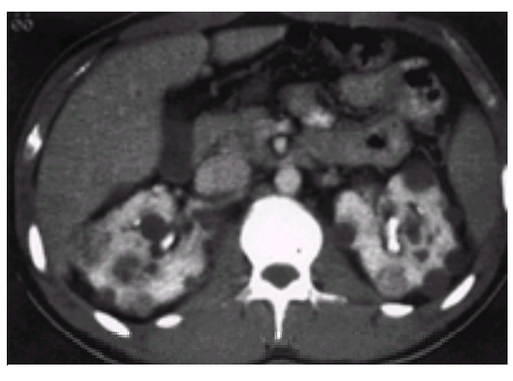

FIGURE 7.4. Abdominal computed tomography of renal masses in a patient with Von Hippel–Lindau disease.

A hereditary form of basophilic papillary renal cancer (type 1) has been also been described. Hereditary papillary renal cancer (HPRC) is inherited in an autosomal dominant fashion and, like all other forms of hereditary renal tumors, is characterized by multiple, bilateral renal tumors. Other associated tumors are not known to occur in patients with HPRC. HPRC is caused by germline mutations in the *met* gene, located on chromosome 7q31 (463,464).

Familial renal oncocytoma (FRO) is characterized by multifocal, bilateral renal oncocytoma (453). Few FRO families have been identified, and the clinical manifestations of this entity are not well characterized. Familial linkage and tumor loss of heterozygosity studies have not suggested the location of a responsible gene. Affected patients have a lifelong risk of recurrent tumors (453).

BHD comprises characteristic skin lesions (fibrofolliculomas), renal tumors, and pulmonary cysts predisposing patients to spontaneous pneumothorax. Renal tumors in BHD are usually chromophobe tumors. A unique aspect of this form of hereditary renal tumor syndrome is the development of other histologic tumor types, although at a low frequency (428).

Treatment Options in Patients with Hereditary Renal Cancer

Patients with hereditary forms of renal cancer are predisposed to develop multiple bilateral renal tumors over the course of their lives. Although radical nephrectomy will cure patients with localized disease, there are quality-of-life issues associated with renal replacement therapy. The largest experience in treating patients with hereditary renal cancer is in patients with clear-cell renal cancer associated with VHL. Management approaches used in VHL patients with renal tumors have ranged from observation to bilateral nephrectomy with renal replacement therapy to renal-sparing operations (80,137,155,200,327,339).

Although observation of patients with renal cancer is not traditionally recommended, there is historical experience with this approach. In the era before the use of abdominal computed tomography imaging, patients were followed with intravenous pyelogram (IVP) imaging studies. IVP studies do not detect small tumors and even some larger tumors. During this era, 23% to 45% of patients with VHL were reported to develop renal cell carcinoma, similar to recent reports, and about one-third of these patients died of metastatic disease (70,126,151,257).

A second approach has been to perform bilateral nephrectomy, removing all renal tumors and their associated risk of metastases (80,155,200). Unfortunately, there is little experience in treating VHL patients with renal replacement therapy. Survival of non-VHL patients managed with dialysis or transplant is only 65% at 2 years (1). Similar treatments of small groups of patients with VHL have had a similar outcome (343). Some transplant centers, however, consider the presence of or potential for VHL-related tumors (renal and extrarenal) a contraindication for renal transplantation.

A third treatment option is renal parenchymal-sparing surgery. Patients with hereditary forms of renal tumors have been predicted to have hundreds or thousands of microscopic tumors present in the normal renal parenchyma (336,446). Surgery in these patients is not thought of as being curative, but rather as “resetting the clock” until small microscopic tumors grow to become clinically detectable. The decision of when to operate can be somewhat arbitrary in these patients.

In patients with sporadic renal tumors, the risk of metastases has been correlated with size of the primary tumor (22,116,133). Small renal cancers were even historically termed *adenomas* to emphasize their benign clinical course (26). Based on these observations, the management of patients with hereditary renal cancer has evolved to use size criteria as an indication for surgery. A French group follows renal tumors in patients with VHL until they reach 2.5 cm in diameter before recommending surgery (63,72); the National Cancer Institute (NCI) group uses 3 cm (193); and a German group uses 6 cm (324).

The large numbers of tumors that are often present in these patients do not allow traditional partial nephrectomy with margin of 1 cm or more of normal renal tissue. Rather, simple enucleation is used to remove the many tumors present (448). Small tumors are easily removed by this technique, but even tumors larger than 3 cm in diameter have been managed in this fashion. The NCI has reported the largest follow-up of patients with VHL treated in this fashion (193).

At the NCI, VHL patients with solid renal tumors were followed with serial imaging studies until the largest solid tumor reached 3 cm in size. At that time, surgery was recommended to remove all solid lesions and all accessible cystic lesions in the kidney. Renal cystic disease was not included in a patient's evaluation for surgery. In addition, the cystic component of solid renal masses was subtracted out when measuring tumor growth toward the 3-cm cutoff.

VHL patients with renal tumors less than 3 cm in diameter followed for a median of 60 months did not develop metastases or require renal replacement therapy (443). VHL patients with larger renal tumors had a risk of developing metastases related to tumor size (Table 7.3) (443). Similar management strategy has been used in patients with other hereditary forms of renal cancer.

Frequency of Metastases	Tumor Diameter (cm)
0/52 (0%)	≤3.0
1/17 (6%)	3.2–4.0
2/10 (20%)	4.1–5.5
4/12 (33%)	6.0–10.0
4/5 (80%)	≥11.0

Comparison of tumor size and the development of metastases in patients with von Hippel–Lindau (VHL). VHL patients with renal tumors larger than 3 cm had an increased risk of developing metastases with increasing tumor size.

TABLE 7.3. COMPARISON OF TUMOR SIZE AND THE DEVELOPMENT OF METASTASES IN PATIENTS WITH VHL

Planning Surgery in Patients with Hereditary Renal Cancer

Patients with VHL develop multiple tumor types, which can cause problems during an operation. Pheochromocytoma can be associated with hypertensive crisis, retinal angioma can bleed during periods of hypertension or with the use of anticoagulation, and central nervous system (CNS) hemangioblastomas can be at risk for bleeding or CNS herniation. Preoperative evaluation of all VHL manifestations is performed to identify tumors in the brain, eye, pancreas, and adrenal. CNS tumors may require treatment before abdominal surgery can be safely performed. Medical blockade of pheochromocytoma is necessary before surgery. Once the patient is cleared for abdominal surgery, a multispecialty approach can allow simultaneous treatment of renal, adrenal, and pancreatic tumors.

Renal angiography has not been helpful for diagnosis of renal tumors, with identification of only 16% of the multiple, small renal tumors present (308). Renal angiography is helpful in defining renal arterial anatomy, including small polar branches, which could be damaged during initial or repeat renal operations.

The multiple tumors found in patients with hereditary renal cancer syndromes do not allow partial nephrectomy with a wide resection of normal tissue around each tumor. Pathologic evaluation of renal tumors in patients with VHL consistently reveals a fibrous pseudocapsule margin (349). The multiple renal tumors and fibrous pseudocapsule lend these tumors well to enucleation (448). Patients with other hereditary tumor syndromes have been well managed with similar surgical treatment (193).

Patients with VHL also develop multiple simple and complex renal cysts. Although these lesions behave in a benign fashion, microscopic examination reveals that at least 21% contain foci of renal cell carcinoma (349). Based on these findings, surgical removal of cystic lesions has been recommended when extensive injury of normal renal parenchyma is not necessary to remove the cysts.

Color Doppler intraoperative ultrasound has been an important contribution to the management of patients with hereditary renal cancer. Additional tumors were found

in 25% of patients with intraoperative ultrasound, contributing to a more thorough evaluation and treatment of each kidney (71).

Results of Surgery in Patients with Hereditary Renal Cancer

The largest single-institution experience treating patients with hereditary renal cancer is at the NCI. There, 28 men and 22 women were reported undergoing a total of 71 surgical procedures (193). Affected patients were identified by screening affected families. Sixty-eight patients had pathologic stage T_1, one had stage T_2, and two had stage T_{3b}. Two patients with pathologic stage T_1 renal cancer had tumor thrombus in minor renal veins. No patient had lymph node or other metastases.

Fifty-three kidneys were treated with enucleation, five with partial nephrectomy, six with enucleation plus partial nephrectomy, and nine with nephrectomy. Patients underwent a median of one renal operation (range of one to four). During a median overall follow-up of 80 months, eight kidneys underwent repeat renal parenchymal-sparing surgery a median of 31 months after the first operation. Forty percent of renal parenchymal-sparing operations were performed with cold renal ischemia (Table 7.4). Eight patients with VHL underwent resection of VHL-associated tumors at the same time, including enucleation of pancreatic neuroendocrine tumors (*n* = 4), bilateral adrenalectomy for pheochromocytoma (*n* = 2), and unilateral adrenalectomy for pheochromocytoma (*n* = 2). The most notable complications were renal atrophy in 3 of 65 kidneys (4.6%) treated with renal parenchymal-sparing surgery and a single intraoperative myocardial infarction resulting in postoperative death. Urinary leakage persisting longer than 30 days occurred in three patients. Similar complications have been encountered in previous series, with the exception of renal failure, which was lower in the NCI series (64,403). No patient in the NCI series treated with renal parenchymal-sparing surgery has required dialysis. Thirty-five percent of kidneys undergoing renal parenchymal-sparing surgery developed a recurrence during the 80-month follow-up.

Surgical Characteristics			
Parameter	***N***	**Mean**	**Range**
Lesions resected per kidney	65	14.7 ± 1.3 lesions	1–51 lesions
Cold renal ischemic time	26	51.1 ± 5.6 minutes	10–120 min
Operative time	71	354.5 ± 19.0 minutes	117–830 min
Estimated blood loss	71	2885.1 ± 494.5 mL	150–23,000 mL
Blood units transfused	71	4.3 ± 0.9 units	0–34 units

TABLE 7.4. THE NCI RENAL PARENCHYMAL-SPARING SURGICAL EXPERIENCE IN PATIENTS WITH HEREDITARY FORMS OF RENAL CELL CARCINOMA

The use of nephrectomy was reduced in the NCI experience. Seven nephrectomies were performed in the first 5 years, with only two in the second 5 years (444). The use of nephrectomy in this series was lower than previously reported (12% versus 26%) in multiinstitutional reports, even accounting for differences in stage (403). This lower rate of nephrectomy may be related to the broad use of the enucleation technique, regardless of number of tumors or location of renal tumors.

Follow-up After Renal Parenchymal-sparing Surgery

Among 65 kidneys managed primarily using enucleation techniques, 35% developed recurrent tumors during 80 months of follow-up, similar to previous studies (403). This high recurrence rate is not surprising, because there are reports of many microscopic tumors in normal renal parenchyma of VHL and HPRC patients (336,446). Evaluation of normal VHL renal tissue predicts 600 microscopic clear-cell renal tumors and 1,100 clear-cell cysts in the average VHL kidney undergoing surgery. Similar evaluation of HPRC patients predicts 3,400 microscopic papillary renal tumors per kidney. These findings support the strategy of watching renal tumors grow to a predetermined size because renal surgery in these patients is not curative in the traditional sense. They also emphasize the need to search for the smallest tumors present during exploration to best treat these patients. Intraoperative ultrasound has been extremely useful for maximizing the number of lesions identified at the time of surgery (71,444). Disease-specific survival in these patients was excellent and may reflect the early detection of small tumors by periodic screening.

The treatment strategy applied to these patients with hereditary renal tumor syndromes is not curative, but is designed to “reset the clock” relative to the time required for microscopic tumors to grow to a size at which they present a significant metastatic risk. This management approach balances the goals of minimizing the risk of renal cell carcinoma metastasis while preserving renal function. Additionally, this approach attempts to minimize the total number of surgeries a patient will require in a lifetime.

MOLECULAR GENETICS OF PROSTATE CANCER

Despite significant improvements in early detection and local curative therapies, carcinoma of the prostate remains a major public health issue. Prostate cancer is now the most common noncutaneous malignancy in the United States and is the cause of more cancer-related deaths in men than any human malignancy other than lung cancer (162). Because of this, we must strive to improve the accuracy of diagnostic tests and prognostic measures. We must improve efficacy while reducing morbidity of local therapies, and we must devise methods to effectively prevent or treat hormone-refractory prostate cancer. A better understanding of the underlying molecular genetic events responsible for prostate cancer initiation and progression will enhance our chances for achieving these goals. This basic knowledge should allow us to develop better diagnostic tests that will eliminate false-positive results of prostate-specific antigen (PSA) screening. In the future, molecular pathology should also be able to accurately distinguish between “clinically indolent” and potentially lethal prostate cancers so that aggressive treatment is prescribed only to those who require it. We should be able to use this knowledge to design therapies that prevent progression of androgen-dependent to androgen-independent disease. Ultimately, we should be able to custom design effective treatments and prevention strategies based on a man's specific genetic makeup, the molecular abnormalities of his tumor, or both.

Currently, our understanding of the molecular genetics of prostate cancer is in its infancy. There is compelling evidence that a small proportion of prostate cancers (approximately 10%) is inherited but that the remaining 90% is caused by a complex interplay between environmental factors and somatic genetic molecular events (56). Several known tumor-suppressor genes (TSGs) are thought to play a role in a subset of prostate cancers, and alterations in various oncogenes, growth factors, and apoptotic pathways have been implicated as well. Recent advances in molecular technology that enable accurate, high-throughput analysis of genomic structure, as well as gene expression profiles, will almost certainly facilitate efforts to understand prostate cancer biology. This section reviews what we currently know about potential genomic and somatic events that may be responsible for prostate cancer development and then discusses the application of genomics and proteomics to prostate cancer investigation.

Hereditary Prostate Cancer

Several epidemiologic studies have demonstrated a familial clustering of a subset of prostate cancer cases, and some investigators have suggested that patterns of affected men can be explained by dominant inheritance of a rare high-risk allele (55,56,169,404). Studies suggest that hereditary cases account for 40% of cases of early-onset prostate cancer (i.e., age less than 55 years) but only 9% of other cases (56,168). There is a familial aggregation of prostate cancer, and an individual man's risk increases with the number of affected family members. Prostate cancer risk is increased twofold to threefold for men with one affected first-degree relative and elevenfold for men with three affected first-degree relatives (442).

To date, linkage analysis has identified four separate prostate cancer susceptibility loci (HPC1 on 1q24-25, PCAP on 1q42-43, CAPB on 1p36, and HPC on Xq27-28) (Table 7.5) (30,146,395,459). Positional cloning efforts are currently underway to identify these specific genes. Although it appears that each one of the genes will only be responsible for a subset of hereditary prostate cancers, their identification will provide important information regarding the underlying biologic mechanism of prostate cancer development.

Chromosomal Band	Locus
1q24-25	HPC1
1q42-43	PCAP
Xq27-18	HPCX
1p36	CAPB

TABLE 7.5. HEREDITARY PROSTATE CANCER SUSCEPTIBILITY LOCI

Genetic Polymorphisms

It has been estimated that 1 in every 300 to 500 bases in the human genome is a single nucleotide polymorphism and that some of these single-base pair differences may alter protein function, contributing directly to a trait or disease phenotype (77). One of the must highly characterized polymorphisms in prostate cancer is within a gene in the chromosomal Xq11-12 region encoding the androgen receptor. Androgen responsiveness of prostate cancer is well documented, and circulating androgens are necessary for prostate cancer development (96). It has been suggested that the length of the highly polymorphic region of the CAG repeat coding for the polyglutamine chain in the androgen receptor inversely correlates with an individual's prostate cancer risk (147,378,401). Data from two separate large, population-based, case-controlled studies have demonstrated this relationship. In the Physicians Health Study, men with an androgen-receptor CAG repeat length of less than 18 had a 50% increased risk of developing prostate cancer compared with those men with CAG repeat lengths greater than 26 (147). A study using a population identified from the Surveillance, Epidemiology, and End Results (SEER) program showed that men with two short repeat lengths (CAG less than 22 and GGN less than 16) had a twofold higher prostate cancer risk than men with longer repeat lengths (401). Epidemiologic studies of CAG repeat lengths in different racial populations support these findings. That is, African-American men (the racial group with the highest prostate cancer incidence) have on average the shortest CAG repeat length, whereas Asian-American men (the racial group with the lowest prostate cancer incidence) have on average the longest CAG repeat length. Caucasians as a group have an intermediate prostate cancer incidence and have an intermediate CAG repeat length (73,368). Studies have also shown that among prostate cancer patients, those with shorter CAG repeat lengths are more likely to develop prostate cancer at a younger age (180) and are more likely to have aggressive prostate cancer with unfavorable pathologic features compared to those with longer CAG repeats (147). The underlying biologic mechanism for this relationship is not known. *In vitro* studies have demonstrated that transactivation of the androgen receptor is inversely related to its polyglutamine length, and some have hypothesized that increased androgen responsiveness predisposes prostate epithelium to malignant transformation. More study is needed to determine whether a short polyglutamine length directly increases prostate cancer risk or is merely associated with this phenotype.

There is epidemiologic evidence suggesting that decreased vitamin D levels, either from reduced exposure to sunlight or conversion of 7-dehydrocholestrol to vitamin D, may predispose to prostate cancer development (81,179). Several *in vitro* studies have also suggested that vitamin D may act as a tumor inhibitor for prostate cancer. Interestingly, different polymorphisms in the vitamin D receptor gene have been reported to be associated with either an increased or a decreased prostate cancer risk (176,208).

Other potentially important genetic polymorphisms associated with prostate cancer development have been observed in members of the glutathione S-transferase family. It has been shown that a single nucleotide polymorphism (SNP) in the glutathione S-transferase Pi gene, resulting in an amino acid change, alters prostate cancer risk by an odds ratio of 0.4 (182). In addition to SNPs, homozygous deletions within the human genome are also commonly observed (354). One of these, at the glutathione S-transferase-0 (GSTT1) locus on chromosome 22q11.2, occurs in 20% to 30% of Caucasian men in the United States. Studies have shown that men who do not have a homozygous deletion at GSTT1 are at increased risk of developing prostate cancer (354).

In the near future, molecular epidemiologic studies will define many more genetic polymorphisms that either predispose to or protect from the development of prostate cancer. It is likely that a man's prostate cancer risk will ultimately be determined by a panel of different genetic polymorphisms and that this information will be critical for designing and executing effective prostate cancer prevention strategies.

Chromosomal Abnormalities

Alterations in chromosomal number and structure are common findings in all human cancers. Cytogenetic studies of prostate cancer have demonstrated alterations on multiple different chromosomes, but the most common finding is loss or rearrangement of sequences on the short arm of chromosome 8 and gain of sequences on the long arm of chromosome 8 (67,290,438). In fact, studies have shown that 8p loss and 8q gain are associated with more aggressive disease (437). PSCA and c- *myc* are two genes located on 8q whose amplification may play a role in prostate cancer progression. The responsible genes on 8p have yet to be determined. Microsatellite-based LOH analysis is a powerful molecular tool used to define regions of genetic loss in attempts to discover TSGs. LOH studies of nonmetastatic prostate cancer revealed a deletion frequency of as high as 86% on the short arm of chromosome 8 and have suggested the presence of at least three separate TSGs located on this chromosome (438). Chromosomal bands 8p21-12, 8p22, 8p23, and 8q12-13 are regions with high rates of LOH (28,342,438). LOH at chromosomal bands 13q, 6q, 16q, 18q, 9p, and 7q31 have been observed less frequently (260,437).

Researchers have found a homozygous deletion in a metastatic tumor focus that maps to 12p12-13, suggesting that there is a prostate cancer metastasis suppressor gene in this region (230). One intriguing candidate gene in this region is p27. This gene encodes a cyclin kinase inhibitor that induces cell cycle arrest in the G_1 phase. This mechanism prevents DNA replication in cells with substantial DNA damage (15). Several studies have shown that reduced levels of p27 are associated with aggressive and metastatic prostate cancers (84,174,460). Other studies have shown that LOH at 8p22 is a common finding in metastatic prostate cancer, suggesting that this region also contains a metastasis suppressor gene (269).

Contemporary scientific data suggest that there are multiple genes responsible for development and progression of prostate cancer and that multiple different genetic pathways for this common human malignancy exist. Defining any of these genetic defects will provide researchers tremendously important insight into the underlying biology of prostate cancer. Examples of some potential candidate genes on chromosome band 8p include FEZ1 (212), NKX3.1 (185), N33 (429), and Dematin (286), among many others. Currently, efforts to determine which genes have tumor-suppressor function in prostate cancer now focus on further defining areas of minimal deletion and sequence analysis of candidate genes within regions of high LOH.

Promoter Methylation

Methylation of cytosine bases in CpG-rich promoter regions is an important mechanism to regulate tissue-specific gene expression. Alterations in methylation patterns are commonly observed in multiple different human malignancies. Reduction in gene expression can be the result of promoter hypermethylation, whereas promoter hypomethylation can cause increases in gene expression. In fact, extensive methylation of the glutathione S-transferase Pi (GSTP1) promoter region is the most common somatic genomic alteration described in prostate cancer to date (265). Immunohistochemical analysis of GSTP1 expression has demonstrated that promoter methylation does in fact correlate with reduced protein expression. Studies of radical prostatectomy specimens have demonstrated loss of GSTP1 expression in the vast majority of invasive prostatic carcinomas and high-grade prostatic intraepithelial neoplasia lesions (44). Researchers have proposed that because GSTP1 functions as a detoxification enzyme, loss of GSTP1 activity can predispose prostate cells to accumulate damaged DNA, leading to malignant transformation. If loss of GSTP1 is an important event leading to prostate carcinogenesis, medication or dietary supplements with detoxification functions may be effective prostate cancer prevention strategies.

It appears that prostate cancer is associated with methylation changes within promoter regions of several other genes as well (Table 7.6). For example, it has been shown that hypermethylation of the CD44 promoter region is a common finding in high-grade localized and metastatic human prostate cancer (284). CD44 is a transmembrane glycoprotein involved in cell-cell and cell-matrix interactions that suppresses metastasis in a highly metastatic prostate cancer model (Dunning rat) (142). Hypermethylation of the p16/CDKN2 gene, which encodes an inhibitor of cyclin-dependent kinase 4, has been observed in a limited number of prostate cancers (189,190,305). It has been shown that inactivation of the p16/Rb pathway can result in cellular immortalization (215). Methylation of the endothelin B receptor gene in

prostate cancer has also been reported, and it has been suggested that this event may be responsible for endothelin-1 secretion (215). It has been shown that exposing androgen receptor–negative prostate cancer cell lines to a demethylating agent increases androgen receptor expression. It has been suggested that promoter methylation may be a cause of heterogeneous androgen receptor expression observed with hormone-refractory prostate cancer (214). It is clear that altered promoter methylation of a variety of genes is a common event in prostate cancer, but it remains to be seen which gene alterations are responsible for prostate cancer development and progression and which merely are associated with the malignant phenotype.

GSTP1	E-cadherin
CD44	Endothelin B

TABLE 7.6. GENES WHOSE EXPRESSION IS ALTERED BY METHYLATION IN PROSTATE CANCER

Tumor-suppressor Genes

A tumor-suppressor gene responsible for early prostate cancer development has yet to be discovered. However, there are several known TSGs that may play a role in prostate cancer progression. The gene for PTEN maps to chromosomal band 10q23.3. The protein product of the PTEN gene is a dual-specific phosphatase with documented tumor-suppressor function in some cultured cells and nude mice (141). Within cancerous prostate cells, PTEN can be inactivated by multiple different mechanisms, including genomic deletions, point mutation, and hypermethylation (53, 161, 409, 450). In general, PTEN inactivation is far more common among high-grade or advanced prostate cancers than in lower-grade and earlier-stage disease (105, 161). In fact, the vast majority of PTEN mutations have been found in patients without organ-confined prostate cancer (105, 161). Collectively, these data suggest that PTEN may be an important metastasis-suppressor gene, but it probably does not play an important role in prostate cancer initiation.

Likewise, p53 mutations are far more common in high-grade metastatic prostate cancer than in earlier lesions (110, 307). Clinical studies have shown that the presence of p53 mutations in prostate cancer correlates with poorer cure rates for both radiotherapy and radical prostatectomy (65, 66, 320).

The WAF1 gene is the primary target of the transcription activation by P53 and is also an important regulator of cell cycle kinetics (111). P21, the product of the WAF1 gene, inhibits the activity of cyclin E and cyclin D, which prevent cells from entering the S phase of the cell cycle (181). A few small preliminary studies suggest that overexpression of the P21 or cyclin D1 protein is associated with higher tumor grade and adverse clinical outcome (2, 365).

Growth Factors

Alterations in a variety of growth factors and their receptors have been implicated in prostate cancer growth and progression. Among the most widely studied growth factor in prostate cancer are members of the epidermal growth factor family, epidermal growth factor (EGF) and TGF-a. Within normal prostates, EGF expression is restricted to stromal cells (134), and epidermal growth factor receptor (EGFR) expression is restricted to basal cells of prostatic epithelium (305). Immunohistochemical analysis of benign prostatic hyperplasia demonstrates overexpression of EGF in hyperplastic glands. In contrast, immunohistochemistry has demonstrated that both EGF and EGFR levels are upregulated in malignant prostate epithelium (95). Studies of prostate cancer cells suggest that EGF and TGF-a play a role in upregulation of EGFR mRNA and protein (384). Furthermore, there is evidence that a variant EGFR (EGFRvIII), lacking the external domain of the native receptor, is overexpressed in prostate cancer cells, and that aberrant expression of EGFRvIII is associated with more aggressive disease (330). Collectively, these studies suggest that autocrine expression of EGF and TGF-a signaling through the EGFR may contribute to the autonomous growth and invasiveness of human prostate cancer cells (231).

The HER-2/neu (erbB-2) gene encodes for another tyrosine growth factor receptor that is a member of the EGFR family. Interestingly, gains in genomic content of the HER-2/neu gene are observed in 40% to 60% of high-grade prostate cancers (361, 381). It has been demonstrated that overexpression of HER-2/neu restores androgen-receptor functions in androgen-independent prostate cancer xenograft model (88).

Overexpression of several fibroblast growth factor (FGF) family members has been associated with prostate cancer progression. Studies have shown that FGF8 mRNA expression is increased in prostate cancer (266) and that overexpression correlates with higher Gleason grade and advanced tumor stage (106). Overexpression of growth factors by prostatic stromal cells may also play a role in prostate cancer progression. For example, expression of FGF2 is restricted to stromal fibroblasts and endothelial cells, and expression levels are greatly enhanced within cancerous glands (148). Interestingly, the receptor for FGF2 is overexpressed in malignant prostate epithelium (148).

Insulin growth factor (IGF) may also play a role in prostate cancer development and progression. IGF-II mRNA is expressed by some prostate cancer cells, and it has been suggested that it may function as an autocrine growth factor (167). All studies have suggested that alteration in the IGF binding proteins may alter bioavailability of IGF and play a role in prostate cancer progression (125). Results of a large retrospective study demonstrated a correlation between higher serum IGF levels and increased prostate cancer risk (61). In this study, men with serum IGF levels in the highest quartile had a 2.4 times greater chance of being diagnosed with prostate cancer compared with age-matched men with lower IGF levels. Prospective studies are needed to determine whether elevated serum IGF levels predispose to prostate cancer development and whether lower serum IGF levels could be an effective prostate cancer prevention strategy.

Other growth factors that have been implicated to play a role in prostate cancer include transforming growth factor-b (TGF-b) (54), hepatocyte growth factor (HGF) (326), nerve growth factor (NGF) (9, 397), bone morphogenetic proteins (BMPs) (12, 207, 424), and platelet-derived growth factor (PDGF) (394), among others. The role of TGF-b in prostate cancer is not entirely clear, because TGF-b inhibits prostate cancer growth *in vitro* (407) but promotes growth and metastasis *in vivo* (18). This paradoxic response may be explained by data suggesting that prostate cancer cells downregulate TGF-b receptors so that increased expression of TGF-b induces host effects that facilitate cancer progression and metastasis (173). Among the metastasis-promoting effects attributed to TGF-b are immunosuppression, angiogenesis, and extracellular matrix deposition (455). HGF (“scatter factor”) is secreted almost exclusively by prostatic stromal cells and binds to the product of the *c-met* protooncogene expressed on prostate epithelium (205). Preliminary data suggest that expression of *c-met* is elevated in prostate cancer and increases with increasing grade, thereby enhancing mobility and cellular scattering (344). BMP and NGF have been implicated in development of bony metastasis and hormone-independent growth, respectively (12, 91).

The realization that alterations in growth factors and growth factor receptors may play a role in prostate cancer progression has led to development of novel therapeutic strategies. A recombinant anti–HER-2/neu antibody (Herceptin) that inhibits growth of breast cancer cells that overexpress HER-2/neu has been developed (122, 201) and is now approved for the treatment of human breast cancer (39). Studies of two prostate cancer xenograft models have shown that Herceptin provides synergistic antitumor activity when combined with paclitaxel chemotherapy (5). Another potential therapeutic strategy explored by researchers relies on EGFR blockade. Interestingly, *in vitro* studies have shown that blockade of the EGFR not only attenuates the actions of EGF, but also IGF-I (352). This suggests that it may be possible to reverse several functional autocrine growth factor pathways by blocking a single receptor site. Although the efficacy for human prostate cancer therapy remains to be seen, both Herceptin and EGFR receptor blockade are good examples of how understanding alterations in growth factors and their receptors can lead to the design of novel targeted prostate cancer therapies. Therapeutic approaches directed at physiologic pathways altered in cancer will likely provide the cornerstone for treatment of hormone-refractory prostate cancer in the future.

Apoptosis

Programmed cell death (apoptosis) is an important regulator of cellular hemostasis, and alterations in apoptotic pathways have been implicated in prostate carcinogenesis. Bcl-2, Bcl-x, and Mcl-1 are proteins that inhibit apoptosis, and Bax is a protein that induces apoptosis (19). Immunohistochemical studies have demonstrated overexpression of Bcl-2 in 25% and Mcl-1 in 81% of prostate cancers (253). Studies have shown that overexpression of Bcl-2 is a predictor of poor clinical outcome in patients undergoing radical prostatectomy or radiation therapy for clinically localized prostate cancer (41,372,400). It has also been suggested that the ratio of Bcl-2/Bax immunohistochemical staining correlates with poor response to radiotherapy (288).

Animal studies have shown that overexpression of Bcl-2 protein augments growth of LnCaP tumors (21), and these findings have been used to design a novel prostate cancer therapy. In preclinical studies, researchers have shown that antisense Bcl-2 oligonucleotides inhibited growth of LnCaP and Shinogi and prevented PSA progression both *in vitro* and in castrated mice with subcutaneously implanted tumors (309). Chemosensitivity to taxol and mitoxanthrone was also enhanced. A phase I clinical trial using antisense Bcl-2 alone or in combination with mitoxanthrone is currently in progress (335).

Angiogenesis

Angiogenesis may play an important role in prostate cancer progression. Both *in vitro* and *in vivo* studies of LnCaP cells demonstrate that cells expressing higher levels of vascular endothelial growth factor (VEGF) exhibit enhanced metastatic potential (17). VEGF is the best-characterized angiogenesis factor to date (109,123), and one immunohistochemical study demonstrated positive staining for VEGF in 80% of prostate cancers compared with only 18% of benign glands (123,124). Some studies of human prostate cancer have shown that increased microvascular density in localized prostate cancer specimens predicts advanced pathologic stage and treatment failure (408), but other studies have failed to demonstrate this relationship (145,363).

Blocking tumor angiogenesis is a potentially exciting new approach to cancer therapy (131). The discovery and characterization of two potent endogenous angiogenesis inhibitors, angiostatin and endostantin, will facilitate the development of prostate cancer therapies targeting angiogenesis (37,119,396). Animal studies using these agents are currently underway (335).

Cell Adhesion Molecules

Alterations in cell adhesion molecules may also play a role in prostate cancer progression. The genes encoding two important cell adhesion molecules, E-cadherin and KAI-a, map to chromosomal bands 16q24 and 11p11.2, respectively. Both regions are frequently deleted in metastatic prostate cancer (104,270), and expression levels of E-cadherin can also be reduced in prostate cancer by promoter methylation (159). Animal studies suggest that KAI-1 can suppress prostate cancer metastasis (206). Likewise, E-cadherin plays an important role in establishing and maintaining ordered intercellular connections and morphogenesis (311). *In vivo* studies of the Dunning rat prostate tumor showed that transfecting tumor cells with E-cadherin downregulates matrix metalloproteinase 2 expression (another factor implicated in prostate cancer progression) and reduces cellular invasiveness (285). Immunohistochemical studies of human prostate cancer tissue have suggested that reduced levels of E-cadherin expression correlate with higher Gleason score and advanced pathologic stage (94). Restoring functional cell adhesion molecules to prostate cancer cells may be one possible strategy that could be used to prevent tumor progression and metastasis.

New Frontiers in Molecular Profiling of Human Malignancies

By the year 2003, the complete map and sequence of the entire human genome will be known, and sequencing of cDNA's coding for all human genes will be completed shortly thereafter (77). This information will provide us with the “periodic table of life” and will be the foundation for understanding both normal and diseased cellular functions. Over the past several years, we have witnessed tremendous advances in gene expression technology. In the near future, it will be possible to rapidly assess expression patterns of virtually all genes and proteins within a particular population of human cells. Advances in microdissection and cell-sorting technology allow one to isolate pure populations of cells from human tissue sections and then extract DNA, RNA, and protein. Differential display and cDNA microarrays are evolving technologies that facilitate high-throughput mRNA expression analysis. Advances in proteomic techniques have also made it possible to assess expression patterns of a large number of proteins simultaneously. Combining new approaches for “molecular profiling” with the complete human genome sequence will provide new opportunities to understand the underlying mechanism responsible for human malignancy. This knowledge should ultimately revolutionize diagnosis and treatment of men and women with cancer.

Tissue Processing and Procurement of Pure Populations of Cells

One of the major limitations to the direct study of molecular changes in human malignancy has been the challenge to obtain pure populations of malignant and benign cells. This difficulty arises because of cellular heterogeneity such as is seen in prostate cancer or the presence of inflammatory cells that infiltrate certain tumors such as renal cell carcinoma. To overcome this investigative hurdle, different microdissection techniques have been developed for the purpose of procuring pure or semipure populations of cells from human tissue sections. One methodology relies on ablating all the unwanted tissue with a laser and then isolating the macromolecules from the remaining tissue. Another methodology, laser capture microdissection (LCM), is currently the most widely used technique (113). LCM allows researchers to visualize a tissue section via light microscopy and then procure the desired cells by activating a 7.5- to 30-micron-diameter infrared laser beam. The laser beam melts an ethyl-vinyl-acetate film in contact with the tissue section, thereby capturing the cells of interest. Lifting up the cap pulls these cells out of the tissue sections. Intact DNA, RNA, and protein can then be extracted from the cap using various lysing buffers and analyzed by conventional methods. The advantage of this technology is that it allows for simple, fast, and reliable microdissection of human tissue sections. This technology facilitates *in vivo* molecular analysis of defined populations of human cells.

High-throughput Gene Expression Analysis

Rapid advances in high-throughput gene expression analysis technology are making it possible to analyze expression patterns of a large number of human genes simultaneously and to study how these patterns are altered in different stages of malignancy. Currently, the most widely used method to analyze gene expression patterns in cancer is through cDNA microarrays (47,100). This technology involves labeling a sample of cDNA, representing the expressed genes from a population of cells, with a radioactive or fluorescent probe. The probe is then hybridized to a nylon filter or glass array slide containing cDNA fragments representing several thousand human genes of interest. Analysis of these experiments allows one to determine relative expression levels for different genes within the same population of cells or different genes within different populations of cells. Researchers have begun to apply this technology to the study of prostate cancer. Using cDNA microarrays to compare gene expression in the androgen-independent and androgen-dependent tumors in CWR22 xenograft model yielded 37 candidate genes that were upregulated by more than twofold in the androgen-independent state (49). Although the biologic relevance of these differentially expressed genes remains to be determined, the use of cDNA microarray will be an important approach to the study of prostate cancer progression. One important caveat to this study and many others is that they use xenograft or cell culture models that may not accurately represent *in vivo* gene expression in human prostate cancer. This is a particularly important problem when it comes to the study of premalignant lesions and early-stage prostate cancer because few good animal models or cell lines are available. The recent development of LCM technology and the ability to isolate RNA from specific populations of LCM-procured cells should facilitate the *in vivo* study of gene expression in human prostate cancer. In fact, preliminary data suggest that this approach can be used to identify several (approximately 40 genes in one experiment) differentially expressed candidate genes (75). Limitations of cDNA microarray technology include potential for artifacts (particularly if using PCR amplification) and the fact that the only genes that will be studied are those that have been placed on the array filter.

Another technique used to determine genes that are important in prostate cancer development and progression rely on generating cDNA libraries from defined populations of cells (279,321,322). This strategy allows one, in theory, to study all genes (both known and unknown) expressed by a particular population of cells. The NCI-sponsored Cancer Genome Anatomy Project (CGAP) has used both bulk tissue and microdissected procured cells to create cDNA libraries from several common human cancers and corresponding normal tissue (www.ncbi.nih.gov//ncicgap/) (112). The primary goals of the project are twofold: (a) aid in discovering new human genes and (b) profile gene expression patterns for particular human cancers and tissue types. It has been estimated that more than 50% of the approximately 100,000 human genes will have been discovered through this initiative (112). This information will be a critical foundation for future prostate cancer studies. The use of microdissected-derived samples has been the cornerstone of the gene-profiling aspect of the CGAP project. In regard to prostate cancer, twelve microdissected-based libraries have been produced from epithelial components of radical prostatectomy specimens, including normal epithelium, premalignant foci, locally invasive cancers, and metastatic lesions (112). This will allow us to define all of the genes that are expressed in normal prostate (prostate unigene set) and those genes whose expression is altered in different stages of malignancy. Research efforts will focus on correlating gene expression profiles with pathologic and clinical outcomes. Ultimately, this strategy will allow us to understand how alteration in a complex network of genes leads to prostate cancer development and progression.

Although gene expression analysis holds great promise for understanding the molecular events underlying prostate cancer progression, the malignant phenotype is ultimately the reflection of quantitative and qualitative changes in cellular proteins. Therefore many researchers believe that proteomic analysis of human cancers provides unique and complementary information to genomic DNA and gene expression studies (8,107). Two-dimensional gel electrophoresis (2D-PAGE) is a highly effective and widely used means of separating a large number of proteins. Advances in 2D-PAGE technology and protein staining methods have greatly improved the reproducibility and sensitivity of protein analysis. It is now possible to separate as many as 10,000 different protein forms with high-resolution 2D-PAGE, and computer software can be used to compare spot patterns between different gels (59,60,441). One of the major advantages of 2D-PAGE protein analysis is that it allows for relatively easy identification of specific protein spots. Unknown proteins can be identified by utilization of an electrospray that can be used to generate additional partial-sequence information. One major limitation with proteomic studies of prostate cancer has resulted from difficulty in obtaining enough material from pure populations of cells. Cell lines are a good source of pure populations of cells, but recent studies suggest that protein expression patterns of cultured tumor cells may differ substantially from those of the same cells *in vivo* (58). One potential strategy to overcome these problems is to analyze proteins isolated from microdissected populations of cells. In fact, researchers have shown that highly reproducible protein profiles can be generated using cellular lysates from populations of benign and malignant prostate epithelium procured by LCM, and that differentially expressed proteins can be identified by this approach.

Although significant technologic advances have been made, the major shortcoming of 2D-PAGE protein analysis remains sensitivity. Therefore cancer researchers should combine these robust proteomic techniques with more sensitive mRNA expression analysis. In the future, advances in technology may allow proteomic analysis of all cellular proteins, even the least abundant ones.

Conclusions

Although current understanding of the underlying biologic mechanisms responsible for prostate cancer development and progression is at a relatively rudimentary stage, there is overwhelming hope and optimism for the future. There has been tremendous progress in the search for genomic alteration associated with prostate cancer development, and it is likely that in the very near future, several specific “prostate cancer genes” for both hereditary and sporadic prostate cancer will be identified. As more genetic polymorphisms are linked with prostate cancer, there will be new opportunities to assess prostate cancer risk with more certainty, and to design rational and effective prevention strategies. The completion of the human genome sequence combined with the revolution in gene and protein expression analysis technology should allow us to classify different prostate cancers more accurately based on molecular and histopathologic features. Ultimately, an improved understanding of prostate cancer biology should be used to improve quality of life for all men with prostate cancer, as well as those at risk for this disease.

MOLECULAR GENETICS OF BLADDER CANCER

Bladder cancer is the second most common urologic cancer and fifth most common malignancy in the United States (163a). Furthermore, bladder cancer is 2.5 times more common in men than women and is the second most prevalent malignancy in older men (130). More than 50,000 patients were diagnosed with bladder cancer in the year 2000, and although the mortality rate from bladder cancer is declining, more than 10,000 deaths were expected (163a). In the United States, urologists are the primary referral for patients with unspecified microscopic and gross hematuria. As a result, the diagnosis and treatment of most bladder cancers is left almost exclusively to the practicing urologist. Our current diagnostic algorithm and treatment options for bladder cancer result in very few cases of undiagnosed and untreated bladder cancers found at autopsy (233). Fortunately, most patients (70% to 80%) have superficial (non–muscle-invasive) tumors that can be managed with bladder-sparing procedures, intravesical agents, and surveillance cystoscopy and cytology. As a result, the majority of patients treated for bladder cancer survive but require diligent follow-up because more than two-thirds of superficial tumors recur and a large percentage of high-grade tumors progress to muscle-invasive disease (192).

In contrast to superficial involvement of the bladder wall, the presence of muscle invasion makes bladder cancer a life-threatening condition. Approximately 50% of patients with muscle-invasive disease will have occult or overt metastases at the time of presentation, and the majority of these patients will die from their disease. Patients with muscle-invasive bladder cancer are managed aggressively with radical cystectomy alone or with adjuvant chemotherapy, radiation, or both for patients with advanced disease. Patients with localized muscle-invasive bladder cancer can enjoy long-term survival, and the use of orthotopic neobladders and nerve-sparing approaches has improved quality of life in appropriate surgical candidates (183). Still, approximately half of patients with muscle-invasive bladder cancer will develop overt metastases within 2 years of treatment. Metastatic bladder cancer is always associated with a high mortality rate despite aggressive chemotherapeutic regimens, and the urologic management of patients with metastatic transitional cell carcinoma usually consists of palliative procedures with or without cystectomy. Although new chemotherapeutic regimens are being investigated (435,439), treatment of metastatic transitional cell carcinoma is clearly an opportunity for molecular biologists and physicians to develop novel treatment regimens based on genetic changes that occur in these highly aggressive and lethal tumors.

Urothelial malignancies have diverse clinical and histologic presentations (114,314). Some patients have large, solitary, noninvasive papillary lesions (pTa); others have multiple noninvasive tumors. Some patients have low- or high-grade papillary or sessile lesions invading into the lamnia propria (pT_1) but not into the detrusor muscle layer of the bladder. Still others have diffuse high-grade flat lesions, carcinoma in situ (CIS, pTIS), confined to the urothelium that are associated with synchronous muscle-invasive lesions (pT_{2-4}) or progression to muscle-invasive lesions. Although the majority (60% to 70%) of patients with low-grade papillary urothelial malignancies experience a recurrence, a significant percentage do not. Some tumors respond to intravesical agents such as bacille Calmette-Guérin (BCG) or mitomycin C; others are resistant. Many patients are treated for years for multiple recurrent tumors that do not progress, but a significant percentage of patients with superficial high-grade disease progress to muscle-invasive or metastatic disease (192).

Transitional cell carcinoma (TCC) of the bladder is the most common histologic type and location of urothelial malignancy in the United States. However, squamous cell carcinoma (SCC) of the bladder is more common in areas inhabited by the microorganism *Schistosoma haematobium* (313). In these areas, bladder cancer is the most common malignancy and provides clues to the importance of inflammation and chronic infection in the etiology of bladder cancer (359). Other tumors, such as adenocarcinomas, neuroendocrine tumors, lymphomas, and pheochromocytomas, are rare primary bladder malignancies. The genetic abnormalities responsible for the histologic diversity in bladder cancer are not clearly defined, and molecular studies have not demonstrated consistent genetic differences between the common histologic types (177,385). Urothelial malignancies affecting the upper tracts of the urinary system (renal pelvis and ureter) are comparatively rare and assumed to have similar genetic changes as bladder cancer. TCC of the renal pelvis accounts for only 10% of renal tumors, and TCC of the ureter is uncommon (4% of urothelial malignancies). However, a hereditary cancer predisposition syndrome known as hereditary nonpolyposis colon cancer (HNPCC) or the Lynch II syndrome is associated with an increased incidence of upper tract urothelial malignancy (287,451). This syndrome and the association with upper tract TCC are discussed later in this chapter.

Oncogenes and Urothelial Cancer

Oncogenes are altered human genes that dominantly transform cells. Unaltered oncogenes (protooncogenes) are involved in important cellular functions such as cell surface signaling, apoptosis, cell cycle regulation, and gene expression or function as growth factors or growth factor receptors. Many protooncogenes were first described in their altered form as part of an oncogenic retrovirus that caused tumors in rodents or birds. The human homologs were subsequently isolated and the corresponding oncogene identified in human malignancies, including bladder cancer. Oncogenes often belong to families of homologous genes, and the three oncogenes to be discussed in urothelial malignancy, ras, myc, and bcl-2, are no exceptions. The genetic alterations in some oncogenes are tumor specific. For instance, c-myc is a DNA-binding nuclear protein associated with chromosome 8q amplifications and overexpression in bladder tumors (278,370), n-myc is associated with amplification on chromosome 2 in neuroblastomas (380), and l-myc is amplified in lung cancer (319). In contrast, mutations in all members of the ras gene family have been described in bladder cancer (121,139,355,387).

Unlike TSGs (described in the following section), alterations in oncogenes usually involve point mutations or chromosomal amplifications associated with increased transcription, increased stability, or increased activity. Inactivating point mutations, intragenic deletions, or gross chromosomal alterations generally do not occur in protooncogenes unless they result in increased stability or increased expression. Two classic examples of gross chromosomal alterations resulting in the protooncogene activation are bcl-2 located on chromosome 18q and c-myc on chromosome 8q. A translocation event between chromosomes 14 and 18 t (14,18) in follicular B cell lymphomas causes deregulation of bcl-2 due to approximation of an immunoglobulin heavy chain enhancer and the bcl-2 transcription unit (431). A similar type of translocation event has been described for c-myc in Burkitt's lymphoma (89). Therefore gross chromosomal alterations are an apparently common mechanism for oncogene activation in lymphoma.

The Harvey ras gene (H-ras) and other members of the ras gene family are involved in cell surface signaling through a variety of pathways including growth factor and growth factor receptor interactions (306). Ras proteins are activated by binding to guanosine triphosphate (GTP) and inactivated when GTP is dephosphorylated by GTPases. Characteristic ras point mutations at codons 12, 13, and 61 in bladder cancer and other malignancies are associated with unregulated activation of ras

proteins potentially causing unregulated signaling for cell proliferation via growth factors (417). Mutations in H-ras were initially described in the bladder cancer cell line T-24 (355) and subsequently shown to be mutated in primary bladder tumors (121). Mutations in Kirsten ras (K-ras) and n-ras have also been described in bladder cancer, but K-ras mutations are more common in colon cancer and n-ras mutations in lymphoid malignancies. The ras protooncogenes are highly homologous, and activation of any ras protein is likely to cause a similar mechanism of cellular transformation. H-ras activation commonly occurs due to point mutations in codon 12 (38), and mutations affecting any ras codon have been described in up to 40% of bladder tumors (128,139,140).

The c-myc, n-myc, and l-myc protooncogenes are well studied and have contributed extensively to our understanding of DNA binding proteins and protein-protein interactions (76). The importance of c-myc in a variety of human malignancies has been reported and usually involves gene amplification or rearrangements as described previously. The c-myc gene is expressed in proliferating cells (226). The myc proteins are transcription factors associated with increased expression of genes involved in DNA replication and cell growth (76,241). Amplification and alterations of the c-myc locus in cancer have been described (29,370); however, the role of c-myc in bladder cancer is not well understood. Although overexpression and amplification of the homologous n-myc gene in neuroblastoma has prognostic implications (380), a similar role for c-myc in TCC has not been demonstrated (278). However, low-level amplification and overexpression of c-myc in TCC has been described and correlated with progression in one study (370).

Overexpression of the bcl-2 protooncogene prevents apoptosis, a form of programmed cell death that involves activation of cellular proteases known as caspases (328). Inhibition of cell death is important in tumorigenesis for several reasons. First, the homeostatic balance is shifted toward cellular accumulation; second, apoptosis removes genetically defective cells that may become malignant if allowed to expand; and third, the toxic effect of chemotherapeutic agents on malignant cells may be abrogated. Bcl-2 is normally located in mitochondrial membranes, where it regulates pore formation. Mitochondrial pores are important in regulating free radical formation and ion fluxes and maintaining membrane potentials within the cell. Intracellular fluxes mediated by these pores can signal caspase activation and initiate the cascade of proteolytic events leading to DNA fragmentation and irreversible cell death. Some caspases are specific for cleavage of bcl-2 whereas others have a more general proteolytic spectrum. Bcl-2 prevents the initiation of these events by blocking the transduction of apoptotic signals to trigger the caspase proteolytic cascade. Therefore decreased bcl-2 expression would be associated with apoptosis and increased expression with resistance to apoptosis.

Expression of bcl-2 has been investigated in bladder as a prognostic marker and as a target for apoptotic directed therapy for bladder cancer (152,225). The tumor-suppressor protein, p53 (discussed later), is an important negative regulator of bcl-2 expression, and molecular studies demonstrate increased expression of bcl-2 in the absence of wild type p53 (223). Other members of the bcl-2 family of genes have apoptotic promoting and apoptotic preventive effects. One example, bax, binds to bcl-2, preventing it from functioning and thereby promoting apoptosis. Bax is transcriptionally activated by p53 and is therefore an effector of p53 regulated apoptosis (223). Other bcl-2–related proteins such as bcl-xL prevent apoptosis, and bcl-xs, bad, and others promote apoptosis. The mechanism of action of bcl-2 and related proteins is incompletely understood, but its location in mitochondrial membranes and regulation of pore formation are important aspects of function.

Tumor-suppressor Genes and Urothelial Cancer

Oncogenes were the first human cancer genes discovered and investigated in detail, but genetic alterations in TSGs appear to be the more common mechanism leading to human malignancies (392). Oncogenes promote tumorigenesis in a dominant fashion, and TSGs prevent or slow tumorigenesis in a dominant fashion. Classically, one allele of a protooncogene acquires an activating mutation, whereas both alleles of a TSG must be inactivated for tumorigenesis (120,239). Unlike protooncogenes, large deletions and chromosomal alterations are common events leading to TSG inactivation. One TSG allele may be completely lost while a point mutation inactivates the remaining allele (16). This phenomenon can be detected through the use of polymorphic markers and is known as loss of heterozygosity (LOH) because one allele of a marker is missing when tumor DNA is compared to normal (germline) DNA in the same patient.

TSGs can be artificially classified into two groups. The first group consists of TSGs associated with hereditary cancer predisposition syndromes and in these kindreds are associated with an inherited mutation in one allele (238). Group one TSGs were initially suspected because of increased occurrence and autosomal dominant inheritance of tumors such as retinoblastomas in affected families. Linkage analysis confirmed the presence of a cancer-predisposing gene and resulted in cloning of the inherited mutated allele (136). Once identified, TSGs are often found to be mutated in sporadic tumors, as was the case for retinoblastoma. Other TSGs were identified as mutated genes in sporadic malignancies and subsequently identified as the altered gene in a cancer predisposition syndrome (293). Investigation of these genes in transgenic mice with homozygous inactivation of the target gene confirmed importance in cell growth and tumorigenesis. The second group consists of candidate TSGs that are located in areas of LOH in sporadic cancers. Members of this second group have not yet been linked with inherited mutations in familial cancer syndromes. These TSGs are located within a common genetically altered region but have not been conclusively shown to be the target of complete inactivation in tumor cells. Several genes in this group are being investigated in bladder cancer (235,236).

TSGs that belong to the first group are retinoblastoma (Rb), p53, adenomatous polyposis coli (APC), VHL, neurofibromatosis type 1 (NF-1), neurofibromatosis type 2 (NF-2), Wilms' tumor (WT-1), tuberous sclerosis complex–1 (TSC-1), and tuberous sclerosis complex–2 (TSC-2). The first TSG products identified in this group were p53 and Rb. Rb was identified by its association with inherited retinoblastoma and subsequently shown to be inactivated in bladder cancer (213,412). The p53 TSG was shown to be mutated in colon cancer (16) and then identified as the inherited and mutated gene in the Li-Fraumeni cancer predisposition syndrome (293). Although these two important TSGs were identified by different approaches, Rb and p53 are functionally linked in suppression of cell growth by blocking the progression through the cell cycle.

Unphosphorylated Rb suppresses tumorigenesis by sequestering a transcription factor known as E2F-1 (236). E2F-1 causes transcriptional activation of genes involved in DNA synthesis and progression through the cell cycle (219,281). When RB is phosphorylated by an assembly of proteins that includes cyclins and cyclin dependent kinases (cdk), it can no longer sequester E2F-1. The result is progression of cells into the DNA synthesis (S) phase of the cell cycle from a growth or gap (G_1) phase. This block in the cell cycle at G_1 is known as a cell cycle checkpoint, and Rb is an important effector of G_1 cell cycle arrest. Cyclin D1 (CCND1) is also important at this checkpoint by its ability to regulate Rb phosphorylation through its association with cdk-4 and -6 (315). Amplification and overexpression of CCND1 has been described in cancers such as bladder (42,264,318,465) and has prognostic significance. CCND1 overexpression can overcome the G_1 cell cycle checkpoint by promoting unregulated phosphorylation of RB and causing increased bioavailability of E2F-1. The ability of cyclin D1 and other cyclins to dominantly promote tumor formation by promoting cell proliferation makes them potential oncogenes in bladder carcinogenesis (315,353,388).

The important and versatile TSG, p53, is mutated in over 50% of human malignancies, including TCC (4,197). The normal or wild type p53 protein has many important functions in suppressing tumorigenesis, such as growth arrest and apoptosis (267,268). Transactivation of a gene known as p21/waf-1/cip-1 by p53 causes inhibition of cdk-dependent phosphorylation of RB and thereby causes inhibition of E2F-1–mediated cell cycle progression (111). As mentioned previously, p53 transcriptionally activates genes such as bax that promote apoptosis and transcriptionally represses bcl-2 that prevents apoptosis (223). Other genes transcriptionally activated by p53 such as GADD45 and FAS/Apo1 also play a role in growth arrest or apoptosis (223). An important signal for many p53 functions is DNA damage from a variety of causes such as chemotherapy or radiation. These agents can block progression through cell cycle checkpoints influenced by DNA repair (222).

Another protein, p14ARF (called p19ARF in mouse) on chromosome 9p and within the same transcription unit as p16 (discussed in the next section), is transcriptionally activated by E2F-1 (20,347). The p14ARF protein interacts with a protein known as mouse double minute–2 (mdm-2), causing it to be degraded (254,347,466). The mdm-2 gene on chromosome 12 is transcriptionally activated by p53 but negatively regulates p53 by binding and targeting p53 for ubiquitin-mediated degradation (184). Mdm-2 is often amplified and overexpressed in tumors (175,262,331) and has oncogenic properties through its physical interaction with the tumor-suppressor properties of p53 (175,332). The interaction of p14ARF with mdm-2 allows increased activity of p53 and negatively regulates progression through the G_1 checkpoint. This entire process serves as a negative feedback loop for E2F-1–mediated cell cycle progression and potentiates the action of other cdk inhibitors such as p21/waf-1/cip-1. Therefore p53 and Rb are functionally related through their effects on the cell cycle. Inactivating mutations that affect either p53 or Rb promote unregulated cell growth, and mutations in both may be synergistic (83,86,170).

The role of Rb and p53 expression in bladder cancer has been a very active area of research. The p53 gene is often mutated in bladder cancer and associated with high-grade invasive lesions (117,118,138,333). Other studies have investigated the role of p53 in tumor recurrence, progression, and response to treatment such as radical cystectomy, radiation, chemotherapy, or intravesical therapy (85,263,276,366,367). Using immunohistochemistry, p53 expression generally correlates with poor outcome in terms of recurrence, progression, resistance, and survival. However, immunohistochemical analysis of p53 has caused some discrepancies when used as the sole assay for p53 mutational analysis in these studies.

Immunohistochemistry correlates with mutations that increase stability of the altered p53 protein product (118). Mutations in p53 correlated with immunohistochemistry when 20% of cells demonstrated nuclear staining in one large bladder cancer series (276). However, a positive immunohistochemical result may not be specific for the mutant protein due to biologic factors (178). This observation, combined with the technical limitations of immunohistochemistry, has led to different results using p53 as an independent variable for clinical outcome in bladder cancer (402). The clinical response of bladder cancer patients to chemotherapy is one recent example.

In one study, mutant p53 (as determined by immunohistochemical analysis) was associated with favorable outcome when cystectomy was combined with adjuvant chemotherapy (87), while in another study immunohistochemical staining of p53 was associated with decreased response to neoadjuvant chemotherapy (367).

The underlying hypotheses for each result is the ability of wild type p53 to induce apoptosis when using agents such as MVAC that cause DNA damage. Tumors with increased p53 staining (mutant p53) cannot undergo p53-mediated apoptosis induced by the chemotherapeutic agents and are therefore resistant. Alternatively, the absence of p53-mediated G_1 arrest may allow tumor cells with damaged DNA to proceed through S phase but arrest at mitosis and subsequently undergo apoptosis (440). Tumor cells with normal p53 presumably repair DNA damage before entering S-phase and then undergo mitosis. The true mechanism is currently unknown and may be dependent on the status of other proteins such as Rb, mdm-2, p21, or proteins involved in DNA repair. In addition, experimental and study design differences may prove to be the most important factor. Although p53 mutation is independently associated with higher grade, stage, and progression in most studies and may have clinical applications in the future, the practicality of using p53 immunohistochemistry instead of routine pathologic staging and grading has not been definitively proven (436).

Immunohistochemical analysis of Rb expression has also been extensively investigated in bladder cancer (82,282). Although mutations in Rb have not been associated with increased reactivity using immunohistochemistry, increased expression has been observed in some tumors (86). Absent or altered Rb staining is associated with muscle-invasive disease, and studies have associated abnormal Rb expression with poor outcome (82,86). Moreover, loss or abnormal expression of Rb combined with p53 immunoreactivity has independent and prognostic value in some studies (83,170). Investigation of p53 and Rb proves that development of bladder cancer is complex and dependent on accumulation of mutations in multiple targets. Mutations in parallel pathways may be important for development and progression of high-grade malignancy, whereas single pathway alterations are necessary for low-grade tumors.

Many chromosomal regions are associated with high rates of LOH in bladder cancer (40,52,199,236,237,310,345,350,360). However, most common and consistent area of LOH in bladder cancer are the long and short arms of chromosome 9 (224,236). At least three genes in this region are important in tumor suppression via their effect on progression through the cell cycle. The ink4a (p16, mts-1, ckn2a), and ink4b (p15, mts-2) genes encode inhibitors of cyclin-dependent kinases, and ink4a/ARF encodes a peptide that regulates p53 activity, as discussed previously. This region has a high rate of homozygous deletions in cell lines and primary tumors (51,220). Methylation and transcriptional repression may also be an important mechanism of inactivation of these genes (158). Moreover, these genes are associated with hereditary melanomas fulfilling the criteria as group one TSGs described previously.

LOH on the short and long arms of chromosome 9 is common in bladder cancer. Over 50% of superficial and invasive TCCs have LOH on chromosome 9 (235). Unlike p53 and RB, where LOH on chromosomes 17p and 13q, respectively, usually occur in high-grade lesions (52,333), chromosome 9p losses occur early and are associated with low-grade superficial TCC in addition to high-grade lesions. These findings suggest that 9p genes are important initiators in TCC, allowing growth advantage until other genetic events select more aggressive clones. Genetic alterations affecting Ink4a appear to be common in tumorigenesis (51,158,334), but the mechanism of inactivation implies that all genes in this region are important TSGs. Both p15 and p16 proteins are cdk inhibitors that function in G_1 (68). By inhibiting cdks, p16 prevents RB phosphorylation, E2F-1 remains sequestered and cells are prevented from entering S-phase. Loss of p16 and p15 activity by homozygous deletion of ink4a and ink4b allows unregulated phosphorylation of Rb and increased E2F-1 activity. Furthermore, loss of ink4a/ARF results in increased mdm-2 (due to the lack of ink4a/ARF-mediated mdm-2 degradation) and increased ubiquinin-mediated degradation of p53. Therefore homozygous deletion of these three genes affects Rb and p53 regulation of the cell cycle.

Regions on chromosomes 3p, 4q, 9q, 8p, 11q, 14q, and 18q are also associated with high rates of LOH in bladder cancer and are undoubtedly locations of group two TSGs (40,52,62,199,236,237,345,350,360). In addition, candidate TSGs on chromosomes 4 and 9 have been identified and are currently being investigated (23,198,236,345,386). The pattern of LOH and gene mutations in bladder cancer suggests a model of tumorigenesis in which inactivation of genes on chromosome 9p and 9q are early events and associated with low-grade papillary lesions (357,399). These tumors have a growth advantage but tend to remain localized to the urothelial mucosa. High-grade lesions such as CIS are associated with early 13q and 17p losses, and progression may be associated with these and other TSGs (310). The important role of TSGs in bladder cancer is well established, and the discovery of other TSGs will most likely enhance our understanding of bladder cancer pathogenesis.

Growth Factors and Growth Factor Receptors

Growth factors and their receptors have been investigated in human bladder cancer (306,392). The met gene (chromosome 7) and its ligand hepatocyte growth factor were described in another section. Trisomy of chromosome 7 in bladder tumors has been described, and therefore met gene alterations may play a role in these tumors. However, the factors most extensively studied in bladder cancer are EGF, EGFR, and ERB-B2 (a 185-kD transmembrane protein homologous to the EGFR) also known as HER-2/neu. Growth factors and their receptors have a normal role in promoting growth, and therefore most alterations cause increased expression by increasing copy number or transcription similar to oncogenes. In addition, alterations in growth factor receptors can affect intracellular signaling (418).

EGF has been studied extensively in bladder cancer and normal urothelium (306,391). Studies have shown increased expression of EGF in the basal layers of normal urothelium and increased expression in TCC. Increased levels of EGF have been detected in the urine of patients with TCC but do not correlate with tumor grade or stage (402). The EGF receptor is an independent predictor of poor survival when overexpressed in TCC (277,303). ErbB-2 is amplified and often overexpressed in bladder tumors (72,302,369). In breast cancer, erbB-2 amplification has been well documented and shown to have prognostic implications (29). Conflicting results have been reported as to the importance of amplification of this gene in bladder cancer progression (371,416).

Hereditary Predisposition and Urothelial Cancer

Although environmental agents such as smoking, organic compounds, and phenacetin have been implicated in the development of bladder cancer, hereditary bladder cancer syndromes have not been clearly defined. Clustering of TCC in families has been described, but linkage to a specific gene(s) had not been described until recently (273,340). Lynch and colleagues (287,451) described an increased incidence of upper tract TCC in an inherited cancer predisposition syndrome known as hereditary nonpolyposis colon cancer (HNPCC). Although colon cancer is the predominant malignancy found in these kindreds, extracolonic tumors, including upper tract TCC, are also prevalent in a subset of families.

The mutated genes responsible for HNPCC are highly conserved genes involved in mismatch repair (MMR) (43,127,261,325,338). At least nine human MMR genes have been identified, and several have been shown to be mutated in families with hereditary predisposition to cancer (hMSH2, hMSH6, hMLH1, PMS-1, and PMS-2); however, the most commonly mutated MMR genes in hereditary and sporadic tumors are hMSH2 and hMLH1 (338). MMR-deficient tumors have a characteristic phenotype referred to as microsatellite instablility (MSI) due to alterations in dinucleotide and trinucleotide repeats (3,210,419).

Several features of MMR in urologic malignancies deserve special attention. As mentioned previously, HNPCC is the only well-characterized hereditary cancer predisposition syndrome with increased risk of TCC. The absence of increased bladder TCC risk in HNPCC is surprising but may reflect subtle differences in cell biology of upper tract and bladder urothelium. Alternatively, the association of an increased incidence of upper tract TCC with HNPCC may have been more easily established due to the low incidence of upper tract TCC in the general population. HNPCC patients develop bladder cancer, and it would be interesting to determine if bladder tumors in HNPCC patients exhibit MSI due to inactivation of the wild type MMR gene allele.

Approximately 10% to 15% of sporadic colon cancers have MMR mutations (3). However, only about 3% of superficial bladder tumors showed MSI (157). An immunohistochemical analysis of hMSH2 expression identified 25% of TCC with reduced expression of hMSH2 and complete absence of expression in 2% (218). Decreased hMSH2 expression was predominantly found in high-grade and recurrent tumors, suggesting that alterations in MMR activity may be involved in recurrence and progression. In addition, cell lines deficient for MMR are resistant to DNA alkylating agents (204). This finding may be important for urothelial malignancies because alkylating agents are sometimes used in the treatment of superficial bladder tumors and MMR deficiency may be important for resistance to other chemotherapeutics.

INFECTIOUS AGENTS AND UROTHELIAL CANCER

Bladder cancer associated with chronic irritation, inflammation, and certain infections usually has the histologic appearance of SCC. The schistosome *S. haematobium* is one of four schistosome species that infects humans (312) and the only schistosomal infection associated with development of bladder cancer. The etiology of the SCC is related to the intense inflammatory response to the *S. haematobium* eggs deposited within the bladder wall. Molecular analysis of SCC from individuals infected with *S. haematobium* suggests that the genetic alterations are similar to nonbilharzial tumors (385). SCC development using *S. haematobium* as a

model system could be useful for investigation of immune response initiation of these tumors and response to treatment.

Markers in Urothelial Cancer

An important area in bladder cancer research is development of markers for early detection of primary or recurrent tumors, progression, and prognosis. Currently, cystoscopy with cytology is an essential component for diagnosis of urothelial malignancies. Insufficient sensitivity for low-grade cancer does not allow cytology to be used independent of cystoscopy. As a result, a number of markers have been developed and assessed for detection of urothelial malignancies (402). Currently, no single marker or test has sufficient sensitivity and specificity to replace cystoscopy and cytology in diagnosis or surveillance of bladder cancer patients.

A novel approach to detection of urothelial malignancies uses the detection of genetic alterations in the form of LOH and MSI (296). The clonal nature of tumors expands and propagates genetic alterations that can be detected using a panel of molecular markers. High sensitivity and specificity has been achieved using this technique in urothelial malignancies. However, sensitivity is achieved by screening large numbers of markers and may be impractical for routine clinical use. Similar approaches using gene expression may prove less cumbersome, but these tests have not been proven useful in a large series. In addition, tests that can predict or direct responses to standard or novel anticancer agents will need further investigation.

Conclusion

Urothelial malignancies are common due to environmental, infectious, and genetic factors. Bladder cancer is the most common manifestation of urothelial malignancy and usually exists as two histologic and pathologic diseases. Superficial disease is easily treated, but recurrence and progression are of major importance. Invasive disease is aggressive and potentially lethal because of high metastatic potential. However, the natural history of bladder cancer and its treatment makes this disease an excellent model for cancer recurrence, progression, and response to treatment. Urologists should be instrumental in the investigation of bladder cancer because management of localized disease is completely within the field of urology. Our goals as urologists, molecular biologists, and physician scientists are to develop better treatment options for advanced and metastatic urothelial malignancies and develop markers for recurrence and progression.

Most patients who have passed a kidney stone do not understand the nature of their disease and want to know why they form kidney stones. Other patients may have an easily identifiable cause such as cystinuria or renal tubular acidosis (RTA) for their stone formation. Specific and effective medical treatment programs exist for these patients. Other patients may benefit from simple measures such as increased fluid intake and dietary moderation. Patients with recurrent stone formation require a medical regimen that is designed to correct any physicochemical abnormalities.

This chapter imparts an understanding of the basic pathophysiology of urinary tract stone formation and enables the urologic practitioner to blend the medical and surgical management of urolithiasis patients.

BASIC PRINCIPLES

Biologic mineralization involves the precipitation of a poorly soluble salt, usually in association with an organic matrix. Supersaturation (SS) of the precipitating phase must be present before crystallization can occur. If at least local SS is not present, then crystallization is thermodynamically impossible. Most medical treatment programs depend on a reduction of SS to prevent further stone formation. The solubility concept is one of the most important aspects of biologic mineralization (262).

The physical chemistry of ions in an aqueous solution involves four basic concepts: ion activity, ion pairing, solubility, and relative supersaturation (RSS). The effective concentration of an ion, such as calcium (Ca^{2+}), in solution is different from its actual concentration. This effective concentration, the chemical activity, depends on the ionic strength of the solution. Through electrical field effects, the other ions in the solution affect the true chemical activity of a particular ion. The ionic strength is a measure of the magnitude of this electrical field and increases as the concentration of ions increases and their valence or charge increases. The activity of an ionic species decreases as the ionic strength increases. For a given total calcium concentration, the activity of Ca^{2+} would be greater in distilled water, which contains only the Ca^{2+} and its accompanying anions, than in urine, which contains many different ions.

The relation between ion activity, $\{Na^+\}$, and ion concentration, $[Na^+]$, is given by the following equation:

where a_1 is the activity coefficient for Na^+. Activity coefficients are always less than 1 and approach unity as the concentration of the solution decreases. The ionic strength of a physiologic salt solution, such as urine, is approximately 0.15 M. The corresponding activity coefficients for the divalent ions Ca^{2+} and $C_2O_4^{2-}$ (oxalate)

are approximately 0.3. The activity of each of these ions is less than one-third of the concentration.

Specific ions of opposite charge, such as Ca^{2+} and sulfate (SO_4^{2-}), can interact to form soluble ion pairs or complexes. These interactions effectively reduce the "ionized" concentrations of the ions involved. Many such interactions are possible in urine. Ionized calcium can be measured directly with an ion-selective electrode, but no satisfactory method has been developed to measure the free ion concentrations of those anions (especially oxalate) that participate in urinary tract mineralization.

Computer programs have been written to calculate the free ion concentrations of the major ionic species in urine, given the total concentrations of the ions, the pH, and the stability constants of the various ion pairs (94,361). (The stability constant is a measure of the strength of the association between the ions forming an ion pair.) These algorithms also permit the calculation of ionic strength, activity coefficients, and activity products. The activity product of a salt such as sodium chloride (NaCl) is given by the product of the activities of Na^+ and Cl^-: $\{Na^+\} \times \{Cl^-\}$. An estimate of SS can be made if the activity product is compared with the thermodynamic solubility product.

A solid salt added to an aqueous solution dissolves to an extent determined by the thermodynamic solubility product of the particular compound. If the solution is at equilibrium with the solid phase, the numeric value of the solubility product is equal to the product of the activities of the constituent ions of the salt. The equation for NaCl solubility is as follows:

where $\{Na^+\}$ and $\{Cl^-\}$ are the activities of Na^+ and Cl^- in equilibrium with pure, solid NaCl. Potassium (K_{sp}) is a constant at a given temperature and pH.

Within the range of physiologic urine pH, the solubilities of two common stone salts, calcium phosphate and uric acid, are pH sensitive. The equation for calcium phosphate solubility is as follows:

As the pH increases, $\{OH^-\}$ increases and hydrogen ion activity (H^+), decreases. More phosphate exists as PO_4^{3-}, and the solubility of $Ca_5(PO_4)_3OH$ decreases. Clinically, calcium phosphate urolithiasis tends to occur in alkaline urine.

The pKa at 38°C of the first dissociable proton in uric acid is 5.5 (98). In an aqueous solution of uric acid at pH 5.5 and 38°C, half exists as dissolved uric acid (HU) and half exists as urate ion (U^-): $HU = H^+ + U^-$. This physicochemical property of uric acid is responsible for the sensitive pH dependence of uric acid solubility in urine. As urinary pH increases, more of the uric acid exists as urate ion, and urate is more soluble than uric acid. The solubility of uric acid as a function of pH is shown in Table 8.1. The dramatic increase of uric acid solubility with increasing pH is the cornerstone of the medical treatment of uric acid lithiasis.

pH	Solubility (mg/L)
5.0	60
6.0	200
7.0	1,600

TABLE 8.1. SOLUBILITY OF URIC ACID AS A FUNCTION OF pH

The ratio of the calculated activity product *(AP)* to the thermodynamic solubility product (K_{sp}) is the relative supersaturation *(RSS or SS):*

If solid crystals of a salt are added to a solution of the salt, they will dissolve if SS is less than 1 and will grow if SS is more than 1. If SS is 1, the crystals will not grow or dissolve. SS (RSS ratio more than 1) of the precipitating salt must be present for stones to form and grow.

The initial step in the actual formation of a crystal is nucleation or the birth of crystals from solution (356). If the supersaturated solution is pure, nucleation may occur homogeneously at a critical level of SS. However, urine contains many foreign surfaces, such as cell membranes, that can act as heterogeneous nuclei. Heterogeneous nucleation occurs at a lower level of SS than does homogeneous nucleation and is the most common, if not the only, type of nucleation that occurs in biologic systems (104). The level of SS at which nucleation occurs often is referred to as the *formation product.* The formation product is not as precisely defined as the solubility product and is most accurately described as a range of SS that permits nucleation.

The range of SS between the solubility product and the formation product is called the *metastable zone* (Fig. 8.1). Spontaneous nucleation does not occur in this zone, but preformed crystals grow until the RSS is reduced to 1.

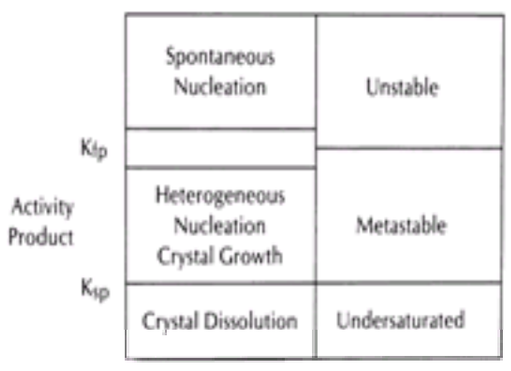

FIGURE 8.1. Schematic representation of states of saturation. K_{sp}, solubility product; K_{tp}, formation product (range).

Ideal crystals are composed of identical units arranged in a repetitive pattern. These units may be atoms, molecules, ions, or groups of these particles. In real crystals, these units are not always identical, and the pattern is not strictly repetitive. Deviations from periodicity, called *dislocations,* commonly occur in crystals

formed in biologic systems. However, all crystalline substances have an approximate periodic structure, or lattice, that can be characterized with x-ray diffraction. If the lattice structure of one crystal is similar to that of a different crystal, the second crystal may be able to nucleate and grow on the first crystal. This oriented overgrowth is called *epitaxy* (179,203). The concept of epitaxy was offered several years ago as a possible explanation for the growth of mixed urinary stones. The clinical association of disorders of uric acid metabolism (hyperuricosuria and hyperuricemia) with calcium oxalate urolithiasis motivated the intensive study of a possible epitaxial relation between urate crystallization and calcium oxalate crystallization (56,164,225). Other investigators have questioned the specific importance of epitaxial crystal growth in clinical urolithiasis (33,195,196). It is likely that mixed stone formation in the urinary tract occurs by heterogeneous nucleation and overgrowth, not by the highly specific mechanism of epitaxy.

More recent *in vitro* studies have shown that the promotion of calcium oxalate crystallization by dissolved urate is not caused by the epitaxial nucleation of calcium oxalate or by the inactivation of urinary glycosaminoglycans (119). A “salting out” mechanism may be responsible for the promotion of calcium oxalate crystallization by dissolved urate (279).

Nuclei will grow to form larger crystals if the urine remains supersaturated for the precipitating phase. The growth units of the crystal are added to growth sites on the crystal surface (216). Available evidence suggests that the growth sites of urinary crystals are screw dislocations (Fig. 8.2). As the crystal grows, the step winds itself into a spiral with the center fixed at the dislocation. Because the step does not disappear during growth, the crystal can grow continuously at a low SS. The crystal grows as long as the bathing solution remains supersaturated for the precipitating phase.

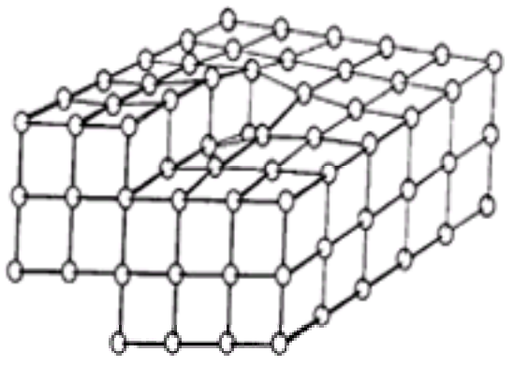

FIGURE 8.2. Schematic representation of a crystal with a screw dislocation.

Many collisions occur between the small crystals in an aqueous solution. Some of these crystals may stick together to form larger crystalline masses. This process is called *aggregation* or *agglomeration;* it is another mechanism by which crystals can increase in size to form a stone. Crystal growth produces a more dense particle than does aggregation (95). The density of actual uroliths is similar to that of pure stone crystals. This implies that urinary tract stones increase in size primarily through crystal growth, not aggregation. However, initial particle retention could still involve crystal aggregation.

CLINICAL STONE FORMATION

Why do some people form many kidney stones? Four factors are involved: urinary SS, inhibition and promotion, particle retention, and matrix (34). Our understanding of the pathophysiology and effective treatment of urolithiasis is based on these four factors.

Supersaturation

Urinary SS for the precipitating stone salt is a necessary condition for stone formation. It is thermodynamically impossible for a stone to grow if the urine is not supersaturated for the particular salt, but continuous SS does not have to be present. Urine may become supersaturated after meals. This effect may be accentuated after the evening meal, because the lack of fluid consumption during sleep permits a decrease in overnight urine volume. Stone growth can occur only at night, even though daytime fluid intake is sufficient to prevent SS.

Inhibitors and Promotors

Urinary SS alone does not explain the presence of stone disease in some individuals and its absence in others. Urine commonly is supersaturated for stone salts, especially calcium oxalate (110,270). Small urinary crystals often are passed by individuals who have never formed a stone (271,359). One explanation for this apparent paradox is the presence of crystallization inhibitors in urine (100). Inhibitors of crystal growth and aggregation have been isolated from human urine, and inhibitors of nucleation may exist (272,280); inhibitors of crystal growth have received the most attention (101). Inhibitors usually are classified according to their ability to inhibit the growth of calcium phosphate or calcium oxalate. Pyrophosphate, citrate, and magnesium are known inhibitors of calcium phosphate crystal growth. Pyrophosphate and citrate also inhibit calcium oxalate crystal growth (299), but most of the calcium oxalate crystal growth inhibition in urine is provided by larger-molecular-weight polyanions: glycosaminoglycans and RNA fragments (21,37,197,293). Heparin, although not found in urine, is a potent inhibitor of *in vitro* calcium oxalate crystal growth.

Acidic glycoproteins have been isolated from human urine and human kidney tissue culture medium (141,212,213). Evidence shows that patients with calcium oxalate nephrolithiasis have intrinsically abnormal acidic glycoproteins (210). These glycoproteins from healthy persons contain g-carboxyglutamic acid and are strong inhibitors of calcium oxalate crystal growth at low concentrations (10 to 7 M). Glycoprotein crystal growth inhibitor from patients does not contain g-carboxyglutamic acid and is a functionally poor inhibitor.

This glycoprotein inhibitor of calcium oxalate crystal growth has been named *nephrocalcin* (209). Nephrocalcin has been isolated from human calcium oxalate renal stones (211) and appears to localize to the proximal tubule cells of the human kidney (312). The g-carboxyglutamic acid residues of nephrocalcin are synthesized by the addition of a carboxyl group to the g-carbon of glutamic acid residues after messenger RNA translation. The same investigators have reported that nephrocalcin and Tamm-Horsfall glycoprotein inhibit calcium oxalate crystal aggregation at concentrations as low as 2×10^{-8} M and 1×10^{-8} M (132).

Tamm-Horsfall protein is a glycoprotein that is produced in the thick ascending limb of Henle's loop. It inhibits calcium oxalate monohydrate crystal aggregation at a low ionic strength and a high urinary pH (131). In highly concentrated urine, Tamm-Horsfall protein readily polymerizes, thereby overwhelming other urinary inhibitors and promoting the agglomeration of calcium oxalate monohydrate crystals (118,294).

Uronic acid–rich protein, another glycoprotein that has been isolated from human urine, also exhibits inhibitory activity against crystal growth (8). It appears to be a more potent inhibitor than nephrocalcin.

Patients who form stones appear to excrete more lipids or acid phospholipids than normal individuals. Urinary excretion of glycolipid, cholesterol, and cholesterol esters also was higher in stone-formers (154). The greater excretion of lipids may reflect sloughing of tubular cells in response to a challenge by oxalate or calcium oxalate crystals. Acid phospholipids from cellular membranes may be involved with crystal nucleation and retention.

Citrate, through its ability to complex calcium and inhibit the growth of calcium salts, may play a role in the pathogenesis of calcium urolithiasis. Citrate is a tricarboxylic acid that, when totally ionized above pH 6.5 at 37°C, has a charge of minus 3:

The following reactions occur with calcium in urine at a physiologic pH:

As the concentration of citrate increases, the reaction is shifted toward the left with increased complexation of calcium. This effect decreases calcium oxalate SS and the potential for crystallization. Citrate weakly inhibits the growth of preformed calcium oxalate crystals, but this action is not as important as complexation.

Citrate is filtered at the glomerulus and reabsorbed primarily in the proximal tubule (309). The ability of renal mitochondria to metabolize citrate by means of the tricarboxylic acid cycle is thought to control the renal clearance of citrate. Metabolic acidosis increases the entry of citrate into the matrix space of mitochondria and decreases the exit of citrate from mitochondria, thereby allowing mitochondrial oxidation of citrate. Cytoplasmic citrate levels decline, reabsorption of citrate from tubular fluid is enhanced, and less citrate appears in the final urine. Metabolic alkalosis has an opposite effect.

The luminal membrane of the proximal tubules (brush border membrane) is equipped with a Na^{+}}-gradient–dependent transport system that is highly specific for intermediates of the tricarboxylic acid cycle, including citrate (157). Metabolic acidosis caused by dietary acid loading increases the intrinsic capacity of proximal tubular brush border membrane to transport citrate from the tubular lumen into the cell interior (143). A corresponding decrease in urinary citrate excretion was seen. A dramatic increase in urinary citrate excretion was seen with dietary alkali loading (with $NaHCO_3$), but brush border membrane transport of citrate was unchanged. These studies demonstrate that urinary citrate excretion is exquisitely sensitive to manipulation of systemic acid–base balance through effects on renal cellular function.

Urine from patients with recurrent calcium oxalate nephrolithiasis tends to have greater calcium oxalate SS and lower inhibitor levels than urine from healthy individuals (76,271), but considerable overlap exists. It is impossible to predict consistently on the basis of SS or inhibition alone who will and who will not recurrently form calcium oxalate stones. A combination of these two factors, the saturation-inhibition index, has discriminated between healthy individuals and patients with recurrent stone formation (269). The saturation-inhibition index is a mathematic combination of relative calcium oxalate and inhibition of crystal growth and aggregation (as measured by the change in particle-size distribution in an *in vitro* crystal growth system). Patients with the greatest saturation-inhibition indexes had the highest recurrence rates. Because SS and inhibition are difficult to measure, this method has not had widespread clinical application.

The concept of urinary risk factors is an extension of the saturation-inhibition index. This concept attempts to account for the multifactoral nature of calcium urolithiasis by considering six factors (236,266,267): urine volume, urine pH, urinary excretion of oxalate, uric acid, calcium, and alcian blue precipitable polyanions (a measure of acid mucopolysaccharides or large-molecular-weight inhibitors). Although no solitary abnormality may distinguish a stone-former, clear discrimination can be made by the presence of several risk factors. A low urine volume has the greatest risk, followed by a high urinary oxalate excretion. A high urine pH or uric acid excretion is associated with a higher probability of forming stones. Hypercalciuria is the least important risk factor.

Crystal Retention

Freshly voided urine samples from most healthy persons intermittently contain small crystals (usually calcium oxalate dihydrate), but only 5% to 10% of such persons will ever develop an actual kidney stone. These crystals probably form in the papillary collecting ducts and are flushed out with the urine before they grow large enough to become lodged in the lumen. Anatomic abnormalities or adherence to the epithelium may prevent these particles from leaving the kidney. This increased particle retention permits the crystals to grow larger, further reducing the likelihood that they will be passed spontaneously (35). This condition could easily predispose an individual to the formation of kidney stones. An attractive hypothesis is that patients with stone disease may have an increased particle retention time, possibly resulting from an abnormal tendency for small crystals to adhere to the epithelial lining of the upper urinary tract.

Two theoretical mechanisms have been proposed for crystal retention: free particle or fixed particle. The free particle mechanism assumes that nucleation and initial crystal growth occur in the tubular lumen. The crystalline particles grow with such sufficient rapidity that they become trapped in the papillary collecting ducts, where they grow to form a macroscopic stone (350). Estimates of calcium oxalate crystal growth rates in the distal tubule have cast doubt on the ability of these crystals to grow rapidly enough to occlude the lumen before they are washed out of the collecting ducts (97). Some investigations have suggested that rapid aggregation of small crystals would permit free particle trapping to occur.

More support exists for the second theory, a fixed particle mechanism. Rats with magnesium deficiency develop nephrocalcinosis and stone formation (219). Small stones were found attached to normal-appearing tubular epithelium near the bend of Henle's loop. This intranephronic calculosis may have occurred by crystal nucleation on the luminal membrane or attachment of a passing crystalline particle. Carr (38) suggested that crystals floating in the renal pelvis could be trapped in forniceal lymphatic vessels and grow to macroscopic size. Papillary tip stones could originate from crystals that had become attached to the epithelial lining of the distal collecting ducts and had grown out of the lumen to form a papillary cup (351). Randall's plaques (254) are macroscopic subepithelial deposits of calcium crystals. Although older studies found a poor correlation between the incidence of stone disease and the incidence of Randall's plaques, it was still hypothesized that the epithelium over the plaque could erode, and a calyceal stone could develop from crystal growth on the plaque (252). More recent studies of Randall's plaques have found that they are not just subepithelial deposits (326); they appear to extend deep into the papilla and are intimately associated with collecting tubules and vasa recta. These same investigators found that papillary plaques were more common in patients with calcium oxalate and calcium phosphate stones than in patients without a history of stone disease (180). Endoscopic examinations found that most patients with calcium stone disease had Randall's plaques.

Investigators have induced calcium oxalate nephrolithiasis in rats with intraperitoneal injections of oxalate (146,151). Calcium oxalate crystals were found in the tubular lumina, in the intercellular spaces between cells, and attached to the tubular epithelial basal lamina. Necrosis of tubular cells was responsible for exposure of the tubular basal lamina. Oxalate itself may be toxic to renal epithelium (166,331), and renal tubular epithelial damage can result in the shedding of membranous cellular debris, thereby providing a substrate for heterogeneous nucleation (153).

The attachment of crystals to the kidney epithelium may involve a specific molecular interaction between stone crystals and the epithelial membrane. Rat renal inner-papillary collecting tubule cells have been isolated in primary cultures and used as a model for the study of crystal-membrane interactions (358). Riese and colleagues (258) developed a mathematic model of the binding of calcium oxalate crystals to these cells. This binding is location specific, saturable, and inhibitable. Calcium oxalate crystal binding appears to be related to cell membrane polarity (259). This binding is enhanced if a monolayer of cultured cells is depolarized by disrupting the normal intercellular tight junctions. These results suggest that the crystals preferentially attach to a basolateral cell membrane component. Renal epithelial cells also can endocytose calcium monohydrate crystals (175). Other studies continue to confirm the ability of calcium oxalate monohydrate crystals to specifically bind to cultured renal epithelial cells (22,163,176).

The most provocative hypothesis regarding stone formation involves nanobacteria (147). Nanobacteria are sterile-filterable, Gram-negative, atypical bacteria that have been detected in bovine and human blood. They produce carbonate apatite on their cell walls and could potentially act as nidi for the precipitation of other stone salts, such as calcium oxalate. The smallest apatite units in kidney stones resemble the site and morphology of nanobacteria by scanning electron microscopy (48). One investigator has isolated nanobacteria from more than 90% of nonstruvite kidney stones.

Meticulous work by Delatte and associates (72) revealed that small calcium oxalate stones are not uniformly round but have one surface with a concave depression. A small crystalline aggregate of calcium phosphate sometimes was found in this depression. Clinically significant growth of calcium oxalate stones may be initiated by epithelial precipitation of calcium phosphate that subsequently is overgrown with calcium oxalate (114,124,341).

Matrix

Kidney stones contain a variable amount of organic material called *matrix.* The matrix content of most urinary calculi is 2.5% by weight (25). Cystine stones contain approximately 10% matrix. The rare matrix calculus is a soft, radiolucent body that occurs in patients whose upper urinary tracts are infected with urea-splitting bacterial organisms (253). The matrix content of these calculi averages 62%.

Macroscopic examination of whole renal calculi reveals concentric laminations and radial striations (25). Scanning electron microscopic studies of fractured calcium oxalate calculi demonstrate fibrous material bridging adjacent crystals (321). These findings support the proposal that matrix acts as a ground substance (153).

Other investigators believe that the presence of matrix in urinary stones is serendipitous (99). Nonspecific physical adsorption of organic compounds on growing crystals may account for at least some of the matrix found in calculi (169). Electron microscopic examination of calcium oxalate crystals incubated with g-globulin or albumin has revealed an amorphous coat of material covering the crystals (146). This continuous coat is consistent with simple adsorption.

Few studies have attempted to isolate and precisely identify the chemical composition of matrix. The best known investigations found similarities between urinary mucoproteins and matrix material that was extracted from renal stones with ethylenediaminetetra-acetic acid (EDTA). A mucoprotein material, matrix substance A, was identified in urine from patients with recurrent stone disease (27). This organic compound constituted approximately 85% of the total organic matrix of kidney stones. One-third of matrix substance A was carbohydrate and two-thirds was protein. Aspartic and glutamic acids were the most common amino acids found in the protein component. The carbohydrate component contained galactose, mannose, methylpentose, glucosamine, and galactosamine (24). Studies of dialyzed ultrafiltrates of matrix also found aspartic and glutamic acids. Alkaline hydrolysis revealed the presence of g-carboxyglutamic acid (174). Proteins containing this amino acid have a strong affinity for calcium ions.

Urinary stone protein, or uropontin, is an aspartic acid–rich glycoprotein that is found in stone matrix (161). It binds calcium and has the same structure as osteopontin, which is found in bone and other mineralized tissue (36). Increased staining of distal renal tubular cells for this glycoprotein is seen in rats that have been induced to form stones by the administration of glyoxylic acid (160).

Uropontin also has been isolated from urine and is a potent inhibitor of the nucleation, growth, and aggregation of calcium oxalate crystals and the binding of these crystals to renal epithelial cells (202). Uropontin concentration in urine appears to vary inversely with urine volume. Its ability to prevent calcium oxalate crystallization would increase as urinary concentration increases.

EPIDEMIOLOGY

In the United States and in other technologically developed countries, urolithiasis commonly occurs as upper tract stones. Bladder stones are more common in less-developed countries (7). Epidemiologic data suggest that climate, geography, and diet are important factors in the pathogenesis of urolithiasis (261). The best-known example of this influence is the apparent existence of “stone belts.” These are geographic areas that are associated with a high prevalence of stone formation (134). A questionnaire survey of hospitals estimated that, during 1952, 0.95 persons per 1,000 population were admitted to a hospital with a diagnosis of urinary calculi (26). A rate of 1.93 per 1,000 population in South Carolina and 0.43 per 1,000 in Missouri provided evidence of geographic variability. Each of the southeastern states had a high rate of urinary calculi. A more recent study found that 1.64 persons per 1,000 population were admitted to a hospital with the diagnosis of urolithiasis, an increase of 75% over the 22-year period (303). High rates were again found in the southeastern states, especially in the Carolinas (North Carolina, 3.0 per 1,000 population; South Carolina, 2.7 per 1,000 population), but the differences were not statistically significant.

Studies of hospitalization rates may underestimate the number of patients with urolithiasis because not all patients with stones are hospitalized (145). A study of residents of Rochester, Minnesota, found that 51% of patients with stone disease were seen only as outpatients. These investigators precisely defined their epidemiologic terms and the population under study. *Incidence* was defined as the first symptomatic and diagnosed episode in a person's life. The *incidence rate* was the ratio of the number of persons who experienced such initial episodes during a specified period to the size of the population at the midpoint of the period. *Prevalence* was the number of people who had had at least one symptomatic episode, whereas *recurrence* referred to episodes that followed the initial episode. Patients with asymptomatic stones, urinary tract infections, or struvite calculi were excluded from this study.

Six hundred seventy-two persons had their first episode of symptomatic urolithiasis while a resident of Rochester, Minnesota: 468 (70%) men and 204 (30%) women. The first episode tended to occur between the ages of 30 and 60 years. The annual age-adjusted incidence rate for males was 1.1 per 1,000 population and for females it was 0.36 per 1,000 population. The incidence rates for females were stable over the 25-year study period (1950 to 1974), but the male rate per 1,000 population increased from 0.8 to 1.24. This increase was statistically significant and most apparent in the group of men aged 50 to 70 years. Prevalence was estimated to increase to a peak of approximately 12% in males older than age 70 years. Prevalence in females was less than 5%. Recurrences tended to occur during the first year: 15.9% in males and 12.4% in females. Annual recurrence rates for subsequent years was 3.7% for males and 2.0% for females.

Studies of racial differences in the incidence of urolithiasis have been inconsistent. A retrospective review found that the frequency of urinary stones in Caucasian patients was three to four times that in African American patients (289). More African American women than African American men formed stones, and the most common type of stone formation in African American patients was struvite and carbonate apatite. Stones tended to occur at a younger age in African American males.

Normal pregnancy causes hypercalciuria, but pregnancy is not a stone-forming condition (57,182). Abnormal crystalluria is not seen in pregnant patients, and more frequent stone production is not seen in stone-formers who become pregnant. A prospective study of 11 women revealed no change in urine volume (183). Although citrate excretion increased during pregnancy, this increase was not proportional to the increase in urinary calcium. Citrate failed to increase in parallel with calcium excretion, even though the urine pH rose. SS for calcium oxalate and brushite was as high in pregnancy as in patients with proven calcium nephrolithiasis. One explanation for the lack of clinical stone formation is the relatively short duration of pregnancy. Another explanation is an increase of protective mechanisms, such as crystal growth inhibition. Nephrocalcin excretion may increase during pregnancy.

Many explanations have been offered for the increasing incidence of kidney stones in the world population. These include increased dietary protein intake, increased intake of refined sugar, decreased dietary fiber, and increased affluence. Recurrent stone formation is associated with a greater expenditure on food (378). There is a positive correlation between monthly income and urinary excretion of calcium, uric acid, and inorganic phosphorus. Stone-forming patients may consume less dietary fiber than those who do not form stones (260). One explanation is that fiber, possibly through its phytate content, binds calcium in the gastrointestinal (GI) tract and prevents its absorption. The relationship between stone disease and sugar consumption is more controversial. Increased dietary sugar can increase urinary calcium excretion (338), but epidemiologic data show an inverse relationship between sugar consumption and hospitalization rates for stone disease (260).

High consumption of animal protein seems to correlate best with affluence and stone disease (266,268). Individuals on a high-protein diet excrete more urinary calcium, cyclic adenosine monophosphate, and hydroxyproline (93). The increased fixed acid load provided by a high-protein diet may cause mild resorption of bone and reduced renal tubular reabsorption of calcium. GI absorption of calcium is not affected. Calculated urinary SS for calcium oxalate does not change, but urinary citrate excretion and pH decrease. The reduced effectiveness of crystal growth inhibitors at the lower urinary pH would allow the growth of larger crystals.

Salt abuse also is a risk factor for kidney stone formation (111). A high sodium intake significantly increases urinary sodium, calcium, and pH, and decreases urinary citrate (283). Urinary saturation of calcium phosphate and monosodium urate increases, and inhibitor activity against calcium oxalate crystallization increases. The net effect is a higher likelihood for the precipitation of calcium salts in urine.

The relation between the composition of drinking water and urolithiasis has been examined in several studies. Dissolved calcium and magnesium are responsible for the hardness of water. The incidence of urolithiasis tends to be higher in areas of the United States that have softer drinking water (44,304). Another study examined two specific geographic regions: North and South Carolina, which had soft water and a high stone incidence, and the Rockies (Colorado, Idaho, Montana, Nevada, Utah, and Wyoming), which had hard water and a low stone incidence (300). No significant differences were found for the concentration of calcium, magnesium, or sodium in home tap water. An incidental finding was that individuals drinking private well water had a greater risk of stone formation than those drinking public water. The authors concluded that water hardness should be a minor concern with respect to stone formation.

Patients with calcium stone formation often are advised to limit their intake of dietary calcium. This advice is based on the presence of hypercalciuria in up to half of patients with idiopathic calcium urolithiasis (ICU). However, restriction of dietary calcium may increase the risk of stone formation by enhancing dietary oxalate absorption and urinary oxalate excretion (188). A prospective study in a cohort of 45,619 men without a history of kidney stones found an inverse relationship between the relative risk of kidney stone formation and dietary calcium intake (62). Stone formation was negatively correlated with fluid intake but positively correlated with intake of animal protein.

The inverse relationship between stone formation and dietary calcium content is consistent with the hypothesis that mild hyperoxaluria is more important than hypercalciuria in the pathogenesis of urolithiasis (263). One of the determinants of urinary oxalate excretion is intestinal oxalate absorption. Intestinal oxalate absorption is influenced by the oxalate-to-calcium ratio of the diet, because oxalate that is bound to calcium is not absorbed. Enhanced absorption of “free” oxalate could occur if dietary calcium is restricted or intestinal absorption of calcium is enhanced (108).

Oxalobacter formigenes is a specific oxalate-degrading, anaerobic bacterium that colonizes the GI tracts of vertebrates, including humans. It appears to maintain a symbiotic relationship with its host by regulating oxalate absorption (2). It catabolizes free oxalic acid, thereby preventing absorption, and also enhances oxalate secretion from plasma. Fecal samples from patients with Crohn's and other inflammatory bowel diseases lack *O. formigenes* and have a low rate of oxalate degradation (3). When noncolonized laboratory rats were colonized with live bacteria or treated with a preparation of oxalate-degrading enzymes derived from *O. formigenes,* they developed increased resistance to a subsequent high oxalate challenge, excreted far lower levels of oxalate, and did not develop crystalluria, as seen in control animals (302).

Excessive sweating also may contribute to stone formation. Moderate physical exercise lowers urinary pH and citrate excretion due to a mild metabolic acidosis (285). Although the total excretion of stone-forming salts decreases, the greater decrease in urine volume results in an increase in urinary calcium oxalate SS and the concentration of undissociated uric acid (secondary to an increase in total uric acid concentration and a fall in urinary pH). Nephrolithiasis is more prevalent in machinists chronically exposed to a hot environment (e.g., a glass plant) (23). These individuals had higher urinary uric acid concentrations than individuals who worked in an environment with a normal temperature. This biochemical difference was clinically expressed by uric acid stone formation in 39%.

Another study found a positive association between urinary stone disease and consumption of carbonated beverages (e.g., sugared cola) (301). A negative association existed between coffee and beer consumption and stone disease in the Rockies. Primary intake of milk, water, or tea was not associated with urinary stone disease.

The widespread consumption of iced tea has been suggested as a reason for the high incidence of urolithiasis in the southeastern United States. Although dietary oxalate is responsible for only 10% to 15% of total urinary oxalate (138), urinary oxalate excretion increases after the ingestion of oxalate-rich foods such as spinach (330). A case-control study from Newfoundland examined tea consumption in stone-formers but found no evidence to support the suggestion that tea drinking is a risk factor for calcium oxalate urolithiasis (46). These investigators calculated that 1 cup of tea would add only 0.5 mg of oxalate to total urinary excretion.

ETIOLOGY

A classification of causes of urolithiasis is given in Table 8.2. The syndrome of ICU accounts for 70% to 80% of stone disease in industrialized nations. Inherited enzyme disorders or renal tubular syndromes are found in fewer than 1% of stone-forming patients. Primary hyperparathyroidism is the most common hypercalcemic condition associated with urolithiasis and is responsible for stone formation in 5% of patients.

Renal tubular syndromes	Enzyme disorders
Renal tubular acidosis	Primary hyperoxaluria
Cystinuria	Xanthinuria
Hypercalcemic disorders	2,8-Dihydroxyadeninuria
Primary hyperparathyroidism	Secondary urolithiasis
Immobilization	Enteric hyperoxaluria
Milk-alkali syndrome	Infection
Sarcoidosis	Obstruction
Hypervitaminosis D	Medullary sponge kidney
Neoplastic diseases	Urinary diversion
Cushing's syndrome	Drugs
Hyperthyroidism	Idiopathic calcium urolithiasis
Uric acid lithiasis	Hypercalciuria
Idiopathic	Normocalciuria
Gout	
Low urine output states	
Myeloproliferative diseases	

TABLE 8.2. CAUSES OF UROLITHIASIS

Renal Tubular Acidosis

RTA is a syndrome of disordered renal acidification that causes a hypokalemic hyperchloremic metabolic acidosis (156). The inability to excrete normal amounts of acid into the urine may be responsible for the entire syndrome, because the administration of sodium bicarbonate corrects the hyperchloremic acidosis and the excessive urinary losses of potassium, calcium, and phosphorus (297).

Two basic types of defective urinary acidification have been identified in these patients. Patients with type 2 RTA (proximal) have a defect in the reabsorption of filtered bicarbonate, a process that occurs in the proximal tubule (204). When the plasma bicarbonate is reduced only moderately, the urinary pH is inappropriately high, but with the development of a more severe systemic acidosis the bicarbonaturia disappears and the urinary pH decreases to a normal minimum. Patients with the most frequently studied disorder, type 1, or classic, RTA (distal) have a normal capacity to reabsorb filtered bicarbonate but cannot lower the urine pH below 6.0, regardless of the severity of the systemic acidosis (325).

Classic RTA may exist as a primary or secondary form. The primary form may be subdivided into infantile or adult types. Adult, or persistent, primary RTA occurs predominantly in females. Most of the cases are sporadic, but the disease may be inherited as an autosomal-dominant trait (32). The reclamation of filtered bicarbonate is intact in the proximal tubules, but the distal tubule is unable to generate or maintain steep lumen-peritubular hydrogen ion gradients.

The electrolyte abnormalities are responsible for the symptoms. Chronic acidosis may contribute to the impaired growth of children with type 1 RTA (191), because the retained acid is buffered in bone (86). Although urinary wasting of calcium and phosphorus may lead to osteomalacia, the hyperchloremic acidosis is so readily detected that patients rarely are left untreated long enough to develop this complication. Urinary potassium wasting may result in severe hypokalemia and a flaccid paralysis.

Nephrolithiasis occurs in 70% of patients with distal RTA (142,347). Multiple calculi usually are present in both kidneys. Nephrocalcinosis is found in approximately three-fourths of adults with type 1 RTA (28). Stone formation is related to hypercalciuria, relatively alkaline urine, and low urinary citrate excretion. Reduced urinary excretion of pyrophosphate, sulfate, and inhibitors of hydroxyapatite and of crystal growth also may contribute to clinical stone formation.

The diagnosis of distal RTA is made when systemic acidosis (serum bicarbonate less than 20 mEq/L) is present and urine pH is greater than 5.5 (42,167). An ammonium chloride (NH_4Cl) load often is used as a stress test to confirm the diagnosis. Liquid NH_4Cl (100 mg/kg as a 5% solution) is given in the evening; the patient voids at 6 AM on the following day, drinks three 8-ounce glasses of water, and voids again at 7:30 AM. The pH of this latter urine specimen is measured with a pH meter. The pH of this urine sample is between 5.0 and 5.5 in a healthy individual. If the pH is greater than 5.5 and the serum bicarbonate is greater than 20 mEq/L, the NH_4Cl load is repeated. The urinary pH measurement is repeated in 4 hours.

The distal tubular acidification mechanism is intact in type 2 or proximal RTA, but the reabsorption of filtered bicarbonate is reduced in the proximal tubule (205). Proximal RTA usually is associated with an underlying disorder of proximal tubular function, such as Fanconi's syndrome, hereditary fructose intolerance, Wilson's disease, or multiple myeloma. The most common cause of proximal RTA in adults is intestinal malabsorption that leads to vitamin D deficiency, hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia (207). Proximal RTA is not associated with stone formation.

Previously, infants and children with a distal acidification defect and bicarbonate wasting were believed to have had type 3 RTA. This term is no longer used because the bicarbonate wasting is thought to reflect the same defect in renal acid excretion that causes type 1 RTA in adults (192). The reduction in acid excretion is secondary to the renal bicarbonate wasting as a cause of the acidosis. Adults with type 1 RTA excrete 1% to 3% of filtered bicarbonate, whereas infants and children with this disorder excrete 6% to 14% of filtered bicarbonate.

The term *type 4 RTA* has been applied to an acidification defect that may accompany a reduction in the renal clearance of potassium. This disorder is thought to involve the cation-exchange segment of the distal nephron, where aldosterone stimulates hydrogen ion secretion. Type 4 RTA may be the most common form of RTA, and often is associated with the syndrome of hyporeninemic hypoaldosteronism (18). Hyperkalemic distal RTA also has been found in patients with obstructive

uropathy (18). Type 4 RTA is not associated with nephrolithiasis.

Some patients with recurrent calcium urolithiasis are not systemically acidotic but are unable to lower their urine pH after an NH_4Cl load (31). Both proximal and distal acidification defects have been identified in stone-formers with the syndrome of incomplete RTA (10,221,337). Patients with these disorders tend to develop stone disease at an earlier age, have more frequent recurrences, and grow larger stones. Hypocitruria and hypercalciuria usually are present. The hypercalciuria is unexplained because these patients do not have systemic acidosis. Serum electrolyte concentrations are normal, and a standardized acid loading study is required for the diagnosis of incomplete RTA.

Urolithiasis is a complication of long-term treatment with carbonic anhydrase inhibitors (241,336). Carbonic anhydrase, which catalyzes the hydration of carbon dioxide, is present in both the proximal and distal nephrons. Because carbonic anhydrase aids the proximal reclamation of filtered bicarbonate and the distal secretion of hydrogen ions, the administration of an inhibitor of the enzyme, such as acetazolamide, causes a proximal and distal RTA. Treatment with acetazolamide produces alterations in the ionic composition of urine, such as a low citrate concentration, which closely resemble those found in untreated distal RTA (126,308). All of the changes can be reversed by stopping administration of the carbonic anhydrase inhibitor.

Cystinuria

Cystine is a disulfide composed of two cysteine molecules (Fig. 8.3), and its pKa is 8.0. Cystinuria is an inherited disorder of amino acid metabolism in which transport of *c*ystine, *o*rnithine, *l*ysine, and *a*rginine in the renal tubule and GI tract is defective. (The mnemonic "COLA" or "COAL" can be used to remember these four amino acids.) The defect is transmitted as an autosomal-recessive trait. This disorder would be a metabolic curiosity if it were not for the relative insolubility of cystine in urine (61,63). Approximately 300 mg of cystine is soluble in 1 L of urine at a pH of 7.0; the solubility of cystine more than doubles as the pH rises above 7.5 (Fig. 8.4). Homozygotes excrete large amounts of cystine, lysine, arginine, and ornithine in their urine.

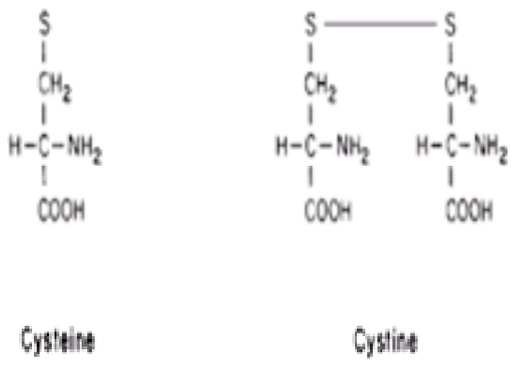

FIGURE 8.3. Structures of cysteine and cystine (a disulfide).

FIGURE 8.4. The pH dependence of the solubility of cystine. (Modified from Dent CE, Senior B. Studies on the treatment of cystinuria. *Br J Urol* 1955;27:317, with permisison.)

Cystinosis, another recessively inherited metabolic disorder, may be confused with cystinuria. Cystinosis is characterized by the intracellular accumulation of excessive quantities of cystine (291). Crystal deposition occurs in the cornea, conjunctiva, bone marrow, lymph nodes, leukocytes, and internal organs. All patients with nephropathic cystinosis have a generalized amino aciduria, but the daily excretion of cystine is only 5% to 10% of that found in patients with cystinuria. Children with cystinosis tend to produce a relatively alkaline urine, and stone formation rarely occurs.

Cystinuria is manifested clinically by the formation of homogeneous radiodense calculi that may have a branched configuration. Multiple small satellite stones may accompany a large stone. The stones have the gross appearance of maple sugar and tend to be hard and tough. Hexagonal cystine crystals may be present in a voided urine sample, especially one that is concentrated and acidified. The diagnosis is confirmed by the analysis of a stone and the finding of increased urinary cystine on an amino acid analysis. Urine can be screened with the cyanide-nitroprusside test, which is positive if more than 75 to 125 mg of cystine per gram of creatinine is present (63). This test does not differentiate homozygotes from heterozygotes. A new test kit based on the reaction of cystine with nickel ion and sodium hyposulfite has been marketed by Mission Pharmacal Company (107). This convenient method can be used to screen patients who are interested in extracorporeal shock wave lithotripsy (ESWL), but whose stones have a radiographic appearance strongly suggestive of cystine.

Urinary excretion of cystine is less than 30 mg per day in healthy adults. Heterozygous adults excrete less than 400 mg of cystine per day and usually do not form stones. Daily urinary cystine excretion is usually greater than 400 mg in homozygous cystine stone-formers. No overlap in cystine excretion has been demonstrated between well-confirmed homozygotes and heterozygotes (60).

Hypercalcemic Disorders

Primary hyperparathyroidism is the most common disorder associated with hypercalcemia and urolithiasis. It is found in approximately 5% of patients with stone disease (6). The diagnosis is based on the presence of hypercalcemia with an inappropriately elevated parathyroid hormone (PTH) level.

PTH is synthesized in the chief cells of the parathyroid gland and is split into at least two major fragments after being secreted into the circulation (148). The N-terminal fragment is responsible for the biologic activity and has a short half-life. The C-terminal fragments have longer half-lives but no biologic activity. PTH increases bone resorption, increases renal reabsorption of calcium, decreases renal absorption of phosphate, and augments renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, thereby increasing intestinal absorption of calcium (177,320). All of the effects of PTH tend to increase the serum concentration of calcium, which exerts negative feedback control over the secretion of PTH. The phosphaturia in patients with primary hyperparathyroidism may lead to hypophosphatemia, but most patients have normal serum phosphate concentrations. A liberal dietary phosphate intake may compensate for the phosphaturia.

A single adenoma, usually chief cell, is responsible for the disease in 80% of patients (113). Chief cell hyperplasia is found in most of the remaining 20%. The hypercalcemia and inappropriately high PTH levels found in patients with primary hyperparathyroidism are caused by the relatively autonomous function of the adenomatous or hyperplastic tissue.

The clinical presentation of primary hyperparathyroidism has changed over the past 20 years. Generalized osteitis fibrosa cystica is extremely rare, and the incidence of urolithiasis has decreased. A population study in Rochester, Minnesota, from 1965 through 1976, found that the average annual incidence of cases of primary

hyperparathyroidism increased from 7.8 persons per 100,000 population to 51 per 100,000 population (127). This dramatic increase in the apparent incidence occurred immediately after routine measurement of serum calcium was begun in 1974. The frequency of urolithiasis decreased from 51% to 4%. The proportion of patients without symptoms or complications increased from 18% to 51%. A more recent study found that fewer than 2% of patients with renal stones had primary hyperparathyroidism (295). Bone demineralization occurs with a similar frequency in patients with and without stone disease (306).

The reason for stone formation in patients with hyperparathyroidism and urolithiasis is not known. Patients have urine that is supersaturated with respect to calcium stone salts whether or not stone disease is present (233), and the magnitude of SS is not greater for patients with stones. Patients with hyperparathyroid-induced stone formation may have been predisposed to form stones. One study found that hyperparathyroid stone-formers excreted less citrate than non—stone-formers (4).

Immobilization may be complicated by hypercalcemia, hypercalciuria, and stone formation. The hypercalcemia and hypercalciuria may be especially severe in adolescents with active bone growth. Approximately 10% of patients with traumatic spinal cord injuries develop renal calculi (77). The risk of stone formation is greatest during the first 3 months after injury. Urinary calcium excretion exceeds normal levels at approximately the fourth week of immobilization and reaches maximum levels at 16 weeks. The hypercalciuria may persist for 12 months but resolves by 18 months. Resorption of bone appears to be the primary process. Serum calcium levels are elevated or in the high-normal range. Hypercalcemia and nephrolithiasis also have been reported in patients with multiple fractures (218).

Hypercalciuria and hyperphosphaturia occur during the weightlessness of space travel, but there has been no evidence of clinical stone formation (181). Long-term bed rest is used as a model to study the effects of weightlessness on metabolism. Such studies at simulated high altitudes disclosed that urinary losses of calcium were significantly smaller at a higher altitude. Exercise does not prevent hypercalciuria (140).

Nephrocalcinosis and renal insufficiency may occur with the milk-alkali syndrome and vitamin D intoxication. Stone formation also occurs in sarcoidosis, where there is increased intestinal calcium absorption, hypercalcemia, and hypercalciuria (39,128). Hypercalcemic patients with sarcoidosis have elevated serum levels of 1,25-dihydroxyvitamin D. Healthy persons produce this active metabolite of vitamin D only in the renal tubule. There is evidence that patients with sarcoidosis convert 25-hydroxyvitamin D to the active compound in the granulomas (171). Hypercalcemia also occurs in patients with other granulomatous diseases, such as tuberculosis, berylliosis, and coccidioidomycosis.

Uric Acid Lithiasis

Uric acid is the endproduct of purine metabolism in humans. Uric acid has two dissociable protons (Fig. 8.5), the first with a pKa of 5.5 and the second with a pKa of 10.3 (98). The limited solubility of this weak acid accounts for its propensity to form renal calculi (Fig. 8.6). Uric acid solubility is approximately 15 mg/dL at a pH of 5, but is 200 mg/dL at a pH of 7.

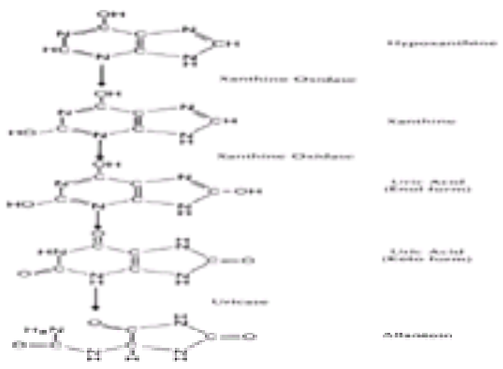

FIGURE 8.5. Metabolic pathway for conversion of hypoxanthine to xanthine and uric acid. Most ureotelic mammals, except humans, have hepatic uricase that converts uric acid into the more soluble allantoin.

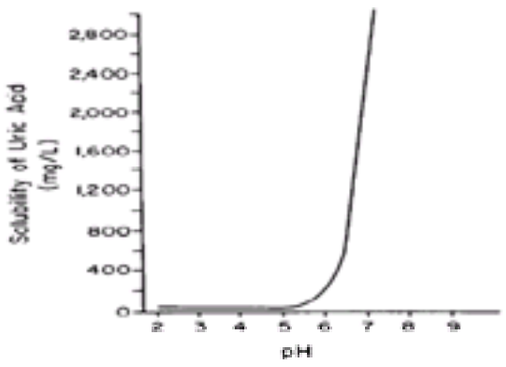

FIGURE 8.6. The pH dependence of the solubility of uric acid at 38°C. (Modified from Finlayson B, Smith A. Stability of first dissociable proton of uric acid. *J Chem Eng Data* 1974;19:94, with permission.)

Uric acid excretion depends on the biosynthesis of new purines and, to a lesser extent, on preformed dietary purines (90,121). A series of enzymatic reactions leads to the formation of the mononucleotide, inosine monophosphate. Dietary nucleic acids can be catabolized to form two other mononucleotides: adenosine monophosphate and guanine monophosphate. Cleavage of the phosphate group by nucleotidases forms the corresponding nucleosides: inosine, guanosine, and adenosine. The action of nucleoside phosphorylases forms the purine bases: hypoxanthine (from inosine), guanine, and adenine. Xanthine oxidase converts hypoxanthine to xanthine and uric acid (Fig. 8.5). The purine salvage enzymes, hypoxanthine-guanine-phosphoribosyltransferase (HGPRT) and adenine phosphoribosyltransferase, can reconvert the purine bases to the mononucleotides. This is the purine salvage pathway.

An X-linked deficiency of HGPRT is responsible for two clinical syndromes (370). Enzyme activity is virtually absent in the Lesch-Nyhan syndrome, a disease characterized by uric acid overproduction and a central nervous system disorder (e.g., mental retardation, spasticity, choreoathetosis, self-mutilation). HGPRT activity is partially deficient in the second syndrome, which is characterized by uric acid overproduction and severe gout, but no neurologic abnormality. Uric acid lithiasis may occur in both syndromes.

Biosynthesis of purines from amino acids also provides a way to eliminate waste nitrogen as uric acid (121). This is the major pathway of waste nitrogen disposal in birds and uricotelic reptiles. Loss of water and electrolytes is minimized by discharging a semisolid uric acid mass through a cloaca. In most ureotelic mammals, except humans, urate that enters the glomerular filtrate is reabsorbed in the proximal tubule and recycled through the liver for conversion to water-soluble allantoin by hepatic uricase. Allantoin is freely excreted by the kidney. Uricase is not present in humans, and uric acid cannot be converted to the more soluble allantoin. Plasma and urine uric acid levels in humans are an order of magnitude greater than those in most mammals. The high concentrations of uric acid are precariously held in solution, a situation that predisposes humans to gout and uric acid lithiasis.

The dalmatian coach hound also is predisposed to uric acid urolithiasis (377). Normal quantities of uricase are present in the liver, but uric acid conversion to allantoin is slow and incomplete. This, together with defective tubular reabsorption of urates, leads to hyperuricosuria and stone formation.

Uric acid lithiasis accounts for 5% to 10% of stones formed in the United States. Approximately one-fourth of patients with primary gout develop uric acid stones. Uric acid lithiasis is found in approximately 40% of stone-forming persons in Israel (9). Uric acid bladder calculi are a common problem in children of rural Southeast Asia.

Patients with uric acid lithiasis may excrete too much uric acid or excessively acidic urine (259). Overproduction of uric acid, as occurs in some patients with gout, may be responsible for the hyperuricosuria. Purine and protein gluttony also may increase uric acid excretion. Most patients with uric acid lithiasis do not have gout or any recognizable disorder of purine metabolism. Serum and urine uric acid levels are usually normal in patients with idiopathic uric acid urolithiasis. Many of these patients have a persistently low urine pH. Although some investigators have found an isolated defect in renal tubular ammonia secretion, the mechanism of the low urinary pH is still poorly understood. Urinary pH also tends to be low in gout (120).

Gouty patients who are treated with uricosuric agents may be at risk for uric acid stone formation. This can be prevented with an increased fluid intake and urinary alkalinization. Patients with myeloproliferative disorders are also at risk for uric acid stone formation, especially with the initiation of chemotherapy or radiotherapy. The increased purine load may even lead to intratubular precipitation of uric acid and anuria.

Disorders that reduce urine volume are associated with uric acid precipitation in an acid urine. Patients with ileostomies or chronic diarrhea can lose large amounts of fluid and bicarbonate. Maintenance of an adequately dilute urine can be difficult for these patients because oral fluids and electrolytes are not well absorbed. The diarrhea or ileostomy output may increase as fluid intake increases. Small bladder calculi composed of uric acid may be found in men with prostatism. These patients reduce their urinary frequency by reducing their fluid intake. Pure uric acid is radiolucent, but gradual incorporation of impurities (usually metals such as calcium) makes larger stones (more than 2 cm diameter) faintly radiopaque. Identification of smaller stones can be accomplished with excretory urography, sonography, or computed tomography (CT). Large uric acid stones may have a branched configuration (Fig. 8.7).

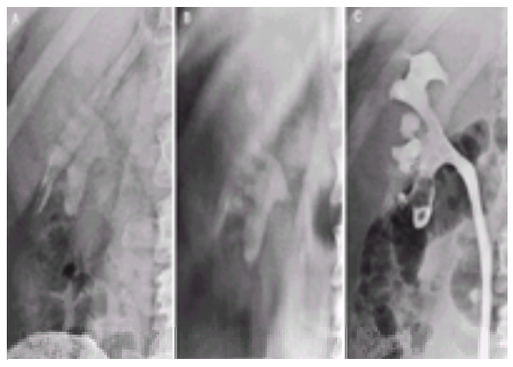

FIGURE 8.7. A: Plain abdominal radiograph that demonstrates a large branched right renal calculus. **B:** Plain tomographic film. **C:** Retrograde pyelogram that demonstrates a filling defect. Analysis of the removed stone material revealed 98% uric acid.

Xanthinuria

Xanthine is less soluble than uric acid (Fig. 8.4). Its solubility increases with rising urine pH, but the effect is not as great as that with uric acid. The pKa of the first dissociable proton of xanthine is 7.7. Like uric acid, xanthine is radiolucent. Xanthine calculi have been reported to occur in xanthinuria, a rare, inherited deficiency of xanthine oxidase (75). Serum and urine uric acid levels are low, but urinary excretion of hypoxanthine and xanthine is elevated. Stone formation has occurred in approximately one-third of patients.

Urinary excretion of hypoxanthine and xanthine is more commonly elevated in patients who are being treated with a xanthine oxidase inhibitor such as allopurinol (Fig. 8.8). Xanthine stone formation during allopurinol administration has been reported in patients with Lesch-Nyhan syndrome and in patients with myeloproliferative disorders who are receiving chemotherapy (29).

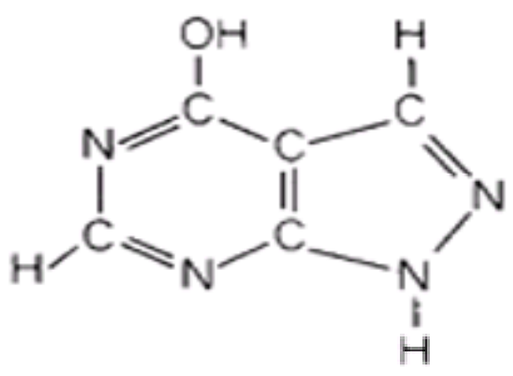

FIGURE 8.8. Structure of allopurinol, an analog of hypoxanthine and xanthine.

2,8-Dihydroxyadeninuria

2,8-Dihydroxyadeninuria is an inherited disorder caused by a defect of the purine salvage enzyme, adenine phosphoribosyltransferase (105,372). Adenine is converted to 2,8-dihydroxyadenine (2,8-DHA), which is insoluble over a wide range of urinary pH. Stone formation and renal failure have been described, usually in children (102). Like uric acid, 2,8-DHA stones are radiolucent. Uric acid stones are hard and yellowish, whereas 2,8-DHA stones are friable and brown or gray. Enzymatic analysis with uricase avoids mistaken identification as uric acid, and infrared spectroscopy or x-ray crystallography confirms the diagnosis. “Uric acid” stones in children must always be suspect and subjected to a sophisticated analysis. The failure to diagnose this disorder can lead to needless recurrent stone formation and even renal failure (40).

Primary Hyperoxaluria

Primary hyperoxaluria is a rare, inherited disorder of glyoxylate metabolism. Clinical manifestations include recurrent calcium oxalate nephrolithiasis, nephrocalcinosis, and chronic renal failure. Extrarenal deposits of oxalate, or oxalosis, develop in the presence of renal failure.

Approximately 10% of oxalate excreted in urine is absorbed from the GI tract. The remainder is derived from endogenous metabolism. Oxalate is produced in mammals as an endproduct of the oxidative metabolism of ascorbic acid (Fig. 8.9) and by oxidation of glyoxylic acid (Fig. 8.10). The major precursor of oxalate in humans is glyoxylate.

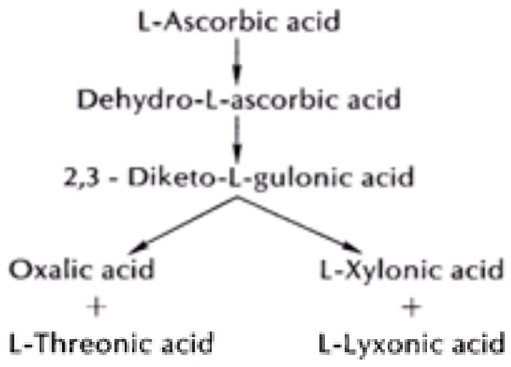

FIGURE 8.9. Oxidative metabolism of ascorbic acid leads to the production of oxalate.

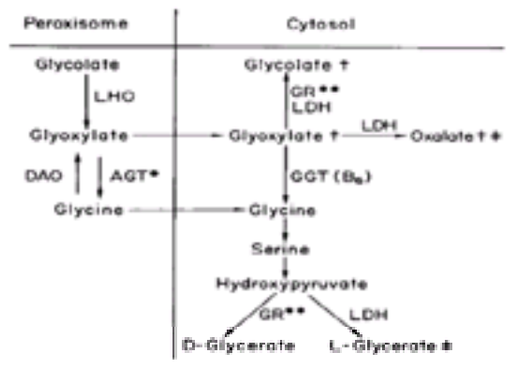

FIGURE 8.10. Pathways of oxalate metabolism in humans. A deficiency of peroxisomal AGT* is responsible for primary hyperoxaluria type 1 (67,68) and results in elevated urinary levels of glycolate †, glyoxylate†, and oxalate†. A deficiency of cytoplasmic GR** is responsible for primary hyperoxaluria type 2 and results in elevated urinary levels of L—glycerate‡ but normal levels of glycolate and glyoxylate. *Peroxisomal enzymes:* LHO, L-a-hydroxy acid oxidase/glycolate oxidase; DAO, D-amino acid oxidase/glycine oxidase; AGT, alanine: glyoxylate aminotransferase/serine: pyruvate aminotransferase. *Cytosolic enzymes:* GGT, glutamate: glyoxyl aminotransferase/alanine:2-oxoglutarate aminotransferase (pyridoxine is a cofactor); GR, glyoxylate reductase/ D-glycerate dehydrogenase; LDH, lactate dehydrogenase.

Type 1 primary hyperoxaluria, or glycolic aciduria, was thought to be caused by deficiency of the cytoplasmic enzyme a-ketoglutarate-glyoxylate carboligase (367). More recent investigations have shown that this disorder is caused by a deficiency or functional abnormality of peroxisomal alanine-glyoxylate aminotransferase in the liver (Fig. 8.10) (67,68 and 69). This enzyme acts on glyoxalate and alanine in peroxisomes to produce pyruvate and glycine. Glutamate-glyoxylate aminotransferase is a cytoplasmic enzyme that acts on cytoplasmic glyoxylate and glutamate to form glycine and 2-oxoglutarate. Pyridoxine (vitamin B_6) is a cofactor in this latter reaction. Urinary excretion of oxalate, glyoxalate, and glycolate is elevated in type 1 primary hyperoxaluria, which is the most common form of the disease.

Type 2 primary hyperoxaluria, or L-glyceric aciduria, is caused by a deficiency of the enzyme glyoxylate reductase/ D-glycerate dehydrogenase (Fig 8.10) (43,366). Urinary excretion of oxalate and L-glyceric acid is elevated, but glycolate excretion is normal, as is that of glyoxylate.

Primary hyperoxaluria is a rare disorder. An extensive review in 1964 reported on 63 typical and 47 atypical cases (137). The disease had become clinically manifest in more than half of the patients by age 4 years. Almost half had died of renal failure by 20 years of age.

The disease should be suspected in patients who are young, have a family history of urolithiasis, and have nephrocalcinosis or large, radiodense calculi on plain abdominal radiographs. Urinary oxalate excretion generally is greater than 100 mg per 24 hours, except in the presence of renal failure. Differentiation between types 1 and 2 is made with urinary glycolate measurements. Glycolate excretion is normal in type 2 but elevated in type 1.

Secondary Urolithiasis

Stone formation may be associated with a group of unrelated conditions: small bowel dysfunction; urinary tract infection with bacterial organisms that produce urease; obstructive uropathy; structural anomalies such as medullary sponge kidney; urinary diversion; and pharmacologic agents. Although all of these disorders may be associated with stone formation, they may not be its primary cause. It is important to search for underlying disorders, such as primary hyperparathyroidism, cystinuria, RTA, or idiopathic hypercalciuria. Prevention of further stone formation requires treatment of any underlying metabolic disorder and the immediate cause of stone formation.

Enteric Hyperoxaluria

Dietary oxalate is a relatively minor source of urinary oxalate in healthy persons, but patients with small bowel disorders may develop hyperoxaluria and recurrent calcium oxalate stone disease. GI absorption of dietary oxalate is more avid in these patients. Enteric hyperoxaluria was first described in the early 1970s and was partly responsible for the abandonment of jejunoileal bypass surgery as a means to control obesity (217,317). Major sources of dietary oxalate are the green leafy vegetables such as rhubarb, spinach, and kale. Tea, cocoa, chocolate, and pepper also have a high oxalate content. The average daily diet contains 100 to 900 mg of oxalate (365).

The acid medium in the stomach releases oxalate from foodstuffs. After combining with free dietary calcium in the alkaline medium of the small intestine, most of the oxalate exists as insoluble calcium oxalate. The small amount of free oxalate that does exist can be absorbed. The colon seems to be the major absorptive area. Patients with ileostomies rarely develop hyperoxaluria (83). The reaction between intestinal calcium and oxalate prevents the absorption of no more than 10% of dietary oxalate by healthy persons.

Patients with a variety of chronic GI disorders such as small bowel resection, inflammatory small bowel disease, chronic pancreatitis, or a jejunoileal bypass may malabsorb fat. The intraluminal concentration of fatty acids increases and calcium is bound to form calcium–fatty acid soaps (85). Less calcium is available to bind oxalate, and more free oxalate is available for absorption. Evidence also shows that malabsorbed fatty acids or bile acids increase colonic permeability to oxalate (82). Patients with enteric hyperoxaluria may absorb up to one-third of their dietary oxalate.

The incidence of nephrolithiasis in inflammatory bowel disease is 2% to 3%, but ileal resection increases the risk to 10% (81). The primary risk factor is increased urinary excretion of oxalate. In comparison with the primary hyperoxalurias, excretion of L-glyceric acid and glycolic acid is normal.

Elevated urinary oxalate is not the only risk factor in these patients (319). The multiple risk factors are shown in Table 8.3. All factors increase the propensity for calcium oxalate precipitation. Reduced urinary volume and pH may promote uric acid stone formation.

Malabsorbed Component	Urine Composition
Fatty acids, bile acids	Increased oxalate
Water	Decreased volume
Electrolytes	Decreased ionic strength
Bicarbonate	Decreased pH, decreased citrate
Magnesium	Decreased magnesium
Protein	Decreased sulfate, decreased phosphate, decreased pyrophosphate

Modified from Smith LH, Werness PG, Wilson DM. Enteric hyperoxaluria: associated abnormalities that promote formation of renal calculi. In: Rose GA, Robertson WG, Watts RWE, eds. *Oxalate in human biochemistry and clinical pathology*. London: Wellcome Foundation, 1979:224, with permission.

TABLE 8.3. ENTERIC HYPEROXALURIA RISK FACTORS FOR UROLITHIASIS

Another form of enteric hyperoxaluria is that possibly associated with ascorbic acid (310,344). The metabolic pathway for *in vivo* conversion of ascorbate to oxalate is shown in Fig. 8.6. *In vitro* conversion of ascorbate to oxalate may occur in saline solutions or pooled urine samples, especially those that have not been acidified (278). This may produce a factitious hyperoxaluria in patients who are consuming large quantities of vitamin C. A further confounding factor is that some methods used to measure oxalate may not be able to distinguish ascorbate metabolites from oxalate (122). Patients should be advised not to take large amounts of vitamin C when they are collecting a 24-hour urine specimen for chemical analysis.

Infected Renal Lithiasis

Infected renal lithiasis refers to the pathologic occurrence of stones composed of magnesium ammonium phosphate ($MgNH_4PO_4 \cdot 6H_2O$, or struvite). Stones caused by infection are not pure struvite—careful crystallographic analysis of infected stone material from humans has revealed a mixture of struvite, carbonate apatite [$Ca_{10}(PO_4)_6 \cdot CO_3$], and hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] (116).

Infection of the urinary tract with urease-producing bacterial organisms is a necessary prerequisite for the formation and growth of struvite stones (117). The enzyme urease catalyzes the formation of ammonia and carbon dioxide (CO_2) from urea:

The formation of ammonia leads to an increase in urinary pH:

When urine is physiologically alkaline, ammonia levels are low, but when urease is present, the urine is alkaline and ammonia levels are high.

The higher pH also leads to the further dissociation of phosphate:

Under these conditions, urine is supersaturated for magnesium ammonium phosphate, and precipitation of this material occurs.

Because all of the reactions occur in aqueous solution, CO_2 exists as carbonic acid:

In the presence of an alkaline pH, the carbonic acid dissociates to form bicarbonate:

The CO_3^{2-} can precipitate with PO_4^{3-} and Ca^{2+} to form carbonate apatite.

Proteus species most commonly are associated with infection stones, but some species of *Klebsiella, Pseudomonas* and *Staphylococcus* may produce urease (116). Virtually all *Proteus* species produce urease, whereas *Escherichia coli* never produces urease. *Ureaplasma urealyticum* will induce alkalinization and crystallization of magnesium ammonium phosphate and calcium phosphates in synthetic urine, and a recent clinical review found this organism in 25% of patients with infection stones (19). Even some anaerobic bacterial organisms produce urease.

Infection stones account for 15% to 20% of all urinary stones. Struvite stones frequently have a branched or staghorn configuration, but not all branched calculi are infection induced. Cystine and uric acid stones also may have a branched configuration.

Some patients with metabolic stone disease may have urinary tract infections with bacteria that do not produce urease. The stones do not contain struvite, and the infection is not responsible for the stone formation. The infection can be treated successfully with antibiotics alone in half of these patients.

Some patients with metabolic stone disease may develop recurrent urinary tract infections with urease-producing bacterial organisms. Struvite may then precipitate on a core of calcium oxalate or cystine. Some investigators have found an underlying metabolic disorder in more than 50% of patients with struvite stone formation (256,296). Prevention of further stone formation requires the identification and treatment of any such metabolic disorder. Other investigators found that recurrent stone formation was negligible in a group of patients who had operative removal of their stone material, specific antimicrobial therapy, and postoperative irrigation of the collecting system with hemiacidrin solution (307). This study implies that metabolic disorders are relatively unimportant in the pathogens of struvite urolithiasis.

Obstruction

Stone formation may be associated with obstructive uropathy. The most common example is uric acid bladder stone formation with bladder outlet obstruction, usually from prostatic hyperplasia. Upper urinary tract obstruction may delay the normal washout of crystal aggregates and gravel. These particles may continue to grow and form macroscopic stones. Persistent infection with urease-producing bacterial organisms may occur in the presence of urinary stasis and result in struvite stone formation. Most patients with obstruction do not form kidney stones.

Medullary Sponge Kidney

Medullary sponge kidney is characterized by dilated collecting tubules in one or more renal papillae. In the absence of complications, it is an asymptomatic and benign condition, but urinary tract infection and nephrolithiasis are frequent complications (373). The diagnosis is made by excretory urography; linear or spherical

tubules in the renal papillae are filled with contrast medium.

The role of medullary sponge kidney in the pathogenesis of nephrolithiasis has not been clarified, but 20% of patients with calcium urolithiasis may have this disorder (373). Other investigators found medullary sponge kidney in fewer than 5% of their calcium stone–forming patients (220). Medullary sponge kidney is found more commonly in women than in men. Patients with medullary sponge kidney and nephrolithiasis have the same spectrum of metabolic abnormalities as the overall population of calcium stone-formers (220,243). Calcium oxalate is the most common stone salt found in patients with medullary sponge kidney (125).

Polycystic Kidney Disease

Nephrolithiasis occurs in approximately 20% of patients with autosomal-dominant polycystic kidney disease (ADPKD). Approximately half of the patients are symptomatic, even though most of the stones are in calices or attached to the papillary tips. Careful intravenous urography or CT is required to distinguish stones from parenchymal or cyst wall calcification. Tubular ectasia is found in 15%, but the relationship of this radiographic finding to the pathogenesis of the stone formation is unknown.

Most of the calculi are composed of uric acid, often in association with calcium oxalate. The distorted renal anatomy and urinary stasis may contribute to stone formation, but most patients have concurrent metabolic abnormalities. A retrospective review at the Mayo Clinic found hypocitraturia in 67% of patients, hyperuricemia in 19%, hyperoxaluria in 19%, hyperuricosuria in 15%, hypercalciuria in 11%, and primary hyperparathyroidism in 5% (342). A defect in the transfer of ammonium to the final urine may prevent patients with ADPKD from responding appropriately to acidosis. This would explain the hypocitraturia found in a majority of patients.

Urinary Diversion

Stone formation and recurrent infections may be associated with urinary tract diversion. Urease-producing bacterial infections may lead to struvite stone formation. The diversionary procedure also may produce metabolic abnormalities that encourage stone formation. GI bicarbonate loss and hyperchloremic acidosis are known side effects of ureterosigmoid anastomoses (189). The systemic acidosis may lead to hypercalciuria and hypocitruria. Osteomalacia has been reported to develop in patients with ureterosigmoidostomies and a metabolic acidosis (305). Occasional patients with ileal conduits develop a hyperchloremic acidosis (84,159). Most stones form in the presence of *Proteus* infections and are composed of struvite. Because excess conduit length may contribute to the bicarbonate loss and chloride absorption, these metabolic derangements may occur more frequently with the new continent diversionary procedures. The use of nicotinamide to block intestinal chloride transport may be a useful preventive measure (158).

The incidence of calculus formation after augmentation cystoplasty has been reported to be as high as 50% (239). Urinary tract infection, mucus production, foreign bodies, and hypocitraturia have been identified as potential risk factors (155). The acidic environment provided by gastrocystoplasty retards mucous production and bacterial overgrowth (240). As expected, stone formation occurs less frequently than after enterocystoplasty.

Drugs

The metabolic effects of some drugs lead to stone formation. Acetazolamide, a carbonic anhydrase inhibitor, produces changes in urine composition that are similar to those found in distal RTA. Kidney stones have formed in patients who have received this drug for the treatment of glaucoma. Nephrolithiasis also has been reported in patients who have received long-term acetazolamide for the treatment of periodic paralysis and myotonia (336).

Drugs or their metabolites may have limited solubility in urine. These compounds may be absorbed onto calculi already present in the urinary tract or may precipitate to form new stones. Approximately 50% of an ingested dose of allopurinol is excreted as oxypurinol, an oxidative metabolite. Oxypurinol, like xanthine, is less soluble than allopurinol or hypoxanthine. The solubility of oxypurinol decreases with a decrease in pH. Radiolucent oxypurinol stone formation has been reported in a patient with regional enteritis who was receiving allopurinol for the prevention of recurrent uric acid lithiasis (327). Persistent oliguria and aciduria contributed to the precipitation of oxypurinol. Rarely, xanthine stones have formed in patients treated with allopurinol.

Triamterene and its metabolites have been identified in renal calculi. Some investigators have suggested that their precipitation may be a causative factor in the formation of calcium stones (364). Other investigators found that triamterene and its metabolites adsorb to stone matrix (360). Because stones that contain triamterene have an unusually high matrix content, triamterene and its metabolites may be a passive constituent of renal calculi. Clinical studies of patients receiving a combination of triamterene and hydrochlorothiazide (Dyazide) suggest that nephrolithiasis is not a clinically significant side effect (144).

Sulfonamides were one of the first classes of drugs to precipitate in the urinary tract, but numerous other drugs and their metabolites have been identified in renal calculi (70). Sulfadiazine urolithiasis has been reported in patients with AIDS who have received this drug for the treatment of toxoplasmosis (41,199). Another example is the report of several ceftriaxone stones in a 13-year-old boy treated for acute bacterial meningitis (51). Infrared spectrophotometry found that 92% of the stone material was ceftriaxone disodium; calcium oxalate monohydrate and protein comprised the remaining 8%.

Indinavir is a protease inhibitor used for treating HIV-1 (288). Indinavir was the third such drug introduced into the United States and is the most widely prescribed drug in this class of retroviral agents. Indinavir therapy has been associated with a 4% incidence of nephrolithiasis. Indinavir crystalluria (platelike rectangles and fan-shaped or starburst forms) can be found in 20% of patients and often is associated with irritative voiding symptoms (162).

Pure indinavir stones cannot be seen with CT scanning unless intravenous contrast is used (332). Symptomatic urolithiasis usually can be treated with hydration alone.

Several factors can predispose an individual to the urinary precipitation of a drug: a high renal excretion rate, a low solubility of a drug or its metabolites, a low urine volume, and prolonged treatment at a high dose. The appearance of synthetic compounds in renal calculi is to be expected as new drugs are introduced and analytic methods of stone analysis become more sophisticated.

Urinary calculi also may form on foreign bodies in the urinary tract (65). Foreign-body stones in the upper urinary tract have been associated with ureteral catheters, nephrostomy tubes, sutures, biliary calculi, shrapnel, and acupuncture needles. Renal papillary necrosis with calcification of the sloughed papillae may mimic nephrolithiasis (Fig. 8.11).

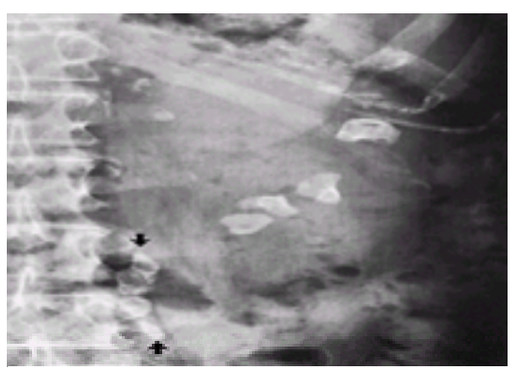

FIGURE 8.11. Multiple calcified bodies in left kidney and ureter *(between arrows).* The radiolucent centers could represent uric acid or necrotic renal papillae *(arrows).* Histologic examination revealed necrotic calcified renal papillae.

Ammonium acid urate calculus formation has been reported in women with a history of laxative abuse (79). Urinary volume over 24 hours and excretion of sodium, potassium, and citrate were low. GI loss of fluid and electrolytes led to chronic extracellular volume depletion and intracellular acidosis (low urinary citrate and

potassium).

Idiopathic Calcium Urolithiasis

The diagnosis of ICU is one of exclusion and is applicable in 70% to 80% of North American and Western European patients with urolithiasis. If pure uric acid lithiasis, cystinuria, RTA, primary and secondary hyperoxaluria, and hypercalcemia have been excluded in a patient with calcium oxalate or mixed calcium oxalate and/or calcium phosphate stone formation, this diagnosis may be applied. However, a patient may have more than one disorder. Primary hyperparathyroidism and ICU or cystinuria and ICU may occur in the same patient.

Careful metabolic studies of patients with ICU reveal a multiplicity of abnormalities: hypercalciuria, mild hyperoxaluria, hyperuricosuria, crystal growth–inhibitor deficiencies, hypocitruria, and “incomplete” RTA. One or more of these abnormalities may be found in the same patient, and some of the abnormalities may be related to the others, such as hypocitruria to incomplete RTA. Some patients with ICU may have no clearly recognizable disorder other than calcium stone formation.

Between 50% and 70% of these patients have hypercalciuria (264). Most healthy men receiving a 1-g calcium diet excrete less than 275 mg of calcium over 24 hours. The corresponding figure for women is 250 mg per 24 hours. A more convenient way to remember is that urinary calcium excretion should not exceed 4 mg/kg per 24 hours. Most patients with ICU and hypercalciuria are thought to have primary intestinal hyperabsorption of dietary calcium (234). Increased absorption of dietary calcium may slightly increase the serum calcium concentration and suppress PTH secretion. The increased filtered load of calcium and decreased tubular reabsorption results in hypercalciuria. The urinary calcium loss compensates for the enhanced intestinal absorption, thereby maintaining serum calcium within a normal range. In the past, patients with absorptive hypercalciuria have been separated into three categories that depended on the serum phosphorous level and the level of dietary calcium at which hypercalciuria ensued.

A positive correlation exists between urinary calcium excretion and sodium excretion (255). Another study found that a group of hypercalciuric subjects on a 200-mEq sodium diet converted to normocalciuria on an 80-mEq sodium diet (208). The sensitive relationship between urinary calcium and sodium and the normal day-to-day variation of sodium intake may confound the results of standard 24-hour urine collections.

It is not known if absorptive hypercalciuria is caused by a primary intestinal defect or by a more complex metabolic disorder. Several investigators have found elevated vitamin D metabolites in one-third to one-half of patients with absorptive hypercalciuria (298). Some patients with absorptive hypercalciuria have low serum phosphorus levels. The stimulation of 1,25-dihydroxyvitamin D synthesis in the kidney by hypophosphatemia could lead to increased intestinal calcium absorption (115); the primary event would be a “renal leak” of phosphate. However, other investigators do not think that vitamin D and its metabolites play a critical role in the pathogenesis of absorptive hypercalciuria (215,222).

Two sources exist for calcium that appears in urine: GI absorption and bone resorption (172). Augmentation of intestinal absorption of dietary calcium is responsible for most of the increase in urinary calcium. Increased bone resorption is an unlikely primary source because the magnitude and duration of the hypercalciuria would lead to overt bone disease. Nevertheless, calcium balances are slightly but significantly negative in patients with idiopathic hypercalciuria. The existence of a generalized disorder of calcium homeostasis is further supported by an elevation of urinary hydroxyproline excretion that is seen in some patients. This reflects bone resorption. Lumbar bone density is significantly lower in patients with absorptive or fasting hypercalciuria compared with normocalciuric stone-formers (246). Bone loss in these patients also may be related to environmental factors such as intake of sodium or animal protein.

A familial basis of some types of hypercalciuria is supported by a high frequency of calcium stone disease and hypercalciuria in first-degree relatives of stone-formers (89). Most family studies of idiopathic hypercalciuria are broadly consistent with an autosomal-dominant mode of inheritance. However, the complexity and high variability of the inheritance patterns suggest that idiopathic hypercalciuria is a polygenic trait and involves alleles at several loci.

A smaller group of patients with hypercalciuria may have impaired renal tubular reabsorption of calcium (53,222). Fasting urinary calcium excretion is elevated, the serum concentration of calcium is reduced, and parathyroid function is stimulated. The elevated PTH level tends to restore serum calcium to normal levels by mobilizing bone calcium and enhancing intestinal absorption. Renal hypercalciuria and absorptive hypercalciuria are differentiated by measuring PTH levels and fasting urinary calcium excretion. PTH levels should be elevated in renal hypercalciuria but normal in absorptive hypercalciuria. Fasting urinary calcium excretion should be high in renal hypercalciuria but normal in absorptive hypercalciuria.

Early studies found renal hypercalciuria in more than 50% of patients with hypercalciuria, but this proportion decreased to 10% with later studies. This discrepancy may have been the result of differences in the specific immunoassays used to measure PTH. More intensive fasting tends to reduce the proportion of patients with renal hypercalciuria. Renal and absorptive hypercalciuria may represent extremes of a variable disorder rather than distinct clinical entities. A uniform elevation of intestinal calcium reabsorption may better explain the data than separate absorptive and renal forms of hypercalciuria (54).

Many studies have examined calcium metabolism in nephrolithiasis, but relatively few have investigated the role of oxalate in ICU. The paucity of such studies is related to the difficult nature of oxalate measurement in urine. Several investigators have found a mild but definite increase in urinary oxalate excretion in a subset of patients with ICU (12,265). A mildly elevated urinary oxalate is a greater risk factor for the precipitation of calcium oxalate than is a mildly elevated urinary calcium, because normal urinary oxalate levels are tenfold lower than normal urinary calcium levels. A small increase in urinary oxalate leads to the precipitation of a greater volume of crystals than does a comparable increase in urinary calcium.

Patients with mild hyperoxaluria do not appear to have a specific disturbance of glyoxylate metabolism. The hyperoxaluria is thought to be secondary to intestinal hyperabsorption of oxalate and calcium (186). The mechanism is analogous to that for enteric hyperoxaluria, but intraluminal intestinal calcium is reduced by hyperabsorption, not by complexation with fatty acids. Less calcium is available to bind oxalate, thereby permitting more avid absorption of free oxalate. A similar situation may occur when patients with recurrent calcium lithiasis are instructed to limit their dietary intake of foods that contain calcium. Isolated dietary calcium restriction may increase the risk of stone formation by allowing oxalate excretion to increase without a commensurate decrease in calcium excretion (17).

Intestinal hyperabsorption of oxalate may not be solely secondary to calcium hyperabsorption and reduced complexation. A more widespread defect in cellular transport of oxalate may exist. Transport of oxalate across red blood cell membranes differs in healthy persons and patients with recurrent calcium oxalate nephrolithiasis (13,14,103). The mean transmembrane oxalate flux rate in stone-forming patients was triple that in healthy control subjects. This meant that oxalate could cross the red blood cell membrane faster in patients with ICU. A similar situation in the luminal membrane of the GI tract could provide another mechanism for oxalate hyperabsorption.

Some patients with ICU have a concurrent disorder of uric acid metabolism. These patients tend to have a more severe form of stone disease, manifested by more frequent stone formation and a greater need for surgical intervention (52). Specific epitaxial overgrowth of calcium oxalate on uric acid or monosodium urate has been suggested as a possible explanation, but it is doubtful that this occurs in the urinary tract. Heterogeneous nucleation could occur, but freshly voided urine specimens from patients with ICU rarely contain uric acid or urate crystals (359). The binding of macromolecular inhibitors by another form of urate (colloidal) was proposed and has been supported by some studies (281). The reduction of hyperuricosuria with allopurinol also increased calcium oxalate–crystal growth inhibition (226), and hyperuricosuric calcium oxalate nephrolithiasis has been treated successfully with alkalizing agents (235).

A quantitative or qualitative disorder of crystal growth inhibition has been proposed as a possible reason for stone formation in patients with ICU. As discussed in the section on clinical stone formation, citrate is a complexor of calcium and a weak inhibitor of calcium oxalate crystal growth. Some investigators have found a subgroup of patients with ICU who have low urinary citrate levels (194,277). Hypocitnaturia in patients with distal RTA may enhance stone growth. Although the most beneficial action of citrate is through complexation of calcium, its weak inhibitory effects would help prevent further stone formation. Pharmacologic citrate preparations, through their alkalizing property, have successfully prevented further stone formation in patients with hypocitraturic calcium lithiasis (236).

Persistently alkaline urine has been found in another subset of patients with ICU but no clearly identifiable acid–base disorder (273). Careful analysis of stone material formed by patients with ICU reveals the presence of calcium phosphate, albeit in small amounts, in most of the stones. Because calcium phosphate preferentially precipitates at an alkaline pH, small calcium phosphate crystals may provide heterogeneous nuclei for the overgrowth of calcium oxalate. This mechanism may become more important as alkalizing agents are more commonly used to treat patients with ICU.

Patients with incomplete RTA are not systemically acidotic, but they have an impaired ability to acidify their urine after an ammonium chloride load. This implies the

presence of a renal tubular defect in hydrogen ion secretion. The hypocitruria found in some patients with ICU may be the result of a subtle intracellular acidosis.

Defective tubular reabsorption of calcium is thought to be the cause of renal hypercalciuria. All of these disorders may be different manifestations of a more widespread tubular dysfunction. Evidence for this was provided by a study of the effects of hydrochlorothiazide and acetazolamide on the urinary excretions of calcium, sodium, and magnesium (334). These diuretic agents were chosen for their known actions at different sites in the nephron. Hydrochlorothiazide augmented sodium, calcium, and magnesium excretion to a greater extent in patients with ICU than in control subjects. With acetazolamide, the increase in sodium excretion was less in the patients than in the control subjects. The abnormal responses to both diuretics were most significant in patients with hypercalciuria during fasting. Such studies implicate a disorder of renal tubular transport as the primary abnormality in ICU. GI hyperabsorption of calcium would be a secondary phenomenon.

EVALUATION

The goal of a metabolic evaluation is to identify any physiologic or environmental factors that could be responsible for or exacerbate clinically active stone formation. No single approach is universally accepted, but it is possible to provide the general principles of a practical and efficient evaluation. The specifics of three different approaches were presented at a recent National Institutes of Health Consensus Development Conference on Prevention and Treatment of Kidney Stones (247,369,376).

History

The clinical history may help determine the cause of stone formation. The important elements in the history are outlined in Table 8.4. Inherited disorders, such as primary hyperoxaluria, cystinuria, and RTA, are clearly associated with urolithiasis, but even ICU tends to occur within families. Idiopathic stone formation and uric acid lithiasis are more common in males, whereas primary hyperparathyroidism and RTA are more common in females. Although ICU is the most common type of stone disease in children and adults, the classic inherited disorders associated with stone formation are more common in children than in adults.

Age at onset	Diet
Sex	Medications
Family history	Previous stone passage
Geographic residence	Interventional procedures
Occupation	Previous stone composition
Fluid intake	Urinary tract infections

TABLE 8.4. CLINICAL HISTORY

Residence in a geographic area with a high incidence of stone disease, such as the southeastern United States, may have some epidemiologic importance, but temporary residence in an arid climate may be more pertinent. People who are not acclimated to these conditions may have a low urine-output state as a result of large fluid losses from perspiration and respiration. Long-distance runners may have the same problem. Evidence suggests that stone formation may be more common in marathon runners than in the general population (201). Urine volume tends to be low in patients who must perform manual labor in a hot environment. Easy access to fluids and bathroom facilities may not be possible with some occupations. A low urine-output state is a byproduct of many occupations.

Excess dietary intake of calcium, oxalate, or protein and a low fluid intake may encourage the formation of stones. Stone formation also is associated with certain medications: vitamin D, absorbable alkali (calcium carbonate), and carbonic anhydrase inhibitors (acetazolamide). Patients need not consistently overindulge to form a stone. Brief periods of dietary indiscretion or poor fluid intake may initiate crystallization. A similar consideration applies to medications, particularly those associated with a nutritional fad.

A patient's past experience with stone formation and passage may provide clues about the cause of the stone disease and the patient's motivation to pursue a lifelong treatment program. A history of multiple stone passages and rapid recurrent stone formation may indicate a fundamental metabolic cause such as primary hyperparathyroidism or RTA. The necessity for multiple interventional procedures implies the growth of larger stones. Struvite lithiasis should be suspected if the patient has a history of infection with urease-producing bacterial organisms. The composition of previously analyzed stones should be sought. If old stones have not been analyzed, they should be examined and sent for formal analysis. It often is possible to determine a stone's composition just by looking at it. Cystine and uric acid stones are good examples.

Physical Examination

Recognizable physical abnormalities may be present in a few disorders associated with urolithiasis (Table 8.2): sarcoidosis, Cushing's syndrome, hyperthyroidism, and gout. Patients with neurogenic bladder dysfunction may be at risk for recurrent urinary tract infections and infected stone formation. Calcium stones may form in a recently immobilized patient. Extensive abdominal scarring is seen in some patients with small bowel disorders and should raise the possibility of enteric hyperoxaluria. Most patients do not have physical findings related to their stone disease, and laboratory studies are required to uncover the cause.

Laboratory Evaluation

The extent of the laboratory evaluation of a particular patient depends on the severity of the stone disease. A 40-year-old man who has passed several dozen calculi over the past 10 years needs a more extensive metabolic evaluation than a 60-year-old woman who has a 1-cm asymptomatic renal pelvic stone but no previous history of stone disease. Patients who have formed a single calcium stone have the same range of metabolic abnormalities as do patients with recurrent stone formation (224,328). Hypercalciuria was present in 50% to 75% of patients; approximately 5% had primary hyperparathyroidism, and 20% to 30% had no identifiable metabolic disorder. The patients with single stones were older when they passed their stones, had a higher incidence of urinary tract infection, and were more likely to have had surgical or endoscopic intervention. These authors recommended that single-stone-formers have the same evaluation and be treated no differently from other patients with stone disease.

Patients who have formed a single stone may be willing to modify their diet and increase their intake of fluids, but are unwilling to take a medication for several years. The benefit of an extensive metabolic evaluation in such a patient is not readily apparent. A utilitarian evaluation of a single-stone-former would include an assessment of calcium metabolism and renal function (usually obtained as a multichannel chemical analysis of serum), a urinalysis and culture, and a stone analysis. These studies should detect obvious hyperparathyroidism, infected stone formation, and most of the disorders for which specific therapy is especially beneficial (e.g., uric acid lithiasis and cystinuria). A more extensive evaluation usually is reserved for those patients who prove to have metabolically active stone disease.

A complete metabolic workup should include the studies listed in Table 8.5. An isolated elevated serum calcium level should be confirmed on two or three separate occasions. The normal range varies among laboratories, but one should be suspicious of a serum calcium level greater than 10.1 mg/dL. Total serum calcium includes ultrafilterable calcium and protein-bound calcium. Ultrafilterable calcium, that which enters the glomerular filtrate, is composed of ionized calcium and a small amount of complexed calcium. Approximately half of total serum calcium is protein bound, primarily to albumin. The critical fraction that is controlled by the homeostatic mechanisms of the body is ionized calcium, but it is difficult to measure reliably ionized calcium. Total serum calcium usually is measured and corrected for serum albumin.

Serum	Urine chemistry (24-hr volume)
Calcium	Calcium
Phosphorus	Phosphorus
Uric acid	Uric acid
Creatinine	Oxalate
Alkaline phosphatase	Cystine
Urine	Citrate
Urinalysis	Sodium
Culture	Magnesium
Fasting pH	Stone analysis
24-hr volume	

TABLE 8.5. LABORATORY EVALUATION

Serum phosphorus varies with age, sex, renal function, and diet, but may be low in patients with primary hyperparathyroidism and some patients with ICU. Serum alkaline phosphatase activity may be elevated in patients with hyperparathyroidism. Elevated serum uric acid levels are found in some patients with uric acid lithiasis, but calcium stone-formers also may have hyperuricemia. A serum bicarbonate measurement usually is included in a multichannel analysis and may be decreased in patients with RTA or with small bowel disorders associated with malabsorption.

A urinalysis should be performed promptly after collection. The pH is best measured in a morning urine specimen after an overnight fast. A pH less than 5.5 eliminates distal RTA. A short urinary acidification test can be performed if the pH is not less than 5.5. Uric acid stone-formers may have a persistently low pH. A high urine pH (more than 8.0) is found if the urine is infected with a urease-producing bacterial organism. The infection must be eliminated to accurately assess the pH. Ingestion of alkali or citrate preparations also raises the pH.

Red blood cells and white blood cells usually are seen with urolithiasis, and bacteria may be visible if an infection is present. A urine culture will confirm the presence of an infection, but some patients with struvite stone formation will have negative bladder urine and even renal pelvic urine cultures. Bipyramidal-shaped calcium oxalate dihydrate crystals can be found in healthy persons. Multiple small, platelike or dumbbell-shaped calcium oxalate monohydrate crystals often are found in patients with hyperoxaluria, usually the primary disorder. Calcium oxalate monohydrate crystals are birefringent and will appear as bright specks with polarized microscopy. The presence of hexagonal cystine crystals is virtually diagnostic of cystinuria. A 24-hour urine collection is the traditional mainstay of a metabolic stone evaluation. The most important and often most neglected measurement is the volume. Many patients with recurrent calcium stone formation have a 24-hour urine volume that is approximately 1 L. The basic principles of the medical treatment of urolithiasis are dietary moderation and a consistently high urine volume. Patients can easily monitor their progress by measuring their 24-hour urine volume at home.

Urinary excretion of calcium, phosphorus, oxalate, and uric acid is a function of dietary intake. Increased urinary oxalate is found in patients with primary or secondary hyperoxaluria. Dietary oxalate content has its greatest impact in patients with enteric hyperoxaluria. Uric acid excretion may be elevated in uric acid or calcium oxalate stone-forming patients. Urinary calcium excretion has received much attention. Elaborate protocols have been devised to differentiate the renal and absorptive hypercalciurias and the various types of absorptive hypercalciuria (231). The goal has been to institute specific pharmacologic therapy, but these calcium tolerance tests have achieved limited clinical utility (170).

Urinary cystine excretion can be screened with the traditional cyanide-nitroprusside reaction or newer spot tests (107). A positive reaction should be followed by a quantitative amino acid analysis. Urinary citrate excretion is decreased in patients with distal RTA and intestinal malabsorption. Citrate is low in the presence of a urinary tract infection because bacteria metabolize citrate. Urinary magnesium excretion is of some interest to investigators but is not clinically useful. Urinary sodium excretion may be elevated in some patients with hypercalciuria.

Computer programs have been written to calculate urinary saturations for the major stone-forming salts (94,262) and are available commercially (237). These programs are useful in research, but their widespread clinical utility has not been demonstrated. Examination of the 24-hour urine volume and the total excretions of the major ions should provide enough information to make sound clinical decisions.

Stone material that has been passed or removed should be analyzed. Many different crystalline components have been identified in urinary calculi (Table 8.6), and several methods have been used to identify accurately these constituents (333). The composition of some calculi, such as cystine, can be identified with simple macroscopic or microscopic analysis. Whole stones covered with calcium oxalate dihydrate crystals have a burr or “hair-on-end” appearance. If the whole stone is available, an attempt should be made to separate the nucleus from the rest of the stone because the composition of the nucleus may differ from that of the outer layers. Optical properties (i.e., crystal system, optical sign, refractive index, angle of extinction, and birefringence) can be measured with polarization microscopy (251). The limited number of crystalline components in urinary calculi can be identified from these optical properties. X-ray powder diffraction has been the standard method for stone analysis because it enables almost absolute identification of crystalline materials and mixtures of these materials (206). The equipment is expensive, and the procedure is time-consuming.

Substance	Mineralogic Name	Formula
Calcium oxalate monohydrate	Whewellite	$CaC_2O_4 \cdot H_2O$
Calcium oxalate dihydrate	Weddellite	$CaC_2O_4 \cdot 2H_2O$ to $2.5H_2O$
Magnesium hydrogen phosphate trihydrate	Newberyite	$MgHPO_4 \cdot 3H_2O$
Magnesium ammonium phosphate hexahydrate	Struvite	$MgNH_4PO_4 \cdot 6H_2O$
Hydroxyapatite	Hydroxyapatite	$Ca_{10}(PO_4)_6(OH)_2$
Carbonate apatite	Carbonate apatite	$Ca_{10}(PO_4)_6 \cdot (OH)_2 \cdot (CO_3)_{1-3}$
Calcium hydrogen phosphate dihydrate	Brushite	$CaHPO_4 \cdot 2H_2O$
Tricalcium phosphate	Whitlockite	$\beta\text{-}Ca_3(PO_4)_2$
Octacalcium phosphate		$Ca_8H(PO_4)_6 \cdot 2.5H_2O$
Uric acid		$C_5H_4N_4O_3$
Uric acid dihydrate		$C_5H_4N_4O_3 \cdot 2H_2O$
Ammonium acid urate		$C_5H_4N_4O_3NH_4$
Sodium acid urate monohydrate		$C_5H_3N_4O_3Na \cdot H_2O$
Cystine		$(-SCH_2CHNH_2COOH)_2$
Xanthine		$C_5H_4N_4O_2$
Calcium sulphate dihydrate	Gypsum	$CaSO_4 \cdot 2H_2O$

TABLE 8.6. CRYSTALLINE CONSTITUENTS OF HUMAN URINARY CALCULI

Infrared spectroscopy is becoming the most widely used method of stone analysis (20,133,363). Finely powdered stone material is pressed into a transparent tablet with optically pure potassium bromide. The infrared spectrum is recorded and compared with a library of standard spectra. Infrared spectroscopy is rapid and relatively inexpensive, and it permits the identification of noncrystalline components and artifacts. This method is especially useful for identifying drugs and their metabolites. Other methods of stone analysis such as thermogravimetric technique (275), scanning electron microscopy with energy dispersive x-ray analysis (150), and CT (136) have been proposed, but they appear to have limited applicability.

Activity

The propensity to form stones varies from patient to patient as well as in a particular patient over time. An arbitrary method for assessing activity was developed at the Mayo Clinic (315). The concept of stone activity enables one to evaluate the need for long-term pharmacologic therapy and the response to such therapy. Two basic categories of activity are defined: surgical and metabolic. A patient with renal colic, obstruction, or infection associated with a stone has surgically active urolithiasis.

Metabolic activity refers to the precipitation of stone material. Urolithiasis is metabolically active in patients who have had growth of old stones, formation of new stones, or the passage of gravel within the past year. These criteria must be documented radiographically. If a patient's stone disease meets none of these criteria, the urolithiasis is metabolically inactive. If previous radiographs are unavailable or of poor quality, the metabolic activity is said to be indeterminate. Such patients are

instructed to increase their fluid intake and avoid dietary excesses. They receive follow-up until the metabolic activity can be determined.

The distinction between surgical and metabolic activity is important because a symptomatic stone may have formed several years before. No specific medical treatment may be needed after the immediate surgical problem is resolved. Metabolically active urolithiasis may exist without symptoms. No surgical intervention may be needed, but specific medical therapy may be required to prevent further stone formation.

One of the goals of urolithiasis research has been the development of a method to predict stone activity when a patient is first evaluated (123). Several measures have been proposed, including the previously discussed saturation-inhibition index, but none has had greater utility than this simple, time-dependent method of assessing activity. Recurrent stone formation is common, but it cannot be predicted from standard laboratory evaluations in individual patients (178).

Radiographic Evaluation

The assessment of metabolic activity depends on the availability of high-quality radiographs. Tomographic views provide more detail than standard radiographs because the overshadowing effects of bowel gas and intestinal contents are lessened. Spiral CT scans have virtually replaced intravenous pyelography in the evaluation of patients with ureteral calculi (64,352). Renal calculi can be seen easily on such studies, but plain or tomographic radiographs usually are easier to use for longitudinal follow-up. Relatively radiolucent stones such as uric acid or cystine are best monitored with ultrasonography or CT scanning.

The radiographic appearance of a stone depends on the composition of the stone, its thickness and orientation, surrounding tissues or bowel contents, and radiographic technique. A stone may rotate and give the illusion of a change in size. This rotation cannot be prevented, but its possible occurrence should be remembered when radiographs are examined. All stones, except uric acid, are clinically radiopaque. Even large uric acid stones appear faintly radiopaque from incorporated impurities. Small cystine and struvite stones may be difficult to see on plain radiographs. Relative radiodensities of the common stone salts have been measured and, in decreasing order, are apatite, whitlockite, brushite, whewellite, weddellite, cystine, struvite, and uric acid (276).

MEDICAL MANAGEMENT

With few exceptions (dissolution of uric acid and cystine stones), the goal of medical treatment is to prevent the formation of new stones or the further growth of old stones. This prophylaxis must be effective and continuous. Patients must understand that prevention of further stone formation probably will require lifetime treatment.

The therapy of urolithiasis is based on two principles: a reduction of urinary SS, and an increase in net inhibitory activity. The latter can be achieved by increasing the quantity of inhibitors, by increasing the potency of inhibitors, or by corresponding decreases in promoter activity.

The purpose of a high fluid intake is to lower urinary SS. The dilution reduces ionic strength, complexation, and the concentration of inhibitors, but these side effects are more than offset by the reduction of SS. It is impossible for stone formation to occur in urine that is undersaturated for the particular stone salt. All patients with renal calculi should be counseled to increase their fluid intake. An 8-ounce glass of fluid should be consumed hourly while awake, and 8 to 16 ounces of fluid should be consumed if the patient is up at night. Approximately half of the fluid should be water. The patient should produce at least 2,500 mL of urine per 24 hours. The fluid intake should be consistent. A liberal intake of fluids during the day but poor intake during the night does not uniformly lower SS, especially after a heavy evening meal. Patients can use a container of known volume to inexpensively monitor their 24-hour urine output. A fixed numeric goal is helpful because most patients are poor estimators of their fluid intake and urine output.

A dietary history should be taken and dietary excesses eliminated (238). The traditional recommendation has been a low-calcium diet, but this may increase urinary oxalate excretion. Urinary SS can be lowered with a low-calcium, low-oxalate diet, but patients are less likely to adhere to a more complex program. The same criticism applies to a low-carbohydrate diet, a high-fiber diet, and a low–animal protein diet, although the last may be useful in the treatment of idiopathic uric acid lithiasis. Because dietary therapy requires long-term patient compliance, the encouragement of dietary moderation may be the best advice (135).

Fluid and dietary therapy should be used in all patients with urolithiasis and should be the only initial therapy in patients with ICU. One hundred eight patients with ICU of indeterminate metabolic activity were treated initially with fluid and dietary therapy at the Mayo Clinic (139). No stone growth or new stone formation was seen in 58% of these patients during a mean follow-up period of more than 5 years. Of those patients with hypercalciuria alone, 70% proved to have metabolically inactive stone disease. The existence of metabolically active stone formation should be proved before a patient is committed to lifelong pharmacologic therapy (314).

Renal Tubular Acidosis

The metabolic abnormalities of patients with distal RTA are corrected with replacement of sodium, potassium, and bicarbonate. Daily, 90 to 150 mEq of base usually is required and may be given as sodium bicarbonate or citrate (Bicitra, Polycitra, or Urocit-K). Total body potassium levels are low in untreated patients, and the serum potassium level may decrease as the acidosis is corrected. Potassium should be replaced while monitoring serum levels. Urinary calcium excretion decreases, and urinary citrate increases to a normal level with correction of the systemic acidosis.

Sodium bicarbonate, sodium citrate, potassium bicarbonate, and potassium citrate are equally effective in increasing urinary citrate (30). The advantage of citrate is that it produces a more even and longer-lasting effect on renal citrate excretion than bicarbonate. The advantage of potassium citrate over sodium citrate is that a long-term reduction of urinary calcium is seen with the former but not the latter (249,250).

Cystinuria

The goal of therapy is to reduce the urinary SS of cystine (130). Urine volume over 24 hours should be maintained at 3 to 4 L. The solubility of cystine in normal urine is approximately 300 mg/L but increases as the pH increases (Fig. 8.4). If the 24-hour urinary cystine excretion of a patient is known, the information in Fig. 8.4 can be used to calculate the urine volume and pH required to solubilize adequately all of the cystine. The pH usually must be increased to 7.5 to 7.8. This degree of alkalinization may be difficult to maintain and can promote the coprecipitation of calcium phosphate.

A carbonic anhydrase inhibitor such as acetazolamide can be used to maintain urinary alkalinity throughout the night, but these agents probably should be avoided because they induce changes in urinary composition that favor the precipitation of calcium phosphate. If a cystine stone becomes covered with a layer of calcium phosphate, further attempts at dissolution will be fruitless.

Cystine is two cysteine molecules linked by a disulfide bond (Fig. 8.3). The drug D-penicillamine (Cuprimine) reacts with cystine to form penicillamine-cysteine, a mixed disulfide that is more soluble than cystine in urine. The dose of D-penicillamine is 250 to 500 mg four times daily. It is given 30 minutes before meals and at bedtime. D-penicillamine is a potentially toxic drug that should be used for attempted stone dissolution or in patients whose disease cannot be controlled with hydration and alkalization. Adverse reactions include skin rashes, fever, arthralgias, and lymphadenopathy. A potential pyridoxine deficiency can be avoided with prophylactic pyridoxine (50 mg twice daily) therapy. Stone dissolution may require several months to 1 or 2 years.

Urinary cystine excretion also can be lowered by limiting dietary methionine. This therapy severely limits protein intake and is rarely, if ever, used.

a-Mercaptopropionyglycine (a-MPG, or Thiola) shares chemical properties with D-penicillamine but appears to have fewer adverse effects (230). A multicenter study of 66 patients with cystinuria found that the effectiveness of a-MPG in reducing cystine excretion was equal to that of D-penicillamine. A mean dose of 1,193 mg of a-MPG per day maintained daily cystine excretion at 350 to 560 mg. In 59 patients who had taken both drugs, adverse reactions forced 31% to stop taking a-MPG and 60% to stop taking D-penicillamine.

Captopril, an angiotensin-converting enzyme inhibitor, contains a sulfhydryl group that can participate in a thiol exchange reaction to form captopril-cysteine that has a 200-fold greater solubility than cystine (313). Captopril further lowers urinary cystine excretion by a mechanism other than thiol exchange. Captopril may be a useful drug for the treatment of cystinuria (245,329), but a sufficient dose may cause orthostatic hypotension. Other physicians question the clinical utility of captopril (59).

Other metabolic disturbances may occur in patients with cystinuria. A comprehensive metabolic evaluation of 27 patients with homozygous cystinuria revealed that 19% had hypercalciuria and 22% had hyperuricosuria (286). Hypocitruria was found in 44%. Recurrent stones in cystinuric patients may be composed of calcium or

uric acid, not cystine. It is important to remember that multiple metabolic abnormalities may exist in a single patient.

Hypercalcemic Disorders

The primary cause of hypercalcemia determines the therapy. If surgical treatment of a stone is contemplated in a patient with primary hyperparathyroidism, a parathyroidectomy should be the first procedure, although concomitant parathyroidectomy and ESWL, ureteroscopic stone removal, or percutaneous stone removal have been performed safely (349). Patients should have careful follow-up after parathyroidectomy to ensure that the hypercalcemia has been corrected and stone formation has ceased. Persistent stone growth may be caused by another disorder.

An adequate intake of fluids should be encouraged in all immobilized patients. Oral orthophosphates decrease urinary calcium excretion in immobilized patients and may be used if fluid therapy is unsuccessful (112). Corticosteroids should reduce the hypercalciuria in patients with sarcoidosis.

Uric Acid Lithiasis

The medical treatment of uric acid lithiasis is satisfying because uric acid stones can be dissolved. Fluid intake should be increased to achieve a 24-hour urine output of 3 L. The solubility of uric acid can be increased 10-fold by raising the urine pH to 6.5 (Fig. 8.6). A sodium bicarbonate or citrate preparation can be used to accomplish this (130). A daily dose of 300 mg of allopurinol, a xanthine oxidase inhibitor (Fig. 8.5 and Fig. 8.8), reduces the amount of uric acid excreted in the urine.

When all three elements of this program are used, most uric acid stones can be dissolved within 3 months. The allopurinol can be stopped after the stones are dissolved. New stone formation usually can be prevented by maintaining an alkaline urine. Overexuberant alkalization may precipitate a layer of calcium phosphate over the stone. Dissolution then becomes impossible. Use of carbonic anhydrase inhibitors should be avoided for the same reason.

Xanthinuria

Patients who form xanthine calculi while taking allopurinol should discontinue the drug. Patients with xanthinuria secondary to an inherited deficiency of xanthine oxidase should maintain a high urine volume and restrict their dietary intake of foods that contain purine. Because the pKa of the first dissociable proton of xanthine is 7.7, the solubility of xanthine cannot be increased significantly by physiologic alkalization.

2,8-Dihydroxyadeninuria

Xanthine oxidase is responsible for the oxidation of adenine to 2,8-DHA (40,102,106). Treatment consists of fluids and allopurinol without urinary alkalization. The solubility of 2,8-DHA is not affected by urinary pH. Dietary adenine may contribute to stone formation and should be reduced. Lentils and other grains have a high adenine content (50).

Primary Hyperoxaluria

Large doses of pyridoxine (50 mg four times daily) reduce oxalate excretion in 20% to 50% of patients (109). Neutral orthophosphate (1.5 to 2.0 g per 24 hours of elemental phosphorus in four divided doses) may halt the growth of existing stones and prevent the formation of new stones (318). Sodium citrate increases urinary citrate excretion, reduces calcium oxalate saturation, and reduces stone formation in patients with primary hyperoxaluria (173).

Renal transplantation has been attempted in patients with primary hyperoxaluria and renal failure, but oxalate mobilization from preexistent oxalosis may lead to deposition of oxalate in the transplanted kidney (71). Transplantation should be performed soon after the onset of renal failure, because oxalate is not removed efficiently by hemodialysis (73,185).

Hepatic or combined hepatic-renal transplantation has been performed for the treatment of primary hyperoxaluria (190,357). This aggressive approach corrects the enzymatic defect. Urinary oxalate and glycolate return to normal levels, and extrarenal deposits of oxalate are mobilized.

Enteric Hyperoxaluria

Dietary intake of oxalate and fat should be restricted. An additional advantage of a low-fat (50 g) diet is that bothersome steatorrhea is reduced. Dietary calcium supplementation has been used to increase precipitation of calcium oxalate within the GI lumen (324), but this may increase urinary calcium. Stone disease usually can be controlled without resorting to calcium supplementation. Cholestyramine (12 g daily in three or four divided doses) binds acidic compounds, including oxalate, in the colonic lumen. Oxalate absorption decreases, steatorrhea decreases, and water absorption and urine volume may increase. Intestinal bicarbonate loss reduces urinary pH and citrate excretion. Some patients may even have a mild metabolic acidosis. These abnormalities can be corrected with base replacement. If metabolically active stone formation persists in patients with an ileal bypass, the normal anatomy of the GI tract should be restored (80).

Infection Stones

Surgical removal of a struvite stone generally is necessary to preserve renal function and reduce long-term morbidity and potential mortality (256). Urine cultures should be obtained and specific bactericidal therapy should be started 48 hours before surgery. All infected stone material should be removed. Antibiotic treatment should be continued for 10 to 14 days after surgery. Postoperative irrigation of the collecting system with hemiacidrin has been advocated to dissolve any minute retained stone fragments (5,214).

The patients should be maintained on antibacterial prophylaxis for 3 to 12 months. Adjunctive urinary acidification with ammonium chloride (2 g per day) has been used in conjunction with long-term antimicrobial therapy (379). Small retained fragments may dissolve with this regimen. The proper antibacterial agents suppress bacterial growth, and because of the decrease in urease production, urinary acidification can be achieved with ammonium chloride. Ammonium chloride (1.5 to 3 g per day) is a more effective urinary acidifier than either methenamine hippurate (2 g per day) or ascorbic acid (1.8 g per day) (355).

Acetohydroxamic acid, a urease inhibitor, may prevent the further growth of struvite stones and rarely may lead to dissolution of the stone material (368). Up to 50% of patients may experience side effects from the drug, including tremulousness, headache, or deep vein thrombosis.

The Shorr regimen combines a low-phosphorus diet with aluminum hydroxide capsules to achieve selective dietary phosphorus depletion (168). A few uncontrolled studies suggest that the Shorr regimen is an effective therapy for struvite urolithiasis, but the diet is difficult to follow. Low-phosphorus diets also increase urinary calcium excretion and promote crystalluria (362).

Most investigators report recurrent stone growth in 25% to 30% of patients (116). If recurrent metabolic stone formation is excluded, recurrent struvite stone formation occurs in 10% to 15% of patients. The lowest reported recurrence rate was only 2% (307).

Idiopathic Calcium Urolithiasis

Patients who consume adequate amounts of fluid and in whom dietary excesses have been eliminated may continue to have metabolically active stone formation. Several effective treatment programs are available.

Thiazide Diuretics

Thiazide diuretics are particularly effective when significant hypercalciuria is present. Hydrochlorothiazide 50 mg twice daily or trichlormethiazide 2 mg twice daily will reduce urinary calcium excretion, crystalluria, and urinary SS for calcium oxalate and calcium phosphate (374). The mechanism of action is thought to be stimulation of renal tubular calcium reabsorption, possibly by extracellular volume contraction (165). A high-sodium diet can blunt or prevent the hypocalciuric effect of thiazides. Moderate sodium restriction may be needed to reduce urinary calcium excretion. Up to 90% of patients who are treated with thiazides cease further stone formation.

Thiazides also may prevent stone formation in normocalciuric persons. This is a controversial finding, but may be related to a reported reduction in oxalate excretion after long-term thiazide therapy (58,375). Another study found that hydrochlorothizide did not reduce oxalate excretion, at least in patients with renal leak hypercalciuria (343). Side effects, including fatigue unrelated to the hypokalemia; hypomagnesemia; muscle weakness and cramping; decreased libido; impotence; and abnormalities in serum calcium, glucose, and uric acid, occur in up to 10% of patients.

There is some evidence that the treatment of all hypercalciuric patients with thiazide diuretics may be inappropriate (248). These investigators examined the effect of hydrochlorothiazide in 12 patients with absorptive hypercalciuria and in 10 patients with renal hypercalciuria. At short-term (3 to 6 months) follow-up, urinary calcium was significantly decreased in both groups. At long-term (30 to 120 months) follow-up, half of the patients with absorptive hypercalciuria were again hypercalciuric. The increased long-term stone formation seen in those patients with absorptive hypercalciuria was not statistically significant.

Yet another study found that chlorthalidone at a daily dose of 25 or 50 mg reduced the predicted rate of calculous events by 90% (87). This was a double-blind, randomized study that did not differentiate the mechanism of the hypercalciuria.

Orthophosphate

Orthophosphate has been the treatment of choice in patients with normocalciuria (314). It also may be effective in patients with hypercalciuria. Orthophosphate decreases urinary calcium excretion and increases inhibitor activity (371). Increased calcium complexation and decreased free calcium ion activity are a result of increased urinary phosphate, citrate, and pH. Calcium oxalate SS decreases, but the SS of hydroxyapatite or brushite does not change. Excretion of the inhibitors, pyrophosphate and citrate, increases, and the more alkaline pH increases the potency of pyrophosphate as a crystal growth inhibitor. Orthophosphate also may reduce 1,25-dihydroxyvitamin D synthesis (348).

Orthophosphate usually is given as the neutral or mildly alkaline salt. The total daily dose should provide 1.5 to 2.0 g of elemental phosphorus. Patients may lose previously formed stone material during the first 3 to 6 months of therapy. If radiographs document that stone mass is being lost and no new stone material is precipitating, patients should be reassured that the medication is preventing further stone growth and that the troublesome stones were formed before drug therapy was started. Calcium stone formation ceases in 90% of patients taking orthophosphate (339).

Diarrhea is the most common complication of orthophosphate therapy. The dose may be halved until the diarrhea subsides, and then gradually increased to a therapeutic level. Orthophosphates should not be used in the presence of secondary urolithiasis resulting from infection or obstruction or in the presence of renal failure (glomerular filtration rate, less than 30 mL per minute).

Cellulose Phosphate

The purpose of cellulose phosphate therapy, unlike orthophosphate therapy, is not to provide absorbable phosphate. Cellulose phosphate binds calcium in the intestinal lumen and decreases calcium absorption (227). Cellulose phosphate should be used only in patients with absorptive hypercalciuria, because it may result in a negative calcium balance in those patients with normal intestinal calcium absorption or renal hypercalciuria. The usual dose is 5 g two or three times daily.

When given alone, cellulose phosphate may be ineffective or even increase calcium oxalate crystalluria (10). Urinary oxalate excretion increases with cellulose phosphate therapy alone, probably because intestinal absorption increases. Less calcium is available to complex dietary oxalate in the intestinal lumen. Cellulose phosphate also binds magnesium and decreases urinary magnesium excretion. Supplementation of cellulose phosphate therapy with magnesium (1 to 1.5 g magnesium gluconate per day), a low-oxalate diet, and a high fluid intake will effectively halt stone formation in almost 80% of patients (223).

Magnesium

Magnesium oxide (193) and magnesium hydroxide (66) have been advocated for the treatment of ICU, but the effectiveness of this therapy has not been demonstrated systematically. [The same criticism may be applied to clinical trials of thiazides and orthophosphates (45).] Anticipated benefits of increased magnesium excretion are increased complexation of oxalate and phosphate and a slight increase in crystal growth inhibition. Some investigators have reported prevention of recurrent stone formation in 80% of treated patients. Approximately 1 g of magnesium oxide or 250 to 750 mg of magnesium hydroxide have been given in two or three divided daily doses.

Ettinger and colleagues (87) used a prospective, double-blind, randomized clinical trial to examine the effectiveness of chlorthalidone or magnesium hydroxide in the prevention of recurrent calcium oxalate stone formation. The duration of the study was 3 years. Compared with historic control subjects (pretreatment rates of stone formation), all of the treatments, including placebo, appeared to prevent recurrent stone formation. With appropriate controls, chlorthalidone was more effective than placebo or magnesium hydroxide. The placebo groups had 56% fewer stones than predicted; the low-dose magnesium hydroxide group had 62% fewer stones. Both low-dose and high-dose chlorthalidone reduced the predicted rate of new stone formation by 90%.

The pitfalls of clinical trials of thiazides have been reviewed by Churchill and Taylor (47). Without a control group, it is difficult to determine how much of a decrease in new stone formation is caused by regression to the mean and how much is a result of treatment.

Allopurinol

The use of allopurinol in patients with hyperuricosuric calcium urolithiasis has been controversial (96). Early reports were encouraging (55), but later reports were less optimistic (198). Two adverse effects of hyperuricosuria have been proposed: heterogeneous nucleation of calcium oxalate on urate crystals and binding of large-molecular-weight calcium oxalate–crystal growth inhibitors to colloidal urate (91). An allopurinol-induced reduction of urate excretion could preclude either mechanism. Allopurinol has even been reported to decrease urinary oxalate excretion (292). Allopurinol does not appear to have a direct effect on calcium oxalate precipitation. The most conservative approach may be to use allopurinol as a secondary drug in those patients who have abnormal uric acid metabolism. Tiselius and colleagues (340) concluded that empiric allopurinol is ineffective in the treatment of recurrent calcium oxalate stone disease in the absence of hyperuricosuria or hyperuricemia.

Between 10% and 20% of patients with idiopathic calcium urolithiasis have hyperuricosuria as an isolated metabolic abnormality. Ettinger and colleagues (88) found that allopurinol effectively prevented recurrent stone formation in this subset of patients. They recommended allopurinol instead of thiazides for patients with isolated hyperuricosuria, even though thiazides can be as effective. The risk of allergic reactions is increased with the simultaneous administration of thiazides and allopurinol.

Potassium Citrate

Potassium citrate has been used to treat patients with ICU and hypocitruria (228). The alkalizing effects of citrate increase urinary pH and urinary citrate excretion. Complexation of calcium with citrate increases, and ionized calcium and calcium oxalate SS decrease. Inhibition and calcium oxalate crystal growth increases slightly (increased citrate excretion and greater potency of pyrophosphate at a more alkaline urinary pH). In a study by Pak and Fuller, further stone formation ceased in almost 90% of ICU patients with hypocitruria. Citrate excretion increased to the normal range, whereas urinary pH was maintained at 6.5 to 7.0.

Several liquid preparations of citrate contain sodium. The effects of sodium citrate and potassium citrate on urine composition have been compared (284). Urinary pH and citrate excretion increased with both compounds, but calcium excretion decreased only with potassium citrate. The higher urinary pH increased brushite (calcium phosphate) saturation in both groups of patients, but a supersaturated condition was obtained only in those patients treated with sodium citrate. The failure to reduce urinary calcium excretion may have contributed to this latter effect.

In a trial by Pak and associates, long-term treatment with potassium citrate (20 mEq three times daily) reduced stone formation in 98% of patients, and stone formation ceased in 80% (236). Minor GI complaints were the most common side effects. No patients had melena or occult fecal blood. Although potassium citrate therapy of ICU is becoming more popular, not all investigators think that it is more beneficial than thiazides or even a placebo (242).

Pak and Fuller (228) studied 37 adults with a history of recurrent calcium oxalate stone formation. Seventeen had hypocitruria as an isolated abnormality, 18 had

absorptive hypercalciuria, and 2 had hyperuricosuria. Potassium citrate (30 to 80 mEq per day) was administered to 25 patients. Twelve patients took thiazide, allopurinol, or both. Sustained increases in urinary citrate, potassium, and pH were seen with potassium citrate therapy. Only 4 patients continued to form stones, for a remission rate of 89%.

In spite of some early skepticism, studies continue to support the clinical effectiveness of potassium citrate (1,129). A randomized, double-blind study in patients with idiopathic hypocitraturic calcium nephrolithiasis found that, compared with a placebo, potassium citrate (30 to 60 mEq daily in wax matrix tablets) significantly reduced stone formation (16). This reduction in clinical stone formation was accompanied by increases in urinary citrate, pH, and potassium. Citrate has even been used to prevent the deposition of calcium oxalate on fragments that remain after ESWL (335).

Potassium citrate may be useful in patients who do not respond to thiazides (236). Thirteen patients had hypercalciuria that was corrected by thiazide treatment, but stones continued to form. The addition of potassium citrate to thiazide therapy prevented the development of hypokalemia and caused a sustained increase in urinary citrate and pH. Urinary calcium, oxalate, sodium, or volume did not change. Stone formation was reduced in all patients, and a complete remission occurred in 77%.

Citrus fruit juices are rich sources of potassium and citrate. The ingestion of these juices potentially represents an alternative to potassium citrate in the management of hypocitraturia calcium and uric acid nephrolithiasis. A study of eight healthy men and three men with hypocitraturic nephrolithiasis found that, compared with potassium citrate, orange juice delivered an equivalent alkali load and caused a similar increase in urinary pH (354). Orange juice increased urinary oxalate without altering calcium excretion, whereas potassium citrate decreased urinary calcium without altering urinary oxalate. Orange juice lacked the ability of potassium citrate to reduce calcium oxalate saturation. Nevertheless, orange juice should be beneficial in the treatment of calcium and uric acid lithiasis.

Other Agents

Some patients with ICU and mild hyperoxaluria have been treated with pharmacologic doses of pyridoxine (200 to 400 mg per day) (15). Oxalate excretion decreased by approximately one-third. The proposed mechanism is stimulation of pyridoxal-5-phosphate–dependent transaminases that are responsible for the conversion of glyoxalate to glycine (Fig. 8.10). Less glyoxalate would be available for conversion to oxalate. Pyridoxine also decreased urinary glycolate excretion and increased erythrocyte glutamic oxaloacetic transaminase activity. Individuals who consume large quantities of pyridoxine (2 to 6 g per day) may develop a sensory neuropathy (290).

Pentosan polysulfate is a structural analog of heparin but has little anticoagulant activity (282). Up to 4% of an oral dose is excreted in the urine. This agent was used initially to treat patients with interstitial cystitis (244). Pentosan polysulfate is also a potent inhibitor of calcium oxalate crystal growth (187). A 50% reduction in the rate of calcium oxalate crystal growth was achieved with a concentration of 2.4×10^{-9} M. A daily dose of 300 mg should provide a urinary concentration of 10 mg/L and increase inhibition by one-third. A recent clinical trial of this compound found no difference in the rate of stone formation before and during treatment, although patients who continued to form stones reported that they were smaller and more easily passed spontaneously (92).

Potassium-magnesium citrate is similar to potassium citrate, but the magnesium may lower urinary oxalate by binding oxalate in the intestinal tract (232). It also causes a greater rise in urinary citrate and pH. Consequently, it may be more effective than potassium citrate in inhibiting the crystallization of uric acid and calcium oxalate in urine.

BLADDER CALCULI

Bladder calculi commonly are found in children who live in lesser developed countries and in men with bladder outlet obstruction. Bladder stones usually are freely movable in the bladder, but may be fixed to a bladder wall suture placed during a previous surgical procedure. The usual symptoms of bladder outlet obstruction may be present: urinary hesitancy, frequency, and nocturia. Patients also may have hematuria, dysuria, suprapubic pain that often radiates to the tip of the penis, and an interrupted urinary stream.

The diagnosis of a bladder stone usually is confirmed by radiographic examination, ultrasonography, or cystoscopy. Because many bladder stones are composed of radiolucent uric acid, the absence of a radiopaque shadow on a plain abdominal radiograph does not exclude the presence of a stone.

PROSTATIC CALCULI

Most prostatic calculi are found in men aged 50 to 65 years. Prostatic calculi are formed by the deposition of calcium salts on corpora amylacea. Corpora amylacea are laminated organic structures that are thought to form around desquamated epithelial cells in prostatic alveoli. Prostatic calculi may be associated with prostatic hyperplasia or prostatitis or may be asymptomatic. They may be seen on a plain roentgenogram of the pelvis and frequently can be palpated by rectal examination. Asymptomatic prostatic calculi require no treatment, but they often are removed during a transurethral prostatectomy for benign prostatic hyperplasia.

URETHRAL CALCULI

Urethral stones may form in the urethra or may migrate from the bladder or upper urinary tract. Primary or native urethral calculi usually are associated with chronic stasis and infection. Virtually all urethral calculi in women have been found in a urethral diverticulum. Men with urethral stones often have urethral strictures, a history of prostatic surgery, or coexistent bladder stones. Calcium phosphate and calcium carbonate are the most common chemical constituents.

Primary urethral calculi may be asymptomatic because they grow slowly with the urethral lumen or a diverticulum. Migrant stones may become symptomatic when they drop into the prostatic urethra. Patients may have dysuria, a weak urinary stream, or retention. Two-thirds of urethral stones are found in the posterior urethra, and one-third are found in the anterior urethra.

Fewer than half of urethral stones are diagnosed radiographically. Retrograde urethrography can define urethral anatomy in men but usually does not reveal a urethral diverticulum in women. Cystourethroscopy confirms the diagnosis.

CHILDHOOD UROLITHIASIS

Bladder stone disease was common in children in 18th century Europe (274). Boys younger than 10 years of age typically were affected. The prevalence of pediatric bladder stone disease became less common as Europe became industrialized. The occurrence of bladder stones in children was virtually unknown in Norway by 1831 (287). The disappearance of this disease is probably related to the concurrent improvement in nutrition. The disease still exists in less well-developed nations in Asia and the Middle East.

Bladder stone disease has been studied extensively in Thailand (78,346). Boys younger than age 10 years usually are affected. The stones are composed of a mixture of calcium oxalate and ammonium acid urate. Concurrent renal lithiasis typically is not present. A low intake of breast milk and early rice supplementation provide a diet low in protein and minerals. Urinary excretion of phosphate, sulfate, sodium, potassium, and magnesium is low. Urinary excretion of oxalate, calcium, uric acid, and ammonia is high. The high oxalate excretion is thought to be caused by consumption of local vegetables and plant leaves that have a high oxalate content. The hot climate and low fluid intake also contribute to crystallization.

Of patients with urinary calculi, 2% to 3% are children (345). Bladder stone disease is now uncommon in Europe and the United States. Most children with urolithiasis present with renal or ureteral calculi. Most patients have stones composed of calcium oxalate, calcium phosphate, or mixtures of these stone salts (184,311). Most children with urolithiasis have bacteriuria that is secondary to stone formation, but most of these organisms do not produce urease. One study found struvite stone formation in one-third of the patients (184). All had a history of multiple urologic procedures, diversionary procedures, or indwelling drainage devices. *Proteus* was the most common bacterial organism. Other investigators found a lower incidence of infection-induced stone formation.

The spectrum of causes is the same in children as it is in adults. One-third to one-half of patients have ICU. One study reported finding primary hyperparathyroidism in 6% of the pediatric patients (184), but most authors think that hyperparathyroidism as a cause of urinary stone formation in children is extremely rare. Some of the discrepancy may be explained by the rarity of any kind of urolithiasis in children. Other metabolic causes of stone formation in children are distal RTA, cystinuria, and primary hyperoxaluria. Inflammatory bowel disease also is responsible for recurrent calcium oxalate stone formation in children (49). The pathophysiology is the same

as that for enteric hyperoxaluria in adults.

A subsequent review of 221 pediatric patients referred to the Mayo Clinic found an almost even split between boys and girls (108 versus 113, respectively) (200). Analysis of stone material from 122 of the patients revealed calcium oxalate in 45%, calcium phosphate in 24%, cystine in 8%, struvite in 17%, and uric acid in 2%. A metabolic predisposition to form stones was found in 52%: hypercalciuria in 34% and hyperoxaluria in 20%. Other factors predisposing to stone formation were structural abnormalities or chronic infection.

Episodic gross hematuria may precede overt urolithiasis in children with hypercalciuria (323). Hypercalciuria was present in approximately 40% of children with gross hematuria but without urinary infection or proteinuria. Many children had concurrent abdominal or suprapubic pain, dysuria, and urinary frequency. Three-fourths of the children with hypercalciuria had a family history of urolithiasis. The hematuria resolved during anticalciuric therapy with hydrochlorothiazide or dietary calcium restriction.

The frequency and prognostic importance of hypercalciuria in children with hematuria were examined in a prospective multicenter study (322). Hypercalciuria was found in 76 (35%) of 215 patients (aged 3 to 18 years) who had unexplained isolated hematuria. No patient had proteinuria, urolithiasis, infection, or a systemic disorder. The children with hypercalciuria tended to be white males, have a family history of urolithiasis, and have gross hematuria with calcium oxalate crystalluria. Oral calcium loading tests showed renal hypercalciuria in 26 patients, showed absorptive hypercalciuria in 15 patients, and were not diagnostic in 35 patients. One week of dietary calcium restriction normalized urinary calcium excretion in those patients without renal hypercalciuria. During the follow-up period of 1 to 4 years, more hypercalciuric than normocalciuric children developed urolithiasis or renal colic. The authors also concluded that oral calcium loading tests offered little diagnostic benefit over 24-hour urinary calcium excretion measurement after dietary calcium restriction. Hydrochlorothiazide will correct the hypercalciuria (353).

Chapter References

The surgical management of urinary calculus disease has evolved considerably over the past two decades. Twenty years ago, open procedures for stones were some of the most frequently performed urologic operations. Since then, however, stone management has been at the forefront of “minimally invasive” intervention. Specifically, the introduction and refinement of percutaneous and ureteroscopic access to the upper tracts, along with the nearly simultaneous development of both extracorporeal and intracorporeal lithotripsy, has relegated the role of open surgery to less than 1% of patients undergoing intervention for their stone disease. This chapter reviews the indications to intervene for urinary calculi, the basic physics of the most frequently used devices for both extracorporeal and intracorporeal lithotripsy, and the respective roles of extracorporeal and intracorporeal lithotripsy with percutaneous or ureteroscopic access and open surgery. The results and complications associated with each of these forms of intervention are reviewed as well.

PATIENT EVALUATION

Radiographic Evaluation

A thorough radiologic evaluation is one of the most important aspects of the overall investigation of urinary stone disease. These studies are invaluable aids in assessing three major issues that must be addressed before selecting appropriate treatment: stone burden and location, urinary tract anatomy, and overall and ipsilateral renal function.

Plain Abdominal Radiography

More than 90% of stones within the urinary tract are radiopaque, and a plain film of the kidney, ureter, and bladder (KUB) is often the initial radiographic examination obtained in patients with nephrolithiasis. The KUB should be performed before any subsequent films that use contrast media because contrast may prevent the visualization of any calculi.

It is important not to overlook stones that may be obscured when they overlie bony structures, such as the sacrum or transverse processes of the lumbar vertebrae. These stones can be more easily identified using oblique views in addition to those obtained in the anteroposterior position. In addition, nephrotomograms can also be used to assist in the identification of small, less radiopaque calculi within the kidneys.

Intravenous Pyelography

An intravenous pyelogram (IVP) can be instrumental in defining the relationship of calculi to the pyelocalyceal system and ureter. The exact location of the stones, the presence or absence of obstruction, and renal or ureteral anomalies are important pieces of information that can be gleaned from the IVP. In addition, the IVP can approximate renal function in both the affected and the contralateral kidney as suggested by the promptness of contrast excretion, thickness of renal parenchyma, and amount of pyelocaliectasis. However, for more precise information on renal function, a differential renal scan should be obtained.

For patients with an apparent ureteral calculus, delayed films are obtained for as long as necessary to specifically identify their location and to prove their presence within the urinary tract. An IVP may also suggest the presence of radiolucent stones, and it may also identify anatomic abnormalities that contribute to stone formation such as a ureteropelvic junction obstruction or calyceal diverticula.

Renal Ultrasonography

Ultrasonography (US) can be used as a screening tool for hydronephrosis or stones within the collecting system. Additional information provided by sonographic examination of the kidneys includes an estimate of the amount of renal parenchyma present and identification of otherwise radiolucent calculi, because a classic

“sonographic shadow” will often clearly identify stones that may not be visualized on standard plain films. However, the middle ureter and distal ureter are often not satisfactorily visualized on US due to the presence of bowel gas anteriorly and the bony pelvis posteriorly. US may also be useful in the acute setting to rule out other causes of abdominal pain and during follow-up of patients with recurrent nephrolithiasis because its use avoids x-ray exposure.

Computed Tomography

Computed tomography (CT) scanning is particularly useful in helping identify the etiology of otherwise radiolucent filling defects within the renal pelvis or ureter. In addition, obstruction, anatomic anomalies, or other urologic problems such as a vascular insult that can mimic ureteral colic can also be easily identified.

Nonenhanced spiral CT is currently the preferred diagnostic tool in the assessment of patients with acute flank pain (182). This technique is more sensitive than either simple radiography or US. All stones, with the exception of certain drug-related crystals, are visualized by this method, which is also fast and cost-effective. Moreover, other manifestations of obstruction, such as periureteric and perinephric stranding, and periureteric edema and hydronephrosis are easily identified (Fig. 9.1). Finally, spiral CT scan has the advantage of being able to definitively identify other causes of acute flank or abdominal pain such as appendicitis, diverticulitis, cholecystitis, or abdominal aneurysmal disease.

FIGURE 9.1. A: Dilation of left renal collecting system *(arrow)*. **B:** Dilated left ureter overlying psoas muscle *(arrow)*. **C:** Calculus in proximal ureter *(arrow)*. **D:** Reconstructed computed tomography imaging confirms partially obstructing proximal ureteral calculus.

Radionuclide Evaluation

Renal radionuclide studies provide rapid and safe information about total and differential renal function. These tests are specifically advantageous because they are noninvasive, require no bowel or other specific preoperative preparation, subject the patient to only minimal radiation exposure, and are apparently free of allergic complications. A differential renal scan should be performed in those patients in whom an obstructing stone might have resulted in a permanent and significant reduction in renal function, because nephrectomy may be the procedure of choice for kidneys that, after relief of obstruction, will supply less than 10% to 15% of overall function.

THE ACUTE STONE EPISODE

Classic symptoms associated with an acutely obstructing urinary stone include colicky flank pain with or without nausea or vomiting. The pain may radiate anteriorly or even to the groin, ipsilateral testicle, or labia. Stones in the distal ureter may also result in frequency, urgency, and dysuria. If the obstruction is associated with infection, high-grade fever or even sepsis may ensue. If a patient demonstrates these classic findings and has a previous history of recurrent radiopaque nephrolithiasis, further studies are warranted to address the size and location of the stone to determine the appropriate course of treatment. Stones 4 mm or smaller in largest diameter have a greater than 90% rate of spontaneous passage with conservative measures alone; however, stones 6 mm or larger have only a 10% rate of spontaneous passage (121).

For patients who lack classic symptoms and are experiencing their first stone episode or who are known to form radiolucent stones, either a nonenhanced spiral CT or an IVP should be performed. Sonography may be used to assess hydronephrosis and intrarenal calculi, but it may be especially insensitive for the diagnosis of ureteral stones.

If the patient is clinically stable and has no evidence of systemic infection, progressive obstruction, or obstruction of a solitary kidney, conservative management may be offered with pain medications alone such as nonsteroidal antiinflammatory drugs or narcotic analgesics. However, in the presence of obstruction with infection, unrelenting pain, or significantly compromised renal function, urinary drainage should be instituted on an emergent basis, either as ureteral stent placement or as percutaneous nephrostomy drainage.

INDICATIONS FOR INTERVENTION

Although the use of newer, less invasive modalities has become the standard of management for nearly all patients requiring intervention for stones, the indications to intervene have remained essentially unchanged. These include chronic or progressive obstruction from the stone; pain, infection, or hematuria associated with the stone; or active stone growth despite appropriate medical management (Table 9.1). In addition, even in the absence of an otherwise clear indication, stone removal should be considered for any “high-risk” patient, such as an airplane pilot, who cannot afford to experience an inopportune episode of renal colic.

Chronic or progressive obstruction from the stone
Pain, infection, or hematuria associated with the stone
Active stone growth despite appropriate medical management

TABLE 9.1. INDICATIONS FOR INTERVENTION

SHOCK WAVE LITHOTRIPSY

Since the first patient was successfully treated with shock wave lithotripsy (SWL) in 1980, rapid acceptance and widespread use have made this form of stone therapy the treatment of choice for more than 80% of all patients undergoing intervention for renal and ureteral calculi. Although the basic principles of SWL remain unchanged, a number of technologic advances and modifications in currently available lithotripters have significantly expanded the clinical applications of lithotripsy. The rapid acceptance and widespread application of SWL have also led to many advances in lithotripsy technology and have stimulated numerous studies to better

understand the basic physics and the bioeffects of this modality.

Following the initial success of the first-generation lithotripter (Dornier HM-3), more than 20 different models of second-generation lithotripters were developed, utilizing various energy sources, focusing schemes, coupling media, and stone localization techniques (135,144). Moreover, several “third-generation” lithotripters, characterized by their dual imaging and variable power capabilities, have recently been developed and are either commercially available or undergoing clinical trials both in Europe and the United States (14,92,104,152). Although the fundamental principles of SWL remain unchanged, these advances in lithotripsy technologies have generally led to improved safety and, in some cases, improved cost-effectiveness of urolithiasis treatment.

Basic physics and animal studies performed in the past two decades have greatly advanced our understanding of the mechanisms of stone fragmentation, as well as tissue injury and renal functional alterations, induced by SWL. A basic understanding of the physical and biologic effects of high-intensity shock waves is important to ensure the safety and efficacy of SWL treatment. This knowledge is essential for the optimization of SWL technology to achieve maximal efficacy of stone fragmentation while minimizing adverse effects on renal tissue.

Not all stones are amenable to SWL, and clinical studies have demonstrated that the size and composition of the calculi, along with location and renal and ureteral anatomy, all significantly affect successful stone fragmentation and clearance. This section provides a critical review of our current understanding of SWL and offers insights into the future of this innovative technology.

Historical Aspects

Physicists at Dornier Systems, Ltd., and Friedrich Shafen, Germany, began experimenting with shock waves and their travel through water and tissue in 1963. Throughout the 1970s, numerous experimental lithotripters were developed that used new methods of transmitting shock waves, as well as different techniques of stone localization. In addition, experimental studies were being performed both *in vitro* and *in vivo* examining the effects of shock waves on various organs and tissues.

In 1980, Chaussy and associates successfully treated the first human patient, and they then reported their initial series of 72 patients in 1982 (25). Subsequently, nearly 2,000 articles have been published in the peer-reviewed literature detailing the use of SWL for the management of renal and ureteral calculi. Moreover, numerous second- and third-generation devices have been introduced and are currently being used throughout the world. Enhancements in these newer lithotripters may ultimately prove to facilitate stone fragmentation while reducing tissue injury.

Lithotripsy Design

All lithotripters share four main features: an energy source, a focusing device, a coupling medium, and a stone localization system (Table 9.2). The original Dornier HM-3 design uses a spark plug energy generator with an elliptical reflector for focusing the shock waves. A water bath transmits the shock waves to the patient with stone localization provided by biplanar fluoroscopy. Modification of the four basic components of this first-generation lithotripter has provided the development of second- and third-generation devices, of which more than ten machines are currently either available commercially or undergoing clinical trials (136).

Shock wave generator	Coupling medium
Shock wave focusing	Stone localization

TABLE 9.2. MAIN LITHOTRIPTER COMPONENTS

Shock Wave Generation

All lithotripters share the four aforementioned features, but it is the mode of shock wave generation that determines the actual physical characteristics of that particular lithotripter. The objectives for using different types of energy sources include maximum efficacy (the overall stone-free rate) and maximum efficiency (cost-effectiveness, including need for secondary treatments). The two basic types of energy sources for generating shock waves are point sources and extended sources. The electrohydraulic machines use point sources for energy generation, whereas extended sources are incorporated into the piezoelectric and the electromagnetic devices.

Electrohydraulic Generators

The electrohydraulic generator is located at the base of a water bath and produces shock waves by an electric spark gap of 15,000 to 25,000 volts and 1 ms duration. This high-voltage spark discharge results in the rapid evaporation of water, which generates a shock wave by expanding the surrounding fluid. The spark plug is located in an ellipsoidal reflector that concentrates the reflected shock waves at a second focal point, F_2, with F_1 being the origin of the primary shock waves (Fig. 9.2). The spark-gap method of shock wave generation was pioneered by the first-generation Dornier HM-3 lithotripter and is also used in the Direx, Medstone, Northgate, and Technomed machines, among others.

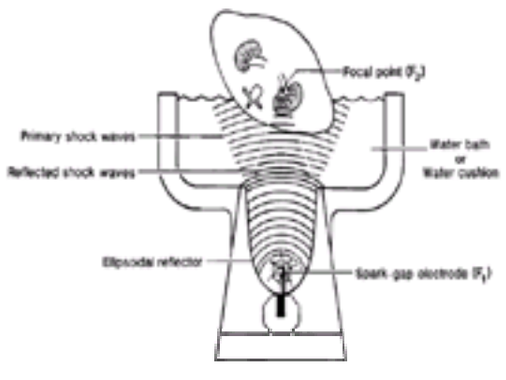

FIGURE 9.2. Schematic of electrohydraulic shock wave generator.

Piezoelectric Generators

Piezoelectric shock waves are generated by the sudden expansion of ceramic elements excited by a high-frequency, high-voltage pulse. Thousands of these tiny elements are placed along the inner surface of a hemisphere at the base of a pool of water. Although each of these ceramic elements moves only slightly in response

to a pulse of electrical energy, the summation of the simultaneous expansion of multiple elements results in a high-energy shock wave directed to the focal point at the center of the sphere. The shock wave is propagated through either a small water basin or a water-filled bag to the focal point, F_1 (Fig. 9.3). The spherical focusing mechanism of the piezoelectric lithotripters provides a wide point of shock wave entry at the skin surface and a very small focal point.

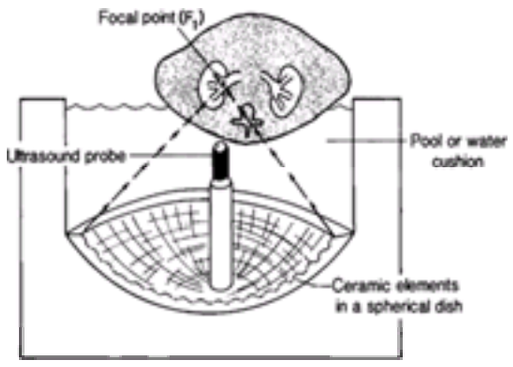

FIGURE 9.3. Schematic of piezoelectric shock wave generator.

Electromagnetic Generators

In electromagnetic devices, shock waves are generated when an electrical impulse moves a thin, circular metallic membrane, which is housed within a cylindric “shock tube.” The resulting shock wave, produced in the water-filled shock tube, passes through an acoustic lens and is thereby directed to the focal point, F_1 (Fig. 9.4). The shock wave is coupled to the body surface with a moveable water cushion and coupling gel.

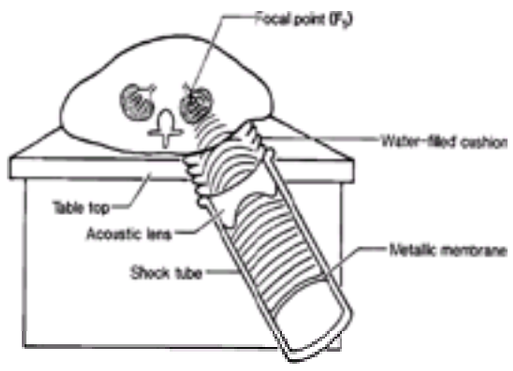

FIGURE 9.4. Schematic of electromagnetic shock wave generator.

Shock Wave Focusing

Shock waves must be focused to concentrate their energy on a target such as a calculus. The type of shock wave generation dictates the method of focusing used. Machines that use point sources, such as spark-gap electrodes, generate shock waves that travel in an expanding circular pattern. All of these machines use ellipsoid reflectors for focusing the shock waves at the second focal point, F_2.

Because a single piezoelectric element produces a very small amount of energy, larger transducers with multiple ceramic elements are required for piezoelectric lithotripters. The array of ceramic elements is positioned in a spherical dish that allows focusing in a very small focal region, F_1. The vibrating metal membranes of the electromechanical lithotripters produce an acoustic plane wave that uses an acoustic lens for focusing the shock wave at F_1.

Coupling Medium

The original Dornier HM-3 machine uses a 1,000-L water bath to transmit the shock waves to the patient. This method of coupling requires unique positioning of the patient, because the anesthetized subject has to be lowered into the tub and the calculus accurately positioned at the second focal point. Remote monitoring and the physiologic effects of almost total body immersion thus produced unique challenges for the anesthesiologist. Second-generation lithotripters were designed to alleviate the physiologic, functional, and economic problems of the large water bath, and current models use an enclosed water cushion, or a totally contained shock tube, to allow simplified positioning and “dry” lithotripsy.

Stone Localization

Stone localization during lithotripsy is accomplished with either fluoroscopy or US. Fluoroscopy provides the urologist with a familiar modality and has the added benefits of effective ureteral stone localization. Moreover, fluoroscopy allows the use of contrast material to help delineate the anatomy of the collecting system. However, fluoroscopy requires more space, carries the inherent risk of ionizing radiation to both the patient and medical staff, and is not useful, without adjunctive contrast injection, in localizing radiolucent calculi.

Sonography-based lithotripters offer the advantages of stone localization with continuous monitoring and effective identification of even radiolucent stones, without radiation exposure (135). In addition, US has been documented to be effective in localizing stone fragments as small as 2 to 3 mm and is as good as or better than routine KUB to assess patients for residual stone fragments following lithotripsy (1). The major disadvantages of US stone localization include the basic mastery of the use of ultrasonic techniques by the urologist and difficulty in localizing minimally obstructing or nonobstructing ureteral stones.

Anesthesia Requirements

Three factors contribute to the need for anesthesia during SWL: shock wave pressure (power), area of the shock wave at its skin entry site, and size of the shock wave focal point. The intensity of the shock wave is determined by the type of generator used and the amount of power (usually electrical charge) supplied to the shock wave generator. The original electrohydraulic design delivers the most powerful shock waves but also causes the greatest amount of discomfort for the patient. Therefore either general, regional, or local anesthesia is used in the original spark-gap machines. Recent studies have demonstrated the ability to reduce anesthesia requirements with the first-generation electrohydraulic devices (123).

The size of the focal point and the area of shock wave entry at the skin are both determined by the configuration of the focusing device (Fig. 9.5). The increased area of skin entry and diminished focal size have lessened the need for general or regional anesthesia in patients treated with second- or third-generation lithotripters. Currently, variable-power electrohydraulic lithotripters provide the advantage of a wide range of shock wave intensities to allow for either a reduction in anesthesia requirements or increased fragmentation efficacy with higher power under general or regional anesthesia. Using the lower power setting, however, causes the overall stone-free rate to decrease, while increasing the number of shocks required per treatment and the re-treatment rate. Therefore, to achieve an anesthesia-free status, one must expect the number of secondary treatments to increase. Therefore the efficiency of that lithotripter will be diminished.

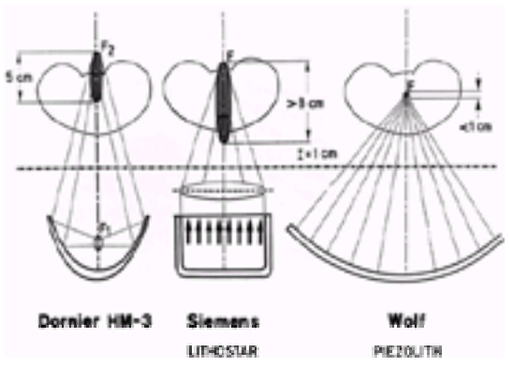

FIGURE 9.5. Configuration of focal regions for three types of shock wave generators.

Shock waves generated by a piezoelectric source tend to be less powerful than those from an electrohydraulic source. This leads to a higher re-treatment rate, but when combined with other design modifications, it allows treatment of stones without anesthesia (135). The wide aperture of the focusing sphere, the larger skin entry zone, and the small focal point combined with lower peak pressures make piezoelectric machines truly anesthesia free.

Design characteristics of the electromechanical lithotripters tend to place them between the other two machine types in terms of anesthesia requirements. The electromagnetic devices have a relatively small skin entry site and a large focal area. Electromagnetic lithotripsy is usually performed with intravenous or oral sedation, with or without the use of local anesthesia at the skin entry site. A transcutaneous electrical nerve stimulator may provide adequate analgesia during lithotripsy with electromagnetic lithotripsy (31).

Indications and Contraindications

Indications for SWL in urinary tract stone management are the same as the indications for surgical intervention. These include renal colic or chronic pain, urinary obstruction, infection, or decreasing renal function. Relative contraindications to SWL include large stone size (i.e., calcium oxalate stones greater than 2.5 cm in diameter or struvite stones greater than 5.0 cm in diameter), most cystine stones, active infection, proximate calcified abdominal aortic or renal artery aneurysms, distal obstruction, pregnancy, and poorly informed patients (167) (Table 9.3).

Large stone	Active infection
Calcium oxalate >1.5 cm	Proximate calcified abnormal aortic or renal artery aneurysm
Struvite >3 cm	
Significant dilation of collecting system	Pregnancy
Distal ureteral obstruction	Poorly informed patient
Untreated coagulopathy	

TABLE 9.3. RELATIVE CONTRAINDICATIONS TO SHOCK WAVE LITHOTRIPSY

Results: Clinical Considerations

Efficiency Quotient

The determination of lithotripter efficiency with regard to adequate stone fragmentation requires a delicate balance between the completeness of stone fragmentation and the need for anesthesia or analgesia. As the shock wave intensity is decreased to allow for “anesthesia-free” lithotripsy, the ability to adequately fragment stones is also reduced, thereby decreasing lithotripter efficiency. Diminished efficiency can be seen as an increase in the number of treatments needed to render a patient stone free or as an increased need for auxiliary procedures before or following lithotripsy. Auxiliary procedures would include placement of a percutaneous nephrostomy tube, formal percutaneous nephrostolithotomy, ureteropyeloscopy, or placement of a ureteral stent.

An “efficiency quotient” can be calculated by determining the stone-free rate obtained by various lithotripters in relation to the need for repeat lithotripsy, as well as the number of auxiliary procedures performed to render patients stone free (40). Using this efficiency quotient, one can make more valid comparisons between different types of first- and later-generation lithotripters.

Reports for many second-generation lithotripters have revealed stone-free rates similar to those obtained from the original electrohydraulic lithotripsy devices. If one also considers the need for repeat lithotripsy as well as the number of auxiliary procedures performed, however, the efficiency quotients of the lower-power, second-generation devices and the original electrohydraulic machines might not be equivalent. The efficiency quotient offers the urologist a more reliable gauge for comparing the effectiveness of individual lithotripters than does the stone-free rate alone (144).

With their higher re-treatment rate, second-generation lithotripters increase the time commitment necessary for both patient and treating physician. However, the decrease in stone fragmentation efficiency may be compensated by the fact that many of the second-generation devices allow for office-based lithotripsy and require no hospitalization or intravenous lines, no anesthesia or analgesia, and no recovery room charges. Therefore some physicians and patients may accept the inconvenience of multiple repeat treatments if the safety and ease of operation of the second-generation machines outweighs the disadvantage of diminished lithotripsy “efficiency.” In fact, it is probably not possible to have true anesthesia-free capability with a lithotripsy device that rates high on an efficiency quotient scale. To achieve anesthesia-free status, one has to expect the number of secondary treatments to increase, and therefore the efficiency quotient of that lithotripter will be diminished.

“Small” Calculi

The first-generation Dornier HM-3 represents the gold standard in terms of efficacy (overall stone-free rate) in stone fragmentation. As the shock wave pressure and focal point area of second- and third-generation machines have been reduced, so has the requirement for anesthesia or analgesia. However, the price paid for anesthesia-free lithotripsy is an increase in the secondary treatment rates and a subsequent reduction in efficiency. Although there is a compromise in efficiency with the piezoelectric lithotripters, the decreased efficiency may be balanced by the fact that each treatment can be performed as an “office” procedure, without anesthesia or analgesia. Electromagnetic lithotripsy, usually performed with intravenous or oral sedation, has been found to require a mean of approximately 3,600 shock waves per treatment, with stone-free rates of 69% to 80% and re-treatment rates of 7% to 21%.

“Large” Calculi

With increased stone volume, the efficacy of all lithotripters decreases significantly. With a Dornier HM-3, the stone-free rate may be as low as 30% for patients with a dilated collecting system and a stone or group of stones with total volume greater than 3 cm (105). Although the stone-free rate for large calculi is approximately 70% for patients with normal collecting system anatomy, many clinicians advocate the use of percutaneous nephrolithotripsy as the initial form of therapy in this setting

(120,158).

In some situations, the combination of percutaneous nephrolithotripsy and SWL can be more effective than SWL alone. With this type of combination therapy, stone-free rates approaching 85% to 90% have been reported, even for large calculi (168).

Stone Location

Stone location in the collecting system is another important determinant of the outcome of SWL. Treatment of renal pelvic and upper ureteral stones may result in stone-free rates of 85% to 92% (91). In contrast, stone-free rates for patients with lower calyceal calculi are less than 60%, compared with 75% to 80% for those with middle and upper calyceal stones (106). Recent studies have also documented the importance of lower pole renal anatomy and its impact on stone clearance following SWL (49).

Stone-free rates of 65% to 70% for lower ureteral calculi (below the pelvic brim) have been achieved through various modifications in patient positioning and lithotripter design. However, ureteroscopy for the management of calculi in a similar location is successful in 95% to 100% of patients, and ureteroscopic extraction is now generally considered the first line of therapy for stones in the distal ureter (190).

Stones in calyceal diverticula have long been a source of treatment controversy. SWL provides improvement or resolution of symptoms in many patients but is generally unsuccessful in rendering such patients stone free. Percutaneous management of these stones, by contrast, produces significantly higher stone-free rates (12,87). These data suggest that stones in calyceal diverticula should be managed with SWL only when specific criteria regarding stone size and diverticular emptying are met (169).

Stone Composition

As the stone composition varies, so does the efficacy of SWL. “Harder” stones such as calcium oxalate monohydrate and cystine require an increased number of shock waves at higher intensity levels to achieve adequate fragmentation. Even at these higher settings, however, results with cystine calculi have been inferior to those with calcium oxalate stones (30). Most investigators advocate the use of percutaneous or “combination” therapy for large cystine calculi (27).

Auxiliary Procedures

Another area of controversy has been the efficacy of, and indications for, the use of ureteral stenting before SWL. Although some reports advocate the liberal use of ureteral stents before lithotripsy, the benefits of anesthesia-free lithotripsy would be diminished if an anesthetic or analgesia were required for stent placement. In fact, a recent clinical series evaluating the use of ureteral stents with lithotripsy found no improvement in stone-free rates or postlithotripsy complications in patients with ureteral stents. However, use of stents was associated with a significantly higher incidence of patient morbidity, including discomfort, frequency, urgency, and hematuria (109,137). Urologists generally exercise their own judgment regarding the merit of ureteral stenting in individual patients, and patients with large calculi or those requiring general or regional anesthesia for lithotripsy are more likely to undergo stent placement.

Current Lithotripters: Limitations

In the two decades since the first clinical application of SWL by Chaussy and associates (25), technical refinements have produced more than 15 second- and third-generation devices. These designs have concentrated on altering the methods of shock wave generation, focusing, coupling, and localization, with the primary goal of equaling the stone-free rate of the Dornier HM-3 while increasing the safety, convenience, and cost-effectiveness of treatment. The new devices are designed to offer equivalent or better stone fragmentation, to decrease or eliminate anesthesia requirements, and to decrease radiation exposure from x-rays. Despite great technical progress, however, these new machines still have important shortcomings.

In general, second-generation lithotripters can be divided into a higher-power electrohydraulic and electromagnetic group and a lower-power piezoelectric group. Disadvantages of the first group include pain and attendant anesthesia requirements and as yet poorly quantified renal tissue damage. Disadvantages of the second group include a small focal size of the shock wave, with the need for a greater total number of shock waves, and a higher re-treatment rate.

The apertures of the electrohydraulic and electromechanical lithotripters are relatively small, leading to a smaller skin entry site and larger focal zone. This creates the need for general or regional anesthesia or heavy intravenous sedation. The larger aperture of the treatment dish of the piezoelectric lithotripters results in a large area of skin entry and a small focal zone. The discomfort produced by treatments with these machines is minimal enough to allow for anesthesia-free lithotripsy (135).

The relatively large focal region of electrohydraulic lithotripters exposes a larger amount of normal renal tissue to maximal shock wave pressures, and both animal and clinical studies have demonstrated more acute renal parenchymal injury from electrohydraulic and electromagnetic lithotripters when compared with piezoelectric units. However, one drawback of the small focal region in the piezoelectric machines is that it mandates constant monitoring of the effects of treatment on the targeted calculus. Accurate focusing of the shock wave is mandatory, because there is a rapid dropoff in pressure outside the small focal zone. The requirement of exact focusing is not necessary with the electrohydraulic or electromagnetic machines, which have a much larger area of maximal shock wave energy. As noted previously, for the advantage gained by performing anesthesia-free lithotripsy, one loses efficiency of stone fragmentation. Currently, it appears that it is not possible to have true anesthesia-free capabilities with a very “efficient” lithotripter.

Additional limitations of current lithotripsy devices relate to the method of stone localization. Although lithotripters using fluoroscopy can visualize the entire urinary system, they have the disadvantage of exposing the patient to a significant amount of radiation. In addition, it is often difficult, if not impossible, to identify small calculi within the kidney or ureter, or any radiolucent stones without the aid of contrast injection.

The devices that use sonography for stone localization potentially can be used for both renal and biliary lithotripsy, and they pose no risk of radiation exposure. Their main disadvantage is that they offer poor visualization of middle and lower ureteral stones. Efforts to develop echogenic ureteral stents, as well as new modes of sonography to aid in ureteral stone localization, are now in progress.

The Ideal Lithotripter

SWL can be used effectively to treat most renal and ureteral calculi with minimal morbidity and convalescence. Research in lithotripter design is ongoing, however, with attempts to improve performance and ultimately to design the “ideal lithotripter.” Such a device should be physically compact and portable, thereby allowing a lithotripter to be transported or shared between smaller institutions. In fact, a number of mobile lithotripsy units are currently in operation. The ideal lithotripter should also be adaptable for other endourologic procedures, as well as for biliary lithotripsy. Many of the current machines that use fluoroscopic stone localization can be used for percutaneous or ureteroscopic stone removal, and the US-based machines can easily be used for both urinary and biliary calculi.

By having an adjustable energy source, the ideal lithotripter would allow for anesthesia-free treatment of smaller or “routine” calculi, yet would have the potential power required to fragment either very hard or large renal or ureteral stones. This capability would allow for effective and efficient lithotripsy treatments, with the knowledge that in some cases, sedation or anesthesia must be administered to allow the use of the more powerful shock wave energy.

Finally, the ideal lithotripter should be economical to install and operate. This would entail minimal site renovations before installation of the lithotripter and little or no daily operating costs once the machine is on-line and running.

New-generation Lithotripters

A number of new-generation lithotripters have incorporated many of the characteristics of the ideal lithotripter (28). The basic design of these third-generation machines includes dual imaging capabilities, as well as variable shock wave power (Table 9.4). Currently, a number of third-generation lithotripters are currently in use across the globe. These include the Dornier MFL 5000 (HM5), Dornier Compact S, Siemens Lithostar Plus, Storz Modulith SL20 and SLX, and Wolf Piezolith 2500 (77,93,107,118,138,177).

Dual imaging	Ultrasonography
Fluoroscopy	Variable power

TABLE 9.4. NEW-GENERATION LITHOTRIPTERS

Dual Imaging

Dual imaging capability entails having both fluoroscopic and sonographic localization systems available in the same machine. Such a design has the advantage of using fluoroscopy for imaging stones within the kidney and the ureter, while having the option to use sonography for the identification of radiolucent renal or biliary calculi. Another advantage of a sonographic localization system is that it allows the operator to target a stone using fluoroscopy initially, and then to switch to sonography to avoid excessive use of ionizing radiation.

Interestingly, while the Dornier, Siemens, and Storz machines have all added US capabilities to provide dual imaging, none of these systems provides “in-line” imaging for both the fluoroscopic and sonographic localization devices. For example, with the Dornier and Siemens devices, one can use sonography to target a radiolucent or biliary tract calculus, yet the patient must be moved “blindly” to the fluoroscopy unit, which is in line with the shock wave generator. Alternatively, one can use the fluoroscopic localization system with the Storz machine, yet only the US is in line with the shock wave generator. The Wolf Piezolith 2500 is currently the only third-generation device that has both fluoroscopy and sonography in line with the piezoelectric shock wave generator (Fig. 9.6). This permits rapidly changing from fluoroscopic to sonographic stone localization, without moving the patient off the treatment dish.

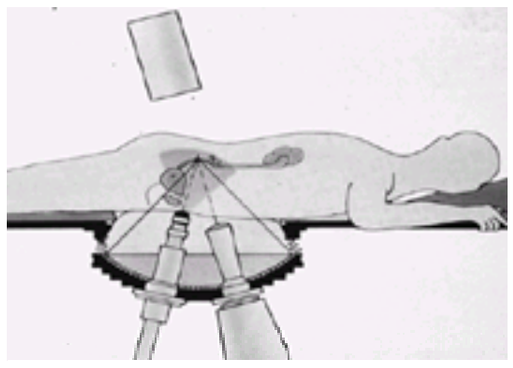

FIGURE 9.6. Illustration of dual imaging capabilities (fluoroscopy and ultrasonography) in newer-generation lithotripters.

Variable Power

All of the third-generation devices discussed here have variable-power shock wave generators. This capability allows the shock wave energy to be tailored to the requirements of a particular stone. The operator can turn down the generator power to provide significantly reduced anesthesia and analgesia requirements with the Dornier, Siemens, and Storz machines, as well as to provide totally anesthesia- and analgesia-free lithotripsy with the Wolf device. Moreover, the shock wave intensity can be increased with all these machines to allow adequate fragmentation of extremely hard or large calculi. However, when used in the high-power mode, these lithotripters will require some form of anesthesia or analgesia.

The ideal shock wave machine that allows anesthesia-free lithotripsy with maximum efficiency has yet to be developed. However, by varying the shock wave energy, a highly efficient shock wave can be administered, with the understanding that anesthesia or analgesia will be required when high shock wave pressures are used. Alternatively, with a small or fragile stone, the shock wave energy can be significantly decreased to allow the use of minimal analgesia or even anesthesia-free lithotripsy. With the availability of variable-powered lithotripters that use electrohydraulic, electromagnetic, or piezoelectric energy sources, urologists must continue to monitor the amount of energy delivered to limit the incidence of potentially significant renal injury.

Conclusions

SWL has revolutionized the treatment of urinary calculi, and this technology can be considered the treatment of choice for almost any renal calculus smaller than 2 cm and for most nonimpacted ureteral calculi. Under these circumstances, stone-free rates approaching 90% can be expected, although for larger renal stones or impacted ureteral calculi, endoscopic technique should probably be considered first-line therapy.

Whereas the original lithotripter design requires general anesthesia, requires a 1,000-L water bath, and subjects patients to fairly high doses of ionizing radiation, second-generation devices incorporate technical refinements that increase the safety and convenience of this procedure. Although a decrease in shock wave pressure and focal point size has diminished or eliminated anesthesia requirements, this development has been associated with a rise in the re-treatment rate. An efficiency quotient can be used to compare the relative benefits and disadvantages of various second-generation machines. Current lithotripters do not seem to have the ability to rate high on the efficiency quotient scale while still maintaining anesthesia-free capabilities. Third-generation machines, however, with modifications to allow variable shock wave power and dual imaging capabilities, may represent a step toward achieving this goal. As research continues and new devices become adaptable to multiple tasks, we will come closer to making the “ideal lithotripter” a reality.

In the past decade, significant progress has also been made in the realm of basic SWL physics research. The majority of this effort has been devoted to further characterization and better understanding of the dynamics of cavitation bubbles induced by SWL, as well as the role of cavitation in both stone fragmentation and tissue injury. There is now increasing evidence to suggest that appropriate control of cavitation during SWL can lead to significantly improved stone fragmentation or reduced tissue injury, and this topic should be a major focus of SWL research in the near future. In addition, several new competing mechanisms of tissue injury have been proposed, and their validity will be tested by carefully designed experiments both *in vitro* and *in vivo.* For improved SWL therapy, it is also important to understand the stress wave propagation and the corresponding dynamic fatigue process of both stones and tissue during SWL. Knowledge gained from SWL basic research will become indispensable for the improvement of SWL technology and for the design of better clinical treatment protocols for SWL.

PERCUTANEOUS STONE EXTRACTION

Historical Aspects

Rupel and Brown (151) used an operatively established nephrostomy tract to extract an obstructing renal calculus in 1941. Nearly 15 years later, Goodwin and associates (63) reported the use of percutaneous nephrostomy drainage to provide relief of obstruction and infection. However, removal of a renal calculus via a percutaneous tract established specifically for that purpose was not performed until Fernstrom and Johansson (54) used such a technique successfully in three

patients 20 years later. Subsequently, safe and effective means to fragment even large calculi were introduced, and percutaneous stone extraction gained acceptance as the procedure of choice for management of most patients with upper tract calculi in the late 1970s and early 1980s. As such, during that era, any patient who would have otherwise required open stone extraction was instead considered a potential candidate for percutaneous management, and the indications for this procedure were essentially identical to the indications to intervene for any stone.

Contemporary Indications and Contraindications

SWL has significantly affected the general indications for percutaneous stone management. These indications are now well defined and are nearly identical to the contraindications to SWL. As such, most of these indications are more relative than absolute. As the twenty-first century begins, the indications for percutaneous management of upper tract calculi include unusual body habitus precluding SWL, obstruction distal to the stone, cystine stones, stones associated with upper tract foreign bodies, and large or otherwise complex stones. Relative indications for percutaneous management rather than SWL may include the presence of an implanted cardiac pacemaker or defibrillator and a proximate calcified aortic or renal artery aneurysm. Another important indication for percutaneous management is failure of SWL. Currently, the only absolute contraindication to percutaneous stone extraction is an irreversible coagulopathy.

In 1987, Leroy and associates (103) at the Mayo Clinic reported a contemporary experience with percutaneous stone management in the era of SWL. During 1 year at their tertiary care center, 854 patients were managed with SWL while 143 with renal or upper ureteral calculi were managed percutaneously. In regard to their current indications and results for percutaneous management, the authors concluded that despite the increased complexity of patients undergoing percutaneous management, excellent results could still be achieved with acceptably low morbidity.

Patient Preparation

As with any intervention, the patient should be apprised of the potential risks and benefits of percutaneous lithotomy as compared with the applicable alternatives. In these often complex cases, this should include the risks of requiring secondary intervention, transfusion of blood products, infection, or rarely, emergent open operative intervention. Although complications can occur, most patients will ultimately benefit from a percutaneous procedure by experiencing a relatively short hospital stay and period of convalescence, especially compared with open operative intervention (17,19,20,139).

Standard preoperative preparation includes assurance of the availability of blood for possible transfusion with a blood type and screen, although formal crossmatching is generally not necessary. Patients with urinary tract infection are treated for approximately 1 week with sensitivity-specific antibiotics on an outpatient basis and are then intravenously “on call” to the procedure. The need for prophylactic antibiotic in the face of a sterile urine is unproven (24), although we generally use a “short course” protocol in this setting that consists of a first-generation cephalosporin given just before percutaneous access and continued for 24 hours following stone extraction.

Technique

The exact technique of percutaneous stone extraction used is specific to the size, location, configuration, and presumed composition of the stone. However, the procedure is always performed with the same four sequential steps: establishment of percutaneous access, dilation of the tract, stone manipulation with fragmentation and extraction, and postextraction drainage and tamponade of the tract. Techniques of percutaneous access are addressed elsewhere in this volume. As such, the percutaneous procedures described herein start with the assumption that access has been established.

The patient is in a prone or slightly oblique position with the ipsilateral side elevated to approximately 20 degrees (Fig. 9.7). For patients with rotational anomalies such as horseshoe kidneys, the contralateral side is elevated instead to allow a more medial rotation of the otherwise anteriorly projected renal pelvis. This allows the posterior infundibula and calices to project more laterally, thus fluoroscopically simulating a more orthotopic position of the kidney. At this point, before percutaneous stone manipulation, a second wire should be placed as a safety wire using a 9- or 10-Fr introducer set. Over the remaining “working” wire, the tract is dilated to 30 Fr using either sequential fascial dilators or, preferably, a 10-Fr, 12-cm balloon over which is back-loaded a 30-Fr working sheath (Fig. 9.8). At this point, then, a 30-Fr working sheath will be in place with a safety wire alongside.

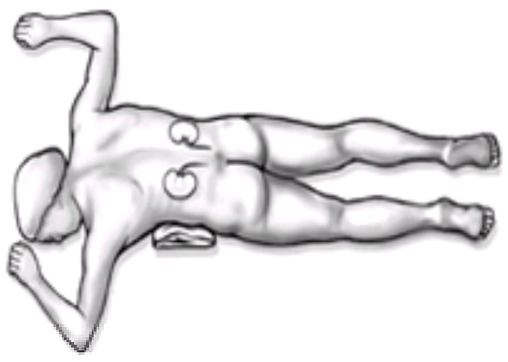

FIGURE 9.7. A prone-oblique position is standard for percutaneous procedures.

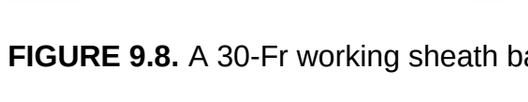

FIGURE 9.8. A 30-Fr working sheath back-loaded over a 10-Fr, 12-cm balloon dilator.

Stone extraction itself can be accomplished with a variety of techniques using direct vision through a nephroscope along with fluoroscopic guidance. At most centers, percutaneous stone extraction is accomplished using ultrasonic lithotripsy guided by direct vision through a rigid nephroscope. This approach was first described by Alken and colleagues (2) in Germany and Marberger and colleagues (115) in Austria, and it was subsequently popularized in the United States by Segura and associates at the Mayo Clinic (159) and Clayman and associates at the University of Minnesota (32).

The nephroscope is readied by attaching the light, suction, and irrigation, and it is then inserted through the working sheath. Once proper positioning in the pyelocalyceal system is ensured, the working wire, which is still within the sheath, is removed, taking care to keep a safety wire in place alongside the sheath. The irrigant of choice for percutaneous nephroscopy is normal saline. This prevents the possibility of hyponatremia that might result from intravascular absorption if hyposmotic solutions are used (155). At the outset of nephroscopy, vision may be obscured by blood clots, which are easily evacuated by adjusting the irrigation and suction from the nephroscope sheath or by using suction through the US wand while ultrasonic energy is being applied to the clot.

Stones with a smallest diameter less than 9 or 10 mm are small enough to extract intact through an appropriate-size working sheath. Such stones are simply grasped

under direct vision using rigid graspers or endoscopic forceps passed via the working port of the nephroscope (Fig. 9.9). However, most stones managed percutaneously are too large to be extracted intact, and intracorporeal lithotripsy will be required. The most commonly used modality for this has been ultrasonic lithotripsy (33). The US wand (Sonotrode) with its own suction attachment is introduced via the working channel of a rigid nephroscope (Fig. 9.10). Under direct vision, the tip of the Sonotrode is pressed against the stone while suction is applied through the hollow Sonotrode, holding the stone in place. This allows the stone pieces to be evacuated via the Sonotrode as fragmentation proceeds. Fragments that are too large to pass through the Sonotrode, but now measure less than 9 mm, are easily extracted using grasping techniques via the nephroscope under direct vision, bringing the pieces out through the working sheath that remains in place. The process of ultrasonic fragmentation with suctioning of fragments or forceps extraction continues until all visible stone has been removed.

FIGURE 9.9. Small stones—those less than 10 mm—can often be extracted intact using graspers or baskets passed via the working port of the nephroscope under direct vision.

FIGURE 9.10. A: Rigid nephroscope with offset lens allows passage of a rigid Sonotrode. **B:** The nephroscope and ultrasound wand are placed through the working sheath. The ultrasound wand is abutted against the stone and ultrasonic energy applied, with simultaneous suction of fragments through the hollow Sonotrode.

Although ultrasonic lithotripsy can reliably fragment most stones, some stones are physically too hard to fragment with this modality. For the most part, this includes large calcium oxalate monohydrate stones, which often appear extremely dense and homogenous on plain radiographs, and some mixed calcium oxalate–uric acid stones. In such patients, intracorporeal lithotripsy can be performed effectively with several alternative modalities, including electrohydraulic lithotripsy (EHL), which has proven both safe and effective in this setting (116,141). The EHL probe is passed through the working port of the nephroscope under direct vision, and the stone is fragmented into smaller pieces, which are individually grasped and removed, or further fragmented and suctioned out with a US wand. Newer, even more contemporary alternatives to both electrohydraulic lithotripsy and ultrasonic lithotripsy include the holmium laser (175) and variations of electromechanical lithotripsy such as the Lithoclast (41).

For infundibular or calyceal calculi lying at acute angles to the percutaneous tract, visualization, fragmentation, and extraction often require flexible nephroscopy (101,146). Although flexible nephroscopy can be successful when used during the initial percutaneous procedure, even a moderate amount of bleeding may obscure vision. As such, flexible nephroscopy will often be even more successful when performed via a mature tract. In either case, a working sheath is again in place and the flexible nephroscope is passed through this under direct vision (Fig. 9.11). Fluoroscopic guidance is even more important during flexible nephroscopy than rigid nephroscopy to ensure proper orientation. When the stone is visualized, a grasping forceps, prongs, or basket can be passed through the working port of the flexible scope and the stone engaged and withdrawn intact. Alternatively, larger stones can be fragmented with either the holmium laser or EHL, both of which allow intracorporeal lithotripsy via these flexible instruments.

FIGURE 9.11. Flexible nephroscopy performed through a working sheath allows access to stones lying in otherwise inaccessible infundibulocalyces.

When visual and radiographic control ensure that all accessible stone has been extracted, nephrostomy drainage is instituted. Our preference is to pass a 24-Fr nephrostomy tube through the working sheath and position it fluoroscopically with its tip in the renal pelvis, at which time the working sheath is removed. The remaining safety wire is then used to pass a pyeloureteral catheter with its distal tip in the distal one-third of the ureter and the proximal end coiled at skin level (Fig. 9.12). This pyeloureteral catheter is secured in place and acts as a precautionary measure that allows rapid access back to the pyelocalyceal system should that be required before elective removal of the nephrostomy tube.

FIGURE 9.12. At the completion of the procedure, a 24-Fr nephrostomy tube is positioned in the renal pelvis, and a 6-Fr pyeloureteral catheter is left in place alongside.

Specific Indications

Body Habitus Precluding Shock Wave Lithotripsy

Patients in whom an unusual body habitus precludes SWL provide some of the most challenging indications for percutaneous stone extraction. This indication occurs most frequently in patients with morbid obesity to the extent that the stone cannot be positioned at the focal point or within the “power path” of an extracorporeally generated shock wave (179). In these patients, both the percutaneous access and tract dilation are more difficult, at least in part because fluoroscopic imaging is compromised. Furthermore, once an adequate tract has been established, stone fragmentation and extraction can be severely hampered by limitations in the length of available instrumentation.

In many cases, the limitations in length of instrumentation can be overcome by allowing the tract to mature for several days following the initial dilation and placement of a large-caliber nephrostomy tube. During this time, the kidney tends to fall back posteriorly toward skin level such that access with standard nephroscopic instrumentation can then be accomplished. Furthermore, a mature tract can be used to pass readily available alternative instruments such as standard flexible cystoscopes or even rigid cystoscopes, which are longer than most available nephroscopes. Working laparoscopes may also be of value in this setting because of their length (60).

Kerbl and associates (89) have proposed using a flank position for percutaneous management of patients with morbid obesity. A suggested advantage of this position is that it may result in less restriction of pulmonary dependent chest wall movement, which then facilitates both anesthesiologic access and ventilation. Furthermore, the flank position allows the abdominal pannus to fall anteriorly, which may result in a decrease in the amount of tissue to be traversed to access the kidney. Overall, although there are clearly difficulties inherent in percutaneous stone management in morbidly obese patients, there may be little difference in overall success rates and ultimate morbidity compared with nonobese patients, at least when the procedure is performed by those experienced in these techniques (22,129).

Another contraindication to SWL regarding body habitus is occasionally seen in patients with severe scoliosis or body contractures preventing adequate positioning of the stone. In these patients, access may be difficult because of the altered anatomy. In some, the kidney may be located in a relatively anterior position, such that prevention of injury to adjacent solid or hollow viscera becomes an important consideration. Skoog and associates (164) have suggested using CT guidance to obtain access in patients with horseshoe kidneys or other fusion anomalies, and we have also found CT or US guidance valuable in preventing injury to adjacent organs in patient with severe scoliosis or other related anatomic abnormalities (Fig. 9.13).

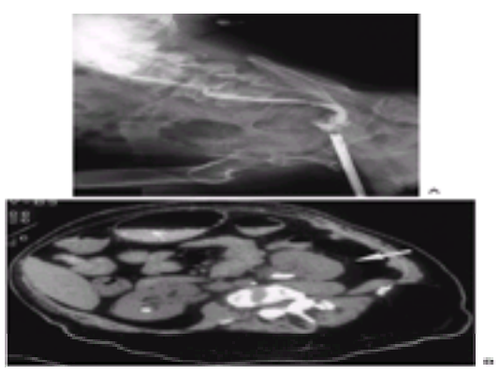

FIGURE 9.13. A: Retrograde study reveals renal pelvic stones that are difficult to see because they overlie the spine in this patient with severe body contractors. **B:** Computed tomography scan without contrast shows bilateral renal pelvic calculi and suggests an appropriate “window” *(arrow)* for safe percutaneous access.

Cystine Stones

Although small cystine stones can at times be managed successfully with SWL, in our experience, most cystinuric patients requiring intervention have larger stones at the time of presentation, and these tend to respond poorly to that modality. Fortunately, however, cystine stones are very amenable to most forms of intracorporeal management, including ultrasonic and holmium laser lithotripsy. At our center, percutaneous ultrasonic nephrolithotomy remains the preferred approach for the majority of cystinuric patients requiring intervention (27), although at a few centers, a ureteroscopic approach is being used with increasing frequency, even for pyelocalyceal cystine stones (64).

Upper Tract Foreign Bodies

Urologic practice has seen an increasingly frequent use of self-retaining stents, nephrostomy tubes, and dilating balloons, and this has led to a corresponding increase in the number of patients requiring management of “retained” upper tract foreign bodies. In many cases, these foreign bodies can be managed with retrograde endoscopy using standard ureteroscopic instrumentation. However, a ureteroscopic approach may be precluded by a prior urinary diversion, making access difficult if not impossible or by the formation of calculi on the foreign body that are too large for ureteroscopic management. When ureteroscopic management has failed or is contraindicated for any of these reasons, a percutaneous approach is indicated (Fig. 9.14) (180). For these patients, the site of the access to the foreign body is chosen as for any stone, and this then depends on its size and location within the pyelocalyceal system. Standard nephroscopic instrumentation, including forceps, graspers, or baskets, may be used in conjunction with any form of currently available intracorporeal lithotripsy.

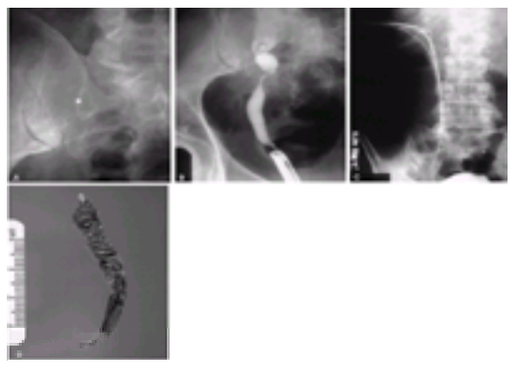

FIGURE 9.14. A: Plain radiograph reveals a metallic foreign body over the iliac bone. This represents the tip of a balloon catheter that became dislodged during an attempted balloon dilation for a ureteral stricture. **B:** Retrograde study confirms ureteral stricture below the level of the foreign body, which precludes its removal via retrograde ureteroscopic access. **C:** Antegrade approach using flexible instrumentation. **D:** The foreign body was extracted intact via an antegrade approach. The ureteral stricture was subsequently managed in an antegrade endourologic fashion.

Distal Obstruction

Successful SWL requires spontaneous passage of the resulting stone fragments. As such, obstruction distal to the targeted stone is a contraindication to SWL as primary treatment. For most affected patients, the distal obstruction will relate to the ureter or ureteropelvic junction (UPJ), although the same principle applies to stones in calyceal diverticula or those in calices associated with true infundibular stenosis. In these patients, percutaneous management is ideal because it provides an opportunity both to remove the stone and provide permanent relief of obstruction as described herein.

Calyceal Diverticular Calculi

Stones in calyceal diverticula are often amenable to a percutaneous approach (11,13,85,162). Ideally, the access should involve direct puncture of the diverticulum containing the stone (Fig. 9.15). Working and safety wires can either be coiled within the diverticulum or occasionally, under fluoroscopic control, passed through the diverticular neck, into the main pyelocalyceal system, and down the ureter. The tract is dilated and a working sheath placed. Nephroscopic stone removal proceeds in a standard fashion following which the diverticular neck is often better visualized. If a wire has not already been passed across the neck, it can often be done at this time and the diverticular neck subsequently dilated. When the neck has been managed with dilation, a nephrostomy tube is left across it into the main pyelocalyceal system for several days. An adjunct to help identify the diverticular neck in these patients is cystoscopic placement of an open-end ureteral catheter up to the renal pelvis at the outset of the procedure. During nephroscopic visualization of the calyceal diverticulum, dilute methylene blue can be injected in a retrograde fashion through the ureteral catheter, and this often allows ready identification of the diverticular neck.

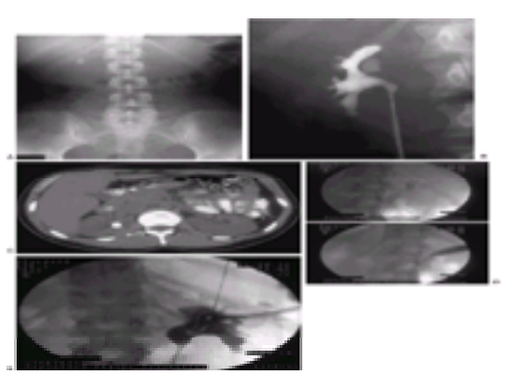

FIGURE 9.15. A: Plain radiograph reveals a 1.5-by-1-cm calcific density in the area of the right kidney. **B:** Retrograde study reveals this to be a stone in a calyceal diverticulum that does not fill with contrast. **C:** Computed tomography scan without contrast reveals a somewhat posteromedial location of the diverticulum, which as such can be managed percutaneously. **D:** Fluoroscopic control of direct percutaneous access to the diverticulum and dilation of the tract. **E:** Diverticular neck has been dilated and a 24-Fr nephrostomy tube left across it with its tip in the renal pelvis.

An alternative to dilation of the diverticular neck, especially when it cannot be visualized directly or intubated fluoroscopically, is simple fulguration (122). A nephrostomy tube is left in place in the diverticulum, but not across the neck. This acts to “marsupialize” the diverticulum, which does not have secretory urothelium.

Infundibular Stenosis

Stones located in calices drained by long, narrow infundibula or those in calices associated with true infundibular stenosis often require percutaneous management, and the best approach is again a direct one to the involved calyx (Fig. 9.16). In a situation analogous to stones in calyceal diverticula, subsequent access through the involved infundibulum at times cannot be obtained until the stone is extracted. Therefore the working and safety wires may be coiled in the involved calyx and then passed under direct vision once the nephroscope has been introduced.

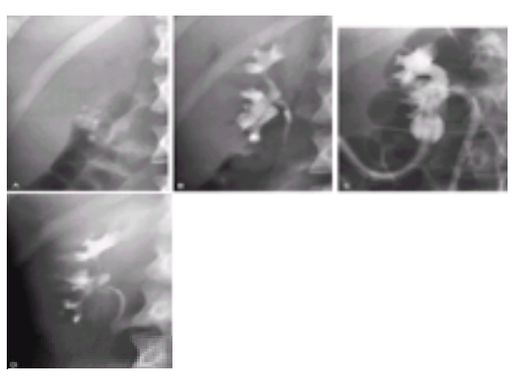

FIGURE 9.16. A: Plain radiograph reveals multiple stones in the lower pole of the right kidney following failed shock wave lithotripsy performed 2 years earlier. **B:** Intravenous pyelography reveals dilation of the involved lower infundibulocalyceal system as a result of localized infundibular stenosis. **C:** Direct access to the involved infundibulum allows direct stone removal. The infundibulum was then dilated percutaneously and a nephrostomy tube left across the infundibulum into the renal pelvis. **D:** Follow-up urogram reveals complete resolution of the localized hydrocalices following percutaneous dilation of the infundibular stenosis.

In contrast to management of calyceal diverticular necks, a stenotic infundibulum should always be dilated rather than fulgurated because the calyx contains secretory urothelium. The infundibulum can be dilated using sequential fascial dilators or a balloon catheter under direct vision, fluoroscopic control, or both. Following stone extraction and dilation of the infundibulum, a large-caliber nephrostomy tube is left indwelling across the infundibulum into the renal pelvis.

Ureteropelvic Junction Obstruction

The association of upper tract stones with ureteropelvic junction obstruction provides an ideal setting for percutaneous management because this allows simultaneous extraction of the stones and relief of obstruction (126). Percutaneous management of the stones is performed in a standard manner with the caveat that for this procedure, percutaneous access is best accomplished via a more superolateral calyx or infundibulum that will allow direct endoscopic access to the ureteropelvic junction with rigid instrumentation (Fig. 9.17). However, stone extraction should precede the actual endopyelotomy incision to prevent extravasation of irrigant or stone particles during stone fragmentation and removal. At completion of the stone removal and endopyelotomy, a relatively large-caliber stent is left indwelling for approximately 4 weeks.

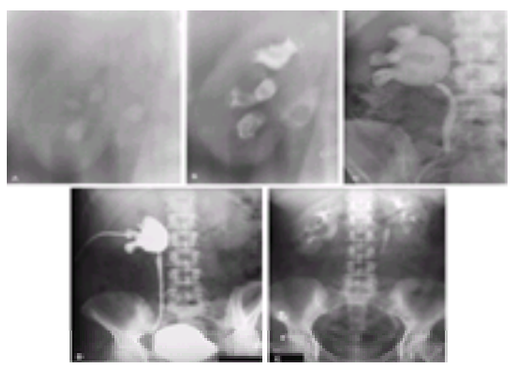

FIGURE 9.17. A: Opaque radiodensities overlying the right renal outline. **B:** Following intravenous contrast injection, dilated calices are visualized with the stones appearing as relatively radiolucent filling defects. **C:** Retrograde study confirms the stones to be associated with primary ureteropelvic junction obstruction. **D:** Percutaneous management of the stones has been performed via superolateral access, which allows direct visualization of the ureteropelvic junction for simultaneous percutaneous endopyelotomy. This follow-up nephrostogram shows resolution of the stones and patency of the endopyelotomy stent such that the nephrostomy tube is removed at this time. **E:** Follow-up intravenous pyelogram performed 1 month after stent removal confirms resolution of the stones and the obstruction.

Transplanted and Pelvic Kidneys

Stones in renal allografts or autografts require several management considerations, including the facts that they are generally solitary kidneys and that retrograde access to the ureter may be impossible following the requisite ureteral reimplantation. Relatively small stones (less than 1 cm) may often be treated with SWL, but consideration should be given to percutaneous management for even moderate-size stones. This is because of the inherent difficulty of obtaining retrograde access in the face of potential obstruction from post-SWL fragments and the need to ensure a stone-free result.

Percutaneous access to transplanted kidneys is generally straightforward because the kidney lies at near skin level. The only real difference from the procedure performed in native kidneys is that the patient is in a supine rather than prone position. When renal function is adequate, access can be obtained with standard fluoroscopic imaging after intravenous contrast injection, although US or CT guidance may otherwise be necessary. Once the tract is established, the procedure proceeds as for native kidneys with standard tract dilation, stone manipulation, and nephrostomy drainage (Fig. 9.18).

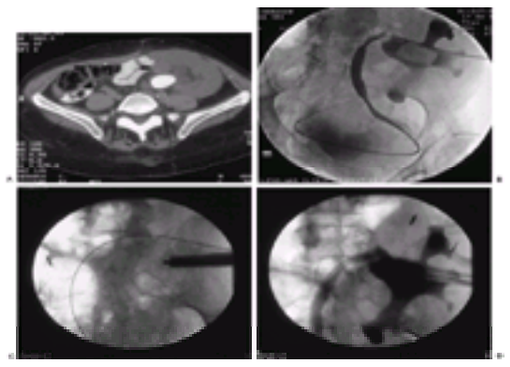

FIGURE 9.18. A: Computed tomography scan without contrast in this combined pancreas-kidney transplant patient reveals a large stone in the transplant renal pelvis on the left side. **B:** Percutaneous access is straightforward, although the patient is in the supine rather than prone position. **C:** As for native kidneys, rigid nephroscopy with ultrasonic fragmentation and suction is generally the preferred form of management. **D:** Follow-up nephrostogram shows resolution of the stone without any obstruction or extravasation.

Management of stones in congenital pelvic kidneys poses different problems. In contrast to transplanted kidneys, congenitally pelvic kidneys are deeper within the pelvis, and peritoneal contents, including small and large intestines, may be interposed. In such cases, percutaneous access may safely be obtained using laparoscopic control.

Proximate Calcified Arterial Aneurysms: Cardiac Pacemakers and Defibrillators

A cardiac pacemaker or implanted defibrillator is no longer an absolute contraindication to SWL (29,36). However, the presence of an implanted cardiac defibrillator may preclude such treatment because the stone is often obscured from vision in at least one plane by the defibrillator. In such cases, percutaneous management often becomes the primary modality of choice for these patients. Likewise, the presence of a proximate calcified aortic or renal artery aneurysm is at times considered a contraindication to SWL, and therefore an indication for percutaneous management (21). When SWL is considered inappropriate in any of these circumstances, percutaneous management is accomplished in a straightforward fashion using standard techniques as described earlier.

Large or Complex Calculi

Some patients with large, extensively branched, or otherwise complex stones may be managed definitively with a percutaneous approach alone (Fig. 9.19) (35,59,165,188). The best candidates are those in whom the stone burden is primarily central rather than peripheral, and our preference is to use percutaneous monotherapy for those patients in whom the stone can be safely accessed via one or two tracts. For patients with more extensively branched and peripherally located stones in whom complete extraction would require more than two or three tracts, percutaneous management can be used as a primary approach for “debulking” before adjunctive SWL as part of a planned, combination “sandwich” approach (Fig. 9.20) (88,156,170). In such cases, the initial percutaneous debulking reduces the stone burden for subsequent SWL. Furthermore, the placement of a large-caliber nephrostomy tube at completion of the primary percutaneous procedure allows proximal diversion with prevention of obstruction and subsequent bacteremia or sepsis from passage of fragments subsequent to SWL. A secondary percutaneous procedure can then be done via the mature tract or tracts within 24 to 48 hours of the shock wave procedure to hasten clearance of stone fragments and allow early nephrostomy tube removal (171).

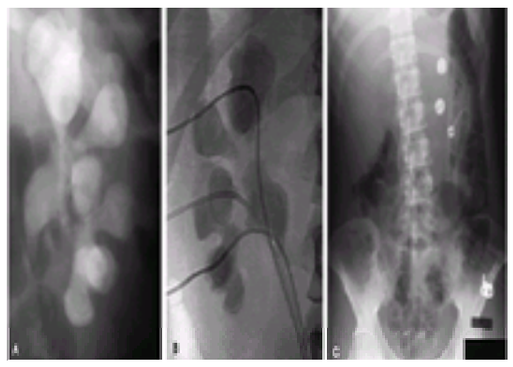

FIGURE 9.19. A: Plain film in this 22-year-old woman with recurrent proteus urinary infection reveals a complete, fully branched staghorn calculus overlying the left kidney. **B:** Reverse fluoroscopic view of percutaneous access via three tracts. **C:** Plain film from follow-up nephrostogram shows complete resolution of the stones.

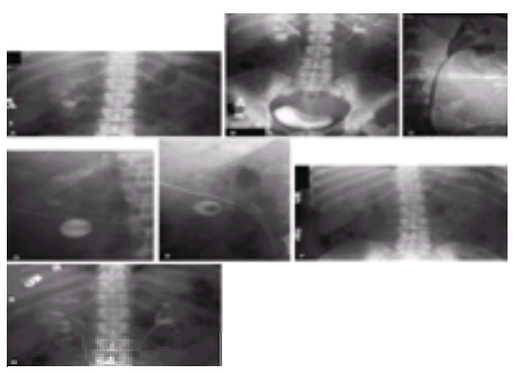

FIGURE 9.20. A: Plain film reveals a complete staghorn calculus filling the collecting system of the right kidney. **B:** Intravenous urography confirms an otherwise well-functioning kidney. Note that the kidney is "high riding" such that percutaneous access to the upper infundibulocalyceal portion of the stone would require access above the eleventh rib with subsequent risk of hydrothorax or pneumothorax. **C:** As an alternative, percutaneous debulking is performed via a lower infundibulocalix allowing access to the pelvic and lower infundibulocalyceal portions of the stone. **D:** Scout film from initial nephrostogram reveals mid and upper infundibulocalyceal fragments remaining that are inaccessible to rigid access via the lower-pole percutaneous tract. These inaccessible residual fragments are treated with shock wave lithotripsy. **E:** Twenty-four hours following shock wave lithotripsy, the previously inaccessible upper infundibulocalyceal fragments have migrated to the renal pelvis, where they are easily managed with second-look nephroscopy. **F:** Scout film from follow-up intravenous pyelogram 6 weeks later reveals no residual stone fragments. **G:** Following contrast injection, the kidney is seen to be well functioning.

Failed Shock Wave Lithotripsy

Percutaneous management can be used as a "salvage" procedure for essentially any patient who has failed SWL. When failure of SWL has led to obstruction resulting from ureteral stone fragments, initial percutaneous drainage allows recovery of function and treatment of any associated infection. When the patient is stable, tract dilation and stone manipulation can proceed in a standard fashion. Following percutaneous management of any pyelocalyceal stones, remaining ureteral fragments can be extracted in an antegrade or retrograde fashion ureteroscopically using flexible or semirigid instrumentation.

Postoperative Care

An estimate of the volume of irrigation and output should be kept during stone extraction. Generally, furosemide 20 mg is given intravenous at termination of the percutaneous procedure. Vital signs are monitored closely, and serial blood counts are obtained as determined by the clinical course. For the first 24 hours postoperatively, intravenous fluids are administered at a rate fast enough to ensure a sustained diuresis. For patients with documented urinary infection associated with the stone disease, sensitivity-specific antibiotics are continued intravenously for at least 48 to 72 hours while the patient is in the hospital and then orally until the first follow-up visit, at which time the need for chronic antibiotic prophylaxis is determined. In patients without a history of infection, prophylactic antibiotic coverage can be discontinued within 48 hours of an uncomplicated percutaneous stone extraction.

One to two days after stone removal, a nephrostogram is obtained and any residual fragments seen on this study that appear accessible to the percutaneous tract are managed with repeat rigid or flexible nephroscopy, often performed with light intravenous sedation. If there are no residual stones and no obstruction or extravasation is noted on the nephrostogram, the pyeloureteral catheter is removed and the nephrostomy tube clamped for approximately 12 hours. The tube is removed if there has been no flank pain, fever, or increased drainage around the tube during that time. The patient is then discharged home and allowed to return to full prehospitalization activity 7 to 10 days later.

If extravasation or obstruction is noted on the initial nephrostogram, the nephrostomy tube is left to provide drainage and serial studies are obtained. Ureteral obstruction found at this time usually results from blood clots or edema, either of which should resolve spontaneously within 24 to 48 hours. Occasionally, obstruction results from small stone fragments in the ureter that often pass spontaneously, or they may be managed with antegrade or retrograde manipulation.

Complications of Percutaneous Stone Removal

Hemorrhage

Bleeding is one of the most significant complications associated with percutaneous stone removal. At least some bleeding is apparent in all cases, and it can become evident at any time during or after the procedure. Management then depends on timing and severity of the bleeding.

Bleeding during access or tract dilation generally responds to placement of the next size dilator, which effectively tamponades the tract. The more recent use of balloon dilation, rather than sequential fascial dilation, may decrease the incidence of bleeding during this step. If significant bleeding occurs during stone manipulation, the procedure should be temporarily halted and nephrostomy drainage instituted for a couple of days.

Bleeding through the nephrostomy tube is often evident at the completion of even a relatively uncomplicated procedure. Successful management in almost all such cases can be achieved by temporarily plugging the nephrostomy tube and allowing the collecting system to tamponade. Generally, the nephrostomy tube can be unplugged several hours later, at which time effluent will be markedly clearer. Bleeding that occurs during removal of the nephrostomy tube is best managed by immediate reinsertion. When the tract has matured for even 24 hours, fluoroscopic control is generally not required for this. Delayed hemorrhage (bleeding occurring several days following removal of the nephrostomy tube) is best managed conservatively, that is, with close monitoring of vital signs, bed rest, hydration, and transfusion as necessary.

Bleeding at any time that does not respond to conservative measures that include transfusion is best managed by renal angiography and selective or even superselective arterial embolization. Open operative exploration should be reserved only for failure of all other modalities because such surgery generally leads to partial, or more likely total, nephrectomy (90).

Extravasation

Extravasation of irrigating solution, contrast, or urine is perhaps the most frequent complication of percutaneous technology. Obviously, some degree of extravasation

of all of these occurs during any percutaneous procedure; fortunately, in a control setting, this is generally a benign and self-limiting problem. Extravasation does imply urothelial disruption, which may be minor or more severe. However, the ability of the collecting system to repair itself in the setting of proximal diversion and drainage is remarkable.

Obviously, the collecting system is purposely perforated to obtain access to the pyelocalyceal system. Unplanned perforation generally occurs at the medial pelvic wall or ureteropelvic junction and may be the result of access, tract dilation, or stone manipulation. Potential adverse effects of this injury can be minimized by maintaining a sterile urine, carefully monitoring irrigation input and output during the procedure, use of a safety wire at all times to ensure access back to the collecting system, and perhaps most important, use of normal saline as the irrigant of choice rather than distilled water. In that way, the potential complicating effects of hyponatremia are essentially obviated; otherwise, large amounts of hypotonic solution may be absorbed.

Essentially all minor degrees of extravasation and even some major ones can be managed with nephrostomy drainage alone as long as the nephrostomy tube is confirmed to be in the collecting system, urine is aggressing, and the patient is clinically stable. In such cases, especially when the injury occurs in the renal pelvis or at the ureteropelvic junction, it is preferable to have a stent across the ureteropelvic junction either as a percutaneous pyeloureteral catheter or as an indwelling ureteral stent in addition to the nephrostomy tube. Again, as long as the patient is stable, serial nephrostograms can be obtained and the nephrostomy tube removed as soon as the extravasation is no longer radiographically evident and distal patency is ensured. When satisfactory drainage cannot be ensured, or when the patient is clinically unstable, open operative exploration and repair is indicated.

Extrarenal Organ Injury

Injury to a hollow or solid organ other than the kidney occurs in 1% to 5% of patients. Intraperitoneal extravasation can occur from breaching the peritoneum, and the treatment is generally conservative, although paracentesis may be required. On the right side, injury to the liver can occur; this will usually respond to conservative measures because analogous percutaneous intervention is often performed purposely for such procedures as percutaneous biliary drainage. On the left side, splenic injury can occur, and although initial management is again conservative, open operative exploration and repair may be required.

With the recent increasing use of upper pole and supracostal access, hydrothorax, hemothorax, and pneumothorax are becoming more frequent. Management depends on the patient's clinical picture. If the patient is completely stable with no ventilatory or respiratory embarrassment, observation alone may allow spontaneous resolution. Alternatively, simple aspiration on a one-time basis may be adequate, although placement of a chest tube for a few days may be required.

Duodenal or colonic injury may also occur (191). In many cases, even when such injury involves the colon, conservative management may again be successful and consists of withdrawing the nephrostomy tube back to the colon to provide percutaneous colostomy drainage. An internal stent should also be placed into the involved collecting system to separate the colonic and urinary streams. In all cases, conservative management should also include the use of intravenous antibiotics. The patient should initially be placed on nothing-by-mouth status, and this should be followed by a low-residue diet.

Another important consideration in determining whether the patient is a candidate for further conservative management versus open operative repair is whether the injury is intraperitoneal or extraperitoneal. In most cases, this can be determined on the radiographic study used to initially make the diagnosis, whether it is a nephrostogram or a CT scan. Generally, extraperitoneal injuries can be managed using these nonoperative techniques. However, injuries that are intraperitoneal should be given careful consideration for immediate open operative repair.

Results

Percutaneous nephrolithotomy has been documented to be both safe and efficacious. In a community setting, approximately 90% of targeted stones can be removed successfully, and at experienced subspecialty care centers, this rate can approach 100% (9,102,147,160). Furthermore, morbidity for the procedure is acceptably low, even in patients with comorbid medical conditions and complex stones (22,103), and early return to prehospitalization employment and recreational activities can be expected for most patients, especially in comparison with open operative intervention (17,19,20,139). Most important, both functional and morphologic studies have repeatedly shown that percutaneous nephrolithotomy has little if any clinically significant adverse effect on renal function (58,117,119,154,184), even in patients with preexisting renal insufficiency or anatomically solitary kidneys (23,172).

URETEROSCOPY

The advent of ureteroscopy has significantly affected the management of ureteral calculi. Semirigid ureteroscopy can be used in conjunction with pneumatic, laser, and electrohydraulic lithotripsy probes to successfully fragment ureteral calculi (81,112,132), and flexible, actively deflectable ureteropyeloscopes have made access to the upper ureter and intrarenal collecting system a safer, and at times less tedious, procedure (4,6,140). These instruments can be advanced under direct vision or fluoroscopic guidance directly to the level of the stone, which may be fragmented or, when especially small, extracted intact.

Ureteroscopy is a versatile technique that can be used to treat stones throughout the urinary tract (52,161), although a small working channel (2.4 to 4.0 Fr) often limits the size and usefulness of the adjunctive instrumentation that is used for actual stone retrieval. This limitation on available instrumentation has necessitated the use of intracorporeal lithotripsy for the management of most ureteral and intrarenal calculi, and various modalities for intracorporeal stone fragmentation such as the holmium laser, pneumatic lithotripter, and electrohydraulic lithotripter can be used to fragment stones. Although the choice of intracorporeal fragmentation technique is often based on the location and composition of the stone, the experience of the physician and availability of equipment more often dictate this decision (173).

The major advantage of ureteroscopy compared with open operative or percutaneous intervention is decreased morbidity and trauma for the patient because most ureteroscopic cases are performed as an ambulatory surgical procedure with the patient returning to work within 1 to 2 days (78).

Semirigid Ureteroscopy

The technique of rigid transurethral ureteroscopy has undergone significant refinements. Early ureteroscopes were large, fixed-lens systems that, although smaller than the cystoscopes of the day, were still cumbersome to use due to their large (11- to 13-Fr) size, and ureteral dilation was often required for instrument insertion (15). The current generation of semirigid ureteroscopes incorporates fiberoptic light and image bundles into small metal frames (Fig. 9.21) (46,55,82). This miniaturization of the ureteroscope often obviates the need for ureteral dilation, which saves time and allows the visualization of ureteral mucosa unaltered by the trauma of dilation.

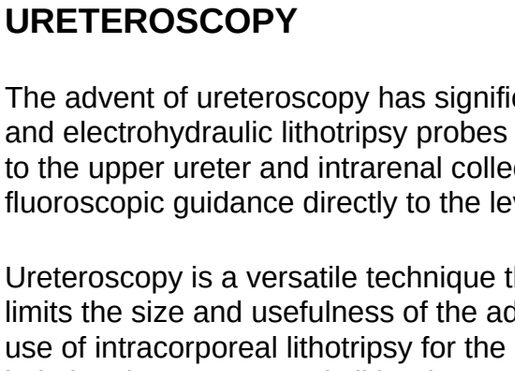

FIGURE 9.21. A: Semirigid ureteroscope. (Karl Storz Endoscopy, Inc., Culver City, California.) **B:** Semirigid ureteroscopes. (Richard Wolf Medical Instruments, Vernon Hills, Illinois.)

Semirigid ureteroscopes using fiberoptic image and light bundles were introduced in the late 1980s. These mini-ureteroscopes were initially designed for use with laser lithotripsy of ureteral calculi. Initial ureteroscope design used two 2.1-Fr channels for both irrigation and instrument passage. Although these channels were too

small to allow use of standard 3-Fr ureteroscopic accessories, they would easily accept laser lithotripsy fibers and guidewires. Since the first mini-ureteroscope was introduced, a number of other semirigid fiberoptic ureteroscopes have been developed that use either one or two working channels. All share the benefits of significantly reduced outer diameter and increased ease of passage (Fig. 9.22).

FIGURE 9.22. Distal tip of semirigid ureteroscope. (Richard Wolf Medical Instruments, Vernon Hills, Illinois.)

Indications

Semirigid mini-scopes are ideally suited for both diagnostic and therapeutic maneuvers performed in the lower half of the ureter. The semirigid mini-scopes are somewhat easier to manipulate in the distal portion of the ureter and therefore allow more rapid ureteroscopic procedures. However, the flexible ureterorenoscope is the ideal instrument to access the proximal half of the ureter, as well as lesions within the renal collecting system. Therefore a combination approach with both instruments is thought to allow easy and safe access to the entire upper urinary tract.

Technique

The standard technique involves passage of a 0.038-inch floppy-tipped guidewire under both cystoscopic and fluoroscopic guidance at the outset of the procedure. The semirigid ureteroscope is then passed under direct vision alongside the guidewire to the level of interest. If the ureteral orifice will not accept the ureteroscope, ureteral dilation is performed with a 10-Fr introducing catheter or, if necessary, a standard 15- to 18-Fr ureteral dilating balloon (34,83,86). Instruments used with the semirigid mini-ureteroscopes include stone baskets, grasping forceps, electrohydraulic lithotripsy probes, laser lithotripsy fibers, Bugbee electrodes, biopsy forceps, and brushes.

The most common indication for use of semirigid ureteroscopy is for the management of symptomatic ureteral stones. However, further refinements in the semirigid endoscope and holmium laser technologies now allow management of other forms of ureteral pathology, including ureteral obstruction and urothelial tumors (55,57,65,127,163).

Complications

Complications of semirigid ureteroscopy are usually minor and in most cases can be treated with placement of an indwelling ureteral stent (71). The most common complication developing during ureteroscopy is ureteral perforation, which has been reported in 2% to 6% of contemporary cases (97). The perforation is usually a result of stone fragmentation (EHL or laser lithotripsy) as opposed to passage of the ureteroscope. Occasionally, stone material may migrate through a ureteral perforation. Several studies have suggested that there are no long-term sequelae if a non–infection-related stone has migrated completely through the wall of the ureter (51,98,109,124). However, if stone fragments remain within the wall of the ureter, a ureteral granuloma with subsequent stricture formation may result (45,66,148).

The most significant complication of ureteroscopic stone retrieval is ureteral avulsion. This complication is usually a result of basketing a stone that is too large to be extracted intact. When in doubt, intracorporeal stone fragmentation should obviate the possibility of avulsion. Although endourologic techniques have been used to manage ureteral avulsion, essentially all of these significant complications will require ureteral reconstruction (113,134,189).

Flexible Deflectable Ureterorenoscopy

Innovations in fiberoptic technology have propelled the further development of flexible ureteropyeloscopes. The widespread use of these new instruments has enabled diagnostic and therapeutic procedures to be performed routinely within the upper ureter and kidney. With the addition of active deflection capabilities, these newer endoscopes are often able to access the entire upper urinary tract, including all of the intrarenal collecting system (7,8,67) (Fig. 9.23), and even lesions or stones located in the lower pole or extremely lateral calyces can now be reached.

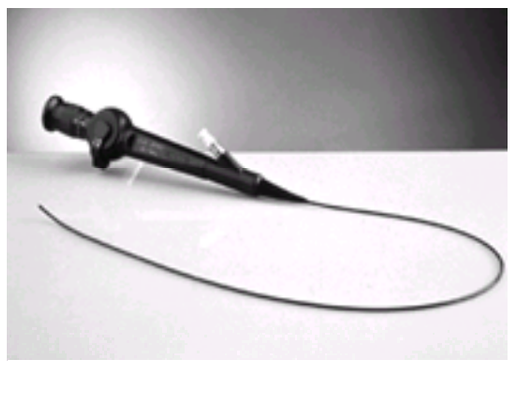

FIGURE 9.23. A 7.5-Fr flexible ureterorenoscope. (Karl Storz Endoscopy, Inc., Culver City, California.)

In addition to the more conventional uses of flexible deflectable ureteropyeloscopes, many special applications of these instruments have and will be used to take advantage of their unique capabilities. However, many of the attributes that make flexible ureteropyeloscopy a useful and effective tool can lead to potential complications, as discussed later in this chapter.

Technique

Perhaps the most difficult aspect of flexible ureteropyeloscopy is introducing the instrument into the distal ureter, because the flexibility of these small instruments, which allows their manipulation throughout the entire upper tract, may also act as an impediment to their passage. Appropriate dilation of the intramural ureter and introduction of the instrument are integral factors for the performance of flexible ureteropyeloscopy (Table 9.5).

Initial retrograde pyelogram
Passage of two 0.038-inch guidewires (safety and working wire)
Dilation of intramural ureter
Passage of flexible ureteroscope over working wire
Passage alongside wire if using access sheath
Use of fluoroscopic monitoring to confirm position of wires and scope

TABLE 9.5. PASSAGE OF FLEXIBLE URETEROSCOPE

Dilation of the Intramural Ureter

The majority of actively deflectable, flexible ureteropyeloscopes measure between 7.5 and 9.0 Fr in diameter, thus requiring some dilation of the intramural ureter. Dilation can be accomplished successfully with metal cone-tipped bougies, graduated flexible dilators, flexible olive-tipped metal dilators passed over a guidewire, or a ureteral dilating balloon. Currently, balloon dilators are the quickest, most effective, and potentially safest method to perform dilation of the intramural ureter (48).

Introduction of the Flexible Ureterorenoscope

Several techniques can be used to pass the flexible ureterorenoscope into the distal ureter. Most of these scopes can be passed directly over a guidewire that has been placed in the collecting system. This procedure is similar to other endourologic or radiologic techniques that use a guidewire for instrument passage. Care must be taken to follow the instrument fluoroscopically, prevent kinking of the wire, and avoid coiling of the flexible scope in the bladder.

Our current procedure for passage of an actively deflectable, flexible ureteropyeloscope entails initial placement of a 0.038-inch floppy-tipped wire up to the renal pelvis, usually using a 6-Fr open-end ureteral catheter to help guide the floppy guidewire into the ureteral meatus. Intermittent fluoroscopic monitoring during the entire case is an integral part of the procedure that allows confirmation of ureteroscopic position at any time. After the ureteral catheter has been removed, a second guidewire, or safety guidewire, is passed alongside the original (working) guidewire. Fluoroscopy should again be used to confirm that both wires are coiled within the renal pelvis.

If necessary, a 10-Fr introducing catheter or a 5-mm balloon dilator is passed over the working guidewire. Again, fluoroscopic visualization combined with direct view through the cystoscope will confirm inflation of the balloon with adequate dilation of the intramural ureter.

After removal of the balloon dilator, the flexible ureterorenoscope is passed directly over the working guidewire. Using both direct vision through the ureteropyeloscope and fluoroscopic monitoring, the flexible ureteropyeloscope is passed up to the area of interest either in the ureter or renal collecting system. Once the area of interest has been reached, the working guidewire can be removed and the working port used either for irrigation or passage of adjunctive diagnostic or therapeutic instruments. The safety guidewire remains coiled within the renal pelvis at all times.

Flexible guide tubes made of Teflon or similar materials are also available to assist in passage of flexible ureteropyeloscopes. These guide tubes can be easily placed over a flexible dilator similar to the placement of a nephroscopy sheath during percutaneous endoscopic procedures (3,166). Early versions of these flexible guide tubes were limited by kinking in the bulbar urethra. However, newer ureteral access sheaths may further facilitate passage of the flexible ureteropyeloscope (Fig. 9.24) (94).

FIGURE 9.24. A: Ureteral access sheath passed over safety guidewire. (Applied Medical Resources, Laguna Hills, California.) **B:** Ureteral access sheath in place. **C:** Flexible ureteroscope passed alongside guidewire within access sheath.

Whatever method is used, it is strongly recommended that fluoroscopy and a safety guidewire be used in every case. These two modalities will allow continuous monitoring of the procedure and provide access to the renal pelvis should a problem occur during passage of the telescope. As long as safety guidewire access is maintained, a ureteral stent can usually be placed in the event of a complication.

Current Applications

The most common indication for flexible ureteropyeloscopy is for removal of symptomatic calculi located throughout the ureter or within the intrarenal collecting system. Under direct vision, various intracorporeal lithotripsy devices, stone baskets, grasping forceps, or snares can be manipulated to fragment or entrap ureteral or renal calculi or fragments under direct vision with fluoroscopic monitoring. During withdrawal, distal progression of the scope is monitored fluoroscopically and with visual documentation of the moving ureteral mucosa. This helps ensure that the ureter is not entrapped as the stone or fragment is being extracted.

Limitations

With the development of flexible deflectable ureteropyeloscopes, ureteral and renal calculi can often be accessed successfully. However, a major limiting factor in using these smaller endoscopes to manage urinary stones is the small size of the working channel; the currently available flexible deflectable ureteropyeloscopes have working ports ranging from only 3.6 to 4.0 Fr in diameter. Current instrumentation to be used through the working ports of these instruments includes a vast number of baskets, graspers, electrodes, and laser fibers. Unfortunately, not all urologists have access to the myriad number of accessories that are available for use through the flexible deflectable ureteropyeloscope.

The limited size of the working channels of these flexible deflectable ureteropyeloscopes not only limits the instrumentation that can be used but also severely restricts irrigant flow, and this will have a negative impact on visualization during the actual therapeutic procedure. Studies have demonstrated that irrigant flow through a flexible deflectable ureteropyeloscope with a 3.6-Fr working channel is only 32 mL per minute with gravity irrigation, which is only 40% of the total flow that can be achieved through a 13-Fr rigid ureteroscope (186). Moreover, when placing a 3-Fr instrument through the 3.6-Fr working channel, the gravity irrigant flow will be reduced to only 2 mL per minute, which will significantly affect visualization.

Two potential ways to augment irrigant flow, and thereby enhance visualization during flexible ureteropyeloscopic procedures, would be to either limit the size of the instrument used through the working channel or to forcefully inject irrigant fluids. By reducing the instrument size to approximately 1 Fr (about the size of a laser fiber or small electrohydraulic lithotripsy probe), one can increase irrigant flow to 24 mL per minute with gravity irrigation, a 1,200-fold increase (187).

Raising the irrigant pressure, either by using a mechanical pump or forceful hand irrigation, can also significantly increase irrigant flow. However, one should be aware of the potential deleterious effects that can be induced by forceful hand irrigation because studies have demonstrated that this maneuver can raise intrarenal pressures to more than 400 mm Hg, and these pressures have been demonstrated to cause rupture of the intrarenal collecting system in animal studies (157). One must be cognizant of the potential deleterious effects of such high intrarenal pressures generated by forceful hand irrigation, and consider using a “pop-off” valve or, alternatively, a mechanical irrigator that will limit the amount of irrigant pressure (50,187).

Intracorporeal Lithotripsy

The extremely small working channels of the semirigid and flexible endoscopes, which range from 2.4 to 4.0 Fr, has limited the size and usefulness of instruments that can be passed and used for stone removal. For larger stones, baskets or grasping forceps are often inadequate and potentially dangerous to accomplish successful stone extraction. This limitation of available instrumentation has prompted the use of intracorporeal lithotripsy for the management of most larger ureteral and intrarenal calculi.

Even with the availability of SWL for the management of urinary tract stones, intracorporeal lithotripsy still provides significant advantages in select cases. Because fragmentation is performed under direct vision, the stone can be entirely removed and there is no need to wait for fragments to pass, as with SWL (Table 9.6). Although the choice of intracorporeal fragmentation is often based on the location and composition of the stone to be treated, the experience of the clinician and availability of equipment often dictate this decision.

Electrohydraulic lithotripsy	Laser lithotripsy
Ultrasonic lithotripsy	Pneumatic lithotripsy

TABLE 9.6. INTRACORPOREAL LITHOTRIPSY MODALITIES

Selection of Modality

A number of modalities can be used for intracorporeal lithotripsy of both urinary and biliary tract calculi. Although there is no “best” device, considerations for choosing a specific technology include efficacy, safety, and cost. Electrohydraulic lithotripsy, using the small EHL probes, offers a combination of low cost and flexible endoscopic delivery. However, if a holmium laser is available, this multipurpose laser offers perhaps the best option. Both ultrasonic and pneumatic lithotripsy offer the advantage of rapid fragmentation, even with very large or hard stones, but use is limited to rigid or semirigid delivery systems.

Modalities

Electrohydraulic Lithotripsy

The principles of electrohydraulic lithotripsy were initially described and developed by a Russian engineer in 1950 (147). This technology had been used extensively for the destruction of bladder stones, and in 1975, reports were published on its use for the fragmentation of ureteral stones (142,143). The EHL unit consists of a probe, a power generator, and a foot pedal. The probe is made up of a central metal core and two layers of insulation with another metal layer between them. Probes are flexible and available in varying sizes. Commercially available EHL units are manufactured with power up to 120 volts. The electrical discharge is transmitted to the probe where a spark is generated at the tip. The intense heat production in the immediate area surrounding the tip of the probe results in a cavitation bubble, which produces a shock wave that radiates spherically in all directions (193). Collapse of the bubble causes a second shock wave. These shock waves, repeated at a frequency of 50 to 100 per second, result in destruction of the stone.

EHL will effectively fragment all kinds of urinary calculi, including cystine, uric acid, and calcium oxalate monohydrate stones (178). Because the probes are small and flexible, they can be used through flexible endoscopes to fragment stones that are inaccessible for ultrasonic lithotripsy through a rigid instrument. The primary disadvantage of EHL is that in general, the resultant fragments have to be either washed out during intraoperative irrigation, or grasped with forceps or baskets.

The first experience with electrohydraulic lithotripsy in the ureter entailed a 6-Fr EHL probe that was fluoroscopically guided to the obstructing calculus. The most common cause of failure in this early experience was the operator's inability to pass the probe to the level of the stone. Additional early experience with EHL in the ureter described the use of a 9-Fr probe that provided excellent fragmentation of the stone, although 40% of the patients had ureteral extravasation following the procedure. This high complication rate was believed to be mainly attributable to the large probe size. The use of a smaller 5-Fr EHL probe through a rigid ureteroscope was compromised by decreased stone visualization because the probe occupied the majority of the working channel of the rigid ureteroscope (70).

The development of an even smaller 3-Fr EHL probe used through a flexible endoscope was first reported in 1988 (10,42,53). Recently, 1.2- to 1.9-Fr EHL probes have been developed that have been effective in fragmenting ureteral, intrarenal, and biliary tract stones. An additional benefit of these small-caliber probes is that they allow improved visualization through the flexible endoscope because a larger portion of the working channel is available for irrigation (80,133).

Power settings of the EHL unit normally range from 60 to 90 volts, and normal saline irrigation can be used with modern units. Excellent fragmentation of most ureteral calculi is to be expected, and intracorporeal lithotripsy with EHL for both urinary tract and biliary calculi offers a safe, effective, and cost-efficient modality when small-caliber, flexible lithotripsy probes are used.

Ultrasonic Lithotripsy

Ultrasonic energy was first used to fragment kidney stones in 1979. Commercially available units consist of a power generator combined with a US transducer and a probe that form the Sonotrode. A piezoceramic element in the handle of the Sonotrode is stimulated to resonate, and this converts electrical energy into US waves (23,000 to 27,000 Hz), which are transmitted along the hollow metal probe creating a vibrating action at its tip. When the vibrating tip is brought in contact with the surface of a stone, the stone can be disintegrated. The probe must be rigid because sound waves cannot be transmitted without energy loss along flexible probes. The probes come in varying sizes and are passed through the straight working channel of a rigid endoscope with a 30- or 90-degree-offset lens. Suction tubing can be connected to the end of the Sonotrode probe, thus converting the unit into a “vacuum cleaner” for stone fragments (62,84,185). Smaller 2.5-Fr solid US probes are available for use through rigid ureteroscopes (26), and these can be used for rare cases in which fragmentation of large, distal ureteral calculi with EHL or laser lithotripsy has been ineffective. In all cases, normal saline at body temperature should be used as irrigant.

We continue to use US mainly for the fragmentation of large renal calculi during percutaneous nephrolithotripsy procedures. The large, hollow US probes offer the advantage of effective stone fragmentation while allowing simultaneous aspiration of the fragments. This is especially useful when treating renal calculi in which a

large volume of stone must be removed. US is now used only rarely via a ureteroscopic approach.

Laser Lithotripsy

The development of the pulsed dye laser for fragmentation of ureteral calculi was initiated in 1986 (47,183). Significant advances in laser fibers and power generation systems have propelled laser lithotripsy to the treatment of choice for fragmentation of most ureteral stones. The pulsed dye laser delivers short, 1-ms energy pulsations at 5 to 10 Hz produced from a coumarin green dye. Instantaneous fluid evaporation causes a plasma at the stone surface, resulting in a highly localized shock wave. The 504-nm wavelength produced by the pulsed dye laser is selectively absorbed by the stone, but not the surrounding ureteral wall. Because the energy is delivered in short pulses, minimal heat is generated, again protecting the ureteral mucosa. Initial experience yielded stone fragmentation rates ranging from 64% to 95% (68,80).

Failures are often related to equipment malfunction (4% to 19%) or to resistant stone composition. As such, the use of EHL had often been necessary as an adjunctive measure with the pulsed dye laser. However, use of the pulsed dye laser in the ureter appears to be safe, because no significant intraoperative or postoperative complications have been noted from the laser energy alone.

The primary advantages of laser fragmentation were initially thought to be its increased safety during stone fragmentation and increased irrigant flow through the flexible endoscope due to the small diameter of the laser probes. However, the smaller electrohydraulic lithotripsy probes have been proven to be just as safe and almost as small in diameter as some laser fibers. The major drawback of pulsed dye laser lithotripsy had been the high purchase price of the laser, as well as the need for relatively expensive ongoing maintenance and regular dye changes.

Recently, new solid-state lasers have been developed (Q-switched yttrium-aluminum-garnet, alexandrite, and holmium lasers) for the fragmentation of ureteral calculi. These solid-state systems offer better efficacy rates than the pulsed dye lasers and are significantly less expensive to acquire and to maintain (130).

The holmium laser is the newest laser to be introduced for stone fragmentation. The holmium wavelength is not selectively absorbed and works equally well to fragment stones of varying color and composition (153,176,194). Moreover, the holmium laser has the advantage of being a multipurpose laser system. Not only can it be used for stone fragmentation, but it can also be used for its hemostatic and tissue effects, including incision of urinary tract strictures and prostatic resection (99,145). One potential limitation of the holmium device is its “drilling action” on hard stones. This can often be particularly time consuming when using the smaller holmium fibers (100,181). Moreover, the tissue effects demand a greater degree of caution because injury to the urothelium or damage to the guidewire or endoscope can occur during stone fragmentation.

Our own experience with the holmium laser shows it to be ideal for use through all kinds of flexible endoscopes, and we now use it almost exclusively as our fragmentation modality of choice with both semirigid and flexible ureteroscopes.

Pneumatic Lithotripsy

Another new technique developed for the fragmentation of ureteral, renal, and bladder calculi is pneumatic lithotripsy. The first pneumatic device, the Lithoclast, consists of a pneumatically driven piston that fragments stones by direct contact (Fig. 9.25) (43,74). A major advantage of this device is its efficiency in breaking up calculi of all composition. Pneumatic lithotripters use a semirigid probe and therefore can only be passed through instrumentation with a straight working channel (Fig. 9.26). At present, the smallest pneumatic probe is 0.8 mm, which can be used with the small semirigid ureteroscopes.

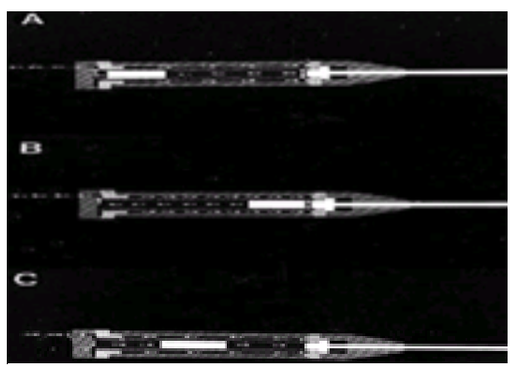

FIGURE 9.25. A–C: Schematic of projectile within handle of pneumatic lithotripsy probe.

FIGURE 9.26. Pneumatic lithotripter. (Lithoclast, Microvasive Urology, Natick, Massachusetts.)

A number of basic science and clinical studies have demonstrated the safety and efficacy of the pneumatic device (44,72). In a randomized, prospective trial, Hofbauer and colleagues (75) compared the fragmentation of distal ureteral calculi with both EHL and pneumatic lithotripsy. Although the fragmentation rates for both devices were similar (85% fragmentation for EHL and 90% fragmentation for pneumatic lithotripsy), ureteral perforation was noted in only 2.6% of the patients undergoing pneumatic lithotripsy, and there was a 17% incidence of perforation in the EHL group. In a clinical experience using pneumatic lithotripsy, successful fragmentation of stones of varying composition located in the kidney, ureter, and bladder was achieved, although ureteral stone migration was a problem in a limited number of patients who had significantly dilated proximal ureters (178).

Two recent innovations have expanded the use of pneumatic lithotripsy for the intracorporeal fragmentation of ureteral calculi. A suction device (Lithovac) has been developed to aid in removal of stone fragments during pneumatic lithotripsy (Fig. 9.27) and limit the proximal migration of ureteral calculi (39,73). In addition, flexible pneumatic probes are under development that will allow the use of pneumatic lithotripsy with flexible ureteroscopes (108,174,195).

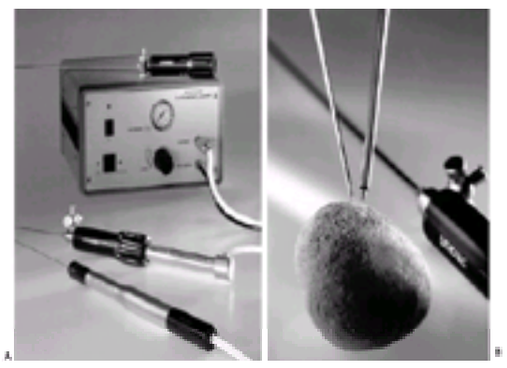

FIGURE 9.27. A: Lithovac suction device with Lithoclast. (Microvasive Urology, Natick, Massachusetts.) **B:** Close-up view of pneumatic probe within 5-Fr Lithovac and 9-Fr Lithovac. (Microvasive Urology, Natick, Massachusetts.)

Ureteroscopic Management of Renal Calculi

Most renal calculi are currently treated with SWL. However, certain predictors of inadequate fragmentation or clearance of residual fragments preclude successful treatment with this modality. The factors that may predict a poor outcome of SWL for management of renal calculi include large stone size (greater than 1.5 cm), “hard” stone composition (calcium oxalate monohydrate or cystine), distal ureteral obstruction, and “adverse” intrarenal anatomy.

Limitations of Shock Wave Lithotripsy

The size and composition of renal calculi are obvious predictors of SWL success or failure, but the impact of renal anatomy combined with stone location is less well defined. Recent studies have suggested that for larger stones located in lower pole calices or calyceal diverticula, or for those associated with significant dilation of the intrarenal collecting system, clearance of fragments will be less predictable. For most of these conditions, percutaneous nephrolithotomy is often the best alternative to both access the stone and achieve complete clearance of all fragments. However, certain instances may preclude the use of percutaneous stone removal, and thus favor ureteroscopic management. These factors include the coexistence of ureteral calculi or strictures in addition to the renal calculi, irreversible bleeding diatheses, renal anomalies, or morbid obesity (Fig. 9.28).

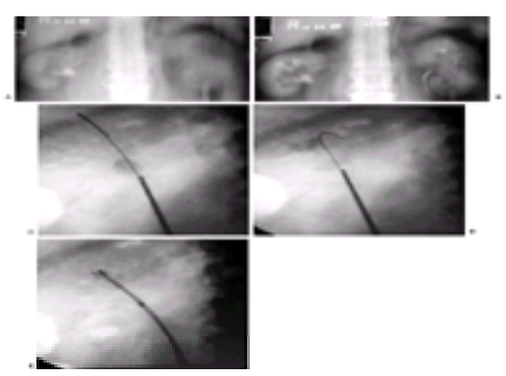

FIGURE 9.28. A: KUB of obese (205-kg) woman with 2-cm stone at ureteropelvic junction. **B:** Intravenous pyelogram showing obstruction of right collecting system. **C:** Ureteropelvic junction stone initially accessed with semirigid ureteroscope and 320-micron holmium laser fiber. **D:** Proximal migration of large stone fragment. **E:** Residual stone easily fragmented with flexible ureterorenoscope and 200-micron holmium laser fiber.

A major factor that now allows for routine ureteroscopic access and management of intrarenal calculi has been the introduction of holmium:yttrium-aluminum-garnet (Ho:YAG) laser lithotripsy. The holmium laser is an efficient and relatively safe device that will fragment stones of any composition. The major advantage of the holmium laser is that these small fibers can be placed through small, flexible ureteropyeloscopes. Both the 200- and 365-micron fibers can be placed through a flexible ureterorenoscope, although the 200-micron fiber is preferred when managing intrarenal calculi because the smaller fiber diameter allows for greater ureteroscopic deflection (100,194). However, the smallest EHL probes are even more flexible, and they may be beneficial in some instances requiring very acute ureteroscopic flexion for stone visualization.

Our preferred settings for the holmium laser are 0.6 to 0.8 joules at 6 to 8 Hz. Studies have demonstrated that increasing the power to more than 1 joule will rapidly damage the small-caliber 200-micron fiber. Moreover, the relatively low power required to fragment calculi also allows the use of low-power holmium lasers. These low-power units provide 25 to 30 W of power, at a significantly reduced cost as compared with the high-power, 80-W lasers (95).

As mentioned, even though the 200-micron fiber is highly flexible, one can still lose anywhere from 10 to 45 degrees of tip deflection of a 7.5-Fr flexible ureteroscope when a 200-micron laser fiber is placed through the working channel (100,133). Another recent innovation, in the form of nitinol baskets and graspers, now allows for virtually full deflection of the flexible ureteroscopes such that a 3-Fr nitinol basket or grasper can be passed through a deflected endoscope with minimal loss of tip deflection (Fig. 9.29) (76,96).

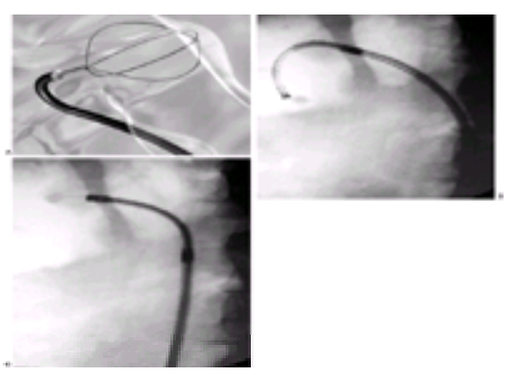

FIGURE 9.29. A: Nitinol stone grasper. (Microvasive Urology, Natick, Massachusetts.) **B:** Nitinol grasper can be passed through a fully flexed flexible ureteroscope to access lower pole renal calculus. **C:** Lower pole calculus repositioned into lateral calyx to allow for laser fragmentation with a 200-micron holmium laser fiber.

One useful technique for stones that are difficult to access is utilization of a nitinol basket or grasper to reposition them. For example, lower pole calyceal stones can be brought back up to a less dependent portion of the collecting system, such as the renal pelvis or an upper pole calyx, and this then allows for easier fragmentation with a holmium fiber.

OPEN OPERATIVE INTERVENTION

Contemporary Indications

Whereas the indications to intervene for stones have not changed significantly with the advent of new technology, the indications for open operative intervention have narrowed considerably (128). Currently, these indications include an associated anatomic abnormality that would best be managed with open operative intervention at the time of stone extirpation, a failure of or a contraindication to both SWL and percutaneous management, or in the urologist's judgement, a stone so large and complex that a single open operative procedure would more likely render the patient stone free, with less risk, than would the option of a complicated percutaneous procedure with or without adjunctive SWL.

The type of open operative intervention planned takes into consideration several factors, the most important of which are stone size, configuration, and location relative to the pyelocalyceal system. The approaches to be discussed in this section include standard and extended pyelolithotomy, simple nephrolithotomy, coagulum pyelolithotomy, calyceal diverticulolithotomy, anatrophic nephrolithotomy, partial nephrectomy, and nephrectomy.

Specific Techniques

Pyelolithotomy

A pyelolithotomy had been perhaps the most commonly performed open operative procedure for patients with renal calculi, but this was supplanted almost 20 years ago by the advent of percutaneous and shock wave technology. Currently, the only indications for this procedure are a failure of or contraindication to both SWL and percutaneous nephrolithotomy or the presence of an associated abnormality such as ureteropelvic junction obstruction, which could then be managed simultaneously. However, even in that setting, open pyelolithotomy is performed less often today because percutaneous stone management can be combined with percutaneous endopyelotomy.

Czerny (37) is credited with performing the first removal of a stone via an incision in the renal pelvis in 1880. However, that approach remained controversial because most surgeons of the time favored nephrolithotomy. In 1913, Lower (111), at The Cleveland Clinic, popularized a vertical pyelolithotomy, which remained the preferred approach to uncomplicated renal pelvic calculi for many years. In 1965, Gil-Vernet (61) advocated a transverse rather than a vertical pyelolithotomy based on his studies of the functional anatomy of the renal pelvic musculature.

Standard Pyelolithotomy

Today, almost any patient whose stone could be managed via a pyelotomy incision can and should be managed with either percutaneous or shock wave technology such that the role of pyelolithotomy is now extremely limited. Currently, then, the indications for a standard pyelolithotomy, within the context of the limited indications for open operative intervention, include stones limited to the renal pelvis with minimal or no branching (Fig. 9.30). The procedure is performed through a standard flank incision, generally with twelfth-rib resection, or through a dorsal lumbotomy. Either of these approaches allows rapid access to the renal pelvis posteriorly.

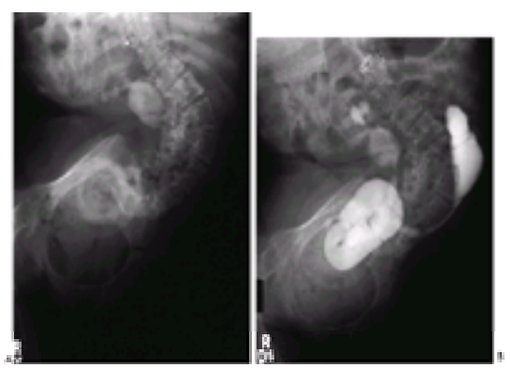

FIGURE 9.30. A: Plain film in this myelodysplasia patient status post–urinary diversion reveals a large calcification filling the right upper quadrant. **B:** Loopogram reveals free reflux into a nonfunctioning shell of a left kidney and hydronephrosis on the right associated with the large renal pelvic calculus. Percutaneous access to this stone is hindered by the severe scoliosis and would require supracostal puncture with risk of injury to the pleura or liver on the right. Open pyelolithotomy was indicated with consideration for simultaneous left nephrectomy.

The retroperitoneum is entered and Gerota's fascia opened posteriorly at the lower pole of the kidney. The proximal ureter is identified and surrounded with a vessel loop. This aids dissection and prevents distal stone migration during the subsequent procedure. The dissection is then carried proximally along the posterior aspect of the ureter, up toward the renal pelvis. Once the pelvis is exposed posteriorly, stay sutures are placed in preparation for the transverse pyelotomy. This incision is made well away from the ureteropelvic junction itself, and it is carried as far laterally on the pelvis as is necessary to extract the stone under direct vision (Fig. 9.31A). The stone is removed with a Randall's forceps and the vessel loop on the ureter is relaxed (Fig. 9.31B). An 8-Fr red rubber catheter is then passed antegrade down the ureter to the bladder to ensure ureteral patency. The renal pelvis is thoroughly irrigated and the catheter removed. The pyelotomy is then closed in a single layer using running or interrupted 4-0 absorbable suture placed full thickness through the posterior renal pelvic wall such that peripelvic adventitia, musculature, and mucosa are all encompassed with each bite (Fig. 9.31C). In all cases, external drainage is provided with a Penrose or closed-suction drain placed near but not on the pyelotomy incision.

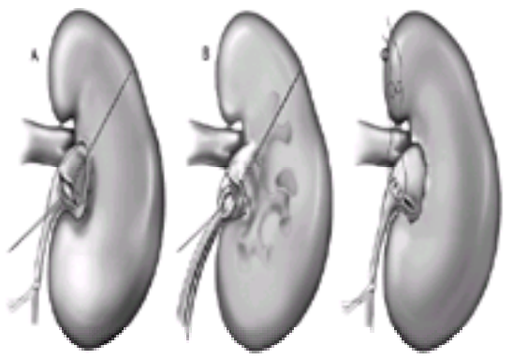

FIGURE 9.31. A: The pyelotomy incision is performed horizontally on the renal pelvis between stay sutures, taking care to avoid the ureteropelvic junction. **B:** The stone is extracted under direct vision with standard stone forceps. **C:** The pyelotomy incision is closed with full-thickness, interrupted, absorbable suture.

In uncomplicated cases, there is no need for an internal stent, although this should be considered in the presence of recent infection or if there is any question of residual calculi. Nephrostomy tubes are indicated only in the most complicated cases, such as in the setting of previous surgery with intense inflammation and scarring or if there is a question of ureteral patency or residual calculi. This allows excellent access for antegrade radiographic studies in the postoperative period.

Extended Pyelolithotomy

In 1891, Disse described fibrous extensions from the renal capsule that extended to the posterior renal pelvis and normally acted to separate the renal sinus from the retroperitoneal space. An extended pyelolithotomy, as advocated by Gil-Vernet in 1965 (61), takes advantage of dissection into the renal sinus to gain access to the

intrarenal collecting system. This approach gained favor in Europe even for management of some extensive staghorn calculi. In general, though, its use had been limited to management of relatively large renal pelvic stones with or without extension into one or more infundibula, but without dumbbell-shaped calyceal extensions or associated infundibular stenosis (Fig. 9.32). However, these indications are now considered only within the narrower context of current indications for open operative intervention.

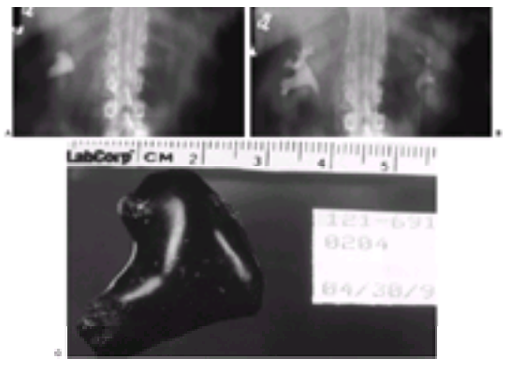

FIGURE 9.32. Intravenous urogram. **A:** Scout film. **B:** Following contrast injection, a large renal pelvic calculus is revealed extending from the upper to the lower infundibula. The patient had failed percutaneous management elsewhere and was adamant in her request for open operative intervention. Anatomically, this patient is a good candidate for an extended pyelolithotomy. **C:** Stone removed from this patient with an extended pyelolithotomy incision.

The posterior aspect of the renal pelvis is exposed as described for a standard pyelolithotomy. Dissection is then carried into the renal sinus by incising the fibrous tissue between the posterior hilar lip of renal parenchyma and the renal pelvis itself, and the plane between the renal pelvis and peripelvic fat is entered. Further exposure of the intrarenal collecting system can then be accomplished using vein retractors, or specifically designed Gil-Vernet renal sinus retractors, to elevate the posterior parenchymal lip. Dissection into the sinus then continues using a moist gauze or Kittner sponge (Fig. 9.33A). As described by Wulfsohn (192), temporary occlusion of the renal artery done in association with local hypothermia can serve to soften the renal parenchyma and allow further exposure of the intrarenal collecting system, which may be necessary in select cases.

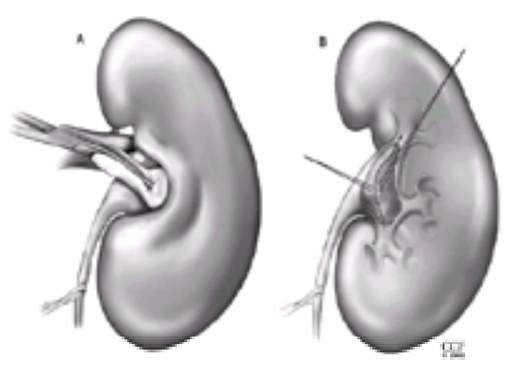

FIGURE 9.33. A: A moist gauze or sponge is used to develop the avascular plane posteriorly between the renal pelvis and parenchyma. **B:** An extended pyelolithotomy requires a curvilinear incision that extends from the upper infundibulum across the renal pelvis and into the lower infundibulum.

A curvilinear transverse pyelotomy is then performed between stay sutures, taking care to keep well away from the ureteropelvic junction. The pyelotomy is then extended along both the upper and lower infundibula, thus creating a renal pelvic flap, which affords access to even large calculi with early branch formation (Fig. 9.33B). Any infundibular extensions that remain after extraction of the renal pelvic stone can be removed using Randall's forceps.

For more extensive stones, this approach can be combined with a simple or lower pole nephrotomy. For dumbbell-shaped calyceal extensions near the mid or superior poles that cannot be withdrawn via the infundibulum, a nephrotomy incision is made directly over the stone. This approach is best reserved for those patients in whom the stone is associated with cortical loss and local cortical thinning.

Lower pole infundibulocalyceal extensions of pelvic calculi can be managed by extending the inferior aspect of the pyelotomy incision onto the posterior renal parenchyma itself as a pyeloinfundibulotomy, directly over the involved lower infundibulum (Fig. 9.34). The infundibulonephrotomy incision thus performed is in an avascular plane between the junction of the posterior and basilar segments of the kidney.

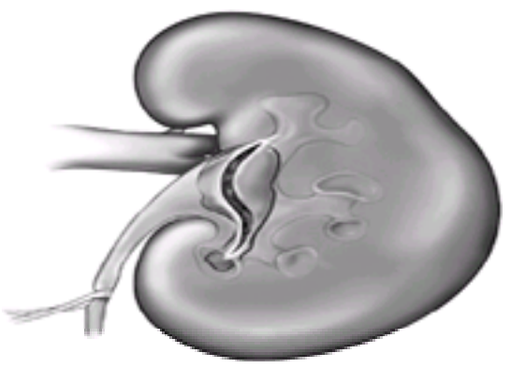

FIGURE 9.34. A pyeloinfundibulonephrotomy incision can be made on the anterior aspect of the kidney through a relatively avascular plane between the junction of the posterior and basilar segments of the kidney. Such an incision can be used to manage renal pelvic calculi extending into the lower infundibulocalyceal system.

As for a simple pyelolithotomy, on removal of all visible and palpable stone material, a catheter is passed antegrade down the ureter and the intrarenal collecting system is thoroughly irrigated. If multiple stones have been present, intraoperative radiography, fluoroscopy, US, or pyeloscopy should be performed to exclude the presence of residual calculi.

The pyelotomy incision is closed as for a standard pyelolithotomy. For cases requiring extensive dissection, placement of an internal stent may be desirable. External drainage is routinely provided.

Coagulum Pyelolithotomy

In 1943, Dees (38) combined human fibrinogen and clotting globulin to form an extractable cast of the upper collecting system, which he used to remove multiple renal calculi. Several authors have since reported their own modifications of the coagulum “recipe” to both simplify the procedure and reduce the risk of complications. At the authors' institution, we have used the technique described by Fischer and associates in 1980 (56). In that protocol, cryoprecipitate is the fibrinogen source and is

converted to fibrin using thrombin as the active catalyst. Calcium chloride in the mixture serves to increase the tensile strength of the coagulum by neutralizing the citrate already present in the cryoprecipitate and by acting as a cofactor in the conversion of prothrombin to thrombin. To further obviate the risk of transmission of blood-borne disease, McVary and O'Conor (114), in 1989, reported the use of autologous cryoprecipitate in this setting.

The contemporary indication for a coagulum pyelolithotomy is the presence of multiple stones scattered throughout the collecting system, again in context of the otherwise limited contemporary indications for open operative intervention. Stones in calices drained by relatively narrow infundibula cannot be extracted with this method because the dumbbell-shaped calyceal extensions of the coagulum would simply break off as the pelvic portion is removed. However, any residual coagulum left within the collecting system is of no consequence because it will dissolve spontaneously in 24 to 48 hours in response to urokinase normally present in the urine.

Exposure of the renal pelvis is accomplished as described for pyelolithotomy. Again, an occluding vessel loop is placed about the proximal ureter to prevent distal migration of either stone fragments or the coagulum itself. The volume of the pyelocalyceal system is now estimated by puncturing and draining the renal pelvis with a 14-gauge angiocatheter. The pelvis is filled to capacity with a measured amount of saline, and the volume of coagulum prepared is then based on the amount of saline required for gentle distention. The estimated amount of required cryoprecipitate is then drawn up into one large syringe while the requisite volume of thrombin and calcium chloride is combined together in a second syringe. The amount of each constituent required is based on a ratio of 1 mL of cryoprecipitate to 2 units of thrombin and 1 mg of calcium chloride.

At this time, the angiocatheter that had been left in place in the renal pelvis is used to again completely drain the pyelocalyceal system. The thrombin and calcium chloride are then injected into the syringe containing the cryoprecipitate, and the complete mixture is injected into the renal pelvis within 45 seconds (Fig. 9.35A), after which time clotting will have irreversibly begun. At this point, assuming the measured capacity was correct, there will be complete filling and gentle distention of the renal pelvis. Care should be taken not to overdistend the system because this could result in pyelovenous backflow of the cryoprecipitate, and rarely, a pulmonary embolus can develop in this setting as reported by Pence and colleagues in 1981 (131).

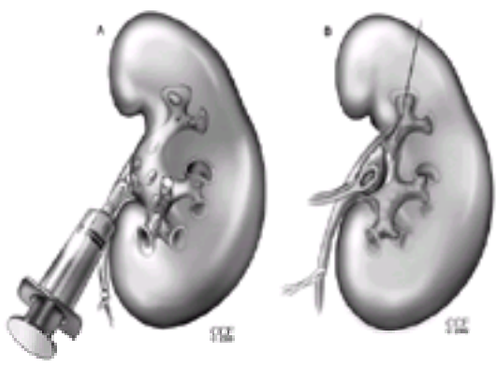

FIGURE 9.35. A: The proximal ureter is secured with a vascular tape as the coagulum, consisting of cryoprecipitate, bovine thrombin, and calcium chloride, is injected into the collecting system. **B:** A pyelotomy incision is made and the coagulum is extracted.

After 5 to 10 minutes, the coagulum should be well established. A standard or extended pyelotomy incision is made and the coagulum extracted (Fig. 9.35B). If the procedure has been performed correctly, the coagulum has formed a cast of the collecting system and multiple stones will be trapped within the substance of the coagulum (Fig. 9.36).

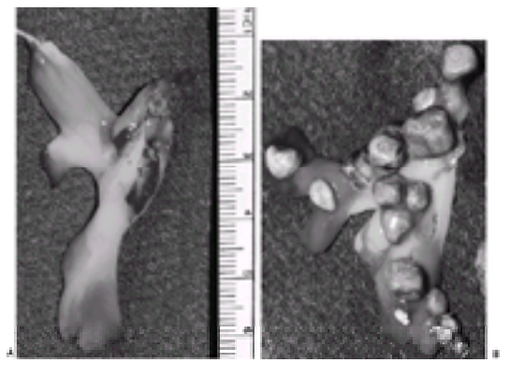

FIGURE 9.36. A: The coagulum has assumed the shape of the pyelocalyceal system. **B:** Multiple stones entrapped within the substance of the coagulum.

As for any procedure involving a patient with multiple stones, intraoperative radiographs, fluoroscopy, US, or pyeloscopy is then performed as necessary to exclude the presence of residual calculi. Because the procedure is always performed in patients with multiple calculi, it is generally prudent to leave an internal stent at this time to prevent migration of any potentially unrecognized residual stones in the early postoperative period. External drainage is routinely provided with a Penrose or closed-suction drain.

Calyceal Diverticulolithotomy

Calyceal diverticula are transitional epithelium-lined cavities in the renal parenchyma. Communication with a calix or infundibulum is implied by definition, although that communication may not be demonstrable at the time the patient is initially examined. Because some calyceal diverticula are associated with localized urinary stasis, they may be a source of stone formation, although as reported by Hsu and Streem (79), metabolic factors also play a role. The indications to intervene for calyceal diverticular stones are the same as for any upper tract stones, although the indications for open operative intervention are considerably narrower. In highly select patients, SWL can be successful (169), although ureteroscopic and percutaneous techniques are generally considered more definitive (11,13,85,162). When these techniques are contraindicated or have failed, open operative intervention may be considered.

Preoperative planning generally includes a CT scan for three-dimensional radiographic localization (Fig. 9.37). The kidney is exposed via a standard flank incision. Generally, the diverticulum is readily apparent by inspection and palpation, although intraoperative localization can be performed when necessary with intraoperative fluoroscopy or US. In all cases, confirmation that the suspicious area represents the diverticulum can be performed by using a small-gauge needle to aspirate urine from the diverticulum or to “sound” the calculus.

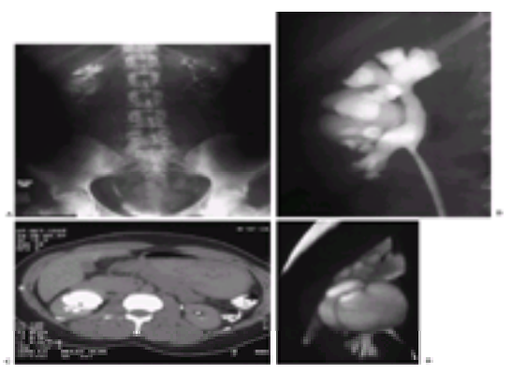

FIGURE 9.37. A: Intravenous urogram in this patient with chronic right flank pain suggests the presence of a large calyceal diverticulum in the central aspect of the kidney. **B:** Retrograde study confirms filling of a central calyceal diverticulum. **C:** Computed tomography reveals the diverticulum to be located anteriorly with thinning of the overlying parenchyma. **D:** Three-dimensional reconstruction confirms the anterior location of the diverticulum and allows better evaluation of the relationship to the collecting system. The anterior location of this diverticulum and the thin overlying parenchyma suggest that the best approach is either open or laparoscopic diverticulolithotomy.

When the diverticulum is associated with thinning of the overlying parenchyma, appropriate management is marsupialization. The thin parenchyma overlying the diverticulum is excised, and the calculi are removed. The diverticular neck can then be identified and is oversewn with absorbable suture or simply fulgurated. The lining of the diverticulum may also be fulgurated either with electrofulguration or an argon beam coagulator. The rim of remaining parenchyma is then oversewn with absorbable suture or simply fulgurated.

Occasionally, identification of the diverticular neck may be difficult. This can be circumvented with placement of a ureteral catheter at the outset of the procedure. Dilute methylene blue can then be injected retrograde via the ureteral catheter, and the diverticular neck is identified as the methylene blue flows into the diverticulum.

In some cases, the diverticulum may be located deep within the renal parenchyma. With the aid of intraoperative US, the area containing the diverticulum can easily be identified. In such cases, however, rather than unroofing, a local wedge resection is more appropriate. In all cases, a Penrose or closed-suction drain is placed near the site of excision, and the wound is irrigated and closed in a standard fashion.

Although open calyceal diverticulolithotomy and diverticulectomy should be a part of the urologic armamentarium, many patients who otherwise would have required open operative intervention because of a failure of or contraindication to less invasive techniques can and should be managed with a laparoscopic approach as described by Ruckle and Segura in 1994 (150).

Anatrophic Nephrolithotomy

Most opaque staghorn calculi are composed of magnesium-ammonium-calcium phosphate and are associated with urinary infection that will always recur as long as the stone is present. In 1994, the American Urological Association (AUA) Nephrolithiasis Clinical Guidelines Panel made recommendations regarding the management of these branched, infection-related stones (158). The AUA Nephrolithiasis Clinical Guidelines Panel stressed that left untreated, these stones are invariably associated with recurrent infection, loss of renal function, and high rates of renal-related morbidity and even death. In reviewing outcome probabilities for management of such stones, the AUA Nephrolithiasis Clinical Guidelines Panel concluded that any newly diagnosed struvite staghorn calculus was an indication for intervention. The AUA Nephrolithiasis Clinical Guidelines Panel further recommended that most such stones could be managed with percutaneous nephrolithotomy or SWL, either alone or in combination. However, open operative intervention was recommended as an appropriate option in cases where the stone was so extensive that an unreasonable number of percutaneous or shock wave procedures would be required to achieve a stone-free result.

In affected patients, the most common relative indication for open operative intervention is the finding of a massively sized, complete, fully branched staghorn calculus with multiple dumbbell-shaped infundibulocalyceal extensions associated with relatively narrow infundibula (Fig. 9.38). Multiple areas of true infundibular stenosis would also be a relative indication for open operative intervention so that this anatomic abnormality could be managed simultaneously. In such cases, the most appropriate open operative approach is generally anatrophic nephrolithotomy as initially described by Boyce and Smith in 1967 (16). With this procedure, the stones are removed through an incision that is least traumatic to overall renal function, that is, an incision through a relatively avascular plane in the kidney. The renal artery will temporarily be occluded during the procedure to provide a bloodless field in which to work, and the kidney must therefore be protected from the resulting ischemic insult. Finally, areas of true, functionally significant infundibular stenosis are addressed such that adequate drainage is provided from all parts of the collecting system.

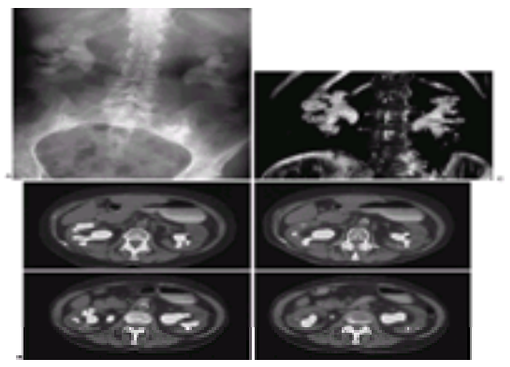

FIGURE 9.38. A: Plain abdominal film in this patient with significant renal insufficiency and proteus urinary infection reveals extensive, fully mature staghorn calculi bilaterally. Anatrophic nephrolithotomy is a reasonable approach compared with the option of multiple percutaneous and shock wave procedures. **B:** Standard computed tomography scan without contrast helps delineate the stone and the thickness of the overlying parenchyma. **C:** More recently, three-dimensional reconstruction has been used for more precise anatomic definition.

Our preference is a flank approach with resection of the eleventh or twelfth rib, with medial extension of the incision to the lateral border of the rectus muscle. The peritoneum is reflected medially, and access to the retroperitoneum is attained. The proximal ureter is surrounded with a vessel loop to prevent distal migration of stone fragments during the subsequent procedure. The kidney is then completely mobilized and the renal pedicle isolated. The renal artery is surrounded with a vessel loop and mannitol, 12.5 g, is given intravenously for protection during the subsequent renal ischemic episode (Fig. 9.39). Further dissection of the renal artery is accomplished until the anterior and posterior divisional branches are identified. The first major branch of the renal artery generally represents the posterior division (Fig. 9.40).

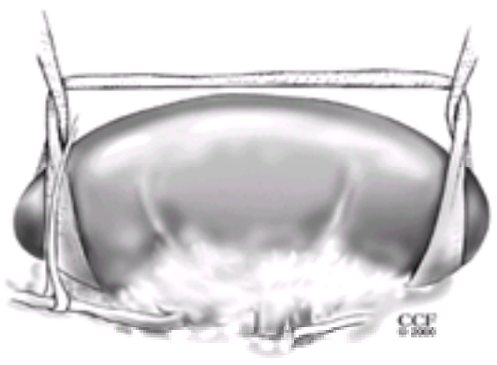

FIGURE 9.39. The kidney is mobilized and the renal artery identified and surrounded with a vessel loop. The kidney may be elevated into the wound using a Jones roll as a sling.

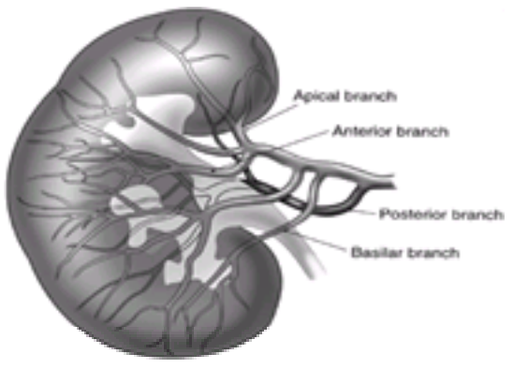

FIGURE 9.40. The first major branch of the renal artery generally represents the posterior division.

As described by Brodell in 1901 (18) and subsequently by Graves in 1954 (69), there is an avascular plane between the junction of the blood supply to the anterior and posterior segments of the kidney. At the surface of the kidney, this generally lies on the posterior aspect approximately two-thirds of the way from the renal hilum to the true lateral border of the kidney. When desired, this can be further delineated by temporarily placing a vascular clamp on the anterior division of the renal artery (Fig. 9.41). Ten milliliters of methylene blue is then injected intravenously into the systemic circulation. This will stain the posterior renal segment and thus help identify the appropriate line of incision and further dissection into the renal parenchyma. Although delineation of the arterial blood supply in this manner may be useful, it may not be a requisite for a successful nephron-sparing result (125).

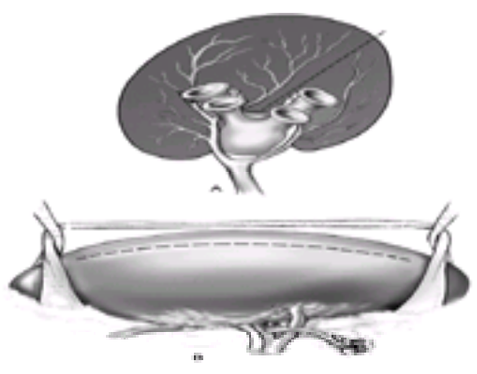

FIGURE 9.41. A: An avascular plane exists between the junction of the blood supply to the anterior and posterior segments of the kidney, and this plane generally provides the correct line of dissection for anatrophic nephrolithotomy. **B:** Temporary occlusion of the posterior branch of the renal artery can help delineate the optimal line of incision in this plane.

A bowel bag is the placed beneath the kidney and wrapped around the pedicle as a reservoir for ice slush. An additional 12.5 g of mannitol is given, and the main renal artery is subsequently occluded with a vascular clamp. At this point, the renal vein may also be occluded to ensure a blood-free surgical field. The kidney is packed with slush with a goal of obtaining a core temperature of 10°C as protection from the subsequent renal ischemic insult.

Once the kidney has reached core temperature, the capsule is incised longitudinally between the anterior and posterior segments, but extended only to the apical and basilar renal segments. The incision through parenchyma continues in a plane along the line of demarcation between the anterior and posterior arterial segments, down toward the renal pelvis. The correct plane generally runs just anterior to the posterior row of infundibula and calices. If small arterioles or venules are cut and identified during this incision or during the subsequent dissection, these are managed using fine chromic figure-of-eight absorbable suture.

The stone is now identified either by palpation in one of the involved posterior infundibula or calyceals or by direct visualization. Once the initial stone-bearing infundibulocalix is open, a longitudinal infundibulotomy is performed and extended down to the renal pelvis (Fig. 9.42). Similarly, each involved posterior infundibulocalix is subsequently opened longitudinally as far as necessary to extract any stone, and the infundibulotomy is carried down its anterior aspect toward the renal pelvis.

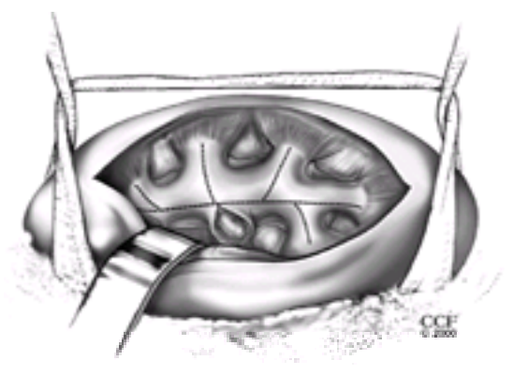

FIGURE 9.42. The collecting system is entered with an incision into one of the involved posterior infundibulocalyces containing stone.

Once the pelvic and posterior infundibulocalyceal aspects of the stone are identified, the anterior and polar portions are exposed, again with sequential longitudinal infundibulotomies. However, these are performed on the posterior aspect of the anterior segmental infundibula and central aspects of the polar infundibula. The infundibulotomies should begin at each infundibulopelvic junction and extend outward toward the calix as far as necessary to provide adequate exposure for stone removal.

Eventually, the entire staghorn calculus is exposed and ready for removal (Fig. 9.43). In some cases, the entire stone can be delivered intact, but piecemeal extraction is usually required. Infundibulocalyceal extensions may break off due to a relatively soft and friable intrinsic nature of the stone, or alternatively, the entire stone may not have been in continuity to start. If infundibulocalyceal extensions of the stone are not extracted with the main portion, the involved infundibulum should be dilated or further incised out toward the calix to ensure complete visualization and stone removal.

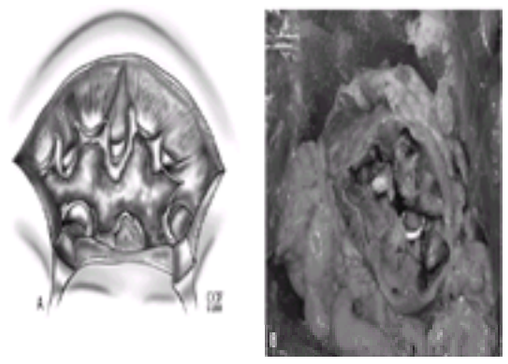

FIGURE 9.43. A: The entire stone is now exposed after performing sequential longitudinal infundibulotomies and opening the lateral portion of the renal pelvis. **B:** Intraoperative view of completed anatrophic incision with entire collecting system exposed. Note the bloodless field availed by clamping of the renal artery. The kidney is packed in ice slush to minimize the adverse effect of renal ischemic injury.

Once the bulk of the stone is removed (Fig. 9.44), each infundibulocalix is individually explored both visually and with palpation to exclude residual fragments. Occasionally, residual fragment can be palpated through thin parenchyma, but the infundibulum leading to the stone cannot be visualized. In such cases, a small nephrotomy made directly over the palpable stone is acceptable. The stone is extracted, and the nephrotomy is closed with absorbable sutures. The entire collecting system should now be thoroughly lavaged with iced saline using appropriately sized red rubber catheters placed sequentially into each infundibulocalix.

FIGURE 9.44. Staghorn calculus removed with anatrophic nephrolithotomy.

Because an optimal result requires removal of all stone fragments, several adjunctive maneuvers can be performed to identify and remove any potential residual stones, including intraoperative static radiography (Fig. 9.45A), fluoroscopy (Fig. 9.45B), US, and intraoperative pyeloscopy using flexible instrumentation (Fig. 9.45C).

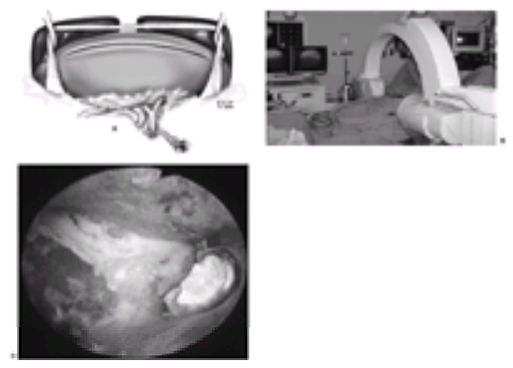

FIGURE 9.45. A: Intraoperative organ films had been a standard part of the procedure to exclude the presence of residual fragments. In general, such static radiography has been replaced with more contemporary adjunctive techniques such as intraoperative real-time fluoroscopy, ultrasound, or pyeloscopy. **B:** Intraoperative fluoroscopy has become a standard part of these stone procedures to exclude the presence of residual fragments and to help locate them for removal. **C:** Residual calyceal stone identified during intraoperative flexible pyeloscopy.

When all identifiable stone has been removed, a red rubber catheter is passed antegrade down the ureter, and the ureter is irrigated with saline. An internal stent may be placed at this time, and although this is not mandatory, it should be considered in those patients who may have residual fragments and in patients with compromised renal function. Nephrostomy tubes are used even less frequently and generally only for patients with severely compromised renal function and thinned parenchyma.

The collecting system is now reconstructed using fine absorbable suture (Fig. 9.46A). In areas of significant infundibular stenosis, infundibulorrhaphy is performed by suturing the adjacent borders of involved infundibula on their mirror-image sides, thus converting two or more stenotic infundibulocalyceal systems into one larger portion of the renal pelvis (Fig. 9.46B). Alternatively, isolated infundibular stenosis or polar infundibular stenosis can be managed with an individual infundibulorrhaphy that involves horizontal closure of the initial vertical infundibulotomy in a Heineke-Mikulicz fashion (Fig. 9.46C). However, when no infundibular stenosis is present, separate closure of the collecting system may not be necessary (125).

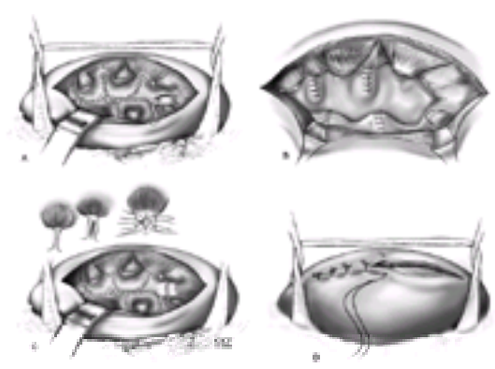

FIGURE 9.46. A: Closure of the collecting system begins with reconstruction of the incised infundibula and continues until the pelvis has been reapproximated. **B:** Infundibular stenosis is managed with infundibulorrhaphy. The lateral aspects of two adjacent infundibula are sutured to one another, creating widely patent, compound infundibulocalyces. **C:** Isolated polar infundibular stenosis is managed with a Heineke-Mikulicz infundibulorrhaphy. **D:** The renal capsule is approximated

using running or interrupted mattress 3-0 chromic sutures taking a small bite of renal parenchyma.

The renal capsule is now approximated with running or interrupted 3-0 chromic sutures incorporating only a very small bite of renal parenchyma (Fig. 9.46D). At this time, an additional 12.5 g of mannitol is given intravenously and the vascular clamps are removed. Perirenal fat can be reapproximated over the nephrotomy incision, and external drainage is provided with a Penrose or closed-suction drain placed near, but not directly on, the nephrotomy incision itself.

Partial Nephrectomy

A partial nephrectomy is considered when stone disease is associated with a localized area of irrevocably poor renal function as can occur in the setting of chronic obstruction, especially with infection (Fig. 9.47). In such cases, removal of the diseased portion of the kidney along with the stone may be the best option, especially when localized xanthogranulomatous pyelonephritis may be present.

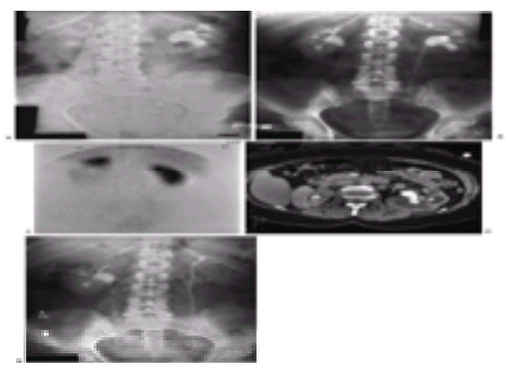

FIGURE 9.47. A: Plain film in this patient with recurrent urease-producing infection reveals a fully branched staghorn calculus overlying the left kidney. **B:** Intravenous urogram suggests contrast excretion from the lower pole, although this is a partially duplicated system, and function in that portion of the kidney was not proven on this study. **C:** Nuclear renogram reveals function only in the upper portion of the collecting system on the left side. The contrast in the lower pole on the left seen on the intravenous pyelogram was due to a “yo-yo effect” in the partially duplicated ureters. **D:** Computed tomography scan reveals thinning of the parenchyma in the involved lower portion of the collecting system. **E:** Following lower-pole partial nephrectomy, a well-functioning upper-pole system remains, as seen on this postoperative pyelogram.

Nephrectomy

Nephrectomy is indicated only rarely for management of renal calculi. The specific indication is stone disease associated with a nonfunctioning or poorly functioning kidney that is irrevocably damaged and would be unlikely to support life off dialysis should it be the sole kidney (Fig. 9.48). This generally implies renal function less than 10% to 15% of overall function, or a glomerular filtration rate of less than 15 mL per minute. In these cases, salvageability of the kidney is best determined preoperatively with radiographic evaluation that includes a differential nuclear scan. We have also found CT scanning to be especially useful in determining the residual cortical thickness and to search for evidence of xanthogranulomatous pyelonephritis, which is best managed by nephrectomy. If there is any question as to recoverability of function in the setting of chronic obstruction, placement of percutaneous nephrostomy provides temporary relief of obstruction and allows follow-up differential renal functional studies.

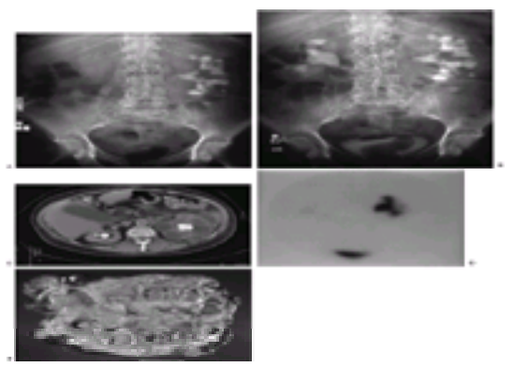

FIGURE 9.48. A: Scout film reveals a large, extensively branched staghorn calculus overlying the left kidney in this patient with recurrent urinary infection. **B:** Intravenous urogram shows prompt function on the right. However, there is no evidence of contrast excretion on the left side. **C:** Computed tomography scan in this same patient shows marked thinning of parenchyma and multiple cystic areas in the kidney consistent with local hydrocalices, and suggestive of xanthogranulomatous pyelonephritis. **D:** Renal scan shows essentially no function in the left kidney (posterior view). **E:** Nephrectomy specimen reveals chronic pyohydronephrosis. Pathologic examination confirmed xanthogranulomatous pyelonephritis.

Ureterolithotomy

Open ureterolithotomy is rarely performed in contemporary practice. Essentially, the only indication today is a failure of, or a contraindication to, all less invasive procedures, including SWL, retrograde ureteroscopic management, and percutaneous antegrade management. In such cases, an extraperitoneal approach is used with the incision positioned at the level of the stone. The peritoneum is reflected medially, the ureter is identified, and the stone is palpated. Generally, extensive ureteral mobilization is not necessary and should be avoided whenever possible. The ureter proximal to the stone is controlled by placement of a vascular tape (Fig. 9.49A). This prevents proximal migration of the stone up into the dilated ureter during the subsequent procedure. A longitudinal ureterotomy is then made directly over the stone using a “banana blade.” The stone is extracted with an appropriate-size stone forceps (Fig. 9.49B). The ureter is then thoroughly irrigated distally and proximally with a small-caliber red rubber catheter, and distal patency is ensured by passage of the catheter all of the way into the bladder. The ureterotomy is closed with interrupted fine absorbable suture (Fig. 9.49C) and the area drained with a Penrose drain. In the face of extensive ureteral edema or infection, strong consideration should be given to leaving an internal stent placed intraoperatively before closure of the ureterotomy.

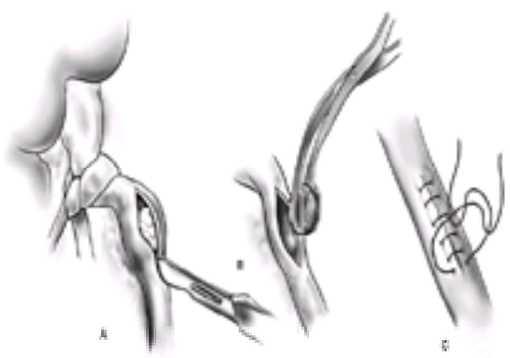

FIGURE 9.49. A: The ureter is isolated and controlled proximal to the stone using a vessel loop. **B:** A longitudinal ureterotomy is made directly over the stone, and the stone is extracted. **C:** The ureterotomy is closed using fine, absorbable interrupted suture to approximate the seromuscular layer.

Complications

Retained calculi can occur in up to 20% of patients, and when such retained stones are symptomatic or associated with infection or obstruction, further intervention is required. Fortunately, today, almost all such retained stones can be managed with SWL or percutaneous techniques, although these procedures should be delayed at least 4 to 6 weeks after the initial open operative intervention.

Persistent urinary drainage is uncommon and generally implies a local area of devascularization or distal obstruction. In most cases, such fistulae resolve spontaneously with conservative measures, including provision of local drainage and assurance of distal patency, at times with placement of an internal stent.

Bleeding into the collecting system or around the kidney almost always resolves spontaneously, and conservative, supportive measures are the initial treatment. When bleeding results in the need for multiple transfusions or an unstable cardiovascular status, intervention is indicated. In most cases, the treatment of choice is selective angiographic embolization because open surgical exploration generally results in nephrectomy (5).

The risk of an operative procedure must be weighed against its benefit so that the patient can be given a realistic view of the probable outcomes of both the nonoperative and the operative approaches. Although determining risk is simple in theory, it is extremely difficult in practice. Because of the wide variety of surgical procedures performed and the uniqueness of each patient, attempts to quantitate the risk factor have not met with great success. Many investigations have been unable to correlate accurately risk with any specific factor; however, a loose association has been shown with poor general health, advanced age, emergency operation, and the site of the surgical procedure (41).

In an attempt to quantitate the risk associated with an anesthetic, irrespective of procedure performed, the American Society of Anesthesiologists (ASA) has proposed a classification of physical status: Class I is a normal healthy person, class II is used for patients with mild to moderate systemic disease, class III represents patients with severe systemic diseases that are not incapacitating, class IV indicates an incapacitating systemic disease that is a constant threat to the patient's life, and class V denotes a moribund patient not expected to survive more than 24 hours without an operation. This classification allows a general assessment but is not specific enough to accurately quantitate risk.

The most important factor in evaluating the risk of an operation is the functional status of the cardiovascular system. Pulmonary function also significantly affects the risk of anesthesia; perhaps the most common postoperative complication involves the respiratory tract. Hypoxemia secondary to respiratory dysfunction, when combined with myocardial disease, significantly increases the risk of myocardial infarction and death following the procedure.

The death rate from anesthesia, taking into account all operative procedures, has been estimated to be approximately 0.3%. Of patients who die as a result of the anesthetic and operative procedure, approximately 10% die in the period of induction, approximately 33% during the operative procedure, and the remainder within the first 48 hours after operation (32). The death rate attributed to anesthesia in patients who are ASA class I or II is much less and is estimated to be about 1 in 500,000 (27).

Preoperative assessment is undertaken to determine the risk of the proposed procedures and to identify abnormalities that can be corrected to reduce morbidity and mortality. The assessment should include an evaluation of the blood count and blood volume; the integrity of the hemostatic mechanisms; an evaluation of the cardiac function; an assessment of pulmonary function; and a review of the metabolic status, which should include an assessment of the liver, the kidneys, the immune system, the patient's nutritional status, the integrity of the adrenal glands, and an evaluation of any systemic diseases, such as diabetes, obesity, and thyroid disease.

BLOOD COUNT

All preoperative patients in whom a significant blood loss is anticipated or who are suspected of having an abnormal blood count require determination of a packed cell volume or hematocrit level. A value between 30% and 50% is acceptable. As the hematocrit level falls below 30%, the viscosity of the blood is reduced and flow characteristics through the small vessels improve. However, this is offset by the decreased oxygen-carrying capacity of the blood. Patients with chronic renal failure often have hematocrit levels of 20% to 24% and tolerate surgery well, provided there has not been a recent short-term change in the hematocrit level. The disadvantage is that there is little margin for error in terms of major blood loss. Patients with hematocrit levels above 55% have marked increased viscosity in their blood and are prone to thrombosis during periods of major fluid shifts. Therefore, except under extenuating circumstances, a hematocrit level between 30% and 50%

should be sought in the preoperative preparation of the patient.

BLOOD VOLUME

The status of the patient's blood volume also must be assessed. Hypovolemia may be a consequence of secondary hyperaldosteronism, Addison's disease, acute blood loss, vomiting, diarrhea, pancreatic fistula, ileostomy, intestinal obstruction, pheochromocytoma, and neuroblastoma, among others. When these disorders are present, the blood volume must be restored through preoperative fluid administration and/or pharmacologic manipulation. a-Adrenergic blockade allows for volume expansion through relaxation of peripheral vasoconstriction with homeostatic volume restoration over a several-week period in patients with a pheochromocytoma and in hypertensive patients with a neuroblastoma. Fluid loss into the bowel, as occurs in bowel obstruction, diarrhea, or hemorrhagic blood loss, is not appropriately corrected by pharmacologic means; however, drugs may be used as temporary blood pressure stabilizers—intravenously (IV) when such losses are sufficient to cause cardiovascular instability—until fluid volumes can be restored generally.

The central venous pressure (CVP) is an indirect measure of the blood volume and competency of the heart to receive and propel blood. Provided heart disease is not significant, it is an accurate measure of volume status. A normal CVP ranges between 4 and 8 cm H_2O with reference to the left atrium (4 cm below the angle of the sternum). A low CVP suggests hypovolemia, and an elevated CVP suggests volume overload. A pulmonary artery catheter (right sided, Swan-Ganz) is necessary to determine accurately the volume status in patients with cardiac disease, those with chronic obstructive pulmonary disease, and patients in whom the CVP does not correlate with the clinical status (a high CVP in the presence of hypoperfusion). Although the CVP is adequate, a pulmonary artery catheter may be preferred in the patient with multisystem trauma, septic shock, decompensated cirrhosis, severe pancreatitis, or peritonitis, as well as in those receiving massive transfusions. In these circumstances, major fluid shifts can be more accurately titrated with a right-sided heart catheter. A normal pulmonary wedge pressure ranges between 12 and 15 cm of H_2O. This catheter also allows for the measurement of cardiac output and peripheral vascular resistance. Restoration of circulating volume and correction of metabolic disorders may require several weeks of proper fluid and pharmacologic manipulation. The use of right-sided heart catheterization to monitor fluid administration in critically ill patients has been questioned recently. In one study in which similarly critically ill patients were compared, those who had right-sided heart catheterization had a higher mortality and greater utilization of resources than those who were managed without a cannula in the pulmonary artery (16).

A kidney in the diuretic state is less prone to injury; therefore patients who have operations on their urinary tract should be volume replete before and during surgery. The usual practice of nothing by mouth past midnight requires an intraoperative catch-up of fluids. Most patients tolerate this quite well; however, in the critically ill or those who are severely compromised, maintenance of normal fluid balance minimizes postoperative complications. This can be accomplished by beginning the IV fluid administration the night before surgery and giving the patient normal replacement fluids (see Fluids and Electrolytes).

HEMOSTASIS

The competency of the hemostatic mechanisms is assessed by history that addresses bleeding tendencies, bruisability, or a family history of bleeding disorders and serum studies. *A platelet count, a prothrombin time (PT), and a partial thromboplastin time (PTT) serve as good screening tests for major surgery.* PT and PTT are thought by many to be unnecessary in patients when there is no reason to suspect a coagulation problem. It is important to remember that there may be a qualitative platelet defect such as occurs in uremic patients and those taking aspirin, which would not be picked up by a routine platelet count.

RENAL FUNCTION

It has long been known that the onset of acute renal failure in the critically ill patient is a poor prognostic sign with an excessively high mortality. Many believed that acute renal failure was merely an indication of systemic organ failure accounting for the increased mortality. However, more recent data suggest that renal failure alone increases mortality, even if the degree of insufficiency is not enough to require dialysis. This makes it imperative to aggressively treat patients who have even modest elevations of their serum creatinine (5).

CARDIAC FUNCTION

Cardiac function is evaluated by history, physical examination, an electrocardiogram (ECG), and in select cases, a gated blood pool scan to provide ejection fraction. A previous myocardial infarction is of particular significance. *As a group, patients with a history of a myocardial infarction have a tenfold increase in the probability of having a subsequent postoperative infarction. A further analysis reveals that the time elapsed since the infarction is of prime importance.* One-third of patients who have operations within 3 months of their myocardial infarction will have another. Patients who have operations 6 months or longer after their myocardial insult have their risk of postoperative infarction reduced to approximately 6% to 8%. A postoperative infarction generally occurs within the first 7 postoperative days and has a 50% to 75% mortality (91). Other factors that appear to be particularly important in predicting myocardial dysfunction in the operative and perioperative period include (a) an S_3 gallop and/or jugular venous distention; (b) a preoperative cardiac rhythm other than sinus; (c) more than five premature ventricular contractions per minute; (d) an intraperitoneal, intrathoracic, or aortic operation; (e) an age greater than 70 years; (f) aortic valvular heart disease; (g) the necessity for an emergency operation; and (h) a poor general medical condition as reflected by an arterial blood gas abnormality, decreased renal function, and/or evidence of hepatic disease (40). Clearly, the most important predictors are the presence of congestive heart failure with jugular venous distention and/or an S_3 gallop and a history of a myocardial infarction within the preceding 6 months. These two findings carry with them a significant risk of death from the anesthetic.

Hypertension also increases the risk of an operative procedure, particularly if associated with coronary artery disease. Hypertensive patients have wider and more frequent blood pressure swings during anesthesia and are more likely to have associated cerebral vascular and coronary artery blood flow compromise.

Patients should continue antihypertensive medicine if they are normotensive, or the dosages should be adjusted to achieve a normal blood pressure. In general, medications should not be discontinued in the preoperative period. The monoamine oxidase (MAO) inhibitors may be an exception because they can interfere with anesthetic management.

Patients thought to have severe cardiac disease are best prepared preoperatively with a right-sided heart catheter placed in the pulmonary artery, inotropics or antiarrhythmics given as needed, and careful fluid resuscitation. An evaluation of cardiac and respiratory status can be performed by noting the patient's resting pulse, having him or her walk briskly a short distance, and then rechecking the pulse. If the pulse rate does not rise to twice the resting level, the patient is probably not at significant risk.

An excellent assessment of cardiac reserve can be accomplished by the determination of the ejection fraction. This may be performed by an isotopic method or by ultrasound. If the ejection fraction exceeds 50%, it is likely that the patient's heart will tolerate the procedure well. If the ejection fraction is between 40% and 50%, the patient is at increased risk for myocardial dysfunction but is still acceptable from a cardiac standpoint. If the ejection fraction is less than 40%, the patient is at an increased risk and requires exceedingly close monitoring for cardiac malfunction, which is likely.

The need for sufficient cardiac reserve is made apparent by the fact that in the critically injured patient, a high normal or moderately increased cardiac output and oxygen consumption portends a much better prognosis with significantly reduced mortality compared with those in whom little increase is noted (5).

RESPIRATORY FUNCTION

Respiratory status is evaluated by history and determination of exercise tolerance. A smoking history of more than 20 pack-years is particularly significant. If the respiratory status is at all questionable, simple spirometry is an excellent screen. If the forced expiratory volume in 1 second (FEV_1) is under 15 mL/kg and the vital capacity is less than 1.5 L or the maximum voluntary ventilation is under 50%, further pulmonary function tests and additional preoperative preparation are in order.

METABOLIC STATUS

The metabolic status of the patient is assessed with regard to the hepatic, renal, and immune function, as well as the nutritional and adrenal status. If indicated by history, hepatic function is determined by evaluation of liver enzymes, PT, and albumin. In patients with compromised hepatic function, preoperative preparation includes improving the nutritional status (see Nutrition) and, in those with an impaired clotting mechanism, the administration of fresh-frozen plasma and vitamin K. Cirrhotic patients with ascites are prepared preoperatively by improving nutritional status, limiting sodium intake to 1 to 2 g per day, and reducing ascitic fluid by

judicious use of spironolactone with or without other diuretics. Renal dysfunction is addressed in another chapter; however, renal function abnormalities generally do not significantly impair the operation, provided fluid and electrolyte balance is corrected. It still has a significant impact on postoperative survival in the critically ill though (5).

The patient's immune status, if in question, may be examined by determining whether the patient is allergic to cutaneous skin tests. Unfortunately, little can be done to alter the immune status unless it is caused by nutritional deficiency. A nutritional assessment also should be performed (see Nutrition). Medications of particular significance include antihypertensives and steroids. Adrenal insufficiency resulting from intrinsic disease or suppression secondary to exogenous steroid administration demands administration of preoperative, intraoperative, and postoperative steroids. The dose should be approximately ten times the resting nonstressed level and administered in three equally divided doses. Because the normal basal production of cortisol is about 35 mg per day, a replacement of an equivalent of approximately 300 mg of cortisone is indicated. Cortisol equivalent (100 mg) is administered several hours before the operation, 100 mg intraoperatively and 100 mg 8 hours postoperatively. The dosage is gradually tapered to maintenance levels over several days, or if the adrenal glands function normally, it may be discontinued altogether. If postoperative complications occur, however, the ten-times basal level dosage should be continued until the complications have resolved. All patients who have taken steroids preoperatively do not of necessity require preoperative, high-dose steroid replacement. In one study, patients who received less than 5 mg of prednisolone per day had a normal pituitary-adrenal axis. If the adrenal gland's ability to respond to stress is at all questionable, an adrenocorticotropic hormone (ACTH) stimulation test may be performed.

SYSTEMIC DISEASE

The evaluation of systemic disease generally involves a determination of the carbohydrate (diabetes) and thyroid status. In diabetic patients, it is important to avoid hypoglycemic ketosis or hyperosmolarity. This is best accomplished if the blood glucose level is maintained between 125 and 250 mg/dL. If the patient is taking insulin, half the usual dose is given on the morning of surgery and an IV dextrose-containing solution is begun. During the operative procedure, blood glucose levels are determined and regular insulin administered as necessary. In the postoperative period, blood glucose levels must be determined every 4 hours and regular insulin administered IV or subcutaneously for diabetic patients with major alterations in glucose metabolism. For patients who are particularly labile, an insulin infusion pump may be used in the postoperative period. Continuous monitoring of blood glucose levels must be performed throughout the period of administration, particularly when metabolic aberrations, sepsis, and trauma coexist, because these can significantly alter glucose utilization and cause wide fluctuations in serum levels.

METABOLIC RESPONSE TO INJURY

Basal Metabolic Rate

Uninjured humans at rest expend a definable amount of energy to perform physiologic work—the work required to maintain cardiac output, endocrine function, body temperature, hepatic function, respiration, renal function, and so on. The amount of energy required to maintain these functions at rest is called *basal metabolic rate* and is expressed in calories per hour per square meter of body surface. Basal metabolism is the energy expended by the cells that constitute the active mass of the body; fat, extracellular fluid, and bone make no direct contribution to the metabolic rate. The energy used in physiologic work is derived from chemical energy, which in the course of the performance of the work is converted to heat and lost from the body. Therefore the basal metabolic rate, or energy expenditure, may be determined by direct calorimetry in which the heat lost from the body is directly measured. Direct calorimetry is difficult to perform and often impractical in the critically ill. Thus indirect methods of estimating the basal metabolic rate are more commonly used. The heat lost may be indirectly estimated from (a) oxygen consumption, carbon dioxide (CO_2) production, and nitrogen excretion; (b) measurement of energy intake and losses, coupled with the measurement of changes in body composition; or (c) measurement of insensible water loss, assuming that this represents 25% of the total heat loss. The basal metabolic energy requirement depends on patient age, sex, and lean body mass. A 1-month-old infant requires about 40 kcal/kg body weight per day. The requirement increases with age and body mass, so boys between the ages of 15 and 18 years consume 1,700 kcal per day and girls between the ages of 12 and 18 years require 1,400 kcal per day. The energy requirement remains relatively stable during the active years of life. With progressive aging, however, it decreases to 1,300 kcal per day for men and 1,100 kcal per day for women (74). The difference in metabolic rate between men and women probably relates to the fact that women have a larger proportion of fat per unit body weight. Indeed, if basal metabolic rate is expressed per unit fat-free body weight, it is remarkably similar for both males and females over an age span of 20 to 60 years (1.3 kcal/kg per hour).

Hypermetabolism

The response to injury is characterized by an increase in the basal metabolic rate, even though the patient remains at rest. The intensity of this hypermetabolic response depends on the severity of the injury, the patient's nutritional status, and the presence or absence of infection. Patients in good nutritional balance undergoing an elective operation will have a change in metabolic rate of no more than 10% in the postoperative period, provided there are no complications. In contrast, patients with multiple fractures have an increase of their resting energy expenditure by 10% to 25%, those with major infections by 20% to 50%, and those with major thermal burns by 50% to 125%. In the early posttraumatic period, satisfaction of these energy demands results in degradation of body protein (manifested by a negative nitrogen balance), depletion of energy reserves, and loss of body weight. The initial catabolic response in which body protein, fat, and carbohydrate are depleted is gradually reduced and reversed later in the recovery period. An anabolic phase ensues, provided adequate nutritional intake occurs, in which new protein is laid down and carbohydrate and fat reserves are repleted. The hypermetabolic response also gradually diminishes as the wounds heal and as infection is eradicated.

In the early postinjury period, energy requirements are satisfied by glucose, derived mainly from liver and muscle glycogen and by fatty acids released from adipose tissue. Glycogen reserves are rapidly depleted (usually within 48 hours). Fat stores, however, which supply the bulk of the energy requirement during this period, continue to supply fatty acids for many days. Protein catabolism also occurs, even though it may not serve as a primary energy source. Amino acids are released primarily from skeletal muscle at rates three to four times normal and are essential for maintenance of cellular metabolism. Moreover, the gluconeogenic amino acids serve as a source of new glucose and provide the basic glucose structure that is necessary for normal metabolism. Alanine is the most important gluconeogenic amino acid, and its principal site of uptake is the liver. It is part of the glucose-alanine cycle in which its deamination in the liver results in new glucose formation. When glucose undergoes anaerobic glycolysis in muscle, the resultant pyruvate is transaminated, producing alanine and completing the cycle. Rapid depletion of glucose stores coupled with the inability of the two carbon fragments of the fatty acids to serve as a source for gluconeogenesis make protein the only available substrate from which new glucose can be synthesized. Protein catabolism can be reduced but not eliminated by providing exogenous glucose (nitrogen-sparing effect of glucose). Also, certain amino acids can be used as energy sources thus sparing glucose. For example, glutamine from muscle is taken up by the intestine where it is used as respiratory fuel (94).

Catecholamines and Glucocorticoids

Posttraumatic catecholamine levels are elevated and promote hepatic glycogenolysis, inhibition of insulin release, stimulation of glucagon production, and stimulation of fat hydrolysis with the release of free fatty acids. This hormone is produced almost exclusively by the adrenal medulla and has been implicated as the mediator of the hypermetabolic response in injured patients (94).

Glucocorticoid levels are also characteristically elevated and remain so throughout the recovery period. The increased production is the direct result of an increased ACTH secretion by the anterior pituitary. It is presumed that the pituitary is stimulated to release ACTH by the action of the nerves from the periphery responding to the traumatic injury and perhaps by a direct effect of the elevated epinephrine levels. Patients who have sustained severe trauma that requires a prolonged period of convalescence, such as thermal burns, often have marked adrenal hyperplasia. Glucocorticoids promote gluconeogenesis and inhibit the action of insulin.

Insulin

Immediately after injury, circulating levels of insulin and glucose are elevated. Insulin facilitates glucose transport across cell membranes and inhibits both the release of amino acids from muscle and the release of free fatty acids from adipose tissue. In the posttraumatic period, hyperglycemia is common, possibly as a result of the development of insulin resistance. Glucose tolerance curves performed during this period simulate those observed in diabetes and have led many to refer to this state as the *diabetes of injury* (49).

However, the mechanism of the hyperglycemia may not be one of insulin resistance. More recent evidence indicates that glucose oxidation is unimpaired and that the hyperglycemia is caused by an increase in gluconeogenesis rather than a reduction in peripheral utilization. Moreover, glucose flow studies have clearly demonstrated that glucose turnover rate is increased above normal (59,95). Others suggest that the amount of circulating insulin is inadequate for the concentration of

glucose.

Glucagon

The increased production of catecholamines after injury is known to stimulate the a-cell of the pancreatic islets, resulting in increased circulating levels of glucagon, a hormone that promotes glycogenolysis and gluconeogenesis. The relation between the concentration of insulin and glucagon (the insulin-to-glucagon molar ratio) determines whether the major influence is toward glucose breakdown or glucose formation. Early after injury, although the level of insulin is elevated, glucagon is disproportionately increased, and the ratio of the two favors gluconeogenesis at the expense of protein formation. As healing occurs, the molar ratio reverses, favoring glycolysis and protein formation. After injury, the hypermetabolic response and hormonal balance direct the metabolism and utilization of carbohydrate, fat, and protein. They set the stage for a negative nitrogen balance and weight loss, both of which are related to the extent of injury. The protein that is catabolized to satisfy energy and substrate requirements is derived mainly from skeletal muscle. Alanine and glutamine released from the muscle are transported to the liver, where they are converted to glucose (gluconeogenesis). With protein breakdown, urinary excretion of nitrogen (predominantly as urea), potassium, phosphate, creatinine, magnesium, zinc, and sulfate are greatly increased, reflecting catabolism of protoplasmic mass.

NUTRITION

The metabolic response to the trauma of operation or injury is characterized by hypermetabolism, which if left unchecked, results in increased tissue breakdown, loss of lean body mass, and depletion of essential intracellular constituents. The prevalence of malnutrition in hospitalized patients has been said to range between 30% and 50%. Protein-calorie malnutrition is characterized by (a) weight loss, (b) hypoalbuminemia, (c) decreased skeletal muscle mass, (d) reduced fat stores, and (e) decreased total lymphocytes (92).

Malnutrition has increased the incidence of clean-wound infections, prolonged postoperative ileus, impaired wound healing, depressed immunocompetence, increased the patient's susceptibility to sepsis, inhibited vital organ function, and increased the risk of respiratory infections and respiratory insufficiency (56,64,89). Moreover, severe malnutrition results in loss or malfunction of various intestinal enzymes. Lactase seems to be particularly sensitive to variations in nutritional status. Thus a patient who develops a lactase deficiency because of malnutrition will be incapable of absorbing supplements that contain milk or milk by-products. This greatly limits the type of supplements that can be administered orally.

If malnutrition is allowed to persist, morbidity and mortality significantly increase. Loss of body protein appears to be the critical factor determining the point at which the nutritional depletion compromises the ability of the host to respond appropriately to the injury. Mortality and morbidity associated with weight loss and starvation are directly related to the loss of essential protein stores: Death occurs with the loss of 25% of body nitrogen or 33% total body weight (68). Therefore it is essential to limit and ultimately reverse the loss of body protein to promote early recovery and reduce the incidence of life-threatening complications.

Nutritional Requirements

The daily caloric requirement for resting humans is approximately 25 kcal/kg body weight. Hypometabolic, starved humans may require somewhat less, but it is generally at the expense of limited organ function. Most surgical patients are hypermetabolic and require an additional 5 to 60 kcal/kg body weight. *Thus, when the total caloric requirement in the average surgical patient are calculated, 30 to 35 kcal/kg body weight is used.* Daily protein intake requirements are normally about 0.8 g/kg body weight per day, but under conditions of acute stress, they may be as high as 2.5 to 3.5 g/kg body weight per day. Although protein provides only 4 kcal/g, it is the number of grams of protein that is important, with satisfaction of caloric requirements being provided by the addition of carbohydrate or fat. For each gram of protein administered, 25 kcal (carbohydrate or fat) should be provided. Protein consists of amino acids that are either essential or nonessential. The former cannot be manufactured by the body, whereas the latter can.

In selected circumstances, it may be important to limit the total intake of protein or to alter the protein composition of the infusion. In patients with renal and hepatic failure, excessive amounts of protein may result in an excessively elevated blood urea nitrogen (BUN) and/or serum ammonia level with systemic manifestations of uremia in the former or hepatic encephalopathy in the latter. In these cases, 0.5 to 1.0 g protein/kg body weight may be appropriate.

Alteration of the composition of the protein infusion also may be helpful. Essential amino acid infusions without their nonessential counterparts may lessen the rise in serum urea in patients with acute renal failure, and branched-chain amino acids, which are metabolized by muscle and do not require the liver for metabolism, may be more appropriate in patients with hepatic disease. Certain amino acids also have been added to nutritional regimens because they appear to play a more central role during injury than their counterparts. Glutamine serves as a vehicle for nitrogen transfer between tissues; it is also the most important substrate for renal ammoniagenesis, a regulator of protein synthesis, and an essential precursor in nucleic acid biosynthesis (76,93). Glutamine-supplemented nutritional regimens improve nitrogen balance (88). Glutamine may be administered in its more stable form as the dipeptide alanyl-glutamine or glycyl-glutamine. Arginine has potent secretagogue activity, and its administration may have trophic effects in the immune system and, when given, has been shown to improve weight gain and wound healing (4).

Fats have a high caloric value and provide 9 kcal/g. They also are classified as either nonessential or essential, depending on whether the body can manufacture them. Fats that cannot be manufactured by the body include linoleic, arachidonic, and linolenic. Only linolenic is absolutely essential because a fatty acid deficiency will not develop if it alone is provided. Vitamins must be provided daily, particularly the water-soluble vitamins, because they are depleted rapidly. Sodium, potassium, calcium, magnesium, and phosphate also must be provided in sufficient quantities on a daily basis. Trace elements, such as zinc, copper, iodine, manganese, and selenium, must be provided regularly over long-term periods.

A stable weight is often a good indication that basal needs are being met, provided that loss of lean body mass is not hidden by an increase in extracellular water. If the patient is incorporating exogenous protein into endogenous stores, he or she is said to be in a positive nitrogen balance. Nitrogen balance may be grossly calculated by assuming that 1 g per day of nitrogen is lost in the feces, if the patient is stooling, and about a quarter of a gram of nitrogen is lost through the skin. The remaining nitrogen loss occurs in the urine. Approximately 80% of the nitrogen lost in the urine is lost as urea nitrogen. Therefore it becomes apparent that the nitrogen balance of any patient may be calculated quickly by measuring the 24-hour urine and its urea content. The amount of urea nitrogen excreted is multiplied by 1.25 to give the total nitrogen excreted in the urine. If an additional 1 to 2 g is added for skin and stool loss and this quantity is subtracted from the protein nitrogen intake, a positive or negative number is obtained. These urine collections are appropriate for patients in whom bowel is not interposed in the urinary tract. Patients with bowel interpositions alter urea excretion so that this measurement cannot be performed accurately. If the nitrogen balance is positive, the patient is lying down or retaining protein (anabolism); if negative, body protein is being broken down for energy requirements (catabolism).

Nutritional Status

Several modalities have been used to determine whether the patient is malnourished and, if so, to quantitate the degree of nutritional deprivation. Among the indices most often used are weight loss, reactivity to skin-test antigens, creatinine excretion index, middle-arm circumference measurement, tricep skinfold thickness, the measurement of lymphocyte count, serum albumin, serum transferrin, retinal-binding protein, and thyroxine-binding prealbumin. A history of a recent weight loss is particularly important in determining current nutritional status. It must be remembered, however, that this may underestimate loss of lean body mass, because when body protein is metabolized, there is an obligate increase in extracellular fluid. Therefore the weight loss may not accurately reflect the loss of lean body mass. A patient who has lost fewer than 10 pounds in the preceding 3 months is said to be mildly malnourished; between 10 and 20 pounds moderately malnourished; and more than 20 pounds, severely malnourished. A patient's current weight can be compared with height/weight tables and a percentage deviation from normal obtained.

Reactivity to skin-test antigens has been used frequently to determine a patient's immune status. Indirectly, the response to these antigens reflects the patient's nutritional status. If a patient is known to be allergic to one of the antigens and is anergic when tested or if anergic to agents that normally cause a response, severe malnutrition is present. Antigens commonly used are dermatophytin, mumps, purified protein derivative (PPD), streptokinase, and streptodornase. The importance of this index is illustrated by the fact that in several series, cancer patients did not respond effectively to chemotherapy or surgery if their skin-test antigens were negative. However, if the patients were nutritionally repleted, approximately half converted to a positive status and then responded to either chemotherapy or surgery (18,22). More recent data have called into question the reliability of skin-test antigens in critically ill patients. The creatinine excretion index measures the lean body mass or muscle protein stores as does a measurement of middle-arm circumference. Triceps skinfold measurements indicate the status of fat stores. Lymphocyte count is a measure of visceral protein status and should normally be above 2,000 cells/mm^3. If the lymphocyte count is between 1,200 and 2,000 cells/mm^3, the patient is said to be mildly nutritionally depleted; between 800 and 1,200 cells/mm^3, moderately nutritionally depleted; lower than 800 cells/mm^3, severely nutritionally

depleted.

Albumin levels are another measure of visceral protein status. Serum albumin has been demonstrated to accurately reflect the patient's nutritional status. In one series, the only parameter that correlated with an increased hospital stay in nutritionally depleted patients was their albumin status (2). Others have found it to be an accurate predictor of the success of a nutritional regimen and an indicator of the degree of nutritional repletion (12). There is a 20% increase in wound infections if the serum albumin concentration is less than 2.9 g/dL (78). If the albumin level is between 3 and 3.5 g/dL, the patient is said to be mildly nutritionally depleted; between 2.5 and 3.0 g/dL, moderately nutritionally depleted; less than 2.5 g/dL, severely nutritionally depleted.

Serum transferrin levels also have been used as an indicator of visceral protein status. Transferrin determinations may not be readily available but can be calculated if one obtains a total iron-binding capacity (TIBC). The formula for calculation is as follows:

$$\text{Serum transferrin} = (0.8 \times \text{TIBC}) - 43$$

If the level is between 150 and 200 mg/dL, the patient is mildly nutritionally depleted; between 100 and 150 mg/dL, moderately nutritionally depleted; less than 100 mg/dL, severely nutritionally depleted. Retinal-binding protein and thyroxine-binding prealbumin are also measures of visceral protein status and are helpful in select cases.

In practice, it is often difficult for the busy clinician to seek out the various tables required for a complete nutritional assessment. *Three modalities are conveniently used to assess the patient's status: weight loss, lymphocyte count, and albumin level.* With these indices, the patient can be placed into one of four categories: normal nutritional status or mildly, moderately, or severely nutritionally depleted. If one is still unsure, skin-test antigens may be used. If the patient is anergic to a battery of skin-test antigens, he or she is considered severely malnourished irrespective of the previously mentioned indices (Table 10.1).

Measurement	Mild	Moderate	Severe
Weight loss (lb)	<10	10–20	>20
Lymphocyte count (cells/mm^3)	1,200–2,000	800–1,200	<800
Albumin (g/dL)	3.0–3.5	2.5–3.0	<2.5
Serum transferrin (mg/dL)	150–200	100–150	<100
Skin-test antigens	+	+	Anergy

TABLE 10.1. NUTRITIONAL ASSESSMENT: THE CATEGORIZATION OF PATIENTS INTO MILD, MODERATE, OR SEVERELY NUTRITIONALLY DEPLETED

The amount of calories required per day for repletion also must be calculated so that appropriate amounts may be administered. The patient's weight times 25 gives the basal metabolic requirement of the patient. Depending on the severity of the insult, an additional 5 to 60 kcal/kg is added. In children, the amount of kilocalories metabolized varies according to weight. For the first 10 kg, 100 kcal/kg is metabolized; for the second 10 kg, 50 kcal per kg; and for each kilogram over 20, 20 kcal/kg (Table 10.2). The success of the regimen is determined by the return of the serum values to normal; the return of an allergic response to the skin-test antigens, if previously anergic; and weight gain. Moreover, periodic, crude measurements of nitrogen balance as previously described, if positive, will confirm that the amount and composition of the calorie load are appropriate. Having determined how much the patient requires, one must determine the route of administration: enteral, IV, or a combination.

	Body Weight (kcal/kg)
Children	
First 10 kg (0–10)	100
Second 10 kg (10–20)	50
Each additional kg >20	20
Adults	25

TABLE 10.2. BASIC CALORIC REQUIREMENTS OF UNINJURED HUMANS AT REST

Enteral Feedings

Enteral feedings are preferred if possible because complications are decreased and a more balanced, physiologic diet can be provided. Enteral diets are either nonelemental or elemental. Nonelemental enteral feedings consist of undigested and minimally digested protein hydrolysates, fat, and carbohydrates, whereas elemental diets consist of medium-chain triglycerides, glucose, and amino acids. *Enteral feedings can be provided either by a small feeding tube, a gastrostomy, or a feeding jejunostomy. Generally, nonelemental enteral feedings are preferred, provided the gut is not diseased, because they have lower osmolality and are cheaper.* The advantages of an elemental diet include its bulk-free and lactose-free composition (30). Therefore patients with severely diseased bowels or patients who have been chronically starved are probably better served with an elemental diet—at least at the outset.

One should begin with the enteral feeding diluted to half strength at a rate of 50 to 75 mL per hour in the adult. If this is tolerated, the volume is increased to 2,500 to 3,000 mL per 24 hours, and if tolerated, osmolality is increased to full osmotic content (i.e., approximately 1 kcal/mL will be administered at 500 to 1,000 mOsm/kg). Complications include abdominal cramps, diarrhea, and diaphoresis. If any of these symptoms occur, the infusion is slowed, the osmolality is reduced, or both. Once the symptoms disappear, a gradual return to the strength and rate desired is begun. If diarrhea continues to be poorly controlled, the administration of paregoric 5 mL in divided doses may be helpful.

Isosmotic Intravenous Nutrition

Carbohydrate, protein, and fat substrates may be infused individually or in combination in near-isosmotic concentrations. Because of their isosmotic character, not only may they be administered by peripheral vein but also the rate of administration may be rapidly changed to satisfy a change in fluid requirements or even stopped so that medications, colloid, and blood may be administered. These properties make such solutions advantageous during periods of critical care when instability of the patient is not uncommon.

An understanding of the metabolic effects of each type of caloric source with respect to energy provision and its potential for endogenous protein preservation and maintenance of optimum organ function is essential if the proper substrate or combination of substrates is to be administered to acutely ill patients. The provision of glucose in dosages up to 100 g per day decreases protein loss as measured by the loss of urinary nitrogen. This protein-sparing effect is directly proportional to the quantity of calories administered. Infusion of larger quantities of glucose results in disproportionately lesser reductions in nitrogen losses. Supplying 700 protein-free calories to fasting normal humans results in maximum reduction of protein losses. Increasing the nonprotein caloric intake is without further effect in the sparing of

body protein. Indeed, positive nitrogen balance cannot be achieved even with high-dose glucose infusions. Starved, unstressed humans given approximately 700 g of glucose maintain a negative nitrogen balance of about 1.5 g/m ^{2} per day. If the same total caloric load is given, however, but part of the glucose calories are replaced by an equivalent amount of amino acid calories, the negative balance is eliminated (96). Supplying dietary protein with calories further improves nitrogen balance. Thus, on a fixed adequate protein intake, energy level is the deciding factor in nitrogen balance, and at a fixed adequate caloric intake, nitrogen intake is the determinant of nitrogen balance (9). Similarly, in critically ill, traumatized patients and in those with superimposed bacteremia, at low-dose levels (or those that can be easily achieved employing isosmotic solutions), glucose has the same effect on nitrogen sparing as does an equivalent caloric load of amino acids (63). Thus, at low-dose levels, total caloric load, whether derived from protein or carbohydrate, determines the degree of nitrogen sparing, whereas when the caloric load is increased, amino acid intake becomes a more dominant determinant of nitrogen balance.

Fat emulsions also may be administered by peripheral vein and have the advantage of providing high caloric loads in relatively small volumes because fat provides 9 kcal/g, whereas glucose and protein provide a little less than 4 kcal/g. The effect of fat emulsion on nitrogen sparing, however, is not equivalent to equal caloric amounts of glucose or amino acids. In normal unstressed humans, equivalent caloric amounts of infused fat emulsion and glucose result in a lesser degree of nitrogen sparing for the former. When amino acids are added to equivalent caloric amounts of fat emulsion or glucose, the latter combination results in a less negative nitrogen balance. In severely injured humans some investigators failed to observe any reduction in nitrogen sparing with the infusion of large doses of soybean fat emulsions. Conversely, more recent studies have demonstrated adequate utilization of fat calories in the immediate posttraumatic and postoperative period. In view of the degree of nitrogen sparing observed in normal and injured humans, when used in combination with amino acids, fat emulsions seem helpful in sparing nitrogen, but glucose and amino acids are more effective than fat, calorie for calorie.

Although there are no distinct differences in nitrogen balance in comparing low-dose isosmotic administration of glucose and amino acids, there are clear advantages to infusing a medium-dose combination of the two substrates. First, their effect is augmentative, and the impact on calories is not limited when protein is provided. Second, amino acids administered alone cause a constant rise in BUN that is not observed when glucose is added. Third, altered hepatic and renal transport occur in critically ill patients who are given amino acids as their sole caloric source. The altered transport properties may be restored to normal by the addition of glucose. An appropriate combination that provides maximum nitrogen sparing per gram of nutrient administered while maintaining optimal hepatic, renal, and cardiac function consists of a liter solution in which half is provided as 10% dextrose and the other half as a 7% to 8% amino acid solution. Fat emulsions given in 500-mL amounts once or twice a day provide additional calories. Because these solutions may be administered by peripheral vein and because alterations in infusion rate and even abrupt cessation of infusion can be accomplished without untoward effects so that blood, antibiotics, and other medications can be given, these infusates are an ideal means of preserving normal metabolic function of vital organs while limiting nitrogen loss in early posttraumatic, postoperative, and unstable critically ill patients. Unfortunately, it is generally not possible to achieve positive nitrogen balance with isosmotic solutions because the amount of calories required would necessitate excessive fluid administration. If illness is protracted and oral alimentation is not possible, positive nitrogen balance is achieved by administration of hyperosmotic solutions (hyperalimentation).

Hyperosmotic Intravenous Nutrition

Hyperosmotic IV solutions, which are capable of providing enough nitrogen and calories in an acceptable volume, are made up of equivalent amounts of a 50% dextrose and 7% to 8% amino acid solution, providing approximately 1 kcal/mL of solution. Electrolytes including potassium, sodium, calcium, magnesium, and phosphate are added as required (Table 10.3). Trace elements (zinc, copper, manganese, chromium) and multivitamins also are added as required. In addition, essential fatty acids are provided by the administration of 500 mL of fat emulsion two to three times a week.

Ingredient	Concentration
Amino acid (7%–8%)	500 mL
Dextrose (50%)	500 mL
Potassium (KCl)	60–150 mEq
Sodium (NaCl)	60–180 mEq
Calcium (Ca gluconate)	5–15 mEq
Magnesium ($MgSO_4$)	8–24 mEq
Phosphate (K_2HPO_4)	15–20 mmol
Trace elements	—
Multiple vitamins	—

TABLE 10.3. COMPOSITION OF HYPERALIMENTATION SOLUTIONS

Because the hyperalimentation solution is hyperosmotic, it must be administered through a central venous line and its rate of administration rigidly controlled. If long-term or home hyperalimentation is to be administered, the solution should be given through a long-term indwelling catheter, such as a Broviac or Hickman catheter. The catheters are placed in the superior vena cava, tunneled subcutaneously under the skin beneath the anterior chest wall, and brought out at about the level of the nipple—between it and the sternum. We have kept catheters functional as long as 21 months in adults and 14 months in children. In most cases, hyperalimentation will be administered for limited periods, and a percutaneous central line is placed. The central venous line must be placed and maintained with an assiduously sterile technique; otherwise, infection will invariably follow. The IV line is placed in the superior vena cava, either by a subclavian or internal jugular puncture. A sterile dressing is applied with an antibiotic ointment placed over the catheter entrance site. On alternate days, the dressing is changed and a new sterile dressing, iodophor preparation, and iodophor ointment are applied. A millipore filter is placed in line. The filter is changed and cultured every 24 hours. The IV tubing is changed with each bottle. The hyperalimentation solutions are made fresh daily and stored refrigerated. No medications, blood, or other fluid should be administered through the hyperalimentation line, nor should CVP measurements be made using the catheter through which the hyperalimentation solution is being administered. Fluid should be administered initially at low rates (50 mL per hour) until tolerance has been achieved (blood glucose remains below 200 mg/dL), after which the rate of infusion may be gradually increased until the proper caloric load is achieved. Usually, 3 to 4 L per day is given, providing 3,000 to 4,000 kcal per 24 hours. Blood must be monitored for glucose concentration periodically, when high, either the infusion rate must be reduced or insulin administered.

Blood glucose levels may be particularly difficult to control in the immediate postoperative and posttraumatic period. Insulin given IV every 4 hours, adjusting it to blood glucose levels, usually suffices. Occasionally, blood glucose levels can be better controlled with a continuous insulin infusion. Two to three units of regular insulin are administered per hour in a concentration of 1 U/mL of saline solution. If these simple measures do not control the glucose level or large amounts of insulin are required, the solution should be tapered or fat should be substituted for the glucose. It is apparent that high-dose insulin can lower serum glucose, but it is probable that under these conditions abnormal metabolism at the mitochondrial level occurs, obviating any beneficial effect of lowering the serum glucose.

Similarly, after IV fat administration, the serum must be observed for clearance. Normally, immediately after the infusion of IV lipid, the serum is lipemic. It should be totally clear approximately 8 hours after infusion. This may be checked by obtaining serum cholesterol and triglyceride levels, or grossly, at the bedside by drawing a blood sample, spinning it down, and observing the serum for lipemia. Plasma osmolality and sodium, potassium, chloride, CO_2, BUN, creatinine, calcium, phosphate, and glucose also should be monitored on a frequent periodic basis—initially daily. Magnesium levels should be monitored regularly, but somewhat less frequently.

When discontinuing the infusion, the clinician should gradually taper the rate over 24 to 36 hours. A prolonged infusion should never be stopped abruptly because severe hypoglycemia may ensue. On the other hand, many patients with home hyperalimentation tolerate abrupt cessation of the infusion well. These patients generally infuse their hyperalimentation solution over a 12-hour period while sleeping and immediately cease infusion when ambulatory. Critically ill and hospitalized patients are generally better served by tapering rather than abrupt cessation. Complications are not uncommon with hyperalimentation and can be life-threatening. Placement of the central venous catheter has resulted in pneumothorax, hemothorax, hydrothorax, brachial plexus injury, venous thrombosis, and embolism. Because of the nature of the solution infused and the central venous location of the catheter, infectious complications have been reported and must be recognized and immediately corrected. Alterations in glucose metabolism may result in hyperglycemia, glucosuria with an osmotic diuresis, and in severe cases, hyperosmolar nonketotic dehydration and coma. The mortality in the last situation can be as high as 50%.

Early recognition of hyperglycemia and its treatment by reducing the rate of infusion and/or administration of insulin correct these complications. A sudden change in glucose concentration in a patient who is receiving hyperalimentation should suggest sepsis. Patients with nonketotic hyperosmolar coma characteristically have

blood glucose levels in excess of 500 mg/dL and must be treated aggressively, often with large doses of insulin and fluid. Ketoacids in diabetic patients given inadequate insulin for the additional carbohydrate load and postinfusion hypoglycemia resulting from rapid withdrawal of glucose in the face of persistently elevated endogenous insulin levels also may occur and are treated by increasing insulin and glucose infusions, respectively. Rarely, the complete metabolism of glucose for energy needs results in an elevated partial pressure of CO_2 (Pco_2) and CO_2 narcosis with respiratory insufficiency. Blood gas determinations confirm the diagnosis. Treatment is directed at reducing the amount of CO_2 produced for energy requirements by providing a greater share of the caloric load as fat. Alterations in amino acid metabolism may result in hyperchloremic metabolic acidosis, plasma and amino acid imbalances, hyperammonemia, and elevated BUN levels (26). Alterations in the content of the infusion or rate of infusion must be made. Hypophosphatemia and hypercalcemia and hypocalcemia are corrected by addition or removal from the infusate of the appropriate inorganic ion. Vitamin deficiencies; essential fatty acid deficiencies; trace mineral deficiencies; and abnormal plasma potassium, sodium, and magnesium levels have been reported and are corrected by appropriate addition or removal of the particular substance. Trace minerals and essential fatty acid deficiencies are not encountered when fresh-frozen plasma and fat emulsions are administered as previously described. Finally, alterations in liver enzymes, cholestatic jaundice, and fatty infiltration of the liver complicate long-term administration. Indeed, the administration of more calories than required results in lipogenesis and fatty infiltration of the liver. This may be eliminated in patients receiving long-term hyperalimentation by administering it in a cyclic manner. Glucose is periodically withheld, and only amino acids and fats are infused for an 8-hour period. This has reduced and, in fact, cleared fatty livers.

Once the amount of calories for maintenance of basal needs and restitution of adequate nutrition is determined, the route may be chosen. If the amount of calculated calories can be administered by oral or tube feedings, this is preferred. It appears that patients require fewer calories to maintain body functions and normal weight status if they are given orally rather than IV. If the gut cannot be used and the total caloric requirements must be replaced, IV hyperosmolar solutions must be used. If the gut is temporarily unavailable and will be functional soon, isosmotic IV solutions may be used to limit catabolism until the gut is functional.

Perioperative Total Parenteral Nutrition

The benefits of perioperative nutrition have been difficult to assess in properly controlled studies. It has been shown conclusively to be of benefit only in severely malnourished patients. For all others, it seems to add risk rather than benefit. Indeed, overfeeding can be detrimental because it increases septic complications and compromises immune and hepatic function. In the severely malnourished patient who cannot take oral alimentation, total parenteral nutrition should be administered 7 to 10 days preoperatively. This reduces complications by 10%. The enteral route is preferred, if possible, because it reduces septic complications and maintains structure and functional integrity of the gastrointestinal tract (92).

Intravenous Nutrition for Specific Organ Malfunction

Surgical patients who have sustained acute renal failure have been successfully managed by providing them with hyperalimentation solutions. Providing adequate amounts of calories in these patients can be difficult because fluid administration may be limited. This can be obviated by either frequent dialyses or continuous plasma filtration. Unfortunately, dialysis and plasma filtration result in 6 to 10 g of amino acids lost per day. This amount must be added to the usual requirement to attain optimum balance. Mortality in surgical patients with acute renal failure is exceedingly high. According to some reports, mortality may be reduced significantly by the provision of adequate calories and essential amino acids (1). Hyperalimentation in patients with acute renal failure unfortunately does not reduce the frequency of dialyses, although it may have some effect on lessening the duration of renal failure. Essential amino acids have been found to be more efficacious than a combination of essential and nonessential regimens by some groups. It appears that those given essential amino acids have a less rapid rise in BUN and reduced mortality compared with a similar group given essential and nonessential amino acids in the hyperalimentation solution (36).

Patients who have hepatic failure or hepatic encephalopathy are often nutritionally depleted. Straight-chain amino acids are metabolized by the liver, whereas branched-chain amino acids are metabolized by muscle. Amino acid profiles examined in patients with hepatic failure reveal that the concentrations of straight-chain amino acids are elevated, whereas the branched-chain amino acids are diminished. The assumption is that of the two major sites of amino acid metabolism, liver and muscle, the liver is incapable of metabolizing amino acids. Moreover, it has been proposed that if the amino acids the liver metabolizes are withheld while those metabolized by muscle are given, the nutritional status of the patient might be improved. In one series, patients with cirrhosis given branched-chain amino acids had an 87% improvement in their condition, and 75% of those with hepatitis were improved after the administration of branched-chain amino acids (37). Patients with significant hepatic disease probably should have a limited protein intake, ranging between 0.5 and 1 g/kg body weight. Simultaneous administration of oral neomycin and lactulose, by reducing gut flora and ammonia metabolism, may enhance protein tolerance.

More directed use of nutrients are currently being studied. L-Arginine and L-glutamine stimulate host defenses and increased wound healing. Glutamine may preserve the intestinal barrier in stressed patients and essential fatty acids and polyribonucleotides may enhance immune function in cancer patients. Thus in the future, it may be possible to assess a patient's specific needs and provide a selected nutrient regimen to meet these needs (78).

FLUIDS AND ELECTROLYTES

Body Fluid Compartments

The treatment of many fluid and electrolyte disorders requires a knowledge of the body fluid compartments and the ability to calculate them in a given individual. Specific therapy of postobstructive diuresis, dehydration, hypovolemia, and water intoxication requires that knowledge for appropriate therapy. *Total body water constitutes approximately 60% of the body weight in males and 50% in females.* For a lean person, 10% is added; for an obese person, 10% is subtracted because muscle cells contain the greatest fraction of water. *The total body water is divided into compartments: extracellular, intracellular, and transcellular* (Table 10.4). *The extracellular fluid compartment composes approximately 20% of the body weight and is divided into plasma (4.5%), interstitial fluid (16%), and lymph (2%). Because the blood volume is made up of solids and plasma, it can be calculated by multiplying the body weight by 7%.* Intracellular fluid composes 30% to 40% of the total body weight and is accessible only by freely diffusible molecules. Transcellular fluid constitutes 1% to 3% of the total body weight and is composed of pleural, peritoneal, cerebrospinal, intraocular, salivary, and digestive secretions. It is in equilibrium with the extracellular fluid and in disease conditions may increase in amount, particularly during trauma. This is the so-called third space, fluid that is unavailable to the intravascular compartment in situations of injury.

Compartment	%
Total body water	50–60
? Extracellular fluid	20–22
?? Blood plasma	4.5
?? Interstitial fluid	16
?? Lymph	2
? Intracellular fluid	30–40
? Transcellular fluid	1–3

TABLE 10.4. BODY FLUID COMPARTMENTS

The osmolality of the plasma is an indication of the endogenous substances contained in that compartment and is helpful clinically in situations of dehydration and hypervolemia. The osmolality is generally measured by freezing-point depression but can be calculated conveniently by doubling the sum of the sodium and potassium concentrations and adding to that quantity the blood glucose level divided by 20 plus the blood urea level divided by three. These latter two substances are osmotically active and may contribute significantly to the total osmotic content.

The amount of fluid necessary to maintain homeostasis is equivalent to the urine output plus insensible loss plus abnormal losses minus the water produced by the metabolism of fat, carbohydrate, and protein (Table 10.5). Each of these entities must be calculated for the individual patient if optimum fluid balance is to be achieved.

	Requirement
Urine output (UO)	= 30–50 mL/hr (adult) 1–2 mL/kg/hr (child)
Insensible loss	= 10–15 mL/kg/24 hr (adult) 25–45 mL/100 kcal (child)
Abnormal loss	= Measured external or estimated third-space loss
Water of metabolism	= 0.1 × 25 × body weight (adult) 0.1 × kcal met (child)

Note: Basic fluid requirement = (UO + Insensible loss + Abnormal loss) – H_2O metabolism.

TABLE 10.5. FLUID REQUIREMENTS

The amount of urine necessary to maintain proper balance is dictated by the physiologic limits of the kidney for solute and water excretion. *In resting humans, the products of normal metabolism produce a solute load that requires a minimum of 400 to 600 mL of urine for excretion.* Traumatized and critically ill patients are hypermetabolic and may produce twice the normal solute load, necessitating a minimum of 800 to 1,200 mL of urine excretion per day. Conversely, excessive output may lead to a washout of the renal medullary osmotic gradient, resulting in impaired concentrating capabilities of the kidney. The fluid intake required to produce large urine outputs also may result in fluid retention and vascular overload. Thus there are limits between which urine output should be maintained. The adult kidney is most efficient in maintaining balance when fluid intake is sufficient to produce a urine output of 800 to 1,200 mL per day, or 30 to 50 mL per hour. Urine output in children should be maintained between 1 and 2 mL/kg body weight per hour.

Insensible loss refers to the water lost from the respiratory tract and skin. The amount lost depends on the ambient temperature and humidity, as well as the patient's body surface area and body temperature. *The normothermic adult in a comfortable environment loses 800 to 1,000 mL per day (10 to 15 mL/kg of body weight per 24 hours).* Insensible losses in children are conveniently related to caloric consumption. A child will lose 25 to 45 mL of H_2O for each 100 kcal metabolized. The amount of calories consumed per day may be calculated by multiplying the body weight by 100 for each of the first 10 kg, by 50 for each of the second 10 kg, and by 20 for each additional kg body weight in excess of 20 kg (Table 10.2). Therefore a 10-kg child loses about 350 mL per day and a 20-kg child about 420 mL. Insensible losses increase by about 10% for each degree centigrade of temperature elevation above normal.

The water produced by metabolism is calculated from the caloric expenditure of the patient. The amount of water produced in milliliters is numerically equal to 10% of the total amount of kilocalories consumed. The resting adult metabolizes approximately 25 kcal/kg of body weight per 24 hours, whereas the child's caloric expenditure is calculated on a graduated basis as previously described. *An 80-kg adult who consumes 2,000 kcal (25 kcal/kg × 80 kg) produces 200 mL of H_2O, whereas a 12-kg child who consumes 1,100 kcal (10 kg × 100 kcal/kg + 2 kg × 50 kcal/kg) produces 110 mL of H_2O.* Because these volumes are small, the water of metabolism is often disregarded in total fluid calculations in patients with functioning kidneys.

Abnormal losses refer to fluids lost from the body by nasogastric suction, fistula drainage, vomiting and diarrhea, or the vascular system by third-space sequestration (e.g., retroperitoneal edema, operative trauma, ascites, bowel obstruction). The volumes of these losses are measured when external drainage occurs or estimated when sequestration is present and added to the total daily fluid requirements.

The total daily fluid requirement in an adult is calculated by adding the desired urine output, the insensible loss adjusted for temperature elevations, and measured or estimated abnormal losses. By monitoring the patient's urine output and weight, the clinician can determine the appropriateness of the calculated fluid requirement. The patient who is not receiving total caloric replacement should lose approximately 1 pound per day unless, as in the immediate postoperative period, obligate third-space sequestration of fluid is occurring. If the urine output or weight status is inappropriate, the fluid administered is adjusted accordingly. An example of total fluid replacement calculation follows: an 80-kg febrile (38°C) adult with a nasogastric tube draining 400 mL per day would require 1,200 mL urine output (50 mL per hour × 24 hours) plus 1,320 mL insensible loss (15 mL per kg of body weight per 24 hours × 80 kg + 10% of this quantity for the 1° temperature elevation) plus 400 mL abnormal loss (nasal gastric output) for a total of 2,920 mL per 24 hours.

Total fluid replacement in children may be calculated from the calories metabolized. One milliliter of fluid is administered for each kilocalorie metabolized. *Thus a 25-kg child would require 1,000 mL for the first 10 kg, 500 mL for the second 10 kg, and 100 mL for the final 5 kg, for a total of 1,600 mL per day* (Table 10.2).

Basic Electrolyte Requirements

The average young adult eating a regular diet receives approximately 70 to 120 mEq of sodium, 60 to 80 mEq potassium, 15 to 24 mEq of magnesium, and 80 to 140 mEq of chloride per day. Although the kidney is extremely effective in conserving sodium because it can reabsorb in excess of 99% of that filtered, total renal function is better preserved if enough sodium is administered so that maximum conservation of that filtered is unnecessary. Potassium, on the other hand, is not as efficiently conserved and therefore must be provided to avoid potassium depletion. Because magnesium is stored, patients who are in good nutritional balance before their illness do not require replacement, provided the period of IV therapy is limited. Patients whose nutritional status is marginal or who have alcoholic cirrhosis often require magnesium replacement at a rate of 5 to 20 mEq per day. IV sodium, potassium, and chloride requirements may be satisfied by providing the adult with about 75 mEq of sodium chloride and 40 mEq of potassium chloride per day.

Baseline electrolyte requirements for children are best calculated on the basis of caloric expenditure. Minimum 24-hour requirements are 3 mEq of sodium per 100 kcal, 2 mEq of chloride per 100 kcal, and 2 mEq of potassium per 100 kcal. Thus the 30-kg child would require 1,700 kcal. The sodium requirement is 17 × 3 = 51 mEq, the chloride requirement is 17 × 2 = 34 mEq, and the potassium requirement is 17 × 2 = 34 mEq.

Abnormal losses must be added to these basic requirements. The fluid lost from the body may be analyzed for its electrolyte content to determine accurate replacement (Table 10.6). Fluid sequestered in a third space generally mimics the electrolyte content of plasma and therefore can be replaced accordingly.

	Sodium	Potassium	Chloride
Gastric	60	10.0	90
Jejunum	105	5.0	100
Ileum	120	10.0	105
Cecum	80	20.0	50
Bile	175	5.0	100
Pancreas	170	4.5	75

TABLE 10.6. AVERAGE ELECTROLYTE CONTENT OF GASTROINTESTINAL LOSSES

Anuria

The fluid and electrolyte requirements for patients who are anephric or anuric are calculated from insensible and abnormal losses. *With insensible loss, an adult*

should receive 10 to 15 mL/kg of body weight per 24 hours, whereas a child should receive 25 mL of fluid per 100 kcal expended. The caloric expenditure is estimated on the basis of weight as previously described. Half of the fluid is administered as 10% dextrose in water and the other half as 5% dextrose in 0.2N saline solution. Potassium is generally not administered unless serum studies indicate the need for replacement. Abnormal losses are added to these basic requirements. These calculations are merely estimates of the patient's needs; therefore fluid and electrolyte therapy must be continuously adjusted according to serum electrolyte analyses, patient weight, and when appropriate, urine output.

Volume and Sodium Disturbances

Dehydration

When the patient's minimum fluid requirements are not met, a water deficit accompanied by weight loss occurs. A 4% loss of body weight resulting from a water deficit requires emergent rehydration. A 6% loss of body weight caused by lack of hydration results in a life-threatening condition often manifested by signs and symptoms of shock. The water lost may be relatively isotonic, in which case the dehydration is normonatremic, or hypotonic, which causes hypernatremia to occur.

Dehydration in urologic patients may be caused by postobstructive diuresis, prolonged vomiting and diarrhea, and diabetes insipidus. Postobstructive diuresis may be either physiologic or pathologic. Physiologic diuresis occurs when volume overload precedes the relief of the obstruction or when serum urea is elevated. The kidney responds appropriately when it is unobstructed by excreting the excess volume in the former circumstance or undergoing an osmotic diuresis as a result of the excess urea in the latter situation. The diuresis is self-limited because it ceases when the kidney has returned the body to a homeostatic condition. Rarely, a pathologic diuresis is superimposed on the physiologic diuresis and occurs as a result of specific defects that cause a decreased proximal and distal tubule sodium reabsorption and lack of concentrating capabilities of the kidney, resulting from a reduced medullary osmotic gradient (65). Such patients do not respond to antidiuretic hormone (ADH) or mineralocorticoid administration. Appropriate therapy consists of replacing insensible losses as previously outlined in addition to measured losses. Because the sodium content in the urine usually ranges between 50 and 70 mEq/L, urine output is replaced with 0.5N saline solution. It is important not to overhydrate these patients because such therapy often perpetuates the pathologic diuresis and prevents reestablishment of the medullary osmotic gradient, prolonging the concentrating defect. As the concentrating ability of the kidney returns, fluid therapy is reduced accordingly. It is often helpful in patients who have severe diuresis to follow serum osmolalities and daily weights, adjusting therapy accordingly.

Gastric losses are repleted with 0.5N saline or normal saline solution to which potassium chloride is added. Diarrheic losses are replaced with lactated Ringer's solution. Diabetes insipidus may occur as a result of a lack of ADH, collecting duct unresponsiveness to endogenous ADH, or lack of a medullary osmotic gradient. Patients are often slightly hypernatremic and mildly dehydrated. The urinary sodium content is generally low. Fluid administered should have a relatively modest sodium content until results of urinary electrolytes become available. The diagnosis should be sought expeditiously because specific therapy will often correct the disorder.

Volume Excess

Volume overload may be the result of either hypotonic or isotonic fluid excess. Hypotonic fluid excess results in the water intoxication syndrome manifested by clouded sensorium, irrational behavior, changing neurologic signs, stupor, seizures, and coma. Water intoxication most commonly occurs as a result of hypotonic irrigant absorption through the prostatic bed in patients undergoing transurethral resections. The first signs of volume overload are usually a rising CVP and mental confusion. Blood pressure changes are not often noted initially. If a minimum amount of water is absorbed and central nervous system (CNS) symptoms are not present, fluid restriction with judicious use of diuretics will suffice. In more severe cases in which significant hyponatremia and CNS disorders occur, the treatment should include fluid restriction coupled with hypertonic sodium chloride (3%) administration. Diuretics are not effective in the presence of significant hyponatremia and should be used sparingly until the serum sodium is returning to normal. Inappropriate secretion of ADH, often as a consequence of malignant tumors, is another cause of hypotonic fluid excess and also may result in hyponatremic fluid overload. These patients are often successfully managed by fluid restriction.

Isotonic fluid excesses are usually iatrogenic and are a consequence of excessive administration of fluids that contain sodium. The development of congestive heart failure, inappropriate weight gain, or peripheral edema depends on the severity of the overload. Such patients are treated with diuretics and fluid restriction.

Potassium Disorders

Hyperkalemia usually occurs in urologic patients as a result of acute renal insufficiency, addisonian crisis, trauma, shock, and diabetic acidosis. Life-threatening elevations in serum potassium often produce significant ECG alterations. *Peaking of the T wave, lengthening of the PR interval, prolongation of the QRS complex, and loss of the P wave occur with progressive hyperkalemia.* As potassium continues to rise, the ECG may ultimately resemble a sine wave. Calcium gluconate protects the heart from the adverse effects of potassium and may be administered in severe cases of hyperkalemia. *Treatment consists of IV administration of hypertonic sodium bicarbonate, which results in a shift of hydrogen ion out of the cell and concomitant movement of potassium into the cell, causing a temporary lowering of serum potassium.* Glucose and insulin therapy (10 units of regular insulin plus 50 g of glucose) are recommended only in extremely urgent situations. Potassium is temporarily bound during glucose transport, thus effectively removing it from the serum. Because these measures are only temporary, simultaneous institution of therapy to lower the serum potassium permanently is mandatory. This may be accomplished with ion exchange resins (Kayexalate given by mouth or by rectum), peritoneal dialysis, or hemodialysis.

Hypokalemia usually results from excessive upper gastrointestinal losses, diuretic therapy, steroid administration, and hyperaldosteronism. Metabolic alkalosis is often associated. Therapy is directed at eliminating the disorder and replacing the loss. Administration of solutions that contain sodium in the face of hypokalemia may promote renal potassium loss, particularly in patients with primary hyperaldosteronism. When sodium losses occur concomitantly with potassium deficits, both must be replaced simultaneously. If rapid replacement therapy is required, the ECG should be continuously monitored. If ECG changes occur, the infusion must be slowed or stopped until the abnormalities resolve.

Hypercalcemia

Hypercalcemia in urologic practice is generally the result of metastatic tumor to bone, hydrochlorothiazide therapy, or hyperparathyroidism. The symptoms of hypercalcemia include anorexia, weakness, somnolence, polyuria, and coma. Initial therapy involves the establishment of a sodium diuresis by administering IV saline solution and nonthiazide diuretics. If the diuresis must be prolonged, careful monitoring of serum potassium and magnesium concentrations is essential to prevent deficiencies.

Inorganic phosphate administration will rapidly lower serum calcium but results in metastatic calcification of soft tissues. Ethylenediamine tetraacetic acid (EDTA), a chelating agent, also rapidly lowers serum calcium but has many associated complications. These two agents should not be used unless life-threatening hypercalcemia occurs. On rare occasions, emergency therapy is required in patients with hyperparathyroidism who have uncontrollable serum calcium levels.

Mithramycin and steroids also have been used to control hypercalcemia. With both agents a decrease in serum calcium does not usually occur for 24 to 48 hours. Mithramycin, a cytotoxic agent used in the treatment of malignancies, has many serious side effects including bone marrow depression, renal failure, and hepatic toxicity. It should be used only in patients with neoplasms and then only when more conventional methods fail. The dosage is 1 to 2.5 mg per day for 3 days. Steroids are somewhat less effective and are best used in disorders in which vitamin D sensitivity is etiologic. Dialysis also may be used, particularly in patients with associated renal failure.

Bone resorption and release of calcium may be controlled by the oral or IV administration of etidronate disodium. This drug is useful for controlling hypercalcemia in patients with metastatic disease. It is not useful for treating an acute hypercalcemic crisis. In this situation, saline infusion and diuretics are indicated. Etidronate disodium may be added to the regimen to allay the recurrence of hypercalcemia. If used, adequate renal function and urine output must be present because the drug is excreted in the urine.

A saline diuresis should be the first modality tried, reserving the other forms of therapy for specific indications. It is important that diagnostic studies be instituted early to define the cause of hypercalcemia so that definitive therapy may proceed without delay.

Hypermagnesemia

Hypermagnesemia interferes with neuromuscular transmission both peripherally and centrally. The signs and symptoms include deterioration of mental function, drowsiness, muscular paralysis, and in severe cases, coma. Nausea, vomiting, peripheral vasodilation, and hypotension also may occur. The ECG shows prolongation of the QT interval. Persistent hypermagnesemia may cause soft tissue calcification and interfere with bone mineralization. Hypermagnesemia rarely occurs with normal renal function. Patients with decreased renal function who ingest medications that contain magnesium may be particularly prone to the disorder. Urologic patients in whom magnesium-containing solutions are used to irrigate the urinary system for dissolution of stones also may manifest hypermagnesemia. This is particularly true when the irrigant, such as Suby's solution G or citric acid, glucono-delta-lactone magnesium carbonate (Renacidin), is used at increased pressures in areas where vascular beds are exposed. When the symptoms are severe, emergency treatment with calcium gluconate may be necessary. In patients with normal renal function, however, hydration and furosemide administration generally suffice. Rarely, patients with decreased renal function or those with severe neurologic symptoms require hemodialysis to return magnesium levels to normal.

Hypomagnesemia may be a complication of aminoglycoside therapy, hepatic disease, or nutritional deficiency. Symptoms include somnolence and weakness.

Anion Gap

The anion gap is the difference between the sum of the major cations, sodium and potassium, minus the sum of the major anions, bicarbonate and chloride, and is normally about 16 mEq/L. The anion gap is of considerable importance in distinguishing among several types of acid–base disturbances. Most of the acidoses commonly found in urologic practice do not have an increased anion gap: hyperchloremic metabolic acidosis, renal tubular acidosis, uremic acidosis, and the acidosis accompanying diarrhea or excessive ileostomy drainage. An increased anion gap is most commonly associated with ketoacidosis; lactic acidosis; hyperosmolar, hyperglycemic, and nonketotic coma; and occasionally, uremic acidosis. Rarely, hyperchloremic metabolic acidosis caused by enteric urinary absorption may present with an anion gap.

Acid–Base Disturbances

Acid–Base Balance

Under normal dietary conditions, humans generate acid at 70 to 100 mEq per day, equal to 1 mEq/kg of body weight per 24 hours. This acid load is buffered by both extracellular and intracellular buffers that include hemoglobin, protein, inorganic phosphate, organic phosphate, and the bicarbonic–carbonic acid buffer system. Organic phosphate represents the principal intracellular buffer, whereas the bicarbonic–carbonic acid buffer system constitutes the major extracellular buffer. Under normal circumstances, these buffers can accommodate approximately 15 mEq/kg of body weight of hydrogen ion without causing major shifts in systemic pH. *Acid–base disturbances are classified into one of four basic types: (a) metabolic acidosis, (b) metabolic alkalosis, (c) respiratory acidosis, and (d) respiratory alkalosis.* Irrespective of the primary cause of the acid–base abnormality, the body compensates by establishing an acid–base disturbance. Thus, in patients with metabolic acidosis, there is compensatory respiratory alkalosis, and in those with respiratory alkalosis, there is compensatory metabolic acidosis, and so on. The compensatory mechanisms are generally incomplete, so despite compensation, the pH generally remains on the side of the primary disturbance. Therefore, if the pH is below 7.38, the primary disorder is acidosis; if above 7.42, the primary disorder is alkalosis. The Pa co_2 distinguishes between respiratory and metabolic. A patient with a pH of 7.44 and a Pco_2 of 48 would have a primary alkalosis, which would be metabolic in view of the elevated P co_2. The disturbance is a primary metabolic alkalosis with a secondary compensatory respiratory acidosis. The lungs are the primary mediator of the respiratory compensation and the kidneys the mediator of metabolic compensation. Clinically, the four types of acid–base disturbances are not classified as pure and are generally compensated as described. For illustrative purposes, however, each is discussed individually.

Metabolic Acidosis

Metabolic acidosis may be caused by a decreased extracellular bicarbonate concentration or may be a consequence of an increased extracellular volume without a proportional increase in bicarbonate content. The latter explains the acidosis of dilutional hyponatremia and water intoxication. A shift in hydrogen ion from the cell to the extracellular fluid compartment and net loss of body bicarbonate account for the acidosis. Decreased extracellular bicarbonate concentration may be caused by either a decrease in renal bicarbonate reclamation or by the consumption of serum bicarbonate resulting from an excessive acid load to the systemic circulation. In the former, the acidosis develops slowly, whereas in the latter it has an acute onset. Decreased generation of bicarbonate by the kidney occurs in uremic acidosis, renal tubular acidosis, and aldosterone deficiency. An increased production of metabolic acid may occur because of increased protein intake or an increased rate of tissue catabolism; increased production of endogenous organic acids, such as lactic acid (shock) and ketoacids (diabetes); the administration of exogenous acids, such as ammonium chloride; and finally, extrarenal losses, such as gastrointestinal losses of bicarbonate in patients with diarrhea or an ileostomy.

Excessive drug ingestion (salicylate intoxication) also may cause an acidosis. The effects of an acute acidosis include dilation of arterioles, impairment of cardiac contractility, and systemic venous constriction, whereas chronic acidosis results in depletion of bone alkaline stores caused by the buffering capacity of the bone. The bone generally buffers 30 to 40 mEq of acid per day in chronic acidotic states. The differential between a renal or extrarenal cause can conveniently be made by checking the urinary pH. If the acidosis is caused by exogenous or nonrenal mechanisms, the urinary pH is acidic. Conversely, if the mechanism is caused by a lack of bicarbonate generation and reclamation, the urinary pH is persistently alkaline.

Metabolic Alkalosis

When metabolic alkalosis occurs, there is a net addition or increase in extracellular bicarbonate concentration. Because the kidney has a great capacity to excrete bicarbonate, two conditions must be met for metabolic alkalosis to occur. First, there must be a mechanism for increasing extracellular bicarbonate concentration, and second, there must be a mechanism to prevent the kidney from excreting the excess bicarbonate. This may occur as a result of increased loss of hydrochloric acid from the stomach after vomiting or nasogastric tube drainage; increased loss of hydrochloric acid in the stool of patients who have a defect in chloride reabsorption in the ileum and colon (congenital chloridorrhea); potassium depletion, which results in a shift of hydrogen ion into the cell; contraction of the extracellular volume without a proportional decrease in bicarbonate content; an increased renal production of bicarbonate resulting from the use of a diuretic; respiratory acidosis; primary hyperaldosteronism; and hypoparathyroidism. Excessive ingestion of alkali, such as the milk alkali syndrome, also may be causative.

Respiratory Alkalosis

Hyperventilation results in respiratory alkalosis and is always caused by stimulation of the respiratory center. This may be the result of hypoxia, drugs, toxins, CNS disorders, or psychogenic causes, or hyperventilation may occur as a compensatory mechanism for metabolic acidosis. When primary, sepsis always must be suspected.

Respiratory Acidosis

Respiratory acidosis results from hypoventilation and may be caused by depression of the respiratory center from CNS disease, drugs, defects in nerves and muscles of the respiratory center as a result of disease or injury, thoracic cage disorders, airway obstruction, or chronic pulmonary disease.

FLUID AND ELECTROLYTE ABNORMALITIES ASSOCIATED WITH GENITOURINARY IRRIGANTS

Water Intoxication

Water intoxication in urologic practice is generally a result of excessive nonelectrolyte irrigant absorption during endoscopic or endourologic procedures. As the nonelectrolyte fluid is absorbed, volume expansion and dilutional hyponatremia occur. The clinical manifestations of this syndrome (TUR syndrome) were first described in 1946 after a transurethral resection (TUR) of the prostate in which the patient was noted to become restless. There was dark red discoloration of the serum, progressive oliguria, azotemia, and pulmonary edema, followed by death. The development of the syndrome was associated with an 18.5% mortality (20). As more experience has been gained with TURs, this syndrome has become better defined. After substantial volume expansion with resultant hyponatremia, patients generally complain of nausea, become mentally confused or restless, and have sensory disturbances; if allowed to progress, blindness, convulsions, hypotension, coma, oliguria, and death supervene.

During a TUR, some fluid is invariably absorbed; however, the amount is usually insufficient to cause the clinical manifestations of water intoxication. The amount of fluid absorbed is directly related to (a) the pressure of the irrigant, which is a function of the height the bag is placed above the prostatic fossa; (b) the intravesical pressure; (c) the intraprostatic pressure; and (d) the CVP. The duration of the resection, the size of the gland, the quality of resection, and the type of resection equipment used also play a role. Blood loss, like volume absorption, has been correlated with the time of resection. As a rule, 20 mL per minute of fluid are absorbed and 2 mL per minute of blood are lost during resection. A continuous-flow resectoscope is more likely to produce significant water intoxication than the inflow–outflow method. Perhaps most important is the quality of resection because frequent capsular penetration and entrance into venous sinuses predispose the patient to the development of water intoxication. The first sign that should arouse suspicion is an increase in CVP or left atrial pressure (Swan-Ganz). A change in blood pressure is generally not an early sign and in fact may not be noted, even when the syndrome is severe enough to cause blindness.

The pathophysiology of the TUR syndrome has been reasonably well elaborated. After nonelectrolyte irrigant absorption, serum sodium and chloride fall as volume overload occurs. Tachypnea, hypertension, and subsequent bradycardia resulting from the carotid reflex may occur. As electrolyte changes occur from dilution, cardiac output falls, plasma volume is variable, and body weight increases. As the extracellular osmolality decreases, cerebral edema occurs, causing confusion, seizures, and blindness. Pulmonary edema also may occur with hypoxemia, cyanosis, and acidosis, and alteration of the clotting factors may occur with hemorrhage, hemolysis, anemia, and shock. Patients at increased risk for development of this syndrome are those who have cardiac disease and have been on a low-salt diet with diuretic supplementation and patients with hydronephrosis, salt-losing nephritis, urinary retention, or chronic illness and malnutrition.

Treatment of Water Intoxication Syndrome

Patients who are symptomatic and manifest severe neurologic abnormalities require rapid correction of their electrolyte status. This may be accomplished by the simultaneous administration of a potent diuretic, such as furosemide, with the restoration of serum sodium content by the infusion of hypertonic saline solution. The sodium deficit is calculated by subtracting the current serum sodium from the desired serum concentration and multiplying the value by the quantity 0.2 × body weight in kilograms (extracellular fluid volume). This gives the milliequivalent amount required to return the serum sodium to the desired value. Half of this amount is administered rapidly, after which a second serum sodium concentration is obtained and the therapy modified accordingly. If the patient has neurologic symptoms or signs, 3% sodium chloride is used. On the other hand, if neurologic abnormalities are absent, normal saline may be used. The volume is determined by the number of milliequivalents calculated. For example, an 80-kg man whose serum sodium is 110 mEq/L would require 400 mEq to return serum sodium to 135 mEq/L. Half, or 200 mEq (about 400 mL of 3% sodium chloride), would be given rapidly, monitoring the neurologic, pulmonary, and cardiac status. The remainder would be given as needed, depending on a repeated serum measurement and clinical status. For patients who are less symptomatic and have a less severe hyponatremia, the administration of a potent diuretic and the infusion of normal saline solution may suffice.

Other Problems with Irrigants

If the area of instrumentation is infected, the irrigant may carry bacteria with it, resulting in bacteremia occasionally followed by sepsis. Other electrolyte abnormalities depend on the specific irrigant used. Currently, five types of isotonic fluids are in general use: sorbitol, 3.3%; glucose, 5.4%; glycine, 1.5%; mannitol, 3.0%; and urea, 1.8%. Water is also used; however, it is not isotonic.

Water

Because water is not isotonic, it can result in significant hemolysis of red blood cells when it enters the systemic circulation. This hemolysis results in an increased level of serum potassium and, during a typical TUR, elevated serum levels of free hemoglobin. However, it has been shown that hemoglobin is not toxic in levels up to 600 mg, provided it is not combined with abnormal serum proteins. In the latter case, it may in fact be nephrotoxic.

Sorbitol (3.3%)

Sorbitol is metabolized completely either to carbon dioxide and water or to dextrose. It also may be excreted by the kidneys. The use of this solution may result in an elevated level of serum glucose, which may be particularly severe in noncompensated diabetic patients. The same propensity to water intoxication occurs with this fluid as with any other urologic nonelectrolyte irrigant fluid. Rarely, sorbitol may result in an osmotic diuresis with dehydration and a hyperosmolar state. This solution should be used with caution in diabetic patients.

Glucose

Glucose solutions are no longer generally used because they are sticky and are not comfortably handled in the urologic suite. If used, however, they have the same complications as sorbitol.

Glycine (1.5%)

Ammonia intoxication has been reported after the use of glycine. Patients particularly prone to this complication are those with impaired hepatic function who presumably are unable to clear the ammonia generated from glycine metabolism. If the patient receives large doses of glycine, it may also cause salivation, nausea, and light-headedness.

Mannitol (5%)

The main side effect of mannitol is an osmotic diuresis that can result in dehydration and hyperosmolality. Occasionally, this solution may cause systemic acidosis.

Urea

Urea is no longer conventionally used because of its permeability to the intracellular and extracellular space. Its use results in elevated serum urea concentrations and also may cause an osmotic diuresis.

Volume Deficits

With significant loss of body fluids, dehydration, hyperosmolality, and neurologic disturbances occur. If allowed to persist, hypotension and death supervene. With a 4% loss of body weight caused by a water deficit, emergency rehydration is in order. These patients are generally symptomatic. A 6% loss of body weight caused by a water deficit results in shock and often death. Common urologic disorders that lead to dehydration include postobstructive diuresis, which results in a urine with a sodium content of 50 to 70 mEq/L and a potassium content of 10 to 40 mEq/L. These patients' urinary fluid losses may be replaced accurately with 0.5N saline solution. Prolonged vomiting or diarrhea also may result in significant dehydration. The former is replaced with 0.5N saline solution plus 40 mEq/L of potassium chloride if renal function is normal, and the latter is replaced with Ringer's lactate. Finally, diabetes insipidus may result in significant dehydration. This syndrome is discussed in detail in the section on polyuria. During replacement therapy and in the follow-up period, daily body weight, serum sodium, and serum osmolality are measured to determine the efficacy of therapy.

FLUID AND ELECTROLYTE ABNORMALITIES ASSOCIATED WITH URINARY INTESTINAL DIVERSION

Intestinal Conduits

The intestine's primary function is to selectively absorb electrolytes and nutrients. This function makes it less than an ideal structure as a urinary conduit or storage vehicle. Urine exposed to its surface is altered because some constituents are reabsorbed and others are diluted as a result of intestinal secretion. The extent to which the fluid is altered depends on the surface area to which it is exposed, the time of exposure, and the composition of the urine.

Electrolyte transport occurs throughout all segments of the bowel. In the jejunum, sodium absorption is coupled with glucose transport, whereas in the ileum and colon, sodium and chloride are actively absorbed. In these segments of bowel, there may be an exchange between sodium and hydrogen and chloride and

bicarbonate. Thus with hydrogen absorption, sodium is secreted; with chloride absorption, bicarbonate is secreted. The movement of these ions depends on cyclic adenosine monophosphate (cAMP), and therefore blocking this enzyme alters transport properties (45). Metabolic disorders of intestinal urine transport are treated by choosing specific drugs that block this enzyme system. Water moves according to its concentration gradient; thus hyperosmotic urine results in the movement of water into the conduit from the systemic circulation. Hypoosmotic urine, on the other hand, may result in a net movement of water into the extracellular space. The flux of water is particularly prominent in the jejunum, less so in the ileum, and least in the colon. Metabolic abnormalities brought about by intestinal alteration of urine are often compensated for by the kidney's ability to increase and alter its excretion rates of unwanted solutes. Severe metabolic disturbances often manifest themselves only when renal function is compromised, particularly when the serum creatinine concentration exceeds 2 mg/dL.

Syndrome of Hyperchloremic Metabolic Acidosis

The ingestion of acetazolamide (or acid), diarrhea, and intestinal fistulae can cause hyperchloremic acidosis; however, the most common cause in urologic practice is intestinal interposition. *This syndrome occurs in patients who have ileum or colon interposed in the urinary tract; is most common in patients in whom the urine remains in contact with the intestinal mucosa for extended periods, particularly those with ureterosigmoidostomies; and is most severe with compromised renal function*. The acidosis usually does not manifest an anion gap; however, recent evidence suggests that an anion gap may occur rarely in those patients with rectal bladders, continent diversions, and other bowel substitutes in which the urine remains in contact with the intestinal mucosa for extended periods. This anion gap is most likely caused by an increased absorption of phosphate, sulfate, and ammonium, resulting in decreased total body elimination of these anions.

Four hypotheses have been proposed to explain the acidosis: (a) renal tubule acidification defect, (b) intestinal absorption of ammonium, (c) intestinal bicarbonate secretion, and (d) active intestinal chloride transport. A renal tubule acidification defect seemed likely because many of these patients had ascending pyelonephritis. Pyelonephritis affects the distal tubule, and it was proposed that this interfered with the kidneys' ability to acidify (55). It is clear that a distal tubule acidification defect will make the acidosis worse, but it is unlikely that it is the primary mechanism because many patients with normal renal function also manifest the acidosis (87).

The second hypothesis proposed that the urea excreted in the urine is split to ammonium by intestinal bacteria, thereby increasing ammonium absorption, which accounts for the acidosis (7,80). Because ammonia derived from urea is not an acid (when hydrated with water, it is a base), this mechanism does not explain proton addition (hydrogen ion) to the systemic circulation. It may be, however, that ammonia serves as a proton acceptor from acid secreted in the urine and then is actively reabsorbed. Data from our laboratory suggest that ammonium is transported and results in significant proton loads to the patient.

The third mechanism proposed is bicarbonate secretion by the intestine. Clearly, the ileum and large bowel are capable of significant bicarbonate losses because patients with ileostomies and those with severe diarrhea can lose enough bicarbonate to become acidotic. Several experiments also have demonstrated bicarbonate loss in measurable quantities in patients with ureterosigmoidostomies (21). However, the amount of bicarbonate lost to the body in most cases of intestinal interposition seems insufficient to explain the severity of the acidosis. Experimental evidence in animals suggests that this plays only a minor role in most cases (52).

The final mechanism proposed is that active chloride transport is the primary cause of the acidosis (31). The hypothesis is that chloride is actively transported and then requires a cation to preserve electrical neutrality to diffuse across the membrane. The cation may be either hydrogen or ammonium, whichever is most available. Thus in effect hydrochloric acid and/or ammonium chloride enter the systemic circulation in sufficient quantities to account for the acidosis. The evidence to support this hypothesis comes from experiments that showed that when ion fluxes are measured across the intestinal segment exposed to urine, net hydrogen uptake is directly proportional to chloride transport. Moreover, chlorpromazine (Thorazine) and niacin, two drugs known to block chloride transport through their effect on cAMP, limit this acidosis (50,51).

From intestinal vesicle experiments it appears that the primary mechanism for the acidosis is the transport of ammonium across the intestinal epithelium in exchange for a proton. Chloride is absorbed to maintain electrical neutrality in exchange for bicarbonate. The net effect is absorption of ammonium chloride in exchange for carbon dioxide and water (60).

Other electrolyte abnormalities associated with hyperchloremic metabolic acidosis include hypokalemia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypersulfatemia. Hypokalemia may be severe because the chronic acidosis falsely elevates the serum potassium and therefore obscures the severity of the total body potassium deficiency. On correction of the acidosis, these patients often require considerable replacement of potassium to replenish body content. The intestinal loss of potassium can be reduced by the administration of spironolactone.
