The mechanism of hypocalcemia and hypomagnesemia is not clear. It has been suggested that chronic acidosis results in depletion of bicarbonate stores in the skeleton with release and loss of calcium initially through the urinary tract. The hypocalcemia is merely a reflection of total body depletion. Reports of rickets and growth retardation in some of these patients (8) suggest that abnormal calcium metabolism may be clinically significant. Large losses of calcium in the urine with stimulation of calcium reabsorption by the tubule through the mechanism of parathormone would result in magnesium excretion by the binding of all available transport sites for calcium under maximum parathormone stimulation. Thus excessive magnesium loss through the urinary tract results in hypomagnesemia. Initial experiments in our laboratory suggest that the increased intestinal absorption of sulfate results in its blocking renal reabsorption of calcium and magnesium (62). Whatever the mechanism, it is clear that hypocalcemia and hypomagnesemia occur most commonly when renal function is significantly impaired. In patients with normal renal function, serum concentrations of these two ions are rarely more than slightly depressed.

Urea and creatinine also are reabsorbed by the bowel and may result in elevated serum levels that do not accurately reflect renal function. Because transport properties vary somewhat for various portions of the bowel, electrolyte abnormalities specific for each segment are described subsequently.

Jejunum

The jejunum is seldom used for intestinal diversion because of the severe fluid and electrolyte abnormalities that occur when it is used as a conduit or storage vehicle for urine. *These segments lose large quantities of sodium chloride and absorb significant amounts of potassium and urea.* With the extensive sodium and chloride loss into the lumen of the intestine, the osmotic gradient this creates necessitates the movement of water from the systemic circulation into the lumen of the intestine. This results in substantial fluid losses to the body. Some hydrogen absorption and bicarbonate loss also may occur. These patients become hyponatremic, hypochloremic, hypovolemic, hyperkalemic, and azotemic. They also may have a mild acidosis and an associated serum hyperosmolality (13,46). In response to these abnormalities, there is an increased secretion of aldosterone and renin, thus further reducing urine sodium concentration and thereby increasing the concentration gradient of sodium between serum and lumen, enhancing secretion by the jejunum. When short segments are employed for conduits and drainage is unimpeded, recent reports suggest that severe electrolyte abnormalities occur in fewer than 10% of patients (33).

Ileum

The ileum is perhaps the most commonly employed segment for urinary diversion. *Chloride is absorbed and bicarbonate secreted and ammonium absorbed in exchange for hydrogen ion by this segment.* Although rarely a clinical problem, these patients may develop hypokalemia associated with the hyperchloremic metabolic acidosis (19). The metabolic abnormality is more common in patients with compromised renal function. Although water does move into the conduit if urine flowing through it is hypertonic, because the ileum does not secrete large amounts of osmotically active agents such as sodium and chloride, the amount of fluid lost is not as extensive as for the jejunum.

Colon

The colon also transports chloride in exchange for bicarbonate, so patients with colon segments are prone to develop hyperchloremic metabolic acidosis. These patients are more likely to become hypokalemic, hypomagnesemic, and hypocalcemic than patients with ileal segments. However, they are less likely to become hypovolemic because fluid fluxes are less prominent in the colon than in ileal or jejunal segments. Indeed, patients with colon conduits can actually concentrate to about 400 mOsm/kg, as opposed to ileal segments in which the gradient generally does not exceed 350 mOsm/kg (61).

Treatment

The treatment of hyponatremic, hypochloremic, hyperkalemic, metabolic acidosis found in jejunal segment patients consists of oral sodium chloride, bicarbonate, and fluids. When severe, IV administration of saline solution in large volumes and the establishment of a diuresis correct both the hyponatremia and hyperkalemia, as well

as the hypovolemia.

Hyperchloremic metabolic acidosis is treated by oral chloride restriction, bicarbonate replacement (either in the form of sodium bicarbonate or Polycitra), and drainage of the area of storage. In patients with a Koch pouch, rectal bladder, or ureterosigmoidostomy, this requires catheterization of the segment. Studies have shown that chlorpromazine and niacin may be effective. These drugs block active chloride transport in the intestine, thereby limiting the acidosis. This has been demonstrated in experimental animals and in patients (50). The advantage to these drugs is that a sodium or potassium load is not given as when bicarbonate or Polycitra is used. This may be particularly useful in patients who have congestive heart failure or those with severely compromised renal function in whom an excessive sodium or potassium load would be inappropriate. High dosages and prolonged use of chlorpromazine may result in the development of extrapyramidal symptoms including tardive dyskinesia. The side effects of niacin are usually minimal but may consist of agitation and flushing. Because of the CNS effects of chlorpromazine, we prefer to use niacin in children and chlorpromazine in adults.

BOWEL PREPARATION

Urologic operations in which bowel is used as a conduit or storage vehicle for urine are invariably elective; therefore proper preparation of the bowel may be planned preoperatively. The major risks involved in operating on the bowel include wound infection, anastomotic breakdown, and peritoneal infections . *In unprepared bowel, the wound infection rate varies between 32% and 58%. This incidence may be reduced to 6% to 9% if mechanical and antibiotic bowel preparation are used* (14). Breakdown of the intestinal anastomosis is more common when performed on unprepared bowel. Antibiotics appear to have a protective effect on the anastomosis, particularly if the blood supply is compromised. In experimental animals, an unprepared bowel that is devascularized results in perforation and death, whereas an antibiotically prepared bowel that is devascularized heals. In a clinical study comparing colon anastomoses in prepared and unprepared bowel, the total number of complications and the number of anastomotic breakdowns were increased in the unprepared group. In this study, if the patients were steroid dependent, had peritonitis, received prior irradiation, or had diabetes mellitus or chronic renal failure, the chance of anastomotic breakdown was significantly increased (3). Finally, intraperitoneal abscesses are more common when unprepared bowel is operated on.

In mechanical preparation of the bowel, the enteric content is reduced, and in antibiotic preparation, the bacterial organisms are reduced. The mechanical bowel preparation reduces the amount of bacteria but not the number of bacteria per milliliter of feces. Spillage of enteric contents is less likely because there is less of it to spill; however, with a spill, the inoculum is the same as if the spill occurred in unprepared bowel. More recent evidence indicates that excessive mechanical bowel preparations are unnecessary. Two to four liters of polyethyleneglycol may be given orally the day before surgery, or 2 days before surgery, clear liquids are begun and 30 to 60 mL Phospho-Soda is given orally. On the day before the operation, 30 mL of Phospho-Soda is given (Table 10.7).

	Conventional		PEG + Electrolytes	
Preoperative Day	Diet	Cathartic	Diet	PEG
3	Low-residue plus supplements		Regular plus supplements	–
2	Clear liquids		Low-residue plus supplements	–
1	Clear liquids	30–60 mL Fleets Phospho-Soda	Clear liquids	2-4 L PEG + electrolytes

PEG, polyethylene glycol.

TABLE 10.7. MECHANICAL BOWEL PREPARATION

The mechanical preparation reduces the amount of enteric contents, not the number of bacteria in a single inoculum. Therefore the mechanical bowel preparation is supplemented with an antibiotic bowel preparation (Table 10.8). The risk of wound infection and other infectious complications is reduced from 30% to 6% when antibiotics are combined with the mechanical preparation. Antibiotics also protect vulnerable and ischemic bowel. The disadvantage to giving antibiotics in preparation for bowel surgery is that it increases the incidence of tumor implantation on the anastomosis, and it might play a role in the development of pseudomembranous enterocolitis (15). The former is generally of little consequence to the urologist; however, the latter can be a significantly morbid and sometimes fatal complication. It seems unlikely, however, that antibiotics are solely responsible for the development of the latter syndrome because there has been no change in its incidence in the preantibiotic and postantibiotic eras. It was originally thought to be caused by a staphylococci but recently, *Clostridium difficile* and the endotoxin that it elaborates have been implicated. The most important factor in its initiation is intestinal ischemia. Other risk factors include bowel preparation, nasogastric tubes, gastrointestinal surgery, narcotics, advanced age, cancer chemotherapy, and renal disorders. The diagnosis is made by identifying the cytopathic toxin of *C. difficile* in the stool. Treatment is directed at repopulating the bowel surface with normal enteric flora and the administration of antibiotics to which the organism is sensitive: vancomycin, aminoglycosides, metronidazole, and ciprofloxacin.

Preoperative Day	Kanamycin	Neomycin + Erythromycin	Neomycin + Metronidazole	Tinidazole + Doxycycline
3	1 g kanamycin p.o. q.h. × 4, then q.i.d.	–	–	–
2	1 g kanamycin p.o. q.i.d.	–	1 g neomycin q.i.d. + 750 mg metronidazole q.i.d.	–
1	1 g kanamycin p.o. q.i.d.	1 g erythromycin + 1 g neomycin at 1, 2, and 11 PM	1 g neomycin q.i.d. + 750 mg metronidazole q.i.d.	2 hr preoperatively: 1,600 mg tinidazole + 400 mg doxycycline infused IV over 2 hr

TABLE 10.8. ANTIBIOTIC BOWEL PREPARATION

SHOCK

An all-encompassing definition of shock is impairment of cellular function caused by either a reduction in effective delivery of oxygen and nutrients to the cell or inability of the cell to use these substrates. Shock may be classified as hypovolemic, neurogenic, endocrine, anaphylactic, cardiogenic, and septic.

Hypovolemic Shock

When loss of blood, loss of fluid, or sequestration of fluid is etiologic, cardiac output and blood pressure fall while plasma renin and ADH levels rise. The sympathetic nervous system is stimulated, which results in the constriction of arterioles and major veins, an increase in heart rate and strength of contraction, a reduction in microcirculatory flow and sludging, and mobilization of glucose for energy production. If hypotension and peripheral vasoconstriction continue, a decrease in transmembrane potential occurs, membrane permeability increases, and fluid is sequestered, particularly in muscle cells. If the perfusion defect continues, cellular death supervenes.

Hypovolemic shock is generally divided into three phases. The first phase occurs with volume deficits between 0% and 10% and begins with a sequestration of fluid resulting in cellular edema. During this phase, the blood volume deficit is counteracted by stimulation of the sympathetic nervous system, which results in peripheral vasoconstriction and increased heart rate in an attempt to maintain blood pressure. ADH, renin, and aldosterone also contribute to the vasoconstriction and reduced

urinary excretion in an attempt to restore extracellular fluid volume. The second stage occurs with a blood volume deficit of 15% to 20%. Cardiac output and arterial pressure are significantly reduced, despite the compensatory mechanisms previously described. The low blood pressure and the intense adrenergic discharge result in tachycardia, tachypnea, cutaneous vasoconstriction, pallor, diaphoresis, piloerection, apprehension, and restlessness. The third stage occurs when the deficit exceeds 25%. During this stage, tissue perfusion is inadequate, and if it persists for long periods, cellular death occurs. Vital organ function is severely impaired, capillary membrane integrity is lost, and disseminated intravascular coagulation may occur. It is at this point that irreversible shock follows.

Treatment

Hypovolemic shock caused by third-space fluid loss, as occurs in burns and retroperitoneal dissections, is treated with isotonic fluid replacement. Many advocate partial replacement with 5% albumin, suggesting that the total fluid requirement is less with a smaller amount extravasating into the third space and pulmonary interstitium. Other studies suggest that crystalloid is more likely to produce pulmonary edema than solutions of 5% albumin, hetastarch, or dextran. Others disagree, stating that colloid is unnecessary and that only crystalloid should be used in the initial phases of resuscitation. *When blood loss is the cause, whole blood is administered, which is appropriately typed and crossmatched.* Dextran may be used as a blood substitute for volume expansion; however, it carries the risk of creating clotting abnormalities through antigen–antibody reactions. Prolonged use of dextran also may engender renal failure. Hetastarch is a polysaccharide that is available in a 6% solution. It has replaced dextran as the drug of choice for volume expansion when blood and albumin are unavailable because renal and bleeding complications are less common. If after adequate volume resuscitation cardiac output is insufficient, ionotrophes and vasoconstrictors may be in order (see Cardiogenic Shock).

Attention also must be paid to the patient's ventilatory status. Hypoventilation with hypoxemia severely augments the deleterious effects of underperfusion.

In the successfully treated patient, there are three phases of fluid dynamics. The first phase follows the insult and is characterized by sequestration of fluid and cellular edema. This accounts for the major initial pathophysiologic problems encountered in hypovolemic shock. The sequestration generally ceases between 24 and 36 hours, provided the patient has been adequately resuscitated. In the ensuing 2 to 3 days, a homeostatic period occurs in which the sequestered fluid remains unavailable to the intravascular space. At approximately 4 to 7 days after the insult, the third phase is initiated in which the fluid is mobilized. It is during this phase that patients with limited cardiac reserve may develop congestive heart failure as the fluid is mobilized from the third space into the intravascular space. The judicious use of diuretics may be necessary to rapidly restore intravascular volume to normal.

Neurogenic, Endocrine, and Anaphylactic Shock

Neurogenic shock results from a sudden loss of vasomotor tone caused by a neural injury. This commonly occurs in traumatic injuries to the CNS.

Endocrine deficiencies resulting from a lack of function of the adrenal glands or pituitary result in circulatory failure. Uncontrollable diabetes may result in an osmotic diuresis with resultant hypotension.

Anaphylactic shock is the result of an acute systemic autoimmune reaction that causes a marked increase in vascular permeability with sequestration of edema fluid, bronchospasm, and laryngospasm. This sequestered fluid leaves the intravascular space, resulting in hypotension. Of patients who develop intraoperative anaphylaxis, 5% to 10% die (90). Agents that have been implicated in triggering the response include neuromuscular blocking agents, IV anesthetics, antibiotics, radiocontrast, blood products, protamine, and latex. Latex allergy may result in an anaphylactic-like reaction with symptoms as mild as nausea and flushing to angioedema, bronchospasm, and cardiovascular collapse. Three groups of patients appear to be at high risk: (a) myelodysplastic patients, (b) those with congenital urologic abnormalities, and (c) health care workers. In high-risk patients, consideration should be given to prophylactic administration of prednisone, diphenhydramine, and ranitidine (47).

Treatment

Neurogenic shock is treated with isotonic fluid administration until blood pressure returns to normal levels. Patients with adrenal insufficiency or pituitary insufficiency are treated with replacement corticosteroids and fluids that contain sodium. Anaphylactic shock is treated with epinephrine, fluids, antihistamines, and corticosteroids.

Cardiogenic Shock

Cardiogenic shock occurs when the heart fails to act effectively as a pump. This may be brought about by a myocardial infarction, cardiac arrhythmia, or depression of myocardial contractility resulting from a metabolic aberration. Rare causes include mechanical blockage that may occur in a tension pneumothorax, vena caval obstruction, and cardiac tamponade. The most common cause of the disorder is clearly myocardial infarction. Approximately 10% to 15% of patients with an acute myocardial infarction will develop cardiogenic shock. Mortality in this group is exceedingly high, approaching 75% (38). These patients present with cold, clammy skin; hypotension; tachycardia; anuria; and oliguria and are often confused and agitated. The pathophysiologic process includes a decreased cardiac output, decreased ejection fraction, normal or increased CVP, increased pulmonary capillary wedge pressure, and increased left ventricular end-diastolic pressure.

Treatment

Because hypotension results in decreased coronary artery perfusion with a propensity toward limiting the amount of oxygen delivered, one of the first hallmarks of therapy is to provide the patient with oxygen. Decreased oxygenation of the injured myocardium will result in progression of the infarction. Oxygen is administered by face mask, nasal prongs, or rebreathing bag. Patients with chronic pulmonary disease need to be monitored carefully if their respiratory drive is secondary to hypercapnia. These patients may require intubation. It is during the initial postmyocardial infarction period that life-threatening cardiac arrhythmias often occur. Therefore these patients need to be continuously monitored, and a large-bore IV line must be available to administer antiarrhythmogenic drugs. Often, these patients have a slight metabolic acidosis, which must be corrected with bicarbonate administration. The placement of a pulmonary artery catheter is generally indicated because the diagnosis can be conveniently made using this device, and treatment is often dictated by measurements performed. With the pulmonary artery catheter, cardiac output, preload, and afterload can be determined and will verify the diagnosis by revealing a decreased cardiac output. Preload is determined by pulmonary capillary wedge pressure measurement and afterload by peripheral resistance calculation. When the peripheral resistance is normal, an agent is chosen that will improve the cardiac output by increasing myocardial contractility. Dobutamine or isoproterenol is the drug of choice. When there is an increase in peripheral resistance, therapy is directed at increasing cardiac output and decreasing afterload. The afterload may be reduced with nitroprusside, and cardiac output can be increased with either dobutamine or isoproterenol. The dosage of nitroprusside must be monitored carefully because it may result in thiocyanate intoxication. When peripheral resistance and cardiac performance are decreased, the use of vasopressors, such as dopamine and epinephrine, is useful (44).

Septic Shock

Septic shock, unlike hypovolemic shock, does not necessarily result in a perfusion deficit to the tissues. Rather, it results in an inability of the body cell mass to effectively use substrate delivered to it. Septic shock is an important cause of morbidity and mortality among hospitalized patients. Approximately 25% to 40% of patients who sustain a bacteremia develop septic shock (72). In most cases, it originates from an infection with Gram-negative enteric bacilli. *Escherichia coli* is the most common pathogen followed by *Klebsiella, Enterobacter, Serratia,* and *Pseudomonas* species . Gram-positive organisms occasionally cause sepsis, and rarely, viruses, fungi, rickettsia, and protozoa, have been implicated. The genitourinary tract is the most common source, followed, in decreasing order of frequency, by the gastrointestinal tract, the respiratory tract, wound infections, infected IV catheters, and pelvic infections. Urosepsis in the critical care setting carries with it a 25% mortality (71). Patients at increased risk for the development of septic shock include those who have cirrhosis, diabetes mellitus, and neoplastic diseases (67). Radiotherapy and/or chemotherapy particularly predispose the latter group of patients to sepsis. Mortality ranges between 40% and 90%.

Endotoxin, a lipopolysaccharide protein complex, which is part of the cell wall of Gram-negative bacteria, has been implicated as the initiating agent in the pathophysiologic process. Because other than Gram-negative organisms also cause the syndrome, it is clear that if endotoxin is an initiating agent, it is not the only one. The infecting organism activates proinflammatory cytokines. Prominent among these cytokines are tumor necrosis factor-a, interleukin-1 and interleukin-6, among others (10). Other cytokines that have been implicated include interleukin-6 and interleukin-8, a platelet-activating factor, interferon-g, macrophage-derived proteins, and arachidonic acid metabolites. As a result of the production of these substances and the presence of bacteria, many biochemical and immunologic pathways are activated. The complement, kinin, and clotting systems are stimulated and activation of polymorphonuclear leukocytes occurs, and the release of the b-endorphin histamine and prostaglandins is facilitated.

There are two phases of septic shock: the hyperdynamic and the hypodynamic. In the first phase, patients are hypotensive and have warm, dry skin. Arterial vasodilation, an increase in body temperature, hyperventilation with respiratory alkalosis, and an increase in pulse pressure and cardiac output occur. Although the absolute value of cardiac output in patients with septic shock is generally increased, it cannot achieve adequate perfusion of essential organs. These events may be heralded by a shaking chill, which is followed by a rapid rise in temperature. Lactic acidosis may supervene, indicating the cell's inability to utilize or obtain oxygen and substrate. However, the degree of lactic acidemia does not correlate with the lack of oxygenation in septic shock, nor is it of any prognostic significance (79). The vasoactive kinins, histamine, and prostaglandins result in vasodilation and perhaps some vasoconstriction in various vascular beds. b-Endorphin produces cardiovascular depression, vasodilation, capillary leakage, and hypotension (43).

As sepsis continues, myocardial depression occurs, with a reduced ejection fraction and left ventricular dilation. The activation of the kinin system results in the release of bradykinin, an agent known to produce vasodilation of arterioles. Activation of the complement system results in depletion of the C3 and C5 components (72). The white blood cell count is elevated with a shift to the left; rarely, however, sepsis may result in a depressed count—a poor prognostic sign. Blood glucose is elevated as a result of the increased levels of glucagon, growth hormone, and catecholamines. Progression of the disease leads to leukocyte aggregation with development of disseminated intravascular coagulation, vascular endothelial damage producing capillary leak with interstitial edema, and depression of myocardial function. Platelet aggregation results in the release of vasoactive substances. Pulmonary platelet aggregation has been suggested as the initiating event in the adult respiratory distress syndrome (ARDS). Myocardial depression increases capillary permeability, and impaired cellular function leads to the second phase of septic shock, a hypodynamic state in which unresponsive hypotension and death occur.

Treatment

Treatment is directed at supporting the patient and defining the source of infection so that it can be eliminated. *Initially, blood, urine, sputum, and wound drainage, if present, are sent for culture. IV administration of bactericidal antibiotics is begun immediately.* The choice of antibiotics is dictated by the suspected source of the sepsis. An aminoglycoside at full dosage is administered initially. Dosage level subsequently is adjusted to the renal function. If an intraabdominal source is suspected, anaerobic coverage is added: clindamycin, chloramphenicol, or metronidazole. If a pulmonary source seems likely, a cephalosporin is added; if the urinary tract is suspect, ampicillin is given. *Blood pressure is supported with crystalloid and/or colloid infusions, the rate dictated by the blood pressure, CVP or right atrial filling pressure, and urine output. Crystalloid resuscitation is begun, but if it is inadequate to return filling pressure to normal, colloid is added.* It has been suggested that colloid infusion results in less capillary leakage with less subsequent interstitial edema formation. Corticosteroid administration is generally not recommended, except for specific circumstances of adrenal insufficiency. Recent studies show no benefit to their administration (73,81). Indeed, their administration may even be harmful.

The use of antiendotoxin antibodies has improved survival in some studies. Gram-negative bacilli share a common core lipopolysaccharide. In a series in which antiserum to this antigen from human volunteers was given to septic patients, mortality was reduced by 50% (97). Most subsequent studies have not confirmed these findings (81). In select cases, continuous intraperitoneal lavage also may be helpful. This therapy is particularly amenable to patients who are septic as a result of pelvic inflammation and abscesses. Dialysis catheters placed into the depths of the pelvis and irrigated with saline and antibiotic solutions are particularly helpful in these patients (69).

If hypotension occurs after adequate fluid resuscitation or if it persists, blood pressure may be supported with dopamine. In addition to its inotropic effect, the advantage of dopamine over other agents is that it increases renal blood flow. However, dopamine increases intrapulmonary shunting; therefore dobutamine may be preferable in patients with pulmonary complications. Although dobutamine does support blood pressure, it does not improve renal blood flow. In dopamine-resistant situations, norepinephrine (Levarterenol) may be particularly effective because of both its a- and b-effects. However, neonates and young children have a diminished response to both dobutamine and dopamine and therefore epinephrine is more useful in the immediate resuscitative period (10). b-Endorphins released in response to the stress of shock may be partially responsible for the hypotension. It is clear that pituitary endorphins play a role in the pathophysiology of shock, but their exact role is somewhat controversial. The cardiodepressant effect of endorphins is mediated by opiate receptors in the CNS (29). Naloxone, an inhibitor of b-endorphin binding, may result in significant improvement in the blood pressure and reversal of myocardial depression (75). Others have found that naloxone administration is not associated with an improvement in blood pressure or survival (24). Thyrotropin-releasing hormone also has been used effectively in patients with persistent hypotension. This drug apparently acts centrally, as does naloxone, and like naloxone, it requires an intact sympathoadrenal-medullary axis to be effective. Thyrotropin-releasing hormone and naloxone have an additive effect (24). The prostaglandins PGI and thromboxane A_2 may mediate some of the cardiovascular changes in shock but are not solely responsible for myocardial depression (11). They contribute locally to vasodilation, and it has been found experimentally that blocking the vasoconstrictor thromboxane A_2 in animals improves survival (17).

Antitumor necrosis factor antibodies, anti–interleukin-1 antibodies, and other inhibitors of cytokines have been used with mixed results. Some of the cytokines appear to be protective and thus indiscriminate blockade can be detrimental (81). Other forms of therapy directed at specific pathophysiologic mechanisms such as antiendothelium–leukocyte adhesion antibodies have been developed and may have promise. At this time their clinical role is undefined.

When afterload or ventricular wall tension is increased, cardiac output may be limited. Afterload can be reduced by selective use of vasodilators. Phentolamine (Regitine), an a-blocker, dilates both veins and arteries. It is particularly useful in patients with increased sympathetic tone. Nitroprusside is a short-acting vasodilator whose predominant effect is on the smooth muscle of the arteries. It is an excellent agent for titrating blood pressure in the short-term situation. Nitroglycerin is particularly useful in patients with an associated ischemic myocardium because it improves collateral flow to the heart while dilating the peripheral vasculature.

Sinus rhythm is the most effective rhythm for optimum cardiac output. When supraventricular and ventricular arrhythmias occur in association with a diminished cardiac output, restoration of normal sinus rhythm may be all that is required.

VENOUS THROMBOEMBOLISM

Pelvic operations have a high propensity for thromboembolic disease. Its prevention in the urologic patient is of particular importance because many operations are performed in the pelvic area. Urologic patients are often placed in lithotomy position, which impairs venous return. Because most thrombi develop in venous plexus along the calf and usually begin during the operation, it is easy to appreciate the significance of impaired venous return that is promoted by positioning.

Risk factors that increase the likelihood of thromboembolic disease may be grouped into three categories: stasis, intimal injury, and hypercoagulability. Stasis includes immobility, congestive heart failure, obesity, and varicose veins. Intimal injury is manifested in vascular disease, previous thrombosis, trauma, and surgery. Hypercoagulable states are associated with advanced age, postoperative state, malignancy, and myocardial infarction.

The prevention of thromboembolic disease has been a subject of considerable controversy. Elevation of the foot of the bed, avoidance of extremity compression, early ambulation, physical therapy, and leg wraps all have been used in an effort to prevent the sequelae of thromboembolic disease. Unfortunately, none of these devices has been shown to be of particular efficacy in the prevention of the disorder. More recently, the development of an alternating pressure cuff on the lower extremities, which facilitates venous return, has been shown to be effective (82). Intermittent compression boots have undergone many modifications, the most recent of which is asymmetric compression rather than circumferential, with the intention of being more effective prophylaxis (which is unproven). The role of excellent nursing care is emphasized when one considers the improvement in venous flow as a function of the various methods advocated. Moving the legs is as effective in promoting venous return as any of the aforementioned methods.

In several studies, the use of mini-dose heparin, that is, 5,000 units administered subcutaneously every 12 hours, has been suggested to decrease the incidence of pulmonary emboli. One study found a substantial reduction in pulmonary emboli as diagnosed by routine postoperative scans (54). Other studies have failed to show any significant difference with and without the use of mini-dose heparin. It is clear, however, that in patients undergoing pelvic lymphadenectomy, administration of preoperative and postoperative mini-dose heparin results in a greatly increased incidence of lymphocele formation (53). Therefore, in urologic practice, prophylactic mini-dose heparinization in the preoperative and postoperative periods has not been successful; consequently, it rarely has been used. Low-dose warfarin therapy also has been used for prophylaxis of deep venous thrombosis. In one study, it was as effective as alternate compression stockings; complications were minimal (34).

Pulmonary emboli may occur silently and be an incidental finding on a chest roentgenogram, or they may suggest their presence by causing dyspnea; chest pain; hemoptysis; and rarely, when massive, circulatory collapse. On physical examination, the pulmonic portion of the second heart sound may be increased, a parasternal heave may occur, on occasion a friction rub can be heard, and the ECG often shows right-sided heart strain as evidenced by right-axis deviation. The chest radiograph, when positive, reveals a lucent area that lacks vascular markings. Later a wedge-shaped infiltrate develops. Pulmonary scans may be used to support the

diagnosis, but the definitive study is a pulmonary angiogram or magnetic resonance angiogram (MRA). Therapy is directed at identifying the source and treating it while administering anticoagulants to the patient, initially with a continuous heparin infusion. If the pulmonary embolus is large or saddle-type and is causing circulatory collapse that is unresponsive to supportive measures, a pulmonary embolectomy is indicated. In select circumstances, the use of thrombolytic therapy is most effective in dissolving emboli. Urokinase, streptokinase, and recombinant tissue plasminogen activator (rtPA) have all been used. Although rtPA results in a more rapid thrombolysis than the other two drugs, it has not shown increased efficacy, because at 24 hours, the resolution is similar no matter what agent is used (43). It should be noted, however, that in postoperative patients, vascular suture lines and puncture sites are likely to bleed with the use of these drugs. Because thrombolytic therapy increases the risk of hemorrhage without significantly affecting long-term outcome, it is useful in very limited circumstances, such as in nonoperative patients with renal artery emboli or massive pulmonary emboli.

Patients who have had a pulmonary embolus documented by one of the aforementioned studies or those in whom the clinical suspicion is high should be treated preferably by anticoagulation. Patients who have pulmonary emboli and are not treated have a 50% chance of another embolus—half of whom die from the event (48). Thus treatment should be instituted without delay. Heparin is the initial drug of choice. Low-molecular-weight heparin is as safe and effective as unfractionated heparin in preventing pulmonary emboli (23). The advantage of the former is that it can be given twice daily subcutaneously (57). The activated partial thromboplastin time (aPTT) should be kept between 2.0 and 3.0 times control [International Normalized Ratio (INR)]. After stabilization, the patient may be given warfarin and the heparin tapered. Following heparin therapy, oral anticoagulants should be administered according to the risk of recurrent pulmonary emboli. In patients who have an initial episode and no ongoing risk factors, 4 weeks of therapy is required. For those with continuing risk factors, at least 3 months of therapy is required (58). Thrombolytic therapy for acute deep venous thrombosis has been used in an attempt to reduce recurrent deep venous thrombosis and the postthrombotic syndrome. Generally, urokinase is given in repeated boluses. However, its usefulness may be limited because it may be successful only if the agent is infused directly into the thrombus, making it difficult to administer (42).

Vena Cava Filters

Anticoagulants are occasionally contraindicated, in which case a vena cava filter inserted percutaneously should be considered. Complications include malposition, migration, arrhythmia, wound infection, recurrent pulmonary emboli, and recurrent deep venous thrombosis (83). Rarely, a massive saddle pulmonary embolus may require a pulmonary embolectomy when the aforementioned measures are unsuccessful in maintaining the patient's blood pressure.

The efficacy of vena cava filters in patients who have thrombophlebitis and are at risk for pulmonary emboli has been evaluated in a large multiinstitutional study. The use of heparin alone or heparin plus a filter was compared in these patients. Those who had filters had a decreased occurrence of symptomatic and asymptomatic pulmonary emboli. However, no effect was observed in immediate or long-term mortality. Moreover, the initial beneficial affect of filters was offset by a significant increase in deep vein thrombosis—related to thrombosis at the filter site (23).

RESPIRATORY DYSFUNCTION

Respiratory Insufficiency

Inadequate ventilation in the posttraumatic and postoperative periods results in hypercapnia, hypoxemia, or both. The primary goal of therapy is to provide the patient with the capability of maintaining an arterial oxygen partial pressure of at least 60 mm Hg on an inspired oxygen content as close to room air as possible. To achieve this goal, oxygen delivered by nasal prongs, rebreathing mask, a face mask, or an endotracheal tube with respiratory support may be required. However, there are constraints to the amount of oxygen that can be delivered. Limitation of the amount may be a consequence of the device used for delivery, but more commonly, the amount that can be safely delivered is limited by the fact that inhalation of high oxygen concentrations results in pulmonary toxicity. The hazards of high concentrations include suppression of the respiratory drive in patients with chronic pulmonary disease, retrolental fibroplasia (primarily a disease of the newborn but also described in adults), segmental atelectasis caused by the greater solubility of oxygen compared with nitrogen, impairment of respiratory ciliary function, a decrease in pulmonary surfactant, and direct injury to capillary endothelial cells.

The $Paco_2$, which is normally 40 mm Hg, is a primary indication of the adequacy of ventilation. Common causes of hypercapnia include obstructive pulmonary disease, ARDS, metabolic alkalosis, and respiratory depression resulting from sedation or CNS trauma. Hypocapnia may be a result of hypoxia, anxiety, pulmonary embolism, sepsis, and pulmonary insufficiency. Although an indicator of ventilatory adequacy, alteration of P_{co_2} is rarely an indication for respiratory support. Of more importance is the partial pressure of oxygen (Po_2), which should be maintained above 60 mm Hg. A Po_2 less than 60 mm Hg requires a change in respiratory management. A normal Po_2 for a particular patient breathing room air before injury may be estimated by subtracting half the individual's age from 100. If impending airway obstruction is not a problem, initial support of the Po_2 may be obtained by the use of nasal prongs or face masks. Humidified oxygen should be used when possible to prevent drying the nasotracheal mucosa. Oxygen delivered by nasal prongs generally cannot provide an inspired concentration much above 50%. Even though humidified, high-flows have a drying effect on the mucosa; Venturi masks provide constant flows of oxygen ranging between 24% and 40%, depending on the mask. Partial rebreathing masks can deliver in excess of 80% oxygen; however, humidity cannot be added to the system.

On occasion, posttraumatic patients require endotracheal intubation, preferably by the nasotracheal route with a prestretched low-pressure cuff and respiratory support (Table 10.9). Indications for intubation include (a) the facilitation of pulmonary toilet, (b) the prevention of upper airway occlusion, (c) protection against aspiration, and (d) the need for mechanical ventilation. The requirement for mechanical ventilation is assessed by vital capacity, inspiratory force, respiratory rate, arterial oxygen content, and work of breathing. Vital capacity, or the volume of a maximum inspiration after a maximum expiration, is normally 60 to 70 mL/kg body weight. If it is less than 15 mL/kg, ventilatory support is indicated. *The inspiratory force, or amount of pressure that the patient is able to generate against a closed airway, is normally -75 to -100 cm H_2O. Patients who can achieve no more than -25 cm H_2O require mechanical support.* The normal respiratory rate is 12 to 20 breaths per minute. A rate that exceeds 35 breaths per minute suggests the need for ventilatory assistance. The arterial oxygen partial pressure should exceed 60 mm Hg. If this cannot be accomplished by raising the oxygen content of inspired air through the use of face masks and nasal prongs, intubation should be performed. Severe intercostal retractions and a tracheal tug indicate an increased work of breathing and are forerunners of respiratory insufficiency. Initially, the respirator is adjusted to deliver 12 to 15 mL/kg of body weight at a frequency of 8 to 14 times per minute for the adult and 15 to 30 times per minute for the child. Inspired oxygen content (Fio_2) should be the lowest needed to maintain the Po_2 above 60 mm Hg (an Fio_2 of 40% is a good level to begin with, adjusting it as required). Not only must blood gas levels be monitored, adjusting the respirator accordingly, but also the circulatory status must be carefully followed, because occasionally institution of mechanical ventilation will cause a decrease in the cardiac output with lowering of the blood pressure.

Facilitation of pulmonary toilet
Prevention of upper airway occlusion
Protection against aspiration
Need for mechanical ventilation as determined by the following:
1. VC <15 mL/kg body weight
2. Inspiratory force <–25 cm H_2O
3. Respiratory rate >35 breaths/min
4. Po_2 <60 mm Hg despite high ambient O_2 concentration
5. Excessive, prolonged increase in the work of breathing

VC, vital capacity.

TABLE 10.9. INDICATIONS FOR ENDOTRACHEAL INTUBATION

When the Po_2 cannot be maintained by an acceptable Fio_2 (less than 60%), the addition of positive end-expiratory pressure (PEEP) may be helpful. This technique maintains a specified pressure at the end of each respiration rather than allowing end-expiratory pressure to fall to zero. It is particularly useful in ARDS. Initially, 5 cm H_2O pressure is used. If the desired response is not achieved, it is increased in increments of 5 cm H_2O, carefully monitoring the blood pressure for signs of a significant reduction in cardiac output. Usually, no more than 15 cm H_2O is required. On rare occasions, however, as much as 25 cm H_2O pressure may be needed. With the use of PEEP, Po_2 can be maintained at acceptable levels with reduced Fio_2. Other advantages include a decrease in pulmonary shunting and an increase in

functional residual capacity. A proposed advantage is that it drives pulmonary edema fluid from the alveoli and the interstitium into the pulmonary capillaries. Its major disadvantages are a reduction in cardiac output and a diminished urine output. The latter effect is perhaps the result of an increased release of ADH.

One method of anticipating future respiratory difficulties and determining how the patient is progressing on the respirator is by sequentially determining the arterial oxygen gradient, $P(A\text{-}a)o_2$. This gradient is a sensitive indicator of early respiratory impairment. To calculate the $P(A\text{-}a)\ o_2$, the patient receives 100% oxygen for 20 to 30 minutes, arterial blood gases are drawn, and the barometric pressure is recorded. The calculation is as follows: barometric pressure minus water vapor pressure (47 mm Hg) minus the partial pressure of alveolar CO_2. Because alveolar CO_2 rapidly equilibrates with arterial CO_2, the Pco_2 obtained from the blood gas analysis may be substituted. This quantity minus the Po_2 is equal to the arterial alveolar oxygen gradient.

Acute posttraumatic pulmonary insufficiency occurs after major trauma, burns, hypoproteinemia, or inadequate fluid resuscitation during shock, severe sepsis, pancreatitis, or transplant rejection crisis (antigen–antibody reaction). The cause of ARDS is unclear. It appears that neutrophils contribute because the lungs of patients with ARDS are populated by large numbers of them. They release oxygen-free radicals and elastase, two substances that injure tissues. Macrophages release oxygen-free radicals, proteases, prostaglandins, leukotrienes, and cytokines and also have been implicated. Moreover, the cytokine tumor necrosis factor has been shown to play a role experimentally. Finally, defects in surfactant may be etiologic or merely perpetuate the disease (77).

After the initiating event, platelet microaggregates form in the pulmonary capillaries and injure the alveolar capillary endothelium. Vasoactive substances are released, resulting in increased capillary permeability (6). Peribronchiolar edema follows, which causes an increase in small airway resistance and a reduction in pulmonary compliance, making aeration of the lungs difficult. Pulmonary shunting also occurs. The Po_2 falls and the Pco_2 rises, often despite increases in the Fio_2. Clinically, the patient becomes dyspneic, tachypneic, and hypoxemic. Functional residual capacity and lung compliance are reduced, and bilateral pulmonary infiltrates are often present on the chest film. The syndrome should be suspected in the septic or traumatized patient when the Po_2 falls despite efforts to increase the Fio_2.

Treatment involves nasotracheal intubation and mechanical ventilation. PEEP is often necessary. If PEEP results in a reduced cardiac output, inotropic agents may be required to return blood pressure to acceptable levels. The use of colloid to increase intravascular oncotic pressure and thereby draw fluid from the pulmonary perivascular space into the capillaries is controversial, as is the use of steroids. Prophylactic antibiotics administered either by the parenteral route or by inhalation have little to recommend them. Infections are treated when they occur with the antibiotic to which the bacteria are sensitive. Unfortunately, none of the newer pharmacologic therapies has produced impressive results. Methylprednisolone, prostaglandin E, and *N*-acetylcysteine have not been shown convincingly to lessen mortality.

RENAL INJURIES

JACK W. McANINCH
RICHARD A. SANTUCCI

J.W. McAninch and R.A. Santucci: Department of Urology, Wayne State University, Detroit, MI 48201.

Mode of Injury and Presentation
Hematuria
Classification of Renal Injuries
Staging and Assessment of Injury
Computed Tomography
Intravenous Pyelography
Angiography
Other Imaging Techniques
Indications for Operation
Blunt Trauma
Penetrating Trauma
Vascular Injury
Retroperitoneal Hematoma
Operative Exploration and Renal Exposure
Operative Findings and Renal Reconstruction
Parenchymal Injuries
Venous Injuries
Renal Artery Occlusion
Renal Artery Laceration
Renal Pedicle Avulsion
Postoperative Care and Follow-Up
Complications
Chapter References

Trauma is the leading cause of death for persons between 1 and 44 years of age. In addition, each year, millions of dollars are spent to rehabilitate trauma victims. The team approach to management provides the highest level of expertise in reducing morbidity and preventing mortality. The trauma surgeon relies on the urologic surgeon to deal with the complex injuries of the urogenital system. The urologic surgeon may not become involved in the initial resuscitation phases of trauma care because most injuries to the urogenital system are not life-threatening; however, he or she may become the most important member of the team 2 weeks later when urinary extravasation, abscess formation, and septic complications develop secondarily.

The kidney is the most commonly injured organ in the urogenital system (61), and renal injuries are still subject to controversy in diagnosis and management. Despite the current refined approach, many questions remain unanswered regarding when and for what patients a study should be done to evaluate a renal injury. Even when the diagnosis has been established, there is great controversy over operative versus nonoperative management. The urologic and surgical literature is replete with articles debating the merits of the respective approaches (18,22,80). No simple answers exist. One must review the literature critically and become familiar with the variety of approaches in renal trauma care to apply this information to an individual patient.

The following quotation from Erickson's 1860 *Textbook of Surgery* indicates the importance of careful clinical evaluation in patients with major renal injuries:

> If the kidneys are injured, the patient will commonly experience a frequent desire to pass water, and this will be tinged with blood, often to a considerable extent. The absence of blood in the urine must not, however, be taken as an indication that the kidney is not injured; it may be so disorganized as to be totally incapable of secreting, and subsequently no bloody urine finds its way into the bladder. A man was admitted into the hospital under my care for a buffer injury of the back; he passed water untinged with blood, but after death his right kidney was found completely smashed by the blow, with an extensive extravasation of blood in the celluloadipose tissue around it. Here it was evident that the disorganization was so sudden and complete that no bloody urine had found its way into the bladder.

This clinical picture continues to be reported today.

Approximately 8% to 10% of blunt and penetrating abdominal injuries involve the kidneys. In rural settings, blunt trauma accounts for the largest percentage of renal injuries (90% to 95%) (52); in urban settings, the percentage of penetrating renal injuries increases to 20% (85).

This chapter is intended to provide a logical diagnostic approach to the patient with renal injury and to establish a rationale for management that will ultimately preserve the largest amount of functioning renal tissue, while safely managing the patient's other injuries.

MODE OF INJURY AND PRESENTATION

The mechanism of injury to the kidney is broadly classified as blunt or penetrating. Blunt trauma is more common in most centers, accounting for 80% to 90% of injuries, and results from automobile accidents, auto–pedestrian accidents, falls, contact sports, and assaults (1,2,17,47,59). Gunshot and stab wounds cause 10% to 20% of renal injuries and represent the most common causes of penetrating injury. In 1968, Carlton and co-workers (12) reported associated intraabdominal injuries in 80% of their patients with penetrating renal injury. This observation was supported by Sagalowsky and colleagues (85): Of 122 patients with gunshot wounds, all had associated intraabdominal injury. Liver, small intestine, stomach, and colon were the most commonly injured organs. Stab wounds less frequently have associated intraabdominal injury, with reports ranging from 30% to 70% (42,85). This wide variation may be based on the location of the stab wound. Bernath and others (5) noted that stab wounds posterior to the anterior axillary line were associated with intraabdominal injury in fewer than 12% of cases.

Renal injuries from blunt trauma occur consequent to upper abdominal injury and rapid deceleration. Gross or microscopic hematuria is usually present (8,70). These patients often have profuse abdominal tenderness, lower rib fractures, vertebral body fractures, and flank contusions. A palpable abdominal mass with associated shock may be indicative of a rapidly developing retroperitoneal hematoma from a major renal parenchymal or renal vascular injury. Rapid-deceleration injuries usually involve multiple organ systems, and patients are often unconscious and in shock. Head-on automobile collisions and falls from great heights account for the majority of such injuries. Multiple bony fractures usually are present, as are injuries to the abdominal viscera, vascular system, chest, and head. The renal injury seen in such cases is often a renal pedicle avulsion or acute thrombosis of the main renal artery or one of the segmental arterial branches. Hematuria may not be present, and the diagnosis must be established by radiographic imaging prompted by a high index of suspicion (38,91).

Stab wounds to the kidneys generally have their entrance points in the lower thorax, flank area, or upper abdomen. The size of the entrance wound has little correlation with the extent of injury and the depth of penetration. Hematuria, most often gross, is usually present with major parenchymal injuries. The incidence of associated intraabdominal injuries varies greatly and may be related to the entrance site (5). Careful abdominal examination may reveal marked tenderness and generalized rigidity, indicating bowel perforation. Peritoneal lavage is useful for evaluating intraabdominal injury after stab wounds to the torso (27). Hemorrhagic shock is a common presenting sign, and reestablishment of circulatory volume is of prime importance in the initial treatment. Renal imaging should be done in all patients with stab wounds in the upper abdomen, flank, back, or lower chest, whether hematuria is present or not.

Patients with gunshot wounds to the torso that penetrate the kidney often are in a state of hemorrhagic shock with multiple organ injury. Rapid resuscitation is of prime importance, and immediate surgery may be required before diagnostic studies can be performed. The type of weapon—and of the bullet if known—should be ascertained, but the prevailing wisdom is to “treat the wound and not the weapon” (56). The damage that a missile can inflict is related to the kinetic energy expended,

determined from the following formula:

$$KE = \frac{MV^2}{2}$$

where *KE* is kinetic energy, *M* is the mass of the missile, and *V* is the muzzle velocity of the weapon.

In general, the higher the muzzle velocity, the greater the tissue damage, although experimentally the actual wounding effect varies from MV1.5 to MV2.5 (56). Figure 11A.1 demonstrates the method by which bullets of high velocity cause extensive tissue damage: On entering the soft tissue of the body, the bullet creates a temporary pulsatile cavity that can be up to 40 times wider than the diameter of the bullet; a small permanent core of tissue is vaporized; and finally the bullet can tumble or fragment, further widening the area of tissue damage (21). [Many high-velocity projectiles such as the M-16 yaw after penetrating some distance into tissue, causing an enlarged permanent cavity from bullet tumbling (33).] Temporary cavitation and vaporization can cause extensive damage (the “blast effect”), which may not be appreciated at operation. However, experts point out that the relationship between the volume of the temporary cavity and tissue damage is not absolute and that many so-called high-velocity wounds from assault weapons can leave a clean track with little devitalization (33). Intensive debridement may be required to remove the nonviable tissue created by such injuries, but some researchers have suggested that only a few millimeters of debridement may be required in cases of gunshot through muscle, whereas more extensive tissue excision may be needed in solid organs like the kidney and liver (56). This is borne out in analysis of gunshot wounds to the kidney: Injuries from high-velocity weapons require nephrectomy more often than those from low-velocity weapons (31).

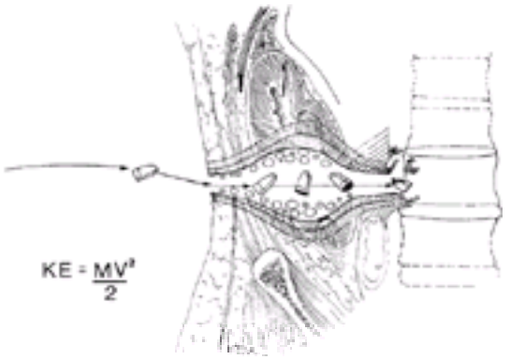

FIGURE 11A.1. Dynamics of missile soft tissue injury. (From McAninch JW. Renal injuries. In: McAninch JW, guest ed. *Urogenital trauma,* vol 2 of Blaisdell WF, Trunkey DD, series eds. *Trauma management*. New York: Thieme Stratton, 1985a:27–49, with permission.)

Most common handguns and many rifles are low-velocity weapons (muzzle velocity of less than 2,000 feet per second), and less extensive debridement may be needed. However, these weapons can cause extensive damage via a number of mechanisms, such as unintentional and intentional bullet fragmentation (34). Increasingly, specialty ammunition is available that is designed to maximize tissue damage after impact, by either intentional fragmentation (Dum-Dum, Devastator, exploding, and other “frangible” ammunition) or an increase in projectile diameter by flattening (hollow-point bullets). The effect of this specialty ammunition, in some cases, is that lower velocity missiles, as from a common handgun, can rival the tissue damage caused even by high-velocity rifles (93). Table 11A.1 lists muzzle velocities of common weapons.

Weapon	Velocity (ft/sec)
0.22 short	1,045
0.22 magnum	2,000
0.38 caliber	1,330
0.45 caliber	1,320
AK-47	1,950
Carbine (0.30 caliber)	1,970
7.62 mm (M-14)	2,400–2,800
5.56 mm (M-16)	3,250

TABLE 11A.1. MUZZLE VELOCITY OF COMMON WEAPONS

HEMATURIA

The presence of blood in the urine is usually the first indicator of renal injury. In most reported series, more than 95% of patients had microscopic or gross hematuria (8,78,82,87,99). However, Bright and co-workers (8) first noted that the degree of hematuria does not correlate with the severity of injury. For example, a renal contusion is diagnosed in a patient with gross hematuria after blunt abdominal trauma, but results on excretory urography are normal. A patient with microscopic hematuria after a rapid-deceleration injury may demonstrate a major renal vascular injury. Guerriero and associates (38) noted gross hematuria in only 10 of 33 patients with renal vascular injuries, and Stables and colleagues (91) found no hematuria in 24% of patients with traumatic renal artery occlusion. In our recent series of 113 grade IV renal injuries, gross hematuria was noted in only 63%, and even microhematuria was absent in 4% (86). All series note the importance of hematuria as an indicator of injury but emphasize that it is a nonspecific finding and does not correlate with the seriousness of the renal damage.

The patient should be evaluated in the emergency room and urine should be obtained for study. Unconscious patients with serious injuries should be catheterized for dipstick urinalysis. If the results are positive, a finding of more than 5 red blood cells per high-power field (RBCs/HPF) would be expected (20). When time permits, microscopic urinary examination should be done.

Nicolaisen and colleagues (78) noted that adult patients sustaining blunt trauma had significant renal injury (defined as minor or major lacerations and vascular injuries) in the presence of gross hematuria or shock (systolic blood pressure less than 90 mm Hg) with microscopic hematuria. Mee and associates (70) subsequently reported a 10-year prospective study of patient selection for radiographic assessment after renal injury. The study included 1,146 patients (1,007 with blunt trauma and 139 with penetrating trauma). Significant injuries were found in 44 patients (4.4%) with blunt trauma, each of whom had either gross hematuria or microscopic hematuria associated with shock. Microscopic hematuria without shock was present in 812 patients with blunt trauma in whom there was no evidence of significant renal injury. Hardeman and associates (41) had similar findings.

Shock is defined as a systolic blood pressure less than 90 mm Hg, and any one measurement at or below this level from the time of evaluation by paramedics in the field satisfies this criterion. This requires careful inspection of paramedic and emergency room records before the determination is made that radiographic assessment is not indicated.

On the basis of available data, the following recommendations apply to the adult patient with blunt trauma: In the presence of gross hematuria or microscopic hematuria associated with shock, radiographic assessment should be done; patients with microscopic hematuria without shock do not require radiographic assessment. However, if physical examination or associated injuries prompt reasonable suspicion of a renal injury, renal imaging should be undertaken. This is especially true for patients with rapid-deceleration injuries, although in the studies of Mee and associates (70) and Hardeman and associates (41) vascular injuries were not missed when the preceding criteria were used.

Renal imaging is required in all patients with microscopic (more than 5 RBCs/HPF) or gross hematuria sustaining penetrating trauma or in pediatric patients. None of the previously mentioned studies found criteria to select patients for imaging who were in the pediatric age group or had penetrating injury.

CLASSIFICATION OF RENAL INJURIES

Categorizing renal injuries according to severity helps in selecting appropriate therapy and predicting results of treatment. Renal injuries can be classified according to the American Association for Surgery of Trauma (75) into five large groups: (a) renal contusions—bruises or subcapsular hematomas associated with an intact renal capsule and collecting system; (b) minor lacerations—superficial cortical disruptions less than 1.0 cm in depth that do not involve the deep renal medulla or collecting system; (c) parenchymal lacerations greater than 1.0 cm in depth without collecting system rupture or urinary extravasation; (d) parenchymal laceration extending through the renal cortex, medulla, and collecting system; or main renal artery or vein injury with contained hemorrhage; and (e) completely shattered kidney or avulsion of main renal artery or vein that devascularizes the kidney (Fig. 11A.2).

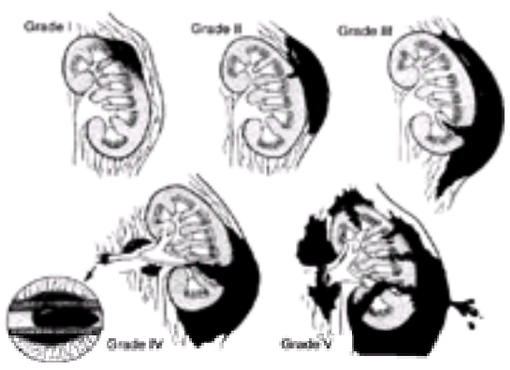

FIGURE 11A.2. Artist's rendition of the Renal Injury Severity Scale of the American Association for the Surgery of Trauma (AAST). Note that grade IV injuries represent parenchymal lacerations extending into the collecting system and injury to the main renal artery or vein with contained hemorrhage. These vascular injuries include traumatic renal artery thrombosis *(inset).* (From Moore EE, et al. Organ injury scaling: spleen, liver, and kidney. *J Trauma* 1989;29:1664, with permission.)

Vascular injuries and major and minor lacerations constitute significant trauma. These patients should have complete radiographic assessment to determine the full extent of injury and select appropriate management. Categorization does not mandate operation, but it does aid the surgeon in directing the care of these patients. Review of more than 2,500 renal injuries indicates, for instance, that no grade I injuries require operative repair, while nearly 100% of grade V injuries require speedy nephrectomy or repair (87). Those in between (grades II to IV) require individualized therapy, with a general trend for more serious intervention (renorrhaphy or nephrectomy) as the grade increases (Fig. 11A.3).

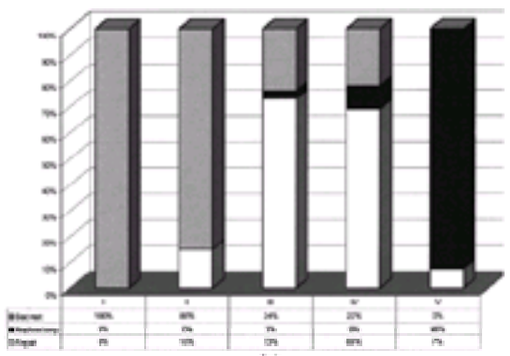

FIGURE 11A.3. Injury scale and treatment of renal injury in 2,500 patients with renal trauma. (From Santucci RA, Mario LA, Segal MR, et al. Classification trees are highly predictive of need for surgery in renal trauma patients. *J Urol* 2000;163[Suppl]:4, with permission.)

STAGING AND ASSESSMENT OF INJURY

Staging is the orderly process by which a renal injury is completely defined by history, physical examination, and radiographic or other imaging techniques. For instance, for a patient with blunt trauma from an automobile accident who has gross hematuria, and in whom renal imaging shows the kidneys to be normal, the injury is categorized as a renal contusion, and no additional studies are necessary. However, if the results of renal imaging are indeterminate or abnormal, additional information will be needed to complete the staging and document the full extent of the injury. Increasing use of computed tomography (CT) scanning has allowed more accurate determination of injury severity than has been available in the past (7,66).

History, physical examination, and the determination of hematuria are the initial evaluative measures. The presence of gross or microscopic hematuria (more than 5 RBCs/HPF) continues to be the best indicator of injury. All patients sustaining penetrating trauma or pediatric patients with positive findings should have radiographic staging. Adult patients with blunt trauma can be selectively imaged. Figure 11A.4 shows a staging algorithm that is a useful systematic approach for renal trauma patients. Patients with gross hematuria or microscopic hematuria associated with shock (systolic blood pressure less than 90 mm Hg) should have radiographic staging studies. If physical examination or extensive associated injuries suggest renal injury, staging studies should be done.

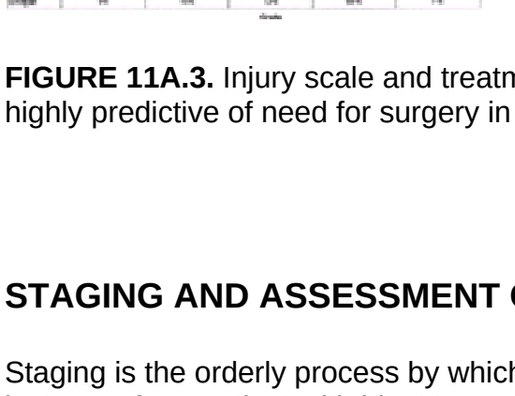

FIGURE 11A.4. Algorithm for the approach to the initial diagnosis and management of renal trauma. CT, computed tomography; IVP, intravenous pyelogram. (Modified from Meng MV, Brandes SB, McAninch JW. Renal trauma: indications and techniques for surgical exploration. *World J Urol* 1999;17:71, with permission.)

Computed Tomography

We aggressively pursue CT scanning in all patients stable enough to allow it (7). Because modern helical CT scanners can produce images before intravenous

contrast is excreted in the urine, we obtain delayed scans (5 to 20 minutes after contrast injection) in all cases of suspected renal injury to allow contrast material to extravasate from the injured collecting system, renal pelvis, or ureter (10,49). For staging renal injuries, CT has several advantages: noninvasiveness, clear delineation of parenchymal lacerations, sensitive detection of urinary extravasation, outlining of nonviable tissue, definition of the extent and size of the surrounding hematoma, detection of associated injury, and provision of three-dimensional views of the kidney and retroperitoneum. CT also has been useful in detecting arterial injury to the kidney (83,92).

In 85 patients in whom incomplete visualization on excretory urography or nephrotomography prompted suspicion of major renal injury (Table 11A.2), CT clearly differentiated major lacerations and detected extravasation more sensitively than excretory urography (Fig. 11A.5 and Fig. 11A.6) (7,32). As a result, CT enabled proper management in all instances. Fifty-two patients were managed nonoperatively, and thirty-three underwent surgery. The renal findings at operation confirmed the observations on CT in all surgical cases. In addition, CT detected major injuries to the liver, spleen, and bowel in seventeen patients.

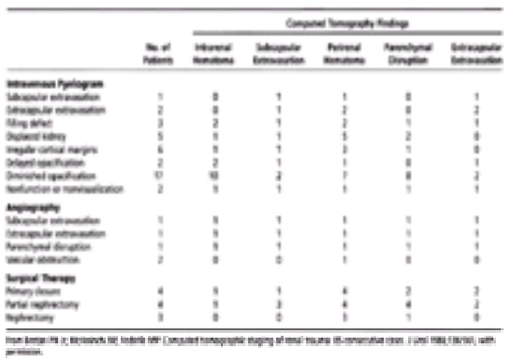

TABLE 11A.2. COMPUTED TOMOGRAPHY IN 85 PATIENTS WITH SUSPECTED MAJOR RENAL TRAUMA

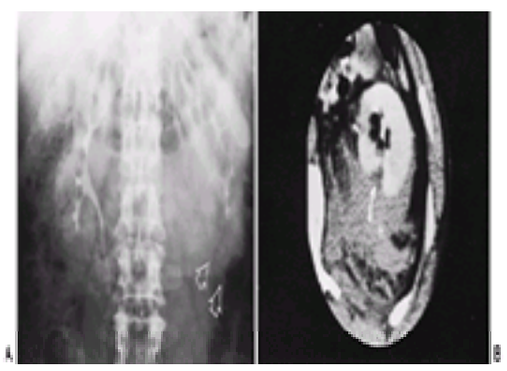

FIGURE 11A.5. Excretory urogram in a young man with abdominal pain and gross hematuria after blunt trauma reveals poor visualization of the lower pole of the left kidney and lateral deviation *(arrows).* **B:** Computed tomography scan shows retroperitoneal hematoma *(H)* and a minor laceration of the renal parenchyma *(arrow).* Nonoperative management was successful.

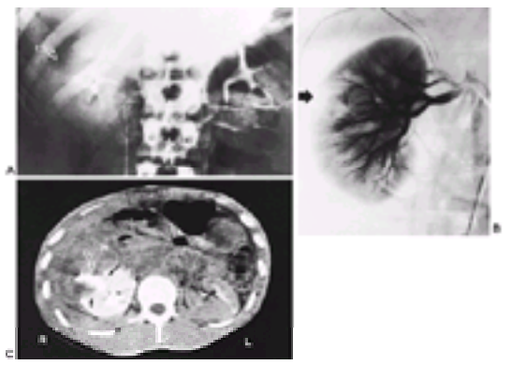

FIGURE 11A.6. Excretory urogram in a patient with a right flank stab wound and microscopic hematuria suggests a defect in the upper lateral border of the right renal parenchyma *(arrow).* **B**: Arteriography shows a minimum defect in the renal cortex *(arrow)* and no extravasation. **C:** Computed tomography scan reveals a large right renal laceration *(black arrows)* with extensive extravasation of opacified urine *(white arrow).* A large retroperitoneal hematoma is also noted *(H).* Operative repair resulted in renal salvage.

CT can indirectly detect major vascular injuries (79) and segmental artery injuries. In the patient shown in Fig. 11A.6, in whom excretory urography failed to visualize the kidney after a rapid-deceleration injury, CT demonstrated a nonenhancing soft tissue shadow of a normal-sized kidney on the involved side. One can use angiography to confirm the diagnosis. The major limitation of CT is the lack of detection of venous injuries to the main renal vein or its segmental branches.

Recent innovations in CT technology have shown potential for further improvement in diagnostic accuracy. Techniques such as calculating the volume of perirenal hematoma with CT, then roughly calculating the rate of renal blood loss, have improved the scan's accuracy in small studies (95). The feasibility of using three-dimensional CT reconstruction of renal injuries has also been demonstrated in a small number of patients (73). Although this appears to be a promising enhancement of standard CT, larger studies are required to determine whether it will improve the utility of standard CT imaging enough to enjoy wide use.

Intravenous Pyelography

In patients without a preoperative abdominal CT scan, an intraoperative “one-shot” intravenous pyelogram (IVP) is obtained. This requires 2 mg/kg of intravenous contrast (hypaque sodium 50% [Diatrizoate], Nycomed) given 10 minutes before a plain abdominal film is exposed (76). Standard IVP with multiple images, as would be done to evaluate nontraumatic upper tract disease, is not done. Intraoperative IVP can usually be performed with minimal disruption to the surgical team's efforts to stabilize the patient and is used not only to identify injuries, but also to confirm a functional renal unit on the uninjured side and to determine the presence of urinary extravasation, which can be difficult to detect intraoperatively. It also can exclude the need for renal surgery if findings are absolutely normal and there is only a nonpulsatile/nonexpanding hematoma (i.e., no absolute indication for exploration).

At our institution, intraoperative IVP has safely obviated renal exploration in 32% of patients (76). Although it can at times be insensitive for parenchymal injury, IVP is highly specific for urinary extravasation (14), and some reports have in fact shown it to be highly accurate in staging renal trauma (25,29,53).

Angiography

In the past, arteriography was the definitive study for staging major renal injuries. With the advent of CT, arteriography has been supplanted. However, it can still provide adequate information for management (54,102). It defines parenchymal lacerations and vascular injuries and is recommended when CT is unavailable. The most common indication for arteriography is nonvisualization of a kidney on excretory urography after major blunt abdominal trauma. Several causes for

nonvisualization exist and should be considered: total avulsion of the renal artery and vein; renal artery thrombosis; absence of the kidney, either congenital or from surgical removal; and severe contusion causing major vascular spasm. Either digital subtraction arteriography or conventional arteriography may be used to evaluate vascular injuries. CT can detect vascular injuries (19), but arteriography gives more detailed information and defines the exact anatomic area of vascular injury.

When injuries to the segmental veins, main renal vein, and vena cava are suspected, venography can be used if the patient is stable enough (81). In these injuries, immediate operative intervention may be required to control bleeding and maintain the patient's hemodynamic stability.

Other Imaging Techniques

Although sonography has been used to evaluate and stage renal injuries (4,50,88), it provides less information than CT or arteriography and is unlikely ever to rival the near-100% accuracy of CT. Sonography can detect renal lacerations, but it cannot definitively assess their depth and extent and in one recent study performed very poorly: Experienced sonographers missed renal injuries 78% of the time (69). Furthermore, it cannot accurately detect vascular injuries. Sonographic techniques are improving, however, and it is possible that future use of newer ultrasound modes or contrast agents might improve diagnostic accuracy (44).

The use of radionuclide scanning has been limited. In 24 patients, Chopp and associates (23) combined this method with high-dose excretory urography and found that the number of arteriograms required for further staging was significantly reduced. This technique appears to provide less information than arteriography or CT (35,101).

Retrograde pyelography is of little benefit in evaluating renal injuries but is most useful in detecting associated ureteral or renal pelvic disruptions and perforations (71).

Although CT is still the imaging mode of choice, magnetic resonance imaging (MRI) may play a complementary role in the evaluation of renal trauma. MRI can be used in cases of severe CT contrast allergy, renal insufficiency when intravenous contrast cannot be given, and when CT scan is unavailable (55).

With an orderly approach to the staging of renal trauma, the full extent of the injury can be defined to allow intelligent and accurate management decisions. The ultimate goal of completed staging is to provide sufficient information for management that results in the preservation of renal parenchyma and the salvage of injured kidneys.

INDICATIONS FOR OPERATION

Blunt Trauma

The indications for operative intervention after renal injury vary greatly from one center to another. Blunt traumatic injuries create the most controversy. Contusions, corresponding to grade I injuries, represent 85% to 90% of blunt renal injuries, and in general, series results indicate that they can be managed nonoperatively. The remaining 10% to 15% of blunt injuries constitute minor and major lacerations and vascular injuries, which correspond to grades II to V. Most vascular injuries, when recognized early, call for operation and reconstruction when possible. Need for renorrhaphy or nephrectomy in our last 2,500 renal injury patients is documented in Fig. 11A.7. Management of minor and major lacerations, however, is highly variable. Peterson (80) suggests avoiding renal operation unless bleeding is life-threatening; in most cases, when an operation is required, a nephrectomy should be performed. Cass (17) takes the opposite view and recommends immediate surgical management of major lacerations with or without extravasation. It is difficult to assess individual series because no group has directly compared operative and nonoperative management in a controlled fashion at one institution. The lack of a uniform classification system also makes comparison between series extremely difficult, although more uniform use of the AAST organ injury severity scale should obviate this problem.

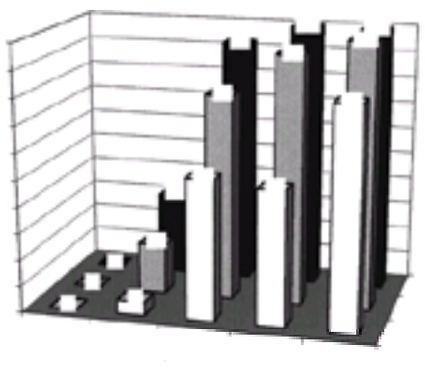

FIGURE 11A.7. The need for renal repair or nephrectomy classified by injury severity (AAST scale) and mechanism of injury (blunt trauma, stab wound, gunshot wound) for 2,500 renal injury patients.

Selecting the patient in whom complications are unlikely to develop with nonoperative management is difficult. Delayed bleeding, persistent extravasation with hematoma, and the potential for infection cause concern. Carlton (11) reported that, in his experience, 90% of the complications from expectant treatment occurred in the 10% to 15% of patients with blunt injuries more serious than contusions. Three studies in which nonoperative management was attempted for major renal injuries reported a threefold increase in complications over prompt operative management (46,53,100). Others have noted that when delayed operation is required to manage a complication, total nephrectomy commonly results (45,47).

We take an aggressive approach to staging the injury and thereby obtain adequate information to select the appropriate management, whether it is operative or nonoperative.

Indications for surgical exploration of the kidney can be categorized as absolute and relative. Absolute indications include expanding or uncontained hematoma and pulsatile hematoma, which might indicate the presence of grade V injury. Relative indications include urinary extravasation, vascular injury, nonviable parenchyma, and incomplete staging. When the degree of urinary extravasation is minor, operation is not required, assuming that no other indication necessitates surgical intervention. Nonviable parenchyma secondary to segmental artery thrombosis without a parenchymal laceration can be followed expectantly with little risk of untoward problems. However, the patient with nonviable tissue involving 20% or more of the kidney in association with a deep parenchymal laceration should have renal exploration and repair to prevent delayed complications. The incompletely staged patient, perhaps already undergoing abdominal exploration for associated injuries, should have renal exploration and repair if necessary (64,68).

In a series of 1,193 patients with blunt renal trauma (68), the preceding indications mandated renal exploration in 31 (2.5%) (Table 11A.3). This experience indicates the high renal salvage rate (87%) that can be achieved in patients who require renal exploration after blunt trauma. With these indications and improved staging techniques, only approximately 2.5% of patients with blunt renal trauma now require renal exploration at our trauma center.

Type of Injury	No. of Operations		
	Repair	Nephrectomy	Total Operations
Blunt (1,193 patients)	27	4	31 (2.5%)
Stab wounds (106 patients)	45	4	49 (45%)
Gunshot wounds	46	7	53 (80%)

TABLE 11A.3. RENAL INJURIES AT SAN FRANCISCO GENERAL HOSPITAL

Penetrating Trauma

Most penetrating renal injuries require operative exploration. Only when preoperative staging clearly indicates that the extent of injury is minor can a nonoperative approach be used successfully. Approximately 70% of patients with penetrating renal injuries at San Francisco General Hospital require operative renal intervention (Table 11A.3). The indications for operative exploration are the same as those listed earlier when careful preoperative staging has been accomplished. Recently, Carroll and McAninch (14) reported that CT provided accurate preoperative assessment in 11 patients with penetrating renal injury and allowed nonoperative management in 8 patients. Associated intraabdominal injuries occur in 80% of patients with penetrating renal injury, and these patients often require immediate surgical intervention with no time allowed for careful preoperative staging (Table 11A.4). In such circumstances, bleeding and life-threatening conditions should be controlled in the operating room, and a “one-shot” excretory urogram should be obtained on the operating table to make certain that at least one normally functioning kidney is present and to gain information regarding the potentially injured kidney. If findings on excretory urography are abnormal, exploration of the ipsilateral kidney should be performed. This careful, selective approach to penetrating renal injuries has not resulted in delayed renal operation at our institution.

Site of Injury	Number of Patients
Liver	36
Spleen	29
Small bowel	28
Colon	27
Mesentery	20

TABLE 11A.4. ASSOCIATED ABDOMINAL INJURIES NOTED IN 109 OF 127 PATIENTS

Bernath and colleagues (5) and Heyns (42) advocate a nonoperative approach for stab wounds. From their data, it appears that when the entrance site is dorsal to the posterior axillary line, the incidence of associated abdominal injury requiring renal exploration is low.

Heyns and van Vollenhoven (43) have unsuccessfully shown that angiography with selective arterial embolization can control complications of delayed bleeding, which occurred in 15% of their patients initially managed expectantly.

Vascular Injury

Vascular injury of major renal vessels has been reported in 1% to 3% of patients with blunt renal injuries (38,58). Total avulsion of the renal artery and vein, seen after rapid deceleration, is the most serious injury because of acute hemorrhage. Acute renal artery thrombosis also is seen in rapid-deceleration injuries and is difficult to diagnose. The degree of hematuria, if present, is often insignificant (91). Many centers recommend that all patients known to be involved in rapid-deceleration accidents undergo excretory urography, whether hematuria is present or not. However, Mee and colleagues (70) noted that gross hematuria or microhematuria was present in all vascular injuries resulting from blunt trauma in their series, and they recommend selective imaging. When nonvisualization is found on excretory urography, immediate arteriography or CT is indicated.

The free movement of the kidneys in the retroperitoneum results in sudden stretch of the renal artery. The arterial intima, having little elasticity, tears, which produces thrombosis within the vessel lumen (Fig. 11A.8 and Fig. 11A.9). This quickly reduces blood flow to the kidney, which may then be viable for only a limited time. Rapid diagnosis and immediate operation are necessary to salvage the kidney (15,60).

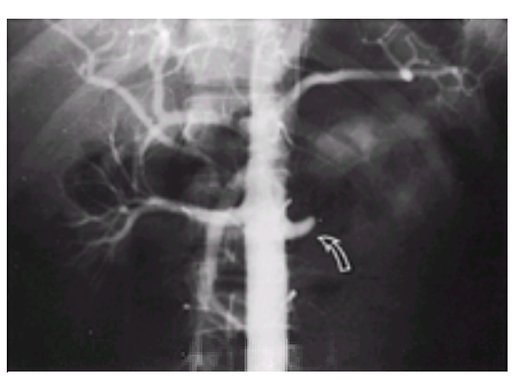

FIGURE 11A.8. In a 29-year-old man with blunt trauma, arteriography demonstrates acute left renal arterial thrombosis. (From McAninch JW. Renal injuries. In: McAninch JW, guest ed. *Urogenital trauma,* vol 2 of Blaisdell WF, Trunkey DD, series eds. *Trauma management*. New York: Thieme Stratton, 1985a:27–49, with permission.)

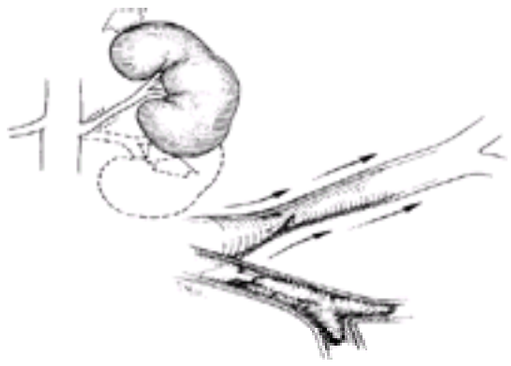

FIGURE 11A.9. Mechanism of arterial thrombosis from blunt trauma. (From McAninch JW. Renal injuries. In: McAninch JW, guest ed. *Urogenital trauma,* vol 2 of Blaisdell WF, Trunkey DD, series eds. *Trauma management*. New York: Thieme Stratton, 1985a:27–49, with permission.)

Venous injuries of the main renal vein or segmental renal branches constitute a serious, possibly lethal, condition. These injuries can result from blunt or penetrating trauma, and massive blood loss can be expected. Preoperative staging for an accurate diagnosis is difficult because excretory urography, nephrotomography, CT, and arteriography do not adequately image venous injuries. Often, particularly on the right side, renal and vena caval injuries coexist (81), and resulting mortality can be as high as 50%.

RETROPERITONEAL HEMATOMA

The general surgeon is often confronted with the unexpected finding of a large retroperitoneal hematoma during exploration for an abdominal injury. Such a hematoma may be found in blunt or penetrating injuries. Historically, exploring the kidney that is surrounded by hematoma has been regarded as hazardous, and complete nephrectomy often has followed (94,99). The urologic surgeon who is called in for consultation should have a systematic approach to evaluating these hematomas. High-dose excretory urography should be performed on the operating room table to evaluate the status of the potentially injured kidney and to confirm the presence of a functioning contralateral renal unit. If the excretory urogram appears normal and no continued expansion of the hematoma is noted, surgical exploration can be avoided. However, when the excretory urogram is indeterminate or abnormal, surgical exploration of the hematoma should be performed. It is imperative to isolate the renal artery and vein before entering the hematoma to control the heavy bleeding that may develop during exploration. In cases of bilateral retroperitoneal hematomas requiring exploration, we choose to explore the kidney suspected of having the lesser injury first, assuming the patient's hemodynamic stability is maintained.

OPERATIVE EXPLORATION AND RENAL EXPOSURE

Once the decision for operative exploration is made, the preferred approach is a midline, transabdominal incision (12,64,89). This allows assessment of other intraabdominal visceral organs and major abdominal vessels. Repair of major vascular, spleen, liver, and bowel injuries should generally be performed before renal exploration and repair. However, if renal bleeding is massive and persistent, renal exploration takes precedence.

To control massive bleeding before renal exploration, it is important to isolate the renal artery and vein individually (Fig. 11A.10A) (9,13,68). The surgeon must be careful to examine the anatomic relationships within the posterior abdomen and posterior parietal peritoneum before beginning vascular isolation. In many cases, the surgical landmarks are distorted by urinary extravasation and massive hematomas. The transverse colon is lifted from the abdomen and placed on the anterior chest. This allows the small bowel to be lifted free from the abdomen superiorly to the right to expose the small bowel mesentery and the posterior parietal peritoneum.

FIGURE 11A.10. Operative approach to renal vessels. **A:** Bowel is retracted superiorly to expose the retroperitoneum, where an incision is made medial to the inferior mesenteric vein over the aorta. **B:** Renal vessels are exposed, and vessel loops are placed. **C:** Hematoma is then entered from a lateral approach. (From McAninch JW, Carroll PR. Renal trauma: kidney preservation through improved vascular control—a refined approach. *J Trauma* 1982;22:285, with permission.)

Anatomic landmarks to be identified at this point are the inferior mesenteric vein and the aorta. If the aorta is covered by large hematoma, an incision can be made in the retroperitoneum just medial to the inferior mesenteric vein; by palpation through the hematoma, the aorta will be found. At this level, the aorta is free of major branches on its anterior surface and is usually easily and safely identified. The aorta is dissected superiorly on the anterior surface up to the area of the ligament of Treitz, where the left renal vein is found crossing anterior to the aorta. This is a major anatomic landmark because the left renal artery originates from the aorta just lateral and superior to the left renal vein, and the right renal artery lies medial and superior as it originates from the aorta (Fig. 11A.10B). Vessel loops of soft silicone can be placed around the individual vessels for retraction and occlusion. In most circumstances, it is unnecessary to occlude the vessels at the time of initial isolation. The right renal vein ordinarily can be isolated through the retroperitoneal incision; however, if it is difficult, mobilization of the second portion of the duodenum readily exposes the right renal vein and vena cava to make the vessel more accessible. Only vessels to the injured kidney need to be isolated.

Once vessel isolation is complete, an incision is made in the peritoneum just lateral to the colon, and the colon is reflected medially to expose the retroperitoneal hematoma in its entirety (Fig. 11A.10C). The kidney should then be totally exposed and mobilized for complete inspection. This can be done quickly and safely without concern for great blood loss because of the vascular control that has been obtained. If heavy bleeding is encountered, vascular clamps or vessel clamps can be used—in our experience, required in 12% of cases. In most circumstances, occlusion of the renal artery beyond 30 minutes is not required, and the kidney tolerates this amount of warm ischemia time well (16). If the time extends beyond this limit, renal cooling is advised during the continued reconstruction process.

Scott and Selzman (89) originally described this technique of early vascular control when exposing a traumatized kidney. Renal bleeding can be prevented and nephrectomy rates reduced. McAninch and Carroll (64) compared a series of patients in whom early vascular control was achieved with another group in whom vascular control was inconsistent (Table 11A.5). The nephrectomy rate in the former group was 18%, and all patients who required nephrectomy had sustained penetrating injuries. In the group with poor vascular control, the nephrectomy rate was 56%—a statistically significant difference. Clearly, when nephrectomy resulting from hemorrhage is prevented, as it can be by this technique, the renal salvage rate is greatly improved.

Procedure	Early Vascular Control (Series II; 39 Patients), Number (%)	Poor Vascular Control (Series I; 34 Patients), Number (%)
Nephrectomy (*n* = 26)	7 (18)*	19 (56)*
Repair (*n* = 47)	32 (82)	15 (44)

*$p < .001$.

TABLE 11A.5. NEPHRECTOMY RATES IN PATIENT SERIES WITH AND WITHOUT EARLY VASCULAR CONTROL

Some authors do not advocate isolation of the renal vessels before exploration. Gonzalez and others (37) found no difference in the nephrectomy rate in 56 patients undergoing renal exploration with or without vessel isolation. However, the nephrectomy rate they report is notably higher than that of groups advocating isolation of renal vessels before opening Gerota's fascia. We believe the maneuver, which can be achieved in less than 15 minutes in most cases, is worthwhile and facilitates complex renal reconstruction.

OPERATIVE FINDINGS AND RENAL RECONSTRUCTION

Parenchymal Injuries

Complete renal exposure is of primary importance (Fig. 11A.11). The kidney is often surrounded by large hematoma, which should be completely swept away so that the entire surface area of the kidney and the hilar vessels is available for inspection. If massive bleeding is encountered from a vascular injury or a parenchymal laceration, temporary occlusion of the renal artery may be necessary to control hemorrhage. This is required in 12% of cases (13). Large intrarenal hematomas that reside in lacerations should be completely evaluated and the margins of the laceration inspected (68). All nonviable tissue should be completely removed. Hemostasis should be obtained on the laceration margins with 4-0 chromic sutures on a fine-tapered needle placed in a figure-of-eight over individual bleeding points (Fig. 11A.12). Chromic suture is preferred because its monofilament characteristics allow it to slide through the tissue without tearing or cutting the renal parenchyma. Larger sutures often cause increasing amounts of tissue ischemia and are unnecessary.

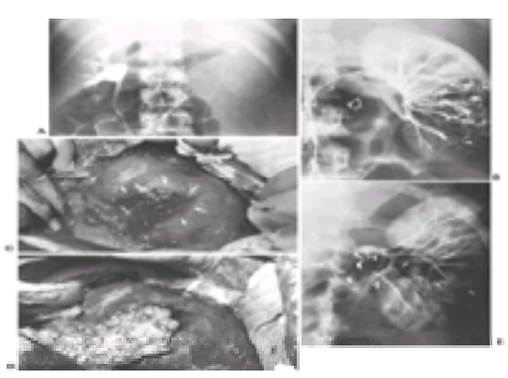

FIGURE 11A.11. A: Excretory urogram in a 19-year-old patient with blunt abdominal trauma and gross hematuria demonstrates poor visualization of the left kidney. **B:** Arteriogram shows numerous areas of vascular extravasation in the middle and lower left kidney. The prompt filling of the renal vein indicates massive arteriovenous shunting *(arrow).* **C:** At operation, a deep parenchymal laceration *(arrows)* was noted on the medial aspect of the kidney near the renal hilum. **D:** The laceration was debrided and the bleeding vessels suture ligated. The defect was covered with an omental pedicle flap. **E:** Selective left renal arteriography 6 months after injury demonstrates complete resolution of arteriovenous shunting and healing of the renal laceration. (From McAninch JW, Carroll PR. Renal trauma: kidney preservation through improved vascular control—a refined approach. *J Trauma* 1982;22:285, with permission.)

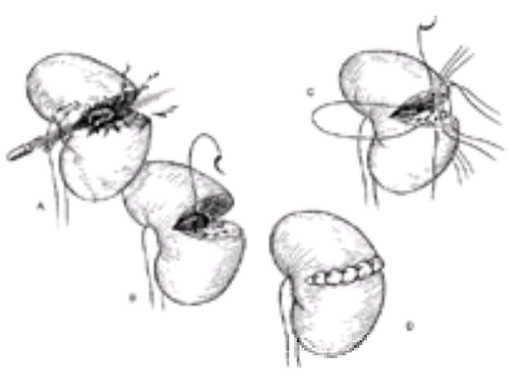

FIGURE 11A.12. Technique of renorrhaphy. **A:** Grade IV injury by gunshot. **B:** Closure of collecting system and ligation of individual bleeding parenchymal vessels. **C:** Closure of the renal defect with multiple interrupted sutures through the renal capsule over gelatin sponge bolster. **D:** Final appearance after repair.

As bleeding within the laceration comes under control, inspection should be directed to the collecting system in the depth of the renal laceration. It may be obvious that the collecting system is open; if so, interrupted sutures of 4-0 chromic or 4-0 polydioxanone should be used. Running sutures of the same material may be used to ensure a watertight closure if the collecting system is wide open. Closure of the renal parenchyma over the repaired collecting system provides another barrier to urinary leakage. Between the margins of the lacerated parenchyma, topical absorbable hemostat such as microfibrillar collagen hemostat is placed (Avitene; Bard). The capsule of the kidney is then closed with multiple 3-0 absorbable sutures such as Vicryl on a small taper needle (Fig. 11A.12C). The sutures are tied carefully over a bolster of absorbable gelatin sponge (Gelfoam; Pharmacia/Upjohn; Kalamazoo, Michigan), assisted by hand approximation of the kidney to achieve apposition (Fig. 11A.12D). This technique provides excellent hemostasis and is an aid in any delayed urinary extravasation or delayed bleeding (65). The gelatin sponge is absorbed within 3 weeks; the risk of future infection or calculus formation from its use is minimal (67). To identify the suture line on postoperative CT scans, we place titanium surgical clips (Autosuture Premium Surgiclip II; US Surgical; Norwalk, Connecticut) on the tied sutures. Ureteral stents are not routinely placed unless a renal pelvis injury is identified and repaired.

Often, the capsule will have been destroyed by the traumatic injury and is not available for use in closure. In such cases, we prefer a pedicle flap of omentum to cover the defect and to aid in hemostasis and prevention of urinary extravasation. The omentum has the advantage of being viable tissue, rich in lymphatic vessels and blood supply, which promotes healing of the injured area. When, as is often the case, omentum is not available and fragments of the capsule remain, a patch of perirenal fat or Vicryl mesh (polyglactin) can be placed over the defect and secured with interrupted sutures that catch the margins of the remaining capsule (without extending into the parenchyma), and these can be tied over an absorbable gelatin sponge bolster. In severe cases of renal injury without preservation of capsule, the entire kidney can be wrapped in a polyglycolic acid (Vicryl) mesh bag. This technique holds the injured kidney together until it heals (77).

Multiple lacerations may coexist, and each laceration can be reconstructed similarly. Occasionally after reconstruction and control of hemorrhage within each

laceration, the entire kidney can be wrapped in omentum to protect it against future problems and to promote wound healing.

Deep lacerations through the upper or lower pole of the kidney may devascularize a large segment of tissue, and a partial nephrectomy may be indicated (Fig. 11A.13A). The capsule should be preserved, and the segmental artery supplying the involved area may require ligation. In most cases, we have been able to spare the segmental vessel, which often supplies additional surrounding tissue, and remove only the nonviable area (Fig. 11A.13B). Hemostasis on the margins of the parenchyma should be achieved with the interrupted suture technique described previously, and the collecting system should be closed carefully (Fig. 11A.13C). To be certain that the closure is watertight, we often occlude the ureter and inject 2 to 3 mL of indigo carmine into the renal pelvis. Any extravasation becomes obvious. Coverage of the renal parenchyma after partial nephrectomy is important. We use any remaining capsule or, if this is unavailable, a pedicle flap of viable omentum (Fig. 11A.13D). If neither of these is available, a free peritoneal graft can be sutured into place over the defect.

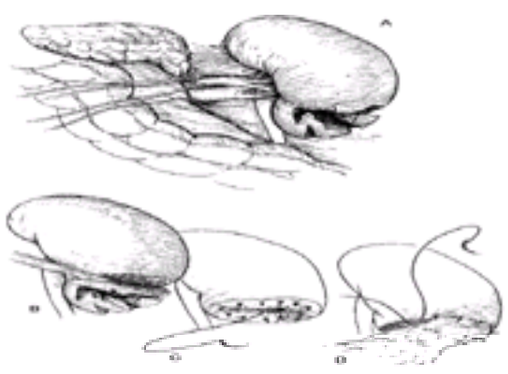

FIGURE 11A.13. Technique of polar nephrectomy for renal injury. **A:** Exposure of kidney with significant lower pole injury. **B:** Sharp amputation of the injured pole. **C:** Ligation of bleeding points with 4-0 chromic suture and watertight closure of the collecting system. **D:** Coverage of the renal defect with omental pedicle flap. (Modified from McAninch JW. Surgery for renal trauma. In: Novick AC, Streem SB, Pontes JE, eds. *Stewart's operative urology.* Baltimore: Williams & Wilkins, 1989:234–239, with permission.)

Retroperitoneal drains are left in place when there is a question of urinary leakage, but careful management is obligatory to prevent infection that may ascend along a drain tract. The drain is removed on postoperative day 3 if analysis of the drain fluid shows it is not urine. In situations in which urinary extravasation does not occur, drains are unnecessary. They should not be left in place in an attempt to drain retroperitoneal hematoma because they are not effective and only provide an avenue for potential infection. Cefazolin (Kefzol) or similarly appropriate prophylactic antimicrobial coverage is given while the drain is in.

Venous Injuries

Venous injuries cause massive bleeding, and repair on the right is complicated by the shortness of the renal vein and the frequent involvement of the vena cava. Complete occlusion of the vena cava above and below the area of injury temporarily controls bleeding until vascular clamps can be applied to the exact areas of damage. Good results can be expected in a majority of renal vein injuries requiring repair (96). Fine 5-0 vascular sutures should be used to close these defects. The severely injured left renal vein can be ligated if necessary because venous collaterals will adequately drain the kidney (9). Segmental renal vein injuries are best managed by ligation of the vessel. This does not cause ischemic damage because of the inner communication of the veins within the renal parenchyma.

Renal Artery Occlusion

Controversy surrounds the treatment of traumatic total renal artery occlusion. Some authors claim that acceptable success rates can be achieved by prompt revascularization (within 4 to 12 hours) (3,57). However, in multiple studies, the success of revascularization has been poor, approaching 0% (24,40,51,96). Current recommendations are to perform nephrectomy in most cases of traumatic renal artery occlusion, except in patients with solitary kidney or bilateral renal artery injury. Percutaneous placement of an endoluminal stent may be the best method of treatment (97).

Renal Artery Laceration

All patients with renal artery injuries must be treated individually in light of recent evidence that renal salvage is often not achieved in this population (51). Only those patients who can safely undergo several hours of operation in the periinjury period are candidates for renal artery repair. Patients with vascular injuries to the main renal artery occurring from blunt trauma who have delayed diagnosis (more than 8 hours) or who are older (seven decades) have little chance of successful arterial reconstruction. In large series, renal lacerations have required nephrectomy in many cases (76%) (9); when vascular repair was attempted, it was successful in only 60%.

Renal branch injuries, on the other hand, are much less significant lesions that can be managed nonoperatively or, when they are discovered intraoperatively, treated by ligation (6). Angiographic embolization of branch artery injuries after stab wounds (30,36) or blunt trauma (28) also has been advocated.

Renal Pedicle Avulsion

Total renal pedicle avulsion, which involves complete laceration of the renal artery and vein from their attachments, requires immediate surgical intervention and does not allow time for diagnostic studies. Authors have suggested renal salvage in these patients only under extreme circumstances: A stable patient who can undergo lengthy operation, solitary kidney, and bilateral injury. If repair is attempted, autotransplantation appears to be the most successful approach (39).

POSTOPERATIVE CARE AND FOLLOW-UP

The postoperative care of the patient with renal trauma is similar to that for any major transabdominal surgical procedure, with nasogastric suction or gastrostomy as needed for bowel decompression and urethral catheter drainage until the patient is stable enough to void. Antibiotics should be given for bowel perforation or severely contaminated wounds. If the urine is infected, preoperative and postoperative antibiotics should be continued through a full 10-day course.

In most circumstances, the urine becomes free of clots within the first 12 to 24 hours and free of gross blood within 48 hours. Serial hematocrit readings should be obtained to make certain that continued bleeding does not occur. When drains are left in place, significant drainage is often noted, although this is commonly intraperitoneal fluid and not urine. One should check the creatinine content of the fluid, which will be many times the serum concentration if urine is present. Intravenous injection of methylene blue also may be used to evaluate possible urinary extravasation. Blood pressure should be followed closely in the early postoperative period as well as later on, for at least 1 year.

Patients can be discharged as soon as retroperitoneal drains are out and they are stable and eating. At the time of discharge, patients are allowed free ambulation without restriction and should be encouraged to return to normal physical activity as soon as the incisional pain subsides.

The patient should be seen in follow-up every 1 to 2 weeks for the first 6 weeks to monitor blood pressure and evaluate the urine for the presence of blood. Hypertension is uncommon, and microscopic hematuria should gradually subside. Approximately 3 weeks after injury, the patient should have a follow-up CT scan of the kidneys to evaluate the anatomic configuration of the kidney and to verify that no obstruction has resulted from perirenal scarring. Renal radionuclide scans are often helpful in evaluating the functional status of the injured kidney.

COMPLICATIONS

Early complications occur within the first 4 weeks of injury and include delayed bleeding, abscess, sepsis, urinary fistula, urinary extravasation and urinoma, and

hypertension (48,90,98). Delayed bleeding can occur from the immediate postoperative period until several weeks later. The greatest risk of delayed heavy retroperitoneal bleeding occurs within the first 2 weeks of injury. Angioembolization is the primary treatment for delayed renal bleeding after trauma (43), but speedy nephrectomy may be required if bleeding is brisk. Abscess may develop in the perinephric space and in most circumstances is noted within the first 7 days. This may be associated with sepsis and is manifested by increasing temperature that may reach 41°C. Prompt surgical exploration and drainage are usually required; however, after appropriate diagnostic procedures, localized abscesses may be drained percutaneously. Symptoms of urinary extravasation in the first 4 weeks of injury may be manifested by a low-grade fever and continued pain in the area of the kidney. CT can aid in establishing the diagnosis and extent of extravasation. Retrograde ureterography should be performed if missed ureteral injury is a possibility. Percutaneous drainage has successfully managed extensive extravasation, but small amounts of urine in the retroperitoneal space appear to be of no particular consequence if they remain uninfected; these often resolve spontaneously without intervention. Hypertension in the postoperative period is uncommon; however, its presence and duration are extremely variable (98). In most circumstances, the hypertension does not require treatment; when indicated, medical therapy usually controls the problem. The hypertension appears to be renin mediated in most cases and is usually transient when it occurs in the early postinjury period.

Late complications include arteriovenous fistula, hydronephrosis, hypertension, calculus formation, and chronic pyelonephritis. Delayed hypertension has been noted by several authors. In a group of patients who had careful follow-up, Jakse and colleagues (48) noted the onset of hypertension some 15 years after renal trauma. Longstanding hypertension persists because of partial renal ischemia, resulting in a renin-mediated type of hypertension (90). Most cases can be managed medically, but surgical intervention may be necessary in unresponsive patients. Montgomery and others (74) have described a cohort of renal trauma patients in whom initial evaluation (CT or IVP) was normal, yet who developed severe renovascular hypertension 2 weeks to 8 months after injury. Subsequent arteriography revealed unappreciated renal artery occlusion, arterial stenosis, segmental artery injuries, or extraparenchymal compression from scarring (Page kidney). Although all were young, these patients presented with complaints, including headaches, chest pain, nosebleeds and fatigue. Vigilance for hypertension is necessary in this population, even when severe renal injury is not expected. Arteriovenous fistulae are caused by both blunt and penetrating injuries but mainly by stab wounds (26). Delayed urinary bleeding is the usual presenting symptom, and many patients have associated hypertension. Angioembolization is the treatment of choice (84), but large fistulae require surgical correction and perhaps nephrectomy. Hydronephrosis can develop in the late postoperative period because of surrounding fibrosis and obstruction to the upper ureter or ureteropelvic junction. This condition may lead to calculus formation or recurrent pyelonephritis or both.

To detect many of these developing delayed complications, a CT scan is strongly recommended within 3 months of major renal injury. Additional follow-up should be done in these patients when persistent problems or suspicion of abnormalities exists.

The sole function of the ureter is to transport urine from the kidney to the bladder. When the ureter is injured, it may become obstructed, creating hydroureteronephrosis and loss of renal function, or a fistula may occur, leading to urinary extravasation into the retroperitoneum or peritoneal cavity. If injury to another structure has occurred at the time of the ureteral injury, a fistula may develop. Most fistulae are to the vagina, skin, or bowel.

Extravasated urine can induce an intense inflammatory reaction, resulting in secondary fibrosis and ureteral obstruction. If the urine is infected, phlegmon and possibly life-threatening sepsis may develop, necessitating emergency surgical intervention.

In the past few years, the use of percutaneous and endourologic techniques has decreased the complications from ureteral injuries and prevented many patients from having to undergo open surgical procedures that once were standard therapy for these distressing problems.

ETIOLOGY

There are two major types of ureteral injuries: those caused by external violence, usually penetrating missiles, and the more common injuries resulting from surgical misadventure. The late complications of radiotherapy or migrating foreign bodies also can cause injury to the ureter. Table 11B.1 lists the various causes of ureteral injury.

TABLE 11B.1. CAUSES OF URETERAL INJURIES

Injury Caused by External Violence

The most common cause of ureteral injury from external violence is gunshot wounds. These wounds account for more than 95% of the lesions (7,8,22,32,38,40,41 and 42,45,54). Knife wounds are the next most common agent, and very rarely, people fall and become impaled on a spike. Uncommonly, the wound from a crushing blow that damages bone involves the ureter. Finally, a well-described but rare injury occurs when the ureter is avulsed from the renal pelvis (Fig. 11B.1) (3,28). This injury is usually seen in a child who has a hyperextensible spinal column. The child is usually struck from behind, and the ureter tenses and snaps against the twelfth rib and transverse processes of the upper lumbar vertebrae. This injury as well as lower ureteral rupture secondary to blunt trauma can be seen in adults as well as children (13,24,26).

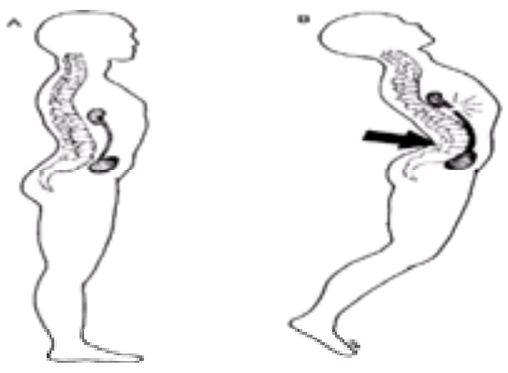

FIGURE 11B.1. A: Normal relation of urinary tract to spine in child. **B:** With a sudden blow to back, the ureter tenses against the hyperextended vertebral column and avulses at the ureteropelvic junction.

Surgical Injury

Ureteral injury may complicate 0.5% to 1.0% of all pelvic operations. Most of these are gynecologic procedures, but urinary tract procedures commonly account for 30%. The most common procedures are hysterectomy, salpingo-oophorectomy, vesicourethral suspension, ureteroscopy, endopyelotomy, and ureterolithotomy (5,9,14,15 and 16,34,47,51,52).

Surgical procedures on the great vessels and colon as well as retroperitoneal tumor excision are the next most common procedures leading to ureteral injury (4,6,31,46,48). As listed in Table 11B.1, many other procedures have been implicated infrequently (2,27). In the last few years, laparoscopic procedures have become a common cause of ureteral injuries (17,55,57).

Radiation Injury

Although radiation injury is often considered when a patient with a previously treated pelvic tumor is found to have ureteral obstruction, the incidence of radiation damage to the ureter is only 0.04%, whereas the incidence of ureteral obstruction caused by recurrent tumor in these patients is more than 95% (12,59).

Migratory Foreign Bodies

The most common migratory foreign bodies that perforate or obstruct the ureter are urinary calculi, bullets, and swallowed objects (18,43).

DIAGNOSIS

External Violence Injury

An excretory urogram or computed tomography (CT) scan with contrast must be performed when a patient has had a penetrating injury of the abdomen, retroperitoneum, or pelvis in the area of the urinary tract; a fracture of the eleventh or twelfth rib; or a transverse lumbar process or the bony pelvis is present. Such a test should also be performed if hematuria is present in a patient who has had significant abdominal or pelvic trauma.

The excretory urogram and CT scan with contrast are the best methods of diagnosing a ureteral injury. In the presence of such an injury, urinary extravasation will be seen on the study as well as some decrease in collecting system visualization (Fig. 11B.2). If a spiral CT scan is performed, the ureter must be seen in its entirety. If it is not, a delayed CT scan must be done or an injury may be missed because of the rapid time of the spiral study (37,50).

FIGURE 11B.2. Woman, aged 26 years, with lacerated left ureter secondary to stab wound of the abdomen. Intravenous pyelogram on the day of injury shows contrast extravasation in the left lower retroperitoneal area.

If the patient is to undergo surgical exploration, the ureter should be dissected from its bed and examined where it lies in proximity to the missile track. If whether an injury is present cannot be determined positively, one vial (5 mL) of indigo carmine should be injected intravenously (IV). Within 7 to 10 minutes, the dye should leak into the periureteral tissues if the ureter has been injured.

If the patient is not going to undergo exploration and the presence of an injury remains questionable, the most definitive study is a retrograde ureterogram. Often, this is not feasible in the trauma patient with multiple injuries. In such a case, ultrasound examination or, preferably, a CT scan may demonstrate the presence of extravasation (25,37).

Surgical Injury

If the urologist is confronted in the operating room with a possible ureteral injury, *the use of IV indigo carmine, as previously described, helps determine whether urinary extravasation is present.* Unfortunately, there is no good way to determine whether ureteral devascularization from the surgical procedure or the blast effect of a high-velocity missile has occurred other than by cutting the ureter and seeing whether it bleeds. Some surgeons advocate the use of IV fluorescein and a Wood's lamp. If there is fluorescence of the ureter, the vasculature is presumed to be intact. The presence of ureteral peristalsis is not helpful in the diagnosis because peristaltic movement may continue in the ureter for hours after it has been removed from the body.

The diagnosis of a ureteral injury generally is not made until many days after the injury has occurred. Table 11B.2 lists the most common signs and symptoms seen in these patients. If a ureteral injury is suspected, an excretory urogram or CT scan is mandatory. If the imaging study shows extravasation, delayed function, or hydroureteronephrosis, a retrograde ureterogram should be done to confirm the type of injury if it is not well delineated in the imaging study. This should be done just before institution of treatment to prevent sepsis from instrumenting a closed space.

Flank pain	1-21 days
Fever	>100°F
Anuria	Bilateral only
Ureterovaginal fistula	1-30 days
Ureterocutaneous fistula	1-30 days

TABLE 11B.2. SIGNS AND SYMPTOMS OF URETERAL INJURIES

In some patients, it may be determined that a percutaneous nephrostomy and possibly antegrade ureteral stent should be placed as therapy (i.e., an ileal diversion

patient). In this instance, an antegrade rather than a retrograde ureterogram should be done.

The proper retrograde study is performed with a Braasch bulb or a cone-tipped catheter and contrast material injected at the level of the ureteral orifice. Passing a whistle-tip catheter into the renal pelvis does not rule out an obstructed ureter and is to be discouraged as a diagnostic study. As discussed later, this may, however, become part of the therapy.

CLASSIFICATION

A useful classification of ureteral injuries is presented in Table 11B.3. An alternative system is that proposed by the American Association for the Surgery of Trauma (AAST) as presented in Table 11B.4 (36).

External Violence	**Surgical Injury (continued)**
Contusion	Transection
Partial laceration	Ligation
Complete laceration	Perforation
Crush	Devascularization
Avulsion	Fistula formation
Surgical Injury	**Radiation Injury**
Crush	
Avulsion	

TABLE 11B.3. CLASSIFICATION OF URETERAL INJURIES

Grade I	Hematoma: contusion or hematoma without devascularization
Grade II	Laceration: <50% transection
Grade III	Laceration: >50% transection
Grade IV	Laceration: complete transection with 2 cm of devascularization
Grade V	Laceration: avulsion with >2 cm of devascularization

TABLE 11B.4. AAST CLASSIFICATION OF URETERAL INJURIES

External Violence Injury

If a missile passes close to but does not penetrate the ureter, a contusion is present. If the ureter is penetrated, either a partial laceration or complete laceration is present. Rarely, a ureter will be crushed, usually in association with a nearby bony injury of the same type, or avulsed from the ureteropelvic junction by a hyperextension injury.

Surgical Injury

A surgeon may crush a ureter with a clamp, avulse a ureter with a retractor, transect the ureter with a knife or scissors, or ligate the ureter inadvertently. A common endoscopic injury is ureteral perforation with a wire, ureteroscope, or other ureteroscopic tool (e.g., basket, laser). If the ureter is stripped of its adventitia and hence blood vessels, it becomes devascularized and necrosis usually occurs in approximately 10 to 14 days. This may lead to fistula formation, as can any of the other aforementioned injuries.

Radiation Injury

Uncommonly, ureteral injury occurs secondary to irradiation of the organ. These lesions may not be seen for months to years after therapy and usually result in ureteral obstruction.

THERAPY

External Violence Injury

Contusion

A contusion may be discovered during exploration in a patient who has had a missile pass close to the ureter, but the structure has remained intact. No therapy is necessary in these patients. If a high-velocity bullet (more than 2,500 feet per second) is implicated, there is always the danger of late necrosis of the ureter. In this instance, placement of an internal stent and drain in the area of the injury should be considered. This problem is seen more often in military conflicts than in civilian life (1,11,44,56).

Laceration

If a partial laceration is present and the ureter that is still in continuity is viable, placement of an indwelling double-J stent and closure of the wound with interrupted 4-0 or 5-0 absorbable sutures gives the best results (49,54,58).Some authors advocate running closure of the wound and elimination of all stents (9). Before the advent of the totally indwelling stent, this was clearly a better way to handle minor lesions because the placement of a transcutaneous stent and formal nephrostomy may increase the complication rate and extend the scope of the procedure (60). With the use of the indwelling stent, drainage is minimal and the patient can be discharged at an early date. All of the devitalized tissue must be debrided, with a Penrose drain placed at the site of the repair and brought out through a separate stab wound.

However, if the remaining intact ureter is of questionable viability or if there is a complete laceration of the ureter, all devitalized tissue must be excised before the decision on a repair is made.

Clearly, the procedure with the lowest complication rate is the ureteroneocystostomy (Fig. 11B.3). This repair can be performed only on a patient with an injury below the level of the iliac vessels. The kidney can usually be mobilized and lowered so that the gap between the ureter and bladder can be decreased a few centimeters. The use of a bladder flap also can help bring the bladder closer to the ureter (Fig. 11B.4) (10). Sometimes merely suturing the bladder to the psoas fascia (psoas hitch) can ensure that there will not be tension on the repair. A nonrefluxing reimplantation is most desirable but cannot always be performed. Because adults, especially women, usually have little trouble with vesicoureteral reflux, this should not result in major problems later in life.

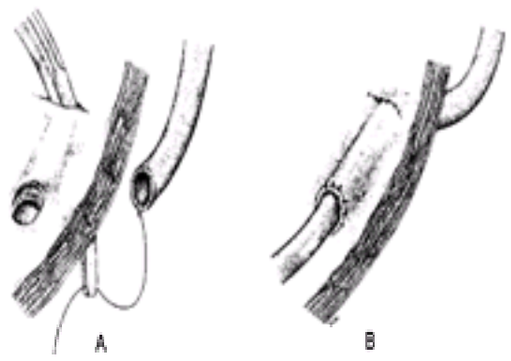

FIGURE 11B.3. Ureteroneocystostomy. **A:** Clamp through bladder wall from mucosa to serosa where ureter will enter bladder. Neo-orifice is created in mucosa of bladder. Submucosal tunnel is created from neo-orifice to entrance of ureter into bladder. **B:** Ureter enters bladder, runs into submucosal tunnel to neo-orifice, and is sewn in place. Stent is in ureter.

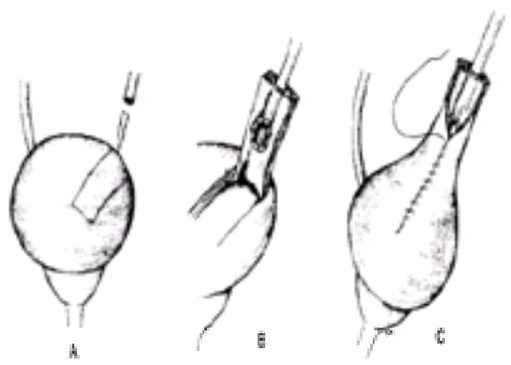

FIGURE 11B.4. A: Bladder flap to be created is outlined on bladder. **B:** Flap is created and ureter sewn in place by means of submucosal tunnel. **C:** Flap is sewn into tube to close bladder defect.

If the injury is too high for a ureteroneocystostomy to be performed, however, a ureteroureterostomy should be done (Fig. 11B.5). Traditionally, this was performed with a running suture of 4-0 or 5-0 absorbable material without stenting. The use of a stent and nephrostomy added major surgical time and complications to the procedure. If the wound was contaminated by bowel contents, stenting was mandatory.

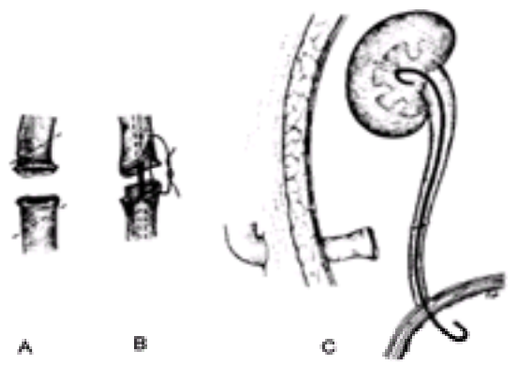

FIGURE 11B.5. A: Traumatized and severed ureter. *Dashed lines* show where spatulated edges will be trimmed. **B:** Ureter is spatulated and suturing begun, with stent in place. **C:** Anastomosis complete, double-J catheter in ureter, placement of Penrose drain by means of stab wound to area of anastomosis.

The use of an indwelling stent and interrupted sutures has become popular with the introduction of the double-J stent. The surgical time is shorter and the margin of safety increased. No matter which technique is used, a Penrose drain should be placed as described previously. If a major length of ureter is lost, consideration should be given to a transureteroureterostomy or merely bringing the cut end of the ureter to the skin as a cutaneous ureterostomy for later definitive repair. Autotransplantation of the kidney to the hypogastric vessels plus ureteroneocystostomy also should be considered (1). This adds major operative time and increases risk to the patient, but in the patient with a solitary kidney it can be lifesaving. There are reports of using the appendix to replace lost segments of the ureter but not with long-term follow-up (33). If immediate reconstruction is impossible, consideration should be given to placement of a nephrostomy and delayed repair.

Crush Injury

When the ureter has been crushed along with other, adjacent tissues, debridement and usually ureteroureterostomy must be performed. All of the previously described techniques should be considered, and whichever seems appropriate should be used.

Avulsion Injury

Avulsion injury is essentially a complete laceration and requires debridement and definitive repair with stenting as described earlier.

Surgical Injury

Before a discussion of the types of repairs that should be used for a surgical injury of the ureter, some comments should be made about the prophylactic preoperative placement of ureteral catheters to identify the ureters at the time of exploration. Before performing a surgical procedure—especially when it is clear that the dissection will be difficult because of prior surgery, inflammation, or an inflammatory disease process such as endometriosis—many physicians place retrograde ureteral catheters into the ureters. It is difficult to verify that this technique actually decreases the incidence of ureteral injury in these patients. Perhaps the best that can be said is that it helps identify an injured ureter when the catheter is seen in the operative field.

Crush Injury

During a surgical procedure, a surgeon may inadvertently crush a ureter by placing a clamp on the structure or ligating it and then removing the clamp or ligature. In such a case, a decision must be made. Has the crushed ureteral segment been devascularized enough that it will eventually necrose and develop either a stricture or, more likely, a fistula? Unfortunately, there is no good intraoperative test to resolve this dilemma.

If there is good evidence that major injury has occurred, the ureteral segment should be excised and either a ureteroneocystostomy or ureteroureterostomy with internal stenting performed as described previously. If the surgeon chooses not to resect the segment, an indwelling stent placed either by opening the bladder or

transurethrally at the end of the procedure is a good safety measure. Placement of a drain in this instance is probably not mandatory.

Laceration Injury

When the ureter has been completely severed either by avulsion or transection and this is recognized intraoperatively, repair by any of the techniques outlined in the section on lacerations associated with external violence should be used. If a laceration is not recognized until after the surgery has been completed, however, various therapeutic decisions will have to be made. *Initially, retrograde ureteral catheterization should be attempted.* Unfortunately, most of the time the catheter cannot be negotiated past the laceration into the proximal ureter. Obviously, this technique is applicable only for a partial laceration. If it is successful, however, a double-J stent should be placed and the patient observed for resolution of the extravasated urine. At the first sign of deterioration, the patient should have a percutaneous or formally placed drain inserted to remove the extravasation.

If the retrograde catheterization is unsuccessful, a percutaneous nephrostomy should be placed and an antegrade stent passed into the bladder. After the extravasation resolves, a double-J stent can be placed for long-term drainage (15,30,39,53).

If drainage of the kidney cannot be established by the percutaneous route, surgical exploration must be performed (21,35). In the first few postoperative days, primary repair should be considered as discussed previously, but if the injury is discovered later in the postoperative period, nephrostomy tube placement and drainage of the extravasation should be done, with delayed repair planned for many months in the future. When large segments of the ureter have been lost, an ileal ureter can be used when primary repair is planned and not done in an emergency situation. Since autotransplantation has gained in popularity, however, this procedure has been used less. Often, in the seriously ill patient with a normal opposite renal unit, nephrectomy is the best choice.

Ligation Injury

When complete obstruction of the ureter is discovered, it is always tempting to return to the operating room and deligate the ureter. Except for ureters ligated at the time of vesicourethropexy, this may be a hazardous procedure and may lead to delayed necrosis and fistula formation. Probably the reason it works so well with vesicourethral suspension is that during this procedure large amounts of tissue are caught in the suture, so devascularization is less of a problem than is mechanical obstruction from angulation. Perhaps if the ureter is loosely ligated and a stent is placed after deligation, this procedure has some merit (19).

The more conservative approach is to place a percutaneous nephrostomy tube in the kidney and attempt to pass a stent antegrade past the obstruction (15,20,30,35,39,53). Retrograde stenting fails almost all of the time. If stenting is successful, balloon dilation, in an effort to disrupt the suture, may be tried but is unnecessary (23). If the ureter has been ligated with chromic suture material, the obstruction will usually resolve in 3 to 4 weeks (20). If it has been ligated with polyglycolic acid suture, it may take 6 to 8 weeks to resolve (Fig. 11B.6). If it has not resolved in 4 to 6 months, formal repair will be necessary by one of the previously described techniques. Once again, the patient who cannot withstand the complications associated with reconstructive procedures may best be handled by nephrectomy.

FIGURE 11B.6. Woman, aged 46 years, who developed a ureterovaginal fistula after an abdominal hysterectomy. **A:** Intravenous pyelography done on postoperative day 10 demonstrates obstruction of the right ureter. **B:** Retrograde ureterogram demonstrates the area of obstruction and some extravasation. **C:** An antegrade ureteral stent was placed beyond the fistula the following day and left in place 9 weeks. **D:** Intravenous pyelography done 6 months later demonstrates resolution of the hydronephrosis and a normal collecting system.

Fistula Formation

If necrosis occurs from any of the injuries listed in Table 11B.3 and the urine either collects in the retroperitoneum or abdomen or tracts to the skin, bowel, or vagina, a percutaneous nephrostomy and ureteral stent should be placed. As with ureteral lacerations, if the procedure is successful, in time the ureter will heal and the fistula will usually close. If a stent cannot be passed, the ureter will usually stricture at the site of the fistula and formal repair will have to be performed 4 to 6 months after the injury with one of the previously described procedures (15,29,30).

Radiation Injury

Radiation injury, although uncommon, is usually discovered months to years after the therapy has been completed. Ureteral stricture formation is usually present. Repair is difficult because irradiated tissue heals poorly. Permanent internal stent diversion is one approach, as is nephrectomy or diversion of the urine into an isolated bowel conduit with both ureter and bowel outside the field of treatment. Occasionally, reconstructive procedures using irradiated tissue wrapped in omentum are successful (59).

POSTOPERATIVE CARE AND COMPLICATIONS

Indwelling ureteral stents can be left in place for up to 6 months without fear of complications. Although many have been in place for more than a year with little difficulty, after 2 months some of them develop calculi and may cause obstruction of the ureter (15). If a drain has been placed, it can usually be removed in a week, even if the stent is left for a longer period. Most patients can be promptly discharged from the hospital and have these items removed in the outpatient setting.

Patients with percutaneous nephrostomy tubes should be taught to irrigate the tubes and to change dressings. A nephrostogram should be done at 3-week intervals to see if the obstruction has been relieved. When the ureter is again draining, the tube can be removed on an outpatient basis. *Stents placed across fistulae should be left in place for at least 4 to 6 weeks and a pull-out ureterogram performed to ensure that the fistula has closed.* If the fistula site can be seen (skin or vagina), it should be inspected every 2 weeks until the site has sealed. The stent should not be removed until the opening is completely closed and the overlying skin or mucosa is intact.

Once all foreign materials have been removed, the patient should be treated with antibiotics to ensure that the urinary tract is sterile. Repeated cultures are recommended.

An excretory urogram or ultrasound should be performed 3 to 6 months after the repair and again a year later. Delayed obstruction is rare but can occur.

With formal surgical repairs, return to full activity takes 4 to 6 weeks. With the use of indwelling stents or percutaneous tubes, time to recovery is no longer than that usually seen with the primary surgical procedure.

The major complications from indwelling tubes, either totally indwelling or exiting from the kidney, are infection, tube obstruction, and calculus formation (15). If patients are instructed in how to irrigate the tubes at home, many trips to the emergency room or office can be avoided. Tubes may have to be changed if they

obstruct, and pyelonephritis must be treated with appropriate antibiotics. Calculi must be handled at the time of tube removal.

BLADDER INJURIES

In the child, the bladder is an abdominal organ and as such is vulnerable to external trauma. As the bony pelvis grows, the bladder becomes protected from injury, especially if it is empty of urine. The bladder is located extraperitoneally in the space of Retzius. Laterally, it is bound by the internal obturator muscles and the lateral umbilical ligaments. Its base is attached to the urogenital diaphragm, and Denonvilliers' fascia, or the rectovesical fascia, binds it loosely posteriorly. Unlike the rest of the organ, however, the dome of the bladder is mobile and distensible.

When the bladder is distended or the pelvis is fractured, the normal protective influence of the intact pelvic ring is lost, and in fact, the shearing force of a pelvic fracture commonly tears the bladder at its moorings. A spicule of bone may lacerate the organ, or it may rupture at the dome by a direct blow to the abdomen without bony injury. Conversely, missiles from an outside force, from internal migration, or in the hands of a well-meaning surgeon, may find the bladder despite its position.

Etiology

Penetrating Injuries

In usual civilian practice, the most common penetrating injuries of the bladder occur from surgical misadventure. Table 12.1 lists the types of procedures and instruments that have been associated with operative injury to the bladder (33,37,41,54,55,69,70,77,97,123,124). Trauma from external violence is most commonly caused by gunshot wounds (23,33,145).

Operative Injury	External Violence
Transurethral Procedures	Gunshot wound
Resectoscope	Knife wound
Lithotrite	Spike impalement
Cystoscope	**Internal Migration**
Urethral instrumentation	***Surgical Drains***
Gynecologic Procedures	Pennrose
Abdominal hysterectomy	Saratoga sump
Vaginal hysterectomy	Foley catheter
Removal of cervical stump	***Intrauterine or Sterilization Devices***
Salpingo-oophorectomy	Lippes loop
Cesarean section	Dalkon Shield
Laparoscopy	Copper-7
Vesicourethral suture suspension	Copper-T
Dilation and curettage	Filshie clip
Suction curettage	***Hip Prosthesis***
Neovaginal construction	Pins
Abdominal Procedures	Trochanteric plate
Hemorrhaphy	***Penile Prosthesis***
Abdominoperineal resection	***Neurosurgical Shunts***
Anterior colon resection	***Swallowed Objects***
Neonatal umbilical artery catheterization	Pins
Laparoscopy	Toothpicks
Aortic bypass grafts	Knife blades
Tenckhoff catheter placement	Bones
Orthopedic Procedures	**Long-dwelling Foley Catheter**
Pelvic fracture manipulation	
Bone screw placement	

TABLE 12.1. CAUSE OF PENETRATING INJURIES OF THE BLADDER

Rarely, injury may occur from migration and erosion of internally placed foreign materials or swallowed objects, most commonly surgical drains, intrauterine or sterilization devices, hip prostheses, penile prosthesis, toothpicks, pins, knife blades, or bones (5,14,21,29,58,67,101,117,131,50). Finally, long-term Foley catheters have been known to erode through the bladder, usually at the dome, where it sits at the tip of the catheter (10).

Blunt Injuries

The most common cause of bladder injuries resulting from external violence is blunt trauma to the abdomen, mostly from motor vehicle accidents but also from falls, crushing injuries to the bony pelvis, or blows to the abdomen (Table 12.2). The full bladder is especially vulnerable to a deceleration injury (23).

Motor vehicle accident	Crush of bony pelvis
Fall	Abdominal blow

TABLE 12.2. CAUSE OF BLUNT INJURIES OF THE BLADDER

In motor vehicle accidents, injuries are seen in passengers wearing seat belts when the force of the collision may focus on the abdomen and thus the full bladder, in the unrestrained child (or, less commonly, the adult) who is thrown by the impact against an unyielding object, or secondary to a pelvic fracture (129).

In our experience with 111 bladder injuries over a 7-year period, 86% were caused by blunt trauma and 90% of the blunt injuries were secondary to motor vehicle accidents (33). A total of 89% of the blunt injuries were associated with pelvic fractures. On the other hand, 9% of patients with pelvic fractures had a concomitant injury to the bladder.

Spontaneous Rupture

It is difficult to understand how a bladder can rupture "spontaneously" as is reported in most large series of these injuries. It is usually seen in the patient with preexisting bladder disease, usually in chronic retention, and is most likely associated with minor blunt trauma or unrecognized trauma in an obtunded patient (1,100).

Diagnosis

Signs and Symptoms

The signs and symptoms of rupture of the bladder are usually nonspecific. The patient may complain of suprapubic pain or relate that he attempted to urinate and could not. The discomfort of a concomitant fractured pelvis or other organ system injury often overshadows the pain from the damaged urinary tract.

Tenderness is present in the suprapubic area and bowel sounds absent, especially if it is an intraperitoneal rupture. Shock is rarely caused by an isolated bladder rupture. When it is present, another cause for the hypotension should be sought.

Bladder perforation during a transurethral surgical procedure with the patient under spinal anesthesia is commonly associated with acute symptoms on the operating table. Extraperitoneal injuries will cause lower abdominal pain, and the patient's blood pressure may begin to rise. Intraperitoneal injuries with extravasation of large quantities of fluid lead to abdominal distention and referred pain to the tip of the shoulder if the fluid irritates the diaphragm.

If recognition of an intraperitoneal injury is delayed, uroascites may develop and cause significant abdominal distention. This may cause respiratory distress and even lower limb venous occlusion, especially in the neonate (37). Peritoneal signs of tenderness and rebound will develop, and if the urine is infected, frank peritonitis may eventually be seen.

Hematuria is a hallmark finding with bladder injuries. In our experience and that of others, *gross hematuria occurs more than 95% of the time, with microscopic hematuria present in the remaining cases* (23,33).

Radiographic Examination

The static cystogram is the only study that will definitely diagnose a ruptured bladder (22,126).*If a urethral injury is suspected because of a pelvic fracture; the presence of blood at the urethral meatus; a high-riding prostate on rectal examination; or marked ecchymosis and edema of the perineum, scrotum, and/or penis, a retrograde urethrogram must be done before attempted urethral catheterization.*

If a ruptured urethra is found, urethral catheterization is usually contraindicated and a suprapubic cystotomy should be performed. If the tube is placed percutaneously, a static cystogram must still be done to rule out a concomitant bladder injury. If the cystotomy tube is placed surgically, the bladder can be inspected at the time of the exploration and the cystogram eliminated.

It is best to perform this examination with fixed equipment in the radiology suite. A satisfactory study can be done in the emergency room with portable equipment and grid cassettes if absolutely necessary. A Foley catheter is placed in the bladder and the bladder emptied of urine. A 300-mL bottle of standard infusion contrast material (25% to 30%) and a similar amount of saline solution are attached to a Y connector and then to the catheter to obtain a 50-50 mixture.

A scout radiograph is taken and then 100 mL of the mixture infused. A second film is exposed to check for gross extravasation. If a bladder rupture is seen, the catheter is immediately placed to straight drainage. If extravasation is not seen, the remainder of the solution is instilled and films are obtained in the anteroposterior, oblique, and lateral projections.

The bladder is then drained of all contrast material and an additional film taken. This is especially important in patients in whom the oblique and lateral films may have been omitted because of concomitant injuries or the patient's clinical state. Small amounts of extravasation may be present behind a contrast-filled bladder and may only be seen on this view. The bladder should also be drained before proceeding with studies of the upper urinary tract. An excretory urogram or computed tomography (CT) scan with contrast should then be performed.

It cannot be overemphasized that *a normal cystogram on a urogram is not sufficient evidence to rule out bladder injury.* Often, a blood clot or omentum temporarily seals a small rent and the bladder will appear intact. Only the static cystogram with full vesical distention and a film taken after drainage can verify that a bladder rupture is not present. Similarly, the bladder image on a CT is limited because, like the cystogram on the urogram, it may not show a leak because it is not forcibly distended (51,57,87,108,128). On the other hand, the CT scanner can be used to image the bladder instead of the conventional radiograph in conjunction with a retrograde cystogram, and a proper diagnosis can be made. Ultrasound diagnosis is still not at the level of accuracy of retrograde contrast injection (40).

Classification

As can be seen in Table 12.3, bladder injuries secondary to blunt trauma are subclassified regarding the extent and location of the injury, whereas penetrating injuries are usually grouped together. However, as discussed in the section on therapy, when considering the treatment of iatrogenic penetrating injuries, extent and location become critical and must be differentiated. The American Association for the Surgery of Trauma (AAST) organ scoring system is presented in Table 12.4 (92).

TABLE 12.3. CLASSIFICATION OF BLADDER INJURIES

Grade I	Hematoma: contusion, intramural hematoma Laceration: partial thickness
Grade II	Laceration: extraperitoneal bladder wall laceration <2 cm
Grade III	Laceration: extraperitoneal (>2 cm) or intraperitoneal (<2 cm) bladder wall lacerations
Grade IV	Laceration: intraperitoneal bladder wall laceration >2 cm
Grade V	Laceration: intraperitoneal or extraperitoneal bladder wall laceration extending into the bladder neck or ureteral orifice (trigone)

TABLE 12.4. AAST CLASSIFICATION OF BLADDER INJURIES

Bladder Contusion

A bladder contusion results from damage to the bladder mucosa or muscularis without loss of wall continuity. Extravasation is not seen on cystogram, but the bladder outline may be distorted (Fig. 12.1). The exact incidence of this injury is difficult to determine because often the diagnosis is made by exclusion in the patient with trauma to the lower abdomen and hematuria. The best overall estimate is that this injury accounts for approximately one-third of all bladder injuries.

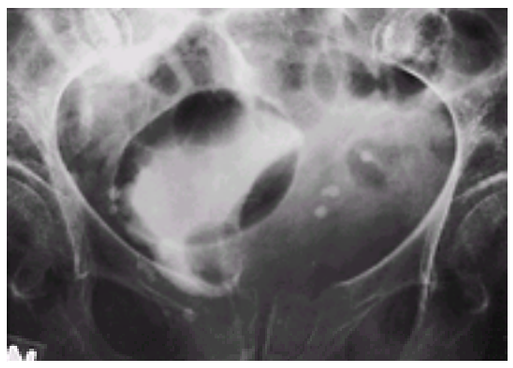

FIGURE 12.1. Bladder contusion secondary to a pelvic hematoma and pelvic fracture. (From Sandler CM, Phillips JM, Harris JD, et al. Radiology of the bladder and urethra in blunt pelvic trauma. *Radiol Clin North Am* 1981;19:195, with permission.)

Interstitial Rupture

Occasionally, an incomplete tear (non–full-thickness tear) of the bladder wall is seen secondary to blunt trauma. As with the bladder contusion, no extravasation is seen on the cystogram (Fig. 12.2). It is important to distinguish this injury from a bladder contusion because the therapy requires a longer period of catheterization because it may represent a full-thickness injury that has sealed with clots or at least needs a longer time to heal as a result of the extent of the damage to the bladder wall.

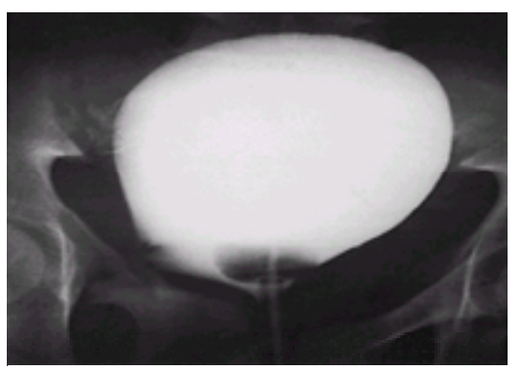

FIGURE 12.2. Interstitial bladder rupture secondary to a pelvic fracture.

Intraperitoneal Rupture

As mentioned, intraperitoneal rupture of the bladder occurs when there is a sudden rise in intravesicular pressure secondary to a blow to the pelvis or lower abdomen. This increased pressure results in rupture of the dome, the weakest and most mobile part of the bladder. Contrast material will fill the cul-de-sac, outline loops of bowel, and eventually extend into the paracolic gutter (Fig. 12.3). This injury is common in children because of the intraperitoneal position of the bladder. Intraperitoneal bladder ruptures probably account for one-third of all bladder injuries and are approximately equal in incidence to extraperitoneal ruptures.

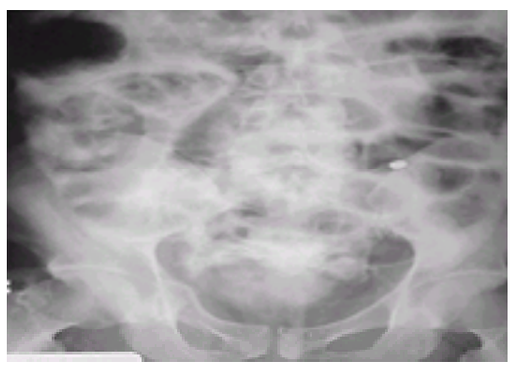

FIGURE 12.3. Intraperitoneal bladder rupture secondary to blunt abdominal trauma.

Extraperitoneal Rupture

Extraperitoneal bladder ruptures are seen almost exclusively with pelvic fractures. The bladder usually is sheared on the anterior lateral wall near the bladder base by the distortion of the pelvic ring disruption. Occasionally, the bladder is lacerated by a sharp, bony spicule. On cystography, flame-shaped areas of extravasation that are usually confined to the perivesical soft tissues are visualized (Fig. 12.4). If there is a large pelvic hematoma, the bladder will often be compressed into the "teardrop deformity." Urinary extravasation may extend to the thigh by means of the obturator foramen to the scrotum by means of the inguinal canal, up the anterior abdominal wall, or retroperitoneally as high as the kidneys (Fig. 12.5). Sixty percent of the time a contracoup bursting rupture opposite the area of fracture is seen as well as an injury near the fracture site (23,33).

FIGURE 12.4. Extraperitoneal bladder rupture secondary to pelvic fracture.

FIGURE 12.5. Computed tomography scan of patient with an extravesical bladder rupture. Note extravasation as high as kidneys.

Intraperitoneal and Extraperitoneal Bladder Rupture

Occasionally, the bladder is ruptured both intraperitoneally and extraperitoneally. These injuries are caused by penetrating trauma or pelvic fractures. The radiologic findings are a mixture of the previous descriptions of the single injuries.

Therapy

Penetrating Injuries from External Violence

All patients with penetrating injuries from external violence should undergo exploration of the abdomen and of the track the missile followed from its entrance wound to its exit wound. The peritoneal cavity should be opened through a midline incision, even if the injury is thought to be entirely extraperitoneal, and the intraabdominal viscera and major vasculature should be examined for damage. All devitalized tissue and debris (e.g., bullets, bone spicules, clothing) should be removed from the bladder and abdomen (23).

If the ureteral orifices are involved in the injury or there is concern about the integrity of the ureters, 5 mL of indigo carmine should be injected intravenously. In 7 to 10 minutes, the blue dye should appear in the bladder. A search for extravasation should be made and the ureters intubated with 5-Fr whistle-tip catheters if there is any concern that they have been damaged.

If a large pelvic hematoma is present, it is best left undisturbed if one can be sure by radiography (plain film, cystogram, urogram, and/or arteriogram) that there is no major disruption of the bladder neck, ureters, or vasculature. The bladder is then entered through its peritoneal surface at the dome and thoroughly inspected.

After debridement, the extraperitoneal vesical defect should be closed with a single-layer running 3-0 chromic or polyglycolic suture through the interior of the bladder. Extensive mobilization of the bladder to ensure a watertight closure or to place the knots on the outside of the bladder will usually only increase bleeding. If it is impossible to close the extraperitoneal defects, they should not be disturbed. With adequate bladder drainage, they will eventually heal without difficulty. Only injuries to the bladder neck must undergo reconstruction.

A suprapubic cystotomy tube may then be inserted in the bladder through a separate stab wound. At least a 24-Fr size should be used to ensure egress of blood clots. Either a Malecot or mushroom tube is recommended. The mushroom style has a firmer flange and is less likely to become dislodged, but the sideholes are small. If the tip of the catheter is excised before insertion, this drawback is overcome.

The tube should be sewn in place with an 0 chromic or polyglycolic purse-string suture, which is then used to fix the bladder to the wall at the site where it crosses the abdomen, again through a separate stab wound. This will ensure a controlled fistula if leakage occurs at the time of tube removal. The catheter should not be brought through the bladder wound because removal may disrupt the suture line, nor should it come through the abdominal incision because this increases the chance for wound infection. *The intraperitoneal bladder incision is closed with a double layer of 3-0 chromic or polyglycolic suture in a running watertight fashion. This is best done after the suprapubic tube is sewn into the bladder but before the tube is brought through and fixed to the abdominal wall.* If bleeding and clot formation are not excessive, a Foley catheter may be used instead of a suprapubic tube (139).

One-inch Penrose drains are placed near the suture lines and brought through separate stab wounds. The drains and suprapubic tubes are sutured to the skin with 3-0 nonabsorbable suture material. The wound is closed in a standard fashion, and a sterile dressing is applied. If the orthopedic surgeon repairs a pelvic fracture at the same time using internal plates, drains and suprapubic tubes should not be used if at all possible to prevent infection near the foreign material.

Iatrogenic Penetrating Injuries

When the bladder is inadvertently injured during a surgical procedure, prompt repair with a double layer of 3-0 absorbable suture material and tube drainage with a Foley catheter or suprapubic tube usually ensures an excellent result. The most common mistake made is not thoroughly inspecting the entire bladder when the injury is discovered, thereby overlooking a second rent in the organ. This is especially disturbing during gynecologic surgery when a lesion of the dome is seen and repaired, but one at the base that also involves the vagina is missed.

Delayed recognition of operative injuries requires individualized attention. *If recognized in the first few days after surgery, immediate correction usually will be*

successful. Although some reports advocate repair of bladder injuries at the time of diagnosis despite the age of the injury, after 1 or 2 weeks, tissue edema impedes proper wound healing, increasing the failure rate of the repair. The success rate is improved by delaying repair for months. Only intraperitoneal injuries and uroascites demand prompt repair when they are discovered.

Injury to the bladder by an endoscope (cystoscope, resectoscope, or laparoscope)—especially if the injury is extraperitoneal and properly recognized, the procedure immediately terminated, and the rent small—can be handled with large-caliber urethral catheter drainage and expectant therapy. These patients must be observed closely, and at the least sign of deterioration, abdominal exploration and repair of the bladder should be performed. If there is any evidence of uroascites or if the urine is infected, formal repair is mandatory.

Internal Migrating Objects

Internal migrating objects are rare injuries that necessitate removal of the foreign material and use of a urethral catheter or suprapubic tube drainage. Formal repair performed as exploration is usually necessary to remove most of these objects and must be done if the injury is intraperitoneal (29,101,131).

Bladder Contusions

Bladder contusions necessitate Foley catheter drainage for a few days or, if minor, no therapy at all. If there is a large pelvic hematoma and marked bladder neck distortion, the patient may have difficulty voiding. These patients may require prolonged catheter drainage. If there is a major injury to the sacrum and the patient cannot urinate, a cystometrogram should be performed to be sure there has not been damage to the sacral nerve roots that innervate the bladder. If no detrusor contraction is seen and the patient continues to be unable to void after multiple trials, intermittent self-catheterization should be instituted. Most of these problems are temporary unless accompanied by major neurologic deficit.

Interstitial Ruptures

As stated in the section on classification, interstitial ruptures are incomplete bladder wall ruptures, or they may represent a small full-thickness rupture that has sealed itself with clot or possibly omentum. They should probably be treated by 10 days of catheter drainage, just as the complete but unrepaired rupture, and followed up closely for a change in clinical status. A cystogram should be performed before catheter removal.

Intraperitoneal Ruptures

All intraperitoneal bladder ruptures caused by blunt abdominal trauma should undergo formal repair. The peritoneal cavity should be opened, all urine and blood evacuated, the viscera and vasculature inspected for injury, and appropriate therapy instituted. The bladder will usually have a large 5-cm or greater rent at the dome. If necessary, it should be widened thoroughly to inspect the interior of the organ. Any concomitant extraperitoneal rents should be closed with a single running 3-0 chromic or polyglycolic suture from inside the bladder. Devitalized tissue should be excised, and after a suprapubic tube has been placed as previously described, the dome wound should be closed with absorbable suture material. The suprapubic tube is brought through a separate stab wound, and a peritoneal drain is placed and brought out through a second stab wound. If the urine is relatively clear, a Foley catheter may be used instead of a suprapubic tube (139). The peritoneal cavity cannot and should not be drained. Closure of the abdomen is as previously described (23).

A few scattered reports indicate that intraperitoneal bladder injuries can be treated with simple Foley catheter drainage (99,121,122). When the literature is carefully reviewed, however, it is clear that most of these authors are discussing iatrogenic transurethral bladder perforations and not wounds caused by external violence. Most patients with intraperitoneal bladder ruptures caused by abdominal blows or a fractured pelvis have large gaping rents and marked uroascites when first seen. These patients must undergo prompt surgical repair because they rapidly deteriorate if not treated in a timely fashion (23). Finally, reports of laparoscopic repair are now appearing in the literature (9).

Extraperitoneal Ruptures

Isolated uncomplicated extraperitoneal bladder ruptures can be handled easily by 10 days of Foley catheter drainage (20,33,99,121,122). As some authors state, one cannot decide to treat only small extraperitoneal ruptures with catheter drainage and formally close large ruptures because it is difficult to relate the amount of contrast extravasation to the extent of the injury (20,23). Extravasation is related to the amount of contrast instilled and to the size of the injury. In our experience, however, extravasation into the pelvis, down the inguinal canal to the scrotum, and up the retroperitoneum as high as the kidneys can be successfully treated with catheter drainage. If the patient has uninfected urine and appropriate catheter care is used, the urine will quickly absorb and the bladder rent will heal.

However, it cannot be stressed enough that the nonoperative catheter drainage therapy is exactly that: No exploration for any reason is being performed, and the catheter is draining well, not poorly and intermittently, being obstructed with clots (76). *If the catheter will not drain easily and the urine does not clear properly, formal repair is best.*

If the patient with an extraperitoneal bladder rupture is to be explored for associated injuries and is not gravely ill, it is best to open the dome of the bladder, not disturb the pelvic hematoma, repair the rupture intravesically, close the bladder, and insert a suprapubic tube or Foley catheter as previously described. If the pelvic hematoma is opened for another reason, a drain should be placed. If it is not opened, no drain is necessary.

Intraperitoneal and Extraperitoneal Ruptures

Intraperitoneal and extraperitoneal ruptures need to be formally repaired as previously described. Most of these patients have major pelvic fractures and often have injured their urethra, bladder neck, or in the female, vagina as well. Prompt reconstruction, even in the face of a marked pelvic disruption, is usually necessary for a good long-term result. These cases all need to be individualized, especially those with major tissue destruction.

Postoperative Care and Follow-up

Postoperatively, if no other injuries are present, oral alimentation may be resumed when gastrointestinal peristalsis returns to normal, usually within 3 to 7 days of the injury. The bladder heals remarkably quickly, and if a good repair was achieved, the suprapubic tube or Foley catheter may be removed within a week. If there is any question about the closure, a cystogram should be performed before tube removal. If extravasation is present, the catheter should be left in place for further drainage and the cystogram repeated on the tenth postoperative day.

When the patient is voiding normally and there is no leakage of urine from the drainage site for 24 hours, the drain may be removed. Routine antibiotics are not necessary, but once the catheter has been removed, the urine should be cultured and appropriate antibiotics given if bacteriuria is present. If the urine is infected at the time of the injury and subsequent extravasation, antibiotics should be begun preoperatively and continued for at least a week. Frequent urine cultures should be obtained to avoid serious complications.

If the patient had an extraperitoneal injury that was treated with Foley catheter drainage alone, a cystogram should be done on the tenth postoperative day. In our experience, more than 85% of bladders are healed by that time, and the catheter can then be removed. Virtually all injuries treated in this manner are healed with less than 3 weeks of catheter drainage. In the rare male patient who has persistent extravasation, a punch suprapubic tube should be placed in the bladder to prevent urethral complications.

Full activity may be resumed within 3 to 4 weeks of surgery unless other injuries or complications dictate further therapy or rest. Other than urine cultures if indicated, no long-term follow-up is necessary.

Complications

The most serious complications for bladder ruptures are secondary to delay in diagnosis. When urine leaks into the peritoneal cavity, it equilibrates with serum, so peritoneal fluid analysis for creatinine and urea will not be helpful in diagnosis. If uroascites becomes marked, respiratory difficulty will develop, especially in infants.

Emergency paracentesis may be lifesaving.

Sepsis from infected urine is a major threat. In the unrecognized intraperitoneal rupture, generalized peritonitis or loculated abscesses may develop. The bladder rent must be closed, the urine diverted, and all purulent collections drained surgically. Appropriate antibiotics must be given.

The mortality of patients with bladder ruptures is approximately 12% (23,33). The cause of death in these patients should never be secondary to the bladder wound if it is properly diagnosed and treated but will be caused by associated visceral or vascular injuries.

Injuries to the bladder neck, urethra, and vagina, if not promptly and properly repaired at the time of the injury, may result in incontinence, fistula, or stricture formation (88). In these cases, reconstruction will have to be delayed for months to allow edema, infection, and induration to disappear. In some patients, a neuropathic bladder may accompany the injury, and voiding may be impossible. Intermittent self-catheterization is a good way to overcome this problem.

URETHRAL INJURIES

Anatomically, the male urethra is traditionally divided into (a) the prostatic urethra; (b) the membranous urethra; (c) the bulbous urethra; and (d) the penile, or pendulous, urethra. When considering injuries to the male urethra, most surgeons use a classification that helps determine appropriate therapy such as (a) *posterior urethral injuries*–those of the prostatic and membranous urethra, above and including the urogenital diaphragm and (b) *anterior urethral injuries*–those of the bulbous and penile, or pendulous, urethra, below the urogenital diaphragm.

Because proper diagnosis is so critical to subsequent management and because both of these anatomic and mechanistic classifications can cause confusion, unified classifications have been developed that may help in the proper evaluation and therapy of these injuries [Table 12.5 (49) and Table 12.6 (92)]. These work best for blunt trauma but can be used for penetrating lesions as well.

Type I	Posterior urethra intact but stretched by pelvic hematoma
Type II	Partial or complete prostatomembranous urethral rupture above intact urogenital diaphragm
Type III	Partial or complete combined anterior/posterior urethral rupture with rupture of urogenital diaphragm
Type IV	Bladder neck injury with extension into posterior urethra
Type IVA	Base of bladder injury with periurethral extravasation (simulates type IV injury)
Type V	Partial or complete anterior urethral injury

TABLE 12.5. CLASSIFICATION OF URETHRAL INJURIES

Grade I	Contusion: blood at urethral meatus; urethrography normal
Grade II	Stretch injury: elongation of urethra without extravasation on urethrography
Grade III	Partial disruption: extravasation on urethrography, contrast at injury site with contrast visualization in the bladder
Grade IV	Complete disruption: extravasation on urethrography, contrast at injury site without visualization in the bladder; <2 cm of urethral separation
Grade V	Complete disruption: complete transection with >2 cm urethral separation, or extension into the prostate or vagina

TABLE 12.6. AAST CLASSIFICATION OF URETHRAL INJURIES

The female urethra is rarely injured (24,138). When it is damaged, however, it is usually accompanied by a severe bony pelvic disruption with concomitant injury to the bladder neck and vagina. It is usually more common in children than adults (2,56,73,88,113,134).

Etiology

Posterior Urethral Injuries

Almost all injuries of the posterior urethra in the male occur in conjunction with fracture of the bony pelvis (35,89,90,105). In modern civilian society, 90% of these injuries are caused by motor vehicle accidents involving automobiles, motorcycle riders, or pedestrians. Falls from a height, industrial crushing injuries, and sporting accidents make up the other 10% of the pelvic fracture patients (25).

This injury is most commonly caused by the shearing force of the bone disruption, with the prostate, attached by the puboprostatic ligaments, being pulled in one direction while the membranous urethra, attached to the urogenital diaphragm, is pulled in another direction.

Penetrating wounds of the posterior urethra from external violence are uncommon but do occur. Urethral instrumentation with perforation of the prostatic urethra, on the other hand, is more frequently seen (Table 12.7). There are two cases in the literature in which a lateral blow to the pelvis and thigh resulted in rupture of the posterior urethra at the junction of the prostatic and membranous urethra with probable concomitant rupture of the puboprostatic ligaments without fracture of the pelvis (34,119).

Posterior Urethral Injuries	***Straddle Injury (continued)***
Fracture of the Pelvis	Kick

TABLE 12.7. CAUSE OF URETHRAL INJURIES

Anterior Urethral Injuries

Similarly, most injuries to the anterior urethra caused by external violence are the result of blunt trauma to the perineum (15,25,89,115). The bulbous urethra is usually crushed against the pelvic arch, generally when the patient falls astride an object. This may be while falling from a height, straddling a fence, or having a foot slip from the rung of a ladder. It is sometimes caused by a kick to the perineum or hitting a bump in the road while riding a bicycle and coming down hard on the seat or the crossbar.

Penetrating injuries of the anterior urethra caused by external objects are less common, but iatrogenic damage resulting from urethral instrumentation, especially inflation of a Foley catheter balloon in the bulbous urethra, occurs frequently (Table 12.7) (127). Surgery of the penis, most notably for penile prosthesis placement—or, later, prosthesis erosion—and circumcision can inadvertently damage the urethra.

Accidents secondary to sexual activity, either intercourse with urethral laceration or fracture of the penis, masturbation by urethral instrumentation, or genital mutilation by a mentally disturbed patient, also have been reported.

Diagnosis

Signs and Symptoms

Patients with a history of trauma to the perineum or who have a fracture of the bony pelvis should be suspected of having a urethral injury. If the patient has attempted to void, he may find he cannot or he may relate that he had the sensation of voiding but no urine came out of his urethra. This patient may have voided into his tissues.

Most patients with a ruptured urethra will have blood at the urethral meatus, and many of them will have swelling and ecchymosis of the penis, scrotum, and/or perineum. This is caused by urine and/or blood leaking into these structures. If the edema is only in the penis, it is probably contained within Buck's fascia. If it extends to the scrotum, perineum, or anterior abdominal wall, it will be contained by Colles' fascia.

In the patient with a fractured pelvis, rectal examination may reveal the prostate to be in a higher position than usual. This “high-riding prostate” is caused by disruption of the urethra with the prostate elevated from its normal position by a large pelvic hematoma, although the prostate also can be high-riding in the absence of a tear (type I injury, see later discussion). If the puboprostatic ligaments did not rupture, the prostate may have been lifted from its bed attached to a comminuted bone fragment. The soft, boggy hematoma will be felt where the prostate is normally found.

If the patient can urinate, he will usually have gross hematuria. It may be grossly bloody only at the beginning of the stream and/or at the end of the stream if the injury is a partial rupture.

Radiographic Examination

Any patient with a suspected urethral injury must have a retrograde urethrogram performed (32,126). Under no circumstances should an attempt be made to catheterize the urethra until this study delineates the anatomy and any damage done to that organ. Injudicious catheterization of the injured urethra carries the risk of converting a partial urethral rupture into a complete urethral rupture and possibly infecting a sterile periurethral or pelvic hematoma.

Trauma surgeons occasionally comment that placement of a urethral catheter is one of the first maneuvers that should be done in a multiple trauma patient, especially one who is hypotensive. They argue that urine output monitoring is critical in determining organ perfusion and proper fluid infusion rates. The urologic specialist should first counter with the point that blood pressure measurements also give the physician an idea of the level of organ perfusion. Second, the specialist should comment that virtually all multiple trauma patients will be sent to the radiology department to undergo appropriate studies within minutes of emergency room evaluation. At that time, a urethrogram can be performed along with other indicated x-ray films.

Some desperately ill patients who may have urethral injuries must be taken directly to the operating room for abdominal exploration before radiographic examination. At the time of surgery in these patients, a suprapubic tube should be inserted into the dome of the bladder for drainage. The lower tract may then be studied in the postoperative period and indicated therapy instituted. If the tube is not needed, it may be removed easily. As is discussed under complications of urethral ruptures, the long-term problems of incontinence, stricture formation, and erectile dysfunction, which seem unimportant at the time of injury, loom large in the postoperative period of these unfortunate men. The less urethral damage done, the more the patient will recover free of these complications.

Ideally, the urethrogram should be performed under fluoroscopic monitoring. If necessary, it may be obtained with fixed or even portable equipment in the emergency room. An easy technique that does not require special equipment is to insert a number 14- or 16-Fr Foley catheter into the urethra so that the balloon of the catheter is just 2 to 3 cm proximal to the meatus. One to two millimeters of saline solution is injected into the balloon to seat it in the fossa navicularis. No lubricant should be used or the catheter may slide out of the urethra.

The patient is then moved to a 25- to 30-degree oblique position, and approximately 25 mL of 25% to 30% contrast media is injected with a Toomey syringe into the urethra. An exposure is taken during the active injection of the contrast medium to distend the urethra and produce a dynamic urethrogram (Fig. 12.6).

FIGURE 12.6. Normal retrograde urethrogram.

A penile clamp (i.e., Brodney or Knudson) also may be used but is cumbersome and may not always be available. Inserting the tip of the syringe directly into the urethra should not be done because the examiner's hand will be exposed to the x-ray beam.

The oblique position is best for demonstrating the entire anterior and posterior urethra. In the anteroposterior position, the bulbous urethra is foreshortened and the urethra, as well as areas of extravasation, will overlap, making the study uninterpretable.

If the urethra is normal, the balloon should be deflated, the catheter advanced into the bladder, the balloon reinflated, and a cystogram performed as previously discussed to rule out a bladder rupture. If a catheter has already been inserted into the bladder, it should not be removed. If a urethral injury is suspected, a urethrogram should be done around the indwelling catheter to rule out urethral damage. This can be done by inserting a 16-gauge Intracath alongside the Foley catheter and compressing the urethra while injecting contrast material.

Finally, an excretory urogram or CT scan should be performed to evaluate the kidneys and ureters. If a large pelvic hematoma is present, the bladder will have a "teardrop" appearance and ride high out of the pelvis (Fig. 12.7). This is commonly called a "pie-in-the-sky" bladder.

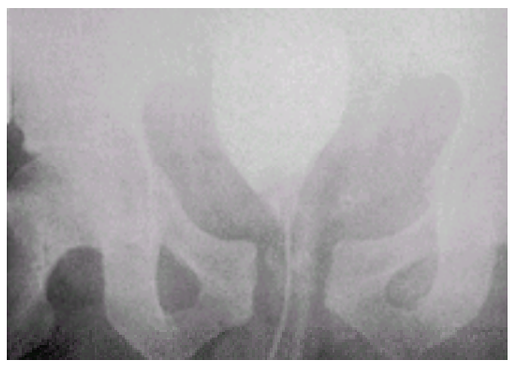

FIGURE 12.7. "Teardrop" or "pie-in-the-sky" bladder from a pelvic hematoma in a patient with a pelvic fracture.

POSTERIOR URETHRAL INJURIES

Classification

As previously stated, virtually all posterior urethral injuries are secondary to fracture of the bony pelvis. Table 12.5 lists the classification of these injuries, which is helpful in planning their management (30,49,125).

Type I Injury

The posterior urethra and proximal bulbous urethra are stretched because the moorings of the prostate to the urogenital diaphragm have been ruptured and a hematoma has collected in the perivesical space (Fig. 12.8). Although stretched, the urethra is not ruptured. This injury accounts for 17% of posterior urethral ruptures.

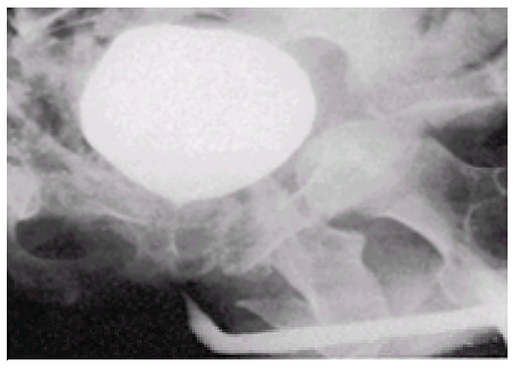

FIGURE 12.8. Type I urethral injury. Posterior urethra is compressed by hematoma. (From Sandler CM, Phillips JM, Harris JD, et al. Radiology of the bladder and urethra in blunt pelvic trauma. *Radiol Clin North Am* 1981;19:195, with permission.)

Type II Injury

Until recently, a type II injury was thought to be the most common type of posterior urethral injury. The classic description is rupture of the prostatomembranous urethra at the apex of the prostate above the urogenital diaphragm. Extravasation of contrast occurs superiorly into the pelvis but is limited inferiorly by an intact urogenital diaphragm (Fig. 12.9 and Fig. 12.10). The rupture may be complete or incomplete. Recent work has shown that this injury is present only 17% of the time.

FIGURE 12.9. Type II partial urethral injury. All extravasation is in pelvis. Also note intraperitoneal rupture. (From Sandler CM, Harris JH Jr, Corriere JN Jr, et al. Posterior urethral injuries after pelvic fracture. *AJR Am J Roentgenol* 1981;137:1233, with permission.)

FIGURE 12.10. Type II complete urethral injury. All extravasation is in pelvis.

Type III Injury (Posterior/Anterior)

Type III is the most common injury seen; it is present 66% of the time. The prostatomembranous urethra is either partially or completely ruptured, and contrast extends into the pelvis. In this injury, however, the urogenital diaphragm and anterior or bulbous urethra also are injured, and contrast material will be seen extending into the perineum and into the bulbous urethra (Fig. 12.11).

FIGURE 12.11. Type III complete urethral injury. Extravasation extends into perineum as urogenital diaphragm is ruptured. (From Sandler CM, Harris JH Jr, Corriere JN Jr, et al. Posterior urethral injuries after pelvic fracture. *AJR Am J Roentgenol* 1981;137:1233, with permission.)

Type IV Injury

Many times, an injury of the bladder neck will extend into the proximal urethra. As has been discussed under injuries of the bladder, these must have immediate repair to prevent incontinence and/or stricture formation (Fig. 12.12).

FIGURE 12.12. Type IV injury. Bladder neck injury with extension into the urethra.

Type IVA Injury

A confusing diagnostic problem occurs in patients with an injury near the bladder base. Contrast may extravasate around the urethra and what is really an extraperitoneal bladder injury can be confused with an injury of the proximal urethra. If the urethrogram is repeated under fluoroscopy, the true site of the injury can be determined (Fig. 12.13).

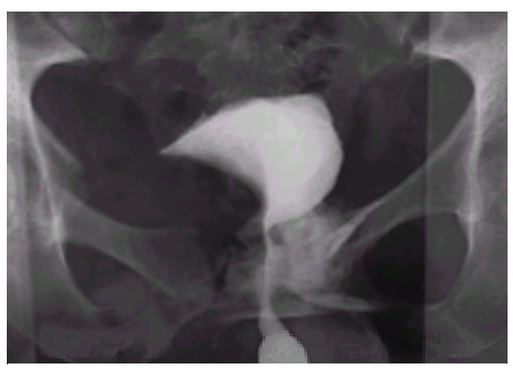

FIGURE 12.13. Type IVA injury. Extraperitoneal bladder rupture with periurethral extravasation simulating a true type IV urethral injury.

Penetrating Injuries

When the posterior urethra has been damaged by an external missile or intraurethral instrument, extravasation will follow the track of the injury. The extent and location of the injury are variable, and when caused by a gunshot wound, the bladder neck also is commonly damaged.

Therapy

Type I Injury

The patient with a pelvic hematoma compressing the urethra often will have difficulty voiding, so a urethral catheter should be left indwelling for a few days. However, once the patient has recovered sufficiently from the injuries to discontinue urine output monitoring and is alert enough to attempt to void, the catheter should be removed. Patients with a severe pelvic disruption, especially if the sacrum is damaged, may have some neurologic deficit and be unable to urinate. A cystometrogram should help determine the status of the bladder. If multiple trials of voiding fail, the patient should be taught clean intermittent self-catheterization while awaiting return of detrusor function. There are reports of delayed rupture of these injuries and some authors recommend suprapubic tube drainage instead of urethral catheter drainage (65).

Partial Urethral Rupture

The patient with minimum partial urethral rupture may be treated with urethral catheter drainage for 14 to 21 days, followed by a voiding cystourethrogram to ensure

healing of the injury. If the catheter does not pass easily into the bladder or if the injury is extensive, urethral catheterization should not be done for fear that the partial rupture may be converted to a complete rupture. The patient should undergo suprapubic cystotomy by either the trochar technique or formal surgical placement. A cystogram must then be done in these patients to rule out a concomitant bladder rupture.

Clearly, the most conservative way to handle all of these injuries is to place a suprapubic cystotomy and not attempt urethral instrumentation. A voiding cystourethrogram through the cystotomy tube should be performed 14 to 21 days after the injury. If extravasation is no longer present and the urethra is of normal caliber or there is only a minimum stricture at the site of the injury, the tube should be removed and the patient allowed to void (32).

If there is a marked narrowing or total occlusion of the urethra at the area of previous extravasation, panendoscopy and a few days of urethral catheter drainage should be performed. The visual urethrotome should be available to incise any strictures that may be present.

If the strictured area cannot be successfully negotiated with the panendoscope, the patient should be left on suprapubic drainage for 6 months and delayed repair by one of the reconstructive procedures discussed later should be performed. Partial urethral ruptures account for approximately one-third of the posterior urethral ruptures.

Complete Urethral Rupture

There are three ways to treat a complete rupture of the posterior urethra: immediate surgical realignment, suprapubic cystotomy and delayed surgical repair, or endoscopic realignment. Immediate surgical realignment is the procedure of choice in the stable patient who (a) is going to have immediate pelvic exploration for a concomitant vascular or rectal injury, (b) has a severe prostatourethral dislocation with perhaps fixation of a "pie-in-the-sky" bladder and prostate to a displaced comminuted bone fragment by the puboprostatic ligaments, or (c) has major bladder neck lacerations or prostatic fragmentation (commonly seen in children) (4,44,47,81,111,135,147).

The procedure is performed through a lower abdominal midline incision. The hematoma is evacuated and a regular or fenestrated 16- or 18-Fr catheter is passed per the urethra through the urogenital diaphragm into the prevesical space. The catheter is identified by sight or feel and brought into the surgical field. The anterior bladder wall is opened and the interior of the organ inspected. Lacerations are repaired with 3-0 absorbable suture. Another catheter is then passed out the bladder neck, through the prostatic urethra, and brought into the surgical field by sight. A single 0 nylon suture is used to tie the tips of the catheters together through their distal most eyes, and the bladder catheter is used to guide the urethral catheter into the bladder (Fig. 12.14A). The bladder catheter is removed, a second 0 nylon catheter is placed through the eye of the urethral catheter, and the suture eventually is brought out through the bladder and abdominal wall as a lock stitch to fix this catheter in place. Some authors have used interlocking sounds or magnetic catheters (116) to effect this alignment, but the high incidence of false passages with this technique has led to its virtual abandonment.

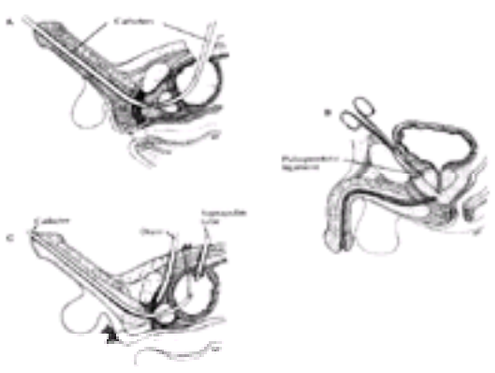

FIGURE 12.14. A: Catheter introduced into urethral meatus and by means of surgically opened bladder into bladder neck, then tied together in prevesical space. **B:** Unruptured puboprostatic ligament cut before repositioning of bladder and prostate. **C:** Urethral catheter lock-stitched to abdominal wall. Prostate kept in position against urogenital diaphragm by vest sutures.

It is now important to verify whether the puboprostatic ligaments have ruptured. If not, they must be transected, freeing the bladder and prostate from their bony attachments. If this is not done and there is severe distortion of the anterior pelvic arch, the bladder and prostate will never be able to be brought down to their normal position alongside the urogenital diaphragm (Fig. 12.14B).

One of the older techniques used to attempt realignment of the prostate was to insert a Foley catheter into the urethra and place it on traction. The idea was to pull the catheter's balloon snugly against the bladder neck and prostate to bring the organ into position. Unfortunately, to effect such a maneuver, if the prostate was still attached to the pubis, the Foley catheter would have to realign the pelvic bone as well. The procedure usually failed to accomplish this, and unfortunately, the force of the balloon on the base of the bladder often caused pressure necrosis of the bladder neck and an irreparable injury followed.

The prostate and bladder should now easily and without tension be repositioned against the urogenital diaphragm. Although some surgeons would attempt directly to anastomose the severed ends of the urethra, an easier and equally effective repair can be effected by placing 0 nylon (Vest) traction sutures through the distal prostate, through the urogenital diaphragm, and onto the perineum, where they are tied snugly over a bolster (Fig. 12.14C). A suprapubic tube is placed in the bladder, a drain in the prevesical space, and the wounds closed.

The Vest sutures and drain can be removed in 14 days, but the urethral catheter should be left in place for 3 weeks. A retrograde urethrogram should then be done around the tube, and if there is no extravasation, it can be removed. A voiding cystourethrogram is then performed, and if the patient voids normally, the suprapubic tube is removed.

Delayed surgical repair is the procedure of choice if (a) the patient is medically unstable or (b) the surgeon is unskilled in performing major urethral reconstructive surgery. In the past few years, more and more urologists have made the delayed repair their procedure of choice for almost all patients with posterior urethral ruptures because the long-term results and complications of the various techniques have become available. As is later discussed, there is evidence that the incidence of stricture incontinence and erectile dysfunction may be lower with the delayed approach to the repair of this injury (59,95,98).

Once the diagnosis of a complete posterior urethral disruption has been made, a suprapubic tube is placed into the bladder either by trocar or formal cystotomy. A cystogram is then performed to ensure that there is no bladder rupture, and nothing more is done about the urethral injury at that time. A cystotomy tube is changed at monthly intervals and the patient has follow-up clinically until the pelvic hematoma has completely reabsorbed, all scar tissue has softened, the pelvic injury has healed, and the patient has been otherwise rehabilitated. This usually takes from 6 to 9 months after the accident.

Before the repair, a cystometrogram is performed to see whether the patient has normal bladder function, as is a combined cystogram and/or retrograde urethrogram x-ray film to determine the length of the urethral defect (Fig. 12.15). Most high-riding prostates and bladders spontaneously return to the pelvis during the delay, as the pelvic hematoma reabsorbs. With this information, a procedure for definitive repair can be made. Broadly the repairs that have been described are (a) a two-stage reconstruction, (b) a one-stage reconstruction, and (3) endoscopic reestablishment.

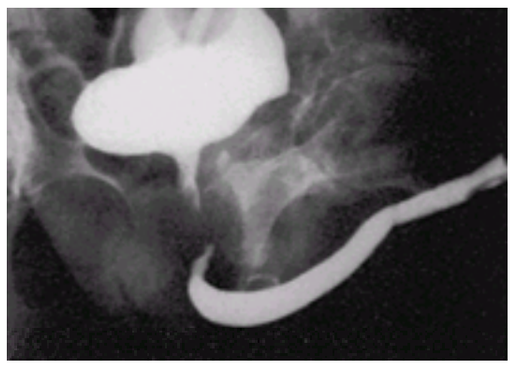

FIGURE 12.15. Combined cystogram and retrograde urethrogram in patient with a complete urethral rupture 6 months after injury.

The two-stage urethroplasty has been used since the early 1950s as a way to repair posterior urethral strictures (64,71,93,95,96). At the first stage, either through a perineal midline or pedicled flap incision, the urethra is incised ventrally through the entire stricture as proximal as the verumontanum. A scrotal or perineal skin inlay flap is then sutured to the cut edges of the urethra with interrupted absorbable suture material (Fig. 12.16). In essence, these techniques cause the strictured urethra to undergo marsupialization. A catheter is placed through the proximal ostium into the bladder, and a pressure dressing is applied to the wound. The previously placed suprapubic tube is removed on the day of surgery and the Foley catheter and dressing a few days later. The patient should void spontaneously.

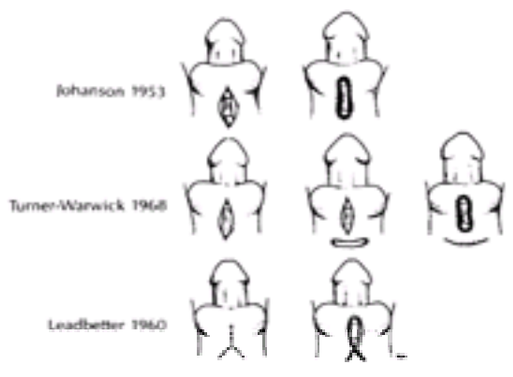

FIGURE 12.16. Various types of first-stage procedures of a two-stage urethroplasty.

Between the first and second stages the ostia, both proximally and distally, must be periodically calibrated. Once all the scar has softened and the wounds have healed, the second stage may be performed. The ostia must remain at least a 26-Fr size. It takes 4 to 6 months to be sure that the urethra is ready for closure.

During the second stage, the inlay is circumcised along with the underlying urethra to form an even tube of at least a 24-Fr caliber. The urethra is closed with interrupted or running absorbable sutures, as are the bulbocavernous muscles, subcutaneous tissues, and skin (Fig. 12.17). Some surgeons prefer nonabsorbable running pullout sutures for closure.

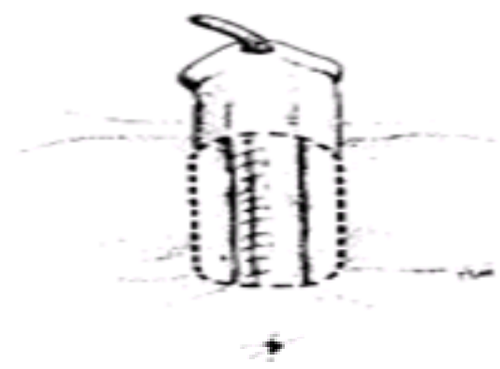

FIGURE 12.17. Second stage of a two-stage urethroplasty. Inlay circumcised *(dotted line)* and neourethra formed and closed. Bulbocavernosus muscles, skin, and subcutaneous tissue will then be closed in layers.

Urethral catheter and/or suprapubic tube drainage is used for 10 to 14 days, and a voiding cystourethrogram is performed when the tube is removed. Catheter drainage should be continued for another week if extravasation is present.

There are basically three techniques described for one- stage reconstruction of posterior urethral strictures. *The original technique was an intussusception of the distal normal urethra into the proximal scarred urethra and prostate* (13,38,102,112). More recently, this procedure has been refined by performing a direct urethroprostatic anastomosis by either bypassing or excising the scarred area (6,31a,68,71,98,102,112,136,137,141,143,146,150). Resection of the symphysis pubis to attain access to the distal prostate is sometimes helpful (110,142).

With all of these procedures, a midline perineal incision is made and carried through the bulbocavernosus muscle to expose the urethra. The urethra with its corpus spongiosum is then dissected free in both directions to obtain adequate length. It is then divided just distal to the stricture, which means almost flush with the urogenital diaphragm.

If the intussusception technique is to be used, a curved sound is now passed by means of the suprapubic sinus tract, where the suprapubic tube has been in place, and guided into the internal urethral meatus. The tip of the sound is felt in the perineal wound at the site of the stricture. An incision is made with a scalpel onto the sound, which is then forced through into the wound. This tract is dilated to 30 Fr (13,102,112).

A small sound is now placed into the suprapubic sinus and out the distal tract and its tip is firmly invaginated into the open end of a 16-Fr red rubber catheter. The sound and catheter are drawn into the bladder and out the suprapubic sinus, and the free end of the catheter is inserted into the distal urethra for a distance of 5 to 8 cm (Fig. 12.18). The edges of the urethra are sewn to the catheter with 3-0 chromic catgut, and the catheter, with the urethra attached, is pulled through the opening in the prostate into the bladder (Fig. 12.19). The cut end of the urethra should be made to rest approximately 1 cm proximal to the verumontanum. A marking suture on the urethra before invagination is helpful to ensure this position. The outer wall of the urethra is now sewn with a few absorbable sutures to the area where it enters the tract.

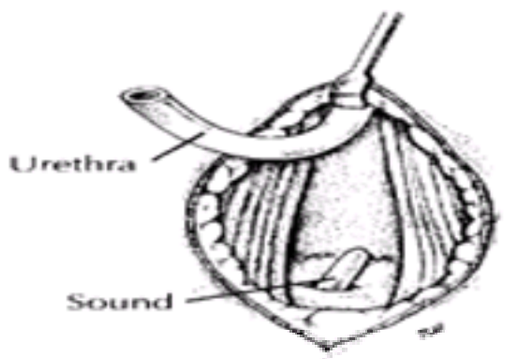

FIGURE 12.18. Urethra severed distal to stricture and retracted. Sound passed by means of bladder into bladder neck and prostatic urethra. Incision over tip of sound allows extrusion of sound into wound.

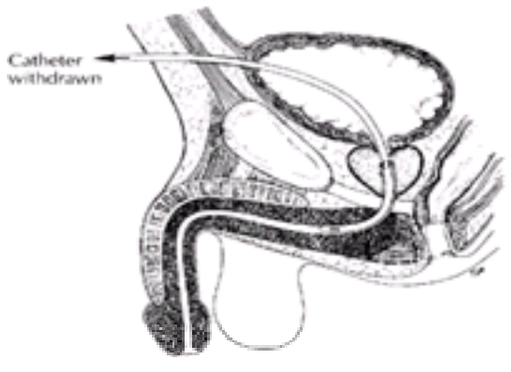

FIGURE 12.19. Catheter previously sewn to cut end of urethra drawn into bladder, intussuscepting bulbous urethra into prostatic urethra.

The catheter, which is now exiting the suprapubic sinus, is fixed with tension to the abdominal wall. A suprapubic tube is inserted into the bladder and placed to straight drainage. The bulbocavernous muscles, subcutaneous tissues, and skin are closed in layers, and a pressure dressing is applied to the wound.

The dressing is removed on the third day. The red rubber catheter will loosen and can be removed in approximately a week. A voiding cystourethrogram should be done on the fourteenth day and the patient allowed to void. A Foley catheter should be placed into the urethra if voiding is difficult and voiding trials should begin. The suprapubic tube can be removed. These patients may need periodic urethral dilation for a few months if voiding becomes difficult.

If an end-to-end prostatourethral anastomosis is to be performed after the urethra has been transected distal to the stricture, it should be spatulated (31a,68,71,98,102,112,135,136,146,150). A curved sound is now passed through the suprapubic sinus into the prostatic urethra. If negotiation of the internal urethral meatus is difficult, a panendoscope can be passed through the suprapubic sinus into the prostatic urethra. Palpation of the tip of the sound or panendoscope in the wound acts as a guide to identify the prostate. Similarly, the light in the panendoscope may shine through the tissues in the perineal wound and help identify the prostate by sight. Now the scar is excised with a scalpel and the prostate beveled from the verumontanum posteriorly to the midprostate anteriorly.

A 16-Fr fenestrated catheter is placed by means of the urethral meatus and drawn into the wound. A 0 nylon suture is tied to the distal eye of the catheter and the suture is drawn out the suprapubic sinus by the sound or panendoscope onto the abdominal wall. The catheter is now pulled into the bladder by the suture to be eventually anchored with the suture to the abdominal wall over a button. The spatulated end of the urethra is now sutured with four 3-0 absorbable quadrant sutures to the beveled-cut end of the prostate. The wound is closed in layers and a suprapubic tube is inserted and placed to straight drainage. A pressure dressing is applied to the wound (Fig. 12.20).

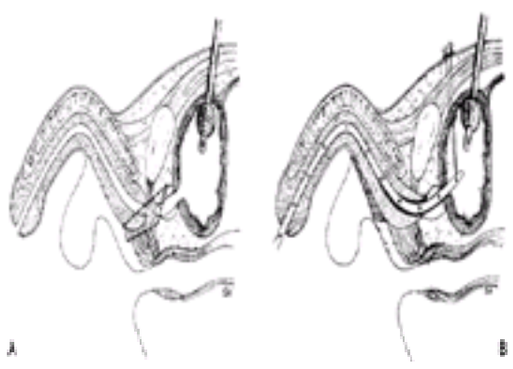

FIGURE 12.20. A: Preoperative status. Suprapubic tube in place. Area bounded by *dotted line* will be excised (includes scar). Prostate and urethra beveled. **B:** Urethra sewn to prostate end to end. Fenestrated urethral stent and suprapubic tube in place.

The dressing is removed on the third postoperative day. The urethral stent is removed in 3 weeks and a voiding cystourethrogram is performed. If the urethra is well healed, the suprapubic tube is removed. If extravasation is present, the patient is kept on suprapubic drainage for another week and the voiding cystourethrogram is repeated. By this time, the urethra should be healed, the patient should void normally, and the suprapubic catheter can be removed.

Occasionally, the prostate and bladder will not descend far enough to allow the anastomosis to be made perineally. If this occurs, a midline abdominal incision should be made and the bladder and prostate freed from above. Many times, gouges will have to be used to remove the underside of the pubis to obtain adequate mobilization. The anastomosis, stenting, and closure are still carried out as previously described in these cases, and a prevesical drain is placed. Because of the increased amount of dead space created when the prostate is dissected from above, the omentum should be freed, brought into the pelvis, and wrapped around the anastomosis to fill in this area. Postoperative management is similar to that described above, except the patient cannot be fed orally until his gastrointestinal tract recovers from the abdominal exploration. The drain can be removed in 1 week.

Transpubic urethroprostatic anastomosis without resection of the scarred area is performed through a lower midline abdominal incision (141,143). A Gigli saw is then passed beneath the pubis on either side of the midline and a trapezoidal piece of pubic bone is removed. This gives access to the anterior surface of the prostate, which is entered. The previously perineally mobilized and spatulated distal urethra is brought through the crura and anastomosed to the prostatic incision with 3-0 quadrant absorbable sutures over a 22-Fr Foley catheter. With this procedure, the prostate is not mobilized nor is the stricture excised. A suprapubic tube and prevesical drain are brought out through the abdomen. The wounds are closed as described previously (Fig. 12.20). The timing of urethral catheter, suprapubic tube, and drain removal is essentially identical to the end-to-end anastomosis procedure.

Some urologists have advocated merely reestablishing urethral continuity by *endoscopic realignment* (3,42,50,61,63,80,118,130). With this technique, a panendoscope is passed by means of the suprapubic sinus into the proximal urethra by one surgeon, and either a visual urethrotome or a resectoscope fitted with a Colling's knife is passed into the distal urethra by a second surgeon. With the light from the panendoscope as a guide, the distal operator cuts through the scar and

into the prostatic urethra. A laser also has been used to create an opening (39). A 22-Fr urethral catheter is then placed into the bladder, removed 1 week later, and the patient is allowed to void. Periodic dilations are usually necessary in these patients (7). Recently, the use of an indwelling metal stent also has been advocated (12,107).

ANTERIOR URETHRAL INJURIES

Classification—Type V Injury

Most anterior urethral injuries caused by blunt trauma are secondary to straddle injuries (15,115). In these instances, the pelvis is usually not fractured and the overlying skin remains intact. Perhaps today there is a greater volume of iatrogenic injuries to the anterior urethra as a result of urethral instrumentation. The following subclassification of these injuries is useful when planning appropriate therapy.

Urethral Contusion

When a patient has undergone a straddle injury and has initial or terminal hematuria but has a normal urethrogram, a urethral contusion has occurred.

Partial Urethral Rupture

When a urethral injury is either caused by external blunt trauma or urethral instrumentation and a retrograde urethrogram demonstrates extravasation of contrast material but the urethra is in continuity and contrast material goes freely into the bladder, the patient is said to have a partial urethral rupture (Fig. 12.21).

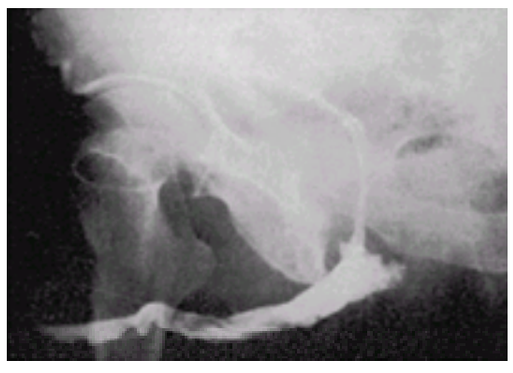

FIGURE 12.21. Partial anterior urethral rupture secondary to Foley catheter balloon blown up in bulbous urethra.

Complete Urethral Rupture

If after blunt trauma extravasation is demonstrated on a retrograde urethrogram and urethral continuity is lost, a complete urethral rupture is present (Fig. 12.22).

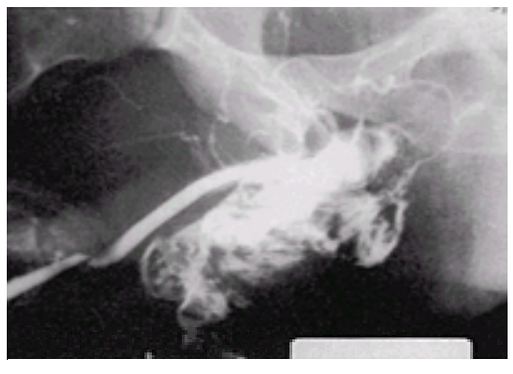

FIGURE 12.22. Complete anterior urethral rupture secondary to a straddle injury. Note the venous extravasation. (From Sandler CM, Phillips JM, Harris JD, et al. Radiology of the bladder and urethra in blunt pelvic trauma. *Radiol Clin North Am* 1981;19:195, with permission.)

Penetrating Urethral Injury

If the urethra has been injured by an external missile, urethral instrumentation, or migration of a penile prosthesis, a partial or complete disruption of the urethra may result. Only major lacerations or those associated with extensive tissue destruction are handled in a unique way from blunt injuries. Because of these therapeutic decisions, however, penetrating injuries are best placed into a separate category.

Therapy

Urethral Contusions

No special therapy is necessary for patients with anterior urethral contusions from blunt trauma. They usually are able to void normally, and their hematuria promptly clears. If necessary, a urethral catheter can be placed for a short period. In the absence of extravasation, there are probably no long-term sequelae of this injury.

Partial Urethral Rupture

If the extravasation on urethrogram is minimal, contained by Buck's fascia, and urethral continuity is good, patients with partial urethral rupture secondary to blunt trauma may be allowed to void or a urethral catheter can be placed into their bladder for a few days. If the injury is extensive and extends outside Buck's fascia, a suprapubic tube should be placed into the bladder and a voiding cystourethrogram repeated in 10 to 14 days. If the urethra is normal or there is only a large-caliber stricture, the tube can be removed and the patient is allowed to void. Periodic urinary flow rates and urethrograms should be done to be sure a stricture does not develop at the site of the injury.

If a significant narrowing has developed, the patient should undergo panendoscopy and visual urethrotomy of the strictured area. A urethral catheter should be left in the urethra for 24 hours and the suprapubic tube removed. When the urethral catheter is removed, the patient should be allowed to void. Periodic urinary flow rates and urethrograms are critical follow-up measures in these patients (17).

Complete Urethral Rupture

Patients with complete urethral rupture from a blunt injury do not do well with primary repair and should have a suprapubic tube placed into their bladders. If extensive perineal extravasation of blood and urine is present, these patients will need close follow-up to determine whether these collections properly reabsorb or need surgical drainage. Occasionally, patients with extensive extravasation delay in presenting to the physician, and erythema, purulence, and frank necrosis may be

present in the penis, scrotum, or perineum. These patients need subcutaneous drains placed, debridement and suprapubic urinary diversion performed, and antibiotics prescribed.

When the skin of the genitalia and perineum become normal and at least 14 days have elapsed from the injury, a voiding cystourethrogram and possibly a combined voiding cystourethrogram and retrograde urethrogram should be done to delineate the injury. A stricture of some magnitude will probably have developed. If urethral continuity is intact, panendoscopy and a visual urethrotomy may be all that is needed to incise the stricture (66,144). If this is successful, a urethral catheter should be placed for 24 hours and the suprapubic tube removed. These patients must have careful follow-up with voiding flow rates and retrograde urethrograms for recurrence of their stricture.

Most of these patients, however, will have developed complete occlusion of their urethra. If infection did not supervene on the extravasation of blood and urine, it will commonly be short. The patient should be left on suprapubic drainage until the perineum is well healed before reconstruction. This will usually take 4 to 6 months. A combined voiding cystourethrogram and retrograde urethrogram will delineate the extent of the stricture to be repaired, as was described in posterior urethral ruptures.

The two-stage urethroplasties previously discussed and illustrated in Fig. 12.16 and Fig. 12.17 have been used to repair strictures of the anterior and posterior urethra (64,78,132,133). Because the strictured area is usually at the penoscrotal junction, a simple midline incision rather than the scrotal or perineal inlay flaps is usually adequate for the first stage.

However, if a short stricture is present, a one-stage end-to-end urethroplasty plus or minus a ventral wall skin patch should be performed (36,84). In this procedure, a midline incision is made over the area of the stricture, which is identified with a urethral sound, and the urethra is mobilized in both directions. The strictured area is then excised and the dorsal wall of the urethra is reanastomosed. A full-thickness skin graft may be taken from the shaft of the penis, defatted, and used to widen the anastomosis. It is sutured in place with 4-0 absorbable sutures (Fig. 12.23). This needs to be done only if there is tension on the anastomosis or the lumen is compromised. A pedicle procedure as later described also can be used for this purpose.

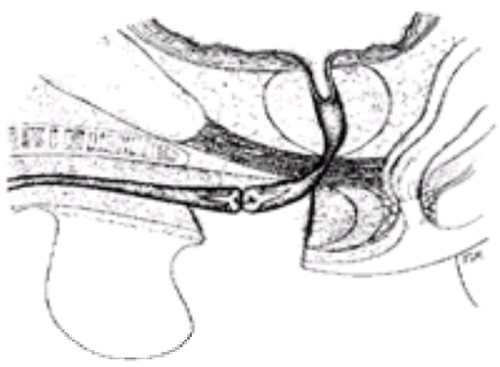

FIGURE 12.23. Strictured area was removed. Cut ends of urethra were spatulated ventrally. Dorsal walls were anastomosed. Ventral defect will be “patched open” with a full-thickness skin graft (see Fig. 12.24).

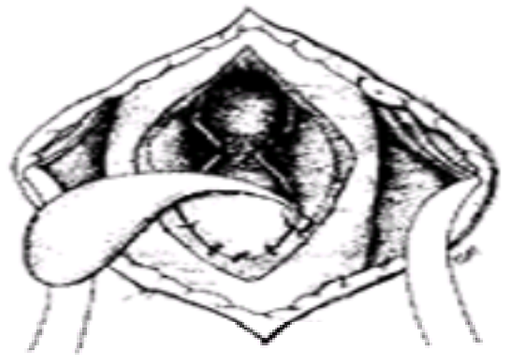

FIGURE 12.24. Free full-thickness skin graft sewn into incised urethra at area of stricture to widen stenotic section.

The bulbocavernous muscles, subcutaneous tissue, and skin are closed in layers. A urethral catheter is left in place for 3 to 5 days and the suprapubic tube continued on drainage for 14 days. A voiding cystourethrogram is performed at that time, and if no extravasation is seen, the suprapubic tube is removed. If extravasation is seen, suprapubic drainage is continued for another week and the study repeated.

If the stricture is long, a one-stage patch graft urethroplasty or pedicled urethroplasty can be performed (16,36,85,86,104). In these procedures, the stricture is identified as previously described for the end-to-end urethroplasty, but the urethra is not mobilized. Instead, the stricture is incised ventrally in the manner of a first-stage procedure of the two-stage technique, and then a free graft may be taken from the skin of the penis, defatted, and the entire incised urethra “patched” open (Fig. 12.24). Buccal mucosa also has been used in these repairs (43). In the pedicled technique, instead of a free graft, a suitable length of skin is freed next to the urethral incision but is left attached to its underlying blood supply. This pedicled graft is then inverted and sewn into the urethral defect (Fig. 12.25). A circular skin flap taken from the distal penis may have a higher success rate than the use of local skin (86) (Fig. 12.26). Postoperative care is similar to that of the end-to-end technique with appropriate attention being given to the donor site.

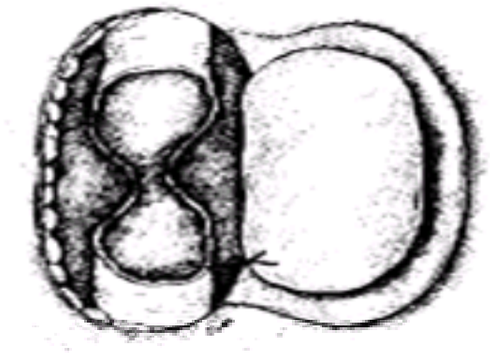

FIGURE 12.25. Pedicled skin graft sutured into area of stricture to widen stenotic section.

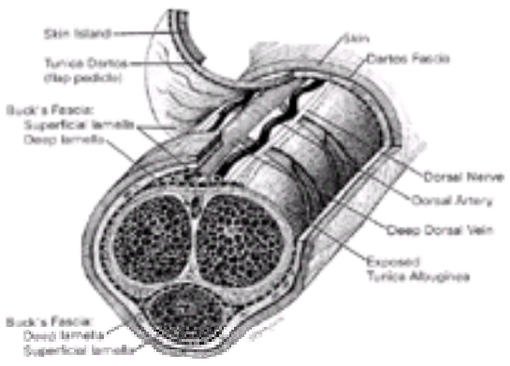

FIGURE 12.26. Flap pedicle with blood supply via tunica dartos. (From McAninch JW, Morey AF. Penile circular fasciocutaneous skin flap in 1-stage reconstruction of complex anterior urethral strictures. *J Urol* 1998;159:1209, with permission.)

Penetrating Urethral Injury

The most common penetrating injuries of the anterior urethra are secondary to urethral instrumentation. Most of these injuries are minor, and patients are usually allowed to void or a Foley catheter is placed in their bladder for a few days. Occasionally, a sound or filiform and follower is forced through the urethral wall and into the rectum. These patients need a suprapubic tube placed in their bladders for a few weeks, and their wounds will usually heal without sequelae. A retrograde urethrogram and/or voiding cystourethrogram should be done to ensure that the injury has healed before the patient is allowed to void.

During dilation of the corpus cavernosum for placement of a penile prosthesis, the urethra may be ruptured. If the prosthesis is not inserted and a Foley catheter is placed into the bladder for a few days, the perforation will heal. Sometimes, a prosthesis will spontaneously erode through the urethra, especially in patients with decreased sensation from neurologic disease, or if a Foley catheter is left in the urethra for a long time in patients with penile prostheses. Merely removing the prosthesis will allow the urethral lacerations to heal. A Foley catheter may be placed for a few days to facilitate the process.

Penetrating injuries that need prompt surgical attention are those caused by external violence. Clean knife or bullet wounds merely need minimum debridement, closure of the defect with absorbable sutures, and suprapubic catheter drainage for 2 to 3 weeks (52). A voiding cystourethrogram and/or retrograde urethrogram should be done before removal of the suprapubic tube.

Dirty wounds with extensive tissue destruction and foreign material in the wound (e.g., metal pellets, oil, grease, hair, clothing) need to be cleansed thoroughly with antiseptic solutions and copious irrigation. Although debridement of devitalized tissue is important, it must be stressed that contused corpus spongiosum tissue is hemorrhagic and ecchymotic and may appear necrotic when it is only badly bruised. If debridement is vigorous, more urethra than is necessary may be removed and discarded, making eventual repair a formidable task. If a large section of urethra is lost, however, the ends of the urethra that are left should be sutured to the skin in the manner of a first-stage urethroplasty. Skin will have to be brought between the ostia to close the wound (Fig. 12.27).

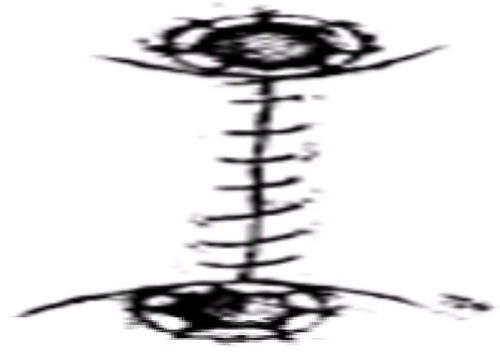

FIGURE 12.27. Damaged urethra has been discarded. Freshened edges of severed urethra sewn to skin. Normal skin brought between ostia to cover defect.

Suprapubic diversion should be done until the perineum has healed. This may take weeks to months. Radiographic studies will demonstrate residual stricture, which can be handled by one of the previously described urethroplasty techniques.

POSTOPERATIVE CARE AND FOLLOW-UP

A discussion of when the stents, drains, and catheters should be removed is included with each of the previously discussed procedures. Antibiotics should be withheld in these patients until they have all tubes removed from their urinary tracts. At that time, they should receive appropriate antibiotics, and eventually urinalysis and urine cultures should be performed to ensure sterilization has been accomplished.

Periodic voiding flow rates should be done at 3-month intervals for at least a year. If flow decreases, a retrograde urethrogram should be performed. Patients with neurologic damage may not be able to void and may have to be taught intermittent self-catheterization. Those with bladder neck damage may be incontinent and need a-adrenergic drugs or collagen injections to become dry (60). Complete neurologic evaluation is imperative in these patients.

RESULTS AND COMPLICATIONS

When the literature is reviewed for the results and complications of these various techniques, it is well established that *the primary realignment patients may have a higher long-term complication rate than do patients treated with delayed repair, despite the technique used* (11,32,44,72,75,83,98,150). The persistent restricture rate with primary repair is approximately 50% (38% to 53%), the erectile dysfunction rate is 36% (20% to 50%), and the major/moderate incontinence rate 14% (3.7% to 21%).

With the delayed procedures, it should be noted that although virtually all partial ruptures heal without stricture, almost all patients with complete ruptures initially develop strictures. After definitive repair, however, it is the rare patient who has a long-term stricture problem. However, the erectile dysfunction rate is similar at approximately 33% (17.6% to 62%) but the major to moderate incontinence rate is lower at 2% (1% to 4%) in well-reported series. It appears to be well worth the trade-off of wearing a suprapubic catheter for 6 or more months when compared with the long-term problems associated with early repair.

There is considerable concern that patients who undergo a transsphincteric urethroplasty and in essence have their internal urethral mechanism destroyed by the procedure, are later at risk for incontinence if a transurethral resection of the prostate is performed. This risk is certainly real. However, when one considers that these are usually young men with 40 to 50 years of life ahead of them and that only 10% of males will need a prostatectomy as they get older, the argument becomes thin for withholding the procedure.

However, when faced with an elderly patient with complete obstruction caused by a posterior urethral rupture who has previously had a transurethral prostatectomy and therefore has no bladder neck continence mechanism, the use of the intussusception procedure should be chosen. With this technique the stricture and sphincter (if it is still intact) are not resected but merely dilated. If the sphincter is intact and the stricture can be kept open with periodic dilations, the patient should be continent

and able to void. If the sphincter has been irreparably damaged, the stricture, if not dilated, will recur.

The long-term results reported with endoscopic realignment are poor when compared to the open procedures (3,7,42,63,80,116,130). Although the incidence of erectile dysfunction is approximately 30% (14% to 42%), which is comparable to the other techniques, it is now fairly well accepted that erectile dysfunction in patients with posterior urethral rupture is most likely caused by the injury and is not aggravated by the repair, no matter what procedure is used.

Similarly, the average major to moderate incontinence rate is 5.5% (0% to 12.5%), which is slightly higher than reported with the delayed repairs (2%) but lower than reported with primary realignment (14%).

The major objection to the endoscopic realignment is the persistent stricture rate of 54% (25% to 100%) and the need to continue with prolonged (possibly lifetime) urethral dilations in approximately 56% (25% to 100%) of the patients. Some authors even recommend leaving an indwelling catheter in the urethra after surgery for up to 3 months to keep the scar dilated and permit epithelization of the tract (3).

This high rate of restricture is because the mucosal edges of the disrupted urethra have been separated by scar and even if reepithelization of the tract does occur, the surrounding scar will persistently contract. Only a proper mucosa-to-mucosa anastomosis, with removal of all surrounding scar, can give the repair a high degree of long-term success without need for continued instrumentation.

INJURIES IN FEMALES

There are few reports of rupture of the female urethra in the literature (2,24,56,88,138). Most of them are in children, and most of them also involve the bladder neck and vagina (88,109,134). These injuries need immediate reconstruction of the bladder neck and repair of all vaginal lacerations to ensure that the continence mechanism will be intact after injury as well as to prevent the formation of vesicovaginal fistulae. Retropubic repair over a stenting urethral catheter and use of a suprapubic tube usually produces a good result. Occasionally, a urethrovaginal fistula will develop and require secondary closure.

INJURIES IN CHILDREN

As previously mentioned, most urethral injuries in females are in children and need immediate repair to prevent long-term complications (2,56,88,120,138). Males are treated by any of the previously described procedures but seem to do best when treated with the delayed technique (48,53,73,113). If the patient has an anterior stricture that can be incised with a visual urethrotome, this is preferable. If restricturing occurs, the child should be taught intermittent self-catheterization to keep the stricture dilated. Eventually, a formal urethroplasty should be performed (73,91,113,140). Transurethral resection of the scar with stenting also has been advocated (148).

FRACTURE OF THE BONY PELVIS

Most patients that have fractures of the bony pelvis have multisystem injuries secondary to high-speed motor vehicle accidents (8,26,31,45,46,62,79,82,94,114). When an anterior arch fracture is present, the probability of a urinary tract injury is high. With a single break of the pelvic ring, 12.5% of patients will have an injury to the lower urinary tract, and with two breaks in the ring, 22% of patients will have such an injury (74,105).

Bladder ruptures, mostly extraperitoneal in nature, are seen 9% of the time, urethral injuries 3.5% of the time, and both a bladder and urethral injury 1% of the time. Aside from the urinary tract complications of stricture and incontinence, in the male, complete or relative erectile dysfunction can be seen in up to 65% of these patients (11,32,83). As previously discussed, there is a wide range of variation in the long-term complication rate depending on the initial care and the reconstructive procedure chosen for the repair of the injury. It must be stressed to emergency room and trauma team personnel that injudicious instrumentation of the urethra in the patient with a fractured pelvis and possible urethral injury may lead to a lifetime of chronic debilitation because of a momentary lapse in the proper management of this injury.

ANATOMY

The adrenal glands are a pair of retroperitoneal organs embedded in perirenal adipose tissue. They lie superior and medial to the upper poles of the kidneys within Gerota's fascia. Their lowest extent, particularly on the left, is close to the renal vessel; thus care must be taken to avoid injury to the renal blood supply during adrenalectomy. Computed tomography (CT) scanning has made it clear that the adrenal glands are anterior to the kidney. The cortex has a characteristic yellow color, which makes it easy to recognize during surgery. The medulla, which is usually not visualized, is brown or red. The glands are flattened with distinct edges and measure approximately 5 cm by 3 cm by 1 cm. The normal human gland weighs 4 to 5 g *in vivo* and 6 g in death (65). The terminal weight increase is caused by adrenocorticotropic hormone (ACTH) release during stress. The shape and size of the glands are variable.

The cortex has a mesodermal origin, arising in utero from the dorsal mesentery near the cranial pole of the mesonephros. The gland differentiates into an outer zone, which will form the adult cortex, and a much larger inner fetal zone, which will be 80% of the gland at birth but rapidly degenerates while the outer portion grows (Fig. 13.1). The net result is that the gland at birth is twice as large as it is a few weeks later. The medulla arises from ectodermal neural crest tissue, which also generates sympathetic ganglion cells. Strands of this chromaffin tissue migrate to the adrenal cortex on its medial side and become centrally located in the gland.

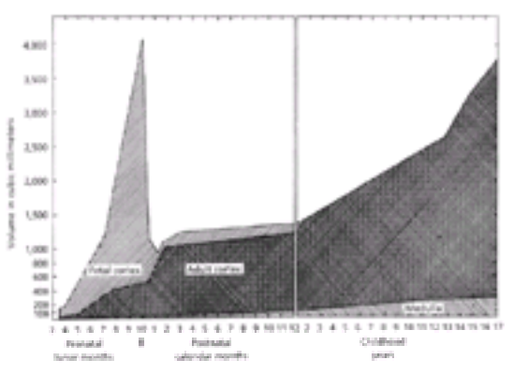

FIGURE 13.1. Growth of the adrenal cortex including the fetal cortex *in utero* and after birth. There is a striking decrease in the size of the fetal cortex after birth and a gradual increase in the adult cortex with aging. (From Bethune JE. *The adrenal cortex. A scope monograph.* Kalamazoo MI: Upjohn Co., 1974.)

Each adrenal gland is supplied with blood from three arteries that are branches of the aorta, renal, and inferior phrenic arteries (Fig. 13.2). These arteries form a plexus in the capsule that gives rise to cortical arteries, which in turn supply sinusoids surrounding the cords of cells in the cortex. There are no veins in the cortex. The medulla has a dual blood supply from major capsular arteries that pass directly through the cortex without branching and from the cortical sinusoids that connect to medullary capillaries. Thus the medullary cells are exposed to the cortical effluent with high concentrations of cortical steroids. The medulla and cortex drain into a large central medullary vein, the adrenal vein, which inserts directly into the vena cava on the right and into the renal vein on the left.

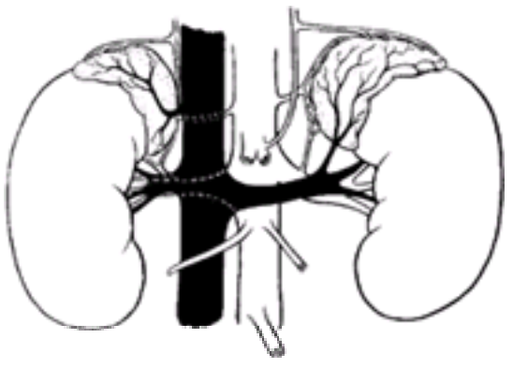

FIGURE 13.2. Blood supply to the adrenal gland. The gland is supplied by three major arteries, the superior, middle, and inferior adrenal arteries, which are branches of the inferior phrenic artery, the aorta, and renal artery. One major vein drains into the renal vein on the left and the vena cava on the right.

The cortical cells have sparse, possibly adrenergic innervation. The medullary cells are innervated by preganglionic sympathetic nerve fibers arising from the intermediolateral column of the lower thoracic spinal cord. These fibers travel with the splanchnic nerves and synapse with a group of medullary cells to form a functional unit. The medullary pheochromocytes are the equivalents of sympathetic ganglion cells.

The adrenal cortex contains three concentric zones: a thin outer zona glomerulosa, a thick zona fasciculata, and a thin zona reticularis (Fig. 13.3). The zona glomerulosa is composed of small (12 to 15 mm) columnar cells with sparse cytoplasm. The cells are packed in clusters and arcades. In humans, the zona glomerulosa may be absent in some areas of the cortex. Aldosterone synthesis occurs in steps in the smooth endoplasmic reticulum and mitochondria where the essential enzymes are located (48).

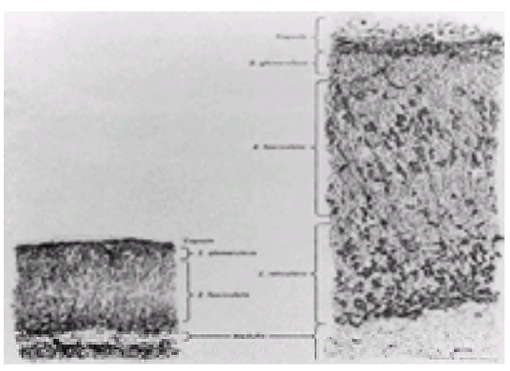

FIGURE 13.3. Histology of the adrenal gland. Note the cortex has three major components: the zona glomerulosis, zona fasciculata, and zona reticularis.

The zona fasciculata consists of polyhedral large (20 mm) cells arranged in straight cords one to two cells thick and filled with lipid droplets. The zona reticularis consists of smaller cells with few lipid droplets. The cells are arranged in now parallel anastomosing cords (Fig. 13.3).

The adrenal medullary consists of chromaffin cells generously supplied with cortex and blood vessels. They are polyhedral and arranged in cords with close association to the vascular spaces. Epinephrine- and norepinephrine-secreting cells are distinct; each contains a specific type of granule (48).

Ectopic adrenal tissue can be found in many locations, particularly near the adrenal glands, kidneys, celiac axis, or testis and spermatic cord. Unilateral congenital absence of an adrenal gland is a rare anomaly. When the kidney is absent, the adrenal is present in its normal position but is more disklike than triangular.

PHYSIOLOGY

The adrenal cortex synthesizes cholesterol and also takes it from the circulation. The first and rate-limiting process in the synthesis of adrenal steroids is the conversion of cholesterol to pregnenolone (Fig. 13.4). The hormones critical to life that are produced by the cortex are (a) the glucocosteroids, particularly cortisol, which affect carbohydrate and protein metabolism, and (b) a mineralocorticoid, aldosterone, which regulates sodium and potassium balance. These hormones must be replaced after bilateral adrenalectomy. The adrenal cortex also synthesizes androgens and estrogens, which in normal individuals are not as important in sexual development and function as their counterparts produced by the testis and ovaries. In certain disease states, these sex steroids have dramatic virilizing or feminizing effects.

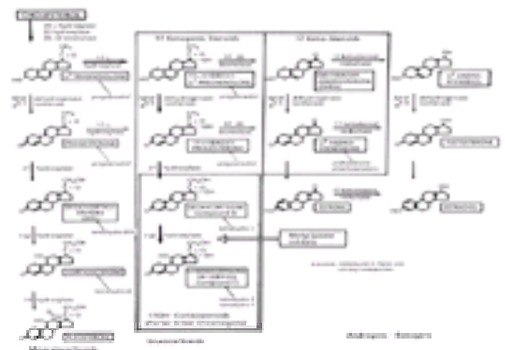

FIGURE 13.4. Biosynthetic pathways for the synthesis of adrenocortical steroids—also the site of metyrapone, urinary metabolites, and the Porter-Silber chromogens.

Steroidogenesis

All adrenal steroid hormones have the same steroid nucleus (Fig. 13.5). A ketone at the 3 position and hydroxyl groups at the 11 and 21 positions are required for potent glucocorticoid activity. An oxygenated carbon at the 18 position results in powerful mineralocorticoid activity. Elimination of the $C_{20\text{-}21}$ side chain and incorporation of an oxygenated carbon at the 18 position create a potent androgen. Aromatization of the A ring generates an estrogen.

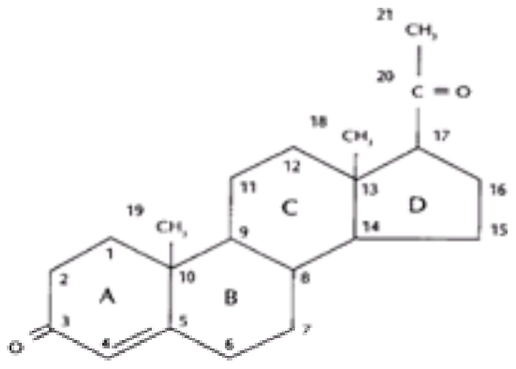

FIGURE 13.5. Common steroid nucleus.

The synthesis of glucocorticoids and sex steroids occurs primarily, although not exclusively, in the zona fasciculata and reticularis, respectively. Aldosterone is synthesized exclusively in the zona glomerulosa. The synthesis pathways for production of these hormones are presented in Fig. 13.4. In certain situations, alternative pathways may become important; for example, if cortisol synthesis is specifically blocked, corticosterone synthesis may be increased to provide the necessary glucocorticoid.

Iatrogenic interruption of these pathways may be useful in diagnosis and treatment. Metyrapone decreases the conversion of cholesterol to pregnenolone. Thus, when the drug is used preoperatively, the levels of all adrenal steroids may be reduced. Metyrapone also inhibits 11-hydroxylation, the last step in cortisol synthesis (Fig. 13.4), resulting in an increase in ACTH and thus cortisol precursor production in the normal individual. Therefore metyrapone can be administered to test the hypothalamic-pituitary-ACTH axis and in the treatment of Cushing's syndrome, especially before surgical therapy. Aminoglutethimide inhibits the desmolase and the aromatase reactions, thus decreasing steroid synthesis. This property has been used in the treatment of hypersecretion of adrenal steroids, prostate cancer, and breast cancer.

Metabolism

Circulating cortisol is 75% to 80% bound to an a_2-globulin, transcortin; 15% is bound to albumin; and only 5% to 10% is unbound. The biologically active factor is the free hormone; thus alterations in the level of transcortin can have physiologic significance. The half-life of cortisol is approximately 70 minutes. Most of the hormone is metabolized in the liver, conjugated, and excreted as glucuronides in the urine. A small fraction of the cortisol (approximately 50 mg) is excreted unaltered in urine. Measurement of the urinary metabolites and free cortisol can be used to evaluate adrenal function.

Plasma aldosterone is weakly bound to a specific binding globulin and albumin. Ninety percent of the circulating aldosterone is cleared in one pass through the liver and then is reduced and excreted in the urine as the 3 and 18 glucuronides. Less than 1% of the aldosterone is excreted as the free hormone. Because of its rapid metabolism, the half-life of plasma aldosterone is only 20 minutes.

Adrenal androgens are excreted in the urine as dehydroepiandrosterone sulfate (DHEAS) and two reduced isomers, androsterone and etiocholanolone (Fig. 13.4). These compounds make most of the urinary 17-ketosteroids. Two-thirds of the 17-ketosteroids come from the adrenal and one-third from the gonad in normal individuals. Elevation of the urinary 17-ketosteroids generally indicates adrenal hyperfunction.

Regulation

ACTH is the regulator of glucocorticoid secretion and is also the primary determinant of the secretion of adrenal sex steroids. It is derived from a 31,000-Da glycoprotein, proopiomelanocortin, which is cleaved in corticotropic cells into ACTH, b-lipotropin, and a glycopeptide (87). ACTH is a single-chain polypeptide containing 39 amino acids. The active component of the molecule is the initial segment of 23 amino acids. The hormone is secreted in irregular bursts throughout the day, but the most active secretion occurs in the early morning, causing the diurnal secretion of cortisol. Cortisol secretion increases within minutes of an elevation in plasma ACTH levels. ACTH binds to an adrenal plasma membrane receptor and activates adenylate cyclase, which in turn raises tissue cyclic adenosine monophosphate (cAMP) levels. The cAMP activates critical protein kinases, which effect the phosphorylation of proteins that increase steroidogenesis.

The secretion of ACTH is controlled primarily by corticotropin-releasing factor (CRF), a protein with 41 amino acid residues, which is synthesized in the median eminence of the hypothalamus and travels to the pituitary by means of the portal-hypophyseal vessels (Fig. 13.6). Arginine vasopressin from the hypothalamus and several nonhypothalamic factors such as lymphokines (60) also can cause ACTH release (82). The peripheral plasma level of CRF in normal human subjects is 0.4 to 6.0 pmol/L (58). CRF secretion is regulated by four main factors: circadian rhythm, glucocorticoid feedback, ACTH feedback, and stress. Stress increases the secretion of CRF and ACTH, whereas there is a negative feedback relationship between plasma glucocorticoid levels and ACTH secretion. This inhibition of ACTH secretion is probably mediated at both the hypothalamus and the pituitary.

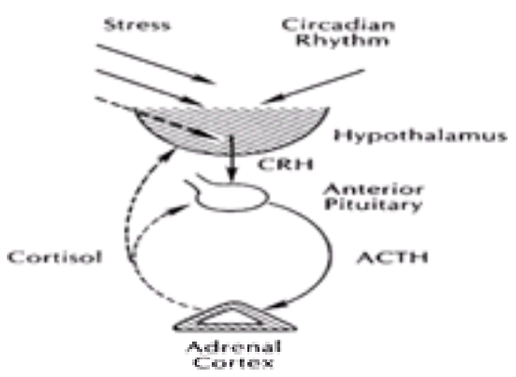

FIGURE 13.6. Hypothalamic pituitary adrenal axis including the long- and short-loop feedback circuits.

Three clinically relevant points related to ACTH secretion are as follows: (a) Some neoplasms secrete ACTH-like substances that can stimulate the adrenal gland to release glucocorticoids and thus cause Cushing's syndrome. (b) After treatment with large doses of exogenous glucocorticoids, not only is the adrenal gland unresponsive, but the hypothalamic-pituitary axis may be unable to secrete normal quantities of ACTH. (c) ACTH is not required for aldosterone synthesis and secretion, and therefore a patient with hypopituitarism does not require mineralocorticoid replacement.

Actions of Glucocorticoids

Glucocorticoids are essential for life. An adrenalectomized person will die even if provided with mineralocorticoids. Adrenal steroids and, indeed, all steroid hormones easily cross the cell membrane to bind with cytoplasmic receptor proteins that are present in target tissues. The steroid may be metabolized within the cell to a more or less active form. The steroid–receptor complex migrates to the cell nucleus, where it attaches to a specific group of genes. This causes the production of new ribonucleic acid, which in turn effects the synthesis of proteins that serve as structural building blocks of enzymes that regulate cellular function in various tissues.

Glucocorticoids are so named because they have major effects on carbohydrate metabolism, including the promotion of liver glycogen deposits and gluconeogenesis. In the starving patient, they allow survival by enhancing proteolysis, preventing death from hypoglycemia. They also have an antiinsulin effect. Thus they are

diabetogenic, causing hyperglycemia during stress or when present in pharmacologic quantities.

Glucocorticoids have many permissive actions in that they facilitate processes that they do not initiate. Several additional effects of glucocorticoids are listed in Table 13.1 along with their clinical implications.

Effect	Clinical Implications
Enhance skeletal and cardiac muscle contraction	Absence results in weakness
Cause protein catabolism	Excess results in wastage and weakness
Inhibit bone formation	Excess decreases bone mass
Inhibit collagen synthesis	Excess causes thin skin and fragile capillaries
Increase vascular contractility and decrease permeability	Absence makes it difficult to maintain blood pressure
Have antiinflammatory activity	Exogenous steroid useful in treating inflammatory diseases
Have antiimmune system activity	Exogenous steroids useful in treating transplantation and various immune diseases
Maintain normal glomerular filtration	Absence reduces glomerular filtration

TABLE 13.1. EFFECTS AND IMPLICATIONS OF GLUCOCORTICOIDS

Actions of Adrenal Androgens and Estrogens

The mechanism of action of the major adrenal androgens DHEA, DHEAS, and androstenedione is similar to that described for the glucocorticoids. These compounds are weak androgens that have little effect in physiologic quantities. In disease states, however, they may virilize a female fetus (adrenogenital syndrome) (see Chapter 57), causing pseudohermaphroditism, and virilize either prepubertal children or adult females with Cushing's syndrome. The effects of excess adrenal androgens are not clinically evident in the adult male, which delays the diagnosis of Cushing's syndrome in some men. Excess adrenal estrogens may cause breast enlargement in children and men.

Regulation of Glomerulosa Function

The primary regulator of aldosterone secretion is the renin-angiotensin system. Renin is an enzyme synthesized in the juxtaglomerular apparatus of the nephron. When released into the circulation, renin cleaves renin substrate, a globulin secreted from the liver, releasing the decapeptide angiotensin I. Angiotensin I is hydrolyzed to angiotensin II, an octapeptide, by converting enzyme, which is found primarily in the lung. Angiotensin II is a potent stimulator of aldosterone secretion. It is rapidly destroyed in the plasma by angiotensinases.

Renin secretion is regulated by a complex intrarenal mechanism (see Chapter 23). Decreased perfusion pressure in the renal artery and decreased chloride absorption at the macula densa cause increased renin release and thus ultimately increased circulating levels of aldosterone. Angiotensin II and aldosterone can inhibit renin secretion through short- and long-loop feedback systems, respectively. Catecholamines may increase renin release, but dopamine inhibits aldosterone secretion in sodium-depleted individuals. ACTH increases the sensitivity of the zona glomerulosa to angiotensin II and stimulates aldosterone secretion, but the latter effect is not long lasting. Potassium also causes an increase in aldosterone secretion. Thus aldosterone secretion is increased in the following clinical settings: (a) stress, (b) hemorrhage, (c) sodium depletion, (d) dehydration, (e) hyperkalemia, (f) congestive heart failure, (g) hepatic cirrhosis, (h) nephrotic syndrome, (i) estrogen administration, and (j) renal artery stenosis.

Effects of Mineralocorticoids

Mineralocorticoids are steroid hormones that effect ion transport in the epithelial cells of the kidney, gastrointestinal tract, sweat glands, and salivary glands, causing sodium absorption and loss of potassium. The target tissue specificity appears to be enzyme and not receptor mediated. Indeed, mineralocorticoid receptors are rather similar to glucocorticoid receptors and are saturated by glucocorticoids in most tissues because of the tenfold higher concentration of circulating glucocorticoids. The physiologic action of aldosterone is due to aldosterone synthetase and 11-b-hydroxysteroid dehydrogenase in target tissues, which metabolizes glucocorticoids into receptor-inactive 11-keto congeners. The C-11 hydroxyl group in aldosterone is protected from this target tissue enzyme by its aldehyde at C-18 (30).

The mechanism of action is to increase production of an uncharacterized protein. Because protein synthesis requires time, the effect of mineralocorticoids is not seen until 1 or 2 hours after the tissue is exposed to the steroid. The most important physiologic effects of these compounds are to increase reabsorption of sodium and secretion of potassium and hydrogen ions in the distal tubule of the kidney. Mineralocorticoids do not cause excessive potassium excretion in sodium-depleted subjects. This fact is clinically important because sodium-depleted patients with hyperaldosteronism do not demonstrate a significant kaluresis. Excess aldosterone causes weight gain, increased blood pressure, hypokalemia, and mild metabolic alkalosis as a result of the physiologic effects described earlier. However, normal subjects “escape” the effects of excessive mineralocorticoids after approximately 14 days, and eventually blood volume returns to baseline levels. The mechanisms of the escape phenomenon, which has been studied intensely for years, remain uncertain. It appears that the rise in blood pressure may produce a pressure natriuresis, and also the arterial natriuretic factor may play a role. Mineralocorticoid deficiency results in sodium loss, and if uncorrected, death from hypovolemic shock. The naturally occurring mineralocorticoids are, in order of potency, aldosterone, deoxycorticosterone, 18-hydroxy-deoxycorticosterone, corticosterone, and cortisol. Table 13.2 lists the active mineralocorticoid and glucocorticoid activity of several naturally occurring and synthetic steroids.

Steroid	Glucocorticoid Activity	Mineralocorticoid Activity
Cortisol	1.0	1.0
Corticosterone	0.3	15.0
Aldosterone	0.3	3,000.0
Deoxycorticosterone	0.2	100.0
Cortisone	0.7	1.0
Prednisolone	4.0	0.8
9-α Flucrocortisol	10.0	125.0
Dexamethasone	25.0	0

TABLE 13.2. RELATIVE ACTIVITIES OF GLUCOCORTICOID AND MINERALOCORTICOID

Adrenal Medulla

The adrenal medulla secretes catecholamines into the circulation. The primary compound secreted by the medulla is epinephrine. Small quantities of norepinephrine and trace amounts of dopamine also are released from the gland. The adrenal medulla usually, but not invariably, acts in concert with the rest of the sympathetic nervous system. The hormones from the medulla are not essential for life.

Synthesis and Metabolism of Catecholamines

Catecholamines are synthesized from tyrosine in the adrenal medulla. The pathways of catecholamine synthesis are illustrated in Fig. 13.7. In approximately 15% of

the granules in the normal medulla, the last step in biosynthesis is the conversion of dopamine to norepinephrine (NE), accounting for the secretion of NE by the normal adrenal and by tumors of the gland. Most of the granules contain phenylethanolamine- *N*-methyltransferase, which converts NE to epinephrine (E), the major hormone of the adrenal medulla. In contrast, sympathetic nerves and other extraadrenal chromaffin tissue do not contain phenylethanolamine- *N*-methyltransferase and thus do not secrete E. This point is clinically useful in attempts to localize a catecholamine-secreting tumor.

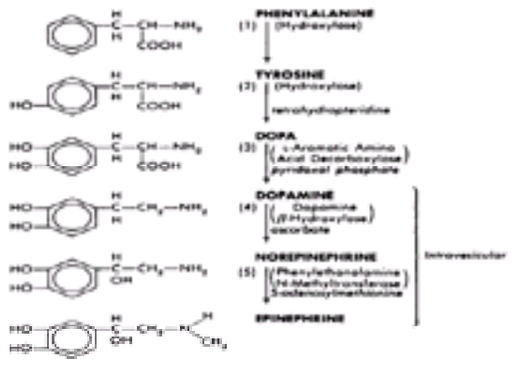

FIGURE 13.7. Biochemical pathways for the synthesis of norepinephrine and epinephrine.

NE and E have short half-lives in plasma, ranging from 1 to 3 minutes. They are degraded by two principal enzymes, catechol- *O*-methyl transferase and monoamine oxidase. Figure 13.8 illustrates the major metabolic pathways for circulating catecholamines. Catechol- *O*-methyl transferase converts NE and E, respectively, to normetanephrine (NMN) and metanephrine (MN). Determination of NMN or MN produces vanillylmandelic acid (VMA), a major metabolic product of catecholamine degradation. Less than 5% of the circulating NE and E are secreted intact in the urine. In a normal individual, NE from sympathetic nerve terminals makes up most of the intact urinary catecholamines, whereas E composes 20% of the total. The vast majority of the catecholamines are secreted in the urine as NMN, MN, VMA, and other metabolites shown in Fig. 13.6. Measurement of these various products is important in the diagnosis of pheochromocytoma.

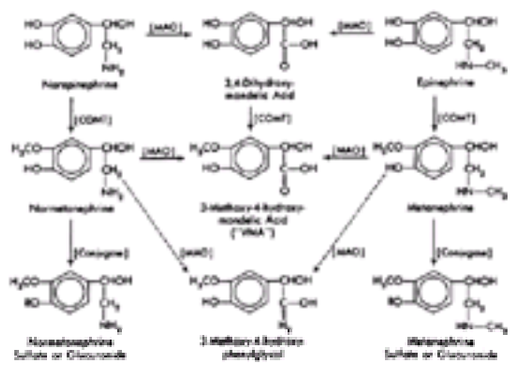

FIGURE 13.8. Metabolic pathways for the degradation of norepinephrine and epinephrine. The urinary metabolites are important in diagnostic evaluation of patients with suspected pheochromocytomas.

Regulation of Adrenal Medullary Catecholamine Synthesis and Secretion

Stimulation of the sympathetic nervous system during stress caused by stimuli such as fear, pain, or hemorrhage results in increased secretion of catecholamines from the adrenal medulla. Hypoglycemia is also a potent stimulator of adrenal catecholamine secretion. In most situations, the ratio of NE to E remains stable, although exceptions do occur. The basal plasma levels of E are 25 to 50 pg/mL. A total of approximately 150 mg is secreted daily. NE release at sympathetic nerve endings may spill over into the intracellular fluid or be retaken up by the tissues. The plasma level of NE is determined by a balance between the amount released into the circulation and the quantities metabolized and retaken up by the tissues.

Actions of Catecholamines

E and NE are potent hormones that activate a_1-, a_2-, b_1-, and b_2-plasma membrane receptors. E primarily stimulates b-receptors but also has some effect on a-receptors, particularly when the plasma levels of the hormone are high. Conversely, NE primarily affects a-receptors. Because these catecholamines can have a and b action, the effects of intravenously administered hormones vary quantitatively and qualitatively with the dose.

For example, at low dosages E causes vasodilation (a b-effect), which may result in hypotension, whereas at higher dosages there is a net increase in vascular resistance, causing hypertension with a larger increment in systolic than diastolic pressure, resulting in an increased pulse pressure. Both compounds have a positive inotropic effect on the heart and therefore increase cardiac output. Intravenously administered E causes tachycardia, whereas NE results in bradycardia because of the vagal reflex response to the increase in blood pressure.

Catecholamines help restore plasma glucose during exercise or stress by stimulating glycogenolysis in the liver, inhibiting insulin secretion, and increasing glucagon secretion. They also facilitate the reuse of lactate by exercising muscle and increase the release of free fatty acids into the circulation.

Excessive concentrations of catecholamines from exogenous sources or endogenous secretion in patients with pheochromocytoma may cause symptoms relating to the previously described effects (see Pheochromocytomas). The symptoms in patients with pheochromocytoma are caused by E and NE. NE elevates the blood pressure and thus may cause headaches.

CUSHING'S SYNDROME

Introduction

Cushing's syndrome is a complex of symptoms and signs caused by excess circulating glucocorticoids. The term is used to describe all patients with the clinical syndrome regardless of the cause. It is important to understand that Cushing's *disease* refers to the form of Cushing's *syndrome* caused by pituitary hypersecretion of ACTH. The most common cause of Cushing's syndrome is exogenously administered glucocorticoids. Twenty-five percent of endogenous Cushing's syndrome is caused by primary adrenal disease (i.e., adenoma or carcinomas). Seventy-five percent of the endogenous disease is excessive ACTH secretion, usually from the pituitary gland but occasionally from an ectopic source. Most patients with pituitary hypersecretion of ACTH (Cushing's disease) have microadenomas, although they may not be obvious during surgery. It is easier to understand the evaluation and treatment of patients with Cushing's syndrome if one keeps in mind that the *first* task of the clinician is to determine whether the patient has Cushing's syndrome. The *second* goal is to determine the cause of the syndrome, and the *final* assignment is to formulate a treatment plan.

Symptoms and Signs

Cushing's syndrome occurs in men, women, and children of all races but is most commonly diagnosed in women between the ages of 20 and 60 years. It is usually characterized by plethoric “moon” facies and central or “buffalo” obesity in the nuchal, truncal, and girdle areas (Fig. 13.9A and Fig. 13.9B). Protuberance of

superclavicular fat pads is the cardinal physical finding that distinguishes Cushing's syndrome from obesity. Serial photographs of the patient are helpful in making the diagnosis because these pictures always document a shift in fat distribution, even if the patient is not obese. The protein wasting secondary to excess glucocorticoids causes easy bruising and thin skin, which results in pink or purple striae. Muscle wasting may cause severe weakness. The weakness is generally proximal and can be observed by asking the patient to do deep knee bends. Emotional symptoms and headaches are common. Adrenal androgens often cause hirsutism in women and prepubertal boys. Oligomenorrhea in women and acne also are common symptoms related to adrenal androgens. Fifteen percent of the patients have urinary stones caused by hypercalciuria. The full-fledged syndrome is easy to recognize, but the differential diagnosis may be difficult, particularly in men and also in women with hirsutism unrelated to Cushing's syndrome. The most prevalent symptoms and signs of the syndrome are listed in Table 13.3.

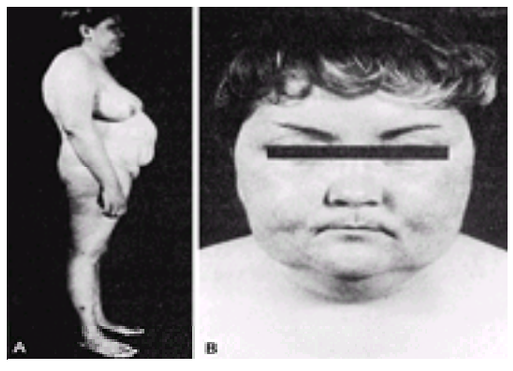

FIGURE 13.9. Typical appearance of a patient with Cushing's syndrome. **A:** Central obesity striae, buffalo hump, and moon facies. **B:** Protuberance of the subclavicular fat pads, hirsutism, facial pigmentation, and the fact that one cannot see the ears, which is typical of patients with Cushing's syndrome. There are also acne fold lesions on the skin.

Symptoms	Signs
Central obesity	Central obesity
Hirsutism	Hypertension
Oligomenorrhea	Hirsutism
Purple striae	Purple striae
Plethoric facies	Plethoric facies
Easy bruisability	Acne
Personality change	Edema
Acne	Muscle weakness
Edema	
Muscle weakness	
Poor wound healing	
Backache	
Polyuria	
Polydipsia	
Impotence	
Growth arrest (children)	

TABLE 13.3. SYMPTOMS AND SIGNS OF CUSHING'S SYNDROME IN ORDER OF FREQUENCY

Common physical findings in patients with Cushing's syndrome are hypertension and edema secondary to the mineralocorticoid activity of the adrenal steroids and, as mentioned previously, plethoric moon facies, central obesity, striae, acne, and hirsutism.

Differential Diagnosis

Cushing's syndrome is caused by the actions of glucocorticoids. Therefore anything that causes excess circulating levels of these hormones can evoke the syndrome. The most common cause is iatrogenic administration of glucocorticoids. Pituitary Cushing's syndrome or Cushing's disease accounts for the majority of the noniatrogenic cases. Approximately 95% of the patients with pituitary Cushing's syndrome have detectable pituitary tumors.

Evidence is mounting that the primary problem in these patients is hypersecretion of ACTH independently or CRF secretion (82). Ectopic secretion of ACTH or CRF (16) from tumors also can cause the syndrome. Finally, primary adrenal adenomas or carcinomas may secrete enough hormone to produce the syndrome. Adrenal tumors tend to be autonomous in their secretion of glucocorticoids, a characteristic that assists in the differential diagnosis of Cushing's syndrome. Most of these tumors are unilateral, but bilateral tumors do occur. Most children with Cushing's syndrome have adrenal neoplasms.

In patients younger than 15 years of age, adrenal carcinoma is the most common cause of Cushing's syndrome. Because most patients with adrenal cortical carcinoma have endocrine symptoms or a mass in the retroperitoneum, the syndrome is rarely suspected because of distant metastasis, although pulmonary and liver metastases are not uncommon and skeletal, brain, pleura, and mediastinal metastases do occur (45). Patients with ectopic or pituitary ACTH-dependent Cushing's syndrome may have hyperpigmentation. Galactorrhea occurs occasionally and only in individuals with pituitary hypersecretion of ACTH. Patients with adrenal carcinoma are characterized by hirsutism and virilism resulting from androgenic adrenal steroids, and individuals with ectopic ACTH tend to have severe manifestations of the syndrome attributable to the high levels of ACTH. The presence of a decreased serum potassium level in patients with this finding is highly suggestive of ectopic ACTH secretion, and the diagnosis should be pursued even if there is also suspicion of a pituitary cause.

The diagnosis of Cushing's syndrome is most frequently entertained when a physician is consulted by an overweight woman concerned about hirsutism. Most of these patients have excessive secretion of androgens from the ovary (50) rather than hyperadrenocorticism. Late-onset adrenal hyperplasia, however, has been reported in 24 of 400 women with hirsutism (54).

Laboratory Diagnosis of Cushing's Syndrome

There are two basic steps in the laboratory evaluation of individuals with suspected Cushing's syndrome: first, determining whether they have the syndrome, and second, identifying the cause.

Many tests have been recommended for diagnosis of Cushing's syndrome. We prefer to screen patients with a determination of the free cortisol in a 24-hour urine specimen. In our laboratory, the normal value is lower than 80 mg per 24 hours. Values vary with age and from laboratory to laboratory. Following are examples of such results (29).

A normal finding rules out Cushing's syndrome unless the clinical level of suspicion is high. If the urinary free cortisol is elevated, we then do a low-dose dexamethasone test. Dexamethasone is a biologically active glucocorticoid that suppresses the secretion of ACTH and thus endogenous adrenal glucocorticoids but does not affect the measurement of the endogenous hormones in the serum and their metabolism in the urine. The patient is given dexamethasone 0.5 mg orally every 6 hours four times daily. At 9 A.M. after the last 3 A.M. dosage, a blood sample is obtained. The normal individual will have a suppressed serum cortisol level of less than 2 to 5 mg/dL. Twenty-four-hour urine levels of free cortisol also should be depressed to less than 20 mg/L on the second and third days. Porter-Silber 17-OH corticoids and ketogenic steroids in the urine should be less than 2.0 and 5.0 mg/g of creatinine, respectively. The best criterion to use for the dexamethasone test is the value of 17-OH corticoids per gram of creatinine. The creatinine corrects for surface area. If the serum and urinary values are normal, the patient does not have Cushing's syndrome; if the values are elevated, Cushing's syndrome is likely. There are exceptions, however, including endogenous depression and alcoholic pseudo-Cushing's syndrome.

In other institutions the morning and afternoon serum cortisol levels and overnight dexamethasone test are used to make the diagnosis of Cushing's syndrome. In the normal individual, there is a diurnal rhythm in serum cortisol concentration, with a peak of 8 to 25 mg/dL at 6 to 9 A.M. and a nadir of less than 7 to 10 mg/dL in the afternoon (Fig. 13.10). Therefore the test is done by drawing blood samples at 8 A.M. and 4 P.M. Normal persons should conform to the stated values and display at

least a 50% decrease between morning and afternoon determinations. This diurnal rhythm is not present in young patients (Fig. 13.10). Patients with Cushing's syndrome usually have elevated values, particularly in the afternoon, and also do not exhibit the normal diurnal rhythm. The overnight dexamethasone suppression test is done by giving the patient 1.0 mg of dexamethasone at 11 P.M. and obtaining a blood sample the next morning at 8 A.M. The normal individual will have a suppressed serum cortisol level less than 5.0 mg/dL, whereas the patient with Cushing's syndrome will have a serum cortisol level greater than 5.0 mg/dL (usually greater than 20 mg/dL).

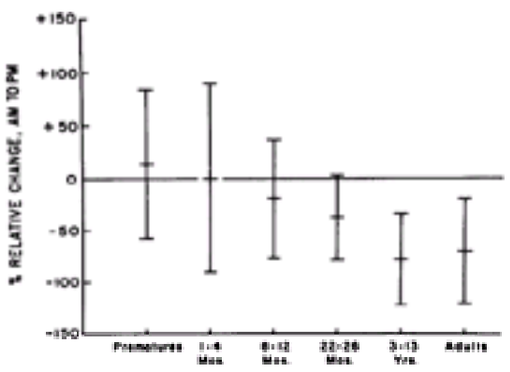

FIGURE 13.10. Diurnal rhythm in serum cortisol levels and its variation with age.

Laboratory Determinations of the Cause of Cushing's Syndrome

Many tests are available to facilitate the differential diagnosis of Cushing's syndrome. None of these tests is always correct, and the diagnosis can be difficult. Disagreement among test results is the rule rather than the exception. The diagnosis can be confused by the fact that pituitary Cushing's syndrome can cause autonomous adrenal hyperfunction when adrenal hyperplasia develops into a discrete adenoma (41). Among the many tests available, we prefer three: plasma ACTH, high-dose dexamethasone suppression, and the metyrapone test. The normal plasma ACTH level in an adult is 10 to 80 pg/mL in the morning and at least 50% in the evening (5,72). The morning plasma ACTH is suppressed to undetectable levels in patients with adrenal adenomas or carcinomas. In patients with ectopic secretion of ACTH, the value is elevated (200 to 1000 pg/mL), and in patients with Cushing's disease, it is normal or high (40 to 100 pg/mL) but elevated inappropriately for the level of cortisol. The high-dose dexamethasone test is done in the same manner as the low-dose test described earlier, except that each dose of the drug is 2.0 mg. Patients with ectopic ACTH secretion or adrenal tumors do not suppress, but those with Cushing's disease do.

Metyrapone inhibits the enzyme 11-b-hydroxylase, thus preventing 11-b-hydroxylation during steroidogenesis (Fig. 13.4). This eliminates the production of cortisol, which in turn increases the secretion of ACTH (because the negative feedback has been removed) and the secretion of adrenal steroids such as 11-deoxycortisol. In patients with ectopic ACTH secretion or adrenal tumors, metyrapone has no effect. Patients with Cushing's disease have an exaggerated response. There is a potential danger that metyrapone will cause adrenal insufficiency and adrenal crisis.

The administration of corticotropin-releasing hormone to patients with Cushing's syndrome caused by adrenocortical tumor usually results in little change in ACTH levels, whereas patients with pituitary microadenomas usually have an exaggerated ACTH response. Nonetheless, because of large individual variations, corticotropin-releasing hormone testing is not recommended for routine use in the differential diagnosis of Cushing's syndrome (82). Oldfield and associates measured the levels of adrenocorticotropin in the peripheral blood and the plasma from both of the inferior petrosal sinuses in 281 patients with Cushing's syndrome. They found that an inferior petrosal sinus adrenocorticotropin level of twice the plasma concentration identified Cushing's disease in 205 of 215 patients (sensitivity 95%) with no false-positive results (specificity 100%). After CRF administration a measured ratio of greater than 3.0:1 was 100% accurate with no false-positive or false-negative results (68).

Localization of Adrenal Causes of Cushing's Syndrome

The techniques currently used to localize adrenal tumors are listed in Table 13.4. Intravenous pyelography, arteriography, and adrenal vein venography are no longer recommended for localizing adrenal lesions in patients with Cushing's syndrome.

Computed tomography or magnetic resonance imaging
Scintiscan: 6-β-iodomethyl norcholesterol (NP-59)
Ultrasonography

TABLE 13.4. LOCALIZATION TEST FOR CUSHING'S SYNDROME

Most tumors of the adrenal that cause Cushing's syndrome are larger than 2 cm and therefore are easily visualized with CT or magnetic resonance imaging (MRI) (Fig. 13.11 and Fig. 13.12) (1,75). The adrenal gland on the affected side in patients with renal agenesis or inferior ectopy is a paraspinal disk-shaped organ that has a linear appearance on CT scan (49). Unilateral Cushing's adenomas are associated with contralateral adrenal atrophy. Adrenal hyperplasia is associated with diffuse thickening, occasionally with bilateral cortical nodularity in 10% to 20%. Adrenal carcinomas are usually larger in size (greater than 6 cm), irregular, with evidence of necrosis, calcification, or local invasion. Upon MRI, adenomas are generally isointense as compared with the liver on T_2-weighted images, whereas carcinomas are hyperintense and inhomogeneous. An intravenous pyelography, especially with tomography, also may reveal an adrenal mass, although it is less sensitive. Adrenal tumors typically displace the upper pole of the kidney laterally (Fig. 13.13), changing the axis of the kidney and the collecting system. They rarely displace the kidney caudally without shifting the axis. Sonography can be a useful screening technique, particularly for large tumors, and is useful in determining whether a retroperitoneal mass extends from or into the kidney or is separated from the kidney and/or the liver. If it is unclear whether a retroperitoneal mass is of adrenal or renal origin, arteriography may be useful because it is often pathognomonic of renal cell carcinoma and also may be useful in planning surgery. However, we do not routinely perform arteriograms in patients with suspected adrenal or renal tumors.

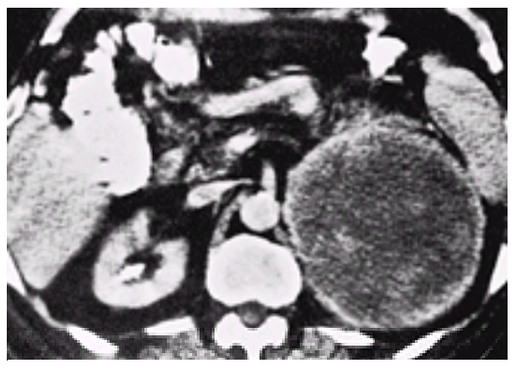

FIGURE 13.11. Computed tomography (CT) scan of a patient with a large adrenal hematoma. CT scans of patients with tumors causing Cushing's syndrome might be quite similar in configuration, although the intratumor density would vary.

FIGURE 13.12. Computed tomography scan of a patient with pheochromocytoma *(arrow).*

FIGURE 13.13. Intravenous pyelography of a patient with an adrenal mass. Note that the renal axis and the axis of the collecting system are deviated with the upper pole pushed outward. This is quite typical of an adrenal tumor. The tumors of the adrenal usually push the upper pole outward rather than pushing the kidney down.

Venography with catheterization of the adrenal veins is an extremely precise technique for diagnosing and localizing endocrinologically active adrenal tumors. However, it is difficult to catheterize the adrenal veins, particularly on the right, and even in experienced hands this method may fail. Also there is danger of damaging the adrenal gland if undue pressure is exerted in the adrenal vein. Adrenal masses also can be identified with scintillation scanning techniques using NP-59 (Fig. 13.14). We have found this technique useful in the evaluation of patients with Conn's syndrome.

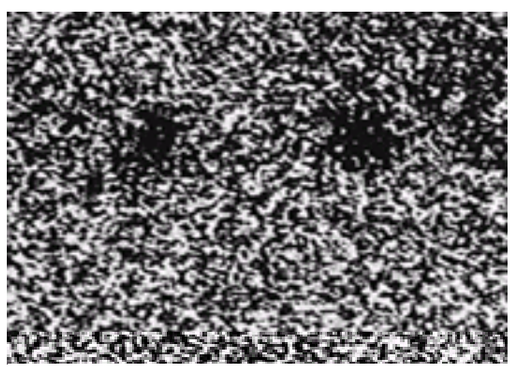

FIGURE 13.14. IP-59 scintillation scan of a patient with bilateral adrenal hyperplasia. Note that both adrenal glands are seen on this scan and are of approximately equal density. If the patient had an adrenal adenoma, the side with the adenoma would be highlighted, whereas the other side would not be visualized.

CUSHING'S DISEASE

Transsphenoidal hypophysectomy, pituitary irradiation, bilateral adrenalectomy, and medical therapy are all used to treat Cushing's disease. The treatment of choice in most centers is transsphenoidal removal of the microadenoma (10,59,81). The current success rate is between 85% and 95%. This treatment is less morbid than bilateral adrenalectomy and avoids the complication of Nelson's syndrome. Pituitary irradiation (cobalt-60) with 4,000 to 5,000 rad has a reasonable success rate in children, approximately 80%, but only approximately a 20% cure rate in adults. Pituitary irradiation with a cyclotron (proton beam) may have a higher cure rate in adults, but this technique is available in only a few locations in the United States. We reserve bilateral adrenalectomy for patients who have failed pituitary surgery. Bilateral adrenalectomy may be complicated in 10% to 20% of cases by rapid postoperative growth of pituitary tumors and hyperpigmentation (Nelson's syndrome). Preoperative pituitary irradiation decreases the incidence of Nelson's syndrome.

Medical treatment with cyproheptadine 6 mg orally four times daily has been reported to cause remission in 60% to 65% of patients with Cushing's disease after 6 to 8 weeks. Mitotane, o,p-DDD, 6.0 g per day, or aminoglutethimide has also been used to treat patients with Cushing's disease, but because of significant side effects, we do not recommend these compounds except for inoperable cases. We prefer metyrapone 1.0 g per day. This drug has a short half-life and must be given every 4 hours. It is monitored by following serum and not urinary cortisol. Hypertension may result from accumulation of deoxycorticosterone. This can be treated with spironolactone. In general, in Cushing's disease medical therapy is used only when indicated to prepare patients for surgical treatment. The major use of medical treatment is in palliation of patients with Cushing's syndrome as a result of malignancies.

Adrenal Tumors

The distinction between a benign adenoma and a malignant adrenal cortical neoplasm is important because of the difference in long-term patient survival. Ultimately, the only method certain to establish the difference is pathologic analysis (86). Nonetheless, a reasonable assessment of the malignant potential can be made using clinical, biochemical, and radiographic information. A recent review of 40 patients (27 adenomas, 13 carcinomas) with ACTH-independent Cushing's syndrome was undertaken at our institution with the primary aim of establishing criteria for the preoperative delineation of adrenal adenomas from carcinomas (22).

The two demographic features that distinguished adenomas from carcinomas were age and tumor size. As compared with carcinoma patients, adenoma patients were significantly younger (39.6 versus 51.5 years) and their tumors were significantly smaller (3.3 versus 8.6 cm). Women constituted the majority of patients in both groups, and left-sided tumors accounted for 70% of cases in both groups. No specific physical finding differentiated adenomas from carcinomas.

All patients had elevated 24-hour urinary free cortisol values and low-normal ACTH levels. No specific biochemical abnormality identified either adenoma or carcinoma patients. Nevertheless, urinary free cortisol, 17-ketosteroid (17-KS), dehydroepiandrosterone sulfate (DHEAS-S), and lactate dehydrogenase (LDH) levels tended to be higher in carcinoma patients. A pure biochemical syndrome of glucocorticoid excess without elevation of 17-KS, DHEA-S, testosterone, or aldosterone was present in 68% of adenoma patients as opposed to only 8% of carcinoma patients.

Some groups have noted the presence of virilization/hirsutism as an important clinical clue suggesting the presence of carcinoma (69). This is based on the premise that carcinomas are less effective than adenomas at converting steroid precursors to glucocorticoids. In our recent review, this was not a discriminating feature (22). Whereas most carcinoma patients presented with a mixed endocrine syndrome (92%), adenoma patients commonly had virilization (93%), and 32% presented with a mixed endocrine syndrome as determined by biochemical analysis. There were a few noteworthy observations. Of the adenoma patients in whom DHEA-S was measured, 44% had subnormal values, and in the two patients with elevated levels the values were only mildly raised. In contrast, only one carcinoma patient had a subnormal level of DHEA-S, and 50% of the carcinoma patients had elevations that exceeded four times the normal value. Overall, the magnitude of the biochemical abnormalities were more severe for the carcinoma patients. These findings support the notion that adenomas in general are more efficient than carcinomas at converting steroid precursors to glucocorticoids; however, significant tumor-to-tumor variability remains. Although steadfast rules do not exist with regard to the preoperative hormonal profile capable of predicting the presence of adenoma versus that of carcinoma, it is likely that patients with ACTH-independent CS, normal 17-KS levels, and subnormal DHEA-S values have an adenoma, whereas those with greatly elevated 17-KS and DHEA-S levels have a carcinoma. Although steroid profiling may not dramatically enhance the management of patients with a small adrenal mass that is likely to be an adenoma, it is important for patients with suspected carcinoma because the steroid values can be helpful in the follow-up of these patients, serving as markers of recurrent disease.

The treatment of Cushing's syndrome secondary to adrenal tumors is surgical removal unless the tumor is unresectable. Preoperative preparation requires specific measures to correct metabolic abnormalities caused by Cushing's syndrome. These patients are prepared for surgery by treatment with metyrapone (250 to 500 mg orally every 4 hours) while awake. To the extent that these drugs reverse Cushing's syndrome, they decrease the operative morbidity and the mortality. Malignant adrenal tumors causing Cushing's syndrome in the adult do not have a good prognosis. The Cleveland Clinic series revealed a 44% 5-year survival in patients with localized disease who made up 49% of 82 patients, and a 13% and 6% 5-year survival in patients with regional and metastatic disease (9). In the M.D. Anderson series, 13 of 18 patients (72%) had recurrent disease (78). Of the 13, 8 patients had local recurrence. The prognosis is better in children.

Bilateral adrenalectomy is indicated for patients with Cushing's disease refractory to hypophysectomy. Postoperatively, these patients require replacement glucocorticoids and mineralocorticoids indefinitely. We usually give hydrocortisone sodium succinate (Solu-Cortef) 100 mg intravenously every 8 hours for the first few days and taper to an oral dose of 25 to 37.5 mg of cortisone acetate and 0.1 mg of fluorocortisone acetate (Florinef) daily.

PRIMARY HYPERALDOSTERONISM

Deming and Luetscher (24) described a sodium-retaining substance in the urine in 1950. Three years later Simpson and associates chemically identified the compound as the 18-aldehyde of corticosterone, aldosterone. Within a year, aldosterone had been synthesized and, remarkably, Conn (19) described the clinical syndrome of primary hyperaldosteronism, or Conn's syndrome. Never before in the history of medicine had an important clinical advance followed so closely on the heels of a basic scientific discovery.

Conn's syndrome is defined as the adrenal hypersecretion of aldosterone in a hypertensive, nonedematous patient. The exact incidence of the disease is not known, but it accounts for approximately 1% of hypertensive patients. It should be pointed out that 1% of 35 million hypertensive patients in the United States is 350,000 people. Women outnumber men approximately 2.5 to 1, and 75% of the patients are between 30 and 50 years of age. Primary hyperaldosteronism should be suspected in any hypertensive patient with hypokalemia. The patients typically have hypertension, muscle weakness, polyuria, hypokalemia, and mild metabolic alkalosis. Table 13.5 gives the incidence of the common symptoms of primary hyperaldosteronism reported in Conn's original description of 103 cases.

Muscle weakness	73%
Polyuria (nocturia)	72%
Headache	51%
Polydipsia	46%
Paresthesia	24%
No symptoms	6%

TABLE 13.5. SYMPTOMS OF CONN'S SYNDROME

In recent years, the diagnosis of Conn's syndrome has been confirmed in many individuals with no obvious symptoms of hypokalemia. There are rare patients with primary hyperaldosteronism who do not have unprovoked hypokalemia.

The headaches are caused by the hypertension, whereas the muscle weakness, polyuria, and paresthesias relate to the effect of hypokalemia on skeletal muscle, the renal concentrating mechanism, and peripheral nerves, respectively.

The major physical finding in patients with primary hyperaldosteronism is hypertension without edema. Mild retinopathy may be present. Routine laboratory evaluation reveals (a) a persistently dilute urine with a pH of 6.5 or higher, (b) a plasma potassium level below 3.5 to 4.0 mEq/L with the patient off all diuretic medication, and (c) mild metabolic alkalosis (elevated serum bicarbonate radical). The serum sodium concentration may be slightly elevated, and mild proteinuria is often present. The electrocardiogram often reveals premature ventricular contractions, depression of the ST segments, T waves, and the presence of U waves. When the diagnosis of primary hyperaldosteronism is entertained, three questions must be sequentially answered: (a) Does the patient have primary hyperaldosteronism? (b) If so, what is the cause? (c) If the disease is the result of an adenoma, what is the location of the tumor?

Does the Patient Have Primary Hyperaldosteronism?

By far the most common cause of hypertension and hypokalemia is essential hypertension treated with diuretics. Also, hypertension, hypokalemia, and hypersecretion of aldosterone are more often caused by secondary hyperaldosteronism than by primary hyperaldosteronism. Any stimulus that compromises renal blood flow may increase renin secretion and thus cause secondary hyperaldosteronism. Common clinical situations that evoke secondary hyperaldosteronism are listed in Table 13.6.

Shock	Cardiac failure
Dehydration	Hepatic cirrhosis
Renal artery stenosis	Pregnancy

TABLE 13.6. CAUSES OF SECONDARY HYPERALDOSTERONISM

Rare causes of secondary hyperaldosteronism include renin-secreting renal tumors and Bartter's syndrome. Bartter's syndrome is characterized by elevations in plasma renin and aldosterone, hypokalemia, and hyperplasia of the juxtaglomerular cells in the kidney.

It is not always easy to determine whether a patient has primary hyperaldosteronism. Many different approaches to diagnosis have been recommended. One of the most difficult problems facing the clinician is which patients should be screened for primary hyperaldosteronism. Certainly, individuals with spontaneous hypokalemia (less than 4.0 mEq/L) and inappropriate kaluresis (greater than 3.0 mEq per day) may have primary hyperaldosteronism. To make the diagnosis we first perform a saline suppression test. With the patient in the supine position a serum sample is obtained for aldosterone, saline is infused at 500 mL per hour for 4 hours, and then another serum sample is drawn. A normal individual will suppress serum aldosterone to less than 10 ng/dL, whereas in patients with primary hyperaldosteronism, the serum aldosterone after saline infusion will be greater than 10 ng/dL. In addition, patients with the disease will have an increased plasma concentration and urinary secretion of aldosterone after potassium repletion to more than 3.5 mEq/L (12).

The captopril test is advocated by many investigators, but we find it less precise than the approach just outlined. The test is done by obtaining serum before and 2 hours after administration of 25 mg of captopril. In secondary hyperaldosteronism, the serum renin rises after the captopril, whereas in primary hyperaldosteronism it does not. Also, the aldosterone-to-renin ratio decreases in secondary hyperaldosteronism but not in primary.

What Is the Cause of Primary Hyperaldosteronism?

Primary hyperaldosteronism may be caused by an adrenal tumor (usually a unilateral adenoma), adrenal hyperplasia (“idiopathic”), deoxycorticosterone acetate-suppressible adrenal hyperplasia (indeterminate hyperplasia), or glucocorticoid-remediable family hyperplasia. The last two forms of the disease occur in adolescents and children, respectively, and are rare. Approximately two-thirds of patients with primary hyperaldosteronism have adrenal adenomas. The major differential diagnosis is between adenoma and hyperplasia. We make the diagnosis of adenoma if (a) there is an anomalous decrease in plasma aldosterone during ambulation, (b) the blood pressure is normalized on spironolactone (400 mg/L for 6 weeks), (c) the serum aldosterone-stimulating factor is *not* elevated (16), and (d) CT or MRI scanning shows a discrete adrenal mass. Biglieri and associates (7) also have noted that the plasma 18-hydrocorticosterone level after overnight recumbency is much higher (greater than 100 ng/dL) in patients with an adenoma than in individuals with hyperplasia. Despite these tests, the differential diagnosis may be difficult. Once the diagnosis of adenoma is made, we attempt to localize the tumor.

Where Is the Tumor?

Methods used to localize adrenal adenomas have included intravenous pyelography, aortography, phlebography, adrenal vein catheterization, radionuclide scan, CT, and nuclear resonance imaging. The NP-59 scan is a useful noninvasive technique. The patient is prepared for 3 days with Lugol's solution (5 drops twice daily) and oral dexamethasone (0.5 mg every 6 hours). The Lugol's solution is continued for 2 weeks. Imaging is done after the 3-day preparation and again in 4 more days. CT scanning often identifies an adenoma (85), but false-negative results may occur because these adenomas are typically rather small. When CT scanning is used, thin-section CT techniques with section thicknesses of 1.5 to 3 mm should be used (37). The accuracy of CT scanning alone in patients with low-renin hyperaldosteronism has been estimated at 73% to 90% (90). This imprecision is due to the fact that CT scans may miss adenomas smaller than 1 cm. Ironically, with the increased sensitivity of CT scans, an additional, perhaps even prevalent, source of inaccuracy is the fact that modern CT scans overdiagnose adenomas because they find small nonfunctioning masses and confuse unilateral macronodular hyperplasia with adenomas (25).

MRI with and without gadolinium administration also can identify an adenoma-causing primary aldosteronism with the same efficacy as CT scanning. Adrenal vein catheterization with sampling and analysis of the effluent is perhaps the most precise way to localize a tumor, but, as pointed out in the discussion of Cushing's syndrome, it is technically difficult (33).

Treatment

The preferred management of primary hyperaldosteronism secondary to adrenal hyperplasia is medical treatment with spironolactone, which inhibits the action of aldosterone on the distal renal tubule. Reduction of plasma volume by diuretic therapy is an important aspect of treating hypertension in these patients. Administration of 200 mg of spironolactone per day (50 mg four times daily) normalizes serum potassium with relatively little effect on the pressure. The addition of hydrochlorothiazide (HCTZ) 50 mg per day (25 mg twice daily) rapidly reduces blood pressure while maintaining serum potassium concentrations within the normal range. Painful gynecomastia is a distressing side effect of spironolactone. Occasionally, agents that interfere with renal tubular ion transport, such as triamterene or amiloride, are also incorporated into a pharmacologic treatment program. Bilateral adrenalectomy has no place in the management of primary aldosteronism because complete adrenal insufficiency may be more difficult to treat than hypertension from aldosteronism.

The treatment of choice for an aldosterone-producing adrenal cortical adenoma is surgical adrenalectomy, which carries minimal morbidity and provides definitive therapy in most cases. Blumfeld and colleagues (8) demonstrated in 1994 that 35% of patients with a unilateral adenoma had normal blood pressure postoperatively without any concurrent antihypertensive medications. In an additional 56% of patients with residual hypertension postoperatively, addition of an antihypertensive agent decreased their blood pressure below 140/90 mm Hg. Thus more than 90% of patients with an adenoma had cure or significant improvement of hypertension following surgical excision. Medical therapy with spironolactone may be indicated for poor surgical risk patients with an adenoma. Occasionally, an adrenal gland removed for a suspected adenoma is found to contain one or more hyperplastic nodules. Although the results of adrenalectomy for hyperplasia are less satisfactory, some patients experience improvement of hypertension postoperatively (56). This therapeutic response is not completely understood and may result from a simple reduction in the amount of adrenal tissue.

Patients with primary hyperaldosteronism from an adrenal adenoma have a significant potassium deficit, which must be corrected preoperatively because hypokalemia increases the risk of cardiac arrhythmias during anesthesia. Supplemental oral potassium alone is not sufficient to overcome the kaluresis experienced by these patients. Preoperative treatment with spironolactone is also necessary both to correct hypokalemia and to facilitate blood pressure control. Some patients with a unilateral adenoma develop contralateral mineralocorticoid suppression, which may become manifest postoperatively as clinical hyperaldosteronism. This problem may also be prevented by preoperative spironolactone therapy because this allows reactivation of the renin-angiotensin-aldosterone system.

Because aldosterone-producing adenomas are invariably small and benign, laparoscopic adrenalectomy has now become the preferred surgical approach. Following adrenalectomy in such cases, there is usually a moderate urinary diuresis of sodium and retention of potassium. This requires appropriate volume replacement and close monitoring of serum electrolyte levels for the first week postoperatively. In some cases, hyponatremia and hyperkalemia develop in the immediate postoperative period secondary to suppression of the contralateral zona glomerulosa, with a resulting aldosterone deficiency. This phenomenon will necessitate mineralocorticoid replacement until the remaining adrenal gland recovers. In general, patients experience a rapid and uneventful postoperative recovery from adrenalectomy for hyperaldosteronism. Hypertension may take several weeks to resolve completely; however, ultimately 80% of patients are cured (56).

ADRENAL INSUFFICIENCY

Adrenal insufficiency was described in 1855 by Thomas Addison—thus the eponym *Addison's disease.* Addison's disease is a rare entity, usually secondary to tuberculosis or autoimmune adrenocortical atrophy. Other causes include amyloidosis, histoplasmosis, blastomycosis, and metastatic carcinoma. Iatrogenic adrenal insufficiency secondary to high-dose adrenal steroid therapy or surgical adrenalectomy is more common. Urologists should be aware that ketoconazole therapy for prostatic cancer may cause reversible adrenal insufficiency (83).

The symptoms of adrenal insufficiency include muscular weakness, fatigability, weight loss, hyperpigmentation, anorexia, nausea, vomiting, and diarrhea. Cardiac tamponade is a rare, often fatal complication of adrenal insufficiency. Hypotension is the cardinal sign. Hyponatremia and hyperkalemia are common. Plasma cortisol levels are low, as are levels of the various urinary metabolites of the endogenous adrenal steroids. The diagnosis can be confirmed by finding an elevated level of serum ACTH and a lack of significant response in serum cortisol after administration of ACTH (Fig. 13.15). Corticotropin-releasing hormone levels have been reported to be either elevated or normal in patients with Addison's disease (82).

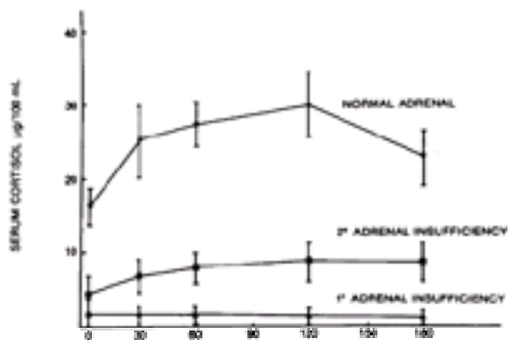

FIGURE 13.15. Serum cortisol response and response to adrenocorticotropin hormone infusion in normal persons and in patients with primary and secondary adrenal insufficiency.

The initial treatment is 100 mg of hydrocortisone every 8 hours. All patients maintained on adrenal steroid therapy should receive this dose for several days after any surgical procedure. The dose is tapered to a maintenance dose of 30 mg per day, given as 20 mg in the morning and 10 mg in the evening, to mimic the physiologic diurnal variations in serum levels. In patients with adrenal insufficiency secondary to pituitary disease, it is usually not necessary to provide mineralocorticoid replacement. In patients with no functioning adrenal tissue, fluorocortisol 0.05 to 1.0 mg per day will provide adequate mineralocorticoid replacement. The adequacy of the replacement therapy can be determined by monitoring blood pressure, serum electrolytes, renal function, and plasma ACTH and renin activity.

PHEOCHROMOCYTOMAS

Pheochromocytomas are fascinating tumors that secrete catecholamines that cause a variety of symptoms, usually including hypertension. Most pheochromocytomas secrete NE and E. Occasional tumors release only NE, and rare lesions secrete dopa, dopamine, serotonin, somatostatin, ACTH, or E. The tumors are composed of chromaffin cells and may arise anywhere in the body where chromaffin tissue derived from primitive neuroectoderm is located. Approximately 95% of the tumors are located in the adrenal gland, but pheochromocytomas have been found in the bladder, Zuckerkandl's organ, and anywhere in the body that sympathetic nervous tissue is located. Three percent of pheochromocytomas are extraabdominal. Although only 0.1% to 0.2% of hypertensive patients have a pheochromocytoma, they should always be screened because the tumors are curable in 90% of the patients, and untreated pheochromocytomas frequently cause fatal complications such as cardiac arrhythmias, congestive heart failure, myocardial infarct, cerebral vascular accidents, and hemorrhage.

Pheochromocytomas may be familial. Patients with familial pheochromocytomas often have multiple tumors. These Sturge-Weber syndrome cases also are often associated with one of the variants of the multiple endocrine neoplasia syndrome, the most common of which is type 2A, characterized by carcinoma of the thyroid, hyperparathyroidism, and pheochromocytoma. DNA-polymorphism analysis facilitates identification of individuals at risk for this syndrome (80). Pheochromocytoma is also linked with von Recklinghausen's disease (café-au-lait spots) and von Hippel–Lindau disease (angiomatosis of the retina and hemangioblastoma of the cerebellum). Patients with von Hippel–Lindau disease also may have neurologic symptoms including seizures and mental retardation. Neumann and associates (64) reported that 19 of 82 (23%) unselected patients with pheochromocytoma were carriers of von Hippel–Lindau disease or had multiple endocrine neoplasia type 2. They recommended that all patients with pheochromocytoma should be screened for these abnormalities to reduce morbidity in the patients and their families.

Patients with a pheochromocytoma usually present with hypertension, although 15% to 20% are normotensive, and rare patients are hypotensive. Approximately 50% of the hypertensive patients have sustained elevations in blood pressure, and the remainder have characteristic paroxysmal hypertension. Hypertensive patients with sweating, tachycardia, and headaches have more than a 90% chance of having a pheochromocytoma, whereas individuals with none of these characteristics have less than a 1% incidence of pheochromocytomas (70). The common symptoms and signs are listed in Table 13.7.

	Frequency (%)
Symptom	
Headache	80–85
Weakness	75–80
Diaphoresis	65–70
Palpitations	60–65
Orthostatic hypotension	50–60
Nausea and vomiting	35–60
Nervousness	35–40
Constipation	30–35
Sign	
Hypertension	80–85
Retinopathy	50–70
Decreased body weight	40–70
Fasting hyperglycemia	40–50

Adapted from Aruk NO. Pheochromocytomas: diagnosis, localization, and treatment. Hosp Pract 1983;18:187.

TABLE 13.7. SYMPTOMS AND SIGNS OF PHEOCHROMOCYTOMA

Patients, even those with sustained hypertension, often experience paroxysmal symptoms that may occur dramatically and suddenly. The frequency of these attacks is rather variable, and the duration is usually less than an hour. The attacks may be precipitated by emotional, physical, or pharmacologic stimuli. Neurocutaneous lesions, progressive diabetes associated with hypertension, and unexplained intraoperative hypertension all should suggest the presence of pheochromocytoma.

The hypertension is caused by the release of catecholamines from the tumor *and* increased sympathetic neural tone. Bravo and associates (13) have shown that clonidine, a drug that decreases sympathetic tone, reduces blood pressure and heart rate in patients with pheochromocytoma without affecting plasma catecholamines or renin concentrations. Tumors that produce only NE are associated with fewer symptoms than those that release NE and E. The latter compound has a more pronounced affect on b-receptors, causing symptoms such as diaphoresis and palpitations.

Laboratory Evaluation

The diagnosis of pheochromocytoma is made by documenting elevated levels of catecholamines in the blood or urine. The assays are rather precise, but false-positive results can occur secondary to drugs, stress, and other diseases that increase the concentrations of catecholamines (Table 13.8). Modest elevations in hematocrit levels are common as a result of a decreased plasma volume secondary to vasoconstriction.

Drugs	Diseases
Methyldopa	Guillain-Barré syndrome
Theophylline	Neuroblastoma
Ephedrine	Porphyria
Levodopa	Brain tumor
Tricyclic antidepressants	Carcinoid syndrome
Clonidine (withdrawal)	Intrahepatic cholelithiasis

TABLE 13.8. SOME CAUSES OF INCREASED CATECHOLAMINES

Patients can be screened for pheochromocytoma by analysis of a 24-hour urine sample for combined MN (normal 0.2 to 1.3 mg per 24 hours) and VMA. Normal values are shown in Table 13.9. Urinary MN is the best single test. Urinary free catecholamines also can be useful; Duncan and associates (26) have shown that 24-hour urinary NE had a 100% sensitivity and a 98% specificity in a large group of hypertensive patients. An advantage of measuring urinary free catecholamines is that if E is present and NE is absent, the tumor is extremely likely to be located in an adrenal gland. These tests in combination are more than 95% accurate. The pattern most typical of malignant pheochromocytomas is elevated dopamine secretion, often with comparably high NE levels and low E secretions. This is because malignant pheochromocytomas often are deficient in dopamine b-hydroxylase and phenylethanolamine N-methyltransferase.

	Adult (µg)	Infant and Child (Range µg/kg)
NE	80	0.4–1.6
E	25	0.02–1.6
VMA	8	83 ± 25
NMN	450	4.9–20.8
MN	300	3.1–15.6

[a]Catecholamine values for 24-hour urine collection.
E, epinephrine; MN, metanephrine; NE, norepinephrine; NMN, normetanephrine; VMA, vanillylmandelic acid.

TABLE 13.9. NORMAL VALUES FOR CATECHOLAMINES IN URINE[a]

Some authorities have recommended screening patients with an assay of plasma catecholamines. Bravo and Gifford (11) from The Cleveland Clinic have had excellent results with the plasma assay. The blood test also must be carefully done, with a supine and relaxed patient, and the laboratory must be experienced with the assay. In patients with equivocal values of plasma catecholamines, provocative testing may be necessary. Plasma catecholamines greater than 2,000 pg/mL are diagnostic of pheochromocytoma. If the catecholamine levels are between 1,000 and 2,000 pg/mL, clonidine suppression test (11) is performed. The principle behind this test is that in essential (neurogenic) hypertension, activation of the sympathetic nervous system results in an increase in plasma catecholamine. However, in patients with a pheochromocytoma, the increased catecholamines are due to the tumor itself, bypassing normal storage and release mechanisms. Therefore clonidine will not suppress catecholamine release in patients with a pheochromocytoma but will suppress catecholamine release in patients with essential (neurogenically mediated) hypertension. Following a 0.3-mg oral dose of clonidine, a 50% reduction in plasma catecholamines and a catecholamine level less than 500 pg/mL is diagnostic of essential hypertension. However, postclonidine catecholamine levels greater than 500 pg/mL are indicative of pheochromocytoma. If resting plasma catecholamine levels are less than 1,000 pg/mL, a glucagon stimulation test is employed. Glucagon 2 mg is administered intravenously. One to three minutes later, a threefold increase in plasma catecholamine (greater than 2,000 pg/mL) is diagnostic of pheochromocytoma.

Localization of Pheochromocytomas

Once the diagnosis of pheochromocytoma has been made, it is necessary to localize the tumor for surgical planning. CT or MRI of the abdomen and pelvis are the best initial examinations (Fig. 13.12). These are performed because 97% of all tumors, including extraabdominal tumors, are located below the diaphragm. CT is widely available, is cost-effective, and can resolve masses as small as 1 cm. MRI is an alternative that requires no radiation exposure or intravenous contrast; however, it is more expensive. MRI has superior tissue characterization and, unlike benign adrenal adenomas, pheochromocytomas exhibit a high signal intensity on T_2-weighted images (37). MRI also avoids metallic clip artifact, which may be present on CT. Iodine-131-meta-iodobenzylguanidine scintigraphy is also an accurate method for anatomically and functionally characterizing pheochromocytomas (77, 79) (Fig. 13.16). Its main advantage is the ability to image the whole body so that occult extraadrenal or metastatic disease may be identified. Its expense, limited availability, and diminished sensitivity restrict its utility. At present, it is a complementary study to CT or MRI in patients in whom there is a high suspicion of extraadrenal or metastatic disease.

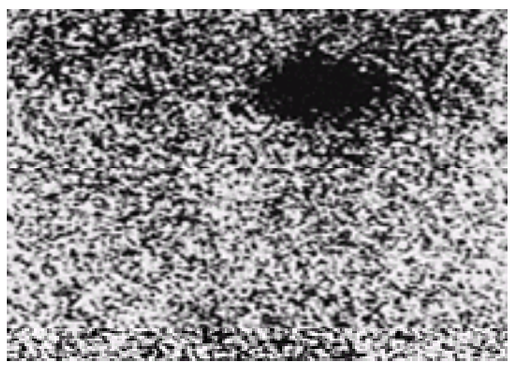

FIGURE 13.16. MIBG scan of a pheochromocytoma.

Treatment

The treatment of pheochromocytoma is surgical removal unless the operation is contraindicated. In the latter situations, medical therapy is indicated. In 10% of patients who have malignant pheochromocytomas, treatment should be governed by the basic principles of cancer management. The diagnosis is not frequently made preoperatively and may be difficult to confirm histologically. Tumors that invade adjacent structures or metastasize are considered malignant. Both a- and b-adrenergic blocking agents and a-methyl- L-tyrosine (metyrosine, which blocks synthesis of NE by inhibiting tyrosine hydroxylase) all can be used to alleviate symptoms in patients with inoperable malignant pheochromocytomas.

The goal of perioperative medical management of the pheochromocytoma patient is to minimize cardiovascular morbidity. Preoperative a-blockade is indicated for 2 to 3 weeks to control the blood pressure and to facilitate intravascular volume expansion. Oral phenoxybenzamine is widely used, although some groups prefer a

shorter-acting agent such as prazosin. Calcium channel blockers (verapamil SR, nifedipine XL) also are used. Advantages of calcium channel blockers include normalization of blood pressure without any of the side effects of chronic a-blockade. There is no orthostatic or “overshoot” hypotension. Furthermore, calcium channel blockers may prevent catecholamine-induced vasospasm and myocarditis. At The Cleveland Clinic, calcium channel blockers are the drug of choice for preoperative preparation of patients with pheochromocytoma. If additional control of hypertension is necessary, we add selective a $_1$-blockade with prazosin. b-Blockade is indicated to treat cardiac arrhythmias or tachycardias, but only in patients with complete a-blockade. Propranolol should be avoided in patients with a history of bronchospastic disease because it causes bronchospasm. If a b-blocker is indicated, low-dose metoprolol is more appropriate.

The other important aspect of preoperative preparation is volume repletion. Most patients with a pheochromocytoma are volume depleted due to catecholamine-induced vascular constriction. Whereas transfusion of whole blood was routine before 1985, it is now more appropriate to hydrate these patients aggressively with a combination of colloid and normal saline the night before surgery. Some groups also use adjunctive preoperative salt loading with a high-salt diet. These measures are integral to preventing hypotension following surgical removal of the tumor.

The surgical approach to pheochromocytoma is based on the size and anatomic location of the tumor. Large pheochromocytomas are removed through an anterior transperitoneal or a thoracoabdominal incision. With the availability of improved localization techniques, it is no longer necessary to explore the abdomen routinely in patients with pheochromocytoma. Therefore, in select patients with a small adrenal tumor and no evidence of extraadrenal disease or multiple tumors, a unilateral extraperitoneal surgical approach may be used (21,46). Laparoscopic adrenalectomy is also currently being performed in some of these cases. Intensive intraoperative hemodynamic monitoring and the availability of rapidly acting vasoactive agents are essential to managing hypertension related to manipulation of the tumor. The anesthetic agent of choice is enflurane, which does not stimulate catecholamine secretion or increase catecholamine-induced cardiac variability. Intraoperatively, one may be faced with hypertensive crises before and during tumor removal, and hypotension following removal of tumor. To manage the hypertensive crisis, phentolamine or sodium nitroprusside may be employed. Bolus diffusion of esmolol, a b-blocker, is especially helpful if phentolamine or sodium nitroprusside affords insufficient control. For hypotension, norepinephrine (4 to 8 mg in 500 mL normal saline) can be used judiciously.

After the tumor is removed, significant hypotension may occur as a result of arterial and venous dilation secondary to catecholamine withdrawal. This situation can be compounded by prior a-blockade or inadequate volume repletion. The primary treatment of choice is volume replacement with crystalloid; pressors should be administered only when volume expansion does not correct the hypotension. Hypoglycemia is another complication that can occur postoperatively and may manifest as hypotension resistant to volume repletion or vasopressors. The blood glucose level should routinely be checked in the postoperative period, and if hypoglycemia is identified, appropriate replacement therapy should be administered.

After removal of a pheochromocytoma, the blood pressure response depends on whether the patient's hypertension was sustained or paroxysmal. Only 75% of patients with sustained hypertension remain normotensive after surgery, whereas 95% of patients with paroxysmal hypertension remain normotensive. The presence of concomitant essential hypertension is the most common reason for treatment failure; however, the possibility of undiagnosed multicentric disease should be aggressively evaluated and ruled out. Long-term follow-up of all patients is important because recurrent or metastatic disease may develop many years postoperatively. Annual measurement of the blood pressure and plasma or urinary catecholamine levels should be used to follow these patients.

We recently reviewed the experience with surgical management, complications, and treatment outcome of histologically confirmed pheochromocytoma in 113 patients at The Cleveland Clinic (84). There were no surgical mortalities. Average length of stay in the intensive care unit was 1.2 days. There were only six major cardiovascular complications all of which occurred in patients who received preoperative medications, including five with a-blockade. Patients receiving no preoperative a-blockade required an average of 956 mL less in total intraoperative fluids, which approached statistical significance, and 479 mL less fluids on postoperative day 1, which was statistically significant. These findings suggest that preoperative a-adrenergic blockage is not essential in pheochromocytoma patients. In our experience, calcium channel blockers were just as effective and safer when used as the primary mode of antihypertensive therapy. These data also affirm that surgery for pheochromocytoma is safe in the modern era.

Malignant pheochromocytomas are difficult to diagnose histologically and often are resected incompletely because of metastases in the lung, liver, bone, or brain. There is no good chemotherapy. Streptozocin has limited antitumor activity. Treatment with cyclophosphamide, vincristine, and dacarbazine has resulted in some response (3). The metabolic effects of residual malignant pheochromocytoma can be ameliorated with phenoxybenzamine, propranolol, or a-methyl- L-tyrosine.

INCIDENTAL ADRENAL MASSES

The incidental adrenal mass is a diagnostic and management dilemma created by the widespread availability of CT scanning (20). Such an “adrenaloma” or “incidentaloma” is a serendipitous finding in 0.3% to 5% of patients undergoing abdominal CT scanning. Most of these tumors (70% to 94%) are benign and biochemically inert (8,63). However, a small minority may be biochemically active or malignant. In this group, the most common abnormality is a Cushing's or pre-Cushing's syndrome in 0% to 18% of patients. Interestingly, in patients with a known extraadrenal malignancy, the autopsy incidence of adrenal metastases ranges from 8% to 38%.

Evaluation of an incidental adrenal mass should be limited and focused. A detailed history and physical examination, stool for occult blood, and a chest radiograph are mandatory. To look for occult malignancy, a mammogram may be performed in the female. Biochemical workup includes serum potassium, and 24-hour urine estimation for catecholamines, metanephrines, and urinary free cortisol. If there is any concern, a low-dose dexamethasone suppression may be performed. In hypertensive patients, a paired serum aldosterone level and an upright PRA should be obtained.

CT characteristics of adrenal masses that suggest malignancy include an irregular ill-defined margin, internal heterogeneity, and larger size. However, significant overlap and inconsistencies in these criteria have limited the diagnostic accuracy of CT scanning in the individual patient. In general, it is accurate to say that 90% of adrenal cortical carcinomas are larger than 6 cm in diameter, with adenomas rarely obtaining such large sizes (4,32,71,42).

However, size criteria per se, are weak and inconsistent discriminators between a benign and malignant adrenal nodule. In Korobkin's (53) analysis of 135 adrenal masses, adenomas were smaller than nonadenomas (2.4 cm versus 4.5 cm); however, the authors emphasized that the considerable overlap between the two groups precluded identification of a highly specific threshold value. Kloos and colleagues (51) mentioned three patients with a 3- to 5-cm, biochemically inert adrenal mass, who were initially advised against an operation at an outside institution. Upon referral to the author's center 3 to 7 years later, these patients were found to have obviously progressed adrenal cortical carcinomas. Linos and Stylopoulos (57) reported three patients who were “incidentally found to have an adrenal cancer measuring 2.6 to 2.9 cm on CT.” An important factor to be considered when discussing adrenal mass size is the reported 20% to 40% CT scan underestimation of adrenal size when compared with their actual size on histopathology examination. CT densitometry has a higher sensitivity-to-specificity ratio. Using a threshold of 10 Hounsfield units, the sensitivity and specificity were 73% and 96%, respectively, for differentiating adenomas from nonadenomas (53).

Although, typically, MRI has been used to differentiate benign from malignant adrenal masses, one must be aware that an overlap of 20% to 30% exists. Compared with the liver or spleen, adenomas are usually isotense on T_1-weighted images and slightly hypertense or isotense on T_2-weighted images. Basically, adenomas change little in intensity from T_1- to T_2-weighted studies. In contrast, adrenal cancer is hypointense compared with liver-spleen on T_1-weighted and hyperintense on T_2-weighted images. Thus a mean signal intensity ratio between the adrenal mass and spleen of less than 0.8 indicates benign adenoma. However, hyperintensivity on MRI is not specific to adrenal carcinoma and can be seen with adrenal metastases, hemorrhage, neural tumors, or other retroperitoneal masses. More recently, chemical-shift MRI imaging was shown to detect a relative loss of signal intensity in 95% of adrenal adenomas compared with 0% of nonadenomas (62). It appears that future diagnostic algorithms may combine the accuracy of chemical-shift MRI and unenhanced CT densitometry for accurate nonoperative differentiation between adrenal adenomas and nonadenomas.

This critical decision when faced with an incidental adrenal mass is whether to perform surgical excision or continue with observation. Surgical excision is indicated for hormonally active masses, tumors 5 cm or larger, tumors with suspicious characteristics on CT or MRI, and masses that are documented to enlarge over time. Observation and periodic (every 6 to 12 months) radiographic follow-up are recommended for those who do not fall into one of the above categories.

Recently, several investigators have reported that a significant minority of patients with incidentally discovered adrenal masses have preclinical or subclinical functioning tumors with no clinical evidence of endocrinologic function, but they demonstrated autonomous cortisol production. Removal of these tumors results in improvement in hypertension, obesity, or diabetes in many of the patients (52,73).

The adrenal is also an extremely common site of metastatic lesions because of its intense vascular supply (6 to 7 mL/g per minute). In fact, adrenal metastatic lesions are more common than primary adrenal cancer. In the presence of a known extraadrenal malignancy, the chance that an adrenal mass is cancerous is approximately

8% to 38% (51). Fine-needle aspiration should be performed if a metastatic etiology is suspected. This can enable diagnosis of a metastatic adrenal lesion but is of limited value in delineating an adrenal adenoma from an adrenal cortical carcinoma (15). Surgical removal of the adrenal gland is indicated only if the adrenal represented the solitary site of metastatic disease.

ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is an uncommon disease, with only 80 to 130 cases per year in the United States (14). Approximately 50% of the tumors are endocrinologically functional. Cushing's syndrome, virilization, and feminization occur in 20%, 9%, and 3% of these patients, respectively, and primary hyperaldosteronism is present in less than 4% (39). Less than 30% of the tumors are localized to the adrenal gland at presentation. Surgical excision or debulking is the treatment of choice. Radiotherapy and chemotherapy have been disappointing, although approximately half of the patients will respond to mitotane for 10 to 12 months (61). Mean survival for localized disease is 5.0 years and for more extensive lesions is 2.3 years (9,18).

OPERATIVE APPROACHES TO THE ADRENAL GLANDS

A wide spectrum of adrenal pathology may warrant surgical intervention. A variety of operative approaches are available for adrenal surgery. The optimal technique must be individualized according to the adrenal pathology, the patient's body habitus and surgical history, and the familiarity of the surgeon with each operative approach.

Posterior Approach

The posterior surgical approach to the adrenal gland was first described more than 50 years ago (89) and continues to find useful application in selected patients undergoing adrenalectomy. The advantages of this approach are that it is extraperitoneal and that adrenalectomy can be done with minimal disturbance of adjacent viscera. Anatomically, a posterior incision represents the most direct approach to the adrenal gland. Because no major muscles are transected, patient discomfort is generally minimal and early ambulation is possible. If indicated, both adrenal glands can be exposed simultaneously through bilateral posterior incisions.

The major disadvantage of the posterior approach is the relatively small operative field, which restricts visualization and exposure of the great vessels. Therefore this approach should not be used to remove large adrenal lesions where wide exposure and early avascular control are necessary. This approach is also contraindicated in patients with a potentially malignant process, in whom an exploratory laparotomy must be done. Based on these limitations, the primary indication for posterior adrenalectomy is in patients with bilateral hyperplasia from Cushing's disease who have failed transsphenoidal hypophysectomy. This approach has also been used in the past to treat small benign adrenal lesions such as adrenal cortical adenomas causing hyperaldosteronism or Cushing's syndrome, and small adrenal pheochromocytomas; these small benign unilateral tumors are now being treated by laparoscopic adrenalectomy at many centers.

The posterior anatomic relation of the adrenal glands is illustrated in Fig. 13.17. The pleural reflection extends below most of the eleventh rib and a variable portion of the medial aspect of the twelfth rib. The right adrenal gland lies more superiorly in the retroperitoneum than its counterpart on the left side. The left adrenal gland can usually be adequately approached posteriorly through the bed of the twelfth rib. The optimal incision for exposing the right adrenal gland is generally through the bed of the rib. In most cases, the location of the adrenal gland in relation to the ribs is known from preoperative imaging studies.

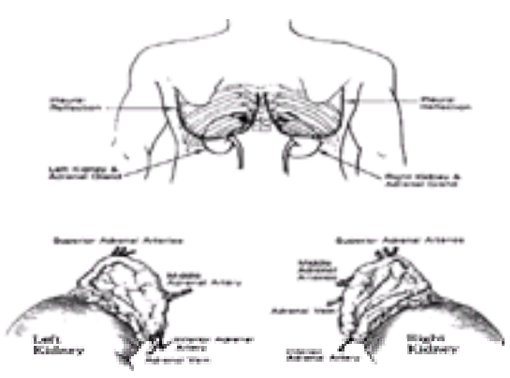

FIGURE 13.17. Sketch illustrating the posterior anatomic relations of the adrenal glands. (From Novic AC. Adrenal surgery. In: Novick AC, ed. *Stewart's operative urology,* 2nd ed. Baltimore: Williams & Wilkins, 1989, with permission.)

The patient is placed in the prone position on a laminectomy frame, which provides flexion at the hips and allows gentle dorsal curvature of the spine from the midthoracic to the lower lumbar levels. An oblique incision is made over the eleventh rib or twelfth rib and extended laterally almost to the midaxillary line (Fig. 13.18). The incision is developed to expose the entire length of the rib and the sacrospinalis muscle medially. The rib is resected subperiosteally, including as much of its medial aspect as possible to optimize exposure of the adrenal gland; such exposure also is facilitated by medial retraction of the sacrospinalis muscle. In operating through a twelfth rib incision, the diaphragm and pleura can readily be mobilized and retracted superiorly. However, in operating through an eleventh rib incision, attempting to mobilize the pleura superiorly may be tedious and can lead to one or more inadvertent pleural entries. In such cases, simply opening the pleural and diaphragmatic layers of the thoracic cavity in line with the incision can be done safely and provides excellent direct exposure of the adrenal gland (66,67). After the retroperitoneal space is entered, Gerota's fascia is incised and the posterior surface of the kidney and adrenal gland is exposed.

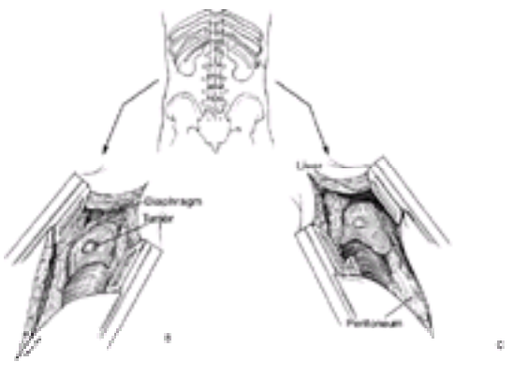

FIGURE 13.18. Sketch illustrating the posterior approach for adrenal surgery **(A),** through the eleventh rib on the right side **(C)** and through the twelfth rib on the left side **(B).** (From Novick AC. Surgery for primary hyperaldosteronism. *Urol Clin North Am* 1989;16:535, with permission.)

On the left side (Fig. 13.19), the attachment between the upper pole of the kidney and the inferior aspect of the adrenal gland is kept intact, so that gentle downward traction on the kidney can be done to enhance exposure. The apical vascular ligament is identified and transected between silver clips to deliver the gland more extensively into the operative field. The lateral borders of the gland are then freed, and the gland is retracted medially to expose its anterior surface. Care must be taken not to injure the pancreas, which lies just beneath the adrenal gland through this approach. The left adrenal vein is exposed as it courses downward just medial and anterior to the upper pole of the kidney to enter the left renal vein. The left adrenal vein is then ligated with 2-0 silk and divided. The upper stump of the vein can be left long and used as a handle for additional lateral traction on the gland. The inferior adrenal artery also is secured at this stage as it courses upward from the proximal aspect of the renal artery. Through use of lateral and upward traction, the left adrenalectomy is completed by securing and dividing the middle adrenal arteries as they course inward medially from the aorta.

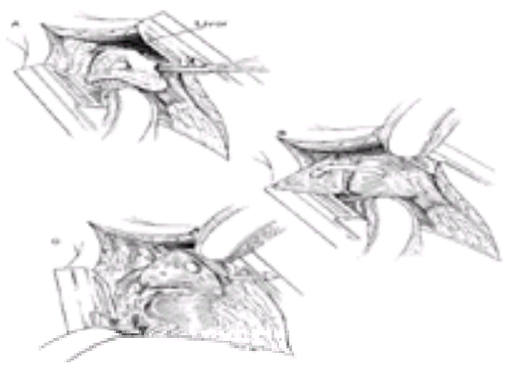

FIGURE 13.19. A–C: The technique of left adrenalectomy through a posterior incision. (From Novick AC. Surgery for primary hyperaldosteronism. *Urol Clin North Am* 1989;16:535, with permission.)

On the right side (Fig. 13.20), the kidney is retracted downward, and the liver is gently retracted upward to facilitate exposure of the adrenal gland. In some cases, the apex of the adrenal gland is adherent to the liver and must be carefully dissected free. The dissection is continued cephalad, and the apical vascular ligament is divided between silver clips. The lateral and inferior aspects of the gland are easily mobilized, and the dissection is carried around to expose the anterior surface medially to the level of the inferior vena cava. The gland is then returned to its normal anatomic position to expose the remaining inferior and medial vascular attachments. Gentle lateral traction on the gland is applied to facilitate identification, ligation, and division of the right adrenal vein. The remaining arterial supply is divided between silver clips to complete the removal of the right adrenal gland.

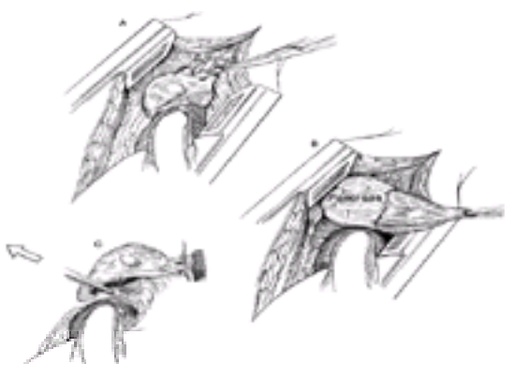

FIGURE 13.20. A–C: The technique of right adrenalectomy through a posterior incision. (From Novick AC. Surgery for primary hyperaldosteronism. *Urol Clin North Am* 1989;16:535, with permission.)

When adrenalectomy is completed, if a transthoracic incision has been used, the diaphragm is reapproximated with interrupted 2-0 silk mattress sutures. Airtight closure of the pleura is achieved using 3-0 silk or chromic sutures with the lung under positive-pressure expansion. Chest tube drainage is generally not necessary unless there has been difficulty in reapproximating the pleura. No surgical drains are used. A chest film is obtained several hours postoperatively in the recovery room to verify that the lung is fully expanded. Incisional discomfort with this approach is mild, and ambulation is generally possible on the day after surgery.

Flank Approach

The extraperitoneal flank approach is an alternative to the posterior approach for removal of relatively small benign unilateral tumors. The flank approach has the advantage of relative simplicity and familiarity to the urologic surgeon. Also, in particularly obese patients, exposure of the adrenal gland through a posterior incision may be compromised; in such cases, the use of a generous extraperitoneal flank incision is preferable for performing adrenalectomy.

When an extraperitoneal flank adrenalectomy is performed, either the twelfth or the eleventh rib is resected to allow entrance to the retroperitoneal space. Alternatively, the retroperitoneum can be entered through an incision in the tenth or eleventh intercostal space. A classic subcostal flank incision is not recommended because of the difficulty in obtaining adequate superior exposure of the adrenal gland.

On the right side (Fig. 13.21), the colon and duodenum are reflected medially, and the liver is reflected upward to expose the kidney and adrenal gland. The kidney with its attached adrenal gland is retracted downward. The anterior, posterior, and apical aspects are mobilized by blunt dissection from the undersurface of the liver posteriorly and from the duodenum and hepatic flexure of the colon anteriorly. The apical attachments of the gland are then divided between silver clips. With the gland retracted laterally, small arterial branches entering the medial aspect of the gland are identified as they course beneath the vena cava. Branches of the inferior adrenal artery coursing upward from the proximal right renal artery are similarly identified. After these vessels have been secured and transected, the right adrenal veinis located, secured, and divided. Residual apical vascular branches are then similarly secured and transected to complete the adrenalectomy.

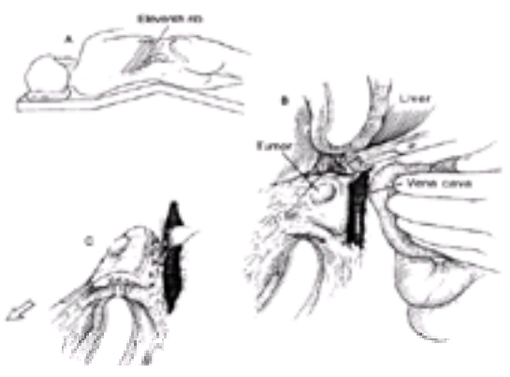

FIGURE 13.21. A–C: The technique of right adrenalectomy through an eleventh rib flank incision. (From Novick AC. Surgery for primary hyperaldosteronism. *Urol Clin North Am* 1989;16:535, with permission.)

Anterior Transabdominal Approach

The anterior transabdominal approach is indicated for adrenal lesions that are either large or potentially malignant. These include suspected or proven adrenal cortical carcinomas, large adrenal cortical adenomas, and large adrenal pheochromocytomas. In these cases, wide exposure is necessary, which cannot be achieved to the same extent through an extraperitoneal incision. With potentially malignant adrenal masses, intraabdominal inspection of other organs for metastatic disease is required. An anterior approach is also mandatory for adrenal malignancies that involve the inferior vena cava (74). The optimal anterior approach is through a bilateral subcostal or chevron incision, which provides much better exposure of the superior and lateral aspects of the adrenal gland than a midline incision. A unilateral extended subcostal incision can be used if the patient is thin and only one adrenal gland needs to be exposed. A vertical midline incision is used only if an

extraadrenal pheochromocytoma is suspected in the retroperitoneum along the great vessels or in the pelvis.

The main advantage of the transabdominal approach is that it provides excellent exposure of both adrenal glands, the vascular pedicles, the abdominal organs, and the retroperitoneum. Its principal disadvantage is that the peritoneal cavity is entered. It is not the most direct avenue to the adrenal glands, and in an obese patient, exposure may be more difficult. Postoperative morbidity is higher than with extraperitoneal approaches because of an increased incidence of ileus, atelectasis, and incisional discomfort.

The patient is placed with a rolled sheet beneath the lumbar spine, and a unilateral extended subcostal or bilateral subcostal incision is made to enter the peritoneal cavity (Fig. 13.22). On the right side, the posterior peritoneum lateral to the ascending colon is incised, the colon and the duodenum are reflected medially, and the liver is retracted superiorly to expose the kidney and adrenal gland. The kidney is gently retracted downward to bring the anterior surface of the right adrenal gland into view. In most cases, it is necessary to release the upper margin of the gland from the liver with sharp dissection to obtain complete exposure. In cases of pheochromocytoma, it is important to secure the adrenal vein as soon as possible to interrupt catecholamine release from the tumor into the systemic circulation. If the vein lies far cephalad, as it often does, division of the arterial supply medially and inferiorly may be necessary before the vein can be exposed satisfactorily and safely. Surgical exposure is facilitated by medial retraction of the inferior vena cava. In cases of suspected malignancy, it is also best to isolate the medial blood supply first and to carry out the lateral dissection later. For tumors confined to the adrenal gland, after the blood supply has been secured, the remaining lateral and inferior attachments of the gland are mobilized and divided to complete the adrenalectomy.

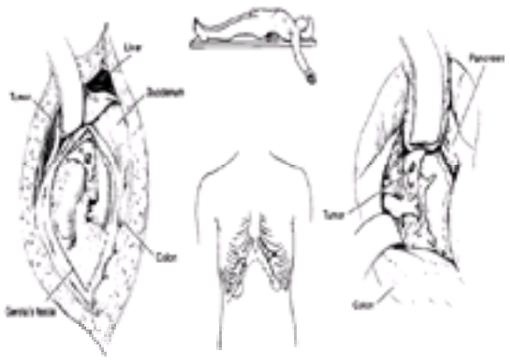

FIGURE 13.22. Anterior transabdominal approach to the adrenal glands. (From Guz B, Straffon R, Novick AC. Operative approaches to the adrenal gland. *Urol Clin North Am* 1989;16:527, with permission.)

On the left side, the adrenal gland is exposed by incising the posterior peritoneum lateral to the descending colon and dividing the ileorenal ligament with medial retraction of the colon and superior retraction of the spleen. The left adrenal vein is identified at its entry into the left renal vein and is then ligated and divided. The inferior adrenal artery also is secured and divided at this time. The adrenal gland is mobilized posteriorly and laterally by blunt dissection. The gland is then retracted downward to expose the superior vascular attachments, which are secured and divided. The gland is then retracted laterally to expose the remaining medial arterial blood supply, which is secured and divided. Residual attachments of the gland to the upper pole of the kidney are divided into sharp dissection to complete the adrenalectomy.

In some cases, an adrenal malignancy may invade the upper pole of the kidney. In this event, radical en bloc removal of both the kidney and adrenal gland within Gerota's fascia is the indicated procedure (Fig. 13.23). The main renal artery and vein are secured and divided in sequence, as in a radical nephrectomy; the ureter also is secured and divided. A plane is then developed posteriorly along the psoas muscle, bluntly mobilizing both the kidney and adrenal mass from behind and laterally. With downward and lateral retraction on the kidney, the medial blood supply to the tumor mass can be better identified. This exposure is facilitated by medial retraction of the vena cava. The medial adrenal arteries are secured and transected. On the right side, as the dissection proceeds upward, the adrenal vein also is identified, secured, and divided. This vein is large and friable, often lies higher than the surgeon expects, and must be carefully dissected free from surrounding structures to prevent avulsion from the vena cava. Should such an avulsion occur, the caval entry is immediately secured with Allis clamps and the defect is oversewn with a continuous 5-0 arterial suture. After the blood supply is secured, the dissection is carried upward and laterally to completely remove the tumor mass and kidney en bloc within Gerota's fascia. A regional lymphadenectomy is then performed from the level of the inferior mesenteric artery to the crus of the diaphragm. Splanchnic nerves and celiac ganglia may be sacrificed if adjacent nodes appear involved by neoplasm.

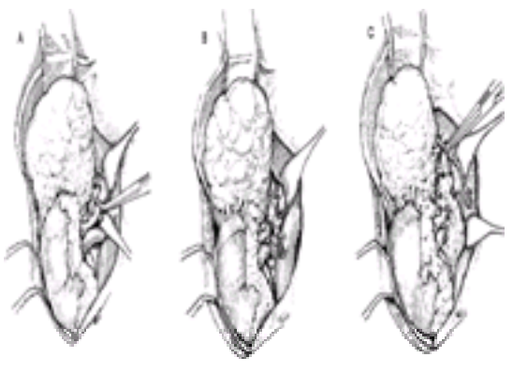

FIGURE 13.23. A–C: Technique of radical nephroadrenalectomy on the right side. (From Novic AC: Adrenal surgery. In Novick AC, ed. *Stewart's operative urology,* 2nd ed. Baltimore, Williams & Wilkins, 1989, with permission.)

Thoracoabdominal Approach

The thoracoabdominal approach to the adrenal gland is desirable for very large tumors that cannot be removed safely through an anterior transabdominal incision. It can be particularly advantageous for large right-sided adrenal masses, where the overlying liver and vena cava can limit exposure. There is less indication for this incision on the left side because the spleen and pancreas usually can be elevated away from the adrenal without difficulty. The thoracoabdominal incision provides excellent exposure of the suprarenal area (17,75); however, exposure of the contralateral adrenal is more difficult than with the anterior approach. Additional operative time is required to open and close a thoracoabdominal incision. Because the thoracic cavity is entered and the diaphragm divided, potential pulmonary morbidity is greater. For these reasons, the thoracoabdominal approach is reserved for patients in whom exposure beyond that provided by an anterior subcostal incision is considered important for complete and safe tumor removal.

The patient is placed in a semioblique position with a rolled sheet inserted longitudinally between the flank and hemithorax (Fig. 13.24). The incision is begun in the eighth or ninth intercostal space near the angle of the rib and is carried medially across the umbilicus. The intercostal muscles are divided to reveal the pleura and diaphragm; the diaphragm is divided circumferentially. On the right side, the hepatic flexure of the colon and duodenum are reflected medially and the liver is retracted upward to expose the adrenal tumor. On the left side, the descending colon is reflected medially with superior retraction of the pancreas and spleen to expose the adrenal gland. The details of adrenalectomy or nephroadrenalectomy are the same as those described for the anterior transabdominal surgical approach.

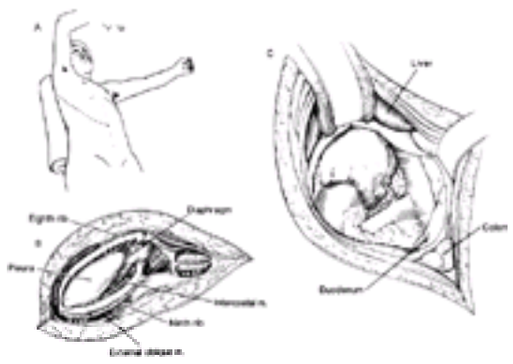

FIGURE 13.24. A–C: Thoracoabdominal approach to the adrenal gland. (From Guz B, Straffon R, Novick AC. Operative approaches to the adrenal gland. *Urol Clin North Am* 1989;16:527, with permission.)

Laparoscopic Adrenalectomy

Laparoscopic adrenalectomy was initially described by Gagner and colleagues in 1992. Since then, the rapid advances in minimally invasive surgery have led to laparoscopy becoming the technique of choice for many surgical adrenal disorders. Advantages of the laparoscopic approach include a shorter hospital stay, less postoperative pain, decreased patient morbidity, more rapid patient recovery, and a superior cosmetic result.

Several studies have confirmed the safety and efficacy of laparoscopic adrenalectomy for benign adrenal disorders such as (a) primary aldosteronism (36,38,88), (b) Cushing's disease or Cushing's syndrome due to an adrenal adenoma (27,38,55), or (c) other benign lesions such as a cyst or myelolipoma. Other indications have included small nonfunctioning adrenal masses with radiographic features suspicious for malignancy, small solitary adrenal metastases, and small adrenal pheochromocytomas (28,47). Laparoscopic adrenalectomy is currently contraindicated in large pheochromocytoma or clinical overt adrenal cortical carcinomas. As an extension of the latter, any radiographic evidence of local tumor invasion, venous extension, or lymphadenopathy would definitely contraindicate a laparoscopic approach.

Laparoscopic adrenalectomy can be performed by either a transperitoneal or lateral retroperitoneal approach. In a recent prospective, but as yet unpublished study, Gill compared these two approaches and found no advantage for the extraperitoneal approach in this setting. Most centers currently employ the transperitoneal approach for laparoscopic adrenalectomy. The availability of 2-mm instrumentation and camera technology has led to the emergence of needlescopic surgery. Data from our group (36) have shown that needlescopic adrenalectomy is feasible and does offer some advantages over conventional laparoscopic adrenalectomy. A description of the technique of needlescopic adrenalectomy follows.

The patient is secured in the flank (lateral decubitus) position with the table flexed and the kidney bridge elevated. With the use of the closed (puncture) technique, a needlescopic (2 mm) port, with *in situ* Veress needle introducer, is inserted into the abdomen just below the costal margin in the anterior axillary line (for a right adrenalectomy) or at the lateral border of the rectus muscle (for a left adrenalectomy). Proper intraperitoneal placement of the tip of the Veress needle is evaluated by the routine saline suction-injection-suction technique. Carbon dioxide pneumoperitoneum is established (15 mm Hg). The 2-mm port assembly is advanced an additional 2 cm into the abdomen, and the Veress needle introducer is removed. A 1.9-mm needlescopic inserted through the 2-mm port visually confirms safe intraperitoneal access. Under needlescopic guidance, a 10/12-mm trocar sheath is placed into the peritoneal cavity at the superior crease of the umbilicus. The needlescope is removed and a 10-mm, 45-degree laparoscope is inserted through the umbilical port. Two additional secondary trocars, whose location varies depending on the side of the adrenalectomy, are inserted under visualization of the 10-mm laparoscope: (a) for a right adrenalectomy, a 2-mm port is located lateral to the xiphoid at the costal margin and a 5 mm port at the lateral border of the rectus muscle, 2 cm below the costal margin; (b) for a left adrenalectomy, a 2-mm port is located at the midaxillary line and a 5-mm port is located at the midclavicular line, both at the costal margin.

Right Needlescopic Adrenalectomy

The surgeon works through the lateral 2-mm port and the 5-mm port, whereas the assistant works through the medial 2-mm port (Fig. 13.25). The procedure is initiated under visualization by the 10-mm, 45-degree laparoscope placed through the umbilical port. The assistant retracts the liver cephalad with a 2-mm grasper placed through the medial 2-mm port; extreme care must be taken to avoid injury to the gall bladder and liver during this maneuver. With the use of 5-mm scissors, introduced through the 5-mm trocar, the triangular ligament of the liver is incised; this allows more secure cephalad retraction of the liver by the 2-mm grasper. The posterior parietal peritoneum is incised parallel to, and 1 cm below, the inferior edge of the liver. Located between the liver and the hepatic flexure of the colon, this horizontal peritoneal incision extends from the paracolic gutter laterally up to the inferior vena cava medially. With the use of a 2-mm grasper, inserted through the lateral 2-mm port, the incised edges of the peritoneum are retracted, and the adrenal gland is identified in the retroperitoneum.

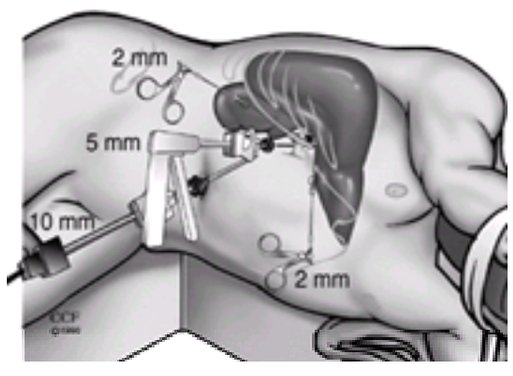

FIGURE 13.25. Needlescopic right adrenalectomy: port placement. Note that the 10-mm, 45-degree laparoscope is placed at the umbilicus. (From Gill IS, Soble JJ, Sung GT, et al. Needlescopic adrenalectomy—the initial series: comparison with conventional laparoscopic adrenalectomy. *Urology* 1998;52:180, with permission.)

Dissection is performed between the medial border of the adrenal gland and the inferior vena cava. This step is facilitated by lateral retraction of the adrenal gland and surrounding adipose tissue by the 2-mm grasper placed through the lateral 2-mm port (Fig. 13.26). Dissection along the right lateral edge of the inferior vena cava brings the main right adrenal vein into view. A 5-mm clip-applier, introduced through the 5-mm port, is used to secure the adrenal vein, which is then divided (Fig. 13.26). At this point in the dissection, the psoas muscle can be visualized through the laterally retracted adrenal gland and the inferior vena cava, signifying the posterior extent of the dissection.

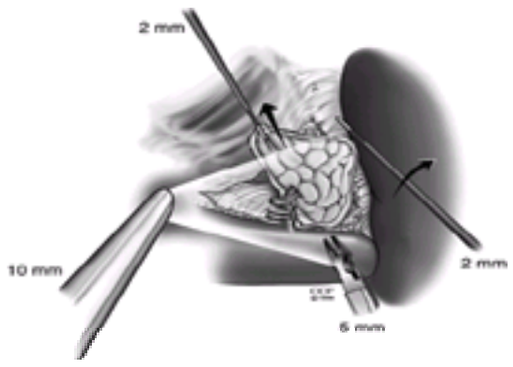

FIGURE 13.26. Needlescopic right adrenalectomy: dissection between the adrenal gland and the inferior vena cava brings the main adrenal vein into view. Care must be taken while retracting the liver cephalad with the 2-mm instrument. The main adrenal vein is clip-ligated by a 5-mm clip-applier inserted through the 5-mm subcostal port. Note that visualization is provided by the 10-mm, 45-degree laparoscope placed at the umbilicus. (From Gill IS, Soble JJ, Sung GT, et al. Needlescopic adrenalectomy—the initial series: comparison with conventional laparoscopic adrenalectomy. *Urology* 1998;52:180, with permission.)

Dissection proceeds along the superomedial border of the adrenal gland, where adrenal branches from the inferior phrenic vessels are clip-ligated and divided. After the superior edge of the adrenal gland is completely freed, the adrenal gland is retracted anteromedially, placing its inframedially and inferior attachments on gentle retraction. With the use of a combination of hook-blade electrocautery and the 5-mm clip-applier, small adrenal branches from the renal artery and vein are secured, and the adrenal gland is mobilized meticulously from the superior aspect of the renal hilum. The avascular plane between the upper pole of the kidney and the adrenal is developed, thus mobilizing the inferior edge of the adrenal gland. The tail of the adrenal gland is freed, completely excising the specimen.

The 10-mm laparoscope is now removed, and the needlescope is introduced through the medial 2-mm port. A plastic bag is inserted through the umbilical port, and under needlescopic visualization, the specimen is entrapped and extracted intact from the umbilicus. After confirming hemostasis, fascial closure of the umbilical port is performed and all ports are removed under needlescopic visualization. The umbilical incision and the 5-mm port-site incision are closed with subcuticular sutures. Each 2-mm port-site puncture hole is closed with a single Steri-Strip.

Left Needlescopic Adrenalectomy

The surgeon works through the medial 2-mm port and the 5-mm port, whereas the assistant works through the lateral 2-mm port. The main differences in a left adrenalectomy include mobilization and medial retraction of the splenic flexure and descending colon, cephalad retraction of the spleen, and control of the left main adrenal vein. Although virtually no colonic mobilization is required during a right adrenalectomy, performance of a left adrenalectomy requires incision of the line of Toldt and formal mobilization of the splenic flexure and part of the descending colon. The splenocolic, splenorenal, and splenophrenic ligaments are incised to completely mobilize the spleen in a medial and cephalad direction. Occasionally, for a larger adrenal mass, the tail of the pancreas must be mobilized off the anterior surface of the adrenal gland.

Dissection along the superior border of the left renal vein identifies the left main renal vein (Fig. 13.27). Clip-ligation of the main adrenal vein is performed with 5-mm clip-appliers (Fig. 13.28). Many aortic branches to the adrenal vein are clip-occluded and divided to free the adrenal gland.

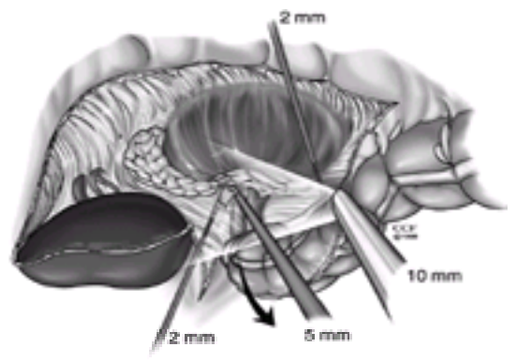

FIGURE 13.27. Needlescopic left adrenalectomy: identification of the left main adrenal vein. Note the T-incision along the line of Toldt. If adequate mobilization of the spleen is performed initially, the spleen stays retracted away from the operative site by gravity alone. Care must be taken while retracting the spleen and colon with 2-mm instruments. (From Gill IS, Soble JJ, Sung GT, et al. Needlescopic adrenalectomy—the initial series: comparison with conventional laparoscopic adrenalectomy. *Urology* 1998;52:180, with permission.)

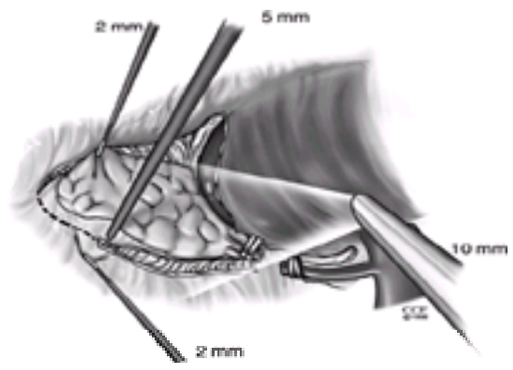

FIGURE 13.28. Needlescopic left adrenalectomy: clip-ligation of the main adrenal vein with 5-mm clip appliers. (From Gill IS, Soble JJ, Sung GT, et al. Needlescopic adrenalectomy—the initial series: comparison with conventional laparoscopic adrenalectomy. *Urology* 1998;52:180, with permission.)

During needlescopic adrenalectomy, visualization is provided by the 10-mm 45-degree laparoscope placed through an umbilical 10/12-mm trocar. From a cosmetic standpoint, the umbilicus is the optimal location to “hide” the mandatory 2- to 3-cm skin incision ultimately required for intact extraction of the excised adrenal gland. Our experience has shown that the diminished trauma of access by the needlescopic technique results in diminished port-site pain, and a superior cosmetic result (Fig. 13.29) (36). Currently, at our center, the needlescopic approach is the technique of choice when performing transperitoneal endoscopic adrenalectomy, except in patients with marked obesity or large adrenal tumors. In the latter settings, a conventional laparoscopic technique is employed with four 10/12-mm trocar sheets placed along the costal margin. The primary port is placed by the closed (Veress needle) technique, and the three secondary ports are inserted under laparoscopic guidance. The technique of laparoscopic adrenalectomy is otherwise similar to the needlescopic technique.

FIGURE 13.29. Patient photograph 2 weeks after needlescopic left adrenalectomy. The port-site skin incisions *(arrows)* are barely visible. (From Gill IS, Soble JJ, Sung GT, et al. Needlescopic adrenalectomy—the initial series: comparison with conventional laparoscopic adrenalectomy. *Urology* 1998;52:180, with permission.)

Recent studies also have shown that needlescopic adrenalectomy is less expensive than the open approach (43) and can be performed on an outpatient basis in select patients (34).

In a recent retrospective study, the results of laparoscopic/needlescopic adrenalectomy were compared with those of open adrenalectomy in 210 patients at The Cleveland Clinic Foundation (35). Laparoscopic/needlescopic adrenalectomy was performed in 110 patients from March 1996 through November 1998. Open adrenalectomy was performed in 100 patients from May 1987 through March 1996. Detailed data are outlined in Table 13.10. There was no significant difference in operative time and the mean specimen weight was similar in the two groups. The laparoscopic/needlescopic approach was clearly advantageous with respect to less blood loss, reduced narcotic analgesic requirements, earlier postoperative oral intake, and a reduced hospital stay. Currently, needlescopic adrenalectomy is currently being performed as an outpatient procedure in many patients (34). Additional recent data from our group have demonstrated that needlescopic adrenalectomy has a reduced overall cost compared with open adrenalectomy (43). Based on data such as these, laparoscopic/needlescopic adrenalectomy is emerging as the standard of care for many patients with surgical adrenal disease.

	Laparoscopic* (n = 110)	Open* (n = 100)	
Specimen weight (g)	29	28.6	
Surgical time (min)	188	218	
Blood loss (mL)	125	563	p = .0001
Narcotics (mg)	38	471	p = .0001
Oral intake (days)	1.0	3.2	p = .0001
Hospital stay (days)	1.9	7.6	p = .0001

*Mean values.

RENAL ANATOMY

The renal parenchyma is divided into an outer cortical zone and an inner medullary area. The medulla is subdivided into inner and outer portions, the former containing the 4 to 12 renal papillae. Each papilla is surrounded by transitional cell epithelium, the complex referred to as a *calyx.* It drains into an infundibulum, and the infundibula join one to another and then to the renal pelvis. A detailed knowledge of the calyceal anatomy is important, because endoscopic location of lesions within the kidney requires the ability to identify, on the two-dimensional roentgenogram, the location of the calyx in which the lesion is present and to correlate it with the gross anatomy of the kidney when visualizing the infundibula from the renal pelvis. The calyces located in the upper and lower poles often are compound and project directly to their respective poles. The remainder are arranged into an anterior and posterior row (Fig. 14.1). The anterior row of calyces forms an angle 70 degrees to the frontal plane; these are the calyces visualized laterally on an anteroposterior (AP) view of an intravenous (IV) urogram. The posterior calyces form a 20-degree angle with the frontal plane and are those visualized medially on the urogram (Fig. 14.2).

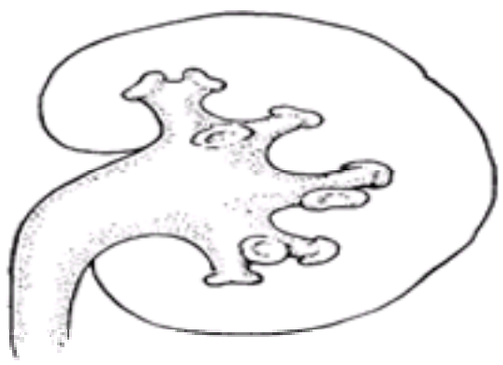

FIGURE 14.1. Calyceal anatomy. The polar calyces project to their respective poles while the middle calyces form an anterior and posterior row.

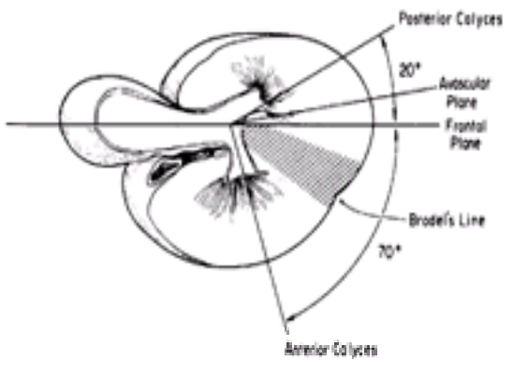

FIGURE 14.2. Location of anterior and posterior calyces. Notice that the anterior calyces form a 70-degree angle with the frontal plane and the posterior calyces a 20-degree angle with that plane. The avascular plane adjacent to Brödodel's line, through which the calyces may be entered without violating segmental vasculature, is depicted.

Segments of the cortex and medulla are served by end arteries, that is, arteries that do not anastomose with other arteries and therefore have little potential for the development of collateral vessels. The segments of the kidneys are the two polar, the anterosuperior, the anteroinferior, and the posterior (Fig. 14.3). The first main branch off the renal artery serving the renal parenchyma supplies the posterior segment. Thus location of this artery allows for identification of the subsegmental anatomy of the kidney. It allows identification of the avascular plane, adjacent to Brödodel's line between the anterior and posterior segments, along which the kidney may be split and calyces entered through the parenchyma without violation of the blood supply to segments of the parenchyma (Fig. 14.2). The arteries branch from the main renal artery into, successively, the interlobar; arcuate; interlobular; and afferent, glomerular, and efferent arterioles. The efferent arterioles supply the proximal tubule from the glomerulus in the cortex from which it arose, and supply the proximal tubule and Henle's loop when it arises from a juxtamedullary glomerulus. The venous drainage follows the arterial supply; however, unlike the arteries, veins intercommunicate between the segments.

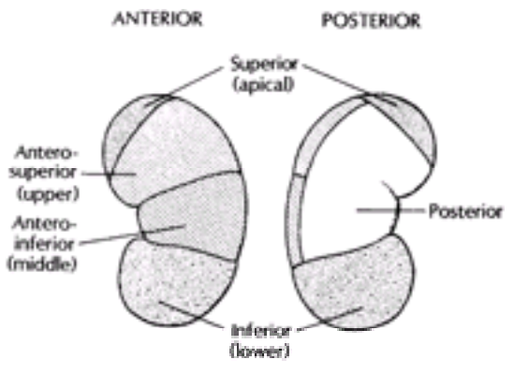

FIGURE 14.3. Segmental anatomy of the kidney. There are five segments: superior, inferior, posterior, anterosuperior, and anteroinferior.

There are two types of lymphatic networks in the kidney: a superficial system that drains the capsule and a deeper system that drains from the hilum (5). Lymphatic vessels in the kidney follow the arterial vessels from interlobular arteries proximally. The exact course of the lymphatic vessels distal to the interlobular arteries is not known. It has been suggested that the medulla contains few if any lymphatic vessels, whereas the cortex may be drained by regional areas from lymphatic vessels that actually do not penetrate deeply into the parenchyma (59). The renal capsule is supplied richly by lymphatic vessels. Capsule lymphatic vessels and parenchyma lymphatic vessels drain to the renal hilum and from there to the great vessel closest to the respective kidney.

The kidneys are supplied by sympathetic nerves from T4 to L4, which course to the celiac, superior, and inferior mesenteric and aorticorenal ganglia. The postganglionic fibers course to the renal hilum and then to the renal parenchyma. Once in the renal parenchyma, they travel with the vessels, eventually making contact with the juxtaglomerular apparatus and the basement membranes of the proximal and distal tubule cells. Innervation of the glomerulus is controversial. Stimulation of these nerves causes vasoconstriction and a short-term reduction in renal blood flow (RBF). Denervation of the kidney results in an increase in electrolyte excretion primarily caused by a diminished proximal tubule fractional reabsorption.

The hilum of the kidney contains the renal vessels, renal nerves, lymphatic vessels, lymph node tissue, and renal pelvis. The renal capsule extends to the renal sinus and incorporates it into the kidney proper.

There are two types of nephrons: cortical nephrons with short Henle's loops and juxtamedullary nephrons with long Henle's loops (Fig. 14.4). There are approximately 2 million nephrons per kidney, seven-eighths of which are cortical and one-eighth juxtamedullary. The arterial supply to the cortical nephrons differs from that of the juxtamedullary nephrons. In the former, the efferent arteriole courses along the proximal tubule belonging to the glomerulus from which it came. This allows that arteriole to reabsorb filtrate that it left behind in the glomerulus. Because these nephrons have short Henle's loops, they play a lesser role in maximum urinary concentration than do the juxtamedullary nephrons with long Henle's loops. The efferent arterioles from the juxtamedullary nephrons course not only along the proximal tubule from the respective glomerulus but also dive deep into the medulla, coursing along their respective Henle's loops. The vessels that follow Henle's loops are called *vasa recta.*

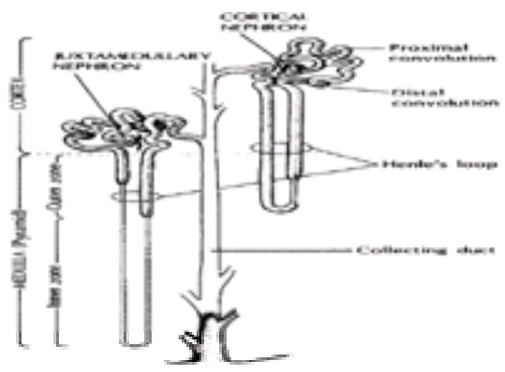

FIGURE 14.4. The renal parenchyma is divided into cortex and medulla and contains two types of nephrons: cortical and juxtamedullary.

The components of the nephron include the glomerulus, the proximal tubule, Henle's loop, the distal tubule, and the collecting duct. The glomerulus consists of an afferent arteriole, capillary and efferent arterioles, a juxtaglomerular apparatus, and Bowman's space and capsule (Fig. 14.5). The afferent arteriole, and to a lesser extent the efferent arteriole, are in intimate contact with the first portion of the distal tubule belonging to that glomerulus. This association is called the *juxtaglomerular apparatus* and consists of two parts: the macula densa, or the dark cells of the distal tubule, and the juxtaglomerular cells, or the endothelial cells of the afferent and efferent arterioles that contain renin granules. It has been postulated that this structure is responsible for the regulation of sodium conservation through the stimulation of aldosterone production and that it acts as a feedback mechanism for the intrarenal regulation of each nephron's blood flow and therefore glomerular filtration rate (GFR) (see the following discussion).

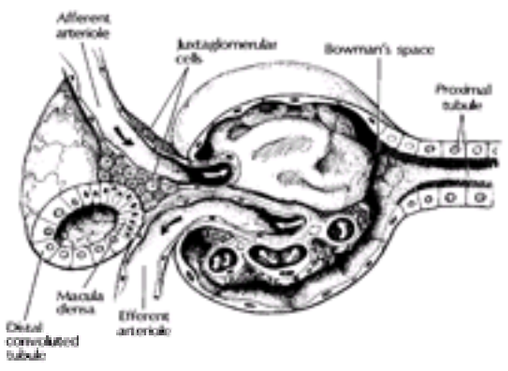

FIGURE 14.5. Glomerulus and juxtaglomerular apparatus.

The glomerular capillary network is the area through which plasma is filtered. The capillaries contain an endothelium, which lies on a basement membrane. On the other side of the basement membrane is Bowman's space. It is on this side of the basement membrane that the epithelial cells, or foot processes (podocytes), are found (Fig. 14.6A). Finally, mesangial cells that support the structures of the glomerulus are found within the glomerular tuft. These cells may play a role in causing arteriole constriction and in providing support for the aforementioned structures. Bowman's space empties into the convoluted proximal tubule. The cells of this portion of the nephron have a dense brush border on the luminal side (Fig. 14.6B) and are attached to each other by impermeable tight junctions. At the end of the proximal tubule, the nephron dives toward the medulla, where it attaches to the thin limb of Henle's loop. This portion of the proximal tubule is called the *pars recta.* Its brush border is less dense, and this area perhaps is less active in filtrate reabsorption than the other portion of the proximal tubule. The thin limb of Henle's loop descends and then turns back on itself and ascends toward its respective glomerulus. As it ascends, it changes to the thick limb of Henle's loop, which has notably different permeability and transport characteristics than the thin limb. The thick limb joins the first portion of the distal tubule whose cells are called the *macula densa*—a component of the juxtaglomerular apparatus. The distal convoluted tubule joins with many others to enter a collecting duct. The collecting duct traverses the parenchyma to the renal papilla (59).

RENAL PHYSIOLOGY

Glomerular Filtration

Plasma, water, and nonprotein crystalloids are separated from blood cells and protein within the glomerulus by a process called *ultrafiltration* (43). Nonchanged molecules with a molecular radius less than 20 Å are freely filtered (60). The forces involved in ultrafiltration are the hydrostatic pressure within the glomerular capillary, the permeability of the glomerular membrane called *hydraulic permeability,* the oncotic pressure of the plasma, and the hydrostatic pressure in Bowman's space. The hydrostatic pressure in the glomerular capillary remains relatively constant throughout its length, whereas the oncotic pressure rises along the course of the capillary as filtrate leaves. The net filtration pressure is the hydrostatic pressure minus the oncotic pressure minus the pressure in Bowman's space. Net filtration is determined by this pressure and the hydraulic permeability of the glomerular membrane. As blood courses along the length of the capillary, the net ultrafiltration pressure declines because oncotic pressure rises as a result of the increased protein concentration as fluid is removed from the capillary lumen (Fig. 14.7). This serves to keep the amount of filtrate constant despite capillary length and thus prevents loss of excessive fluid into Bowman's space. The permeability of the membrane is a function of the permeability of its component parts: the endothelium, the basement membrane, and the epithelial cells (podocytes or foot processes). The basement membrane and filtration slits account for 98% of the resistance, with the endothelium accounting for only 2% of the resistance (18). The podocytes are separated by filtration slits that contain pores having dimensions of 40 to 140 Å. Negatively charged glycoproteins are attached to the surfaces of the endothelial cells, basement membrane, and podocytes. Thus the membrane acts as a barrier by discriminating according to both the molecule's size and its electric charge (an electrostatic barrier).

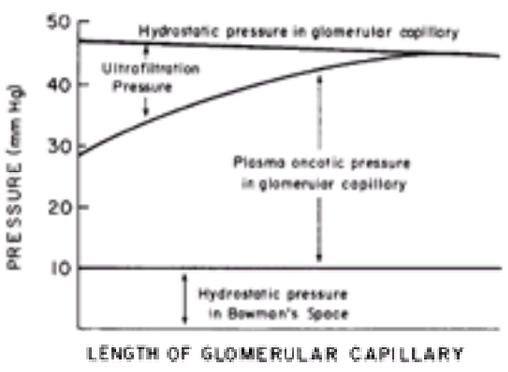

FIGURE 14.7. Forces of glomerular ultrafiltration. As fluid traverses the capillary and as some is filtered into Bowman's space, oncotic pressure within the capillary increases until it completely counteracts the hydrostatic pressure gradient. This limits the amount of fluid filtered into the proximal tubule.

The glomerular mesangium and renal vasculature are sensitive to a number of endogenous hormones. Angiotensin II, norepinephrine, the leukotrienes, platelet activating factor, adenosine triphosphate (ATP), endothelin, vasopressin, serotonin, and epidermal growth factor all may cause vasoconstriction.

The measurement of the quantity of plasma filtered by the glomeruli can be determined by a clearance technique. A clearance is defined as the volume of plasma from which the kidney removes a substance per unit of time. To measure the amount of fluid arriving in Bowman's space or the GFR, a substance is chosen that is freely filtered at the glomerulus but is neither secreted nor reabsorbed by the tubule. Inulin, a starchlike polymer of fructose with a molecular weight of approximately 5,000, is such a substance, the standard against which other substances used to measure GFR are compared. Inulin clearance is independent of serum concentration and urine flow. The clearance is calculated from the following formula:

$$\frac{UV}{P}$$

where *U* is the urine concentration, *V* is the urine volume per unit of time, and *P* is the plasma concentration.

The amount of filtrate removed from the plasma remains relatively constant as a result of the forces previously described. The fraction of fluid in the glomerular capillary bed entering Bowman's space is called the *filtration fraction* and is approximately 20%; that is, 20% of the plasma arriving in the glomerulus leaves as filtrate into Bowman's space.

Tubule Reabsorption

Reabsorption by the tubule epithelium of substances essential to normal body function, such as water, sugars, amino acids, and electrolytes, is critical for

homeostasis. Reabsorption of a substance may be determined by comparing its clearance with that of inulin: if the clearance of the filtered substance is less than that of inulin, it must be reabsorbed. Many substances that are reabsorbed are actively transported, thus having the potential to saturate the carrier mechanism, at which time a transport maximum (T_m) is achieved. T_m is the maximum amount of substance that can be actively transported when all carriers are saturated. Glucose, other sugars, sulfate, amino acids, phosphate, uric acid, and albumin have a T_m. The transport of a number of compounds can be facilitated by sodium transport. Glucose, uric acid, amino acids, and phosphate movement are enhanced in the presence of sodium, a process called *cotransport.*

Not all substances are reabsorbed by an active process. Passive reabsorption accounts for urea movement across the tubule. This type of transport is strongly affected by urine flow. At low flow rates, reabsorption of urea is increased, and at high flow rates urea is flushed from the tubule, thereby lessening its absorption. The flow of urea after filtration is not unidirectional. In certain portions of the tubule, urea is reabsorbed and in others it is secreted. Potassium and weak acids and bases (including drugs) also are secreted and reabsorbed in different portions of the nephron. The process is called *bidirectional transport.*

Tubule Secretion

Substances secreted are usually either weak acids or weak bases; they are foreign to the body and are either not metabolized or are metabolized slowly or incompletely. Secretion is confirmed when a filtered substance's clearance exceeds that of the inulin clearance. Examples of substances secreted include drugs (e.g., diuretics, antibiotics, salicylates), *para*-aminohippuric acid (PAH), and thiamine.

Renal Hemodynamics

Approximately 20% to 25% of the cardiac output flows to the kidneys, more than 90% of which perfuses the cortical region. Even though the medullary region gets only a small fraction of the total RBF, in absolute amounts it is perfused with approximately the same amount of blood as is resting muscle. The blood flow is sensitive to hemorrhage, the cortex being primarily affected. Antidiuretic hormone (ADH), the prostaglandins, renin, and sympathetic nerve stimulation affect RBF. ADH causes vasoconstriction and therefore prevents washout of osmotically active particles from the medulla. Prostaglandins are both vasodilatory and vasoconstrictive. Their vasodilatory action exerts a protective role in diseases causing vasoconstriction (20). Thromboxane, a potent prostaglandin vasoconstrictor, may play a role in altering RBF during obstructive uropathy (49). Others are not convinced that it alters renal hemodynamics. Renin, through the release of angiotensin, also causes vasoconstriction, and its release may be stimulated by an alteration of distal tubule sodium concentration, sympathetic nerve stimulation, and changes in intrarenal blood pressure. Angiotensin II exerts constrictive effects on both afferent and efferent arterioles, with an increased effect on the efferent arteriole. The subtype angiotensin II-2 receptor has been shown to have vasodilatory effects in selected circumstances. Angiotensin receptors also are located on mesangial cells, resulting in changes in glomerular surface area (12).

The renin-angiotensin system has been implicated in distribution of RBF; in regulation of GFR through its effects on afferent and efferent arterioles, on filtration coefficient, and on mesangial contraction; in sodium reabsorption by proximal and distal tubules; in renal concentrating mechanism; in potentiation of renal sympathetic activity; in interaction with prostaglandins; and as a renal growth factor (33). Stimulation of the sympathetic nerves supplying the kidney, through their innervation of the arterioles, causes vasoconstriction by stimulating contraction of endothelial muscle cells.

Finally, endothelin and endothelin-derived relaxing factor play a role in vasoconstriction and relaxation of the renal microcirculation. Under most conditions RBF remains relatively constant by a phenomenon known as *autoregulation.* Over a range of systolic blood pressures from 80 to 180 mm Hg, RBF and GFR remain constant. It has been suggested that the renin-angiotensin system, prostaglandins, the catecholamines, kinins, leukotrienes, ATP, serotonin, epidermal growth factor, platelet activating factor, and other substances regulate RBF by altering vascular resistance in the afferent and efferent arterioles by a complex set of interactions. Through this combined effect, intraglomerularhydrostatic pressure is maintained relatively constant over wide variations in systemic pressure.

RBF usually is measured by a clearance technique (see the following). PAH is used, because it is filtered and secreted by the kidney. Thus the amount of plasma that delivers the amount of PAH found in the urine per unit of time is the amount of plasma that passed through the kidney, or the *renal plasma flow* (RPF) . The calculation is simple. However, from a practical point of view its determination is difficult, because both the renal vein and renal artery concentrations must be known to calculate the amount of plasma delivered to the kidney because the arteriovenous difference is the amount removed in one pass. The renal artery concentration is easily determined from a peripheral venous sample; however, an invasive technique must be used whereby a catheter is passed to sample the renal vein directly. This difficulty can be obviated if the renal vein concentration approaches zero. If the PAH concentration is kept low enough in the systemic circulation, essentially all PAH entering the renal artery is cleared in one pass. Thus the calculation simplifies to a clearance as follows: UV/P of PAH. Because approximately 10% of the arterial concentration remains in the renal vein at low systemic PAH concentrations and because this may vary by as much as 20% under differing experimental conditions, the calculation of RPF determined without actual measurement of renal venous concentration is termed *effective renal plasma flow* to indicate that it is not actual RPF but rather an approximation thereof, because renal vein concentration is assumed to be zero, which actually may not be the case. If the renal vein concentration were known, then actual RPF could be calculated by the clearance technique previously described. RBF may be calculated by dividing the plasma flow by the following quantity: (1 – hematocrit).

Sodium and Water Balance

Sodium is actively transported from the luminal contents to the interstitium. The bulk of energy expended by the kidney is involved in this active process. In the proximal tubule, approximately 60% to 70% of the filtered sodium and fluid is reabsorbed. Because water follows sodium passively and because the proximal tubule is freely permeable to water, the fluid in this portion of the tubule is reabsorbed isosmotically. A constant fraction of the filtered sodium is reabsorbed in the proximal tubule (i.e., glomerulotubular balance), normally approximately 70% despite variations in the GFR.

Glomerulotubular balance appears to be brought about by two processes. The first involves changes in filtration fraction, perhaps brought about by nervous or humoral factors. The second involves the process of cotransport. Because sodium reabsorption is linked to the reabsorption of various substances that are almost completely reabsorbed by the proximal tubule (e.g., glucose), when increases in the filtered load of the substance occur, an increase in sodium reabsorption is stimulated and vice versa.

In the thin limb of Henle's loop, water moves according to its concentration gradient. Thus in the proximal portion, water moves out, whereas in the distal portion it moves back in. Sodium follows passively. In the thick ascending limb, sodium and chloride are actively pumped from the lumen; however, this portion is impermeable to water, and thus the fluid becomes hypotonic. In the distal tubule, sodium is actively removed under the influence of aldosterone. Water moves according to the movement of sodium and its concentration gradient. In the collecting duct, sodium is reabsorbed, and water movement (collecting duct permeability to water) is influenced by the concentration of ADH.

Mechanisms responsible for sodium balance may be classified into three groups. The first factor responsible for sodium homeostasis is GFR, which alters sodium reabsorption through the mechanism of glomerular tubule balance. Occasionally, glomerular tubular balance may be disrupted under circumstances of excessive sodium loads.

The second group of factors include angiotensin and aldosterone. Angiotensin II exerts potent effects on sodium and bicarbonate transport in the proximal tubule (12). Aldosterone is released either as a direct action of hyperkalemia or angiotensin II on the adrenal gland or as a result of the release of renin or adrenocorticotropic hormone (ACTH) (23). Renin is released from the juxtaglomerular cells as either a consequence of a low afferent arteriolar pressure (secondary to hypotension) or decreased distal tubule sodium concentration. Stimulation of the sympathetic nervous system, various prostaglandins, and calcium channel blockers also stimulate renin production. Angiotensin II, vasopressin, endothelin, and adenosine inhibit renin release. Renin is produced in an inactive form and is activated by a serum proteinase. Activated renin acts on a protein substrate to cleave a decapeptide, angiotensin I. Angiotensin I is converted by a converting enzyme to a vasoactive octapeptide, angiotensin II (Fig. 14.8). Angiotensin II results in vasoconstriction and stimulation of the adrenal gland to release aldosterone (33).

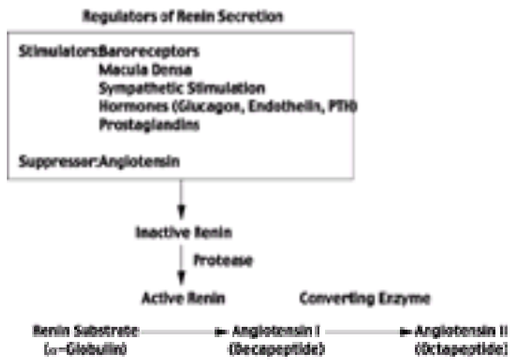

FIGURE 14.8. The renin-angiotensin system. PTH, parathyroid hormone.

Factors in the third group are nervous and/or humoral influences, which alter sodium transport. They are not well-defined; however, their effects are known. For example, volume expansion with sodium results in natriuresis that is caused by a decreased fractional reabsorption in the proximal tubule from 70% to 40% and a decreased sodium reabsorption in the distal tubule. This is not dependent on factors in either group one or two. A substance that may be responsible for some of these effects is *atrial natriuretic factor,* a 28–amino acid polypeptide that has been identified in the atrium. The 28–amino acid residue is the circulating form that is derived from a 126-residue precursor—the principal storage form. It has potent diuretic, natriuretic, and vasorelaxant properties. It also inhibits the release of ADH. The atria are the only established source of atrial natriuretic factor. Its release is stimulated by stretch of the atrium, volume expansion, sodium concentration, osmolality, and certain vasopressor agents (69). Finally, prostaglandins play a minor role in the modulation of sodium and water excretion. Prostaglandins synthesized in the renal medulla act locally to enhance water and sodium excretion by (a) increasing RBF, (b) inhibiting sodium transport from the thick ascending limb of Henle's loop, (c) antagonizing the action of vasopressin on the collecting duct, and (d) inhibiting urea and sodium reabsorption from the collecting duct (19).

Concentration and Dilution

The ascending limb of Henle's loop is impermeable to water, and because sodium and chloride are actively reabsorbed, electrolyte transport occurs without water following. This establishes a hyperosmotic medullary interstitium, which is the primary determinant of the kidney's ability to concentrate. Henle's loop acts as a countercurrent multiplier increasing the concentration of solutes, whereas the vasa recta coursing along with Henle's loop preserve medullary tonicity by serving as countercurrent exchangers. This is particularly important, because plasma flow to the medulla is approximately ten times greater than tubule fluid flow. This unique relationship preserves medullary tonicity and thus concentration capabilities.

Urea recycling helps maintain osmolality in the medulla, both in the medullary interstitium and the tubule lumen. Urea concentration in Henle's loop increases as water leaves. Under the influence of ADH, urea reabsorption in the collecting duct is facilitated as water is reabsorbed. This maintains a high medullary tonicity. Thus during antidiuresis, urea provides 40% of the medullary osmotically active particles, whereas in diuretic states urea constitutes only 10% of the medullary solutes.

ADH adjusts the amount of water that is reabsorbed from the late distal tubule and collecting ducts. ADH increases tubule permeability, thus allowing water to travel according to its concentration gradient. In the collecting duct, where medullary tonicity is high, water is reabsorbed. ADH also causes vasoconstriction of the vasa recta, preventing the removal of solute from the medulla, thereby maintaining a high medullary tonicity. Prostaglandins also may play a role in this regulation by opposing the action of ADH. ADH is released as a result of stimuli from volume receptors or osmoreceptors. Osmoreceptors located in the hypothalamus, when exposed to increased osmolality, stimulate the posterior pituitary to release ADH. Similarly, volume receptors located in the left atrium or pulmonary veins also result in the release of ADH.

Acid–Base Balance

The daily production of 40 to 70 mmol of inorganic and organic acids (i.e., the fixed acids) and 13,000 mmol of carbon dioxide (CO_2), which momentarily generates hydrogen (the volatile acid), requires elimination by the body. This acid load requires buffering so that major pH shifts do not occur locally. The buffers include hemoglobin, protein, inorganic phosphate, organic phosphate, and bicarbonate. Organic phosphate is the major intracellular buffer, whereas the main extracellular buffer is the carbonic acid bicarbonate system. The latter is particularly effective, because the concentration of one component of the pair, CO_2 can be altered rapidly by the lungs.

Perhaps one of the most effective initial methods of buffering the volatile acid load is the reaction hydrogen has with hemoglobin. Oxygenated hemoglobin is more acidic than nonoxygenated hemoglobin. Thus when hemoglobin gives up its oxygen, it can take up a great deal of hydrogen without any overall change in local pH. CO_2 arising from metabolism is hydrated to carbonic acid and dissociates into hydrogen and bicarbonate. The hydrogen is taken up by hemoglobin, and the CO_2 travels to the lungs as bicarbonate. The reverse reaction occurs in the lungs where hydrogen is given up, CO_2 is eliminated, and hemoglobin is oxygenated. Fixed acids initially are buffered by bicarbonate, phosphate, and proteins, thus lessening their effect on systemic pH. In the process of buffering, fixed acids consume bicarbonate. The volatile acid is excreted by the lungs and the fixed acids by the kidney, thus restoring buffer capacity.

The kidney reclaims bicarbonate by two mechanisms. Filtered bicarbonate is reclaimed in the proximal tubule, where 80% to 90% of that which is filtered is reabsorbed. This process occurs by (a) the secretion of hydrogen ion by the proximal tubule cell, (b) the combination of the hydrogen with filtered bicarbonate to form carbonic acid, (c) the dehydration of carbonic acid to CO_2 and water within the tubule lumen, (d) the diffusion of CO_2 into the proximal tubule cell, (e) the formation of carbonic acid, and (f) the removal of hydrogen to be secreted into the lumen thereby, in effect, reabsorbing bicarbonate. Filtered bicarbonate is reclaimed in this manner; however, bicarbonate consumed in the process of buffering fixed acid is restored and the hydrogen eliminated by hydrogen secretion in the cortical collecting tubule. The hydrogen arises from carbonic acid and thus results in bicarbonate generation within the tubule cell. The bicarbonate stores are thus replenished. The hydrogen ion secreted in the cortical collecting tubule by the Na-H antiport is fixed to phosphate, creatinine, and urate. These act as buffers and are excreted as weak acids. Hydrogen excreted in this manner is called *titratable acid* and, as such, lowers urinary pH. Because an intraluminal hydrogen concentration cannot exceed a concentration difference of more than 1,000:1, any amount excreted in excess of this back-diffuses into serum. The kidney is therefore incapable of lowering urinary pH values to less than a pH of 4.4. This mechanism limits the amount of hydrogen ion capable of being secreted. Fortunately, the ammonium system allows for further elimination of hydrogen ion without the need to lower urinary pH.

Ammonia is generated from glutamine in the proximal tubule. Ammonia diffuses across the membrane into the tubule lumen, flows to the distal tubule/cortical collecting duct, and combines with a hydrogen ion to form ammonium. Ammonium may be secreted by a number of transporters, NH4/H exchange being one. The quantitative role of this mechanism is not firmly established. Ammonium is trapped and combines with an available anion—usually chloride, sulfate, or phosphate—to form a neutral salt. The neutral salts do not influence pH and are excreted as such. Distal hydrogen secretion is promoted by increasing the severity of the acidosis, the presence of aldosterone, depletion of potassium, and increased delivery of sodium to the distal nephron. Factors that alter bicarbonate reabsorption in the proximal tubule include the serum concentrations of CO_2, potassium, chloride, phosphate, calcium, and parathormone, and the volume status of the patient. Increased bicarbonate reabsorption occurs with elevated CO_2, decreased potassium, diminished chloride, and elevated phosphate and decreased volume. Increased parathormone, hyperkalemia, and reduced CO_2 decrease bicarbonate reabsorption.

The final regulation of urinary acid excretion occurs in the collecting duct. Collecting duct acid–base balance is regulated by systemic acid–base states, potassium balance, sodium reabsorption, mineralocorticoids, and other peptide hormones (27).

Potassium

Only approximately 10% to 20% of the filtered load of potassium is excreted. It is reabsorbed in the proximal tubule and also may be reabsorbed in the distal tubule and collecting duct under certain experimental conditions. It is secreted in the distal tubule, and it is by this mechanism that most potassium is excreted in the urine. The rate of secretion is influenced by the presence of mineralocorticoids, urine flow, acid–base balance, and sodium intake. Mineralocorticoids stimulate the secretion of potassium, mainly in the cortical collecting duct. Their presence results in sodium reabsorption, but there is not a 1:1 ratio of sodium for potassium. Alkalosis results

in increased potassium secretion, whereas acidosis results in hydrogen secretion at the expense of potassium secretion. Potassium and hydrogen ion transport are linked in some manner explaining this phenomenon. An increased flow rate keeps the concentration gradient high between tubule cell and lumen and therefore promotes secretion. Sodium, by increasing flow rates in the distal tubule or by its effect on the sodium-potassium cellular exchange pump, also increases potassium secretion.

Calcium

The bulk of filtered calcium is reabsorbed in the proximal tubule. However, the remainder is reabsorbed in the thick ascending limb of Henle's loop and the distal tubule. Its reabsorption depends on phosphate, magnesium, and parathormone. Hypophosphatemia decreases calcium reabsorption as does an increase in magnesium concentration. Parathormone increases calcium reabsorption and reduces phosphate reabsorption. Parathormone also stimulates the kidney to produce 1,25-dihydroxyvitamin D_3, which increases gut absorption and bone reabsorption for calcium. Magnesium, calcium, and sodium may share some of the same carriers, because if there is an excess of one, others tend to be excreted; that is, the common pump is saturated by the ion in excess.

Magnesium

Magnesium is reabsorbed in the proximal tubule, thick ascending limb, and distal tubule. Increased sodium, calcium, and mineralocorticoid reduce reabsorption. Osmotic agents, renal vasodilation, glucose, and hyperthyroidism increase excretion (68).

DETERMINATION OF RENAL FUNCTION

Because of the complexity and wide range of functions the kidney performs, the assessment of renal function requires measurement of individual processes occurring in various portions of the nephron. It is not practical to measure each one; therefore, selected functions are determined and, unless otherwise indicated, it is assumed that these reflect the general function of the entire kidney. For convenience these studies are divided into five groups: (a) glomerular filtration, (b) RBF, (c) tubule electrolyte transport, (d) concentration and dilution, and (e) protein conservation.

Glomerular Filtration Rate

GFR is the amount of filtrate arriving in the proximal tubule per unit of time. It assesses the normalcy of RBF, glomerular integrity, and proximal tubule pressure. Its measurement is based on the concept of a clearance (see the following equation). The ideal substance for this measurement is freely filtered at the glomerulus and is not metabolized, secreted, or reabsorbed by the tubule. The material used to perform the clearance must be maintained at a constant concentration in the serum. For inulin this requires maintaining a constant IV infusion, because the substance is not endogenous to the body. Once a constant serum level is obtained, the amount of inulin excreted in the urine is measured per unit time (urine concentration, *U,* multiplied by the volume, *V,* of urine excreted: U × V). To find the amount of serum from which this amount of inulin was extracted, the product is divided by the serum concentration, *P.* Thus U × V/P gives the amount of serum completely cleared of the substance per unit time or the GFR.

A normal GFR (measured by inulin clearance) for a young adult is 130 mL per minute for males and 120 mL per minute for females per 1.73 m^2 of body surface area. Exercise lowers GFR, whereas pregnancy may increase it by as much as 50%. Hydration, either extreme overhydration or dehydration, also may affect filtration rate. In children older than the age of 1 year, when the GFR is corrected to 1.73 m^2 of body surface area, it is the same amount as for adults. In children younger than the age of 1 year, it is less—only approximately 50% of the corrected adult value in the neonatal period. Similarly, the GFR falls with age, until by the age of 60 years it is only 60% to 80% of the young adult value.

Several formulas have been developed to assess GFR from the measurement of serum creatinine alone without the need for a urine collection (30). Perhaps the most widely used formula is the following:

$$\frac{(140 - \text{age}) \times \text{Body weight (kg)}}{72 \times Cr_s}$$

where Cr_s is the serum creatinine concentration.

This gives the GFR for males; for females the value is multiplied by 0.85. This formula is useful for calculating GFR when the need to adjust drug doses arises. It is reasonably accurate when the GFR exceeds 40 mL per minute. This formula is inaccurate in patients with spinal cord injury (muscle wasting), in those with bowel interpositions in the urinary tract, and in those in whom one of the interfering substances is present (see previous discussion). It must be remembered that serum creatinine concentrations vary with muscle mass (more muscular individuals have a higher serum creatinine level), daily protein consumption, and metabolic state of the patient (13,52). Alterations in serum creatinine are a less accurate method of determining renal function.

Because of the inaccuracies of creatinine, other substances and methods have been developed in an attempt to measure GFR accurately without the difficulties encountered with the inulin clearance. Vitamin B_{12}, edetate (EDTA), sodium iothalamate, and sodium diatrizoate have been shown to have clearance rates similar to inulin. However, they appear to have no advantages over endogenous creatinine clearances except in selected circumstances.

Radiopharmaceuticals have enjoyed popularity as a less cumbersome method of determining renal function. The radiopharmaceutical technetium, labeled *pentetic acid* diethylenetriaminepentaacetic acid (DTPA)], is used for GFR measurements, and iodohippurate sodium ^{131}I (Hippuran) is used for RBF determination. Two methods are commonly used to determine GFR and RBF. The GFR or RBF can be calculated from an empiric formula that requires knowledge of the amount of isotope taken up by the kidneys over a 6-minute period (25). The second method involves injecting the isotope and withdrawing serial blood samples over several hours. The amount of isotope is determined in the blood samples, and a disappearance curve is plotted. GFR or RBF is calculated from the half-life of the disappearance curve (10). In patients with relatively normal renal function who are in good health, these methods correlate well with inulin clearances. However, they are inaccurate in patients with significant edema or ascites, in those with intestine interposed in the urinary tract, and in patients with poor renal function.

Renal Blood Flow

The kidneys receive approximately 20% of the cardiac output. Measurement of RBF allows an assessment of the vascular integrity of the kidney and, to a lesser extent, the viability of the renal parenchyma. A clearance technique or isotope washout method is usually employed. Clinically, the clearance method is most convenient, because it requires no special instrumentation and is based on the Fick principle. The amount excreted in the urine (urine concentration, *U,* multiplied by urine volume, *V*) divided by the renal artery minus the renal vein concentration difference gives the amount of plasma required to deliver the substance. Because it is from renal plasma that the substance is extracted, RPF is determined as follows:

$$\text{RPF} = \text{UV/A} - \text{RV}$$

where *U* is urine concentration; *V,* urine volume per unit time; *A,* renal artery concentration; and *RV,* renal vein concentration. Because the determination of renal vein concentration is cumbersome, a substance that is completely extracted in one pass is chosen so that renal vein concentration is zero. Thus the calculation simplifies to UV/P. Because no known substance is extracted completely in one pass, the measurement is called *effective RPF.* PAH, iodopyracet (Diodrast), and Hippuran, when administered at low-dose levels, are removed almost completely and are the agents employed to measure RPF. The renal extraction is approximately 90%; thus there is approximately a 10% error rate. Moreover, not all blood to the kidney is exposed to functioning tubules and glomeruli, so this technique may be significantly inaccurate in disease. Normal values are 600 to 700 mL per minute per 1.73 m^2. RBF may be calculated from RPF by the following equation:

$$\text{RBF} = \text{RPF}/(1 - \text{Hct})$$

where *Hct* is the patient's hematocrit level.

Washout methods involve injecting a bolus of isotope (xenon or krypton) in the renal artery and then measuring the speed with which the isotope leaves renal

parenchyma by recording the rate at which radioactivity diminishes over the kidney by conventional scanning techniques. The concentration of isotope in the kidney as a function of time is plotted. The equation that describes the disappearance curve is of the fourth order or greater. By stripping the curve, that is, generating the equation for the curve, RBF to various segments (cortex and medulla) may be determined (58).

Finally, the disappearance of isotopically labeled Hippuran from the blood or timed accumulation by the kidney may be used as a gross estimate of RBF (see previous discussion).

Tubule Electrolyte Transport

Integrity of transport processes can be determined by assessing the transport of various electrolytes. This is important in certain disease entities, such as renal tubular acidosis (RTA) in which there is a defect in hydrogen ion secretion. That defect may be brought to light by stressing the kidney's hydrogen ion transport process. Other defects, such as distal tubule ammonium dysfunction, as occurs in certain patients who form uric acid stones, and salt-losing nephropathy, may be assessed similarly.

Sodium extraction rate may be used as a crude index of proximal and distal tubule function. The normal kidney under conditions of severe salt restriction should be able to excrete less than 0.1% of the filtered load of sodium in a urine concentration of less than 1 mEq/L.

Distal tubule function may be assessed by the administration of a mineralocorticoid and observation of a decrease in urine sodium concentration and a rise in urine potassium concentration. Distal tubule hydrogen secretion also may be assessed by administering hydrochloric acid, ammonium chloride, or one of the cationic amino acids (lysine, arginine, or histidine) and observing a decrease in the urine pH to less than 5 and/or a lack of ammonia generation.

Concentration and Dilution

Alterations in concentration and dilution indicate distal tubule and collecting duct dysfunction. Many entities affect these functions (Table 14.3), most often pyelonephritis and urinary obstruction. The normal kidney can dilute to an osmolality of 40 mOsm/kg and concentrate to 1,200 mOsm/kg. Concentrating ability is determined by either water deprivation or the administration of vasopressin. Diluting ability is determined by having the patient drink 1 L of water over a short time. The patient will excrete more than half the volume over 3 hours with a urine osmolality of 80 mOsm/kg or less.

Postrenal polyuria	Functional abnormalities
Obstruction	Nephrogenic diabetes insipidus
Intrarenal polyuria	Medullary washout
Anatomic disruption	Prerenal polyuria
Sickle cell anemia	Lack of ADH
Pyelonephritis	Suppressed expanded extracellular fluid
Amyloidosis	Diabetes insipidus
Nephrocalcinosis	Trauma
Metabolic abnormalities	Diuretic agents (other
of ADH–collecting duct interaction	than doxycycline or neuromuscular agents)
Hypercalcemia	
Hypokalemia	
Renal tubular acidosis	

ADH, antidiuretic hormone.

TABLE 14.3. DIFFERENTIAL DIAGNOSIS OF POLYURIA

DETERMINATION OF RENAL FUNCTION IN THE PRESENCE OF INTESTINAL SEGMENTS

The assessment of renal function in patients in whom a segment of intestine is interposed in the urinary tract requires modifying the techniques normally employed to determine renal function in the intact collecting system. This is necessary because the intestine, which is used as a conduit, functions as a vehicle of urine transport and as an absorptive and secretory surface. Thus urine may be modified considerably after transversing intestine, making it difficult to determine whether the measured substance has been altered by bowel absorption or secretion. Many of the substances used to assess renal glomerular function or RBF are absorbed by the intestinal segment. Urea is perhaps the most permeable, but creatinine, inulin, and PAH also are significantly absorbed (36). Their absorption depends on their concentration and the amount of time they remain in contact with the intestine, which is a function of the surface area to which they are exposed and the urine flow rate. Figure 14.9, Figure 14.10 and Figure 14.11 illustrate the dependency of urine flow rate on absorption of urea, creatinine, and inulin in patients with ileal and colon conduits. For clarity, the figures compare the percentage of maximum clearance achieved as a function of flow rate in normal collecting systems and ileal and colon interpositions. The illustrations demonstrate that when urine flow rates exceed 250 mL per hour, intestinal absorption for creatinine and inulin is negligible, and at these flow rates the substances more closely measure the true GFR and RPF (PAH shows a similar flow dependency). These curves were derived from a group of patients with ileal conduits, colon conduits, and intact urinary tracts. Because renal function varied from poor to normal, the patients were compared by factoring each measured clearance by the maximum clearance obtained for that patient. At high flow rates, patients with stomal stenosis tend to diminish their clearance, indicating that at these flows the intestine serves as a functional obstruction (45).

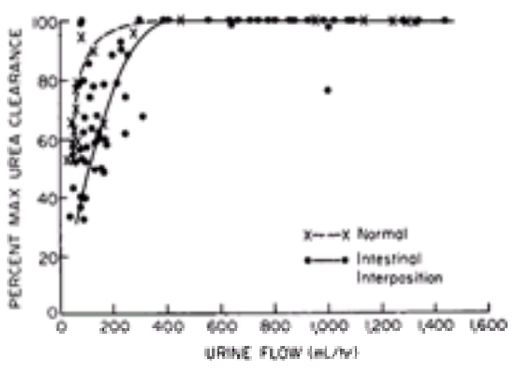

FIGURE 14.9. Flow dependency of urea clearance in patients with normal urinary tracts compared with those with ileal and colon interpositions.

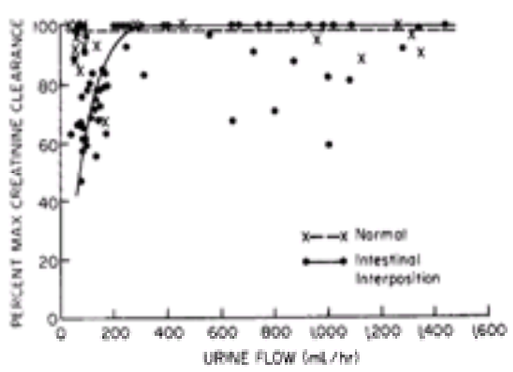

FIGURE 14.10. Flow dependency of creatinine clearance in patients with normal urinary tracts compared with those with ileal and colon interpositions.

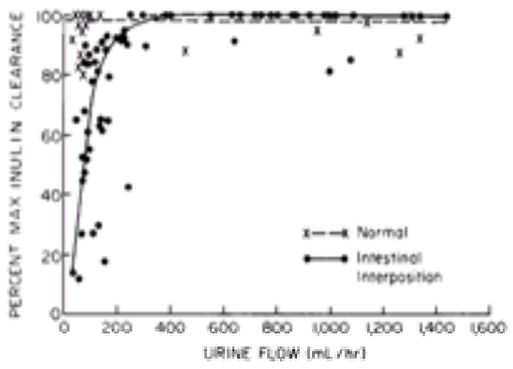

FIGURE 14.11. Flow dependency of inulin clearance in patients with normal urinary tracts compared with those with ileal and colon interpositions.

Measurement of Glomerular Filtration Rate

Because clearance is flow dependent, it is necessary to establish a diuresis in patients with ileal and colonic segments at urine flows between 300 and 700 mL per hour. These flows may be achieved by fluid administration alone. Rarely, a diuretic such as furosemide also may be required. The urine is collected over 1 hour. The volume is measured, and the substance used for the clearance is measured in the serum and urine. Creatinine is perfectly adequate in these patients, provided the serum does not contain excessive ketoacids, cephalosporins, cimetidine, trimethoprim-sulfamethoxazole, or propranolol (51). Because diuretic creatinine clearance parallels diuretic inulin clearance, the former is the clinically expedient method of determining the GFR. Creatinine clearance measured in this manner is approximately 20% less than inulin clearance at GFRs that exceed 20 mL per minute. If the GFR is less than 20 mL per minute, the creatinine clearance may overestimate the inulin clearance as a result of secretion by the renal tubule. At low GFRs (i.e., less than 10 mL per minute), the error rate may be as great as 50% (Fig. 14.12).

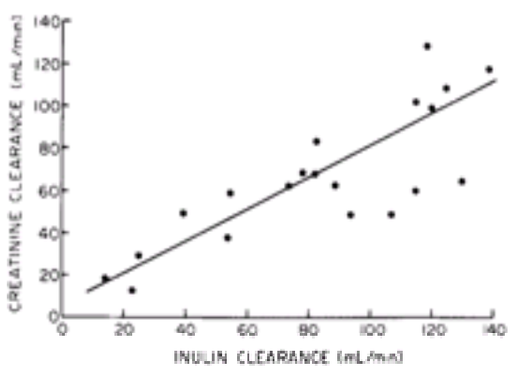

FIGURE 14.12. Diuretic inulin and creatinine clearances in patients with normal urinary tracts compared with those with ileal and colon interpositions. Notice the excellent correlation and that creatinine clearance is consistently 20% less than inulin clearance.

Renal isotope determination of GFRs in these patients is not useful, because there is little correlation between GFRs obtained by this method and those obtained by inulin clearance. This is true at all levels of renal function (45).

Because the bowel absorbs, secretes, and metabolizes creatinine, the calculation of the GFR from serum creatinine, age, weight, and gender by empiric formulas is totally unreliable and not useful in these patients (45).

Renal Blood Flow

PAH clearance obtained when urine flows range between 300 and 700 mL per hour accurately reflects effective RPF. Isotope scans are not accurate in determining RBF in these patients.

Tubule Function

The determination of tubule function by the measurement of sodium excretion and hydrogen ion secretion under conditions of sodium deprivation or hydrogen loading (see previous discussion) cannot be accurately performed in these patients. Although some qualitative indication of the way electrolytes are handled can be obtained, the maximum capabilities of the kidneys with respect to electrolyte transport cannot be determined when urine is analyzed after it has traversed an intestinal segment.

Concentration and Dilution

Because the bowel cannot concentrate much more than 50 mOsm/kg greater than serum, urine traversing an intestinal segment, if more concentrated than serum, is diluted. Thus in patients with ileal and colon conduits, maximum urinary concentration usually does not exceed 400 mOsm/kg. The determination of maximum urinary concentrating ability of the kidney cannot be performed accurately in patients with intestinal segments (45). Although the kidney's ability to dilute can be assessed with the techniques described previously, maximum dilutional capabilities cannot be determined because of absorption by the intestine. Therefore statements about distal tubule and collecting duct function based on maximum concentrating ability in patients with colon or ileal segments are meaningless.

It is clear that patients who have colon or ileal conduits, those with intestine interposed in the urinary tract, and those in whom intestine is used as a urinary reservoir require special manipulations to measure renal function. GFR and RPF can be accurately assessed if, while they are being measured, urine flows range between 300 and 700 mL per hour. They must be measured by classic clearance techniques, not by either isotopic scans or empiric calculation from serum creatinine. Tubule function is most difficult to assess in these patients, and at present there is no good way of determining the kidney's maximum capacity for conserving sodium, excreting hydrogen, or reabsorbing water.

ACUTE RENAL FAILURE

Acute renal failure (ARF) in surgical patients has numerous causes (Table 14.1). Whatever the primary cause, it is associated with significant morbidity and mortality and presents as a progressive rise in blood urea nitrogen (BUN) and creatinine levels, often with a decrease in urine output. ARF is said to be oliguric when the urine output is less than 400 mL per 24 hours and nonoliguric when the urine output exceeds this amount. The initial therapy and prognosis for ARF are determined not only by examining the serum chemistries and state of fluid balance but also depend on the expeditious assignment of patients to one of the three subdivisions of this disease: prerenal, intrarenal, or postrenal. Therefore it is necessary to begin diagnostic procedures that will determine the type of ARF simultaneously with therapy directed at correcting fluid imbalance and electrolyte abnormalities.

Prerenal failure	Vasomotor nephropathy
Excessive nitrogen load	Shock
Myocardial pump failure	Sepsis
Hypovolemia	Transfusion reactions
Intrarenal failure	Crush injury
Occlusion of renal arteries or renal veins	Tubule toxins
Arteriolar damage	Drugs
Malignant hypertension	Myoglobin
Polyarteritis	Poisons
Hypersensitivity angiitis	Postrenal failure
Disseminated intravascular coagulation	Obstruction of the collecting system
Glomerulonephritis	Tumors
Lupus erythematosus	Calculi
Poststreptococcal glomerulonephritis	Infection and inflammatory lesions
Parenchymal damage	Fibrosis
Acute interstitial nephritis	Blood clots
Acute pyelonephritis	Renal papillae
Papillary necrosis	Increased intraabdominal pressure
Diabetes mellitus	Retroperitoneal hemorrhage
Nephrosclerosis	Osmolality, mOsm/L
Sickle cell anemia	Occasional hyaline
Analgesic medications	Occasional hyaline P cast
Cortical necrosis	Tubule epithelial casts
End-stage renal disease	Variable, initially low
Hepatorenal syndrome	
Hepatic arteriolar ligation	

TABLE 14.1. CAUSES OF ACUTE RENAL FAILURE

Immediate Management of Acute Renal Failure

A careful history and physical examination often will suggest the type of ARF; however, the immediate management of this disease is dictated by the extent of serum chemical aberrations and fluid imbalance. Thus initial steps are directed at defining these abnormalities. An electrocardiogram (ECG), serum electrolytes, and urine for microscopic and chemical analysis are obtained. If the serum potassium is elevated, the ECG changes will indicate the rapidity with which the hyperkalemia must be corrected and will serve not only as a baseline against which the success of therapy may be measured but also as an immediate approximation of potassium concentration during the patient's course. Hyperkalemia results in progressive peaking of the T wave, prolongation of the QRS complex, and at high concentrations, absence of the P wave. When the serum potassium is greater than 7 mEq/L or when prominent alterations of the ECG occur (particularly when the P wave is absent), immediate reduction in serum potassium is accomplished by infusing hypertonic sodium bicarbonate and/or administration of insulin and glucose in a ratio of 1 unit per 5 g. Calcium is administered intravenously to stabilize myocardial conductivity. Acidosis and hyperkalemia may be partially corrected by giving bicarbonate, which results in a shift of potassium into the cell with preservation of electroneutrality by concomitant movement of hydrogen ion out of the cell. If some renal function is preserved, potassium secretion is increased in the distal tubule, because bicarbonate reduces the amount of hydrogen ion competing for the common hydrogen-potassium secretory mechanism, thus allowing it increased access to potassium. Glucose and insulin result in movement of potassium into the cell, either by binding it during glucose transport or during glycolytic phosphorylation. These mechanisms result in a transitory decrease in serum potassium, because it moves out of the cell in the former when acidosis recurs and in the latter when substrate has been metabolized. Therefore it is important to lower the total body serum potassium by simultaneously employing an ion exchange resin, such as polystyrene sulfonate (Kayexalate), 10 to 20 g orally or 50 g by enema, both given with sorbitol, or by peritoneal dialysis or hemodialysis. Usually 2 to 3 hours are required before ion exchange resins show an effect or before dialysis can be instituted. Most commonly, alkalization, ion exchange resins, and occasionally, dialysis are all that are required, with glucose and insulin being reserved only for those cases in which hyperkalemia is immediately life-threatening. The state of fluid balance is determined by analysis of intake and output, weight, venous or left atrial filling pressure, physical examination, and history. Inappropriate intake for the amount of output usually accounts for the imbalance; however, therapeutic maneuvers used to treat electrolyte abnormalities also may be contributory. Kayexalate, by exchanging sodium for potassium and sodium bicarbonate, can cause an excessive sodium load and fluid retention. When either overhydration or hypernatremia becomes an urgent problem, dialysis is most effective in correcting the disorder. Usually time is not of the essence, and sodium and fluid restriction will suffice. Low venous or pulmonary wedge pressure, clinical signs of dehydration, a history of blood loss, and hypotension indicate volume depletion and are treated by appropriate fluid replacement.

During the short-term treatment of hyperkalemia and fluid imbalance, an attempt should be made to define the type of ARF involved. A careful history and physical examination often can be diagnostic. The aseptic and atraumatic passage of a Foley catheter is helpful from both a diagnostic and, occasionally, a therapeutic point of view. If the patient is capable of voiding spontaneously and the residual is less than 30 mL, the catheter is withdrawn. If the diagnosis remains unclear after these simple maneuvers, a more sophisticated workup is in order and will include chemical analysis of the urine and serum for sodium, potassium, urea, creatinine, and osmolality; central venous or right atrial pressure determinations; and ultrasonograms of the kidneys. IV pyelography is rarely indicated. The degree of renal deterioration is usually of such an extent that visualization does not occur. Indeed, the contrast material may cause further deterioration of the severely compromised kidney; therefore indiscriminate use of contrast material is to be condemned. If the diagnosis is still in doubt, retrograde or antegrade pyelography or sonography is indicated. The characteristics and therapy for each type of ARF are described in detail in the following sections.

Prerenal Failure

Prerenal failure occurs when there is an excessive nitrogen load or reduced blood supply to the kidney. The former may result from increased muscle catabolism, blood breakdown within the gastrointestinal tract, or excessive protein alimentation. The latter appears in the presence of volume depletion, congestive heart failure, valvular heart disease, or any disease that causes myocardial pump failure.

Pathophysiology

In prerenal oliguria RBF is reduced. When the blood flow is reduced to a level such that the afferent arteriolar pressure falls below 60 mm Hg, reduced filtration pressure results in a decrease in the amount of filtrate delivered to the proximal tubule; glomerulotubular balance is disrupted; and sodium, water, and urea are reabsorbed in increased amounts. A BUN-to-creatinine ratio of greater than 10:1 occurs because creatinine, when filtered, is not reabsorbed by the tubule, whereas urea is reabsorbed in increased amounts. The proportional excretion of BUN and creatinine, which occurs in health, is disrupted and the urea recirculates, thus resulting in the abnormally high BUN-to-creatinine ratio.

Diagnosis

Diagnostic indications of prerenal failure include a serum BUN-to-creatinine ratio that is greater than 10:1, and a central venous pressure (CVP) and right arterial pressure in volume depletion that are low, provided coexisting myocardial disease is not present. The small volume of urine excreted is highly concentrated with a low sodium content (less than 15 mEq/L). The urine urea concentration divided by the plasma urea concentration (U ÷ P urea) is greater than 20:1, and the U/P osmolality is greater than 1.5. The fractional excretion of sodium or the ratio of U/P sodium to U/P creatinine (U/P_{Na}-to-U/P_{Cr}) is less than 1%. The urine sediment may reveal hyaline casts but generally will be free of casts and red and white blood cells (Table 14.2).

Measurement	Normal	Prerenal	Intrarenal	Postrenal
Blood				
CVP, cm water	5–8	Low to normal	Normal to elevated	Normal to elevated
BUN-to-creatinine ratio	12:1	>10:1	10:1	10:1+
Urine				
Sodium, mEq/L	15–40	<15	>40	>40
Potassium, mEq/L	15–40	Variable	Variable	Variable
Osmolality, mOsm/L	400–800	>450	<350	<350
Volume, mL	800–1,500	Low	Variable	Variable, initially low
Urine-to-blood ratio				
Urea	20:1	>20:1	<10:1	<5:1
Osmolality	1.9–2.0	>1.5:1	<1.2:1	<1.1:1
Creatinine	20:1	>40:1	<20:1	<20:1
Fractional sodium excretion, %	Variable	<1.0	>1.0	>1.0
Urine—microscopic analysis	0–1 RBC	Occasional hyaline P cast	Tubule epithelial casts	RBCs and WBCs
	0–1 WBC		RBCs, free hemoglobin, or myoglobin	Malignant cells
	Occasional hyaline P cast			Crystals
	No cellular casts			

BUN, blood urea nitrogen; CVP, central venous pressure; RBC, red blood cell; WBC, white blood cell.

TABLE 14.2. DIFFERENTIAL DIAGNOSIS OF PRERENAL, INTRARENAL, AND POSTRENAL FAILURE

Treatment

The treatment of prerenal oliguria is directed at the primary disease: (a) correction of the lesion that has caused the increased nitrogen load, (b) improvement of the failing myocardium, or (c) volume repletion.

Intrarenal Failure

Acute intrarenal failure may follow an ischemic or a nephrotoxic injury or interstitial or glomerular nephritis. Examples of ischemic injury include sepsis, hemorrhagic shock, aortic cross clamping, and surgical or obstetric misadventures; causes of nephrotoxic injury include drugs (aminoglycosides), crush injuries (myoglobin), and diagnostic agents (IV contrast), whereas the etiology of interstitial nephritis often includes drugs. One-half to two-thirds of the patients will be oliguric, whereas the remainder will have urine outputs exceeding 400 mL per 24 hours. Patients who present with nonoliguric ARF have higher sodium concentrations, greater fractional sodium excretions, shorter hospital stays, and a lower mortality and require fewer dialyses than do those who present with oliguria. Indeed, oliguric renal failure has a mortality of 50% to 70%, whereas mortality is approximately 25% in nonoliguric patients. The importance of the sodium excretion rate is emphasized by the finding that less frequently fatal, nonoliguric renal failure patients have higher sodium excretion rates than oliguric patients. Moreover, in the oliguric ARF patient, a persistent urine sodium concentration less than 40 mEq/L is associated with only a 37% survival, whereas those with a urinary concentration greater than 40 mEq/L have a survival rate of 56% (3). It has been suggested that a low fractional excretion for sodium indicates that the cause of the injury involves tubular obstruction or alterations in renal hemodynamics rather than direct tubular nephrotoxicity (16). The recovery also somewhat depends on the cause of the ARF. Approximately 80% of patients with acute cortical necrosis and 66% of those with thrombotic thrombocytopenic purpura or the hemolytic uremic syndrome do not recover renal function adequate to support life. This is in contrast to patients with acute tubular necrosis and acute interstitial nephritis in whom 62% recover normal renal function. Thirty-one percent show a partial recovery, and only 6% have no recovery whatsoever (7). Another indication of recoverability is correlated with the length of time anuria occurs and the degree to which the kidney takes up nuclide on a renal scan. In one study, infants who remained anuric for at least 4 days after the acute insult and revealed no uptake of radionuclide on scan invariably died of their ARF, whereas infants with ischemic ARF who were nonoliguric and whose kidneys took up the nuclide had a more favorable prognosis (14).

Pathophysiology

A great deal of clinical and experimental data have been accumulated trying to define a pathophysiology for ARF. Unfortunately, most of the information comes from experimental animals, and correlation with the clinical situation often is contrived. A number of proposed mechanisms can be grouped into three areas: (a) vasomotor, increased nephron permeability, tubule obstruction, and decreased ultrafiltration (29); (b) injury to the cell resulting in necrosis or apoptosis; and (c) production of inflammatory mediators that cause injury often introduced by activated neutrophil infiltrations. Because the initiating events are multiple and varied, it is likely that in each case the ARF has been caused by a combination of some of these factors. It is important to understand each of the mechanisms because therapy of established ARF is based on these hypotheses.

The vasomotor theory proposes that there is not only a decrease in total RBF but also a redistribution of intrarenal blood flow. Xenon washout and microsphere injection studies have demonstrated a shift of blood flow away from the cortical nephrons toward the juxtamedullary nephrons (62). Some have suggested that this shift may be protective. Although under normal circumstances the whole kidney receives a blood flow resulting in oxygen delivery that far exceeds demand, the blood flow to the medulla is much less than to the cortex, resulting in limited oxygen reserves. It has been suggested that the medulla is most susceptible to ischemic injury and that the shift in blood flow to the medulla is an attempt to protect this segment (2). The renin-angiotensin system may play a role in the RBF shift. Moreover, prostaglandins also may be contributory. If the initial injury causes an increased release of renin, cortical afferent and efferent arteriolar constriction would result in reduction of cortical blood flow. Because stimulation of the autonomic nervous system releases renin, its role in the cause is unclear, but it may partially explain the occurrence of ARF in patients whose aortas have been cross-clamped. Further evidence for the importance of renin is demonstrated by depleting it in experimental models by either long-term salt loading or antirenin antibodies. A renin-depleted animal has not only a greater chance of recovery but also a more rapid return of function. Moreover, in many patients, renin activity is elevated early in the course of ARF (63). Unfortunately, specific antagonists of renin or angiotensin do not alter the course of these patients once the ARF is established.

Additional evidence for the significance of hormonal regulation of intrarenal blood flow during ARF comes from reports of indomethacin-induced ARF. Indomethacin blocks the synthesis of prostaglandins. PGE_2, a vasodilating prostaglandin, appears to play a significant role in maintaining RBF in the face of pathologic forces that tend to compromise it. Thus in the proper setting, eliminating PGE_2 results in the development or exacerbation of ARF (67). In addition to angiotensin II and prostaglandins, adenosine, increased cytosolic calcium, oxygen-free radicals, and endothelin have been implicated. Although renal vasoconstriction and low RBF may play key roles in the early stages of intrinsic renal failure, later spontaneous increases in RBF often occur without a concomitant increase in the GFR.

The hypothesis of increased tubule permeability proposes that although filtration pressure may or may not be reduced when the filtrate arrives in the proximal tubule, it leaks out, resulting in an effective reduction in filtration. Conflicting data supporting this theory have been reported. Some investigators have demonstrated leakage of labeled inulin and mannitol from the tubule. Moreover, the dye, lissamine green, has been observed to leak out of the tubule. However, others using micropuncture techniques have failed to show increased permeability in split-drop experiments.

Tubule blockade may play a major role in ARF after surgery. Myoglobin can precipitate in the tubule and cause mechanical blockage of the tubule lumen. In models of renal artery cross-clamping, up to 90% of the proximal tubules have been found to be occluded by swollen cells and desquamated proximal tubule microvilli; however, other experimental models that simulate medical causes of ARF are less convincing.

A decrease in ultrafiltration probably plays a major role in many causes of ARF. Numerous studies have demonstrated alterations in the glomerular basement membrane and supporting structures. These alterations result in a decrease in the membrane permeability by as much as 60%. This, coupled with decreased blood flow, results in a lessened hydrostatic pressure gradient and a marked decrease in the delivery of filtrate to the proximal tubule. Perhaps the changes that occur in glomerular membrane properties may explain the dissociation between RBF and GFR, because a decreased glomerular capillary permeability would continue to cause a decreased GFR even with increased RBF (38).

The aforementioned theories fail to explain all aspects of ARF and, indeed, seem not to explain some circumstances of injury. Following severe injuries, cellular necrosis and the initiation of apoptosis occur—the latter resulting in progressive loss of renal tubule cells (31).

Finally, a variety of inflammatory mediators, including tumor necrosis factor, interleukin-1, interleukin 8, and macrophage chemoattractant protein, are produced by the injured kidney. Some of these may be provided by activated neutrophils, which infiltrate the interstitium of the injured kidney.

Diagnosis

The diagnosis of intrarenal failure is based on historic, chemical, and radiologic determinations. The BUN-to-creatinine ratio is 10:1, and the CVP or left arterial filling pressure is normal or elevated. The urinary sodium concentration exceeds 40 mEq/L with a variable potassium secretion—usually less than 20 mEq/L. The U/P osmolality is less than 1.2 and the U/P urea is less than 10. The fractional sodium excretion exceeds 1%. Tubule epithelial cells and tubule epithelial cell casts may be observed in the urine (Table 14.2). A radioimmunoassay of tubule antigens has been developed that successfully diagnoses 80% of patients with acute tubule necrosis (71). This test has not gained popularity because the diagnosis of intrarenal failure may be made with this degree of accuracy by conventional techniques.

Ultrasonography or roentgenographic studies of the abdomen without the administration of pyelographic contrast should be used in an effort to determine whether the acute problem is superimposed on prior renal disease. Preexisting renal disease may be demonstrated by unilateral or bilateral small kidneys indicative of a vascular or infectious cause. An enlarged renal outline may imply either acute renal vein thrombosis or an infiltrative lesion, such as myeloma or lymphoma, or postrenal failure when it is associated with dilated calyces. Radionuclide renal scans or magnetic resonance arteriography occasionally are helpful in cases of bilateral renal artery thrombosis and may suggest that therapy is needed.

The BUN rises between 10 and 20 mg/dL per day, whereas creatinine increases 0.5 to 1.0 mg/dL per day. Plasma potassium increases 0.5 mEq/L per day, and because 50 to 100 mEq of fixed acid is retained, the plasma bicarbonate decreases by 1 to 2 mEq/L per day. In the posttraumatic state, the hypercatabolic response may result in a more rapid rise in the BUN, potassium, and fixed-acid accumulation. A crush injury involving muscle necrosis and myoglobin nephropathy can result in rises in serum creatinine up to 2 mg/dL per day and rapid increases in serum potassium and uric acid. Hypocalcemia often is noted and may have significant cardiac consequences, particularly if the serum potassium is elevated.

Treatment

Careful fluid balance, the judicious use of ion-exchange resins, dialysis, and administration of a potent diuretic when oliguria occurs are the hallmarks of therapy (66). The use of furosemide in the treatment of acute oliguric intrarenal failure is controversial. Several studies have failed to demonstrate more rapid recovery, improved GFR, or reduction in the number of dialyses required, except when cardiac decompensation is present (11). On the other hand, converting oliguria to nonoliguria makes subsequent fluid management less cumbersome. If furosemide is given, a dose of 80 mg is tried; if unsuccessful, it is doubled. One of three responses occurs:

1. Oliguria persists. The patients are treated with replacement of net water requirements (insensible loss – water of metabolism = 10 to 15 mL/kg per 24 hours). If a return in urine output does not occur within 21 days, the chance of recovery of renal function is poor.
2. A diuresis ensues, GFR increases, and an immediate reversal in the rise of BUN and creatinine occurs. It is important to rehydrate the patient in this setting, because this response suggests prerenal oliguria. These patients recover, often obtaining normal renal function.
3. A diuresis occurs, GFR remains low, and BUN and creatinine continue to rise. These patients are treated with replacement of net water loss (10 mL/kg per 24 hours) plus urine output and gastrointestinal and tube losses.

Large sodium losses occur during this phase and require replacement. Potassium losses are small, although rarely they may be excessive and require replacement. Appropriate serum potassium concentrations are maintained by restriction of potassium and the use of ion exchange resins and dialysis.

Mannitol has been found to be useful in patients with ARF resulting from crush injury, but has not been shown to be particularly helpful in other types of renal injury.

Low-dosage dopamine (1 to 2 mg/kg per minute) has not altered the course of ARF; however, some evidence indicates that it is helpful in the hepatorenal syndrome and in preventing ARF if used during the early prodromal period (65). The administration of dopamine to these patients results in a significant increase in the diuresis and natriuresis and, when combined with furosemide, may improve renal function in at least some patients with ARF. Experimental evidence shows a synergistic protective effect with the combination of dopamine and furosemide in several models of ARF. Dopamine causes marked vasodilation of both afferent and efferent arterioles (26). Mannitol has been helpful in preventing ARF (if given before interrupting renal artery flow) and in lessening the toxic effects of myoglobin. No study to date that has been properly performed has shown dopamine to be of any benefit in reducing morbidity or mortality.

b-Blockers have produced variable results, and angiotensin and renin inhibitors have not proved useful. Alkalizing agents, by solubilizing organic acids (drugs) when they are causative, and diuresis, by diluting toxic substances (cisplatin and myoglobin), are helpful prophylactically. Finally, if given early in the course of the disease, calcium channel blockers may be helpful by reducing intracellular calcium in tubule cells that have suffered an ischemic injury and are deprived of ATP.

Atrial natriuretic peptide has been shown to convert some patients from oliguric renal failure to nonoliguric renal failure, but generally has not been found to be helpful in reducing mortality. Insulin-like growth factor has been shown to prevent the decline in GFR in patients with ARF in selected circumstances but also has not been helpful in changing morbidity or mortality.

Perhaps the one drug regimen that all agree is most helpful, particularly in severely malnourished surgical patients, is nutritional support. Hyperalimentation with essential L-amino acids has improved recovery and reduced the number of dialyses required (22).

Dialysis plays an important role in the management of these patients. If the BUN is greater than 100 mg/dL and the creatinine exceeds 12 mg/dL, dialysis is mandatory. Evidence suggests that if the BUN is kept below 70 mg/dL, the incidence of sepsis is reduced from 88% to 63%, bleeding from 60% to 36%, and mortality from 80% to 36% (15). Others have shown consistently that mortality is lowered, extrarenal complications are less frequent, and the clinical course is better in any type of ARF when dialysis is employed before the clinical signs of uremia occur, emphasizing the need to evaluate each patient rather than basing dialysis on some arbitrary number. Dialysis may be accomplished either peritoneally or hemically.

Recent evidence indicates that in the critically ill patient, dialysis under certain circumstances may in fact prolong ARF. This is particularly apparent in unstable patients who become hypotensive when placed on dialysis. In addition, the dialysis membrane may activate the inflammatory cascades, further compromising the recovery of the injured kidney.

Plasma exchange may be useful in treating patients whose renal failure is the result of nondialyzable substances, such as dextran. Slow continuous ultrafiltration with a filter placed between two limbs of a Scribner shunt has been useful in selected critically ill patients. Its advantages include hemodynamic stability, ability to remove large fluid volumes (thus making treatment modalities such as IV nutrition feasible), and no requirement for systemic anticoagulation. It has many disadvantages, among them electrolyte abnormalities, bleeding, clotting of the shunt filter, excessive drug removal, azotemia, hypotension, and bacteremia (57,64).

Mortality in this group is high; however, between 25% and 70% of patients surviving an acute tubule injury eventually recover sufficient renal function to support life without dialysis. Of those recovering, 20% to 40% will have a reduced GFR for 1 year or longer. Abnormalities of tubule function, including renal glucosuria and decreased concentrating ability, may persist indefinitely.

The most frequent cause of death is infection (61). It causes 36% of the deaths and is usually pulmonary in origin. The next most common cause of death is gastrointestinal hemorrhage. Delayed wound healing, poor generation of granulation tissue, anorexia, anemia, and bleeding abnormalities caused by platelet malfunction contribute to the high level of morbidity in this disease. Indeed, even mild ARF significantly affects morbidity, even in the absence of significant comorbid disease (41).

Because of the high mortality of ARF, perhaps the most effective treatment is prophylaxis. Adequate hydration and selective use of dopamine, mannitol, furosemide, and alkalization in patients undergoing surgery who are known to have a high risk for the development of postoperative ARF should lessen the incidence of the disease. Risk factors that carry with them an increased incidence of postoperative ARF include advanced age, cardiac or hepatic failure, sepsis, jaundice, rhabdomyolysis, and massive blood transfusions.

Myoglobin Nephrotoxicity

Rhabdomyolysis has been reported to be the cause of ARF in approximately 5% of all patients with acute renal insufficiency. The prognosis for recovery is excellent, provided rhabdomyolysis is recognized promptly and therapy is begun immediately. There are traumatic and nontraumatic causes of rhabdomyolysis (37). The former include crush injuries, electric burns, arterial occlusion, and surgery. Nontraumatic causes include increased muscle exertion, inflammatory muscle diseases, infection, toxic drugs, and metabolic abnormalities (particularly hypokalemia). In urologic patients, prolonged, exaggerated lithotomy position has been associated with rhabdomyolysis and ARF (24).

After the precipitating event the patient becomes acutely ill with fever, weakness, and pain. The urine is brownish and is dipstick-positive for heme. Because the molecular weight of myoglobin is much lower than that of hemoglobin, it is cleared rapidly from the serum. Thus a spun blood sample will reveal a clear serum in contradistinction to hemolysis, where the serum will be red as a result of retained hemoglobin. A high serum creatinine phosphokinase level establishes the diagnosis. Serum potassium and phosphate often are elevated, and hyperuricemia may be severe. The mechanism of ARF is unclear, but it probably is caused by a combination of events including low flow, prolonged contact of the tubule lumen with myoglobin, and high uric acid concentration. Therapy is directed at establishing a diuresis with either a loop diuretic or by volume expansion, with saline solution combined with either mannitol or a loop diuretic. The diuresis dilutes the toxic myoglobin, removes it from the kidney, reduces the serum uric acid concentration, and modestly alkalizes the urine. Alkalization is advisable initially, because an acid medium promotes myoglobin dissociation into ferroprotoporphyrin and globin. The former is toxic (21).

Radiocontrast-induced Acute Renal Failure

The incidence of reduced renal function resulting from radiocontrast material has been reported to be as high as 12%. The incidence of contrast nephropathy in patients with normal renal function is lower than 2% after angiography and approximately 1.5% after IV urography. In contrast, among patients with diabetes and coexisting renal insufficiency, more than half develop substantial renal damage after IV urography (6). The occurrence of clinically significant ARF in the general population is exceedingly low; it is most commonly found after angiography or IV urography in patients with significant risk factors for the development of the disease. Almost all patients who develop clinically significant ARF have either previously existing renal disease with compromised renal function or diabetes with moderate

renal impairment. However, adult-onset diabetic patients with normal renal function do not appear to be at increased risk for development of ARF. Patients with juvenile-onset diabetes are more likely to develop renal insufficiency even though they do not demonstrate significant renal impairment before the injection of contrast medium. Other factors that have been less well correlated with the development of renal insufficiency after the injection of radiocontrast include advanced age, dehydration, multiple contrast exposure within 24 hours, hyperuricemia, proteinuria, hypoalbuminemia, multiple myeloma, and impaired hepatic function. Dehydration per se does not appear to be a specific risk factor unless the patient has preexisting renal disease. Conversely, in patients with prior renal disease, establishing a diuresis after the injection of contrast medium appears to lessen the incidence of renal deterioration. In patients with multiple myeloma, there is no compelling evidence of any increased risk for contrast-induced renal failure unless there is preexisting renal insufficiency. However, contrast-induced renal failure in patients with multiple myeloma often has catastrophic implications because it is irreversible.

In summary, existing renal insufficiency is the single most important predisposing factor. Moreover, diabetes does not increase the risk of contrast-induced renal failure if renal function is normal and the patient is well hydrated and does not have juvenile-onset diabetes. When radiocontrast-induced renal failure does occur, 75% of patients are oliguric for the first 24 hours after contrast exposure. Prolonged oliguria results in only partial return of renal function. The serum creatinine generally peaks by the seventh postinsult day, and renal function returns to normal in 75% of the cases. Dialysis rarely is required, and almost all patients have an adequate return of function and do not require long-term dialysis (50). The pathogenesis of the disorder has been hypothesized to be the result of direct tubule toxicity, to renal ischemia caused by alterations in blood flow with shunting of blood from cortex to medulla, and to intratubular obstruction. Because contrast agents are uricosuric, tubule obstruction by crystals of uric acid has been proposed as the pathogenic mechanism. Finally, immunologic factors have been proposed, but the evidence is not compelling. It appears that the renal toxicity after contrast exposure is probably the result of direct tubule toxicity and renal ischemia (6).

Postrenal Failure

The causes of postrenal failure are divided into lower and upper urinary tract obstruction. The lower urinary tract is evaluated in the preliminary treatment, as previously indicated, by the passage of the Foley catheter. Obstruction of the upper urinary tract may be the result of ureteral calculi, blood clots, sloughed papillae, ureterovesical or ureteropelvic junction obstruction, ureteral tumors, ureteral stricture, extrinsic compression by retroperitoneal tumors, hemorrhage, fibrosis, tumor, or an inflammatory lesion. Recently, increased intraabdominal pressure has been reported as a cause of postrenal failure.

Pathophysiology

In the patient with postrenal failure, RBF is markedly reduced with a reduction in GFR to 10% of normal or less, causing a decline in filtration with decreased delivery of filtrate to the proximal tubule (47). This may be mediated through the renin-angiotensin system (46) and/or the prostaglandin system. Elevated concentrations of renin, the vasodilator PGE_2, and the vasoconstrictor thromboxane A_2 have been reported in obstructive uropathy (49). The significance of the prostaglandins in the pathophysiology of obstructive uropathy has been questioned recently. Specific inhibitors of thromboxane synthesis have failed to show any major effect on renal hemodynamics (42). Moreover, inhibition of prostaglandin synthesis during the obstructive phase has little influence on return of renal function, whereas inhibition of renin during this phase results in a major improvement in the return of renal function (44). Interstitial infiltration by lymphocytes and activated neutrophils result in cytokine release, which may explain some of the pathologic events. Moreover, apoptosis in the distal tubule and cortical collecting duct are initiated in animals with uretal obstruction. Even though complete obstruction does occur, GFR does not cease but remains modest, and the fluid that is filtered is reabsorbed by the renal tubules, the peripelvic lymphatic vessels and veins, and the perirenal tissues when the urine extravasates around the fornices of the calyx. With the increased hydrostatic pressure within the ureter, destruction of tubule tight junctions occurs, causing increased tubule permeability (46). Permeability is increased throughout the entire nephron, proximal tubule, loop, distal tubule, and collecting duct; there is a reduction in the net sodium and water reabsorption with net addition of sodium by the collecting duct. Increased potassium secretion by the distal tubule occurs in the postobstructed phase, and during recovery, concentrating ability remains impaired for days (47). Although reduced, RBF persists and removes solute from the medulla. Thus after the relief of such obstructions, there is often an excessive volume output with large sodium losses and inability of the kidney to concentrate and excrete an acid load. The loss of medullary tonicity and the rapidity with which it is built up determines the degree and length of time urinary concentration is impaired. Rarely, concentrating ability may take as long as 6 to 9 months to return to normal. Should obstruction occur in the presence of infection or protein depletion and exist for prolonged periods, parenchymal destruction occurs. Under these circumstances complete return of renal function does not occur. The longest report of complete obstruction with the return of renal function to support life is 90 days.

Diagnosis

The diagnosis of upper tract obstruction is established by retrograde pyelography or occasionally by percutaneous puncture and antegrade pyelography. However, it should be remembered that indiscriminate manipulation of the urinary tract must be avoided, because sepsis, the most common cause of death in patients with intrarenal failure, all too often is a consequence of genitourinary manipulation. After lower urinary tract obstruction has been ruled out by the introduction of a Foley catheter, complete anuria demands retrograde or antegrade pyelography. In addition to obstruction, total anuria may be the result of bilateral renal artery thrombosis, aortic vascular catastrophes, acute glomerulonephritis, or cortical necrosis, and it may be present during the first 12 to 24 hours of acute tubular injury.

Abdominal roentgenograms, computed tomography scans, and renal ultrasonograms are useful. The diagnosis may be suggested by the presence of calcification in the course of the ureters; osteoblastic lesions of the bones implying carcinoma of the prostate, which may have invaded the bladder; or large pelves on ultrasonography, implying obstruction. Rarely, the ultrasonogram will show a nondilated system even in the presence of bilateral obstruction (56). Therefore if one's index of suspicion is high, retrograde or antegrade pyelography should be performed even though the ultrasonogram does not show hydronephrosis.

These patients are well hydrated; have normal or slightly elevated CVP; have a BUN-to-creatinine ratio of 10:1 or greater; and a urine microscopic examination may reveal red blood cells, white blood cells, crystals, or malignant cells. Urine sodium concentration is greater than 40 mEq/L, and potassium concentration is variable, usually ranging between 20 and 40 mEq/L. The renal concentrating ability is severely impaired, which is reflected by a U/P urea of less than 5 and a U/P osmolality of less than 1.0. The fractional sodium excretion is in excess of 1%.

Treatment

Therapy is directed at the site of obstruction, requiring a urethral catheter, a suprapubic cystotomy, a nephrostomy, a cutaneous ureterostomy, or indwelling ureteral catheters; double-J stents may be left temporarily until the metabolic status of the patient is stable enough to permit the appropriate surgical procedure. During the postobstructed period, large quantities of urine are excreted with a low osmolality and a high sodium concentration (50 to 70 mEq/L). These defects are unresponsive to ADH and mineral corticoid administration. Volume and sodium should be replaced as lost. D_5½NS is usually the appropriate infusion. Potassium losses are therapeutic initially, but if prolonged and excessive, replacement of potassium may be necessary later. Sodium and potassium conservation return to normal within 48 to 72 hours; however, the concentrating defect may persist for 7 to 12 days, making dehydration a potential danger should fluid be inappropriately restricted. Most of these patients, if they respond with a diuresis, will go on to recovery of renal function. If oliguria persists, the obstruction has caused destruction of parenchyma, and such patients are managed as described for intrarenal ARF.

Postrenal Polyuria

Postrenal polyuria occurs during partial chronic urinary obstruction or after the release of complete bilateral ureteral occlusion (postobstructive diuresis), provided that significant parenchymal damage has not occurred. As described previously, basic defects involve a washout of the medullary concentration gradient and increased tubule permeability. Such patients lose excessive volumes of fluid that generally contain 40 to 80 mEq/L of sodium and variable concentrations of potassium. They are incapable of both concentrating and acidifying their urine. Because there is no medullary osmotic gradient, ADH is ineffective. The management of these patients is as previously described and involves careful intake and output records, daily weights, frequent serum osmolalities, and careful physical examination to determine the presence of dehydration or edema.

Intrarenal Polyuria

Intrarenal polyuria results from an intrinsic impairment of the renal concentrating mechanism. It may be caused by anatomic disruption from disease, metabolic aberrations affecting the ADH–collecting duct interaction, or functional renal derangements (Table 14.3). A reduction in renal medullary tonicity may be caused by anatomic disruptions such as those found in sickle cell anemia. In such patients, portions of the renal medulla are infarcted as a result of low oxygen tonicity and sickling of the erythrocytes. Other diseases, such as medullary cystic disease, pyelonephritis, nephrocalcinosis, and amyloidosis, may similarly disrupt the medulla. Metabolic aberrations of the ADH–collecting duct interaction include hypercalcemia, prolonged hypokalemia, and RTA. These disorders are not uncommon in

postsurgical and posttrauma patients.

Hypercalcemia initially interferes with the action of ADH on the collecting duct epithelium, and if it is corrected early, reversal of the concentrating defect is immediate. Prolonged hypercalcemia with calcium deposition in the thick ascending limb of Henle's loop, the distal tubule, and the collecting duct may result in permanent loss of renal concentrating ability. Prolonged hypokalemia may exert its effect by inhibition of the generation of adenyl cyclase, cyclic adenosine monophosphate (cAMP), or protein kinase and their interaction between ADH and the collecting duct. Restoration of the appropriate potassium level corrects the concentrating disorder. RTA also may cause a lack of concentrating ability. Because RTA often results in low serum potassium concentrations, it may be hypokalemia, not the RTA as such, that is responsible for the concentrating defect. In any event, restoration of normal serum acid–base and electrolyte balance corrects the problem, provided nephrocalcinosis has not complicated the disease.

Finally, other causes of polyuria include functional derangements, such as nephrogenic diabetes insipidus in which the collecting duct appears to be insensitive to circulating levels of ADH, and lack of medullary tonicity from persistent excessive urine output. The management of intrarenal polyuric states involves daily monitoring of body weight and serum osmolality and fluid replacement, volume for volume. Specific metabolic disorders, such as hypercalcemia, hypokalemia, and systemic acidosis, are corrected. Anatomic abnormalities, such as sickle cell disease, pyelonephritis, polycystic disease, myeloma, amyloidosis, and polyarteritis, are not amenable to any specific treatment with respect to polyuria, and therefore these patients are best treated in a supportive manner. Exogenous ADH is not effective in these disorders unless they have a metabolic cause and then only when the abnormality has been corrected.

Prerenal Polyuria

Prerenal polyuria is caused by insufficient ADH or by exogenous or endogenous diuretic agents. The intrinsic ability of the concentrating mechanism to function is maintained; however, if the polyuria is prolonged, it may result in washout of the medullary osmotic gradient, in which case an intrinsic renal defect would be superimposed on a prerenal defect (17). Insufficient ADH activity may result from suppression of ADH release in the pituitary, either as a normal consequence of volume overload or as a consequence of iatrogenic-induced reduction in serum osmolality. The common causes in volume expansion include over-administration of IV fluids, compulsive water drinking, and pathologic stimulation of the thirst center. Dilution of plasma osmolality occurs when sodium loss exceeds that replaced or when water is replaced in an electrolyte-poor fluid. Absence of or insufficient ADH production occurs in cerebral trauma and diabetes insipidus, which may be an inherited or acquired abnormality. Because the intrinsic concentrating mechanism is unaffected in these states, it is of paramount importance to determine the primary cause. If a lack of ADH is responsible, administration of this hormone is therapeutic. However, if volume abnormalities have caused this disorder, their correction will be curative.

Prolonged, persistent diuresis can cause dilation of the collecting system. After the prolonged diuresis, IV urography may reveal bilateral hydronephrosis. This hydronephrosis occurs on the basis of excessive diuresis and not on the basis of any mechanical obstruction. Because diuresis results in an increase in intraureteral pressure as bladder filling occurs, it is easy to understand why ureteral dilation occurs (see Physiology in Chapter 24).

CHRONIC RENAL FAILURE

Chronic renal failure occurs most commonly as a result of glomerulonephritis caused by immunopathogenic mechanisms; diabetes, infection, toxins, obstruction, congenital disorders, and hereditary nephropathies account for the majority of the remaining causes. The loss of renal function is usually insidious, not manifesting itself until late in the disease. The initial symptoms that herald a significant lack of renal function are protean and include fatigue, lassitude, and weakness. As the renal function continues to deteriorate, the patient may complain of a metallic taste, anorexia, nausea, vomiting, abdominal pain, hiccups, and diarrhea. With progression, there is an inability to concentrate, somnolence, twitching, bone pain, pericarditis, and hypertension (and its sequelae). All organ systems are affected at various stages in the disease. The detrimental effects of renal failure can be ameliorated by proper recognition and anticipation of the various complications with appropriate prophylactic therapy instituted before the abnormalities become clinically manifest.

Pathophysiology

As renal function decreases, those nephrons that continue to function increase in size, as do their respective glomeruli. This concept was originally suggested by Bricker and co-workers (9) and is known as the *intact nephron hypothesis.* Although this hypothesis has been questioned, because micropuncture data suggest a heterogeneity of tubule function in disease, it appears that within the constraints of biologic variability, the intact nephron hypothesis has the most evidence to support it and thus best explains the observed deterioration of renal function in chronic renal failure. GFR and RPF decrease, and functional mass decreases in parallel, whereas each individual nephron that continues to function increases its single-nephron filtration rate. Because fewer nephrons are functioning and those that are have increased their activity, if solute excretion is to be maintained, the fractional excretions for the respective solutes must increase. Sodium homeostasis is maintained until late in the disease by the mechanism of increasing single-nephron fractional excretion from less than 1% in health to 10% to 20% in disease. Late in the disease sodium excretion becomes fixed, and the nephron is incapable of varying its fractional excretion according to the needs of the patient, thus resulting in a salt-losing nephropathy. Salt restriction in such patients will result in substantial hyponatremia. This occurs late in the disease process. Similarly, water conservation and excretion are maintained until the GFR falls below 20 mL per minute, at which time the kidney is incapable of compensating for varying water loads or significant water deprivation. The kidney retains a remarkable ability to excrete potassium until late in the process. The increased flow rate obtained by the remaining functional nephrons facilitates potassium secretion. Acidosis, which is associated with increasing renal failure, also promotes potassium secretion. Mild hyperkalemia occurs when the GFR falls below 10 mL per minute. Significant hyperkalemia is uncommon until oliguria supervenes with a urine output less than 500 mL per 24 hours.

Acid–base balance is reasonably well maintained until the GFR falls below 20 mL per minute, then acid–base imbalance is a result of the failure of the distal tubule to maintain ammonia excretion (39). Even in advanced renal failure, not much alkali is excreted. Bicarbonate reabsorption is strongly influenced by the extracellular volume so that late in the disease, when the kidney is not capable of responding to fluid loads, excessive fluid intake often results in bicarbonate wasting.

The determination of renal function using creatinine presents certain difficulties in patients with chronic renal failure. Serum creatinine levels may be deceptively low because of increased metabolism by the gut and decreased muscle mass as a result of muscle wasting from the uremia. When the GFR is less than 15 mL per minute, the creatinine clearance will overestimate the true GFR (inulin clearance) as a result of tubule secretion of creatinine, often by as much as 50% to 100%.

Unfortunately, some aspects of renal function are maintained at the expense of others. Phosphate homeostasis is an excellent example of this “trade-off” phenomenon. As the need to excrete phosphate continues with decreased renal function, the intact nephrons are not capable of increasing their fractional excretion for phosphate. Serum phosphate rises, which results in a fall in serum calcium and the subsequent release of parathormone. Parathormone acts on tubules to increase phosphate excretion, thereby returning serum phosphate to normal levels. The other effect of parathormone on bone reabsorption also occurs, resulting in bone destruction. Bone destruction is the price, or trade-off, paid for maintaining a normal level of serum phosphate.

The increased filtration that each nephron must maintain appears to be responsible for its ultimate demise. It has been shown experimentally that increasing single-nephron GFR results in stripping off the glomerular endothelial cells, thus destroying the charge barrier that prevents deposition of circulating proteins in the glomerular basement membrane (55). The circulating serum proteins are then deposited and accumulate in the mesangium, resulting in the histologic appearance of glomerulosclerosis. Thus an initial insult that reduces renal mass, such as segmental injuries caused by obstruction, reflux, or dysplasia, may have occurred in the distant past, with renal failure occurring slowly over the ensuing years as a result of an increased workload of the remaining functional nephrons, with protein deposition causing their ultimate failure. In chronic renal failure patients in the Christchurch series, 12% of cases were the result of reflux nephropathy, few of which had been infected. These patients began dialysis at approximately 18 years of age, suggesting that the initial insult caused progressive renal deterioration as each remaining nephron was required to do more work (4).

The fact that protein is detrimental to renal function was suggested many years ago (1) and led to the development of the protein-restricted “renal failure diet.” When patients eat this diet, many of the symptoms of uremia are alleviated or reduced. Administration of essential amino acids and their keto analogs have been successful in slowing the rise in BUN; however, the substances are not generally palatable. More recently it has been suggested that dietary protein may cause renal failure in patients who have sustained a renal insult (8). Thus dietary protein restriction may not only alleviate symptoms of uremia in patients with severely compromised renal function but may also prevent the progression of the disease in patients who have a modest decrease in renal function of insufficient degree to manifest signs or symptoms. Protein induces an acute increase in GFR through renal vasodilation and glomerular hyperperfusion. The elevated intracapillary pressures and transcapillary flux of ultrafiltrate eventually disrupt the integrity of the glomerular capillary membrane. Proteinuria ensues, and the increased flux of proteins exacerbates the glomerular capillary injury and causes progressive accumulation of mesangial deposits—the forerunner of focal glomerulosclerosis. Others have suggested that it may not be protein per se that causes the renal injury but rather the high phosphate intake from the protein. The phosphorus-induced renal injury is

mediated through calcium-phosphate deposition in the kidney as a result of an increased filtered load of phosphate per nephron (28). Several prospective studies have shown that dietary restrictions of protein lessen the progression of renal deterioration in certain subgroups of patients, particularly those with advanced disease (54). Other studies have shown a nonsignificant slowing in the progression (34). In children, a multiinstitutional study has failed to show any effect of low-protein diets on slowing the progression of chronic renal failure (70). Proper control of blood pressure has been found to be one of the most important methods of slowing the progression of chronic renal failure.

Complications

Chronic renal failure is a systemic disease and, as such, affects every organ system in the body. The more common complications most relevant to the urologist include bladder and renal and/or perirenal infections, acquired renal cystic disease and renal carcinoma, infertility, impotence, and gynecomastia.

Renal, Perirenal, and Bladder Infections

Urinary tract infection is an important cause of morbidity and mortality in chronic renal failure and has been reported to be responsible for up to 20% of all deaths in patients with end-stage renal disease (ESRD) (35,48). As many as 10% of patients receiving hemodialysis have had, at any one time, a bacteremia secondary to an infection (53). Pyocystis, pyonephrosis, perinephric abscesses, and infected polycystic kidneys are not uncommon (40). The frequent absence of leukocytosis and fever coupled with a low index of suspicion (because a poorly functioning urinary tract is often dismissed) results in a delayed or missed diagnosis. A history of stone disease, congenital abnormalities of the collecting system, and pus from the urethra, coupled with urethral catheterization, renal ultrasonography, or computed tomography usually will lead to the diagnosis.

Acquired Renal Cystic Disease and Renal Cell Carcinoma

Patients on chronic dialysis for extended periods of time have a high propensity to develop cysts in their native kidneys. The incidence has been reported to vary between 35% and 80%. There is also a 100-fold increased risk of developing renal cell cancer in these cysts when compared with the general population (32). The acquired cysts make detection of renal cell cancers difficult. Patients who require periodic follow-up with ultrasound include those who have hematuria, flank pain, or other symptoms or signs that indicate a change in the kidneys.

Infertility

Both men and women who have ESRD are infertile. Even dialysis does not seem to restore their fertility. Serum hormone studies reveal an elevated level of luteinizing hormone and follicle-stimulating hormone and a depressed level of testosterone in the male patients. It appears that the failure occurs at the level of the testes.

Impotence

Gonadotropins are elevated, prolactin is elevated, and testosterone is depressed. Some patients respond to dialysis and others respond to androgen supplementation. A trial of bromocriptine to inhibit the elevated prolactin has been used with success in some patients, but the side effects of the drug usually prevent patients from continuing therapy.

Gynecomastia

Gynecomastia is not unusual, particularly early in dialysis. There is no satisfactory treatment; however, certain drugs aggravate the situation and should be discontinued if possible. The drugs include digitalis preparations, methyldopa (Aldomet), and spironolactone (Aldactone).

Gastrointestinal Tract

Mucosal ulcerations, ascites, pancreatitis, pruritus, and peptic ulceration are not uncommon. However, the symptoms of anorexia, nausea, vomiting, diarrhea, uremic breath, and metallic taste are more common.

Cardiovascular Disorders

Hypertension occurs in more than 80% of patients with ESRD. Three-quarters of these patients are hypertensive because of volume overload. The patient must be overloaded by at least 5% of body weight for hypertension to occur. This can be completely corrected by dialysis and the selected use of potent diuretics. The other 25% of uremic hypertensive patients are volume independent. These patients are labile when dialyzed and often require potent antihypertensives for blood pressure control. Even so, some patients ultimately require nephrectomy for control of their hypertension. Congestive heart failure is not infrequent in these patients. Uremic pericarditis continues to be a frequent complication, even with dialysis. These patients often present with fever, chest pain, leukocytosis, and sometimes, a pericardial friction rub. Often they will respond to dialysis alone, but indomethacin or corticosteroid administration may be necessary. Rarely, cardiac tamponade occurs, signaled by an enlarging cardiac silhouette on chest x-ray films, an elevated venous pressure, and hypotension. Surgical drainage is the treatment of choice. Echocardiography has been used with great success to follow the size of pericardial effusions.

Neuromuscular System

Peripheral neuropathy is usually sensory, with patients complaining of burning sensation in the feet and legs, particularly at night. Its incidence has decreased with the advent of early dialysis. Left untreated, the neuropathy will progress to loss of sensation, muscle atrophy, and motor nerve involvement. Therapy consists of dialysis and replacement of nutritional deficits. Renal transplantation reverses the disorder. Central nervous system disorders include loss of attention, short memory, and disturbed sleep. Without treatment, agitation, seizures, and psychotic behavior with eventual coma supervene. Aluminum intoxication has been implicated, but its role remains controversial.

Hematologic Disorders

The major cause of anemia in uremic patients is the lack of bone marrow production. Other contributing factors include gastrointestinal bleeding; vitamin deficiency states, particularly folate, pyridoxine, and iron; and hemolysis. Therapy consists of dialysis, replacement of nutritional deficits, minimization of blood loss, and occasionally, the use of androgens. The recent introduction of recombinant erythropoietin has markedly changed the management of anemia of renal failure. Most patients can maintain a hematocrit level of approximately 35% if given erythropoietin. These patients report an improvement in their sense of well-being. Transfusion should be reserved for situations in which active bleeding occurs or in cases in which the anemia is severe and unresponsive to erythropoietin, that is, the hematocrit is less than 14%. These patients also have a bleeding diathesis, because platelet function appears to be disturbed. It is a qualitative rather than a quantitative defect. This abnormality will reverse with dialysis alone.

Skeletal System

Osteomalacia and hyperparathyroidism often are seen together in uremia. Renal osteodystrophy includes osteitis fibrosa cystica, osteoporosis, osteomalacia, and osteosclerosis. Hyperparathyroidism results in subperiosteal resorption of bone and, rarely, brown tumor formation. Growth retardation in children and deforming skeletal rickets also occur. Chronic acidosis leads to the osteopenia and depression of skeletal growth in children. The osteomalacia may be a result of aluminum intoxication. The complications are fractures, aseptic necrosis of the hips, bone pain, and deformities. Treatment involves correction of serum phosphorus, usually with antacids that do not contain aluminum, and the administration of calcium supplements and dihydroxyvitamin D_3. (Care must be taken not to give calcium or vitamin D until the serum phosphorus is normal, because metastatic calcification will occur and damage many organs.) Parathyroidectomy is indicated if roentgenographic changes of hyperparathyroidism or metastatic calcification occur.

Arthropathy or joint pain is usually secondary to gout when there is hyperuricemia or to pseudogout when serum uric acid is relatively normal but serum calcium and phosphorus are both high. Both disorders respond to correction of the met abolic disturbances.

Metabolic Disturbances

Metabolic acidosis occurs late in the disease. Hypercalcemia occasionally occurs, usually as a result of secondary hyperparathyroidism or excessive calcium or vitamin D supplementation. Hyperuricemia is extremely common and generally is not associated with gout. Hypermagnesemia is common in patients who are not receiving dialysis. This can be significantly aggravated by compounds that contain magnesium (e.g., antacids). It is important not to give drugs that contain magnesium to patients with ESRD, because these patients are prone to magnesium intoxication.

Treatment

Currently, treatment of ESRD involves four basic approaches. Early in the disease dietary manipulation with the use of selected drugs to maintain serum electrolytes is all that is necessary. As the GFR falls below 10 mL per minute, either peritoneal dialysis or hemodialysis generally will be required. Renal transplantation is the ultimate therapy for the disorder.

Drug Administration

The kidneys are the major route of drug metabolism and secretion. Renal failure necessitates altered handling of most drugs and giving them in the usual dosages to uremic patients will lead to elevated blood levels, toxic symptoms, and perhaps even death. Antibiotics, sedatives, narcotics, and cardiovascular drugs often must be adjusted to an appropriate dosage level. Certain drugs should be totally avoided in uremic patients (Table 14.4). Drugs that commonly require altered dosage schedules are listed in Table 14.5.

Antimicrobials
Methenamine mandelate
Nalidixic acid
Nitrofuramxin
Tetracyclines (other than doxycycline or minocycline)
Neomycin
Analgesics—narcotics
Salicylates
Acetaminophen
Phenacetin
Phenazopyridine
Meperidine
Morphine
Sedatives—tranquilizers
Barbiturates
Glutethimide
Lithium
Ethchlorvynol
Methaqualone
Phenothiazines
Antacids—laxatives
With magnesium
With phosphate
Mineral oil
Antihypertensives
Methyldopa
Guanethidine
Reserpine
Diuretics
Acetazolamide
Mercurials
Triamterene
Spironolactone
Thiazides
Arthritis—gout
Gold salts
Probenecid
Phenylbutazone
Antineoplastics
Nitrosourea
Cisplatin
Neuromuscular agents
Gallamine
Pancuronium
Succinylcholine
Antiarrhythmics
Bretylium
Others
Terbutaline
Acetohexamide
Chlorpropamide

TABLE 14.4. DRUGS TO AVOID IN UREMIC PATIENTS

Antimicrobials
Aminoglycosides*
Cephalosporins*
Penicillins*
Polymyxins
Vancomycin
Flucytosine*
Trimethoprim-sulfamethoxazole
Amantadine
Analgesics—narcotics
Salicylates*
Meperidine
Morphine
Antiarrhythmics
Procainamide*
Quinidine*
N-acetylprocainamide*
Antihypertensives
Clonidine
Diazoxide*
Nitroprusside*
Cardiac glycosides
Digoxin
Digitoxin
Arthritis—gout
Allopurinol
Antineoplastics
Bleomycin
Cyclophosphamide*
Methotrexate
Mithramycin
Neuromuscular agents
Neostigmine
Miscellaneous
Insulin
Cimetidine*
Clofibrate
Methimazole
Niacin
Propylthiouracil

*Dosage significantly

DIETARY SUPPLEMENT HEALTH AND EDUCATION ACT OF 1994

The past few years have witnessed a dramatic increase in the use of herbal products as well as other methods associated with alternative and complementary medicine. This has led to considerable attention on the part of the media, including a cover story in *Time* magazine. Estimates of the amount spent on supplements yearly generally are in excess of one billion dollars per year. Recent reports document that supplement use is common among prostate cancer patients. Unfortunately, these studies also show that patients often do not share this information with their physicians. During my initial visit with patients, I often find that patients spend more on supplements than they do on prescription medications.

What has fueled this shift toward herbal and nutritional supplements? Many patients view herbal products as offering a gentler, more natural form of therapy with fewer side effects. Although this may be true for some supplements, such as valerian, the side effects of many herbal products simply have not been publicized adequately. There is no question that it is much more convenient and pleasant to visit the local health food store than to make an appointment to see a physician, get a prescription, and have it filled. For many patients, this is then followed by a battle to have the cost reimbursed by an insurance company. The use of herbal products also puts the patient in control of his or her treatment.

As the American public turned their attention to natural healing products, the political and legal environment also began to change. One key event was the passage by Congress of a major new law governing the marketing and sale of these products. This law, called the *Dietary Supplement Health and Education Act of 1994,* severely restricted the ability of the U.S. Food and Drug Administration (FDA) to regulate supplements (9). This act represents the result of a struggle, dating back to the early 1960s, between the FDA and forces seeking to provide Americans with less restricted access to supplements. In this process, the FDA has managed to assemble a consistent pattern of failure in the courts and in Congress.

Two elements characterized the FDA strategy. Their stance was that supplements were either unapproved drugs or they were unapproved food additives. If they were drugs, then they had to pass the same review processes that a drug would. If they were to be used as a food additive, they had to pass through the strict review process that a new food additive would pass through. The supplement industry argued that it could not afford to take either path because of the limited profit potential involved. After all, at the end they would not have the exclusivity our system guarantees a new prescription drug.

The FDA sought to restrict the distribution of information on supplements in the form of books, articles, or pamphlets. In this effort, they attacked balanced and scientifically sound as well as distorted and misleading material. The stance was that in any case these represented a marketing effort for unapproved food additives or drugs. In one case, the FDA objected to health food stores selling an herbal product and books on that same product. In the process, they managed to gain the opposition of free speech advocates, further complicating their political and legal difficulties.

The passage of the Dietary Supplement Health and Education Act of 1994 represented a clear repudiation of the FDA position. It is worthwhile to directly quote some of the text of this Act so that you can get a sense of the will of Congress.

> Despite a voluminous scientific record indicating the potential health benefits of dietary supplements, the Food and Drug Administration has pursued a heavy-handed enforcement agenda against dietary supplements for over 30 years. The agency's approach has forced the Congress to intervene on two previous occasions, and yet again with the adoption of S.784.

Key aspects of the Act represent a clear statement of differing philosophy than the philosophy that dominated the FDA and much of establishment medicine.

- “There is a link between the ingestion of certain nutrients or dietary supplements and the prevention of chronic diseases such as cancer, heart disease, and osteoporosis.”
- “Healthful diets may mitigate the need for expensive medical procedures, such as coronary bypass surgery or angioplasty.”
- “Preventive health measures, including education, good nutrition, and appropriate use of safe nutritional supplements will limit the incidence of chronic diseases, and reduce long-term health expenditures.”
- “There is a growing need for emphasis on the dissemination of information linking nutrition and long-term health.”
- “Consumers should be empowered to make choices about preventative health care programs based on data from scientific studies on health benefits related to particular dietary supplements.”
- “Studies indicate that consumers are placing increasing reliance on the use of nontraditional health care providers to avoid the excessive costs of traditional medical services and to obtain more holistic considerations of their needs.”
- “Dietary supplements are safe within a broad range of intake, and safety problems with supplements are relatively rare.”
- “Legislative action that protects the right of access of consumers to safe dietary supplements is necessary in order to promote wellness.”

This Act countered FDA strategy in several ways. First, they declared dietary supplements were foods, not drugs. Instead, they created a new category of food by specifically defining dietary supplements to include dietary ingredients such as vitamins, minerals, herbs or other botanicals, amino acids, or other dietary supplements. A dietary supplement must be intended for ingestion, such as a tablet, capsule, powder, soft gel, gelcap, or liquid form. The Act also specifically states that customers can be provided with publications on supplements in connection with the sale of the dietary supplements. These publications must not be false or misleading, not promote a specific brand of supplement, and provide a balanced view of the available scientific literature. In the store, it must be physically separated from the supplement.

The Act allowed supplements to carry claims that they help preserve general well-being. In addition, they can claim that they help preserve the structure or function of parts of the body. However, they cannot state that the supplements are effective treatment of any disease, because this would be a drug claim. This section of the Act has been the subject of continual discussion and litigation between the FDA and representatives of the supplement industry. In retrospect, this aspect of the Act was not well thought out and was probably not enforceable.

The case of lovastatin is a good example of some of the difficulties involved in distinguishing a drug from a supplement. Lovastatin is an FDA-approved drug for the treatment of elevated cholesterol, marketed by Merck as Mevacor. However, lovastatin also can be found in a range of natural products such as oyster mushrooms

and a form of red yeast used in China to season rice, and ingestion of these natural products will lower cholesterol levels. Extract of red yeast is now being marketed to people concerned about heart disease and information about its lovastatin content is widely available. As far as I can determine, there is no reason why, milligram for milligram, lovastatin in this red yeast extract is not as active as that in Mevacor. Yet, red yeast extract must be marketed as a supplement with an obscure structure-function claim about preserving the structure and function of the heart, whereas Mevacor is marketed specifically for its ability to lower cholesterol: once in the body, they act identically.

The end result of this Act has been mixed. There is no doubt that Americans now have much greater access to nutritional or herbal supplements. However, these supplements range radically in their value. Among these supplements are therapeutic agents with a strong scientific basis and proven clinical value. Most of these lack FDA approval because no company has been willing to take them through the expensive process the FDA mandates. In contrast, other herbal products have no scientific basis and no sound clinical trial documentation of efficacy, and even pose a health risk.

The Act specifically empowers the FDA to oversee quality control of supplements and they are given the power to remove unsafe supplements from the market. In practice, this process has not worked very well. The plain fact is that the quality of supplements on the market is variable. Studies have shown that supplements from some manufacturers can contain 25% or less of the active ingredient than stated on the label. It also appears that supplements on the market are not adequately monitored for hazardous contaminants.

It would appear that there is a great need for increased regulatory supervision of the supplement industry. It would be best if Americans were ensured of the potency and safety of the supplements they purchase. While we wait for these changes, there are some promising trends. Several major pharmaceutical firms have purchased supplement companies and this promises improvement in quality control and standardization. In addition, several major supplement manufacturers are funding clinical trials that specifically document the value of their herbal extracts.

STRESS

Time and again, patients relate how their prostate cancer appeared to develop following a period of stress. They then commonly ask if the stress was responsible for the fact that they now had cancer. Evidence from laboratory experiments do suggest that the stress hormones, epinephrine, norepinephrine, and cortisol, may play a role in the progression of prostate cancer. Patients often turn to alternative or complementary medicine for tools effective in the management of stress.

Problems with the Stress Response

It is important to realize that this stress response is very much designed to handle acute problems. When humans or other mammals are subjected to chronic stress, the continuous elevation of cortisol and catecholamines delays healing; suppresses the immune system; and contributes to high blood pressure, heart disease, and diabetes. Other diseases, such as duodenal ulcers, ulcerative colitis, rheumatoid arthritis, and psoriasis, also worsen during periods of stress. In essence, we are best designed by nature for a life where acute stress is followed by periods of peace and security.

Much of modern thinking about the biology of stress is based on the work of the Canadian scientist, Hans Selye (87). Through elegant laboratory experimentation and astute observation of human behavior, Selye developed a theoretic basis for analyzing the impact of stress that is still useful more than half a century after he first articulated these ideas. He pointed out that there were two distinct types of stress: distress and eustress. Distress would be loss of a job, death of a loved one, threat of debt, or similar events. Eustress would be the excitement associated with skiing down a mountain, reading an exciting novel, watching a football game, a new love, or other consuming passion. Although chronic distress obviously is not good, too much eustress also is a problem. Indeed, blood levels of catecholamines and cortisol elevate in response to both distress and eustress. The conclusion of this line of thinking is that it is important to keep a balance between periods of distress and eustress and periods of peace and quiet.

How can you judge the stress in a patient's life? I have found the stress scale developed by Miller and Rahe to be particularly useful (72). A sense of perspective is necessary in interpreting the results of this test. People differ in how well they tolerate stress. One person may become sick from stress-related illness even though his or her total score on this test may be relatively low. Others tolerate and even prefer a relatively high level of stress. In fact, some people appear to be addicted to catecholamines and only feel fully alive when they are under a high level of stress.

What are some of the symptoms that might tell you when your patients are under too much stress (Table 15.1)? They may find it difficult to concentrate or experience forgetfulness. They may awaken in the middle of the night with their minds churning over unresolved problems from the previous day. They may find that they have lost their appetite or suddenly find themselves overeating. They may become impatient or intolerant of others. They may find themselves losing their temper over minor issues. Their blood pressure may suddenly become higher or other stress-related diseases may worsen. It is important for you to become attuned to how your patients respond to stress and to develop a sense for when you need to advise them of the need to decrease life's stress. I think that having them take the Miller and Rahe stress test will help you recognize when stress has become too much.

▪ Forgetfulness	▪ Irritability
▪ Insomnia	▪ Substance abuse
▪ Altered eating habits	

TABLE 15.1. SIGNS OF STRESS

Epinephrine and Prostate Biology

The prostate gland is well supplied with sympathetic nerves. Activation of these sympathetic nerves plays a central role in ejaculation: without their activity, men experience a dry ejaculation. Obviously, this involves a sudden surge in sympathetic nerve activity. What about catecholamines from the adrenal medulla? Experiments in dogs indicate that ejaculation is fostered by a sudden increase in catecholamine release from the adrenal medulla plus action by the prostatic sympathetic nerves (Table 15.2).

▪ Important for ejaculation	▪ Blockade of α_1-adreno-receptors leads to apoptosis of prostatic epithelial cells and associated stroma
▪ Enhances response to testosterone and epidermal growth factor by normal and malignant prostatic epithelial cells	

TABLE 15.2. CATECHOLAMINES AND THE PROSTATE

What about chronic activation of the prostatic sympathetic nerves? Lee and his colleagues from Northwestern University in Chicago showed that if one cuts the sympathetic nerves to the prostate gland, it shrinks (70,71,98). If one cuts the sympathetic nerves to one side of the prostate gland, that side will shrink. It appears that activity of the sympathetic nerves act in conjunction with testosterone to allow the prostate gland to reach its mature size.

These findings suggest that catecholamines stimulate the growth and/or survival of prostate cells. Direct evidence of this comes largely from the work of Kyprianou from the University of Maryland (22,60). When catecholamines interact with cells, they act through proteins found on the surface of these cells. These proteins, called *adrenoreceptors,* bind to the catecholamines and trigger the cell's response. A wide range of different adrenoreceptors are found in tissues throughout the body. Drug companies have made use of this fact to develop drugs that block the action of only one adrenoreceptor type at a time. Examples of this are the drugs Hytrin, Cardura, and Flomax. These drugs are selective for a_1-adrenoreceptors. Activation of the a_1-adrenoreceptors in the bladder and urethra blocks the flow of urine out of the bladder. Hytrin, Cardura, and Flomax block these a_1-adrenoreceptors, causing relaxation of the muscles in the urethra and bladder, making it easier for men to urinate.

These same a_1-adrenoreceptors also are found on the cells that line the ducts of the prostate gland and the fibroblasts that make up the support network for the gland. Kyprianou and others have shown that the a_1-adrenoreceptor–blocking drugs cause prostate lining cells and the fibroblasts to die. The same appears to be true, at least in the laboratory, for human prostate cancer cells.

How do catecholamines foster the growth and survival of human prostate cancer cells? The best insight into this issue comes from research done by Weber at the University of Virginia. All growth signals coming from cell surface receptors do so by activating an enzyme called *mitogen-activated protein* (MAP) kinase. Epidermal growth factor is one of the most important growth and survival factors for human prostate cancer cells. This growth factor acts by binding to a protein on the surface of these cells that is called the *epidermal growth factor receptor.* The resulting growth signal causes activation of MAP kinase, resulting in increased cancer cell growth. Catecholamines dramatically increase the ability of epidermal growth factor to activate MAP kinase (21).

Stress also has been shown to impair the function of the immune system. The function of natural killer cells appears to be consistently decreased following stress. This may be important for cancer patients because natural killer cells have the capacity to kill cancer cells. Natural killer cells have adrenoreceptors on their surface, and activation of these receptors by norepinephrine or epinephrine blocks the effectiveness of these immune cells. The adrenoreceptor in this case is a b-receptor rather than the a-receptor involved in prostate biology. In the laboratory and in tissue culture, drugs that block the b_2-receptor protect natural killer cells during periods of stress.

In summary, stress causes an increase in the release of epinephrine and norepinephrine from sympathetic nerve endings and from the adrenal medulla. These catecholamines stimulate the response of prostate cells, normal or malignant, to epidermal growth factor and testosterone. In addition, these catecholamines suppress the function of the immune system. If these factors are biologically important, it would be predicted that prostate cancer cells would spread preferentially to the adrenal gland. This is indeed the case. Recent detailed autopsy studies performed in men showed that the adrenal gland is the fourth most common site involved in metastatic prostate cancer (15).

Medical Approaches to Stress Reduction

The benzodiazepines are the most widely prescribed anxiety-relieving drugs. This drug class includes diazepam (Valium), chlordiazepoxide hydrochloride (Librium), and alprazolam (Xanax). The latter is now commonly used to relieve anxiety in cancer patients. There are several problems with the benzodiazepines. The most disturbing issue is that these drugs can be addicting (66). They also can impair coordination, leading to falls, accidents, and motor vehicle crashes. In addition, people treated chronically with these drugs can be troubled by loss of intellectual function. Both loss of coordination and impaired intellectual function are markedly increased if alcohol consumption follows ingestion of these drugs.

Buspirone and antidepressants, such as venlafaxine hydrochloride (Effexor), appear to circumvent many of these problems. Effexor may worsen high blood pressure, and in this situation, sertraline hydrochloride (Zoloft) has been found to be of value. These drugs are much less likely to impair coordination or intellectual function. In addition, they are safer to take in conjunction with recreational use of alcohol. Finally, their use is much less likely to result in addiction. However, as a note of caution, buspirone and the serotonin-reuptake inhibitor class of antidepressants can elevate circulating prolactin levels. Because prolactin promotes the growth and survival of prostatic epithelial cells, it is theoretically possible that these antianxiety drugs might adversely affect the outcome of treatment for prostate cancer.

A number of herbal products are reported to reduce stress. Valerian root is probably the best documented of these (31,59). Valerian is mildly sedating, has no addiction potential, and seems quite safe. Its major limitation is that it appears to be less effective than Effexor or buspirone in lessening anxiety.

Drug-free Stress Reduction

Most communities of any size have programs where patients are taught stress reduction techniques. Often, these are associated with progressive community hospitals or other community-based health care delivery organizations. For many patients, these programs are of great value.

Most of these stress reduction programs are based on what is called the *relaxation response* (Table 15.3). During this response, pulse rate and blood pressure drop, the flow of blood to the hands and feet improves, and brain wave frequency slows (8,18,52). This occurs when a person places himself or herself in a quiet, pleasant environment and focuses his or her attention on something neutral and nonthreatening, such as a single candle flame or fish in an aquarium.

▪ Easy to elicit	▪ Increase in blood flow to hands and feet
▪ Decrease in pulse rate	▪ Decrease in blood catecholamine levels
▪ Decrease in blood pressure	

TABLE 15.3. RELAXATION RESPONSE

Many men are reluctant to engage in these techniques. Some of them are associated with religious or political connotations with which they may not agree. A relatively simple approach will give your patient a sense of what is involved.

First, find a comfortable chair in a quiet, pleasant place. After the patient has relaxed, take his blood pressure.

Have him pick some short word or syllable that he will repeat over and over again. In Hindu meditation, they use the word *om*, but the patient can just as easily use

the word one, five, six, or ten. The key is that it should either have no emotional connotation or a pleasant one.

Next, have the patient close his eyes and repeat the chosen word or syllable. While he does this, have him purge his thoughts of any other concern. He also should try to ignore his surroundings and focus on the rhythm of the repeating word. He should continue this for 20 minutes. At the end of this period, his pulse and blood pressure should be remeasured; nearly always both will have declined significantly.

Patients should approach this with the idea that they are learning a new skill, like playing tennis or golf. They should expect that their comfort and skill will improve with practice. It is a common experience for people to think their initial attempts at meditation are failures. Even when they think they have not done well, it is very likely that engaging in this relaxation response will have had considerable impact on their stress level. If the patient plans to use the relaxation response optimally, he should plan to set aside 20 minutes at least once and, preferably, twice per day.

Will the relaxation response alter the progression of prostate cancer? There have been no clinical trials testing this idea. What we can say is that the relaxation response will lead to a decrease in blood epinephrine levels and a decrease in the activity of the sympathetic nervous system. As we have seen, there is a scientific basis for the hypothesis that blood epinephrine concentration and activation of the sympathetic nervous system might increase the growth of prostate cancer cells. At the very least, this technique may lessen the impact of stress on your patient's health and anxiety level.

ANTIOXIDANTS

Antioxidants represent one of the most common supplement classes ingested by prostate cancer patients. Widely used examples include vitamin C; vitamin E; selenium; and plant polyphenols, such as those from green tea, grape seed, and pine bark. A growing body of scientific and clinical work supports the use of these compounds by patients with cancer and other diseases.

Antioxidant Defense Network

Many biochemical reactions essential for life carry with them the threat of oxidative damage to the tissues of the body. For example, the process by which mitochondria produce the adenosine triphosphate (ATP) that drives your muscles and other tissues creates side products such as hydrogen peroxide that can damage tissues by oxidation. Exposure to sunlight can enhance oxidative damage to skin cells. Chemicals that naturally occur in food can cause oxidative damage. We are able to safely eat these foods only because our bodies do such a great job defending us against oxidative damage; fava beans can cause severe injury if consumed by people who lack the normal defenses against oxidative damage.

It is now known that the body has a comprehensive antioxidant defense network in which each component part has a role to play (25,44). What are the components of this antioxidant defense network?

One group of enzymes function to destroy or detoxify common oxidants. For example, hydrogen peroxide is one oxidant commonly formed as a byproduct as the tissues in the body perform their daily tasks. Several enzymes are capable of detoxifying hydrogen peroxide. The enzyme catalase binds two hydrogen peroxide molecules together to form oxygen and water. A second family of enzymes, called *glutathione peroxidases,* reduces hydrogen peroxide to water. Most of the known glutathione peroxidases require selenium.

A second group of components are vitamins that act as antioxidants. Vitamins C and E are prominent members of this group. Vitamin C is soluble in water and acts as an antioxidant in the water phase of the cell. Vitamin E is soluble in body fat and other lipids, but not in water. For this reason, vitamin E acts as an antioxidant for body lipids.

A third group of components is the dietary antioxidants. It is now apparent that most vegetables and grains contain antioxidants. Tomatoes contain the red pigment, lycopene. Green tea contains antioxidant polyphenols. Onions and garlic have large amounts of sulfur-containing chemicals that are strong antioxidants. Fruits such as blueberries, strawberries, and raspberries are another rich source of antioxidants. It now appears that these plant antioxidants act to bolster the effectiveness of other members of the antioxidant network.

The final component of the antioxidant defense network is a group of proteins that sequester iron and copper. This is important because free iron and copper can stimulate the conversion of peroxides into free radicals that rapidly react with and destroy normal tissues. Under normal conditions, this system is so effective that free iron and copper do not exist in body fluids or tissues. When sequestration of iron fails, it causes hemochromatosis and hemosiderosis. When sequestration of copper fails, it causes Wilson's disease.

When all four components of the antioxidant defense network are functioning optimally, the body can effectively handle attack by a wide range of oxidants without sustaining serious injury. Oxidative damage can include injury to DNA, the genetic material in a cell. This genetic damage can foster the development of cancer or promote the progression of cancer from a slow-growing local problem to one that grows and spreads rapidly. Thus a fully functioning antioxidant network can lower the risk that cancer will develop. However, this network operates so that various components overlap in their function, so that a deficiency in one component can be compensated by the others. For example, a low level of vitamin E may not be of great consequence if selenium, vitamin C, and dietary antioxidants are present at optimal levels. This is an important point to keep in mind when reading the results of clinical trials: any antioxidant can appear to have no impact if the subjects are taking in large amounts of other antioxidants and/or are not exposed to significant oxidant stress. Conversely, if the people in the trial are all subject to some oxidative stress, antioxidants may prove more effective than they would in normal subjects. For example, cigarette smoking subjects the body to increased oxidative stress and smokers may have a greater need for antioxidants than nonsmokers. This will prove important when we discuss some of the clinical trials involving antioxidants and prostate cancer.

Oxidants and the Development of Prostate Cancer

Why should antioxidants alter the risk of dying from prostate cancer? Wilding and his colleagues from the University of Wisconsin have published a series of papers that provide a possible answer to this question (83,84). They have shown that prostate cancer cells exposed to testosterone produce hydrogen peroxide and other oxidants. This led them to propose that testosterone exposure results in the production of oxidants that cause genetic damage. Genetic damage can play a role in the progression as well as the genesis of cancer. The implication of this line of research is that strengthening the antioxidant network may lessen the risk of developing prostate cancer. It may also slow the progression of this disease from a slow-growing cancer limited to the prostate gland to one that has spread throughout the body and become resistant to all therapies. Several antioxidants may alter the natural history of prostate cancer.

Selenium

Over the past few years, our knowledge about selenium and its effects on living organisms has increased dramatically. A search of the National Library of Medicine's online database, PubMed, shows more than 1,000 scientific articles published on selenium since January 1998.

One major factor behind this surge in interest about the health effects of selenium has been Clark and colleague's 1996 publication of a large, randomized, controlled clinical trial that demonstrated a marked reduction in cancer deaths associated with increased selenium intake (23,24). This trial was initiated in 1983 as a randomized controlled trial testing the impact of supplementation with 200 mg of selenium-yeast per day on the risk of skin cancer. This clinical trial enrolled 1,300 individuals residing in the Mid-Atlantic Coastal Plain from Virginia to South Carolina, an area long known to have low soil and water selenium levels. After 10 years, the overall cancer death rate was 50% lower in the subjects taking selenium as compared with the control group (Table 15.4). The cancers responsible for this difference were carcinomas of the prostate, colon, and lung: prostate cancer deaths were decreased by 64%, colon cancer by 40%, and lung cancer by 30%. The four major causes of cancer death are those of the lung, prostate, colon, and breast. Thus selenium dramatically reduced the death rate of three of the four most common causes of cancer death in the United States. Furthermore, no cases of selenium toxicity were reported among the people in this trial who took selenium supplements for years.

▪ Deficiency exists where high rainfall and acid soils are present	▪ The 200-µg dose is recognized as safe and costs $0.10 per day
▪ 200 µg of selenium per day reduces prostate cancer deaths by 60%–70%	▪ Markedly enhances cytotoxic T-cell activity in cancer patients

TABLE 15.4. SELENIUM

Selenium and Prostate Cancer

Since the publication of Clark's paper, there has been one major study designed to test the validity of his findings. In his paper, Clark reported on the correlation between serum selenium levels and the risk of prostate cancer. One criticism of this approach is that serum selenium levels are just a “snap shot” of selenium levels at one point in time, whereas the development of prostate cancer takes many years and is more likely to be influenced by the average selenium level during that time period. Hair and nails are formed at the rate of approximately 1 mm per day, and thus hair or nail clippings are a better estimate of average selenium level. Giovannucci, from the Harvard School of Public Health, examined the selenium content of nail clippings from approximately 34,000 men and found that the risk of developing metastatic prostate cancer decreased as the selenium content of the nail clippings increased (103). When Giovannucci compared the men with the highest and lowest nail selenium content, he found a 65% reduction in the risk of metastatic prostate cancer.

What is the next step in this line of investigation? The National Cancer Institute (NCI) has just funded a large, randomized, controlled trial in which men will be randomized between control, vitamin E, selenium, and vitamin E plus selenium. Colteman, from the University of Texas, San Antonio, is the lead investigator on this clinical trial.

Selenium and the Immune System

A number of studies suggest adequate selenium levels are necessary for proper function of the immune system. The most convincing study is a randomized, controlled clinical trial in patients with head and neck cancer (56). Most patients with this cancer exhibit depression of the immune system. Cytotoxic T cells and natural killer cells are the most important parts of the immune system in terms of resistance to cancer. Natural killer cell function usually is profoundly depressed in head and neck cancer patients. Cytotoxic T-cell number and function also are commonly suppressed. Patients in this study all had untreated squamous carcinoma of the head and neck and were randomized to placebo or selenium at a dosage of 200 mg per day for 8 weeks. This trial was double blind, which means that neither the patients nor the doctors knew who was receiving placebo or selenium until the study was completed.

Plasma selenium levels were measured at the start and during the trial to ensure patients took the selenium as directed. During the 8 weeks, 88.3% of the patients took the assigned selenium dose. At the start of the trial, the average selenium levels in the two groups were 91.3 and 94.4 mg/L of blood plasma. After 8 weeks of selenium supplementation, the average selenium level increased from 91.3 to 105.3 mg/L.

Despite this minor increase in plasma selenium, there were major changes in the immune system. In the patients on placebo, cytotoxic T cells killed only 7% of the tumor cells. After 8 weeks of selenium supplementation, the T cells were able to kill 78% of the tumor cell targets. This is a rather remarkable shift given the short duration of treatment and small increase in selenium levels. To place these findings in perspective, in the Clark study, prolonged administration of the same dose of selenium, 200 mg per day, eventually increased the selenium levels to close to 200 mg/L, rather than the 105.3 mg/L after 8 weeks reported in this paper on head and neck cancer.

Other lines of evidence show the importance of the antioxidant defense network and selenium in protecting the immune system. HIV-1, the virus that causes AIDS, kills because it destroys T cells that are important in the immune response. HIV-1 increases oxidant stress in the T cells at the same time as it appears to weaken key elements of the antioxidant defense system. Selenium plays a major role in the ability of glutathione to act as an antioxidant. A selenium-containing protein, glutathione peroxidase, uses glutathione to convert hydrogen peroxide to water. Without selenium, glutathione peroxidase is unable to accomplish this task. Given this background, the fact that children and adults infected with HIV-1 live much longer if their selenium levels are adequate is not surprising (10,17).

In addition, one additional study examined restoration of normal immune function in the elderly by selenium combined with other nutrients. This study by Girodon, from the Scientific and Technical Institute for Foods and Nutrition, Conservatiore National des Arts et Metiers, Paris, involved a group of institutionalized elderly patients (40). It showed that 20 mg of zinc and 100 mg of selenium significantly increased antibody response to influenza vaccine and decreased the risk of upper respiratory infection.

Selenium and Viral Infections

In addition to its effects on the immune system, selenium can have a direct effect on the progress of viral infections (12). This is best studied in a virus called *coxsackie B.* Although not a household name, coxsackie B infections are common, and this virus can cause serious, life-threatening illness. Coxsackie virus infections typically start in the gastrointestinal (GI) tract, where they can cause nausea, vomiting, and diarrhea. From there, the virus can enter the blood stream and spread throughout the body. This virus can attack the nervous system, causing a disease that results in paralysis similar to that caused by polio. Coxsackie virus can enter muscles, where it can cause severe muscle damage and pain. For example, it can infect the muscles of the rib cage that are used to breathe and make it very painful to take a deep breath. When this virus enters the heart muscle, the damage can be sufficient to require a heart transplant. In fact, coxsackie B virus infections are one of the leading reasons for heart transplant.

The link between selenium and coxsackie B virus starts in China. In the Keshan province of China, soil and water contain little selenium. Residents of this area can have daily intakes of selenium of less than 20 mg per day, compared with 200 mg per day in Clark's trial. Residents of Keshan can develop a form of fatal heart failure called *Keshan's disease.* However, this disease does not occur in residents of this area who manage to receive more than 20 mg of selenium per day. Subsequent studies showed that a disease similar to Keshan disease can be found in several parts of China, all of which are selenium deficient. In addition to being limited to geographic regions low in selenium, Keshan disease only appeared during certain seasons of the year: summer in Southern China and winter in Northern China. Seasonal patterns like this are characteristic of disease of infectious origin. This led the Chinese to isolate viruses from the hearts of people who had succumbed to Keshan's disease. Coxsackie B virus emerged as a common isolate. The Chinese scientists then showed that coxsackie B virus would infect mice and cause heart damage. Furthermore, the damage was much worse in mice on a low selenium diet compared with those on a high selenium diet.

This phenomenon was subsequently investigated by Beck from the University of North Carolina, Chapel Hill (12). Several strains of coxsackie B virus that are able to infect mice are available. These strains differ in the severity of the infection they cause in the mice, ranging from those causing mild disease to those that cause serious illness. Beck showed that the viral strains causing serious illness did much less damage to mice on high selenium diets compared with those on low selenium diets. Of even greater interest, when a viral strain that normally caused mild disease was allowed to infect a selenium-deficient mouse, the virus was permanently altered into a virus that would cause severe disease. Beck then showed that this change in viral virulence induced by selenium was always associated with the same genetic changes. In other words, passage of a mild virus in a selenium-deficient animal caused changes in the genetics of the virus, rendering it much more dangerous. This is currently the best explanation for why severe selenium deficiency can result in potentially fatal heart damage.

Vitamin E deficiency also worsens the impact of coxsackie B virus infection on the heart. In addition, when a mild form of the virus infects vitamin E–deficient mice, it becomes more virulent, just as it did in selenium-deficient mice. Again, the evidence shows that the antiviral activity is not specific for selenium, but reflects the fact that an optimally functioning antioxidant network suppresses the progression of coxsackie B virus.

Selenium and Heavy Metals

Metals such as arsenic, lead, mercury, cadmium, and thallium are all poisonous. Furthermore, industrial uses of these metals have led to large-scale environmental contamination. One of these metals, cadmium, has been specifically implicated as a cause of prostate cancer. Selenium alters the toxicity of heavy metal ions in several ways (99,105). It is important to note that selenium can bind these metal ions into complexes not soluble in water. To a certain extent, selenium can bind to these metal ions in the GI tract, diminishing the absorption of both selenium and the toxic metals. Once selenium has been absorbed, it can form complexes with these metal ions, lessening or delaying the toxicity of these metal ions. One of the side benefits of taking selenium supplements to decrease the risk of prostate cancer or to slow its progression is protection from the toxicity of these metal ions.

Selenium Dose

A daily selenium dose of 400 mg per day is now recognized as the maximum safe daily dose. This number may be increased as studies currently in progress are completed. In Clark's study, a dose of 200 mg of selenium-yeast was ingested for years without a single reported side effect, but with a major impact on cancer deaths. A number of additional studies, both short and long term, document the safety and effectiveness of this dose of selenium.

Forms of Selenium

Commercially available selenium supplements come in a wide range of chemical forms (Table 15.5). The most widely available form is as selenium-yeast, and 200 mg per day costs about 10 cents. This is also the form used in Clark's study.

▪ Selenium-yeast	▪ Selenomethionine
▪ Sodium selenate	▪ Selenocysteine
▪ Sodium selenite	▪ Selenodiglutathione

TABLE 15.5. DOSAGE FORMS OF SELENIUM

Unfortunately, some individuals are allergic to selenium-yeast. Selenomethionine also is widely available and appears safe. However, selenomethionine is not directly used by any of the selenium-requiring proteins in the body. Instead, it gets randomly taken up by all proteins in the body. After these proteins are broken down, the selenium gets recycled into biologically useful forms. Thus although it eventually acts to reverse selenium deficiency, it would not offer the rapid reversal most cancer patients might desire.

Sodium selenate and selenite are available and are rapidly reduced in the body to selenide. The latter is rapidly incorporated into the key selenoproteins in the body. The only disadvantage of these selenium salts is that their absorption from the GI tract is not consistent.

Selenocysteine is the form of selenium that is directly incorporated into the key selenoproteins in the body. Selenocysteine is commercially available and also is present in preparations such as selenoglutathione or selenodiglutathione.

Vitamin E

Vitamin E is soluble in lipids, but not in water. As a result, it largely acts to prevent oxidative damage to the lipids in a cell. In laboratory studies, vitamin E has been shown to act in concert with antioxidants present in the cytosol, such as vitamin C, glutathione, and selenium.

The first evidence that vitamin E might alter the progression of prostate cancer came as an unexpected result of a clinical trial designed to test the role of this vitamin in the prevention of lung cancer in smokers. In this trial, approximately 23,000 male cigarette smokers were randomized to placebo, beta-carotene, vitamin E, or beta-carotene plus vitamin E (48). At the point where men had been on the trial for 5 to 8 years, death rates from prostate cancer were 40% less in the men taking vitamin E alone compared with placebo. In contrast, the men taking beta-carotene experienced a 30% increase in mortality from this malignancy. The group taking beta-carotene plus vitamin E were not significantly different from the control group.

Vitamin E is not a single chemical substance, but a name given to a family of fat-soluble antioxidants (Table 15.6). These compounds differ in their content in foods as well as their ability to act as antioxidants. Although alpha-tocopherol is widely available and the form most commonly is used in laboratory and clinical studies, it is not the most active antioxidant. Recently, the work of two groups suggests that alpha-tocopherol may also not be the most active against cancer cells, including those of the prostate.

Alpha-tocopherol	Alpha-tocotrienol
Beta-tocopherol	Beta-tocotrienol
Gamma-tocopherol	Gamma-tocotrienol
Delta-tccopherol	Delta-tocotrienol

TABLE 15.6. VARIOUS TOCOPHEROL AND TOCOTRIENOLS

Moyad and Pienta, from the University of Michigan, have recently reported that gamma-tocopherol is more active against prostate cancer cells than is the alpha form of this vitamin (74). In contrast, other groups have found gamma-tocopherol no more active than alpha-tocopherol as an anticancer agent (42,53,69). Instead, they have found the most active tocopherol is the delta form. In addition, tocotrienols are considerably more active than the corresponding tocopherols, and the most active preparation currently available commercially is concentrated palm oil tocotrienols. Finally, vitamin E succinate appears to exert anticancer activity equal to or greater than any of the naturally occurring tocopherols or tocotrienols.

There is now evidence that vitamin E kills prostate cancer cells by a unique mechanism. All cells in the body have the capacity to commit “suicide.” This suicide can be triggered by several means. One means of accomplishing this is by activating certain proteins, called *death receptors,* on the surface of cells. These death

receptor proteins are designed so that when they are activated, the cell bearing them rapidly destroys itself. One of the most common of these proteins is called *Fas.* When vitamin E–like chemicals kill prostate cancer cells, Fas rapidly appears on the surface of the prostate cancer cells and appears to undergo activation, leading to cell death. These findings suggest that vitamin E does more than prevent genetic damage caused by oxidants released as a result of testosterone exposure. In fact, it may well be that vitamin E–like molecules actually may be orally active chemotherapeutic agents with low toxicity. This concept has led at least one group to chemically synthesize analogs of vitamin E with the hope of increasing the anticancer activity of this family of compounds.

Plant Monophenols and Polyphenols

Plant phenols are one of the most potent groups of antioxidants. They can occur as monophenols or as clusters of monophenols, called *polyphenols.* Polyphenols are found in a wide range of plant products that have health benefits.

Green Tea

Green tea intake has been associated with a decreased risk of cancers of the prostate, colon, pancreas, skin, and other organs (2,62,93). It seems that green tea prevents the damage caused by a large number of cancer-causing chemicals and even excessive sun exposure.

It appears that green tea cannot only prevent cancer, but is able to stop the growth of or even kill human cancer cells. This ability was documented in human breast, lung, colon, pancreatic, and prostate cancers in tissue culture and in animal models. Growth arrest occurs at the G2/M interface, a portion of the cell cycle where tumor cells are most sensitive to radiation therapy. This is also the same portion of the cell cycle in which paclitaxel (Taxol) and docetaxel (Taxotere) act to block the cell cycle.

The major polyphenols from green tea are epigallocatechin-3-gallate (EGCG), epigallocatechin, and epicatechin-3 gallate. Together, these make up 30% to 40% of the solids extracted from green tea leaves during brewing. The contents of green tea have been examined carefully to determine the chemical in the tea responsible for the anticancer activity. The growing consensus is that most of the useful activity is caused by the polyphenol, EGCG. This compound caused the rapid shrinkage of human prostate cancers growing in mouse xenograft models. It should be pointed out that there is no known mechanism by which an antioxidant can cause cancer cells to stop growing or cause rapid shrinkage of a tumor mass. For this reason, it is likely that EGCG exerts its anticancer activity by a mechanism independent of its antioxidant activity.

EGCG and other green tea polyphenols are sensitive to light and air; they are most stable at a pH of less than 5.5 and when the tea is brewed at 180°F or less.

The amount of EGCG found in green tea appears to be effective as a cancer prevention agent. The amount needed to stop the growth of cancer cells or to cause the cancer to shrink rapidly in mice is much larger—projecting from the animal experiments, a dose equivalent to 10 or more cups per day would be necessary. Human clinical trials have progressed to phase 1, where a dose of green tea extract of 1,000 mg per day (equivalent to 10 to 12 cups per day) was well tolerated. At present, there are no published phase II or III clinical trials.

Proanthocyanidins

Proanthocyanidins are a large group of polyphenols that are widely marketed by the health food industry. Proanthocyanidins are very effective antioxidants, exceeding vitamins E and C in this regard. The proanthocyanidins are made up of the monophenols, catechin and procyandin, strung together like beads on a chain. There are a wide range of specific proanthocyanidins, each with a specific sequence of catechin and procyandins. When these compounds enter the stomach, the stomach acid breaks these chains into fragments composed of one individual catechin and procyandin units, each of which can act as a potent antioxidant. Some of the plant sources of proanthocyanidins can be found in Table 15.7 (45).

▪ Cocoa	▪ Cranberries
▪ Apples	▪ Red wine
▪ Grape seed	▪ Grape skins
▪ French Maritime Pine Bark (pycnogenol)	▪ Blueberries

TABLE 15.7. SOURCES RICH IN PROANTHOCYANADINS

The two richest sources of proanthocyanidins are cocoa and apples. Apples can vary widely in proanthocyanidin content: Red Delicious and Granny Smith have more than twice the concentration of McIntosh and Golden Delicious. Even McIntosh and Golden Delicious look impressive compared with other plant sources of proanthocyanidin. For comparison, red wine and cranberries have only one-third the concentration of these compounds as is found in Golden Delicious and less than one-sixth that found in cocoa.

Total proanthocyanidin content is not the whole story because some of these compounds have unique activities not related to their activity as antioxidants, which is likely based on specific combinations of catechin and procyandin units. For example, cranberries have a proanthocyanidin that blocks the ability of bacteria to adhere to the bladder lining, making cranberry juice a valuable adjunct in the treatment of bladder infections (33).

Cocoa. Chocolate is made by combining cocoa butter with cocoa liquor. Cocoa powder is dried cocoa liquor. Alone or mixed with water, cocoa powder is dark brown, tastes quite bitter, and is marketed as cooking cocoa. Chocolate made only with cocoa powder, cocoa butter, and emulsifying agents is also dark and bitter and is marketed as cooking or baking chocolate. Sweet, dark chocolate that is free of milk or milk fat is marketed with up to 70% cocoa powder and can be quite tasty. It should be mentioned that the cocoa powder content sometimes is listed as “cocoa mass,” not cocoa powder. The antioxidant content of cocoa is very high and helps prevent chocolate from spoiling, making it very stable during prolonged storage.

After ingestion of chocolate rich in cocoa powder, the proanthocyanadins in the chocolate will break down, releasing epicatechins in large amounts. Within 2 hours of consuming 80 g of chocolate, blood levels of epicatechin increase by 1,200% (97). It takes approximately 6 hours for blood levels of this antioxidant to return to baseline. This sudden increase in epicatechin is so effective that it causes a 40% decline in oxidative damage to the fats in the blood.

This information about cocoa is relatively new and the full biologic impact of cocoa has not been fully investigated. In terms of total polyphenols and even epicatechins, cocoa is much richer than green tea. However, green tea has very specific epicatechins, such as EGCG, that act not only as antioxidants, but also act to kill cancer cells, including prostate cancer cells. In addition, extensive epidemiologic studies show a decrease in prostate cancer risk in men who chronically ingest green tea. Similar information is not available for cocoa powder.

Grape Seed Extract. Grape seed extract is another rich, natural source of proanthocyanadins that is widely available and on which a number of papers have been published (85,89). The proanthocyanadins from grape seed extract have been shown to kill head and neck cancer cells without damaging normal cells. It also blocks the development of cancer in rodent skin exposed to chemical carcinogens. It will protect vitamin E in cells exposed to strong oxidants.

In animal models, grape seed extract exhibits potential beneficial effects that do not directly relate to the development or progression of cancer. When the blood supply to the heart is blocked temporarily and then restored, there is an intense wave of oxidative damage to the heart, called *reperfusion injury.* In animals subjected to this, administration of grape seed extract significantly lessens the damage. Finally, again in animals, application of grape seed extract to the skin was reported to

increase hair growth by 230%.

Unfortunately, there are no useful clinical trials testing this preparation in humans. This is particularly striking in view of its widespread commercial availability and its popularity among cancer patients.

Pycnogenol. Pycnogenol, a proanthocyanidin preparation, is an extract obtained from the bark of the French Maritime Pine and is widely available (50,65,78,95). As with grape seed extract, a number of interesting papers have been published on this preparation. In laboratory experiments, pycnogenol protected the cells that line blood vessels from oxidative damage. In animal experiments, it reduced blood pressure by inhibiting angiotensin-converting enzyme. In aged mice, administration over 2 months increased the number of B and T cells, key members of the immune system. It also increased growth of bone marrow stem cells in tissue culture.

Like grape seed extract, the absence of useful clinical trials is striking in view of pycnogenol's wide commercial availability and popularity with patients.

Cranberries. For *Escherichia coli* to successfully attack the bladder, it must be able to attach to the wall of the bladder so that it can avoid being flushed out with the passage of urine. The bacteria does this through the use of fimbria. Cranberries contain a proanthocyanadin that blocks the ability of *E. coli's* fimbria to attach to surfaces (3,33). Even more interesting, prolonged contact with cranberry proanthocyanadin changes the *E. coli* so that it loses the capacity to make fimbria.

There is currently a controversy regarding whether the consumption of cranberries, their juice, or their extract plays a role in the management of urinary tract infections. One comprehensive review of the literature has concluded that the evidence is too weak to support its use (55). Others support the opposite, concluding that cranberries do have a role to play in the treatment of urinary tract infections. The most impressive study was published in the *Journal of the American Medical Association* (JAMA) (6). In this study, women with urinary tract infections were randomized to receive 300 mL of cranberry juice a day or placebo. Those taking cranberry juice had a significant improvement in their recovery from the infection. Conversely, there is little evidence that cranberry juice intake prevents urinary tract infection and it did not help children with recurrent bladder infections (86).

The cranberry is a member of the *Vaccinum* genus, which also includes the blueberry, bilberry, and lignonberry. One paper examined the ability of proanthocyanadins from various members of this genus to block the action of chemicals that cause cancer. In laboratory tests, low-bush blueberry, cranberry, and lignonberry all showed significant activity (13). Blueberry extracts also have been shown to reverse the loss of coordination and the ability to solve maze problems in aged rodents. Unfortunately, there is no evidence that cranberries or other members of this genus prevent cancer or improve mental function in humans.

DIETARY FAT AND PROSTATE CANCER

Enormous controversies exist regarding the link between diet and the risk of metastatic prostate cancer. The situation is so contentious that one can almost pick studies to support any conclusion he or she might favor. There are a number of reasons for this situation. Most studies use crude tools, such as requiring people to remember what they ate in the past or measuring the disappearance of certain foodstuffs from the economy of various countries. The determination of prostate cancer incidence also is difficult because different cultures vary in their willingness to accurately report prostate cancer as a cause of death. Given these problems, only the most robust associations between diet and prostate cancer will be reliable. One of these is the association between a diet rich in animal products, especially red meat, and prostate cancer, suggesting a strong link between a component of meat and the risk of prostate cancer.

Of course, not all studies of prostate cancer and diet are of equal quality. The best type of study would be a clinical trial in which patients were randomly assigned to diets high or low in specific fats. Trials that fit this description are currently in progress. Until they are complete, we have to fall back to our next best option. In this author's opinion, the best studies on diet and prostate cancer are those published by the investigators at the Harvard School of Public Health (34,38). These investigators conducted two trials, one involving physicians and a second involving other health care professionals. In both studies, information on diet was conducted prospectively and did not depend on people accurately recalling the composition of their diet in the distant past. The information from the two studies indicates that dietary fat did not influence the risk of localized prostate cancer, but did increase the risk of metastatic prostate cancer. When specific foods were examined, red meat, dairy fat, egg yolks, and creamy salad dressings emerged as significant risk factors.

Potential Dangers of Omega-3 Fatty Acids

One finding reported by Gann and associates (34) has elicited considerable controversy. These investigators reported that dietary intake of alpha-linolenic acid (ALA) was associated with a dramatic increase in the risk of developing metastatic prostate cancer. ALA is the major plant omega-3 fatty acid and increased intake of this lipid is thought to confer many health benefits. Extensive literature shows the ability of ALA and other omega-3 fatty acids to lower cholesterol, moderate high blood pressure, and suppress inflammation associated with rheumatoid arthritis and other diseases. Many dietitians and other health care professionals recommend that patients increase their intake of ALA to ensure a sufficient intake of omega-3 fatty acid. This fatty acid is present in large amounts in flax seed oil, where it comprises 50% of the total fatty acids present. Canola and soy bean oil are also rich in ALA. However, in addition to the Gann paper, a number of studies on the impact of ALA on prostate cancer have shown either no benefit or an adverse impact (4,27,41,47). These clinical studies have been matched with laboratory research that also shows increased growth of prostate cancer cells exposed to ALA. For this reason, it probably is not prudent for prostate cancer patients to take dietary supplements rich in ALA, such as flax seed oil or essential fatty acid mixtures.

ALA is not the only omega-3 fatty acid. Two others, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), are found in the fat of ocean fish, such as wild salmon or haddock. Fish do not make EPA or DHA, but obtain it from the algae that they ingest. For this reason, the fat in farm-raised salmon will reflect the fact that they have been fed corn or soy meal rather than algae and may not differ significantly from cattle or pigs fed a similar diet. Oil obtained from wild fish appears to have all of the same health benefits of ALA but is not associated with an increased risk of prostate cancer. In fact, several studies suggest a decreased risk of prostate cancer in men who eat several servings of fish a week (77). For more than a century, industrialized countries have made the oceans the garbage dumps of last resort. A large amount of literature can be found on the toxic chemicals that concentrate in the flesh and oils of fish living in the ocean. These range from toxic heavy metals such as mercury, to chemicals such as dioxin. For this reason, fish or fish oil may not be the best source for EPA and DHA.

Fortunately, DHA that is free of ALA and from a source that is not likely to be contaminated by heavy metals or toxic chemicals can now be purchased. Algae that produce DHA are now grown commercially, and the DHA is extracted and sold as 100- or 200-mg capsules. This preparation appears to represent the best source for omega-3 fatty acids (49,57,91).

Animal Fat

Although dietary intake of red meat and animal fat consistently have been associated with increased risk of metastatic prostate cancer, the specific components of meat and animal fat responsible for this increased risk remain controversial.

One fatty acid, arachidonic acid, is present in much greater concentration in animal products. Vegans typically have arachidonic acid levels that are 10% to 30% of those found in meat eaters (81). This fatty acid is known to have a dramatic impact on the behavior of cancer cells, including cancer of the prostate. Arachidonic acid has been shown to enhance prostate cancer growth, to stimulate its spread, and to facilitate its ability to form new blood vessels. In addition, arachidonic acid products have been shown to kill cells of the immune system involved in the control of cancer.

Although a diet rich in meat can supply large amounts of arachidonic acid, most mammals can also produce their own. The “essential” fatty acid, linoleic acid, can be converted to arachidonic acid. Linoleic acid commonly is present in large amounts in many plant oils. In most animals used in diet experiments, such as rats and mice, this conversion is so efficient that a diet rich in plant oils will support high levels of arachidonic acid. This is not the case for humans, who are much less efficient in converting linoleic acid to arachidonic acid.

Dietary arachidonic acid does not cause any acute side effects. The typical American ingests approximately 100 mg of arachidonic acid each day. In clinical studies, people have tolerated five to ten times this amount for close to 2 months with no problems of any kind. It is only at doses of 7,000 mg a day that acute side effects have been seen in humans. The serious problems appear to develop only after chronic ingestion and in the context of preexisting disease, such as cancer (75).

Some investigators have argued that a diet rich in meat, and thus arachidonic acid, should not be of concern because humans evolved eating a diet rich in wild animal meat (67). Because humans survived hundreds of thousands of years on this diet, it is suggested that we must be well adapted to it. Although this idea is attractive superficially, the average life span of humans in primitive societies was typically less than 40 years. The diseases linked to high intake of animal fat, such as heart

disease and cancer, are not common before the age of 50 years, long after the majority of people in primitive cultures would have died. Modern civilization has created an artificial situation, effectively doubling the life span of humans, thereby exposing us to diseases we are evolutionarily ill equipped to handle.

Arachidonic Acid and Prostate Cancer Biology

There is evidence that arachidonic acid is able to stimulate directly the growth of some cancer cells. This does not appear to be the case for prostate cancer cells. Arachidonic acid must be converted to one of several metabolites, called *eicosanoids.* For example, aspirin is able to relieve pain because it blocks the conversion of arachidonic acid to an eicosanoid, prostaglandin E_2 (PGE_2), which causes pain. Table 15.8 shows the major eicosanoids that can be made from arachidonic acid. Of these, 5-hydroxyeicosatetaraenoic acid (5-HETE), 12-HETE, and PGE_2 are known to be made by prostate cancer cells and to play a role in the growth and spread of this disease.

In men older than 50, lymphocytes are common throughout the normal prostate tissue. In radical prostatectomy specimens, it will be found that lymphocytes are uncommon in prostate cancers of Gleason grades of 7 or higher. Arachidonic acid can be converted to a chemical PGE_2. Human prostate cancer cells have long been known to produce PGE_2 from arachidonic acid. In radical prostatectomy specimens, the cancer produced ten times as much PGE_2 as the surrounding normal prostate tissue (20). PGE_2 is toxic to both natural killer cells and cytotoxic T cells and is one potential mechanism by which prostate cancer evades the immune system.

Products of cyclooxygenase	Products of 12-Lipoxygenase

Products of 5-Lipoxygenase	15-HETE and 5,15-HETE
5-HETE and Leukotrienes	

TABLE 15.8. SOME MAJOR EICOSANOIDS FORMED FROM ARACHIDONIC ACID

Arachidonic acid also markedly stimulates the ability of human prostate cancer cells to move and invade. This process requires the conversion of arachidonic acid to a substance called *12-HETE.* Inhibitors of 12-HETE formation are remarkably effective at arresting the movement of human prostate cancer cells (64).

Honn, from Wayne State Medical School in Detroit, has shown that conversion of arachidonic acid to 12-HETE by prostate cancer cells stimulates angiogenesis required for the growth of human prostate cancer (76). Honn and his colleagues first showed that simply adding 12-HETE to prostate cancer cells did not increase the growth rate of these cells. They then inserted additional copies of the gene controlling 12-HETE formation into these human prostate cancer cells. The original cancer cells and those engineered to make large amounts of 12-HETE were injected into mice. The cancers making increased amounts of 12-HETE grew much more rapidly and exhibit increased vascularity, suggesting increased angiogenesis.

In a separate study, Honn and colleagues examined radical prostatectomy specimens to see which cancers had the capacity to make 12-HETE and which did not (35). They found that patients with tumors able to make 12-HETE were much more likely to develop metastatic prostate cancer after radical prostatectomy. These findings are consistent with the capacity of 12-HETE to stimulate cancer cell invasiveness and angiogenesis in laboratory models.

Beginning in the mid-1980s, a series of investigators reported that the addition of arachidonic acid stimulated the growth of prostate cancer cells. None of these investigators was able to determine how arachidonic acid managed to increase the growth of these cancer cells. In a series of papers, it was confirmed that arachidonic acid stimulated the growth of both hormone-sensitive and hormone-independent human prostate cancer cells. It could then be shown that a specific metabolite of arachidonic acid, 5-HETE, was responsible for the growth stimulus provided by arachidonic acid. Furthermore, 5-HETE also acted as a potent survival factor for human prostate cancer cells (36,37).

The pathway by which arachidonic acid is converted to 5-HETE plays a major role in other diseases, including asthma, rheumatoid arthritis, and psoriasis. On the other hand, this pathway does not seem to be necessary for the health of humans or other mammals. Genetic engineering has been used to produce mice that make no 5-HETE. These mice bear offspring that are normal and that mature into normal adults. Therefore a drug that blocks the formation of 5-HETE might be effective against prostate cancer and have few side effects. In fact, several of the herbal products widely used to treat prostatic diseases, such as saw palmetto, block eicosanoid formation, including 5-HETE, in prostate cells (Table 15.9).

▪ Saw palmetto	▪ Cernilton
▪ Pygeum africanum	▪ Boswellia
▪ Stinging nettle	

TABLE 15.9. HERBAL PRODUCTS THAT BLOCK EICOSANOID FORMATION

In summary, prostate cancer cells are known to metabolize arachidonic acid to eicosanoid products that stimulate the survival, growth, and invasiveness of these cancer cells (Table 15.10). Other arachidonic acid metabolites suppress immune function and facilitate tumor angiogenesis. Considered together, these findings provide a rationale for why a diet rich in animal fat might speed the progression of human prostate cancer. As presented in the following sections, a range of herbal products traditionally used to treat prostatic diseases are now known to inhibit the formation of PGE_2, 5-HETE, and various leukotrienes.

▪ Stimulates growth and survival	▪ Contributes to immuno-suppression
▪ Increases invasiveness	
▪ Increases angiogeness	

TABLE 15.10. ARACHIDONIC ACID AND PROSTATE BIOLOGY

Conjugated Linoleic Acid

Conjugated linoleic acid (CLA) recently has appeared on the market as a nutritional supplement, and this was accompanied by a report of significant activity against human prostate cancer in a mouse xenograft model (19). As a result, this supplement is now widely used by prostate cancer patients.

When animals with a rumen, such as cows, goats, or sheep, are fed grass and not grain, they make a special fatty acid called *conjugated linoleic acid.* CLA is incorporated into the meat as well as the milk made by grass-fed animals. It reduces the amount of body fat in the animals and lessens the amount of fat in the milk they produce. This is one reason grain-fed beef has a higher fat content than animals raised on the range.

Originally, CLA was discovered as a component in diary fat that blocked the ability of chemical carcinogens to cause cancer. The benefits of this compound were quickly shown to extend to other diseases in animal models (79). In animal models of diabetes mellitus, CLA was shown to make insulin's action more effective and reduced triglycerides. CLA acts to reduce inflammation in a manner similar to drugs such as aspirin or ibuprofen by blocking the conversion of arachidonic acid into PGE_2.

The initial observations that CLA would reduce the number of cancers in animals exposed to cancer-causing chemicals have been duplicated and appear to be quite impressive (51). In tissue culture, CLA slows or arrests the growth of a wide range of cancers, including human malignant melanoma, colorectal, breast, prostate, and lung cancer cell lines. The activity of CLA against breast cancer has been extended to experiments in mouse models of breast cancer. In these models, CLA slows or arrests the growth of the breast cancer masses. When these CLA-treated cancers are examined under the microscope, CLA is seen to cause an increase in apoptosis (a form of suicide), as well as slowing the rate at which the cancer cells duplicate.

There is currently only one paper on the activity of CLA against human prostate cancer (19). Cesano and colleagues used the most aggressive human prostate cancer cell line available, DU145. When DU145 is implanted in a mouse, it grows and spreads rapidly, killing the mouse in a short period of time. This cell line is hormone independent and is resistant to most cancer drugs. In fact, very few men have prostate cancers even remotely as aggressive as DU145. In this experiment, animals were given a food mixture that contained 1% CLA by weight. In the control mice, the cancer grew and spread rapidly to other tissues. In the mice on CLA, the cancer grew normally for a few weeks, gradually slowed and then stopped. After a few additional weeks, the cancers in approximately 30% of the CLA-fed mice began to turn black and fell off. In the control mice, the cancer had spread to the lungs in 80% of the mice, compared with only 10% in the CLA-fed mice. This dose of CLA caused no side effects in the mouse.

What mechanism best explains all of these effects? In one important study, the growth of human prostate cancers in a mouse model was markedly enhanced by feeding the mice corn oil, a fat rich in linoleic acid. CLA very effectively prevents the conversion of linoleic acid to arachidonic acid and can be expected to block the ability of arachidonic acid to foster the growth and spread of prostate cancer cells (7).

CLA has functions other than just blocking the conversion of linoleic acid to arachidonic acid. A group of proteins called peroxisome proliferator–activated receptors (PPAR) mediate the action of a group of cholesterol-lowering drugs, the most common of which is clofibrate. In addition to the ability to lower cholesterol, these drugs cause fat to accumulate in the liver and can lower the blood sugar. CLA has been shown to activate potently all three PPAR receptors (a, b, and g) (68,73). *In vivo,* CLA exhibits many of the effects one would anticipate from a PPAR agonist: improved glucose tolerance, lowered blood lipids, and increased liver lipids.

The interaction of CLA with the PPARs may play a role in the antitumor activity of these compounds. PPAR-g agonists, such as troglitazone, have shown activity against human prostate cancer *in vitro* and *in vivo* (58). A clinical trial of troglitazone in men with prostate cancer showed slowing or arrest of tumor growth in a significant number of patients. However, no PPAR agonists have been reported to cause tumor necrosis such as that seen in the CLA-treated mice bearing DU145. For these reasons, it is suspected that the ability of CLA to block the growth and spread of prostate cancer cells may result from a combination of its ability to block synthesis of arachidonic acid and its ability to activate PPARs.

Despite these promising results, there are a number of problems with the widespread use of CLA by prostate cancer patients. First, all commercially available CLA preparations are complex mixtures of closely related isomers that differ in their biology and, presumably, their therapeutic effects. For example, one of the isomers appears to be the most active in altering the synthesis of milk fat; no one has identified the isomers most active against prostate cancer. It would be best to have a CLA preparation with a defined isomer composition, preferably limited to those with documented anticancer activity.

Second, no clinical trials have tested the effectiveness of any CLA preparation against cancer. In the mouse studies, the anticancer activity is apparent only after more than 1 month of continuous administration. The action of many drugs is ten times faster in mice than in humans, therefore an effect exhibited in mice after 1 month might take 10 months to be seen in humans. Based on this information, the most promising test of this compound would be in patients who could afford to wait close to a year for its therapeutic impact. On the other hand, humans and mice may differ in some way that allows CLA to act much more rapidly in humans. Without human studies, it is difficult to know if CLA is of benefit to patients with prostate cancer or even in which clinical situation this product will be of greatest value.

Saw Palmetto

Saw palmetto is a compound derived from the fruit extract of the American Dwarf palm tree that is native to the Atlantic Coastal Plain from North Carolina south through Northern Florida. The common herbal preparation of saw palmetto represents the extracted lipids and sterols.

All clinical trials testing saw palmetto in the treatment of benign prostatic hyperplasia (BPH) were reviewed in *JAMA* in 1998 (101). After critically evaluating the quality of the clinical trials and the consistency of the results, the authors concluded that saw palmetto was an effective treatment for BPH. This conclusion has been confirmed in two subsequent extensive literature reviews (14,100). Proscar currently is approved by the FDA as a treatment for BPH and for male-pattern hair loss. In the clinical trials comparing finasteride (Proscar) with saw palmetto as treatment for BPH, finasteride was found to be less successful than saw palmetto.

One problem with these reviews is that they do not take into account the varying potency and quality of commercially available saw palmetto products. There are many different ways to extract these lipids and sterols, yielding products with differences in their biologic effects. In addition, the different brands and preparations are available with varying amount of extract per capsule. Consumer Labs, Inc., has tested 27 of the products on the market and found that only 17 contain an adequate amount of the specific fatty acids and sterols needed to produce a therapeutic effect. A list of the manufacturers that passed this test is available at their website, www.consumerlabs.com

The only sure way of knowing whether a given saw palmetto extract is active is for the manufacturer to sponsor clinical trials that document its activity. Clinical trials are expensive and most herbal product companies have been reluctant to participate in such stringent tests of the value of their products. The economic justification was that the consumer did not demand this investment and the cost of such trials eroded the profitability of their business. A few companies have been foresighted enough to take part in clinical testing of their herbal extracts. In those few situations, we have solid evidence of the value of an herbal product as well as sound

information about the effective dose and possible side effects.

The biochemical basis for the activity of saw palmetto against benign enlargement of the prostate almost certainly includes inhibition of the formation of dihydrotestosterone (DHT) within the prostate gland. Interestingly, although saw palmetto inhibits formation of DHT in the prostate gland, it does not inhibit formation in many other tissues and may not alter blood levels of this hormone (11,28). However, Proscar is effective at reducing prostatic DHT levels but is relatively ineffective in relieving the symptoms of BPH. The action of testosterone and DHT on the prostate gland is markedly stimulated by the hormone, prolactin. Saw palmetto is reported to block the response of prostate cells to prolactin (Table 15.11) (94).

- Decreases synthesis of dihydrotestosterone in the prostate gland
- Decreases responsiveness to prolactin
- Decreases formation of 5-HETE and leukotrienes

TABLE 15.11. SAW PALMETTO

Saw palmetto also has been reported to inhibit the enzyme 5-lipoxygenase, which converts arachidonic acid to the eicosanoid 5-HETE. This eicosanoid is known to stimulate the growth of prostate cells (80). Other products of 5-lipoxygenase, the leukotrienes, are potent mediators of inflammation.

In BPH, the increased size of the gland can arise from an increase in the number of cells lining the prostate ducts as well as an increase in the number of stromal cells in the space between the ducts. With this background, it is interesting to note that saw palmetto has been shown to cause the death of both the stromal cells and the cells lining the prostate ducts (82,92). This has been followed by one study showing that saw palmetto was able to slow the growth of prostate cancer cells and, at high enough concentrations, even kill these cancer cells. To date, there are no clinical trials testing saw palmetto in the treatment of prostate cancer, so it is difficult to know whether this observation is clinically relevant.

In summary, specific saw palmetto extracts appear to have useful activity in the treatment of BPH. This product appears to alter prostate biology through a number of mechanisms, some of which might also be relevant to the treatment of prostatitis and prostate cancer. Unfortunately, clinical trial documentation of the activity of saw palmetto extract is inadequate in the case of prostatitis and completely lacking in the case of prostate cancer.

Black Cohosh Root

The alcoholic extract of black cohosh root is widely used by women in Europe, and now in the United States, as a treatment for menopausal symptoms (46,63,96). Virtually all of the clinical studies have been performed with one preparation, Remifemin, which was originally developed in Europe and is now marketed in the United States. Many men with prostate cancer on hormonal therapy are using Remifemin or other black cohosh root preparations as treatment for their hot flashes and other symptoms of male menopause. In addition, some physicians caring for prostate cancer patients have been recommending it to their patients.

Black cohosh was one of the medicinal plants widely used by various Native Americans. It was also one of the first native herbal products adapted by early European settlers. Interestingly, the most common use for this herbal product by Native Americans and early European settlers appeared to be as a treatment for rheumatism. There is no convincing evidence that the Native Americans used it for menopausal symptoms. The use of black cohosh for this latter problem became widespread during the 1800s in both America and Europe. Its use in America subsided by 1900, but continued in Europe, especially in Germany. At present, virtually all significant clinical and laboratory investigations on black cohosh have been performed by European investigators.

Numerous clinical trials, including randomized controlled trials, have compared black cohosh root, almost always using Remifemin, with placebo and a variety of estrogen preparations commonly used as hormone replacement therapy for women. It is now well documented that this herbal preparation effectively reduces hot flashes in women. Remifemin also appears to be effective in countering the depression, insomnia, and other psychiatric complications of female menopause. This black cohosh extract appears to prevent bone loss in animals after surgical removal of the ovaries, raising the possibility that it might also ameliorate the development of osteoporosis. This possibility has yet to be tested in humans. Remifemin also appears to act on the female genitalia, where it has been reported to cause estrogen-like effects on the vaginal mucosa.

The production of estrogen by the ovaries is stimulated by luteinizing hormone (LH). When the brain senses that sufficient estrogen is present, it decreases the production of LH, shutting down the production of additional estrogen (32). During menopause in women, LH production increases because the brain senses the absence of estrogen. The magnitude of this LH rise has been reported to correlate with the severity of menopausal symptoms. A majority of the studies indicate that a dose of Remifemin sufficient to reverse menopausal symptoms also blocks the release of LH.

As with most herbal preparations, Remifemin is composed of a mixture of different chemicals. Fractions have been identified that can bind to the estrogen receptor and appear to mimic the actions of estrogen. Another fraction can block LH release even though it has no estrogenic activity. These results suggest that it would be possible to prepare black cohosh extracts that selectively suppress the response of the brain to menopausal symptoms, such as hot flashes, depression, and insomnia, that lack any activity at the estrogen receptor.

The side effects of Remifemin appear to be mild. The most common side effect is transient gastric distress, which is seen in approximately 7% of women. In fact, it seems to be as well or better tolerated than the commonly used estrogenic medications. In particular, it appears to be much less likely to cause uterine bleeding. In standard test systems, it also does not cause mutations or stimulate the development of cancers. This is important because naturally occurring estrogens are known to promote the development of cancers of the breast and uterus.

In women with breast cancers that contain the estrogen receptor, there is concern that use of estrogen-based drugs might enhance the growth of the cancer. One of the concerns about soy phytoestrogens is that, at low concentrations, they enhance the growth of the estrogen-responsive human prostate cancer cell line, MCF-7 (30). It is only at higher concentrations that soy phytoestrogens retard the growth of this and other breast cancer cell lines. In contrast, several studies now show that Remifemin retards the growth of MCF-7 in tissue culture at all of the concentrations tested. This has led several commentators to suggest that this herbal product might be safe for postmenopausal women with breast cancer. However, it is dangerous to use such tissue culture data as proof of safety. The only valid study would be to directly test the impact of Remifemin in women with estrogen receptor–positive breast cancer. This testing has not been performed, and the author therefore hesitates to recommend Remifemin to women with established breast cancer or women at high risk for breast cancer because of family history.

How efficacious is the use of Remifemin and other black cohosh extracts in men? No clinical trials in which Remifemin or other black cohosh extracts were administered to men could be found. Black cohosh definitely should not be recommend to men who are not on hormonal therapy. The concern is that it might suppress LH production and this might lead to testicular atrophy. In men already on hormonal therapy, the estrogenic activity of this supplement may cause breast enlargement and other estrogen-dependent side effects. No information could be found about the impact of Remifemin and other black cohosh preparations on prostate cancer growth and spread, and it is impossible to predict its impact on this disease. Its use in men is questionable at best until there is a better understanding of its impact on the physiology of the human male and its effects on prostate cancer.

Lycopene

It has long been known that intake of fruits, vegetables, and grains are associated with a decrease in the risk of many cancers, but the specific components of these

foods responsible for this reduced risk remain a matter of controversy. Lycopene is a member of a broad group of plant pigments, called *carotenoids,* that includes beta-carotene (orange color of carrots) and lutein (yellow color in many vegetables). Carotenoids, especially beta-carotene, have long been thought to play an important role in cancer prevention (93). Lycopene is the red pigment found in tomatoes, pink grapefruit, watermelon, and apricots and is related to beta-carotene and other carotinoids in structure (1). Evidence strongly indicates that intake of tomato products and lycopene offer protection against cancers of the stomach, lung, and prostate. Lycopene also appears to reduce the risk of cancers of the oral cavity, esophagus, breast, pancreas, cervix, and colon. What is more interesting is that none of the 72 studies reviewed in preparation of this chapter report a link between lycopene and an increase in the risk of any cancer. Furthermore, there are no reports of toxicity, regardless of dose.

In a recent review, Giovannucci discussed study after study in which the intake of lycopene, but not other carotenoids such as beta-carotene, correlates with protection from cancer (39). This is consistent with a recent randomized, controlled trial that found that supplemental beta-carotene actually increased the risk of death from prostate cancer. This is an important point, because many dietitians and alternative health practitioners are still recommending beta-carotene to men with prostate cancer. It is important to stress that there is no evidence to support this practice.

Lycopene is well absorbed from cooked tomato products such as tomato sauce or tomato paste, but not from fresh tomatoes. In addition, lycopene absorption is enhanced by the addition of oil (61). The traditional practice around the Mediterranean of consuming cooked tomato products in combination with olive oil appears to have a strong rationale.

Why should lycopene reduce the risk of cancer? Carotenoids can act as antioxidants and as precursors to Vitamin A. Among the common carotenoids, lycopene is the most effective antioxidant and this property may be important given the activity of vitamin E and selenium against this cancer.

Several observations instill confidence in the importance of lycopene. First, the studies that report a reduced risk of cancer associated with lycopene involved the United States, Italy, the Netherlands, Spain, Sweden, Australia, Iran, China, and Japan, indicating the protective effect persists despite widely different dietary patterns, lifestyles, and ethnic background. Second, the protective effect extends to a wide range of human cancers, each of which has its own unique biology and is caused by different mechanisms. Third, in every country and with every cancer examined, lycopene intake never correlated with a significant increase in the risk of cancer.

What is lacking? Final proof of lycopene's importance will require a randomized, controlled clinical trial in which large numbers of people take a placebo or a defined amount of lycopene over a prolonged time period and the impact on cancer frequency and cancer deaths is measured. Because tomato products often are used in prepared foods in ways that are not obvious, this study will be difficult to conduct.

PC-SPES

PC-SPES is a combination of seven Chinese medicinal herbs with the addition of one North American herb, saw palmetto. This herbal product appeared a few years ago and is widely used by patients as a treatment for prostate cancer. The story of this herbal product illustrates the positive and negative aspects of the current regulatory environment with regard to supplements. This product did not proceed through the standard process by which prescription drugs are approved by the FDA. Shortly after this product was introduced, many in the medical field became aware that, in some patients, this product induced a significant decrease in tumor size. Physicians initially had no information about appropriate dosing, side effects, and antitumor activity of this preparation. Physicians specializing in prostate cancer have gathered experience with the use of this herbal product, largely because patients decided to try it on their own.

Reports about PC-SPES began to appear in medical literature. One noteworthy article by DiPaola and co-workers, of the Robert Wood Johnson School of Medicine, New Brunswick, New Jersey, appeared in the New England Journal of Medicine (29). The article showed that this preparation has estrogenic activity, but is distinct from known estrogenic drugs such as diethylstilbestrol (DES) and estradiol. They also found that PC-SPES caused a significant drop in blood levels of the male sex hormone, testosterone. It caused a greater than 50% drop in prostate-specific antigen (PSA) in 6 of 8 patients. The findings reported by DiPaola and co-workers suggest that the activity of PC-SPES in these patients represents a “hormonal” response equivalent to that caused by conventional estrogenic substances such as DES and estradiol.

A phase II clinical trial designed to establish the true effectiveness of PC-SPES was recently reported by Small of the University of California at San Francisco (90). In this study, essentially all of the patients who had not yet received hormonal treatment responded, consistent with the ability of PC-SPES to mimic the action of DES. Of even greater interest, almost half of the patients with hormone-refractory prostate cancer also responded. This response rate in hormone-refractory prostate cancer compares well with the most active cytotoxic chemotherapy regimens. Other groups also have documented the activity of this herbal preparation against human prostate cancer (26).

PC-SPES is not without significant side effects (Table 15.12). Virtually all men treated with this herbal product develop breast tenderness and gynecomastia. In addition, most men experience a loss in sex drive. GI toxicity in the form of diarrhea also can be a problem. Leg cramps are common and usually associated with a low serum magnesium level. Of greater concern, men with preexisting hypertension find its management more difficult. Shortly after the introduction of PC-SPES, a number of men were reported to develop thrombophlebitis and pulmonary embolism. For this reason, it became common practice to place patients on warfarin as prophylaxis against blood clots. However, in the large phase II trial conducted by Small, blood clots were no more common than one would anticipate from that normally seen in men with prostate cancer.

- Gynecomastia and gynecodynia
- Loss of sex drive
- Diarrhea
- Hypertension
- Thrombophlebitis

TABLE 15.12. SIDE EFFECTS OF PC-SPES

Soy and Genistein

It has long been known that the risk of prostate cancer is low in populations where soy consumption is common. Soy contains isoflavones, such as genistein, that are thought to account for the health benefits of this legume. These compounds are alternatively referred to by their specific chemical name, such as genistein; as isoflavones; or as phytoestrogens. The latter term arises from the fact that these isoflavones mimic some of the biologic effects of the female sex hormone, estrogen.

In the laboratory, genistein has well-documented activity against prostate cancer (5,16,88,102,104). High concentrations of genistein and other soy isoflavones cause the death of prostate cancer cells. At somewhat lower concentrations, these isoflavones arrest the growth of prostate cancer and block tumor cell invasiveness. In addition, there are now several studies in which soy products or isolated soy isoflavones have been demonstrated to slow the growth of human prostate cancer cells in mouse xenograft models.

The mechanism by which soy isoflavones might slow the growth and/or spread of prostate cancer remains unclear. Genistein, at concentrations obtainable in humans, can block the action of both the epidermal growth factor and *Her-2/neu* receptors. This means that genistein can theoretically block one of the major mechanisms by which prostate cancer cells become hormone-refractory. Although these isoflavones act as estrogenic compounds in laboratory assays, men on soy-rich diets have

only minor alterations in sex hormone levels. Finally, soy isoflavones appear to block tumor angiogenesis in laboratory models.

There is also considerable controversy about the best soy product to use to obtain high blood levels of genistein and other soy isoflavones. Genistein is absorbed much more effectively from fermented soy products such as miso, natto, and tempeh than it is from soy beans, tofu, or soy milk. In addition, soy phytoestrogen or genistein tablets or capsules currently on the market would easily permit the ingestion of several grams of soy isoflavones per day. An additional complication is that blood levels of genistein may underestimate the levels in the prostate. When genistein levels are measured in prostatic fluid, the concentration is five to ten times higher than in the blood.

Clinical use of soy isoflavones in the treatment or prevention of prostate cancer is made questionable by several problems. Although quite a few epidemiology studies show a correlation between high soy intake and a reduced risk of prostate cancer, a randomized, controlled clinical trial showing that these soy products prolong the life of men with this disease is still lacking (43,54). Clinical trials that show that soy products arrest or slow the growth of prostate cancer are even lacking. The dose and schedule for the administration of soy isoflavones most likely to affect human prostate cancer is not known. On the other hand, many health benefits appear to be associated with the use of soy protein as a substitute for animal proteins. The FDA recently has allowed firms marketing soy protein to claim that these products have a favorable impact on the course of coronary heart disease.

SUMMARY

The Dietary Supplement Health and Education Act of 1994 guarantees Americans ready access to herbal products. Although selected herbal products have impressive therapeutic activity in tissue culture and animal models, with few exceptions, clinical trial documentation of activity is less than impressive. In fact, the common pattern is for initially promising laboratory findings to lead to widespread commercial availability without any intervening clinical investigation. An additional problem of great concern is that the commercially available herbal products vary widely in their quality.

Renal Medullary Carcinoma
Other Tumors
Chapter References

Much of what is known today about renal tumors revolves around data from just the past century. Advances in both pathologic diagnosis and surgical technique have been steady since the first known nephrectomy approximately 140 years ago. Unfortunately, at this time, there is still no highly effective therapy, apart from surgery, for most malignant renal tumors. Nonetheless, continued research in this arena has yielded some important discoveries, and this challenge persists for future generations. As more is learned about the cellular characteristics, and specifically the molecular nature of these tumors, researchers will further target surgical and medical approaches to improve the prognosis of patients with advanced disease.

CLASSIFICATION

Although less common than benign renal cysts, solid tumors of the kidney are most often malignant in nature. The majority of these are adenocarcinomas, commonly called *renal cell carcinomas (RCCs).* However, numerous other lesions have been described in the kidney, and these have been found in all aspects of renal and perirenal tissue including epithelial tissue, vascular structures, neurogenic tissue, and mesenchymal derivatives. Childhood renaltumors [predominantly Wilms' tumor (nephroblastoma)], from embryonic tissue also are seen and are discussed elsewhere in this text.

Over the past decades, investigators have proposed several classification schemes for renal masses, although not one has been universally accepted as being both simple and comprehensive. Stratification has been based on tissue origin, behavior (malignant, benign, or inflammatory), and radiographic appearance. Histopathologic diagnosis, as related to molecular genetics, also has been examined in attempts to find common links between different tumors as well as to locate potential prognostic markers at the gene level (283).

With the advent of new molecular genetic data, specific morphologic and cytogenetic characteristics of the most common renal neoplasms, epithelial tumors, were recently integrated into a standard classification system. In 1997, at a consensus conference (the Diagnosis and Prognosis of Renal Cell Carcinoma) held by the World Health Organization (WHO) in combination with the Union Internationale Contre le Cancer (UICC) and the American Joint Committee of Cancer (AJCC), old categorization systems were modernized. An appreciation for the histologic diversity led investigators to reclassify on the basis of morphology and yet remain consistent with known genetic facts. The descriptive terms applied had historic reference, reflected salient morphologic features, and were unambiguous. The contemporary classification of adult renal epithelial neoplasia was generated as listed in Table 16.1 (239). Regardless of the classification scheme, the clinician must be aware of the behavioral characteristics of the mass once a diagnosis is made.

Benign Neoplasms	Malignant Neoplasms
Papillary adenoma	Conventional (clear cell) renal carcinoma
Renal oncocytoma	Papillary renal carcinoma
Metanephric adenoma	Chromophobe renal carcinoma Collecting duct carcinoma Renal cell carcinoma, unclassified

TABLE 16.1. CLASSIFICATION OF RENAL EPITHELIAL TUMORS

BENIGN EPITHELIAL TUMORS

Papillary Adenoma

Several previous classifications of renal epithelial tumors have included adenoma as a distinct pathologic entity. However, significant controversy exists over the differentiation of adenomas from adenocarcinomas by histologic criteria (88). Distinction is important because adenomas generally are regarded as benign lesions, which do not progress to metastasis, whereas adenocarcinomas have known metastatic potential.

Asymptomatic papillary adenomas are the most common renal epithelial neoplasm. They are exclusive to the renal cortex and have been identified in 4% to 37% of autopsy specimens (88). Based on ultrastructural studies, papillary adenomas originate from a distal tubular cell (71). In addition, associated chromosomal changes (including trisomy 7, trisomy 17, and loss of the Y chromosome) similar to those seen with papillary RCC have been identified (125). Increased frequency of papillary adenomas has been found with smoking (279), end-stage renal disease with hemodialysis (107), and arteriosclerotic renal vascular disease (21).

On gross examination, papillary adenomas appear as very small yellow to pale gray spots in the renal cortex. Recently, Grignon and Eble (88) proposed a constellation of three histologic features to assist in identifying these lesions. First, the cellular architecture must be tubular, papillary, or tubulopapillary in character. Second, the diameter of the tumor should measure less than or equal to 5 mm. Although certain slightly larger lesions may be adenomas, the chance of malignancy is greater with increased sizes. Third, the cells should not histologically resemble clear cell, chromophobe, or collecting duct RCCs. If these criteria are satisfied, the diagnosis of papillary adenoma can be made with greater confidence.

Renal Oncocytoma

Renal oncocytomas are distinct pathologic lesions associated with benign clinical courses. Although earlier reports suggest metastatic potential of certain

oncocytomas, these reports now are thought to have represented cases of chromophobe RCC, a similar but histologically different tumor not recognized at that time. Because chromophobe RCCs are known to metastasize, the distinction between oncocytomas and these carcinomas currently is important for therapeutic decisions and follow-up.

Oncocytoma and chromophobe RCC have many overlapping morphologic, histochemical, and ultrastructural features. Both are thought to arise from cells of the distal nephron (73,285). Some specific nuclear parameters such as binucleation or multinucleation or staining with an antimitochondrial antibody (113-1) can be valuable in distinguishing between the two tumors (252,253). Characteristically, the cytoplasm of oncocytoma cells is uniformly eosinophilic and granular, whereas that of chromophobe RCC is more variable. Both tumors exhibit chromosomal loss on chromosomes Y and 1, but recent research with oncocytomas has revealed a unique recurring chromosomal translocation about 11q13, in proximity to the BCL1 locus, that may serve as a marker for improved classification (167,224).

Oncocytomas are thought to account for 3% to 7% of solid renal tumors (136). They are approximately two times more common in males than in females. Most often, they are discovered as incidental findings on radiographic studies performed for other reasons. Occasionally, oncocytomas present with flank pain, hematuria, or an abdominal mass, but they usually are asymptomatic. The median age of patients at presentation is in the seventh decade, which is slightly older than for RCC.

On gross appearance, oncocytomas (Fig. 16.1) are a tan-brown color and are well circumscribed from surrounding renal parenchyma. Often, a central scar highlights the neoplasm. Necrosis and hemorrhage are not prominent. Although most oncocytomas are unilateral, approximately 4% to 6% are bilateral (46). Histologically, the cells show regular granular cytoplasm due to numerous mitochondria and uniform nuclei with few mitoses. Cases of oncocytosis with innumerable oncocytic nodules throughout the kidney and associated with one dominant tumor have been reported (254). Coexistence of oncocytoma with RCC also has been described in up to 10% of cases (46).

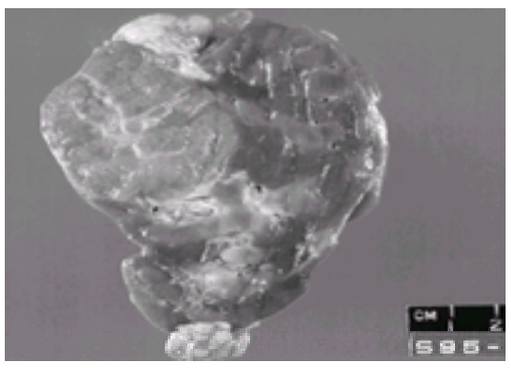

FIGURE 16.1. Oncocytoma with characteristic central scar and demarcation from surrounding renal tissue.

Radiographic studies rarely are diagnostic for oncocytoma because it often appears as any other solid renal tumor. Occasionally, a central scar is visualized on ultrasound studies or computed tomography (CT) scans, but this is nonspecific. Although angiography is now rarely performed for these tumors, a characteristic “spoke-wheel” appearance has been used to describe oncocytoma (273).

Due to lack of a pathognomonic radiographic sign, the diagnosis of oncocytoma rarely is made without an operation. The potential presence of concurrent malignant tumors within oncocytoma makes diagnosis by percutaneous needle biopsy risky. Partial nephrectomy with an adequate margin is the surgical therapy of choice for small tumors, but large or multifocal tumors may require radical nephrectomy for complete excision.

Metanephric Adenoma

Metanephric adenoma is a recently recognized benign epithelial tumor. In a report of 50 cases, investigators concluded that it occurs most commonly in the fifth to sixth decades, with a 2:1 female predilection (44). Some of these tumors present with symptoms of polycythemia, flank pain, mass, or hematuria; however, approximately half are incidental findings on radiographic studies.

Metanephric adenomas characteristically range in size from 3 to 6 cm, with occasional reports of larger tumors (44). The tumors are well circumscribed with a gray, tan, or yellow color and occasional foci of hemorrhage and necrosis (115). Cysts may also be present. Calcifications, represented histologically by Psammoma bodies, are common. Cells are tightly packed and uniform with prominent nuclei and scant cytoplasm (88). Mitoses are rare or absent. Adherence to these histologic criteria will avoid having other, more common renal lesions misdiagnosed as metanephric adenomas (182).

Differentiation of metanephric adenomas from other renal tumors by ultrasound or CT scans is difficult (60). Although no known case has recurred following removal of the tumor, synchronous RCC has been found in several isolated specimens (45). Therefore all solid lesions of the kidney should be treated as malignant unless proven otherwise with tissue diagnosis.

A variant of metanephric adenoma has been termed *metanephric adenofibroma.* In one of the first descriptions, Hennigar and Beckwith (98) reported several tumor cases with an epithelial component identical to metanephric adenoma along with a spindle cell component similar to congenital mesoblastic nephroma. (They originally termed this new tumor a *nephrogenic adenofibroma,* but given its similarity to metanephric adenoma, the name was later modified to metanephric adenofibroma.) The combination of both histologic components is necessary for the diagnosis of metanephric adenofibroma, but careful sampling may be necessary to avoid missing small epithelial nodules (214). Patients with metanephric adenofibroma have ranged in age from 3.5 to 36 years, younger than most patients with metanephric adenomas, and appear to have a benign course.

MALIGNANT EPITHELIAL TUMORS

Renal Cell Carcinoma

Epidemiology

Malignant tumors of the kidney are estimated to represent approximately 2.5% of all new cancer cases in the United States each year. Statistical analysis showed that, for the year 2000, approximately 31,000 new cases and 12,000 deaths would occur (87). Most of these diagnoses are related to malignant renal epithelial tumors, or RCCs, which comprise approximately 85% of all renal neoplasms (161). Males show more than twice the incidence of females in studies of RCCs, with most patients presenting in the seventh and eighth decades of life. The highest rates occur in North America and Europe, especially Scandinavia (161).

Over the past several decades, both the incidence of diagnosis and numbers of related deaths for RCC have risen in the United States and other countries (34). This parallels higher numbers of incidentally discovered tumors found during radiographic screening studies performed for the diagnosis and management of other disorders. Routine ultrasonography, CT, and magnetic resonance imaging (MRI) now discover increased numbers of small lesions in the absence of symptoms (113,251). However, most epidemiologists do not believe that these incidental tumors fully explain the rising incidence of renal cancer (34).

Aside from the rise in small, early-stage kidney tumors, there has also been a smaller percentage increase in the number of higher-stage lesions found (33). This expanding discovery mirrors the overall rising mortality rates that have been observed in recent years. In the United States, these changes are most evident in the African American population, which shows greater increases in both incidence and mortality for RCC when compared with Caucasians (34). The reasons for this racial difference are unclear.

Etiology

Based on information from case-control, genetic, and cohort studies, several risk factors have been associated with the development of RCC (Table 16.2). Most studies with sufficient sample size demonstrate a positive correlation between RCC and smoking cigarettes, which has been associated with up to a 35% increase in risk (282). The data suggest a dose-response relationship, with relative risk increasing with the numbers of cigarettes smoked, as well as a significant reduction in risk associated with cessation. Obesity also has shown positive associations with RCC (33). Greater risk exists for women with elevated weight than for their male counterparts, and the risk appears proportionate to the severity of obesity (161). With its increasing prevalence in the United States, obesity may contribute to the rising incidence of RCC.

Cigarette smoking	Occupational exposures (e.g.,
Hypertension	asbestos, petroleum,
Elevated body weight	cadmium, lead)
Medications (e.g., diuretics)	Genetic predisposition (e.g.,
Acquired renal cystic disease	von Hippel-Lindau disease)

TABLE 16.2. SELECTED RISK FACTORS ASSOCIATED WITH RENAL CELL CARCINOMA

Several epidemiologic studies link hypertension to elevated risks for RCC, with up to a threefold increase in risk reported (33). Diuretics, which often are used in the medical treatment of hypertension, have been particularly implicated (89,213). Acquired cystic disease, found in renal failure patients on hemodialysis, has been associated with higher rates of RCC (110,111). Occupational exposure to asbestos, petroleum, cadmium, and lead also has been reported to produce increased levels of risk (33).

Although relatively rare, familial cases of RCC have been linked to genetic causes. von Hippel–Lindau (VHL) disease, an autosomal-dominant genetic disorder, has long been associated with the development of RCC. The condition is characterized by hemangioblastomas of the retina and the central nervous system, especially the cerebellum, as well as cysts of the kidneys, liver, and pancreas. Pheochromocytomas also have been linked to the syndrome (69). Renal tumors in these patients tend to be small, multifocal, and bilateral.

Pathology and Molecular Genetics

Although collectively termed RCCs, malignant renal epithelial neoplasms are now subdivided under the new classification system, based on prominent morphologic features (239). However, in the past, pathologists long debated the varied histologic appearance of RCC. Of particular note, in the nineteenth century, Grawitz and others advanced the idea that these tumors were derived from malignant transformation of adrenal rest cells within the kidney. This belief led to later use of the term *hypernephroma,* first used to symbolize origin from cells above the kidney but now recognized as a misnomer to describe these tumors (116). Today, investigators know RCCs originate from renal tubular cells.

Although early study was limited to gross structural or numeric chromosomal alteration, investigators later discovered that discrete and specific loss of gene product from somatic cells could be linked to the origination and evolution of certain cancers (Table 16.3). Such thorough cytogenetic analysis of both sporadic and familial forms of RCC helped localize areas of suspect genetic alteration. In a particular major breakthrough, Seizinger and colleagues initially mapped the VHL gene to the short arm (3p25) of chromosome 3 (211).

Tumor	Affected Chromosomes
Conventional (clear cell) RCC	3p, 17
Papillary RCC	3q, 7, 12, 16, 17, 20, Y
Chromophobe RCC	1, 2, 6, 10, 13, 17, 21
Collecting duct carcinoma	1q, 6p, 8p, 13q, 21q

RCC, renal cell carcinoma.

TABLE 16.3. LOCATION OF POTENTIAL CHROMOSOMAL CHANGES IN RENAL CELL CARCINOMA

In one study, researchers noted VHL gene mutations in 57% of patients with sporadic RCC and confirmed its potential involvement with tumorigenesis of that entity (79). Further research has demonstrated that multiple mechanisms of VHL gene mutation, including methylation, deletion, insertion, transition, and transversion, are responsible for the phenotypic variability of the syndrome (79,99). Meanwhile, others have chosen to focus on the inhibitory function of the VHL gene. Current theory proposes that the VHL protein plays a role in tumor suppression by modulating a transcription elongation complex, elongin or SIII, and negatively regulating the accumulation of vascular endothelial growth factor (VEGF) (109,219).

Concurrent with the ongoing research of the VHL protein, there were multiple reports of chromosomal deletions in the same region (3p) with sporadic forms of RCC. Since the late 1980s, the loss of loci on the short arm of chromosome 3 has been the predominant mutation linked to clear cell carcinoma (Fig. 16.2), the most common subtype of RCC (67,284). Increasing focus on a cohort of sporadic tumors identified 86% of cytogenically examined specimens as having a detectable anomaly distal to band 3p11.2-p13 (124). Allelic loss of 3p now is thought to be an early event in the pathogenesis of clear cell carcinoma, whereas others now consider additional allelic losses on chromosome 17 to be associated with the advanced disease.

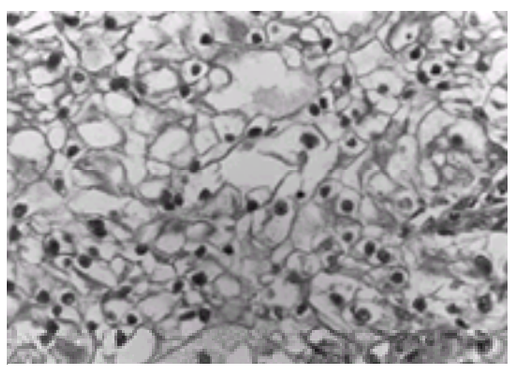

FIGURE 16.2. Histologic appearance of conventional (clear cell) renal cell carcinoma.

Among 60 nonpapillary RCCs studied at Memorial Sloan-Kettering Cancer Center, a significant correlation associating the deletion of chromosome 17p with tumor grade, pathologic stage, and nodal metastasis has been seen (188). Whether deletions of 3p occur in all renal cell cancers is under scrutiny, and many other chromosomal aberrations have been identified. Research to date shows that 3p genomic changes are conspicuously absent from the papillary variant of RCC and therefore reinforces the linkage between genes and representative histology.

Representing 10% to 15% of all renal cell cancers, the papillary carcinoma variant can be inheritable, multifocal, and bilateral, but generally suggests a more favorable prognosis. Long differentiated through immunohistochemistry, papillary RCC has distinct cytogenetic character, associated with loss of the Y chromosome along with trisomies of chromosomes 3q, 7, 12, 16, 17, and 20 (239). Recent research on those affected by hereditary papillary renal carcinoma implicates mutations, activating the MET protooncogene, to chromosome 7q31.1-34 (210). Investigators continue to propose that mutations in the MET protooncogene render the cells more susceptible to errors in chromosomal replication resulting in nonrandom duplication, a proliferative advantage, and the frequent occurrence of trisomy (286).

Chromophobe RCC accounts for approximately 5% of malignant renal epithelial tumors (239). Histologically, they are composed of two distinct cell types, those with granular eosinophilic cytoplasm and those with pale cytoplasm. Ultrastructural analysis shows numerous cytoplasmic microvesicles, and characteristic cytoplasm staining with Hale's colloidal iron is typical (42). Microscopic similarities exist between chromophobe RCC and oncocytoma, although distinctive nuclear features, including wrinkled “raisinoid” nuclei with frequent binucleation and perinuclear clearing are helpful in distinguishing between the two (253). A clinical analysis of patients with chromophobe carcinoma shows that the majority of tumors appear to be localized to the kidney at the time of diagnosis, but clinical behavior seems to be similar to respective stages of clear cell carcinoma (42). Large tumors and those with synchronous papillary carcinoma may be particularly prone to metastasis (192). DNA aneuploidy, especially hypodiploidy, is seen in the majority of cases with noted monosomy of different chromosomes (1,6,10,13,17,21,184) (239).

Collecting duct carcinomas represent a rare group of renal neoplasms. Unlike clear cell carcinoma, they arise from the distal portion of the nephron, commonly strike in a young population, and carry an unusually poor prognosis. Application of the aforementioned chromosomal inspection has discovered a frequent loss of heterozygosity at chromosome regions on 1q, 6p, 8p, 13q, and 21q (184). High density mapping of arm 1q in 13 collecting duct tumors shows an area of minimal deletion around the area located at 1q32.1-32.2 in 69% of the examined specimens (238). Considering these data together gives credence to the idea of a potentially unique set of molecular events in tumorigenesis, different from that of clear cell carcinoma.

RCC, unclassified, is a category reserved for malignant epithelial tumors that do not conform to any of the other subtypes. Of the total group of RCCs, they comprise approximately 4% to 5% (239). Specifically, composites of recognized subtypes, tumors with mucin production, and tumors with extensive sarcomatoid changes without recognizable epithelial elements are examples of this classification.

Pathologic grading of tumor cells has been shown to have prognostic value in cases of RCC (233). Several grading systems exist, although most pathologists rely on nuclear grading for renal lesions. The Fuhrman nuclear grading system is the most widely used in North America, and several studies confirm its relevance for prognosis (82). Nonetheless, all grading is subjective, and problems with standardization are recognized (154).

Clinical Presentation

Significant variability exists in the clinical presentation of RCC. However, a significant number of lesions are not discovered until reaching an advanced stage because small tumors isolated to the kidney are often asymptomatic. Aside from local symptoms produced by the tumor itself, a variety of systemic manifestations have been described. Therefore the clinician must be familiar with some of the extrarenal manifestations and must harbor a high suspicion for diagnosis. Although a classic triad of symptoms (pain, hematuria, and flank mass) has been associated with RCC, all three symptoms rarely are present together (150). Single symptoms occur much more frequently. Hematuria often is listed as the most common symptom, occurring in up to 60% of patients (161). Nonspecific symptoms such as fever, malaise, weight loss, and night sweats are also common. Occasionally, a varicocele from compression or obstruction of the testicular vein is found.

Few other disease entities possess such a propensity for paraneoplastic syndromes as RCC (Table 16.4). Erythrocytosis, anemia, hypercalcemia, hypertension, acute hepatic dysfunction, and amyloidosis all have been associated with renal cancer (150) and sometimes have been the hallmark features at presentation. Questions remain regarding which signals, substances, or cytokines initiate the manifesting signs and whether these are markers for prognosis or recurrence.

Erythrocytosis	Acute hepatic dysfunction
Anemia	Amyloidosis
Hypercalcemia	Thrombocytosis
Hypertension	

TABLE 16.4. PARANEOPLASTIC SYNDROMES ASSOCIATED WITH RENAL CELL CARCINOMA

Several blood and serologic markers have been evaluated, and many have potential utility. Serum ferritin levels have been shown to be significantly elevated and higher than controls when looking at patients with RCC. In this group of patients, a statistically significant increase with advancing stage exists (57). Erythropoietin also can be elevated, presenting in as many as 63% of patients (242). More routine laboratory studies, including hematocrit and platelet levels, can likewise prove credible in regards to prognosis. In a series of stage IV tumors, patients with a normal platelet count had a mean increased survival of 59 months over those with thrombocytosis (platelet count more than 400,000) when controlling for pathologic stage, nuclear grade, and cell type (245). Others point to anemia and serum iron as useful tumor markers for initial evaluation and in follow-up (281). Anemia is the most common hematologic abnormality associated with RCC. Characteristically normocytic, normochromic anemia of chronic disease has been implicated. Following tumor resection, the anemia has usually resolved and some have shown that disease progression coincided with recurrent anemia (86,281).

Hypercalcemia has been associated with RCC and, like anemia, often resolves after removal of the primary tumor. Some elevation in serum calcium will be seen in 10% of patients. Experience shows that recurrent hypercalcemia can be an early sign of undetected skeletal metastasis or herald secondary sites that secrete an inciting humoral factor. Although parathyroid hormone–related protein (PTHrP) has been linked to the syndrome of humoral hypercalcemia of malignancy and has been detected in more than 95% of RCC, no significant correlation was identified when observing intensity of immunostaining of PTHrP and serum calcium levels (84).

Hypertension has been identified in many patients with RCC. A patient may be hypertensive as a consequence of hypercalcemia, but other factors such as polycythemia, arteriovenous fistulae, ureteral obstruction, or renin secretion may be responsible. Sufrin and colleagues noted that the elevated levels of renin were associated with high-stage renal tumors and hypertension (241). In fact, renin secretion is a known characteristic of RCC (103) but lacks specificity, because renin production has been reported with other cancers as well (55).

Acute elevation of liver enzymes (Stauffer's syndrome) has been described with certain cases of RCC (236). The majority of these cases show no evidence of hepatic metastasis from the tumor (19). Moreover, the enzymes often return to normal levels following removal of the renal lesion. Failure of liver function to return to normal has been significantly correlated with decreased survival (66). Recent work has shown that elevated liver enzymes, as well as other paraneoplastic syndromes, may be related to increased systemic levels of interleukin-6 (15,268).

Radiographic Diagnosis

The revolutionary improvements in radiographic diagnosis have radically changed the preoperative, intraoperative, and follow-up investigation of renal lesions. Standard historic, radiographic evaluation consisted of a chest x-ray film, intravenous (IV) pyelography, renal angiography, and possibly, bone scintigraphy. However, radiologists increasingly discover renal lesions incidentally through the newer modalities of ultrasonography, CT, or MRI while pursuing other suspected diagnoses. Although some may consider the plain film dated, one must recognize that 10% of RCCs will contain calcium and be detectable on abdominal plain films (112). Besides abdominal films, a chest radiograph has significant use and is a cost-effective tool for follow-up examination.

Intravenous Pyelography

Although there have been recent shifts away from excretory urography toward new imaging modalities, the intravenous pyelogram (IVP) remains a standard evaluation of the upper tracts for hematuria. On this study, renal masses may produce changes in the nephrogram and/or distortion of the collecting system. Occasionally, calcifications are present and also may be suggestive of a mass (133). The main limitation of IVP is its low sensitivity for small lesions compared with other studies (270). In addition, poor technique may lead to missed lesions altogether.

Angiography

Currently, angiography rarely is used in the initial diagnosis of renal masses, which historically show marked hypervascularity on angiogram. This study has been replaced almost completely by less invasive modalities such as CT and MRI. Nonetheless, angiography still proves useful for surgical planning in certain cases of partial nephrectomy.

Ultrasound

Recent reviews show that in as many as two-thirds of patients with localized RCC, lesions are found fortuitously on ultrasound examination (4). Moreover, incidentally detected tumors are of a lower stage than the comparative symptomatic lesions and result in improved survival (122,187). Noninvasive and cost-effective, ultrasound has inherent advantages. Echogenic criteria are well described and categorized to differentiate simple lesions from complex lesions with malignant potential. The sensitivity of sonography exceeds that of IVP in detecting small renal lesions, but both fall short of CT in relation to lesions less than 2 cm (270). Although descriptive, echogenic features unreliably determine histology. Recent attempted modifications, such as digitization with measuring of the grayscale (221) and Doppler vascularity determinations (119), have provided little absolute data on differing histology.

Real-time dynamic imaging capability does allow for intraoperative sonographic assessment of deep parenchymal lesions (i.e., difficult to palpate), tumor extension into adjacent structures, and pathology with uncertain preoperative staging (185). With the expanding role of nephron-sparing surgery and partial nephrectomy, intraoperative ultrasonography helps determine the boundaries of resection, multicentricity, venous extension, and associated cysts that may not be appreciated with visual inspection or preoperative radiographic evaluation (28,146).

Transabdominal ultrasound has been used to assess the inferior vena cava (IVC) for tumor extension in those undergoing radical nephrectomy. Recently, intraoperative ultrasound has been used to help clarify preoperative findings at the time of surgery (96,138). Newer ultrasound studies including color-flow Doppler and transesophageal echocardiography (TEE) also have proved valuable for diagnosis. Even when a tumor extends beyond the proximal cava or renal vein, TEE facilitates the identification of tumor thrombus migration and air embolization, allowing for immediate intraoperative intervention (220). Color-flow Doppler has been used for cases of equivocal CT scans and has shown excellent accuracy for caval tumor (91,121,220,256).

An occasional diagnostic dilemma involves the identity of a renal cystic lesion by ultrasound. Bosniak developed a classification system for standardizing such lesions and identifying those with higher risk for malignancy (18). In a review comparing Bosniak classification with confirmed pathologic diagnosis, Seigel and colleagues found the incidence of malignancy with Bosniak I, II, III, and IV lesions to be 0%, 13%, 45%, and 90%, respectively (218a). One limitation of the Bosniak classification, which has been extended to cysts found by CT, is its subjectivity.

Computed Tomography

CT has distinct advantages over ultrasound and other modalities. Physicians can rapidly measure cyst densities, gain relational perspective between organs, and provide tumor staging with improving accuracy. New generation, multiphasic helical scanners enable greater detection of lesions, particularly small renal tumors, and foster a more thorough understanding of the capability. In contrast to conventional CT, helical scanning eliminates respiratory misregistration, and rapid acquisition allows for comparison of identical levels obtained before and after contrast. This is helpful in assessments of tumor extension into the renal vein (274). For maximum sensitivity, research shows that the differentiation of attenuation between a lesion and normal renal parenchyma is greatest during the nephrogenic phase, just before excretion of contrast into the collecting system, and not during the corticomedullary phase (39,246). Helical CT technology permits the production of detailed, high-quality three-dimensional (3D) reconstruction in a format remarkably similar to actual parenchymal, vascular, and adjacent structural anatomy. In one study, preoperative staging with 3D helical CT accurately depicted the pathologic character in 95 of 97 tumors; almost all of the renal arteries (96%) and renal veins (93%) were detected (40). Using these data obtained preoperatively readily simulates the surgical perspective and has proven a useful adjunct in nephron-sparing surgery (228,229).

For such reasons, CT has become the preferred method for staging of RCC (Fig. 16.3). Although the patient must ingest oral contrast and receive IV contrast, the procedure has less inherent risk than angiography and provides the surgeon with superior information (201). With CT, one can better define the regional extension of the mass through the renal capsule or into adjacent organs, such as the liver or colon, and detect lymph node and distant visceral metastatic disease. Regarding venous involvement, Lang first reported the efficacy of CT scanning in evaluating extension into the renal vein and vena cava in comparison with angiography and sonography (131). CT has been criticized for its inability to identify the true cephalad extension of tumor thrombus, especially in the intrahepatic vena cava, but the advent of 3D reconstruction has added benefit in the detection of small accessory renal arteries and unusual venous branches (Fig. 16.4). Some suggest comparable vascular anatomic detail and even superior accuracy in relation to arteriography (40). Such data will only further reduce the indications for angiography in the evaluation of renal lesions.

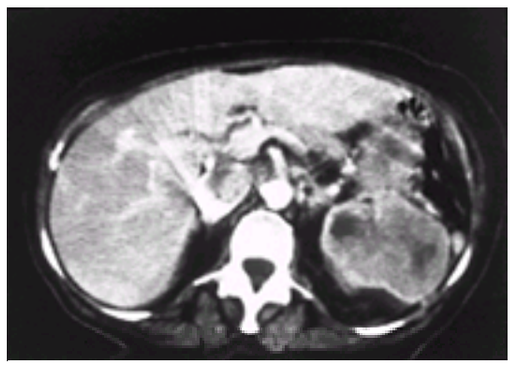

FIGURE 16.3. Axial view of computed tomography scan demonstrating large left renal mass. Also note contrast-filling defect in vena cava from associated tumor thrombus.

FIGURE 16.4. Three-dimensional computed tomography reconstruction view demonstrating excellent anatomic detail of left renal mass.

Magnetic Resonance Imaging

Currently, physicians use MRI in situations in which the patient has preexisting medical conditions such as renal insufficiency or a serious contrast allergy that preclude the administration of contrast material. MRI historically has held an advantage to CT in evaluating renal lesions because it depends less on technique and the first modality capable of multiplanar imagery. RCC appears heterogeneous on T_1-weighted images and then typically becomes hyperintense when compared with normal parenchyma on T_2-weighted images. Spin-echo sequences are used to assess venous involvement.

In particular, MRI has been extremely useful in assessing vascular invasion (Fig. 16.5) by RCC (80). Specifically, MRI is noted for its accuracy in assessing superior extent of tumor thrombus (240). It also delineates the tumor within the cava even when there is total caval occlusion. The modern addition of gradient-recalled echo (GRE) sequences enhances the detail, reducing flow and respiratory motion artifact, and facilitates precise localization and more confident detection of thrombus. In a 1992 study, caval thrombus was identified correctly in 13 of 13 (100%), renal vein thrombus in 23 of 26 (88%), and right atrial thrombus in 4 of 5 (80%) patients (200). In general, MRI remains the preferred study for caval assessment.

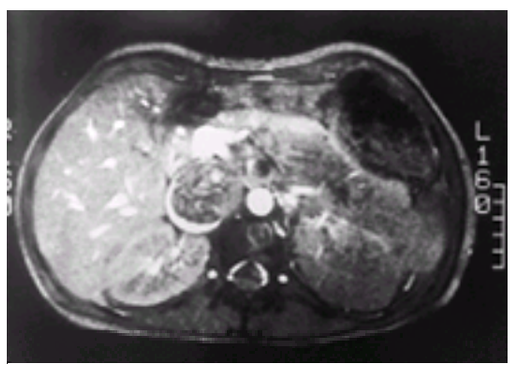

FIGURE 16.5. Axial magnetic resonance imaging view showing left renal mass with caval extension and surrounding contrast material.

Relatively long test time, high cost, obese body habitus that prohibits entry into the scanner, and ferro-magnetic prostheses or subcutaneous metallic foreign bodies are the current obstacles to MRI. Technology is advancing rapidly with open scanners and improving technical software. Much like CT angiography, researchers are using three-dimensional dual-phase MRI with gadolinium in the preoperative staging of renal carcinoma. Of the 18 patients enrolled in a prospective study, 30 of 31 (97%) surgically confirmed renal arteries were detected on preoperative scanning (35).

Positron Emission Tomography

Positron emission tomography (PET), like MRI, is another emerging noninvasive technology with potential applications to staging and detecting tumor recurrence. PET uses select endogenous substances with positron-emitting radioisotopes that accumulate in known sites of biologic activity. The most common radiotracer, 18-fluoro-2-deoxyglucose (FDG), resembles endogenous glucose and readily accumulates in the brain and myocardial tissue due to tissue demand. The renal tubules are unable to reabsorb FDG following filtration, and tracer detection consequently is prominent in the kidneys and bladder as well. In addition to these areas of resultant high uptake, malignant tumor foci generally possess a high rate of glycolysis and can be isolated on whole body imaging.

In one of the few studies that applied FDG PET scanning to RCC, Bachor and colleagues found that FDG PET detected 20 of 26 histologically confirmed renal tumors. Six cases failed to note the tumor focus, and three benign lesions were deemed falsely positive for malignancy (8). These data suggest some limitations with the modality. However, 10 of 10 patients with known progressive RCC in another study had their active metastasis identified with PET, whereas conventional modalities noted only an increasing lesion in 7 of the 10 (102).

FDG allows for detection of small malignant nodes not meeting the pathologic size criteria of CT scanning. Moreover, PET also may prove superior to CT or MRI in situations where postsurgical anatomy or artifactual distortion due to surgical clips decrease the sensitivity and specificity of those examinations (264). Technical considerations such as bowel preparation, IV bolus hydration, bladder irrigation, furosemide washout, procedural length, and cost limit PET to select clinical and investigational situations.

Staging

Staging, like histologic classification, has undergone several modifications to better characterize renal tumors and to establish some prognostic information. In the 1960s, Robson (194) improved the earlier work of Flocks and Kadesky (66a), and his system formed the basis of staging in the following several decades (Fig. 16.6). However, this arrangement suffered prognostically by grouping tumors with renal vein involvement alone, with vena cava involvement, or with lymph node involvement all within the third stage. As a result, this classification basically has been replaced by the tumor, node, and metastasis (TNM) system proposed by the International Union Against Cancer in the 1990s (10).

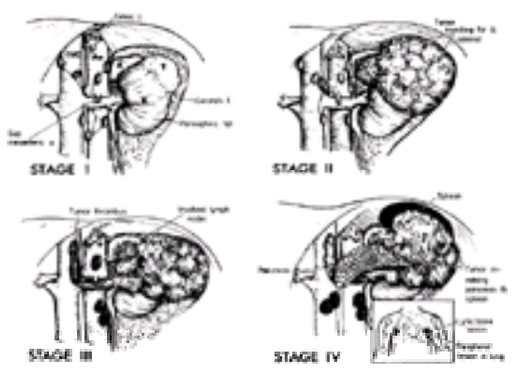

FIGURE 16.6. Robson staging classification of renal cell carcinoma.

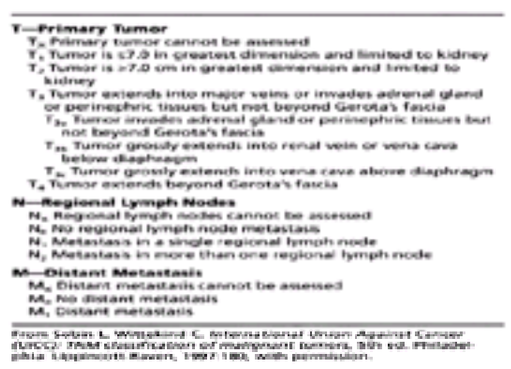
In 1997, the TNM system was further revised, as listed in Table 16.5 (230). Analysis of the first classification of tumor stages revealed little difference in survival between T_1 and T_2 lesions when the distinction was tumor size reaching 2.5 cm (90,250). Therefore the discriminating size between T_1 and T_2 lesions was changed to 7.0 cm in the tumor's greatest dimension. Analysis of this change shows that the new system permits better stratification of cases according to survival, thereby increasing its clinical use (112,157).



T—Primary Tumor
- T_x Primary tumor cannot be assessed
- T_1 Tumor is ≤7.0 in greatest dimension and limited to kidney
- T_2 Tumor is >7.0 cm in greatest dimension and limited to kidney
- T_3 Tumor extends into major veins or invades adrenal gland or perinephric tissues but not beyond Gerota's fascia
  - T_{3a} Tumor invades adrenal gland or perinephric tissues but not beyond Gerota's fascia
  - T_{3b} Tumor grossly extends into renal vein or vena cava below diaphragm
  - T_{3c} Tumor grossly extends into vena cava above diaphragm
- T_4 Tumor extends beyond Gerota's fascia

N—Regional Lymph Nodes
- N_x Regional lymph nodes cannot be assessed
- N_0 No regional lymph node metastasis
- N_1 Metastasis in a single regional lymph node
- N_2 Metastasis in more than one regional lymph node

M—Distant Metastasis
- M_x Distant metastasis cannot be assessed
- M_0 No distant metastasis
- M_1 Distant metastasis

TABLE 16.5. TUMOR NODE METASTASIS CLASSIFICATION FOR RENAL CELL CARCINOMA (1997)

Therapy

The only consistently successful therapy for RCC to date has been surgical treatment for local, locally advanced, and minimally metastatic disease. Nonetheless, case reports of spontaneous tumor regression suggest that the malignancy may be susceptible to immune attack. This consideration, combined with new insights into molecular biology, has spawned significant research into potential immunotherapy for renal tumors. Unfortunately, although some regression has been seen in selected cases, complete response rates remain low. Likewise, both chemotherapy and radiotherapy demonstrate little success in treating this relatively resistant tumor. As the human genetic code is unraveled, clues into the genetic abnormalities of patients with RCC will provide directions for new research that may yield new forms of treatment.

Radical Nephrectomy

The traditional gold standard therapy for patients with localized RCC and a normal contralateral kidney is the radical nephrectomy. This includes removal of the tumor-containing kidney and perirenal tissue within Gerota's fascia (Fig. 16.7). Theoretically, this encompasses the ipsilateral adrenal gland, although the issue of concomitant adrenalectomy often is debated. The question of whether to remove the lymph nodes draining the kidney at the time of nephrectomy is also controversial.

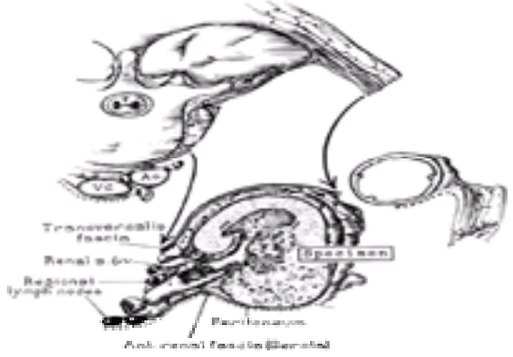

FIGURE 16.7. Radical nephrectomy specimen. Ao, aorta; VC, vena cava. (From Marshall FF. Radical nephrectomy: flank approaches. In: Marshall FF, ed. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:249, with permission.)

In 1869, the first elective nephrectomy was reportedly performed by Gustav Simon to treat a refractory ureterovaginal fistula (158). Removal of the tumorous kidney followed and the method was further developed in the twentieth century. Simple nephrectomy alone for cancer has fallen out of favor and currently is not recommended.

In 1963, Robson described a classic series in which he reported a 66% 10-year survival rate following radical nephrectomy for RCC (195). He attributed this excellent survival rate to early ligation of the renal pedicle and broader removal of the kidney with surrounding tissue, including perinephric fat and lymph nodes, from the crus of the diaphragm to the bifurcation of the aorta. Despite the small number of patients in this particular series, Robson continued to accrue patients for further reports (194) and can be credited with popularizing the concept of radical nephrectomy.

The kidney can be approached through several different incisions because of its location in the retroperitoneum. The urologic surgeon should be familiar with these different approaches and consequently tailor the operation to the individual patient while considering size of the tumor, location of the tumor within the kidney, and body habitus of the patient. Sometimes, the pleural and/or peritoneal cavities are entered as part of the nephrectomy procedure; often, neither of these spaces are violated. The choice of incision depends on the individual surgeon and hospital center, but currently, the most often used approach is the extraperitoneal flank incision. However, all approaches have two basic requirements: early ligation of the renal pedicle and adequate margins of tumor resection.

For the flank incision, the patient is placed in the lateral position with the operating table in the flexed position and the kidney rest elevated. The surgeon usually makes the incision over the eleventh or twelfth rib, and occasionally removes part of the rib to facilitate exposure. The goal is to stay in the extraperitoneal space and to avoid the potential complications of entering the peritoneum. Disadvantages include relatively more postoperative pain from incision of the flank muscles and the risk of pneumothorax from inadvertent entrance into the pleural cavity. Nonetheless, the flank approach provides excellent access to the renal fossa and is especially useful for small, localized tumors.

The transperitoneal approach has been used since the time of early nephrectomies. At that time, there were significant complications of postoperative, often fatal, infections of the peritoneal space; however, these are rare with modern antibiotics. Today, the midline upper abdominal incision and the chevron incision are the most commonly used transperitoneal approaches. Advantages of these include easy identification of the renal pedicles and the ability to examine the abdominal organs. Moreover, the chevron incision permits much easier access to larger tumors. Disadvantages include poor exposure of the upper lateral quadrants with the midline incision and potential for ileus and intestinal adhesions.

The thoracoabdominal incision (Fig. 16.8), popularized by Chute, provides excellent exposure of upper pole tumors but involves entering the pleural space and, usually, the peritoneal cavity (37). With this approach, there is excellent exposure of the vena cava, so many surgeons prefer it for accessing tumors with caval

thrombus. Entry into the chest cavity also allows for removal of any concomitant metastatic lung lesions, if necessary. A chest tube is required postoperatively.

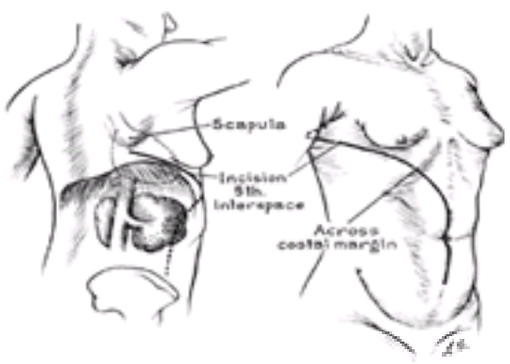

FIGURE 16.8. Thoracoabdominal incision. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena caval tumor thrombus. In: Marshall FF, ed. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:265, with permission.)

Few surgeons use the subcostal incision for radical nephrectomy. Although this incision avoids the risk of unintentional entry into the pleural space, it generally provides relatively poor exposure of the kidney if the approach is kept extraperitoneal. Nonetheless, the benefit of examination of abdominal organs is possible if the incision is carried transperitoneally.

Lymphadenectomy

It has been established that RCC spreads through lymphatic routes. Studies have reported an approximate 20% to 25% average incidence of positive retroperitoneal lymph nodes when the nodes are sampled at the time of surgery (234). In 1935, Parker reported on the lymphatic drainage of the kidney. Based on his work, there are noted differences between lymphatics of the left and right kidneys (177). The left kidney most often drains to paraaortic nodes in the lumbar region, whereas the right kidney drains primarily to the interaortocaval and paracaval nodes (Fig. 16.9). These patterns have important implications when performing lymphadenectomy of nodes draining the kidney (147). One must also consider that anomalous vasculature and retroperitoneal processes, such as large tumors, ureteral obstruction, and caval extension, can alter these diagrammed routes.

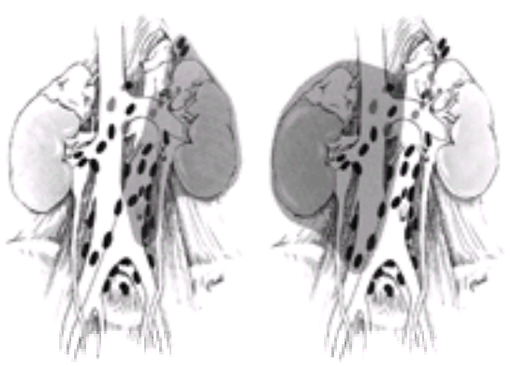

FIGURE 16.9. Lymphatic drainage patterns of the kidneys. (From Marshall FF, Powell K. Lymphadenectomy for renal cell carcinoma: anatomical and therapeutic considerations. *J Urol* 1982;128:677, with permission.)

In 1963, Robson suggested that extended lymphadenectomy at the time of surgery would be beneficial in terms of survival (195). Since that time, several others have advocated the removal of nodes found in the drainage pattern of the kidney as a means of preventing tumor spread. However, the question of whether to remove nodes at the time of nephrectomy remains a controversial issue (181). In essence, all debate focuses on whether the benefits of the added procedure outweigh its risks. Currently, little data exist on patients prospectively randomized to receive nephrectomy with lymphadenectomy versus nephrectomy alone. Preliminary data from a randomized trial sponsored by the European Organization for Research on Treatment of Cancer (EORTC) showed little difference in disease progression between the aforementioned two groups (16,17).

Both proponents and opponents of lymphadenectomy make significant points. Those favoring lymphadenectomy in combination with nephrectomy argue that removal of nodes for pathologic examination will assist with true staging of the tumor and therefore may have prognostic implications. In addition, removing nodes may prove curative by excising metastatic spread along with the primary tumor and consequently improving survival rates. Those against lymphadenectomy argue that distant, often blood-borne metastases, for which lymph node excision provides no therapeutic benefit, occur commonly in advanced RCC (114). Moreover, considering the frequently aberrant distribution of lymph nodes draining the kidney, the removal of retroperitoneal nodes does not guarantee complete removal of lymphatic metastases. Studies that report increased survival with lymphadenectomy are limited by cohort size, lack of standardization, and retrospective analysis (234).

The extent of dissection when performing lymphadenectomy varies between individual surgeons. Limited regional dissection of the hilar nodes will have a much higher false-negative rate than will an extended retroperitoneal dissection. Until a prospective, randomized study with strict protocol regarding extent of node dissection is completed, the role of lymphadenectomy in RCC will be questioned.

Adrenalectomy

Available series report that the incidence of ipsilateral adrenal gland involvement in RCC ranges from 3.2% to 5.7% (202,206,212,257,266). Acknowledging this potential for adrenal involvement, Robson initially described ipsilateral adrenalectomy as part of the radical nephrectomy procedure (195). Recently, however, there has been considerable debate over the necessity of removing the adrenal gland at the time of nephrectomy (212,257,266). Reported benefits of avoiding adrenalectomy include lowered risk for adrenal insufficiency, preservation of adrenal tissue should the contralateral adrenal gland develop metastasis, decreased operative time, and decreased morbidity. Others point to studies showing that patients with adrenal involvement have a higher likelihood of positive lymph nodes or distant metastasis and therefore question the utility of excising the adrenal gland (202,212).

Research shows upper pole tumor location, left-sided tumors, and large tumors as risk factors for adrenal involvement in cases of RCC (202). Renal vein thrombosis also has been described as a risk factor (258). Most surgeons believe that extensive upper pole tumors, which have the propensity to spread to the ipsilateral adrenal gland by local extension, require adrenalectomy as part of the surgical procedure. However, tumors in the midpole and lower pole of the kidney also have shown adrenal gland metastasis, albeit in a much lower percentage; these tumors are thought to spread by hematogenous routes. Adrenalectomy also has been recommended when the adrenal gland contains a single metastatic lesion (212).

CT shows excellent sensitivity for adrenal lesions, and several investigators advocate its use to determine the need for adrenalectomy (75,193,206). Series report the negative predictive value of CT scans to be as high as 100% for adrenal abnormalities (257). Therefore a normal adrenal gland by CT scan makes the possibility of adrenal metastasis quite low. When abnormalities are detected, not all prove to be metastatic lesions because large tumors can cause displacement or poor visualization of the adrenal gland.

Overall, most studies report the yield of routine ipsilateral adrenalectomy at the time of nephrectomy to be quite low. As a result, many surgeons will avoid the adrenal gland in cases of small renal tumors not involving the upper pole. Certainly, those patients with risk factors for adrenal involvement can be identified preoperatively

with radiographic studies, acknowledging that some with microscopic disease may be missed by this method. However, careful follow-up on these patients should identify the development of any other new lesions.

Nephron-sparing Surgery

In 1950, Vermooten was one of the first to suggest the idea of removing only part of a kidney affected by tumor (263). Nonetheless, the standard therapy for renal tumors soon thereafter became radical nephrectomy (145). Nephron-sparing surgery was later revisited, primarily for patients with marginal renal function, bilateral tumors, or a solitary kidney. Long-term studies of nephron-sparing surgery and outcomes now exhibit results comparable with radical nephrectomy in terms of tumor recurrence and survival. As a result, many urologists now advocate the use of partial nephrectomy for patients with a normal contralateral kidney. Overall, nephron-sparing renal surgery now has an increasingly expanded role in the management of even the most difficult localized renal tumors.

Enucleation. Simple enucleation involves separating the pseudocapsule of a tumor from surrounding normal renal parenchyma and coring out the neoplastic tissue from the remainder of the kidney. The advantages of enucleation are its simplicity and minimal disturbance of the kidney, whereas its main disadvantage is the risk of leaving behind residual tumor. Approximately 20 years ago, two small series reported the success of enucleation with regards to renal tumors (30,85). Later investigation also showed enucleation feasible and successful in certain cases of well-circumscribed tumors (149,169). However, CT scans cannot always predict which tumors would be good candidates for enucleation. At this time, most surgeons do not recommend enucleation as a primary treatment for the majority of tumors but rather suggest partial nephrectomy. Nonetheless, in cases of VHL syndrome, where salvage of as much functional parenchyma as possible is preferable, enucleation remains an acceptable procedure.

Partial Nephrectomy. Standard partial nephrectomy differs from enucleation in that a normal rim of renal parenchyma is excised around the tumor specimen. While preserving renal tissue, partial nephrectomy also risks leaving tumor behind and therefore has risk of local recurrence. Studies report such recurrence to occur in approximately 4% to 8% of cases and attribute most instances to undetected multifocal tumors. Nonetheless, partial nephrectomy has proven to have disease-specific and overall survival rates comparable with radical nephrectomy.

The indications for partial nephrectomy have broadened over the years. Previous contraindications such as centrally located tumors (31) and tumors associated with normal contralateral kidneys (100) no longer prohibit consideration of nephron-sparing surgery. However, concerns regarding increased numbers of local recurrences with larger-sized tumors have led several investigators to suggest specific size limitations for the procedure. No consensus exists, but recent recommendations suggest elective partial nephrectomy only for tumors smaller than 2.5 cm (156) or tumors 4.0 cm or smaller (92).

The technique of partial nephrectomy (Fig. 16.10) most often involves the flank approach. Gerota's fascia and the overlying perinephric tissue are resected along with the tumor (186). In most instances, the renal vasculature is temporarily clamped to prevent significant bleeding during removal of the tumor. This requires cooling the kidney with ice slush to lessen chances of ischemic damage. Preoperative knowledge of the renal vasculature supplying the tumor allows for better surgical planning. Although this previously has been accomplished with angiography, newer, less invasive methods, such as 3D helical CT angiography, also are effective (228).

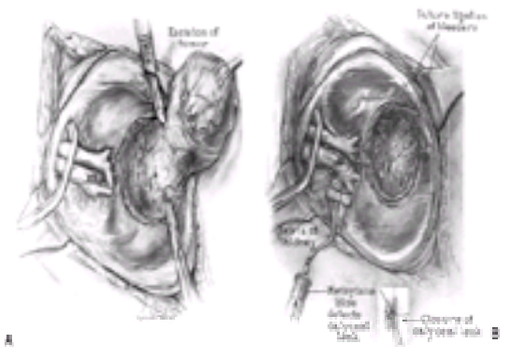

FIGURE 16.10. Technique of partial nephrectomy. **A:** Excision of the renal tumor after occlusion of the main renal vasculature. Vessels are ligated as encountered at the tumor base. **B:** Dye is injected into the collecting system to check for urinary leaks, which are then repaired. (From Marshall FF. Partial nephrectomy. In: Marshall FF, ed. *Textbook of operative urology.* Philadelphia: WB Saunders, 1996:274, with permission.)

Long-term follow-up of partial nephrectomy patients yields excellent survival rates. In a recent review of 485 patients at the Cleveland Clinic, overall and cancer-specific 5-year survival rates were 81% and 92%, respectively (92). Others also have shown excellent long-term tumor control with partial nephrectomy (261), and higher disease-free rates have been reported in patients with a normal contralateral kidney (100). Adequate selection of both individual patients and tumors appears to be the key to successful outcomes.

Cryotherapy. Cryosurgical ablation of renal tumors has received attention over the past few years as an *in situ* form of nephron-sparing surgery. The benefits of freezing tumors in other organs including liver, prostate, cervix, and skin have been described. Several small series have reported minimal complications with excellent local tumor control (14,197). Currently, no sufficient long-term data are available to compare cryosurgery with other modalities.

Cryotherapy may be performed through an open incision or laparoscopically. Typically, there are two phases, freezing and thawing, that cause cellular disruption and tissue ablation (197). In an examination of acute histologic changes of renal tissue after cryoablation, investigators reported extensive coagulative necrosis and hemorrhage beyond the boundaries of the tumor (56). Negative tumor margins apparently are obtained, but long-term pathologic changes are unknown.

High-intensity Focused Ultrasound. Another attempt at nephron-sparing therapy for RCC includes high-intensity focused ultrasound (HIFU). HIFU involves ultrasound waves generated extracorporeally and then focused to a point inside the body, where they induce thermonecrosis of the tissue. Initial studies report HIFU therapy to be safe and efficacious (1,120), yet further investigation regarding long-term results of this new modality is needed for the future.

Laparoscopic Surgery

With the rapid development of minimally invasive surgery, urologists increasingly are using laparoscopy for the treatment of malignant renal tumors. The utility of the laparoscopic approach has been well documented (27,118,153,191), and the addition of hand-assisted techniques also further broadens its appeal, adding dexterity and tactile sensation (278). Retroperitoneoscopy, without violation of the peritoneal cavity, also has been described (76). Initial concerns about tumor implantation at trochar sites and recurrence in the renal fossa have not proven to be significant complications. In a multicenter review of 157 patients with a mean follow-up period of 19.3 months, no patient developed tumor implantation or recurrence in the fossa (27).

Inferior Vena Cava Extension

Studies of RCC show that vena caval extension occurs in approximately 4% to 10% of cases, with a strong male predominance (38,80,135,148,152). All levels of caval tumor thrombus, from the renal vein ostia to the right atrium of the heart, occur. Because there is no adequate medical regimen, surgery offers the only cure for caval extension of tumor. The difficulty of the surgical approach is related to the degree of cephalad extension by the tumor thrombus, and intracaval neoplastic extension may even necessitate cardiopulmonary bypass for a safe and complete excision.

A thorough preoperative history to evaluate intercurrent health problems is mandatory for all surgical candidates. Anesthesia, and sometimes medical, consultations are needed to optimize conditions and prepare patients for often long procedures with intense hemodynamic shifts. Particular attention should be applied to cardiovascular status, especially when cardiopulmonary bypass is considered. Patients with IVC invasion may also have unique presentations. Although rare, symptoms can include massive lower extremity edema from IVC occlusion, ascites from Budd-Chiari syndrome, severe congestive heart failure, intestinal malabsorption, varicocele, or engorgement of the abdominal wall veins. Embolization of a portion of the tumor thrombus also may produce signs consistent with

pulmonary embolus.

A full radiographic evaluation of patients with RCC and vascular extension is required before any operative intervention. The purpose of this is twofold: to discover any metastatic disease and to establish the true cephalad extension of the intracaval tumor. This evaluation can be accomplished by a variety of studies including venacavography, ultrasound, CT, and MRI. Venacavography involves the direct injection of contrast dye into the vena cava. Intravascular tumor can be visualized as filling defects in the contrast-filled cava (Fig. 16.11). However, cavography sometimes requires both antegrade (femoral) and retrograde (basilic) injections to fully delineate tumor extent (Fig. 16.12) (80). Cavography has the obvious disadvantage of exposing remaining normal renal parenchyma to a potentially nephrotoxic contrast load. Because of its invasive nature, there is also a risk of dislodging intravascular tumor.

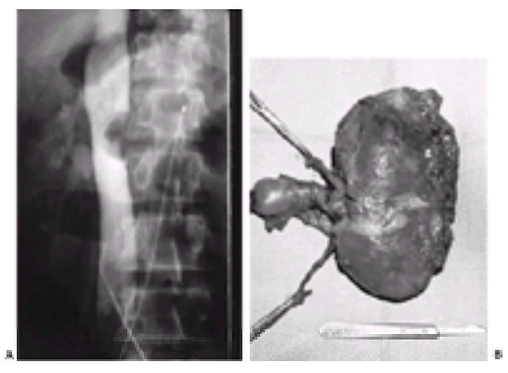

FIGURE 16.11. A: Venacavography demonstrates filling defect, suggesting extension of known left renal mass. **B:** Gross nephrectomy specimen in the same patient demonstrating distended renal vein from tumor thrombus.

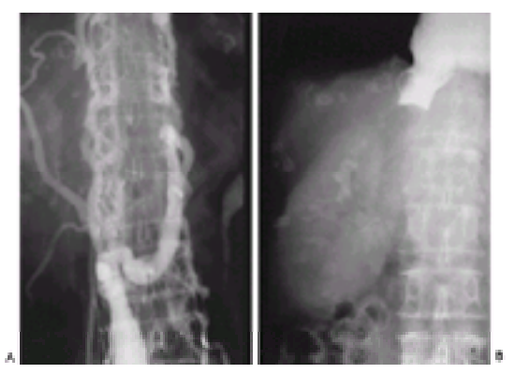

FIGURE 16.12. A: Antegrade venacavography with cutoff of contrast flow in the middle interior vena cava. **B:** Retrograde venacavography in the same patient demonstrating superior extent of tumor thrombus.

Approximately one-third of patients with IVC extension have at least one metastatic lesion (227). Multiple studies have shown that survival rates are poor with radical surgery in the setting of vascular extension and metastatic disease (243,244). Therefore a complete workup for metastatic disease is important before surgical intervention. Radiologic tests, including bone scans, play a valuable role in this setting. Routine serum chemistries and liver function tests also may provide clues to possible disease outside the kidney. Thorough knowledge of preoperative lesions will allow much better follow-up in the postoperative course.

Surgical approach in cases of renal neoplasms extending into the vena cava is dictated by the superior extent of the intracaval or intracardiac tumor. Involvement of intrahepatic and suprahepatic caval levels can create numerous potential technical problems, thereby lengthening operative time. When sections of vena cava must be resected, reconstruction to allow for adequate venous drainage poses new challenges. Furthermore, extension into the right atrium exposes one to the additional potential complications of cardiac surgery and cardiopulmonary bypass.

Exposure of the neoplastic kidney and associated tumor thrombus can be achieved through several operative approaches. Most cases of RCC with IVC involvement occur on the right side, but tumors in the left kidney require bilateral dissection. Regardless of laterality, full exposure is necessary to ensure complete resection of both tumor and thrombus. The thoracoabdominal incision provides excellent exposure for renal tumors but more limited access to the aortic arch for cardiopulmonary bypass. The midline abdominal incision with extended sternotomy also allows for excellent visualization and has the added benefit of more direct access to the heart for cardiopulmonary bypass and hypothermia. However, this approach requires entry into the peritoneal cavity and therefore displacement of the bowel. The chevron incision with extended sternotomy may prove superior for exposure of large tumors in large patients. The most important goal of surgery for renal cell tumors with IVC extension is complete resection, including full removal of caval tumor and resection of any involved caval wall, if possible, because this has tremendous prognostic implications.

Following tumor excision, the vena cava can be reconstructed to allow for venous return from other structures including the contralateral kidney. Reconstitution of venous drainage after tumor removal depends on the extent of the cavotomy incision. Several studies report that at least 50% of the original IVC lumen diameter must be maintained with caval reconstruction to prevent blood thrombus formation and caval occlusion (151). Occasionally, synthetic graft material is used to construct new portions of the IVC (173,174), but harvested native pericardium for this purpose also has been described (151). In some situations, segmental cavectomy with ligation of proximal and distal ends has been used with satisfactory results (265).

Reconstruction of drainage for the contralateral kidney depends on the side of the lesion. For right-sided tumors, the left renal vein can be ligated, if necessary, because there is good collateral blood flow for venous drainage of the left kidney. Anatomic studies have shown this collateral flow to mainly depend on the left ascending lumbar vein, which receives a branch from the left renal vein and then joins the hemiazygous venous system to drain into the superior vena cava (38). The right ascending lumbar vein bypasses the right renal vein and therefore no collateral drainage for the right kidney exists. Because of this finding, the IVC must be reconstructed for left-sided tumors to allow venous return from the right renal unit.

Caval tumor extending into the retrohepatic and suprahepatic IVC requires extensive dissection (148). Significant bleeding can be encountered in posterior mobilization of the liver, particularly the caudate lobe. Some surgeons use division of the caudate lobe veins to allow for improved exposure of the vena cava and associated thrombus (Fig. 16.13). Even resection of the caudate lobe has been described (172).

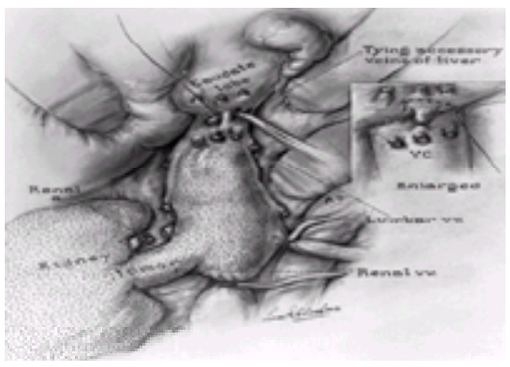

FIGURE 16.13. Removal of vena cava tumor thrombus often requires division of the veins from the caudate lobe of the liver. Ao, aorta VC, vena cava.

Perioperative morbidity and mortality have been well described with surgery involving tumor in the inferior vena cava. Pulmonary embolization of tumor thrombus is a well-recognized complication that sometimes can be avoided by preoperative or intraoperative placement of a vena caval (e.g., Greenfield) filter (20,68). However, a filter can complicate surgery and pose additional risks such as IVC occlusion or renal vein compromise (20). Operative blood loss can be massive, and significant hemorrhage can produce hemodynamic and cardiac effects. Coagulopathy can sometimes occur with prolonged cardiopulmonary bypass. If adequate venous drainage is not ensured for the contralateral kidney, renal failure can ensue.

A variety of studies have examined characteristics of RCCs with tumor thrombi to assess prognostic factors both preoperatively and postoperatively from pathologic diagnosis. However, many of these studies contradict others examining the same factors. Therefore several questions have not been completely answered, and confusion still exists. There is almost complete agreement that incomplete resection of tumor thrombus portends a much worse prognosis than total removal.

Whether tumor extension into the vena cava alone affects prognosis has been examined in several studies. In a retrospective analysis of 71 cases (median survival, 81 months), isolated caval extension offered little prognostic impact (32). However, a later European study reported a significant survival advantage for patients with tumors confined to the kidney versus those with venous extension (137). Most would agree that survival is affected more by associated tumor factors than venous extension alone. Microscopic invasion of the vein wall by tumor cells has been reported as the single most relevant prognostic factor in one study, which showed a 45% chance of disease progression within 1 year of nephrectomy in this group of patients (262). A significant improvement in survival also was noted for patients with freely mobile tumor as compared with invading tumor (69% versus 26% 5-year survival, respectively). Of particular note, resection of the involved caval wall was associated with improved survival (97). Nonetheless, in one series of 26 patients, there was no survival difference between those patients with venous wall involvement and those without (137). Most studies have shown that the cranial extent of tumor thrombus alone has no bearing on prognosis in terms of survival (77,97,127,137). However, several studies report that higher-extending thrombi are associated with significantly decreased survival rates (159,232).

Spread to regional lymph nodes has repeatedly been shown to be a poor prognostic indicator for RCC (12,127). A significant decrease in life expectancy was found in this subgroup when compared with a full cohort of patients with tumors invading the vena cava (13 versus 32 months median survival; $p < .001$) (127). Investigators showed that 5-year survival in a group of 37 patients with IVC tumor extension was 0% for the subset with lymph node metastases (versus 33.6% overall). Multiple studies have also confirmed that the preoperative or intraoperative demonstration of distant metastatic disease combined with caval extension leads to a poor prognosis, even with radical nephrectomy (32,127,244). Such patients have much lower long-term survival rates, usually less than 15%, when compared with those without metastases (135,159,226,244).

For patients with caval thrombi from RCC, 5-year survival rates have ranged from approximately 30% to 60% following surgery, as in Table 16.6 (166). Again, these rates depend on the aforementioned factors. The presence of lymph node or distant metastases is associated with much shorter long-term survival, whereas the superior anatomic extent of the thrombus often does not appear to be as important. Excellent long-term survival has been achieved with complete surgical removal, so the preoperative evaluation to select suitable surgical candidates will have the greatest impact on survival rates.

TABLE 16.6. FIVE-YEAR SURVIVAL RATES IN STUDIES OF RENAL CELL CARCINOMA WITH CAVAL EXTENSION

Cardiopulmonary Bypass and Hypothermia. The use of cardiopulmonary bypass and hypothermia has revolutionized surgery for IVC tumor thrombus extending into the right atrium. Bypass allows for an essentially bloodless field, which greatly assists in accessing and viewing pieces of caval and atrial tumor (Fig. 16.14). Moreover, this helps decrease the risk of tumor embolization during surgical manipulation (275). To date, use of cardiopulmonary bypass has not been shown to decrease survival in cases of renal tumors, but it does allow for full resection of the tumor. Perioperative mortality appears to be related to myocardial dysfunction, whereas short-term survival depends on lymph node and distant metastases (53). Length of bypass and arrest time also impacts survival. The surgeon places cannulas in the aorta and right atrium to allow for shunting of blood through the bypass machine. Systemic heparinization is used to prevent thrombosis. Once bypass has started, a cardioplegic solution is applied to the heart. To avoid subsequent permanent effects, optimal time for bypass is less than 45 minutes (148). Recently, a technique of minimally invasive (small incision) bypass has been described (64).

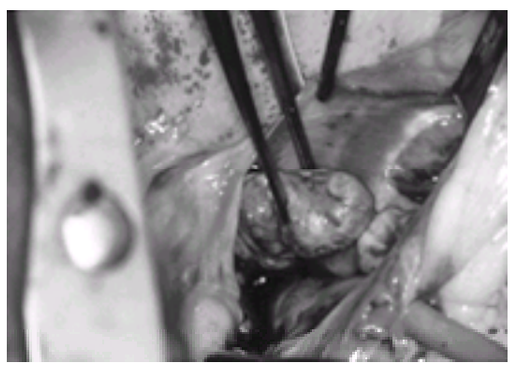

FIGURE 16.14. Removal of atrial tumor thrombus in the bloodless field allowed by cardiopulmonary bypass. Note the close vicinity of the tricuspid valve.

Metastatic Renal Cell Carcinoma

Years of intervention have done little to improve survival in patients with metastatic RCC. Regardless of the therapy used, results have been disappointing, and the search for effective treatment regimens remains a challenge for urologists and oncologists alike. Nonetheless, failure has fortunately bred an ever-expanding list of potential therapies, including chemotherapy and a multitude of immunomodulating options. Few sites in the body are safe from potential metastatic deposits with RCC; however, the most common sites are the lungs, bones, lymph nodes, adrenal glands, and brain (203). At autopsy of patients with RCC, no significant difference in metastatic locations was seen in patients who had undergone previous nephrectomy versus those who had not had surgery (204).

Radiotherapy

RCC has been characteristically regarded as a radioresistant tumor. In the past, several studies have addressed the issue of adjunctive radiotherapy in the treatment of metastatic disease, but none have documented significantly increased survival in that group of patients. Today, radiotherapy most often is used for palliative treatment of symptomatic tumors or metastatic lesions (51,123). Several investigators have used brachytherapy for this purpose (129).

Specifically, radiation has proven effective under circumstances of osseous or brain metastasis by rendering palliation, possibly preventing progression, and improving quality of life. Stereotactically guided high-precision irradiation selectively destroys small intracranial lesions and preserves surrounding brain tissue (11,160). Externally applied radiation alleviates bone pain in up to 77% of treated sites (94). Future applications linking radiation and immunotherapy are under investigation. In an effort to improve tumor targeting, novel phase I trials are investigating both the accumulation and the therapeutic potential of radiolabeled (I-131) monoclonal antibodies (G250) in metastatic RCC (52,237). Early results are encouraging, but much research still is needed to prove efficacy.

Chemotherapy

Standard historic chemotherapeutic regimens have failed to impact disease progression, and ultimately survival, in the majority of patients. An extensive review of more than 83 published trials from 1983 to 1993 showed a 6% response rate in 4,093 adequately treated patients with advanced RCC. The most efficacious agents were continuously infused 5-fluorouracil and floxuridine, with remissions in 10% and 12%, respectively. Circadian infusion, meant to optimize drug metabolism, modestly improved the remission rate to 15% of the patients treated with floxuridine (280). A recent review confirms that chemotherapy options for treatment are limited and suggests use in advanced cases only (3).

Scientists attribute, in part, the unyielding multidrug resistance of RCC to a plasma membrane glycoprotein (P-glycoprotein) that promotes the efflux of therapeutic agent away from the targeted cell. Overexpression of P-glycoprotein has been shown in 80% of tumors, which is much higher than in normal proximal tubular cells (81). Several medications, including cyclosporine (196), tamoxifen (205), and calcium channel blockers (176), have been used in attempts to block the multidrug resistant activity and to enhance the effect of chemotherapeutic agents, but no additive responses beyond that of chemotherapy alone are documented.

Immunotherapy

Because of RCC's resistance to chemotherapy and radiotherapy, alternative approaches have been sought. Physicians long ago suspected an integral role for the immune system in cases of spontaneous regression, and immunotherapy has gathered increased consideration for systemic treatment of metastatic tumors. The first recorded case of spontaneous regression (from the Mayo Clinic in 1928) postulated that antibodies produced by the body were responsible for either rendering the tumor cells inert or destroying them (26). Admittedly rare, almost 100 cases of spontaneous regression exist in the literature (58), and 2 recent reports document partial, transient regression in 5% to 7% of patients with pulmonary nodules without the impact of therapy (144,175). Additional supportive data include modern immunohistochemical analysis demonstrating infiltration of T lymphocytes and macrophages (63) as well as observed clinical responses to infused cytokines, interferons, and interleukins. Approaches applying biologic response modifiers (cytokines), vaccination, and gene therapy are under current study.

Interferons. Since its initial discovery in the 1950s, the family of homologous proteins known as *interferons* has expanded in both number and function. Interferons act on the cellular level, binding to a surface receptor and transducing important regulatory signals. The exact mechanism of antitumor activity is unknown, but research has shown interferons to impart, via signal transduction, potent antiviral, antiproliferative, and immunomodulatory function *in vivo* (106). Specifically, leukocytes produce interferon-a(IFN-a), which subsequently enhances natural killer cell function and induces major histocompatibility complex antigen expression.

Within the family of interferons, many individual proteins have been studied (126). Results from a well-constructed, randomized trial proved no difference, relative to placebo, in outcome of patients treated with interferon-g (IFN-g)-1b for metastatic RCC (78). IFN-a also has been thoroughly tested as a single agent, and promising initial data with this agent prompt further consideration of IFN-a as a therapeutic approach in patients with metastatic disease. An average of 3 to 4 months may transpire before the occurrence of an objective response from the initiation of therapy, but multiple studies show a reproducible response rate of 10% to 20% (24,61,163,260) and a complete response rate ranging as high as 5% (24). The patients most likely to respond are those who have undergone prior nephrectomy with good performance status, have a long disease-free interval, and have lung-predominant metastatic disease (143,208). Nonetheless, the duration of response rarely exceeds 2 years, with a mean time ranging from 5 to 15 months (276), and randomized trials have shown only a modest increase, 2 to 7 months, in survival time (231). In attempts to apply reports of *in vitro* synergy, randomized trials combining IFN-a with vinblastine failed to show improved survival over using interferon as the sole therapy and showed exacerbation of the subsequent interferon side effects, including leukopenia, nausea, vomiting, and neurotoxicity (165).

Interleukins. Another of the biologic response modifiers, interleukin-2 (IL-2), was approved on the basis of safety and efficacy for the treatment of RCC by the U.S. Food and Drug Administration in 1992. Interleukins indirectly affect tumorigenesis by enhancing the proliferation and function of T lymphocytes, and clinical studies for renal tumors suggest an approximate 15% to 19% objective response rate with IV bolus administration (25,74,199). Moreover, the complete response rate registers as high as 9.3% and is durable. More than 75% of the complete responders remain disease free for 3 years, and some in excess of 10 years without evidence of recurrent RCC. Treatment favors those with good performance status, absence of prior immunotherapy, total dose administered, and maximal rebound lymphocytosis after cessation of IL-2 (199).

Toxicity of interleukins can be severe. Many patients suffer with relatively minor symptoms of fever, chills, nausea, vomiting, diarrhea, and general malaise, but high-dose IL-2 treatment also can spur significant hypotension, fluid retention, acute respiratory distress, confusion, and renal failure as a physiologic consequence of the resultant cytokine cascade (178). Intensive monitoring and, frequently, aggressive support that includes maintenance of blood pressure with volume and pharmacologic vasopressors is required with bolus infusion. Even though side effects generally subside with discontinuation of therapy, treatment-related mortality ranges as high as 4% yearly with early experience (74). More recent analysis from the National Cancer Institute accounting for all 1,241 individuals treated with high-dose bolus IL-2 reveals an overall mortality rate of 0.7% with no treatment-related deaths in the last consecutive 680 patients (199).

Attempts have been made to optimize results and diminish the significant and sometimes life-threatening side effects of IL-2. Modifying dosage may diminish the toxicity without changing efficacy in regards to partial or complete tumor regression (22,235). However, the data currently are inconclusive. An ongoing randomized trial specifically addressing the issue reports preliminary results showing the high-dose IV bolus regimen to be the most effective (162). Adding complementary products such as lymphokine-activated killer cells (132,198), tumor-infiltrating lymphocytes (23,62), or IFN-a (164) currently does not produce statistically significant improvement in regards to overall survival over IL-2 alone.

Gene Therapy

Another novel approach, gene therapy, has garnered much attention, and clinical trials of therapeutic gene transfer in the treatment of urologic cancer are underway. Fundamentally, all gene therapy is a procedure of molecular surgery, because physicians sterilely introduce therapeutic DNA into diseased cells by way of a vector. Successful chromosomal integration allows for replication with the remainder of the treated cell's genes. Through the introduction of normal or modified genetic code, the process of carcinogenesis may be reversed or prevented.

Two entirely different gene therapy strategies can be defined. The first is corrective gene therapy, which involves the replacement or inactivation of defective genetic material with genes that prevent, slow, or reverse the events that encompass tumorigenesis. Significant insight into the molecular mechanisms of carcinogenesis is emerging, and potential mutational targets such as the VHL gene are being identified. In fact, introduction of a normal chromosome 3p has been shown to modulate tumor growth rate in an RCC cell line *in vitro* as long as 10 years ago (218). Nonetheless, several impressive limitations, including targeting, efficacy, and efficiency of vector transfer, exist currently with respect to corrective therapy. The second strategy includes treatment with recombinant DNA that selectively enhances killing of malignant cells, directly or indirectly. This cytoreductive gene therapy is further along than corrective gene therapy in terms of clinical application. More than 80 clinical protocols have been approved worldwide (223).

Previous research involving multiple cytokine genes shows that granulocyte-macrophage colony-stimulating factor (GM-CSF) gene–transduced vaccines incite the most vigorous, durable, and specific tumor immunity (5,54). Additional study has found preliminary evidence that GM-CSF genetically transduced, irradiated tumor vaccines induce potent T-cell–mediated antitumor activity without toxicity (222). The action of GM-CSF after gene transfer involves local spread of the cytokine at high concentrations, triggering antigen-presenting cell ingress and activation. This paracrine physiology more closely mimics the natural biology of cytokine action compared with the systemic IV administration of recombinant cytokines. Similar to other immunotherapies, treatment parameters such as mode of delivery, the ideal concentration of stimulatory cytokine, and minimum number of tumor cells for antigen presentation have yet to be determined. The nascent frontier of gene therapy will continue to grow, along with the other novel immunologic approaches under study such as tumor-specific vaccination (105) and monoclonal antibody treatments

(52).

Surgical Resection

The role of surgical resection in the setting of metastatic disease has been questioned (209). Specifically, with the development of improved immunotherapy regimens, the benefits of adjuvant nephrectomy and/or resection of metastatic lesions have been addressed (248,267,277). Nephrectomy also has been performed for the palliation of severe symptoms, such as pain or hematuria. In addition, reasonable 5-year survival rates have been seen in cases of solitary metastatic lesions that have undergone metastasectomy. In all cases, the risks of surgical therapy must be weighed against the potential benefits of removing the malignant lesion. The lack of randomized studies in this area makes this a difficult comparison.

Controversy exists regarding whether to perform adjuvant cytoreductive surgery with immunotherapy and also regarding appropriate timing for the operation. Critics of surgery point to a meager rate of spontaneous regression (1% to 4.4%) with frequent recurrence (144), increased morbidity and operative mortality (13), and deferred subsequent cytokine therapy in some cases (190). On the other hand, proponents believe that excision of the primary tumor serves as an adjunct to systemic immunotherapy for purposes of tissue procurement and elimination of a suspected immunomodulator. Recently, adjuvant surgery for immunotherapy in metastatic RCC has been reported to have beneficial results in terms of survival, although studies are not conclusive (65). Previously, however, it was suggested that nephrectomy alone did not improve survival rates in patients with metastatic disease (47) or, at best, affected outcome in certain favorable patients only (83,168).

Patients with known metastatic disease who present with significant symptoms, including those from pain, hematuria, or paraneoplastic syndromes, may benefit from palliative surgery. Although occasional reports of spontaneous regression of metastatic lesions following nephrectomy have surfaced, palliative surgery has not been shown to have significant effects on overall survival. Nonetheless, palliation of symptoms may improve quality of life. Again, the risks of surgical intervention must be weighed against potential benefits of improved symptoms. A less invasive method of palliation for certain patients involves angioinfarction, in which blood flow to the kidney is blocked by use of an embolic material placed in the renal vasculature. Although theoretically appealing, angioinfarction conveys little prognostic benefit.

The percentage of RCC patients who present with a single detectable metastatic lesion ranges from approximately 1% to 3%, according to available studies (155,170,255). Evidence suggests that aggressive surgical therapy may have beneficial results in this select group of patients. The prototype metastatic lesion responding to surgical therapy is the pulmonary nodule. Moreover, improved survival has been associated with normal performance status, and a disease progression–free interval of more than 24 months from time of nephrectomy (142). Other types of metastatic lesions, including those to the central nervous system (179) and bone, also have shown effective long-term results.

The Future: Molecular Prognostic Markers

Recent evaluation reaffirmed the statistic significance of pathologic staging and nuclear grade in relation to survival (258). On a macroscopic level, metastasis can be qualified and generally portends a poor prognosis. However, the prognosis for patients with locally confined RCC is known to be variable. With ever finer focus, scientists are identifying morphologic character, proteins, antigens, and other prognostic markers that aid in both diagnosis and characterization of a particular lesion. Less specific prognostic signs and symptoms such as weight loss, anemia, hypercalcemia, and elevated liver function tests are giving way to clinicopathologic features discovered through application of immunohistochemistry, flow cytometry, polymerase chain reaction technology, and nucleic acid analysis. Already proven techniques have been expanded to generate better outcome data. For instance, distortion of nuclear shape has a long history in the histologic evaluation of tumors, but by using modern digital technology and mathematic equations for nuclear roundness and ellipticity, investigators found significantly improved prognostication (29).

Modern markers of proliferation such as Ki-67, silver- staining nucleolar organizer regions (AgNOR), and proliferating-cell nuclear antigen (PCNA) are present in cycling cells and therefore have potential utility in estimating the biologic aggressiveness of a given tumor. Several studies have identified the Ki-67 antigen and PCNA to be significant prognostic parameters in regards to survival and tumor recurrence, comparing favorably or even superior to grade and pathologic stage (48,101,249). In contrast to nuclear grading, the evaluation of positive staging is not only less subjective, but also reproducible and simple. In addition, AgNOR, Ki-67, and PCNA all have been shown to be independent predictors of survival and of greater prognostic value than histologic grade in multivariate analysis (48,93). Another measure of abnormal proliferation can be ascertained through detection of aneuploidy. Determinations of ploidy by flow cytometry are proving less reliable however, and in studies of locally confined tumors, conclusions regarding in its relationship to grade, stage, and prognosis are mixed (249).

Along with high proliferative indices, RCC has other inherent qualities ripe for prognostic analysis. Metastasis involves a complex series of events and depends on the cancer's ability to break from the primary location and implant in another area of the body. Two elements believed to be essential in this process are cell adhesion molecules and angiogenesis factors. Cadherins are a large family of transmembrane proteins responsible for mediating cell-to-cell adhesion, and when expression decreases, their inherent ability to modulate and preserve epithelial integrity diminishes. Lack of E-cadherin expression correlates with aggressiveness in several tumors, but only 20% of RCCs express the glycoprotein (117). E-cadherin appears to be localized to Bowman's capsule and other tubular segments rather than to the proximal tubular epithelium. Such evidence brings to question whether E-cadherin plays an integral role in renal cell carcinogenesis.

As a result, more recent focus has shifted to cadherin-6. Shimazui showed this cadherin to be the major one in the proximal renal tubules and RCC itself. Investigating this relationship as related to prognosis, Shimazui's group found that aberrant expression of cadherin-6 connoted poor survival (216,217). These data have been reproduced in a series wherein the majority of renal cell cancers with histology-associated poor prognosis (e.g., high-grade clear cell cancers) showed aberrant expression. The tumors with a historically good prognosis (e.g., low-grade clear cell carcinomas and papillary cancers) exhibited normal cadherin-6 expression (180).

In a similar fashion, the degree of angiogenesis has been shown to correlate with the development of metastases in several cancers including melanoma (225), prostate (271), breast (272), and non–small-cell lung carcinoma (140). In one study, when investigating the relationship to malignant renal epithelial tumors, an immunohistochemical marker of angiogenesis, microvessel density, exhibited no correlation to clinical stage, pathologic stage, or tumor grade (141). However, another investigation showed that higher microvessel density was associated with longer patient survival in clear cell carcinoma; this relationship is contrary to that reported with other types of malignancies (49). RCC is a vascular tumor, but its direct relationship to angiogenesis has yet to be completely determined.

Proteins responsible for apoptosis, such as p53, have been extensively studied in many cancer models, including RCC. The p53 protein binds DNA and is believed to regulate transcription, acting as a “checkpoint” to induce cell cycle arrest (128). When mutated, this tumor suppressor gene inactivates the normal function of DNA damage surveillance. Aneuploid cells originate, carcinogenesis occurs, and tumor progression can ensue (104). Mutant p53 proteins have a prolonged half-life, and with accumulation are detectable with immunohistochemical analysis (130). Yet controversy exists in regards to the frequency of the mutation in RCC (ranging from 4% to 40% of specimens tested) and consequently, its resultant prognostic power. Uhlman found an 87% 10-year, disease-specific survival rate for patients with nonstaining Robson stage I tumors versus a 62% survival with p53 positive-staining tumors (p <.01). Moreover, p53 positivity was an independent predictor of survival, whereas tumor grade was not (259). More recently, others have demonstrated a significant correlation between p53 and nuclear grading and PCNA expression, and these researchers claim p53 to be an independent predictor of survival. Nonetheless, they also recognize the infrequency of staining and believe it to be a useful adjunct to the standard criteria of stage and grade (215). The clinical significance of p53 and other apoptotic markers has yet to be completely elucidated.

MISCELLANEOUS RENAL TUMORS

Renal Angiomyolipoma

Renal angiomyolipomas (Fig. 16.15) are generally benign tumors of the kidney that are named based on their three characteristic histologic components: blood vessels, smooth muscle, and mature adipocytes. Their extensive vascularity is associated with a significant propensity for hemorrhage, which can produce clinical symptoms. However, angiomyolipomas often may grow to large sizes before diagnosis. They can occur as a solitary lesion, in multiple sites within one kidney, or in both kidneys. Rare cases of malignant degeneration have been described (36,59,139), as well as coexistence with RCC (95).

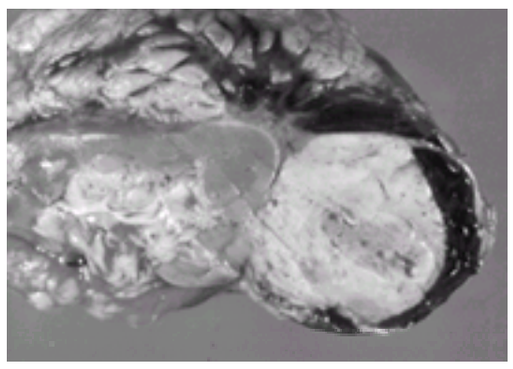

FIGURE 16.15. Gross view of angiomyolipoma.

Angiomyolipomas also are commonly associated with tuberous sclerosis, an inherited syndrome characterized by mental retardation, epilepsy, adenoma sebaceum, and hamartomas of multiple organs including retina, heart, bone, lung, and kidney (108). A significant number of patients with tuberous sclerosis will develop renal angiomyolipomas; therefore careful screening is required. In this group of patients, the tumors tend to occur at a younger age and to be multifocal and bilateral (238).

The size of the tumor appears to significantly affect its symptomatology. Steiner and associates (238) reported that tumors smaller than 4 cm produced no symptoms in their series of patients. However, tumors larger than 4 cm commonly produce symptoms (171,238). Flank pain is the most prevalent symptom at presentation, occurring in up to 70% of symptomatic patients (9). A palpable mass and hematuria, usually microscopic, also are seen. More rare presentations include hypertension and anemia. Rupture of the tumor with subsequent retroperitoneal hemorrhage also may produce significant hypotension, which can progress to hemorrhagic shock.

Often, radiographic imaging alone confirms the diagnosis of angiomyolipoma. The numerous fat–nonfat interfaces with sonography produce an intensely echogenic lesion. Quantifying these echoes with computer assistance may aid in differentiation of angiomyolipomas from other renal tumors (221). CT scans can detect fat densities (–70 to –30 Hounsfield units) within the tumor, and the presence of fat is essentially pathognomonic for angiomyolipoma. The characteristic high signal intensity of fat on T_1-weighted images of MRI scans also can assist in the diagnosis. If fat cannot be detected in the lesion using radiographic studies, the tumor should be treated as malignant until a pathologic diagnosis confirms angiomyolipoma. Percutaneous needle sampling of the tumor for tissue analysis has been described (207).

The management of angiomyolipomas varies based on the individual patient. Once a diagnosis is made, the size of the tumor and the presence of symptoms determine the future course. The goal for therapy is renal preservation, when possible. Small, asymptomatic tumors may be followed with yearly ultrasounds, with no treatment necessary unless tumors become large or symptomatic. Tumors larger than 4 cm that are asymptomatic or mildly symptomatic also may be followed, but investigators recommend semiannual radiographic monitoring (171,238). Patients with extremely large tumors or those with severe symptoms should undergo therapy before the development of retroperitoneal hemorrhage. Embolization of angiomyolipomas often has been successful in control of bleeding and also can be therapeutic (171). Tumors that are poorly suited for angioinfarction or those with questionable diagnosis require surgical exploration for treatment. Nephron-sparing surgery with preservation of normal parenchyma is the preferred approach, when possible. Tumors that replace the entire kidney, multifocal lesions, and those with uncontrollable hemorrhage necessitate total nephrectomy.

Renal Medullary Carcinoma

Renal medullary carcinoma is a tumor found in patients with SC trait or hemoglobin sickle cell disease. It has been described mainly in African American adolescents and young adults, with a male predominance (6,41,43,45,70). This highly aggressive tumor quickly progresses to metastatic disease. Mean survival after diagnosis averages approximately 3 months (6,45), with only rare reports of survival past 1 year (41,183). Multiple failed chemotherapy regimens demonstrate the chemoresistance of this tumor (6,183).

Patients most often present with gross hematuria; therefore this symptom in a patient with sickle cell trait should prompt an appropriate workup (269). The tumor is concentrated in the medulla of the kidney, but satellite nodules in the renal cortex and renal sinus are often noted (45). Infiltrative growth is common (43), and venous and lymphatic invasion usually is present (45). Abnormalities on chromosome 3 and monosomy 11 have been identified in some patients (6). On radiographic studies of the kidney, contrast enhancement and echotexture are consistently heterogeneous (43). Hypovascularity also has been noted on renal angiogram (43,70).

Other Tumors

Aside from the more common tumors discussed previously, numerous other lesions have been described as occurring within the kidney (Table 16.7). In general, these are exceedingly rare tumors; many are derived from mesenchymal elements and are benign in nature (247). Metastatic deposits from other primary malignancies also are seen. Often, no symptoms are present and discovery of the lesion occurs as an incidental or autopsy finding.

Fibroma	Lymphangioma
Fibrosarcoma	Lymphoma
Fibrous histiocytoma	Mesoblastic nephroma
Hemangioma	Metastatic tumors
Hemangiopericytoma	Myxoma
Juxtaglomerular cell tumor	Neurogenic tumors
Leiomyoma	Osteogenic sarcomas
Leiomyosarcoma	Renomedullary interstitial cell tumors
Lipoma	
Liposarcoma	Rhabdomyosarcomas

EPIDEMIOLOGY AND ETIOLOGY

Incidence

Urothelial (transitional cell) carcinoma of the upper urinary tract is an uncommon disease, accounting for 4.5% to 9% of all renal tumors and 5% to 6% of all urothelial tumors (27,43,108,159,160). Renal pelvis urothelial tumors are two to four times more common than ureteral urothelial tumors (89,100,104,117). Upper urinary tract tumors rarely occur before age 40 years and have a peak incidence in the sixth and seventh decades of life, with a mean age at diagnosis of 65 years (7,54). Upper tract urothelial cancers are two to four times more common in men than in women and two times more common in Caucasians than in African Americans (7).

Risk Factors

Association with Balkan Nephropathy

In regions of Bulgaria, Greece, Romania, and Yugoslavia, the presence of an endemic form of nephropathy (termed *Balkan nephropathy*) has been associated with a high frequency of renal pelvic and ureteral tumors. Balkan nephropathy is a degenerative interstitial disease resulting in renal failure in its late stages. The upper tract tumors associated with this nephropathy tend to be low grade and slow growing, which encourages conservative management in these cases. Interestingly, there is no increase in the incidence of bladder urothelial cancer (118). These urothelial tumors occur bilaterally in 10% of these patients and account for 40% of all renal cancers in these geographic regions (125).

Occupational Risk Factors

Workers in the chemical, petrochemical, and plastics industries have been shown to be four times more likely to develop renal pelvic and ureteral cancers compared with the population at large. In addition, workers who are exposed to coal, coke, asphalt, tar, and aniline dyes experience a similar increase in risk (122).

Smoking

Cigarette smoking is a major risk factor for urothelial cancer of the upper urinary tract, as well as the bladder. In a study by Jensen and colleagues (64), 56% of upper tract cancers in eastern Denmark were thought to be caused by cigarette smoking. The associated risk increased with lifetime amount of tobacco use and degree of inhalation. This study suggested that the association of tobacco use with upper tract urothelial cancer was even stronger than with bladder urothelial cancer. The addition of other types of tobacco increased the relative risk from 2.6 to 3.8. McLaughlin and associates (92) calculated that of upper tract urothelial tumors in three areas of the United States, 7 of 10 in men and 4 of 10 in women were attributable to smoking. Cigarette smoking appears to be the most significant acquired risk factor for upper tract urothelial cancer.

Analgesic Use

A number of case reports and epidemiologic studies have linked heavy use of analgesic mixtures with urothelial carcinoma of the renal pelvis. In particular, phenacetin, an aromatic amide with *N*- hydroxylated amines, has been linked in one study to 22% of patients with renal pelvis cancer and 11% of those with ureteral cancers (148). Other studies have been supportive of this association (91,99). The phenacetin metabolite *N*- hydroxyphenacetin, a potent liver carcinogen, may be responsible for the increased risk. The latency period can be as long as 25 years (45).

Prolonged use of nonsteroidal antiinflammatory drugs has been associated with the development of interstitial nephritis. This nephropathy is characterized by capillarosclerosis, a thickening of the basement membrane around the subepithelial capillaries, which is pathognomonic for analgesic abuse. Palvio and associates (114) noted capillarosclerosis in 15% of cases of upper tract urothelial cancer. Combination analgesics result in an even greater frequency of nephropathy, possibly as a result of synergy between aspirin, phenacetin, and other nonsteroidal agents. In a study by Jensen and associates (65), the relative risk for upper tract urothelial cancer attributed to analgesic abuse was greater for women than for men (4.2 versus 2.4).

Coffee Drinking and Artificial Sweeteners

There has been controversy over the association of upper tract urothelial cancer with coffee drinking or the use of saccharin. Although some have noted a slightly

increased risk with the former (132), others have not (99). The preponderance of evidence suggests that saccharin is not associated with urothelial tumors (63,99).

Infectious Agents

Although there has been some evidence that human papillomavirus (HPV) may predispose to the development of bladder urothelial cancer, studies of HPV in upper tract urothelial cancer have not provided confirmation of a similar relationship (6,21,38,161). Chronic bacterial infections of the upper urinary tract have been linked to the development of squamous cell carcinoma, but the association with urothelial cancer is uncertain.

Cyclophosphamide

Cyclophosphamide is an alkylating chemotherapeutic agent widely used to treat lymphomas, leukemia, and other solid tumors. In addition, it has been used in the management of patients with autoimmune disorders such as rheumatoid arthritis, lupus erythematosus, and polyarteritis nodosa. One product of cyclophosphamide metabolism, acrolein, is toxic to the urothelium and thought to be responsible for injury to the mucosa. Cyclophosphamide exposure has been associated with an increased risk of both bladder and upper tract urothelial cancer (18,156).

Heredity

There have been several reported cases of familial urothelial carcinoma of the upper urinary tract. In particular, increased risk has been suggested among families with hereditary nonpolyposis colon cancer (47,84). Increased risk of urothelial carcinoma of the upper urinary tract has been associated with Muir-Torre syndrome, which is a rare autosomal-dominant disorder characterized by sebaceous tumors and at least one visceral malignancy (i.e., colon cancer) (48,73). There has been the suggestion of overlap with hereditary nonpolyposis colon cancer.

Chromosomal Abnormalities

Chromosomal abnormalities have been described in upper tract urothelial cancers. Reports describe gain of chromosome 7, complete or partial loss of chromosome 9, partial loss of chromosome 10, and partial loss of chromosome 21 (11,35,134,155). Some studies suggest that the changes seen are similar to those for bladder urothelial cancer.

Through mapping studies and examination of recurrent bladder tumors, there has been a suggestion that multifocal urothelial tumors arise from a monoclonal origin (83,144,157). In a molecular study of three patients, Sidransky and colleagues (144) showed that inactivation of the same X chromosome occurred in multiple tumor samples. A similar clonal pattern was also seen in the allelic loss of chromosome 9q, a loss that is thought to occur early in tumorigenesis (151). Similarly, Van der Poel and colleagues (157) demonstrated that the same p53 mutation was present in multiple urothelial tumors present in one patient. While allelic loss of chromosome 9 is thought to be an early event, loss of chromosome 17p, containing the site for p53, is thought to be late event (52).

The chronology of genetic alterations in urothelial tumors might shed light on their development. Takahashi and colleagues (151) found that low-grade papillary urothelial tumors rarely acquire additional genetic alterations; genetic divergence and heterotopic spread appear to occur after alterations in chromosome 9. Their findings suggest that most multifocal low-grade superficial urothelial tumors are genetically stable and that alterations in chromosome 9 may be an early event in tumorigenesis.

Location and Distribution

Urothelial carcinoma is two to four times as common in the renal pelvis as in the ureter (89,100,104,117). In the ureter, lesions are more common in the distal portion (40). Zungri and colleagues (168) found that among patients with upper tract tumors, 78% had tumors in the distal ureter and 27% in the proximal ureter.

Upper tract urothelial carcinomas occur in a bilateral and synchronous fashion in 1.5% to 2%; 6% to 8% develop as bilateral metachronous lesions (103,160). Upper tract tumors occur in 2% to 4% of patients with previous bladder cancer. The mean interval between the diagnosis of bladder cancer and upper tract disease varies from 17 to 170 months (109). Carcinoma *in situ* (CIS) of the bladder increases the likelihood of upper tract urothelial cancer in patients with bladder cancer from 13.4% to 21%. The median time from diagnosis of bladder tumor to occurrence of upper tract tumor ranges from 62 to 88 months (25,95,138). Despite successful bacille Calmette-Guérin (BCG) treatment of CIS in the bladder, these individuals have a lifelong risk for developing upper tract tumors and thus should have continued evaluation of the upper tracts in addition to the bladder.

The risk of developing bladder tumors following the diagnosis of upper tract urothelial cancer is significantly higher. This incidence has been estimated at 20% to 48% (40,58,68,76,101,102,129). Although, as noted, some of these bladder tumors are found before or at the time of diagnosis of the upper tract tumor, most occur after the diagnosis of upper tract disease. In a series of 69 patients reported by Mukamel and colleagues (102), most of these bladder tumors occurred within the first year following nephroureterectomy, although late occurrences are noted as well (93). There has been some controversy as to the impact that the diagnosis of a bladder tumor has on survival of patients with upper tract urothelial cancer. In the two series compiled by Krogh and colleagues (76) and Charbit and associates (23), the additional diagnosis of a bladder tumor did not affect survival. However, the two series collected by Reitelman and colleagues (129) and Mukamel and associates (102) suggest that the additional diagnosis of a bladder tumor decreases survival significantly.

The higher rate of metachronous as compared with synchronous bladder tumors following the diagnosis of an upper tract tumor has led to speculation about the method by which urothelial carcinoma is disseminated in the urinary tract. These phenomena suggest that many of the tumors that recur do so as a result of direct seeding downstream or from longer exposure of the causative agent in the bladder.

Some investigators have pursued urothelial mapping as a method of determining the causal link between urothelial cancers in the bladder and the upper tract. Several studies indicate that there are widespread abnormalities in the urothelium of the renal pelvis and ureter in patients with upper tract urothelial carcinoma (68,82,85). Thus the entire urothelium is at risk for the precancerous and cancerous event. Furthermore, there appears to be a correlation between the grade of tumor seen and the degree of disturbance seen in the surrounding epithelium. McCarron and colleagues (90) evaluated 30 consecutive nephroureterectomy specimens and found that in most high-grade neoplasms, the remote urothelium expressed marked atypia or carcinoma. Conversely, the low-grade neoplasms were accompanied by the presence of only varying degrees of simple hyperplasia of the surrounding urothelium. These findings suggest that conservative approaches will be less effective in the setting of high-grade neoplasm because urothelium remains at risk. The incidence of subsequent ipsilateral upper tract urothelial cancer lesions has been reported to range from 14% to 30%, and the incidence of ipsilateral ureteral stump recurrence has been shown to range from 19% to 48% (76,89,150,164).

Others have theorized that tumors in the upper urinary tract occur as a consequence of seeding that occurs as a result of vesicoureteral reflux (164). This suggestion is supported by the findings reported by Babaian and Johnson (7) that 73% of ureteral cancers were in the distal ureter, 24% in the midureter, and 3% in the proximal ureter.

PATHOLOGY

Of upper tract collecting system tumors, 90% are urothelial carcinomas. These may occur as single or multifocal lesions. Grading for these lesions is similar to that for bladder cancer and is based on the worst grade seen. The current World Health Organization/International Society for Urological Pathology (WHO/ISUP) consensus classification of urothelial (transitional cell) lesions was developed in 1998 out of a need to have a universally accepted classification system (Table 17.1) (34,131). The term *urothelial* is preferred over the term *transitional cell.* Although investigators had all agreed that grade was an important predictor of outcome, the use of multiple systems of grading had resulted in a lack of reproducibility. The goal of the WHO/ISUP 1998 classification was to define a classification continuum from normal tissue to invasive neoplasms (Table 17.1) (34,131). Comparison of this 1998 consensus grading system and previous three- and four-tiered grading system is shown in Table 17.2.

Flat lesions with atypia	
Reactive (inflammatory) atypia	
Atypia of unknown significance	
Dysplasia (low-grade intraurothelial neoplasia)	
Carcinoma *in situ* (high-grade intraurothelial neoplasia)	
Papillary neoplasms	
Papilloma	
Inverted papilloma	
Papillary neoplasm of low malignant potential	
Papillary carcinoma, low grade	
Papillary carcinoma, high grade (option to add comment regarding presence of anaplasia)

TABLE 17.2. HISTOLOGIC GRADING CATEGORIES FOR PAPILLARY UROTHELIAL TUMORS

Carcinoma *In Situ* (High-grade Intraurothelial Neoplasia)

CIS (Fig. 17.1) has been characterized as a precursor lesion to invasive cancer. Cells with large, irregular hyperchromatic nuclei that compose a portion of or the entire urothelium define this high-grade lesion. Mitotic activity is commonly seen in the middle to upper urothelium. This designation encompasses lesions that used to be described as severe dysplasia or marked atypia.

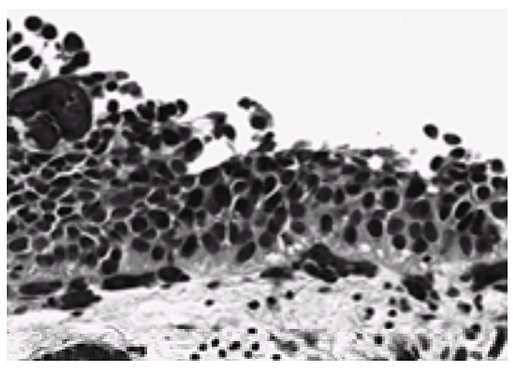

FIGURE 17.1. Urothelial carcinoma *in situ* with pleomorphic cells and hyperchromatic nuclei replacing the full thickness of the urothelium (×200 magnification). (Photo courtesy of Dr. Nader H. Bassily.)

Papillary Urothelial Neoplasms

Papilloma is a discrete papillary growth with a central fibrovascular core. The surface of the papilloma is covered by urothelium of normal thickness and cytology. Although they do not have the ability to invade or metastasize, papillomas do have a tendency to recur. This propensity for recurrence has been associated with subsequent development of carcinoma (17,34,131).

Papillary urothelial neoplasm of low malignant potential is the designation for a lesion in which there is an orderly polar arrangement of cells within papillae. The papillae exhibit minimal architectural abnormalities and minimal nuclear atypia. However, the nuclei are significantly enlarged or the urothelium has more layers than normal. Mitotic figures are infrequent. These lesions pose little risk for invasion or metastases.

Low-grade papillary urothelial carcinomas (Fig. 17.2) represent the next step in the continuum of urothelial change. Although the orderly appearance of the cell layers is preserved, there is now variation in the architectural or cytologic features. Despite the presence of cellular atypia, mitotic figures remain rare (34,131).

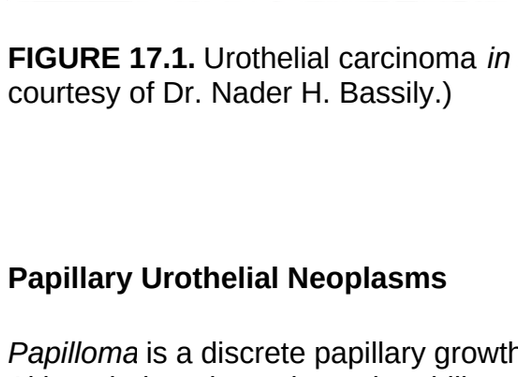

FIGURE 17.2. Low-grade papillary urothelial carcinoma with exophytic papillary fronds covered by thick urothelium. Note the mild nuclear atypia, intact basement membrane, and preservation of normal architecture (×40 magnification). (Photo courtesy of Dr. Nader H. Bassily.)

High-grade papillary urothelial carcinomas (Fig. 17.3) demonstrate disordered appearance even at low magnification. Both the architecture and cytologic features are involved. Marked to moderate cellular pleomorphism, clumped nuclear chromatin, prominent nucleoli, and mitotic figures all can be present. The pathologist may also add an additional comment on the degree of anaplasia during grading (34,131).

NATURAL HISTORY

Patterns of Spread

Urothelial carcinoma of the upper urinary tract can spread by (a) direct extensions through the wall of the collecting system into the renal parenchyma or surrounding structures, (b) lymphatic invasion, or (c) more rarely, vascular invasion. The paraaortic, paracaval, and pelvic lymph nodes are the most common sites for lymphatic invasion. Venous extension into the renal vein and the vena cava has been reported and is associated with poor prognosis (53,66,130). The most common metastatic sites for urothelial cancer of the upper tract are lung (31%), bone (22%), and liver (9%) (58).

Mucosal Spread

Global field changes present in the urothelium at the time of resection of the primary urothelial upper tract lesions may predispose the remainder of the upper tract to recurrence. Mahadevia and colleagues (85) demonstrated with urothelial mapping of nephroureterectomy specimens that widespread abnormalities of the entire urothelium are present concomitantly with the diagnosis of upper tract urothelial cancer. McCarron and colleagues (90) confirmed this finding. This group also demonstrated that the degree of urothelial disturbance parallels the grade of the principal lesion. The widespread nature of urothelial abnormalities may provide a plausible explanation for the high incidence (20% to 64%) of recurrent urothelial carcinoma in ureteral stumps (67,150).

Others have suggested that urothelial upper tract cancers are seeded from bladder tumors when malignant cells are washed into the upper tract through an incompetent ureteral orifice (113). Studies have suggested that patients with bladder cancer and vesicoureteral reflux are 16 to 22 times more likely to develop upper tract urothelial cancer than are bladder cancer patients without concomitant reflux (5,29).

TUMOR STAGE

Stage, along with grade, is an important prognostic indicator for upper tract urothelial carcinomas. Depth of tumor invasion is inversely correlated with survival. In a study of 103 subjects, patients with tumors of the renal pelvis or ureter without invasion beyond the midpoint of the muscularis experienced a 72% 5-year survival rate. Patients with tumors that had extended more deeply (Fig. 17.4) had a 5-year survival rate of only 32% (16).

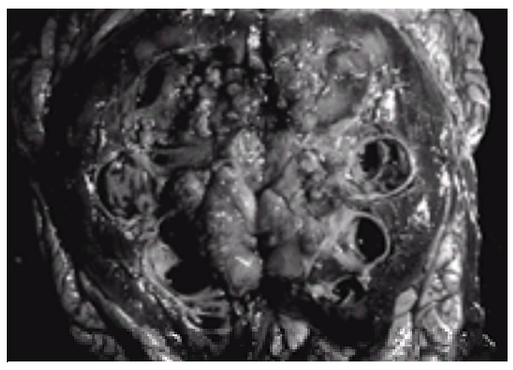

FIGURE 17.4. Gross specimen of stage T_3 urothelial carcinoma of the renal pelvis (extensive tumor, with focal invasion into peripelvic fat).

Renal pelvic and ureteral carcinomas are staged according to an assessment of the degree of tumor infiltration, nodal involvement, and presence of metastatic disease. The American Joint Committee on Cancer (AJCC) system (Table 17.3 and Table 17.4) uses combinations of tumor, node, metastasis (TNM) categories to form stage groupings.

T	**Primary tumor**
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_{is}	Carcinoma *in situ*
T_a	Papillary noninvasive carcinoma
T_1	Tumor invades subepithelial connective tissue
T_2	Tumor invades muscularis
T_3	Tumor invades beyond muscularis into peri-ureteric or peripelvic fat or renal parenchyma but not adjacent organs
T_4	Tumor invades adjacent organs or through the kidney into perinephric fat
N	**Regional lymph nodes**
N_x	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
N_1	Metastasis in a single lymph node, ≤2 cm in greatest dimension
N_2	Metastasis in a single lymph node, >2 cm but ≤5 cm in greatest dimension, or multiple lymph nodes, none >5 cm in greatest dimension
N_3	Metastasis in a lymph node(s) >5 cm in greatest dimension
M	**Distant metastasis**
M_x	Presence of distant metastasis cannot be assessed
M_0	No regional lymph node metastasis
M_1	Distant metastasis

TABLE 17.4. STAGING OF URETERAL AND RENAL PELVIC TUMORS

SIGNS AND SYMPTOMS

Gross hematuria is the most common symptom of urothelial carcinoma of the upper urinary tract, present in 70% to 90% of patients. Flank pain may be present in 8% to 50% of patients and occurs as a result of ureteral obstruction by blood clots or tumor. Constitutional symptoms, such as weight loss, anorexia, and bone pain, are rarely present unless there is metastatic disease. A flank mass due to hydronephrosis or the actual tumor mass is noted in up to 10% to 20% of patients (39).

DIAGNOSIS

Excretory Urography

Upper urinary tract collecting system tumors may produce an intraluminal filling defect, unilateral nonvisualization of the collecting system, or hydronephrosis (4,10,162) on either excretory urography (IVP) or retrograde pyelography. The differential diagnosis primarily includes nonopaque calculi, blood clots, sloughed renal papillae, and fungus balls. Other considerations include fibroepithelial polyp (56), air bubble, granuloma, renal tuberculosis, and leiomyoma.

Although 50% to 75% of patients may exhibit a filling defect (Fig. 17.5), 10% to 30% of patients diagnosed with upper tract urothelial tumors demonstrate obstruction or nonvisualization of the collecting system, which limits the usefulness of excretory urography. Further evaluation of a nonvisualized collecting system usually requires retrograde pyelography.

FIGURE 17.5. Intravenous urogram demonstrating a filling defect indicating a proximal ureteral tumor.

Retrograde Pyelography

Retrograde pyelography allows for excellent visualization of the collecting system and provides opportunity for direct collection of specimens for cytology. A bulb- or cone-tipped ureteral catheter is inserted through the ureteral orifice, and contrast is injected to visualize the collecting system under fluoroscopy. The contrast medium should be diluted to one-third or one-half its original concentration before use, which will allow better visualization of subtle filling defects. Care is taken to fill and view the entire renal pelvis and collecting system. Filling of the collecting system is performed with fluoroscopic monitoring in order to prevent overfilling, which may result in rupture of the renal fornices. Occasionally, dilation of the ureter distal to the ureteral tumor is noted, creating a “goblet” appearance. In this dilated region, a catheter passed distal to the tumor may form a coil; this radiologic appearance is called Bergman's sign (12).

When urine is being collected from the upper tracts for cytology, it is important to consider that the hyperosmotic contrast material injected for the retrograde pyelography may affect the interpretation of the cytology. Thus, once the ureteral catheter has been inserted, it might be advisable to first collect urine and saline barbotage for cytology before injection of contrast material.

Antegrade Pyelography

Puncture of the renal pelvis for either an antegrade study or a needle biopsy is not recommended. Although fine-needle biopsy has been reported as a diagnostic technique for renal pelvis filling defects (107,135), seeding of the tumor along the needle tract has also been reported (145). Alternatives for evaluation of a nonvisualized collecting system, such as retrograde pyelography, ureteroscopy with or without biopsy, or computed tomography (CT) scanning, generally should be used first unless there are specific contraindications.

Computed Tomography

CT can be useful in differentiating between a radiolucent uric acid stone and an upper tract urothelial cancer as the source of the filling defect seen during IVP, as well as for staging of upper tract urothelial cancer. Following intravenous injection of contrast material, pelvic or ureteral urothelial tumors typically have an average radiodensity of between 60 and 80 Hounsfield units (HU). In contrast, uric acid stones have much higher radiodensity, usually greater than 200 HU. Other causes of filling defects have less distinctive radiodensities: papillary necrosis at 20 to 40 HU and blood clot at 40 to 80 HU (94). In a review of 343 published cases, 43% to 77% clinicopathologic correlation between upper tract urothelial cancer and CT scan imaging was accomplished, with 7% to 31% overstaging and 13% to 36% understaging (19,22,94,121). Some of the understaging occurred due to small tumor volume. The most common findings were hydronephrosis in the case of ureteral tumors and filling defects in the case of renal pelvis tumors.

Renal parenchymal invasion (Fig. 17.6) can be seen on CT as an alteration in renal contour. The invasive renal urothelial cancer appears as a centrally located mass that distorts the renal contour. Poorly defined margins of the tumor, obliteration of renal sinus fat, and obliteration or entrapment of the collecting system all may be signs of renal parenchymal involvement (37). The specificity of these finding ranges from 75% to 97%, and the sensitivity ranges from 64% to 78% (19,22,94,121).

FIGURE 17.6. Computed tomography scan demonstrating a centrally located tumor with distortion of the renal contour.

In the case of ureteral tumors, determination of extension is less accurate, with a sensitivity of 67% and a specificity of 77% (94). Lymph node enlargement as a determinant of lymph node metastases has a sensitivity of 47% to 87.5% and a specificity of 94% to 100% (19,22,94,121).

CT urography is an evolving technique that attempts to duplicate and then improve on intravenous urography, taking advantage of the resolution and volumetric data acquisition of CT (149). The protocol varies from institution to institution, but generally it involves imaging during several phases of contrast excretion with three-dimensional reconstruction of images using a variety of algorithms. Although there are no large series yet describing the results of this new technique, it is likely that it will play an increasingly important role as an alternative to intravenous urography. Yet to be determined is the sensitivity of this technique for subtle tissue-density filling defects.

Ultrasonography

Surface ultrasonography provides a noninvasive method for evaluating the upper tracts that does not depend on the adequacy of renal function. In a series collected over a 9-year period (50), ultrasound identified the presence of hypoechoic intraluminal tissue in 16 patients with ureteral tumors. All 10 IVPs and all 3 retrograde pyelograms performed in these patients were abnormal, but only 7 of 11 CT scans clearly demonstrated the tumor. The utility of ultrasonography may be limited if hydronephrosis is absent, or by large body habitus or interference from overlying bowel gas. Information regarding the depth of invasion is unavailable with this technique, and ultrasonography is extremely operator dependent.

To provide more useful information with ultrasonographic imaging, some investigators have employed endoluminal ultrasonography. A 12.5- or 20-MHz transducer is housed within a 6.2-Fr ureteral catheter that is passed in a retrograde fashion up the ureter under fluoroscopic guidance. Liu and colleagues (81) suggest that use of endoluminal ultrasonography can provide information regarding the size and location of the lesion, as well as some estimation of the depth of penetration. In addition to diagnosis of other nonneoplastic causes of filling defects (i.e., stones, air bubbles, and blood clots), this technique may allow for the determination of the location of adjacent vessels before endoscopic resection. The technique has not been widely accepted, however, because it requires an invasive procedure, and as such, it is usually performed at the time of the intended definitive procedure. In this setting, the ultimate utility of the information is uncertain.

Cystoscopy

Cystoscopic examination of the bladder is necessary to rule out the coexistence of a bladder urothelial cancer. As noted, patients with upper tract urothelial cancers are at 20% to 48% risk of having a bladder tumor, either synchronous or metachronous (40,58,68,76,101,102,129).

Cytopathology

Upper urinary tract urothelial cancers can be diagnosed by the examination of voided urine cytology. As with urine cytology in the bladder, the accuracy of diagnosis depends on the grade of the tumor. Accuracy of voided urine cytology ranges from 23% to 92% (30). Improvement in diagnostic accuracy (77% to 92%) can be achieved by obtaining the urine sample through ureteral catheterization. It is worth noting that in a study of retrograde catheterization for urine cytology done following transurethral resection of bladder tumors, 25% of patients with low-grade urothelial neoplasms and 32% of patients with high-grade urothelial neoplasms in the bladder had positive upper tract urinary cytology (133). All of these patients had negative IVP or retrograde pyelography. This suggests that the results from upper tract sampling in the face of concurrent bladder urothelial cancer should be viewed with caution.

The best yields of cytology occur when samples are obtained by saline barbotage of the ureter following catheterization: 87% sensitivity and 100% specificity have been reported with this technique (78). The saline barbotage may improve the accuracy by providing a shearing force to loosen cells from the urothelial lining. Minimo and associates (97) report that the addition of computed DNA measurements and assays for p53 expression can enhance the accuracy of material submitted for cytology in terms of correlation with final histologic grade.

Brush Biopsy

Brush biopsies of the upper urinary tract lesions are performed by passing a fine brush mounted on the end of a guidewire passed through a ureteral catheter into the collecting system up to the level of the filling defect (44). Under fluoroscopic guidance, the brush is gently moved back and forth over the filling defect. Confirmation of the location of the filling defect is obtained fluoroscopically with the injection of dilute contrast. The brush is then removed and the sample is sent for cytologic examination. In one study by Gill and colleagues (42), both sensitivity and accuracy approached 100%. In other series, accuracy has ranged from 78% to 92% (15,165). Accuracy was greater if the cytologic specimens were read as either positive or negative for tumor, rather than requiring accurate grading of the tumor.

Although complications are rare, hematuria and occasionally some flank pain can occur following the brush biopsy of the upper urinary tract. The hematuria is often self-limiting, although severe hemorrhage and perforation of the ureter have been reported (15). There is some concern that denuding the urothelium as a result of the brush biopsy may provide an area for tumor implantation; however, in one retrospective study of 45 patients, there was no evidence of this (143).

Ureteroscopy

Flexible ureteroscopy was first reported in 1964 by Marshall (86), who passed a 9-Fr fiberscope into the ureter to visualize an impacted ureteral calculus. Since then, improvements in miniaturization, light-carrying capacity, fiber optics, and two-way active deflection have made flexible ureteroscopy an important part of the diagnostic armamentarium for upper tract urothelial cancer. Initially, Bagley and colleagues (9) had reported a 79% success rate in visualization of the whole intrarenal collecting system. However, with improvements in the equipment, one group was able to report in 1997 a 100% success rate (32). Ureteroscopy is an excellent modality to assist in the diagnosis of upper tract urothelial cancer when a filling defect of tissue density has been confirmed radiographically, but cytology is not positive for tumor. It is also useful for the evaluation of upper tract tumors to assist in treatment planning and, as described in a later section, the resection of selected tumors.

Use of flexible cup biopsy forceps or basket through the flexible ureteroscope has improved diagnostic accuracy for upper tract tumors. In the study by Keeley and colleagues (71) of 51 cases of upper tract urothelial cancer, 94% of the cases were diagnosed based on cytologic material collected. Grading of the ureteroscopic specimens was achieved in 82% of all cases (88% of diagnostic ones). The authors attributed their success to their sampling technique: ureteroscopic examination followed by aspiration, saline wash, biopsy of the lesions, and then another saline wash following the biopsy. In another study of 45 upper tract urothelial carcinomas, 40 (89%) were definitively diagnosed with ureteroscopic biopsy, and of these, the ureteroscopic biopsy grade matched the surgical pathology grade in 78% (49).

The possibility of pyelovenous or pyelolymphatic migration of malignant cells during ureteroscopy has raised some concerns. In one case report, tumor cells were noted in the submucosal lymphatic and vascular spaces when ureteropyeloscopy was performed immediately before nephroureterectomy (80). The authors suggested that the high-pressure irrigation required during ureteropyeloscopy played a role in forcing tumor cells into these spaces. A more recent study of 96 patients evaluating the long-term consequences of diagnostic ureteroscopy for upper tract urothelial carcinoma was unable to find any adverse effect on overall or disease-specific survival (55). Attempts to make definitive diagnoses of tumor stage with endoscopic biopsies of the upper tract collecting system risk perforation.

Fortunately, deep biopsies are not required because in most cases the grade of the upper tract urothelial tumor is an adequate surrogate for stage, at least for the purposes of planning treatment (70,71).

Ureteral perforation following ureteroscopy has been reported with an incidence of 0% to 4.6% (1,13,46,51). Long-term complications of ureteroscopy, most notably ureteral strictures, have an incidence of 0.5% to 1.4% (1,13,46,51). It is important to note that the lower rates cited for ureteral perforations and strictures have come from more recent series using smaller-diameter (6.9- to 7.5-Fr) flexible ureteroscopes (46,51,154). With these instruments, formal dilation of the intramural ureter is not usually required and ureteral trauma is minimal. These small-diameter ureteroscopes make possible direct visual confirmation and sampling of almost any upper tract urothelial cancer, which should provide for more exact identification and assessment of lesions than was previously available with only radiography and ureteral catheterization.

TREATMENT

Prognosis

Tumor grade and stage are important determinants of long-term outcome in upper tract urothelial cancer. Low-grade and low-stage upper tract urothelial tumors have a good outcome regardless of whether a conservative or more radical surgical approach is taken. Patients with intermediate grade or multifocal disease ultimately have a better outcome with radical surgery. Unfortunately, patients with high-stage and high-grade disease often do poorly regardless of the approach.

In one study, patients with grade 1 tumors had a 100% 5-year survival rate, those with grade 2/4 had an 80% 5-year survival rate, and those with grade 3/4 had a 60% 5-year survival rate (33). Both patients with grade 4/4 cancer succumbed to their disease. In another report, 27% of patients with grade 2 and 73% of patients with grade 3 disease died of their disease (107). In contrast, Mufti and colleagues (101) found survival to be greater than 90% for patients with superficial well-differentiated tumors regardless of whether they were treated with nephroureterectomy or more conservative methods.

Some have found multiplicity of the tumors to be a negative prognostic indicator. In Mazeman's 1976 review (89), patients with multiple tumors in the upper urinary tract experienced a decreased 5-year survival rate (20% versus 37% in individuals with single tumors).

DNA ploidy has been evaluated as an independent prognostic indicator. DNA ploidy relies on flow cytometric measurement of DNA content. Al-Abadi and Nagel (3) were able to find a correlation between DNA ploidy and tumor grade or stage. Although they did not find ploidy to be an independent predictor of prognosis, they did demonstrate that patients with aneuploid tumors did poorly. The poor response of aneuploid tumors was confirmed by Badalament and colleagues (8). In their series, patients with aneuploid tumors had a median disease-free survival of 19 months, and those with diploid tumors had a median disease-free survival of 59 months.

In an attempt to create a uniform management protocol for patients with upper tract urothelial cancer, the National Comprehensive Cancer Network guideline was created (136). Listed in the guideline are treatment algorithms using the latest information available on treatment outcomes. The guidelines incorporate the grade and stage in the management protocols.

Nephroureterectomy

Nephroureterectomy continues to be the preferred treatment for most upper tract urothelial carcinomas. The technique involves a simple nephrectomy and ipsilateral ureterectomy with the removal of a 2-cm cuff of urinary bladder. This procedure may be performed through a single midline incision or through two separate incisions such as a flank incision and a Pfannenstiel or lower midline incision to remove the distal ureter. Others have described endoscopic resection or mobilization of the intramural ureter followed by open en bloc resection of both the kidney and the ureter.

Johansson and Wahlqvist (67) advocate a transabdominal radical nephrectomy with adrenalectomy, in addition to a complete ureterectomy with bladder cuff. The 5-year survival rate of patients who had undergone the radical procedure was 84%, versus 51% for patients who had undergone more conventional resection. This difference was most marked in the high-stage patients (74% versus 37% 5-year survival). For small tumors, a simple nephrectomy with ureterectomy is probably sufficient, but in doubtful cases, or in the presence of a large tumor at high risk for invasion into the renal parenchyma, the inclusion of perinephric tissue as for radical nephrectomy (with or without adrenal gland, depending on tumor extent) is prudent. Komatsu and colleagues (75) also suggest that lymphadenectomy may provide some therapeutic benefit in selected patients. They found two long-term survivors whose nodes were located close to the original tumor. Other authors have not found a survival advantage to lymphadenectomy, reporting the likelihood of cancer death with uninvolved lymph nodes to be essentially the same as for those who had not undergone lymphadenectomy (23).

More recently, there has been the emergence of laparoscopic nephroureterectomy. This technique has been performed using both a transperitoneal and a retroperitoneal approach (41,90,127). Although requiring more specialized surgical skill and (usually) greater operative time, laparoscopic nephroureterectomy appears beneficial to the patient in terms of reduced blood loss, decreased postoperative narcotic use, and more rapid resumption of daily activities. In a series by Shalhav and colleagues (140), the disease-specific survival was identical for both laparoscopic nephroureterectomy and open nephroureterectomy (77%). Keeley and Tolley (72) reported similar success in 18 cases, in which only one patient with pT3 ureteral tumor developed a bladder and retroperitoneal recurrence.

Although laparoscopic nephroureterectomy appears to be a promising new minimally invasive technique, the technical demands and needs for specialized instrumentation make its widespread use unlikely at present. In addition, recent reports (2,111) of port site metastasis of urothelial carcinoma occurring following laparoscopic nephrectomy are worrisome, although in one of these cases (111) the urothelial carcinoma was unsuspected and the entrapment sac was torn during removal. Not only does urothelial carcinoma appear to have a propensity for wound seeding, but also intact specimen removal is desirable because the pathologic stage may have therapeutic implications. As such, when laparoscopic nephroureterectomy is performed for urothelial carcinoma, an incision large enough for extraction of the intact kidney is recommended. The addition of hand assistance to the laparoscopic technique, which allows the use of one hand within the operative field while maintaining pneumoperitoneum, takes advantage of this incision throughout the procedure rather than just at its conclusion. Hand assistance probably shortens operative time and appears to maintain the reduced morbidity of the laparoscopic procedure (163).

Renal-sparing Surgery

In the case of a pelvic tumor, a heminephrectomy or partial excision of the renal pelvis can be performed to remove the neoplasm with preservation of the kidney. Distal ureteral lesions can be managed by simple segmental resection and reimplantation; segmental resection of upper ureteral and midureteral tumors may require ileal interposition or autotransplantation. Conservative management may be indicated for patients with a solitary kidney, bilateral disease, or renal insufficiency. In patients with a functioning, disease-free, contralateral kidney, the indications for renal-sparing management (except for distal ureteral lesions) are less certain. The results of conservative management vary with the grade, stage, and multifocality of the neoplasm.

Open Surgical Approach

Localized surgical resection has been advocated for low-grade, low-stage distal ureteral tumors. Zungri and colleagues (168) demonstrated that survival for pTa disease was 100% regardless of whether the patient underwent more conservative or more radical surgery. In one series, Babaian and Johnson (7) reviewed the records of 44 patients with primary ureteral tumors and found that all of those with low-grade noninvasive disease confined to the distal third of their ureter were disease free following ureterectomy at the time of last follow-up. Segmental resection for low-grade and low-stage ureteral tumors produces results similar to that for nephroureterectomy. Zoretic and Gonzales (167) found that following nephroureterectomy, the 5-year survival rate was 50%. In contrast, the 5-year survival rate following segmental resection for low-grade and low-stage lesions was 71.4%, with ureteral recurrence rate of 6%. Similarly, Mufti and colleagues (101) reported 100% survival for low-grade disease treated with conservative resection.

In the middle and upper ureter, there has been less success with local resection—partially due to the technical difficulties resulting from insufficient remaining ureteral length to allow for reimplantation. Ileal interposition and autotransplantation with direct pyelovesical anastomosis have been described in these situations. In one series of 50 patients who had tumors too proximal to allow for complete resection of the distal portion of ureter, the investigators reported a recurrence rate of 50% at 3 years (89). Similar results have been noted by Strong and Pearse (150), who found a 30% recurrence rate in the portion of the ureter distal to the tumor in patients treated with local resection.

Local resection of the renal pelvic or calyceal tumors has usually been associated with a less favorable outcome. During open surgical local resection of renal pelvic

tumors, the luminal surface of the tumor being removed cannot be isolated as it can be for ureteral resection, and thus there is increased risk of tumor spillage into the surgical field. Open surgical resection of urothelial tumors in a renal calyx may require removal of renal parenchyma as well. Visualization of the calyces is limited, and multifocal disease that is not suspected radiographically might easily be overlooked. Open surgical resection of multifocal renal pelvic and calyceal tumors is technically difficult.

Mazeman (89) and Zincke and Neves (166) have reported recurrence rates as high as 45% to 65% following local resection of the renal pelvic tumors; the actual recurrence rates were dependent on grade. This is worrisome because Charbit and associates (23) noted that as many as 33% of patients had multifocal disease that was not recognized until histopathologic examination was complete, and that when recurrences occurred, 66% of these patients experienced an increase in grade or stage, or both. Mills and Vaughan (96) reported worse prognoses for invasive lesions in their series of 53 cases: patients with submucosal infiltration had an 80% 5-year survival rate, and those with periureteral fat invasion had only a 33% 5-year survival rate.

Findings suggest that the greater the length of the ureter remaining, the greater the chance for recurrence. Many investigators report that partial removal of the ureter results in a high ureteral stump recurrence rate. Recurrence rates range from 20% to as high as 58% (74,106,150) and may occur from 1 to 45 years after resection (102). Mazeman (89) showed that following subtotal nephroureterectomy, nephrectomy and partial ureterectomy, and simple nephrectomy, patients had recurrence rates of 24%, 32%, and 48%, respectively.

All these results taken together would suggest that elective open surgical renal-sparing management of upper tract urothelial cancers should be limited to distal ureteral tumors, or low-grade and low-stage lesions in the middle and upper ureter. Other tumors, such as those in the renal pelvis or higher-grade upper ureteral and midureteral cancers, are ideally treated with nephroureterectomy in the setting of a contralateral upper tract that is functioning and disease free. When open surgical renal-sparing management is chosen for such tumors because renal sparing is imperative (i.e., solitary kidney, bilateral disease, and renal insufficiency), it is technically difficult and carries a substantial risk of recurrence.

Endoscopic Approach

The first series describing ureteroscopic treatment of upper tract collecting system tumors involved the use of 12- to 13-Fr rigid ureteral resectoscopes. Size and rigidity limited the usefulness of these endoscopes. Endoscopic treatment for upper urinary tract disease has been simplified considerably by the development of small-diameter semirigid and flexible ureteroscopes. These have allowed clear visualization of tumors throughout the collecting system (Fig. 17.7). In addition, the application of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser and the holmium:yttrium-aluminum-garnet (Ho:YAG) laser through small-diameter fibers has made the endoscopic treatment of larger tumors more feasible.

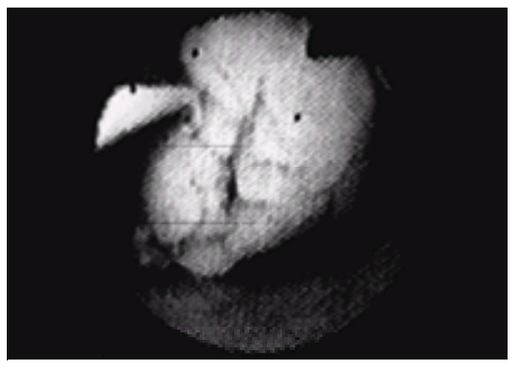

FIGURE 17.7. Endoscopic view of upper tract papillary urothelial carcinoma.

Simple fulguration with electrocautery can be used to treat small lesions or the base of a lesion following resection of the bulk of the tumor. However, fulguration of large portions of ureter may risk stricture formation. The depth of penetration (5 to 6 mm) of the Nd:YAG laser allows coagulation of full-thickness urothelium, but tissue ablation is not optimal with this laser. The Ho:YAG laser produces more ablation than coagulation of tissue, although the process is slow through the small fibers that can be passed through ureteroscopes. Combinations of Nd:YAG and Ho:YAG lasers have been used, taking advantage of the coagulative power of the Nd:YAG laser and the ablative power of the Ho:YAG laser (153).

In one retrospective review of 92 patients treated ureteroscopically, 76% of patients with grade 1 and 2 disease were able to become tumor free (70). Tumor size (larger than 1.5 cm), greater tumor grade, and multifocality predicted poor outcome. Similar favorable outcomes in the endoscopic treatment of low-grade upper tract urothelial cancer were reported by Martinez-Pineiro and colleagues (87). They reported that patients with grade 1 disease had a much lower recurrence rate than patients with grade 2 disease, 27% and 40%, respectively.

Controversy surrounds whether location of the tumor may play a role in treatment outcomes. Ureteral cancers have a lower recurrence rate than renal pelvic tumors. Blute and colleagues (14) reported a 63% failure rate for patients with renal pelvic tumors. One possible explanation to account for this difference is the greater accessibility of the ureter for endoscopic treatment than the renal pelvis. In contrast, Martinez-Pineiro and colleagues (87) reported a higher failure rate for ureteral tumors (36.6% versus 10% for renal pelvic tumors). Tawfiek and Bagley (153) reported that local recurrence rate was essentially the same for renal pelvic tumors (33%) and ureteral tumors (31.2%).

Complications resulting from endourologic management include formation of ureteral strictures and ureteral perforation. The risk of stricture disease following ureteroscopic treatment may be related to need for dilation at the ureterovesical junction and the extent of cautery and ablation required for treatment of the lesion. The use of small-diameter flexible ureteroscopes has reduced the need for formal dilation of the intramural ureter. Although initial reports described stricture rates as high as 25% (137), more recent series have reported more modest rates of 5% to 13% (33,70,87).

Ureteral perforations occur as a result of deep resection and can be managed conservatively with stent placement. Elliot and colleagues (33) report successfully treating two cases of ureteral perforation during endoscopic resection with double-J stent placement. In addition, the theoretic risk of dissemination of malignant cells into the retroperitoneal space has been raised. A case report of extravasation and propagation of tumor cells beyond the collecting system and into the parenchyma following ureteroscopic examination supports this fear (80).

Percutaneous management, another alternative for the renal-sparing management of upper tract urothelial cancer, is more suited for large tumors in the intrarenal collecting system or proximal ureter (Fig. 17.8). Once percutaneous access has been obtained, the tract is dilated to allow placement of a sheath, through which an endoscope with resection loop or biopsy forceps can be used to remove the tumor. Ablation and fulguration with a flexible electrode, rollerball electrode, or laser (Nd:YAG or Ho:YAG) following biopsy of the tumor(s) is useful when disease is extensive or difficult to access (105,110).

FIGURE 17.8. Percutaneous resection of large proximal ureteral tumor. **A:** Fluoroscopic view of lesion. **B:** Resectoscope in place for resection.

Similar to results obtained for ureteroscopic treatment, percutaneous resection or ablation of urothelial cancer has been most successful for low-grade and low-stage disease. In a series of 61 patients followed for a mean duration of four years, investigators reported 95% overall disease-specific survival: 100% for pTa lesions and 80% for T_1 lesions (61). Recurrence rates correlate with grade and stage of disease (24,62,77,116). Jarrett and colleagues (62) reported an 18% recurrence rate for grade 1 disease and a 50% recurrence rate for grade 3 disease. They strongly advocated second- and third-look procedures performed approximately 1 week apart to ensure that complete resection had occurred. Similarly, Clark and colleagues (24) reported a 28% recurrence rate for patients with grade 1 or 2 disease and 50% recurrence for grade 3 disease. Patel and colleagues (116) found a 12.5% recurrence rate for T_a disease and 50% for T_{2b} disease. Other reported recurrence rates range from 11% to 45% (61,120). Orihuela and Smith (110) found lower recurrence rates if second-look nephroscopy was performed, if Nd:YAG laser had been used for ablation, and if BCG had been instilled following resection.

Most complications of percutaneous management of upper tract urothelial cancer are similar to those for percutaneous management of stone disease. The most common complications are bleeding and extravasation. In addition to the cancer-specific risk of forcing cells into the systemic circulation as a result of pyelovenous or pyelolymphatic backflow (as in ureteroscopy), a unique concern associated with percutaneous treatment is the risk of tumor cells seeding the nephrostomy tube tract. Reports of seeding of the nephrostomy tract are numerous (24,36,57,139,141). One group advocates iridium wire brachytherapy within the nephrostomy tube tract to prevent recurrences (116). With this technique, this group did not experience seeding in their series of 28 patients. Others suggest the use of single-stage percutaneous access, tract dilation, and tumor resection as methods to reduce the seeding risk (119). Additional suggestions to prevent pyelovenous or pyelolymphatic backflow include keeping the irrigation fluid bag less than 40 cm above the level of the kidney and making sure that there is a loose fit between the working sheath and the nephroscope. Some investigators have gone as far as to suggest use of sterile water as the working irrigant to take advantage of its cytolytic properties; however, this practice may be associated with dilutional hyponatremia. The long-term effect of percutaneous treatment on renal function is not known. Jarrett and colleagues (62) reported two cases of chronic renal insufficiency that developed following percutaneous treatment.

Adjuvant Therapy

Topical Agents

As in the case of superficial bladder cancer, many investigators have explored the use of topical therapy with BCG, mitomycin C, and thiotepa. Drug delivery into the collecting system has occurred in a variety of manners: retrograde installation using ureteral catheters, direct installation through a percutaneous nephrostomy tube, or resection of the ureteral orifice inducing reflux into the collecting system (56,126,142). Although these reports suggest some benefit from these agents, there have not been any randomized trials to unequivocally demonstrate survival benefit due to the rarity of their application for upper tract urothelial tumors.

Herr (56) described creation of a pyelovesicostomy to allow reflux of BCG into the collecting system. The patient remained tumor free at 13 months of follow-up. Orihuela and Smith (110) reported on six patients who received six weekly courses of BCG via nephrostomy tube following percutaneous resection. The BCG was well tolerated and no incidence of sepsis was reported. Although they had a small number of patients, they found a lower recurrence rate with the use of BCG (16.6% versus 80% without BCG). Patel and Fuchs (115) showed that BCG could be instilled in a retrograde fashion via a transvesical single-J ureteral stent. At 1 year of follow-up, 15 of 17 renal units treated were preserved. In addition, there has been report of reflux of BCG through a ureteroileal anastomosis used as a method to keep one patient recurrence free at 1 year of follow-up (126). The direct routes of administration offer more assured contact of BCG with the upper tract tissue.

Several investigators have reported use of mitomycin C. Smith and colleagues (146) reported the treatment of superficial papillary urothelial carcinoma in the distal ureter with mitomycin C. Despite leaving the primary lesions unresected, both patients became tumor free and remained so after more than 2 years of follow-up. Eastham and Huffman (31) reported on the delivery of mitomycin C via percutaneous nephrostomy tube (continuous infusion of 40 mg in 1,000 mL of saline infused continuously at 50 mL hour) or ureteral catheter (5 mg in 20 mL of saline instilled and held for 30 minutes). Five of their seven patients were disease free 1 to 12 months following treatment.

De Kock and Breytenbach (28) reported the use of six weekly courses of topical thiotepa via retrograde ureteral catheter following local excision of a renal pelvis tumor in a solitary kidney. The patient required two 6-week courses to become disease free and subsequently developed thrombocytopenia. Although there was no recurrence of her renal pelvic tumor, with 6.5 years of follow-up, the thrombocytopenia points out a potential risk of thiotepa. One unusual report of intraureteral use of thiotepa involves the use of a subcutaneously placed Ommaya reservoir in the treatment of bilateral primary urothelial carcinoma of the ureter (123). The patient received four courses of thiotepa injected through the reservoir and continued to receive maintenance treatment via a retrograde ureteral catheter following removal of the reservoir. At 8.5 years following his initial treatment, the patient remained recurrence free.

In the absence of comparative studies between BCG, mitomycin, and thiotepa for topical upper tract therapy, at our institution we prefer percutaneous administration of mitomycin for treatment of residual upper tract urothelial neoplasms or prophylaxis following resection of high-grade disease, in patients who have imperative indications for renal sparing. Our protocol involves six weekly instillations of 30 mg of mitomycin in 60 mL of saline, instilled through a nephrostomy tube continuously for 2 hours at 30 mL hour. The nephrostomy tube is clamped between treatments, minimizing the inconvenience for the patient. Ureteroscopic reevaluation is performed 6 weeks after the last instillation, with repeat endoscopic fulguration or repeat topical therapy (possibly with BCG) in case of disease persistence, and removal of the nephrostomy tube if there is no evidence of disease.

Radiation Therapy

In an attempt to reduce local and regional failure rate, some investigators have explored the use of adjuvant radiotherapy. Cozad and colleagues (26) reported that adjuvant radiation decreased the 5-year local recurrence rate from 25% to 10%. This improvement in local control was also noted by Brookland and Richter (20), who noted an 11% local recurrence rate in patients with high-risk (stage III or grade 3) disease treated with radiation and a 45% local recurrence rate in patients who had not received adjuvant treatment. Although local control was possible, there was no improvement in the recurrence of distant metastasis and in overall survival. Maulard-Durdux and colleagues (88) reported that despite an improvement in local control, metastatic dissemination still occurred in 54% of patients. Ozahin and colleagues (112) also demonstrated this lack of improvement in overall survival in their review of 138 patients.

Chemotherapy

As in the treatment of advanced bladder urothelial cancer, cisplatinum-based chemotherapeutic regimens such as methotrexate, vinblastine, adriamycin, and cisplatinum (MVAC) have been used in both a neoadjuvant and an adjuvant setting (60,79,152). The effectiveness of cisplatinum-based chemotherapy regimens has been similar to that for bladder urothelial cancer. Lerner and colleagues (79), in a study of 28 patients with high-grade and advanced urothelial carcinoma of the upper tract, found a 54% overall response rate [18% complete response (CR) and 36% partial response (PR)] to platinum-based chemotherapy. However, 89% of these patients eventually succumbed to their disease. They suggested that their outcome might have been better if their patients had been able to tolerate a full course of treatment. Owing to renal insufficiency following their nephroureterectomy, all of these patients had required dose reduction. Similarly, Igawa and colleagues (59) found a 52.9% overall response rate for treatment of advanced renal pelvic and urothelial tumors. Although they were able to achieve durable CR, mean time to recurrence for patients with partial response was only 6.4 months.

More recently, investigators have reported success rates similar to that for MVAC using a combination of paclitaxel and carboplatin. Redman and colleagues (128) reported a 51.5% overall response rate (19% CR and 30.6% PR) in phase II trial. Similar results were also seen in a study of 32 patients at the University of Vienna, with a response rate of 71.9% (31.3% CR and 40.6% PR) (124). The toxicities associated with this combination, including myalgias, arthralgias, alopecia, and neutropenia, occur less often than with MVAC (124,128). Despite promising results, the mean time to progression after CR was reported at 7 months and after PR was only 5.9 months (124).

Others have reported additional success with a combination of gemcitabine and cisplatin. Gemcitabine, a cytosine analog, was shown to be active as a single-agent therapy in urothelial cancer (147). In combination with cisplatin, gemcitabine results in an overall response rate ranging from 41% to 52% (69,98,158). Toxicity associated with this combination was mainly hematologic. Median time to progression ranged from 5.5 months to 7.2 months, and median survival ranged from 12.5 to

14.3 months (69,98,158).

Although these new combinations present new therapeutic options in the management of advanced urothelial cancer, the long-term outlook for these patients remains poor.

HISTORY OF LAPAROSCOPY

Urologists have recently embraced laparoscopic surgery as another extension of their endourologic skills. Initially, this would appear to be a new era in urologic surgery. However, careful evaluation illustrates the extent to which we are the products of our past. The curiosity and adventurous thinking of past clinicians established a groundwork on which innovative modern surgeons have developed the potential of many basic concepts of laparoscopy. The first documented attempt to visualize a living human internal organ was by Philipp Bozzini in Frankfurt in 1806 (Table 18.1). He inspected the urethra with a double-lumen cannula; one lumen transmitted light from a candle and the other was for visualization (40). In 1877, Max Nitze in Germany first utilized a lens system for cystoscopy (147). This enabled him to view a magnified image of the urethra and bladder. Nitze, in collaboration with Joseph Leiter, refined his instrument to produce a practical endoscope, which consisted of a metal catheter with light provided from heated platinum wire loops sheathed in a goose quill and cooled by a continuous flow of water (147). Thomas Edison's invention of the incandescent light bulb in the United States in 1880 generated a new era of endoscopes (21).

1806	Bozzini uses a tube and a candle as a light source ("Lichtleiter") to visualize the human urethra.
1877	Nitze creates the prototype for the modern cystoscope.
1880	Edison invents the incandescent bulb.
1901	Kelling inserts a cystoscope into the inflated abdomen of a dog and describes "celioscopy."
1910	Jacobaeus performs laparoscopy on patients with ascites.
1929	Kalk introduces the forelique (35-degree) lens and advocates a separate pneumoperitoneum needle and "dual trocar" technique.
1938	Veress develops a special needle to induce pneumothorax to treat TB.
1952	Forestier, Gladu, and Vallmiere develop an endoscope with a proximal light source and a quartz rod system to transmit the light to the distal end of the scope.
1970s	Semm develops an automated insufflation device that monitors gas flow and intraabdominal pressure, and numerous instruments still used in modern laparoscopy.
1976	Cortesi uses the laparoscope for the first time in urology to localize a cryptorchid testis.
1987	Mouret performs the first laparoscopic cholecystectomy in a human.
1988	Mouret is denounced at Lyon Chirurgical de Francais.
1988	Dubois and Perissat in Europe and Reddick in the United States popularize laparoscopic cholecystectomy.
1989	Mouret is knighted and given the Croix de Chirque, the highest honor of Lyon Chirurgical.
1990	Clayman and associates perform the first laparoscopic nephrectomy.

TABLE 18.1. HIGHLIGHTS IN THE HISTORY OF LAPAROSCOPIC SURGERY

The birth of laparoscopy can be attributed to Georg Kelling, a surgeon of Dresden, Germany. In 1901, he described “coelioscopy,” a technique in which he filled the abdomen of a living dog with air and inserted a Nitze cystoscope to inspect the viscera. In the same year, D.O. Ott, a Russian gynecologist, published his “ventroscopic” technique in which he used a head mirror as a light source and inserted a speculum through a small abdominal or cul-de-sac incision to view the abdominal viscera (318).

Further work by H.C. Jacobaeus in Stockholm, Sweden, involved insertion of a trocar to create pneumoperitoneum in humans, and then insertion of a cystoscope to inspect the peritoneal or pleural space. In 1910, he reported on a series of patients in whom “laparoscopy” was performed, and he commented on cirrhotic changes in the liver, metastatic cancer, and tuberculous peritonitis (189). Bertram Bernheim, in 1911, performed the first diagnostic laparoscopy in the United States when he used a proctoscope and an ordinary light to examine the abdominal cavity (26). Subsequent to the pioneering work of these laparoscopists, new instruments and techniques were developed. Nordentoft used the Trendelenburg position to more easily view the pelvis of a cadaver (157). The sharp pyramidal-pointed trocar was developed by Orndoff in 1920 to facilitate trocar insertion (147).

The introduction of the oblique-viewing (35-degree) lens system by a German, H. Kalk, in 1929 allowed laparoscopy to become widely accepted as a diagnostic tool (205). Kalk also advocated the use of the pneumoperitoneum needle and the dual trocar to allow simultaneous visualization of and passage of instruments into the abdomen. He reported on more than 100 cases of laparoscopy using this technique and published the first color atlas of laparoscopy in 1935 (445). Ruddock, in the United States in 1934, performed peritoneoscopy with a device having integrated biopsy forceps (361). In 1938, Janos Veress of Hungary developed a special needle for inducing pneumothoraces to treat pre–antibiotic-era tuberculosis (429). This needle had a spring-loaded central blunt tip that protected the lung from injury after

the needle passed through the pleura and currently is often used for the creation of pneumoperitoneum.

A major advance in the technology of laparoscopy occurred in France in 1952 when Forrestier, Gladu, and Valmiere used a quartz rod to efficiently transmit a proximal light source to the distal end of the endoscope (15). At the same time, in England, Hopkins and Kapany introduced early fiberoptic technology to endoscopy (157). These developments resulted in a wider acceptance of laparoscopy, particularly for gynecologic diagnostic purposes.

The concept of monitoring intraabdominal pressure during pneumoperitoneum was promoted initially by Raoul Palmer of Paris, as early as 1947 (320). Professor Kurt Semm of Kiel, Germany, a gynecologist and engineer, developed an automatic insufflation device to monitor intraabdominal pressure and gas flow (147). He was one of the innovative researchers and clinicians in the field of laparoscopy. Many of the instruments and techniques devised by Semm are still used today, including thermocoagulation during laparoscopic procedures, hooked scissors, tissue morcellators, the endoloop suture applicator, an irrigation and aspiration device, techniques for intracorporeal and extracorporeal knot tying, needle-holders, clip-appliers, atraumatic forceps, microscissors, and the “pelvic trainer,” designed to teach surgeons laparoscopic techniques (378). Semm expanded the indications for laparoscopy by advocating laparoscopic lysis of adhesions, bowel suturing, tumor biopsy, and incidental appendectomy.

The first case report of laparoscopy in the urologic literature appeared in 1976 when Cortesi and associates (66) used the laparoscope to successfully localize bilateral abdominal testicles in a cryptorchid adult patient. However, surgeons were generally slow to recognize laparoscopy as a valuable diagnostic tool, considering it to be a “blind” procedure, providing incomplete examination of the abdominal cavity. Laparoscopy lost further ground when computed tomography (CT) was developed for clinical use and ultrasonographically directed biopsies became generally available. Despite this turn of events, many pioneering surgeons continued to enthusiastically popularize laparoscopy as a valuable diagnostic and therapeutic modality with significant clinical benefits (135,136,159,180,320).

Therapeutic laparoscopy necessarily lagged behind diagnostic laparoscopy (137). Frimdberg, in Europe in 1978, performed laparoscopic cholecystectomy in pigs (105). In 1987, Philippe Mouret in Lyon, France, performed the first laparoscopic cholecystectomy in a human (328). Interestingly, Mouret was denounced the following year at the Lycee Chirurgical de Francais for performing what was considered a surgical procedure with unwarranted risk for the patient. However, during 1988, Dubois and Perissat in Europe and Reddick in the United States popularized laparoscopic cholecystectomy (86,328,352). Within a matter of months, it became apparent that this minimally invasive approach to the gallbladder was going to revolutionize the practice of general surgery. Laparoscopic cholecystectomy has since become the standard of therapy for routine gallbladder removal. In 1989, Mouret not only was vindicated by reinstatement, but was awarded the Croix de Chirurgue, the highest honor of the Lycee Chirurgical.

Presently, laparoscopic surgery has pervaded not only gynecology and general surgery, but also thoracic surgery. The gynecologic procedures commonly performed are myriad: hysterectomy, ovariectomy, tubal ligation, and, more recently, tubal reconstruction. In general surgery, the three most commonly performed open procedures are all now in the realm of laparoscopy: herniorrhaphy, cholecystectomy, and appendectomy. In addition, other procedures are becoming more commonplace: adhesiolysis, bowel resection, choledocholithotomy, posterior truncal vagotomy, anterior seromyotomy, and Nissen fundoplication (71,81,208,330,377). With regard to thoracic surgery, the laparoscope has also made inroads in the treatment of emphysematous blebs and reflex sympathetic dystrophy and is also being used to perform lung biopsy and to drain loculated empyema. Similarly in cardiac surgery, single-vessel coronary artery bypass is now just beginning to be performed laparoscopically; the entire procedure is done in the closed chest on a beating heart.

The use of laparoscopic surgery in urology paralleled, to a large extent, the aforementioned developments in general surgery. Although Cortesi reported the first urologic laparoscopy to localize cryptorchid testes in adults in 1976, the initial pediatric laparoscopic localization of an undescended testicle was reported by Silber in 1980 (390). Since then, more than 350 laparoscopic procedures to identify an undescended testicle have been reported in the literature (260). The laparoscopic approach is more rapid, less morbid, and of equal accuracy compared with open surgical exploration for an undescended testicle. Over the past 15 years, laparoscopy has supplanted open surgical approaches to the localization of undescended testicles, management of intersex disorders, and the biopsy of pelvic gonadal organs.

However, it was not until the late 1980s, with the advent of interest in pelvic lymph node dissection, that laparoscopy made its entry into mainstream urology. Gynecologists were the first to advocate laparoscopic lymphadenectomy for staging of pelvic cancers (353). The first staging laparoscopic pelvic lymphadenectomy for prostate cancer was attempted by Hald in 1980. However, he found the extraperitoneal approach to be limited and unsatisfactory (150). It was the clinical work of Schuessler and Vancaillie in 1989 that demonstrated the feasibility of completing the staging of patients who had carcinoma of the prostate with the minimally invasive technique of transperitoneal, laparoscopic obturator node dissection (375). The reports of this work initiated a new era in urologic surgery, and soon laparoscopy was applied to a variety of urologic procedures previously approachable only by a flank or an abdominal incision.

The development of a surgical entrapment sack and a high-speed, 10-mm electrical tissue morcellator was integral to the concept of removing large, solid tissue specimens via a laparoscopic approach. In 1990, Clayman and colleagues (62) used this technology to perform the first laparoscopic nephrectomy. Since that time, unique laparoscopic techniques have been used in several medical centers to accomplish a variety of other urologic procedures, including nephroureterectomy, bladder neck suspension, pelvic lymphocelectomy, ureterolysis, and adrenalectomy (5,6,209,215,255,407). Anecdotal reports have included cystectomy, renal cyst decortication, renal exploration, partial nephrectomy, ureteroureterostomy, nephropexy, prostatectomy, and ileal conduit formation (225,265,300,301,322,372,426,441). Many recent applications of laparoscopy to urologic surgery have demonstrated the feasibility of these techniques to complete the intended diagnostic or therapeutic objective and provide the patient with a more comfortable and shorter recuperative period compared with more traditional open surgery. Continued laboratory and clinical research will expand the field of laparoscopic urologic surgery for both therapeutic and reconstructive techniques.

GENERAL LAPAROSCOPIC TECHNIQUE

Laparoscopy has been applied recently to myriad surgical procedures for the urologic patient. Despite this increasing diversity, there exists a set of basic concepts and principles associated with laparoscopic techniques in general.

Access with Gas

The basic principle of laparoscopy is to maximally distend the potential space of the peritoneal cavity, facilitate visualization of the viscera, and insert various instruments to complete the surgical procedure. Various gases have been used to create the working environment of the pneumoperitoneum, including filtered room air, nitrous oxide, carbon dioxide, argon, and helium.

Types of Insufflants

Nitrous oxide will support combustion if present in a high concentration (98). Therefore this gas is not acceptable as an insufflant for modern laparoscopy because of the increased use of laser and electrocautery techniques in most surgical laparoscopic procedures. Indeed, nitrous oxide should not even be used as an anesthetic during any therapeutic laparoscopic procedures. It has been shown that during extended laparoscopic surgery, nitrous oxide may diffuse from the bowel into the peritoneal cavity in concentrations that could support combustion of bowel gas (298). There has been a report of a case of colonic explosion during colonic diathermy in a patient with rectal cancer (9). Thus it is advisable to avoid the use of nitrous oxide even as an anesthetic agent during long laparoscopic procedures.

Carbon dioxide is readily available in most operating rooms and is relatively inexpensive; thus it has become the most commonly used insufflant. Carbon dioxide absorption into the blood during laparoscopic surgery may lead to respiratory acidosis, increased ventilation requirements, and potentially serious cardiovascular compromise. In the clinical setting, the increased CO_2 load is not a problem if the patient is managed with controlled ventilation. As a result, most patients undergoing laparoscopic urologic procedures are managed with cuffed endotracheal general anesthesia and controlled ventilation. Mullet and colleagues (290) showed that CO_2 diffusion into the body, as measured by end-tidal CO_2, increases gradually and then plateaus approximately 10 minutes after insufflation; this observation is not influenced by the duration of intraperitoneal insufflation. During extraperitoneal pelvioscopy, CO_2 diffusion into the body is more marked and does not tend to plateau with the duration of insufflation. The anesthetic records of 62 patients undergoing laparoscopic renal surgery at Washington University were evaluated for hourly estimates of CO_2 expiration (Vco_2) during the preinsufflation period and the first 4 hours of insufflation (446). Vco_2 increased with time, although the increase over the previous interval was less pronounced every hour after the first. Most of the increase occurred during the first 2 hours of insufflation. Multifactorial analysis revealed that the extraperitoneal, as compared with the transperitoneal, approach and the presence of subcutaneous emphysema were strongly and independently associated with a greater increase in Vco_2. Pneumothorax and pneumomediastinum were significantly more common during extraperitoneal (37%) than transperitoneal (3%) laparoscopy. There were five postoperative cardiopulmonary complications, none of which was related to hypercapnia. Thus CO_2 absorption during laparoscopic renal

surgery, which is greater than occurs during pelvic laparoscopy, was highest in patients approached through an extraperitoneal route and in those with subcutaneous emphysema. Nonetheless, with aggressive intraoperative mechanical ventilation, no sequelae of hypercapnia were noted in this series. Also, it must be noted that if one uses a cuffed Hasson cannula, the risk of hypercarbia with the retroperitoneal approaches appears to be eliminated. This type of cannula seals the port site, thereby effectively eliminating subcutaneous emphysema and the associated problems of hypercarbia (303).

Helium is biologically and chemically inert and therefore has been proposed as an alternative insufflating agent. Leighton and colleagues (234), in animal studies, showed that helium insufflated intraperitoneally did not cause hypercarbia, aciduria, or pulmonary hypertension when using the same insufflation conditions as for CO_2. These results support the concept that the transperitoneal absorption of CO_2, not increased dead space, is responsible for the respiratory acidosis observed during pneumoperitoneum.

Argon is an inexpensive inert gas that also has been used for intraabdominal insufflation. Animal studies at Washington University School of Medicine demonstrated that an argon pneumoperitoneum of 20-mm Hg pressure had the same hemodynamic and renal effects as 20 mm Hg of CO_2 (271). Argon is not absorbed as easily as CO_2; thus the degree of respiratory acidosis is less when using this agent as an insufflant. However, any of the inert gases, which are slow to reabsorb, may result in prolonged duration of subcutaneous emphysema that may occur during laparoscopy and also put the patient at a higher risk for problems should a gas embolus develop. There has been one report in the literature of an argon gas embolism during laparoscopic cholecystectomy when an argon beam coagulator was used for hemostasis of the liver bed (249). Gas embolism can occur whenever a large amount of any gas is administered directly into the vascular system; however, the poor solubility of the inert gases compared with CO_2 exacerbates the potential problems due to a gas embolism.

Method of Introduction

The pneumoperitoneum can be established using either a closed or an open technique. The Veress needle is used to penetrate the abdominal wall and deliver CO_2 gas into the abdomen for the closed technique of insufflation. This 14-gauge needle may be 12 or 15 cm in length and is either disposable or nondisposable. The 15-cm needle is useful in the very obese patient to facilitate successful access to the peritoneal cavity. The reusable needle is made entirely of metal and tends to be heavier than the disposable needle, which has a plastic hub; the needle point may become dull with repeated use and therefore must be sharpened regularly. Also, the reusable needle must be disassembled and all the parts cleaned after each use.

The Veress needle consists of an outer 14-gauge sheath with a sharp beveled tip and an inner spring-loaded, blunt tip. The blunt tip retracts back inside the outer sheath on meeting resistance of the fascia or peritoneum. This presents the sharp beveled tip to the fascia and peritoneum, allowing penetration (Fig. 18.1A). The inner blunt tip springs forward immediately on entry into the abdominal cavity and release of resistance (Fig. 18.1B). The hub of the Veress needle may have an indicator to show when the inner blunt tip is retracted or presented. The hub also has a Luer-Lok connector for attaching the aspirating-irrigating syringe of saline and the CO_2 insufflating tubing. There may be a stopcock on this side arm to interrupt the flow of CO_2 into the abdomen.

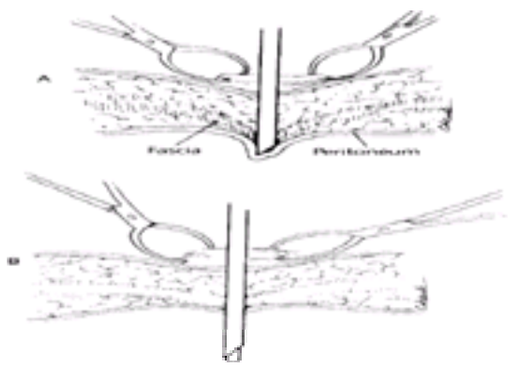

FIGURE 18.1. A: The Veress needle has a spring-loaded, blunt-tip obturator that is pushed back inside the sheath to expose the sharp tip of the sheath during penetration of the fascia and peritoneum. **B:** Immediately upon passing through the fascia and peritoneum, the inner blunt tip springs forward to protect the intraabdominal structures from the sharp needle tip. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

The Veress needle is most commonly inserted at the umbilicus because the peritoneum is closer to the skin at this point on the abdominal wall (Fig. 18.2). The properitoneal layer of fatty tissue, which lies between the linea alba and the peritoneum, is thinnest at the level of the umbilicus. The extremely obese or very thin patient may require special consideration during Veress needle and initial port insertion. Hurd and associates (181) studied the relationship of the umbilicus to the aortic bifurcation using magnetic resonance imaging (MRI) and CT. They assessed the effect obesity has on this relationship. In nonobese patients weighing less than 160 pounds (73 kg), the umbilicus is a mean distance of 0.4 cm caudal to the aortic bifurcation, with a skin-to-peritoneum distance of 2 cm. In obese patients weighing between 160 and 200 pounds (73 and 91 kg), the umbilicus is 2.4 cm caudal to the aortic bifurcation, with a skin-to-peritoneum distance of 2 cm. In obese patients weighing more than 200 pounds (91 kg), the umbilicus is located 2.9 cm caudal to the bifurcation of the aorta, with a skin-to-peritoneum median distance of 12 cm. The authors concluded that Veress needle insertion in the nonobese patient should be at a 45-degree angle from the horizontal (Fig. 18.3) to reduce the risk of major abdominal vascular injury and properitoneal placement (182). Because of the increased distance to the peritoneum in the obese patient and the caudal displacement of the umbilicus in relationship to the aortic bifurcation, the Veress needle should be inserted at a 90-degree angle from horizontal to achieve intraperitoneal placement. In patients who have had previous abdominal surgery, alternative sites may be used for the Veress needle insertion to avoid adhesions.

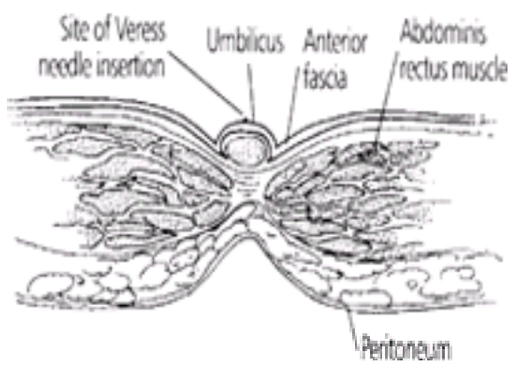

FIGURE 18.2. The properitoneal layer of fatty tissues is thinnest at the umbilicus, providing this site with the shortest distance between the skin and peritoneum. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

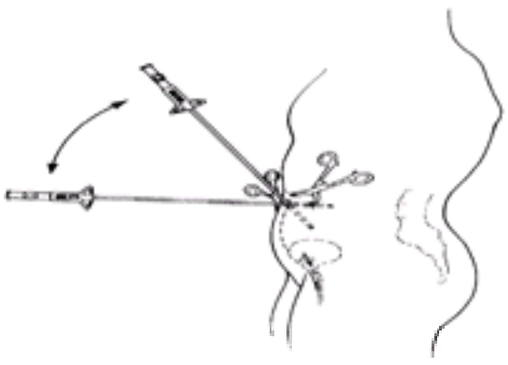

FIGURE 18.3. In the nonobese patient, the Veress needle should be inserted at a 45-degree angle from the horizontal to minimize the risk of injury to the retroperitoneal great vessels. In the obese patient, the increased fatty tissue space between the skin and the peritoneum dictates a Veress needle insertion at a 90-degree angle to the umbilicus to achieve intraperitoneal placement of the needle tip. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

A small skin incision is made with a no. 12 hook blade at the supraumbilical or infraumbilical crease. A sharp towel clip is placed on the skin edges, on either side of the incision, to stabilize the skin during needle insertion. The Veress needle is held like a dart in the dominant hand and passed into the wound. As the needle passes through the anterior abdominal fascia and then the peritoneum, resistance will be felt and also observed due to movement at the spring-loaded hub. A click may be heard as the blunt trocar springs forward into the peritoneal cavity.

The intraabdominal positioning of the Veress needle is confirmed by performing four test maneuvers. First, a 10-mL syringe with 5 mL of saline is attached to the hub of the needle. The syringe is aspirated to determine that no blood or bowel contents enter the barrel of the syringe. Second, the saline is injected through the needle; it should inject easily without any resistance. In the third step, the syringe is used to reaspirate the needle. With a true intraabdominal positioning of the needle, there should be no return of fluid into the syringe. As the syringe is removed from the needle, the small amount of saline remaining in the hub should flow easily into the abdomen. The final test is to advance the needle 1 to 2 cm into the abdomen; neither the tip indicator nor the hub should show any indication of encountering resistance. Only after all of these tests confirm satisfactory intraperitoneal positioning of the Veress needle should CO_2 insufflation begin.

The sterile insufflation tubing, which has been connected to the insufflator, is placed on the Luer-Lok of the Veress needle hub as the needle is held steady by the surgeon. CO_2 insufflation is commenced with a flow rate of 2 L minute or less, and the intraabdominal pressure limit is set at 10 mm Hg. The initial intraabdominal pressure should be less than 10 mm Hg. If the intraabdominal pressure is greater than 10 mm Hg, the needle should be rotated or withdrawn slightly. If the pressure remains high, the insufflation should be terminated and the Veress needle removed and reinserted; alternatively, an open technique for establishing the pneumoperitoneum can be used. The intraabdominal pressure usually remains less than or equal to 10 mm Hg until 500 to 1,000 mL of CO_2 have been insufflated. After 500 mL of gas is instilled into the peritoneal cavity, the abdomen will be slightly and symmetrically distended and tympanic on percussion. The insufflation flow rate can then be maximized and the desired pressure limit set for the primary trocar insertion.

Retroperitoneal Veress needle insufflation can also be performed in those patients in whom a retroperitoneoscopic approach is planned. The procedure is commenced by inserting a Veress needle through either the inferior posterior lumbar triangle (Petit's) in the posterior axillary line just above the iliac crest or the superior posterior lumbar triangle, just posterior to the tip of the twelfth rib. The retroperitoneum is inflated with approximately 2 to 3 L of CO_2, and then a 10- or 12-mm port is inserted at this site. Visualization of the retroperitoneal space with the laparoscope and blunt dissection with this instrument creates a small space within the retroperitoneum that will allow introduction of the dilating balloon catheter.

The dilating balloon catheter is created by cutting the middle finger off of a size 8 Triflex sterile latex surgeon's glove (Baxter Health Care Corp., Valencia, California). The finger of the glove is placed over the tip of a 16-Fr red rubber catheter and secured in place with two 0-silk ligatures so that the openings in the tip of the catheter lie within the finger of the glove. The balloon catheter is back-loaded through a 30-Fr Amplatz sheath until the balloon is retracted just inside the sheath. The assembled unit is inserted through the 10- or 12-mm primary trocar until the tip of the Amplatz sheath lies just at the port opening. The balloon catheter is advanced through the Amplatz sheath 3 to 4 cm into the perirenal space (outside Gerota's fascia), and then the balloon is filled with 1 L of normal saline. This provides an adequate working space and minimizes the risk of balloon rupture from overdistention. The fluid is aspirated from the balloon catheter, which is then withdrawn into the Amplatz sheath, and the balloon and Amplatz sheath are removed from the port. The pneumoperitoneum is established to a pressure of 10 to 15 mm Hg and the laparoscope is inserted.

For the neophyte laparoscopic surgeon, the open technique for obtaining a pneumoperitoneum is recommended. Indeed, some surgeons advocate this approach in all patients undergoing laparoscopic surgery to minimize the risk of vascular, bowel, or omental injury (204). One study has shown that the open technique for placement of the primary port, including establishment of the pneumoperitoneum, is faster, safer, and more cost-effective compared with the closed technique (16). However, this study used the closed technique in the initial 150 patients, changing to the open technique for the subsequent 150 patients (41). It is important to realize that complications can occur, albeit rarely, with the open technique for pneumoperitoneum (363).

The open technique should be used whenever intraperitoneal positioning of the Veress needle cannot be confirmed with confidence. Similarly, patients with multiple previous surgical procedures on the abdomen may have significant adhesions, obviating blind access to the peritoneal cavity.

The open technique of accessing the abdominal cavity involves a small (2- to 3-cm) laparotomy for insertion of a blunt-tip, Hasson cannula. The skin incision is usually made at or just below the umbilicus, unless there are preexisting abdominal scars, in which case a point lateral to the abdominus rectus muscle, farthest from the incisions, is used. Through a transverse incision, the subcutaneous tissue is dissected and the anterior abdominal fascia is exposed and incised (2 cm) (Fig. 18.4A). The properitoneal fat is then bluntly swept off the peritoneum. The peritoneum is grasped, using small hemostats, and elevated (Fig. 18.4B). Scissors are used to incise the peritoneum to admit the surgeon's index finger. Satisfactory entry into the abdominal cavity is confirmed by digital palpation or visual inspection. A 0 Vicryl or silk suture is placed on either side of the fascial incision.

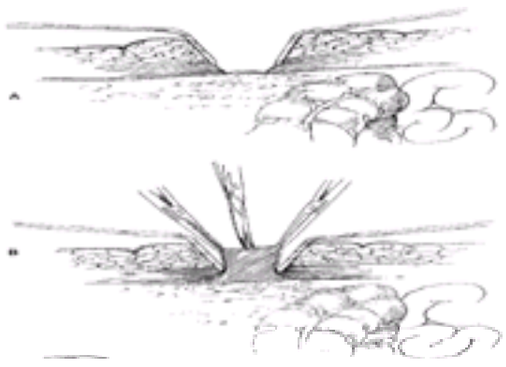

FIGURE 18.4. A: The open technique of port placement requires incision of the skin and fascia to accommodate the planned port and exposure of the peritoneum by bluntly retracting the peritoneal fat. **B:** The peritoneum is grasped and elevated by two small hemostats, and scissors incise the peritoneum to admit the surgeon's finger and then the blunt-tip port. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

The Hasson-type cannula used in the open approach consists of three components: a cone-shaped sleeve, a metal sheath with a trumpet valve to which two struts

are affixed for tying the suture, and a blunt-tipped obturator. The metal sheath can be moved up and down through the cone-shaped sleeve to allow proper positioning before tightly affixing the sleeve to the sheath.

The blunt tip of the obturator within the Hasson cannula is inserted through the peritoneal incision, and the cone-shaped sleeve is slid down snugly against the fascia (Fig. 18.5). The two fascial sutures are secured to the struts on the sheath of the cannula, after the sleeve is secured to the sheath with the set screw. The fascial sutures fix the cannula in place. Sterile insufflation tubing is connected to the cannula and the blunt-tipped obturator is removed. The CO_2 insufflator is set at a high flow rate and the intraabdominal pressure is raised to 15 mm Hg. This port may now receive the laparoscope.

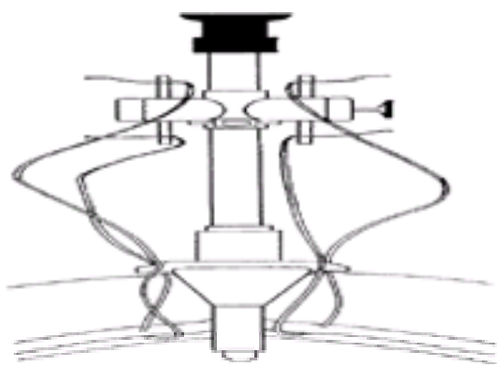

FIGURE 18.5. The blunt tip of the Hasson cannula is inserted through the peritoneotomy, and the cone-shaped sleeve is slid down snugly against the fascia. Two preplaced fascial sutures are secured to the struts on the sheath to hold the port in place. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

An open insertion can also be performed for retroperitoneoscopy. The Hasson cannula is usually placed at the superior posterior lumbar triangle. A 1.5-cm skin incision is made to accommodate the appropriate size of Hasson cannula chosen. A Kelly forceps is used to spread the subcutaneous fatty tissue and expose the fascia overlying the musculature. A 1.5-cm incision is made through the fascia with a no. 12 hook blade. The Kelly forceps are then used to spread the muscle layers into the retroperitoneal space. Next, blunt finger dissection can be performed confirming the retroperitoneal positioning of this incision; the surface of the psoas muscle should be easily palpated with the tip of the surgeon's finger. The balloon catheter, back-loaded through a 30-Fr Amplatz sheath, can then be delivered directly into the retroperitoneal space. The Amplatz sheath is withdrawn, leaving the balloon catheter in position. The balloon is filled with 1 L of normal saline creating the retroperitoneal working space. The balloon is aspirated of the fluid and withdrawn. Alternatively, extensive blunt finger dissection of the retroperitoneal space can be performed in smaller patients in lieu of using the balloon.

The Hasson cannula is now positioned. Stay sutures placed on the fascia are used to secure the Hasson cannula in place. Alternatively, a Hasson with a balloon retention mechanism and an outer soft foam cuff device (Origin Medsystems, Inc., Menlo Park, California) can be used; with this device, no sutures need to be placed and the chances of subcutaneous emphysema appear to be decreased. The pneumoretroperitoneum is established to a pressure of 10 to 15 mm Hg.

Insufflator

The insufflator allows the laparoscopist to create and maintain the pneumoperitoneum. It consists of a valve mechanism, which can be adjusted and monitored, to allow the flow of pressurized gas from the tank into the patient's abdomen. The insufflator unit should consist of gauges that will (a) indicate the rate of flow (liters per minute) of CO_2 from the insufflator; (b) constantly display, on an analog or digital gauge, abdominal pressure (millimeters of mercury); and (c) indicate the total volume of CO_2 (in liters) that has been instilled into the abdomen. A separate indicator measures the line pressure of the gas tank, providing the surgeon with information regarding the amount of CO_2 remaining in the gas tank. The CO_2 is transported from the insufflator to the patient by flexible, inert tubing. The tubing may have an incorporated filter and a Luer-Lok fitting end to snugly attach to the Luer-Lok of the Veress needle or the side arm of one of the laparoscopic ports.

The CO_2 flow rate is adjustable to between 0 and 10 L per minute. A low flow rate of 1 to 2 L per minute is generally used at commencement of the insufflation process. After satisfactory instillation of 500 to 1,000 mL of CO_2, the flow rate is increased to a medium or high flow rate (6 to 10 L per minute) for the duration of the procedure. The insufflator should be placed just below the surgeon's monitor so that a continuous display of intraabdominal pressure is clearly visible to the surgeon throughout the operative procedure.

The insufflator can be preset for a specific intraabdominal pressure so that the flow of CO_2 gas will cease automatically if the preset pressure is exceeded and an alarm will sound to draw attention to the elevated pneumoperitoneum pressure. Intraabdominal pressures greater than 15 mm Hg are associated with decreased venous return due to vena caval compression, impaired ventilation as a result of pressure on the diaphragm, increased risk of CO_2 absorption causing systemic acidosis, and decreased urine output (269). For adult laparoscopic procedures, the intraabdominal pressure set point should be 10 to 15 mm Hg.

The insufflator should be tested for satisfactory functioning before each laparoscopic procedure. An additional reserve of CO_2 should always be available in the operating room.

Clinical studies at Washington University have shown that the volume of CO_2 insufflated and the insufflation pressure of the pneumoperitoneum during laparoscopy are directly related. However, this volume and pressure relationship is completely independent of patient weight, height, and body mass index (a measure of obesity) (267). Increasing the intraabdominal pressure from 15 to 30 mm Hg increases the volume of CO_2 insufflated by 50%. However, in animal studies, when the pneumoperitoneum pressure is compared with the estimated actual intraabdominal volume, the intraabdominal volume increases by only 5% to 6% when the intraabdominal pressure is increased from 15 to 30 mm Hg. These results suggest that increasing the pneumoperitoneum to 30 mm Hg does not significantly increase the actual intraabdominal volume, but the increased pressure may effect greater compression of the intraperitoneal viscera and put the peritoneum under more tension. Therefore increasing the intraabdominal pressure to 25 to 30 mm Hg for the primary port placement may facilitate this step of laparoscopy and minimize potential complications. Clinical studies at Washington University have shown that elevating the pneumoperitoneum pressure to 30 mm Hg for the primary port placement has no deleterious effect on the heart rate, blood pressure, cardiac output, or end-tidal CO_2 (284). Following placement of the initial port, which usually takes less than 10 minutes, the pneumoperitoneum is reduced to 15 mm Hg or less for the duration of the procedure.

Access Without Gas

Increased intraabdominal pressure is associated with significant changes in systemic vascular resistance, blood pressure, and cardiac return (207,235). Insufflation of gas into the peritoneal cavity results in an increase in intraabdominal pressure and vena caval compression with subsequent reduction in venous return to the heart. Insufflation to pneumoperitoneum pressures of 15 to 20 mm Hg is generally well tolerated; however, increases greater than 20 mm Hg often decrease cardiac output and arterial blood pressure.

The Trendelenburg position causes the weight of the abdominal contents to rest on the diaphragm. Insufflation of the abdomen exerts an additional force against the diaphragm. Together these factors restrict lung expansion and decrease pulmonary compliance, resulting in ventilation-perfusion mismatching (376). Absorption of insufflated CO_2 into the vascular system combined with the ventilation-perfusion mismatching leads to significant hypercarbia during laparoscopic procedures (287). General anesthesia with controlled ventilation and close monitoring is able to minimize these effects (8).

Intraperitoneal pressures of 10 mm Hg or greater are associated with decreased renal vein flow and a concomitant decrease in urine output (269). Release of the pneumoperitoneum does result in a return of the renal vein flow and the urine output to preinsufflation values when the prolonged pneumoperitoneum has been at 10-mm Hg pressure. However, after prolonged pneumoperitoneum pressure of 15 or 20 mm Hg, the renal vein flow does not return to preinsufflation levels for up to 2

hours after desufflation.

Alterations in renal vein flow and urine output are seen also with insufflation of CO_2 into the retroperitoneum at a pressure of 20 mm Hg. Animal studies have demonstrated a significant increase in the end-tidal CO_2 following retroperitoneal insufflation. Accordingly, an increased ventilation rate was required to maintain the end-tidal CO_2 between 30 and 40 mm Hg. At necropsy in these study animals, diffuse bilateral distribution of gas throughout the retroperitoneum was noted, although the insufflation was performed through one port on one side of the retroperitoneum.

Wakizaka and colleagues (430) studied the effects of CO_2 insufflation during laparoscopic cholecystectomy on arterial blood gas analysis and urine output. Both the increase in $Paco_2$ and the decrease in pH was larger in the group of patients undergoing laparoscopy at an intraabdominal pressure of 15 cm H_2O, as compared with patients operated at an intraabdominal pressure of 10 mm Hg. At a pneumoperitoneum of 15 cm H_2O, the increase in $Paco_2$ was significantly higher if the operative time was more than 60 minutes, compared with patients with an operative time less than 60 minutes. This change in $Paco_2$ with respect to the operative time was not noted when the intraabdominal pressure was maintained at 10 cm H_2O. Also, obese patients (obesity index greater than 120) developed significantly higher levels of $Paco_2$ during CO_2 insufflation, compared with patients who were not obese.

In an attempt to avoid these complications of pneumoperitoneum, the Laparolift device (Origin Medsystems, Inc., Menlo Park, California) has been developed (299). The abdomen is accessed in a manner similar to the open technique. After the skin, fascia, and peritoneum are incised, a double-bladed lift device is inserted through the peritoneotomy with the blades closed. Once the blades are within the peritoneal cavity and resting against the undersurface of the anterior abdominal wall, they are opened to their maximum angle of 45 degrees. A hydraulic L-arm is secured to the operating table edge and directed over the patient. After endoscopically the positioning of the device's blunt blades are satisfactorily confirmed under the anterior abdominal wall, the lift device is connected to the hydraulic arm. The hydraulic arm then can be raised mechanically to apply between 0 and 15 kg of force on the abdominal wall. Animal studies at Washington University on the effect of pneumoperitoneum on renal function included evaluation of the Laparolift (269). As expected, unlike with a CO_2 pneumoperitoneum, the Laparolift did not have an associated increase in end-tidal CO_2 levels during its use. There was no associated decrease in urine output when applying the Laparolift at forces of 5, 10, or 15 kg. These devices have been used successfully to perform laparoscopic cholecystectomy and pelvic procedures (17,160). However, they are somewhat limiting during procedures, such as laparoscopic nephrectomy, in which the laparoscope and instruments are moved to different port sites during the operative procedure. The hydraulic arm positioned over the patient may limit easy access to some of the ports.

Other mechanical devices have been developed to elevate the anterior abdominal wall, thus creating an intraabdominal space for performing laparoscopic procedures. One of the original concepts used for elevating the abdominal wall was described by Kitano and colleagues (221a). After first obtaining a standard CO_2 pneumoperitoneum, they used a U-shaped trocar to traverse the peritoneal cavity and travel around the falciform ligament; the trocar then was lifted by a winch and framework located above the patient's anterior chest wall. Other groups have used long surgical wires placed in the subcutaneous tissue of the abdomen, or large-caliber suture material passed through the abdominal wall, to winch the abdominal wall anteriorly for exposure (17,160,293). The limited current clinical application of these devices suggests that they may be less than ideal for most laparoscopic surgical procedures.

Transperitoneal Approach: Pneumoperitoneum

Placement of the Primary Port

In the open technique, the primary port (Hasson cannula) is placed first, followed by establishment of the pneumoperitoneum. In the closed technique, the primary port is inserted after establishing an adequate pneumoperitoneum with the Veress needle. The pneumoperitoneum may be established between 15- and 30-mm Hg pressure before insertion of the port (267).

Before the Veress needle is removed, the skin incision is extended to accommodate the size of the planned port (usually 10 or 12 mm). The incision should approximate the diameter of the port as closely as possible to reduce gas leakage around the port during the procedure.

Trocars are available in a vast array of sizes and types and may be reusable or disposable. Trocars consist of two components: a sharp-pointed, removable obturator to facilitate insertion through the abdominal fascia and peritoneum, and an outer sheath through which the obturator passes. The sheath contains a valve or diaphragm through which instruments may be passed without any loss of the CO_2 pneumoperitoneum. A side-arm stopcock on the port allows connection of the insufflating tubing. Laparoscopic trocars have a safety shield that retracts during insertion of the trocar through the fascia and peritoneum to allow exposure of the sharp pyramidal tip of the obturator. When the port tip enters the gas-filled peritoneal cavity, resistance from the fascial and peritoneal tissue is released and the spring-loaded shield moves forward and locks in place to cover the sharp tip of the obturator and reduce the risk of injury to the underlying viscera.

Corson and colleagues (65) studied the force required to insert nondisposable and disposable ports during a pneumoperitoneum of 11.57 mm Hg. Nondisposable trocars required twice the force used to pass through the anterior abdominal wall as compared with disposable trocars. In the animal laboratory, McDougall and colleagues (267) assessed the force required to insert four different types of 10-mm disposable trocars at 15- and 30-mm Hg pneumoperitoneum pressure. There was no significant difference in the force necessary for the insertion of each of the ports at 15- versus 30-mm Hg pressure. Also, there was no significant difference in force of insertion between the two trocar systems with a safety shield versus the nonshielded trocar. A trocar that used an electrocautery cutting current wire at the tip of the blunt obturator did require significantly less force by 1 to 2 kg during insertion when compared with the other three ports at both 15- and 30-mm Hg pressure. Therefore, after placement of the first port at an intraabdominal pressure of 30 mm Hg, it is reasonable to reduce the pneumoperitoneum to 15 mm Hg for all subsequent port placements.

In preparation for primary port placement, the patient is positioned slightly head-down, and the intraabdominal pressure may be increased transiently to 20 to 30 mm Hg. Following an adequate incision at the supraumbilical or infraumbilical crease, the subcutaneous tissues are spread with Kelly forceps in a cephalocaudal direction. This helps push small blood vessels from the path of insertion of the port and allows the incision to assume a more rounded configuration. The abdominal wall may be stabilized by grasping and raising it, beneath the umbilicus, in the surgeon's nondominant hand. Alternatively, a sharp towel clip may be placed just at the skin edge on either side of the incision; one towel clip is held and stabilized by the assistant, and the other is held by the surgeon's nondominant hand.

The surgeon holds the fully assembled trocar in the palm of the dominant hand with the hub of the trocar secured against the thenar eminence. The middle finger is extended along the shaft of the trocar to act as a brake and prevent too sudden or deep an advancement into the abdomen during insertion.

The trocar is inserted with a steady downward pressure and a twisting motion as the fascia is traversed. The pressure must be constant and maintained to prevent disengagement of the obturator from the sheath. If disengagement occurs, a click will be audible, which signifies that the safety shield has locked into position over the sharp obturator tip and further attempts to pass the trocar through the fascia will be futile. The trocar must then be removed and reset before proceeding with insertion.

Immediately upon entering the gas-filled abdominal cavity, the click of the secured safety shield will be heard, and the hissing of CO_2 gas escaping from the open side arm will confirm this position. The side arm is closed, the port is gently advanced 2 cm deeper into the peritoneal cavity, and the obturator is removed. The CO_2 insufflation tubing is connected to the side arm, which is then opened, and insufflation is commenced at a maximum flow rate with the maximum intraabdominal pressure set at between 10 and 15 mm Hg.

A nondisposable trocar may be used as a primary port, although it does not have the safety shield mechanism for the sharp pyramidal tip. Surgeons using nondisposable trocars may prefer to use the open technique for primary port placement to reduce the risk of intraabdominal injuries possibly associated with an unshielded trocar passed blindly into the peritoneal cavity. The Endotip port (Storz Endoscopy, Inc.) is a unique nondisposable trocar. It has a blunt leading tip and a screw configuration along the body of the cannula. This port is screwed through the abdominal wall until the hiss of CO_2 gas from the open sidearm confirms positioning in the abdominal cavity. The port minimizes trauma to the abdominal wall and reduces the risk of intraabdominal injury by providing a blunt leading tip.

Abdominal Inspection

Light Source

An efficient light source will optimize depth perception and image detail during laparoscopic surgery. Laparoscopic light sources are high intensity and use a xenon, mercury, or halogen vapor bulb with an output of 250 to 300 W. There should always be a reserve light bulb available in the operating room.

The intensity of the light output is manually adjustable. Some light-source units have an automatic light-level adjustment that varies according to the level of light reaching the camera; however, they should also have a manual control. Light is transmitted from the light source of the laparoscope by a flexible fiberoptic cable. These cables are light-source and laparoscope specific. It is essential that all the connections fit correctly and snugly to ensure no loss of light transmission to the surgical field. These cables are sterilized before each use and must be handled with care to avoid breakage of the individual fiberoptic fibers of the light cord. The integrity of the light cord can be reviewed before each procedure by connecting the cable to the light source and observing for an even emission of light from the end of the cable; dark areas indicate broken fibers.

Camera

The camera system comprises the camera and a video monitor. The camera locks onto the eyepiece of the endoscope and magnifies the laparoscopic image to provide excellent visualization of fine anatomic details. The camera transmits the optical information from the laparoscope via a cable to the camera box. The camera box electronically reconstructs the image and transmits it to the video monitor where the optical information is displayed for viewing by all operating room personnel. Currently, most laparoscopic cameras are sterilized by soaking or by gas before each use, thereby precluding use of any plastic sterile camera wraps.

Recently, innovative digital technology has been put to use in endoscopic imaging equipment. Image enhancement is a digital-subtraction image processing system that works between the camera and the video monitor; the digital-subtraction process results in contrast enhancement, detail enhancement, edge enhancement, and edge correction of the endoscopic video images in real time. This allows the viewer to accentuate structures that are obscure or otherwise poorly visible to the naked eye. The increased detail recognition improves the potential video diagnostic capabilities and facilitates monitoring of technical operative procedures such as endoscopic suturing and dissection of fine structures.

Depth perception is the product of human binocular vision. Because the pupils of human eyes are separated by approximately 5 cm, each of the eyes sees an object from a slightly different perspective. The optic nerves relay the separate left and right views from the eyes to the brain. The two images are merged by the brain into a single, three-dimensional (3D) image that provides more information than either view separately. Developments in endoscopic video systems have attempted to replicate human binocular vision (367). These video systems consist of a camera system that acquires two separate endoscopic images; a signal processor that digitizes, accelerates, and synchronizes the two video signals; and a video display that alternately displays the two images at a rate of 120 frames per second so that the eyes and brain assemble the two images as if they were coincident. The resultant brain image is a single, three-dimensional image, as in normal binocular vision. The advantages of a 3D video system include restoration of depth perception to aid in definition of the relationship of anatomic structures, easier instrument placement and manipulation, and enhancement of the image, which facilitates more precise intracorporeal tasks such as suturing and knot tying. Some preliminary studies suggest that 3D video has the potential to make minimal-access surgery easier, quicker, less prone to error, and more applicable to advanced procedures (274,282). Work continues with these prototype 3D video systems to improve and refine this technology. At present, these systems are more expensive than the existing one-chip 2D video system and three-chip 2D video system. However, these costs may equalize in time.

The camera should be oriented so that the monitor image is in a “true,” upright position, which is the same as would be seen through an open abdominal incision. This is particularly important when using the 30-degree laparoscope. With this instrument, the camera must be held at all times in the true, upright position; the laparoscope can then be rotated through 360 degrees to provide visualization around and over intraabdominal structures, as well as up to the anterior abdominal wall. When a 0-degree laparoscope is used, the camera should be positioned in the true, upright position; then the laparoscope eyepiece can be locked onto the camera because rotation of the 0-degree endoscope will not change the straight-ahead field of vision as long as the camera is maintained in its true orientation.

Insertion of a cold or room temperature laparoscope into the warmer abdominal cavity may produce fogging of the lens and blurring of the monitor image. Accordingly, it is helpful to keep the laparoscope immersed in hot saline until insertion into the abdomen. Wiping the end of the lens with an antifog solution or povidone-iodine solution may also reduce condensation forming on the instrument. The insufflation of the cold CO_2 gas through the laparoscope port may also produce cooling and subsequent fogging of the laparoscope during the procedure. Therefore, following insertion of the second port, it is helpful to transfer the CO_2 insufflation tubing to the side arm of this port. It is important to maintain a watertight seal between the camera and the endoscope. Moisture collecting on the eyepiece or camera will produce blurring of the image and require disconnection of the two pieces and careful wiping to completely dry these surfaces before reconnection.

Video monitors are available from a variety of manufacturers in 13- or 19-inch sizes. The larger monitors provide a larger picture but poorer image resolution. Most monitors with higher resolution capabilities of 1,125 lines of resolution must be used with a camera system capable of providing the appropriate input.

Abdominal Inspection

The initial critical function of the first port inserted into the abdomen is to facilitate insertion of a 10-mm laparoscope to perform a complete inspection of the abdomen. The endoscope must be fully prepared for use before establishment of the pneumoperitoneum. The preparation of the endoscope involves several steps. The camera is locked onto the eyepiece of a 0- or 30-degree laparoscope. The 30-degree laparoscope allows more versatility in visualizing around or over intraabdominal structures, but this endoscope requires a conscientious camera operator to maintain proper orientation because the camera must remain true and stable while the shaft of the endoscope is rotated to take full advantage of the 30-degree angulation of the lens. The light cable is connected to the light post of the laparoscope and the intensity of the light is turned up to the maximum setting. The laparoscope is then directed toward a white gauze pad and the image on the monitor is focused sharply on the monitor screen. While still focused on the white gauze pad, the camera “white balance” button is pressed until the indicator shows that white balancing has been completed. This ensures a naturally colored monitor image. As a final step it is helpful to prewarm the endoscope with warm saline and wipe the tip of the endoscope with an antifogging solution to reduce fogging of the endoscope on introduction into the warm abdominal cavity.

For primary ports of 10 mm or greater in size, a 10.5-mm reducer must be applied to the sheath before insertion of the laparoscope. These reducers may be detachable, or attached and flip on and off the sheath. With the sheath appropriately reduced, the 10-mm laparoscope is introduced into the abdominal cavity. The bowel immediately below the port should be examined for any evidence of bleeding or injury that may have occurred during the primary port placement. Blood dripping from the port may suggest a through-and-through bowel injury or abdominal wall vessel injury, which is better delineated after the second port has been placed, facilitating transfer of the laparoscope and examination of the primary port site. Blood dripping along the port may obscure the lens and make visualization difficult until the endoscope can be moved to an alternative port and the bleeding vessel controlled with electrocautery or a transcutaneous hemostatic suture.

With the laparoscope positioned satisfactorily in the peritoneal cavity, the surgeon proceeds with a systematic examination of the entire abdomen. The laparoscope is first directed caudally toward the pelvis, where the midline posterior wall of the bladder can be seen with the broad urachus (i.e., median umbilical ligament) extending up toward the umbilicus (Fig. 18.6). On either side of the bladder, the medial umbilical ligaments are usually quite prominent as they travel just lateral to the bladder; they also are umbilically directed. In very obese patients, the medial umbilical ligament may be difficult to identify. Lateral to the medial umbilical ligaments are the internal inguinal rings on either side of the pelvis. Extending from the internal inguinal ring, the vas deferens (male; Fig. 18.6A) or the round ligament (female; Fig. 18.6B) can be identified, passing medially to cross the free edge of the medial umbilical ligament before descending deeper into the pelvis. Also exiting from the internal inguinal ring are the gonadal vessels as they course cephalad just under the peritoneal membrane in the retroperitoneum. In female patients the midline uterus and laterally positioned ovaries are visualized. The laterally lying colon will also be visualized, and on the right side the cecum and appendix are apparent. There are often adhesions from the descending colon to the lateral pelvic wall. Coursing along the anterior abdominal wall are the inferior epigastric vessels, just medial to the internal inguinal ring and lateral to the medial umbilical ligament. These structures are more easily visualized using the 30-degree laparoscope.

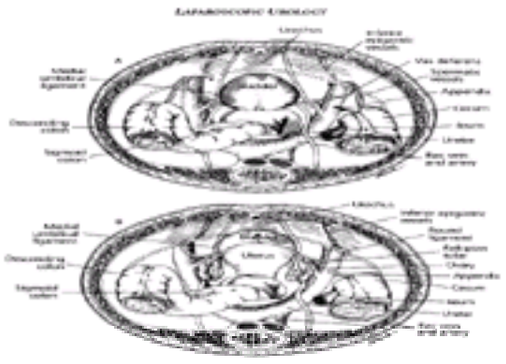

FIGURE 18.6. A: Laparoscopic examination of the male pelvis will include identification of the midline urachus and bladder, medial umbilical ligaments on either side of the bladder, bilateral internal inguinal rings, and spermatic vessels. The vas deferens may be seen just beneath the peritoneum, passing medially from the internal ring and crossing the medial umbilical ligament. **B:** Laparoscopic examination of the female pelvis will include identification of the midline urachus, bladder and uterus, medial umbilical ligaments on either side of the bladder, bilateral internal inguinal rings, and ovaries and fallopian tubes. The round ligament passes from the internal inguinal ring medially to cross the medial umbilical ligament. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

The laparoscope is then rotated to a cephalad orientation to view the upper abdomen. The liver, gallbladder, stomach, and spleen are examined. The omentum and small bowel should be assessed for any possible injury during Veress needle insertion or port placement. Also, there is usually an adhesion present from the splenic flexure of the colon to the abdominal sidewall.

Placement of Additional Trocars

After the abdominal examination has been completed, attention is directed to placement of additional ports to facilitate performance of the planned surgical procedure. The exact pattern of the port arrangement will depend on the type of procedure to be performed and the surgeon's preference. It is advisable to use a 10-mm trocar for the second port placement, allowing transfer of the 10-mm, 30-degree laparoscope for visualization of the primary port. This size endoscope is mandatory if omental, bowel, or abdominal wall vascular injury during primary port placement is suspected. Also, if one is planning to use any of the GIA-type laparoscopic staplers, a 12-mm port is necessary.

Secondary ports are positioned such that they are not too close to each other; if placed too close together, they will limit maneuverability because the sheaths interfere with each other on the abdominal surface, and the movement of instruments within the ports causes them to strike against one another and impede access to the surgical site (Fig. 18.7A).

FIGURE 18.7. A: Ports placed too close together will limit the movement of the sheaths on the abdominal surface and cause the instruments to strike against one another and obstruct access to the surgical site. **B:** Optimal port placement allows the assistant to grasp tissue opposite the surgeon's grasper, thus creating traction and countertraction. The surgeon may then use a cutting device to incise the intervening exposed tissue. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

Pressure on the abdominal wall at the planned secondary port site and simultaneous laparoscopic visualization assist in determining the exact port site in relationship to the surgical field; the 30-degree laparoscope is most useful for this procedure. After selection of the port site, the room lights are dimmed and the area of the abdominal wall is transilluminated with the laparoscope inside the abdomen. The tip of the laparoscope is moved upward until it is just underneath the abdominal wall. Large superficial abdominal wall blood vessels can be identified and avoided using this technique. Trocars should not be placed through the abdominus rectus muscle. The inferior epigastric vessels can be visualized with the laparoscope; they are positioned just lateral to the medial umbilical ligament and caudal and medial to the internal inguinal ring. The 30-degree endoscope is useful for this maneuver to facilitate the secondary port placement immediately medial or lateral to the inferior epigastric vessels.

A transverse skin incision is made with the no. 12 hooked blade to precisely accommodate the size of the chosen port. Pressing the port, without the obturator, against the skin to leave an imprint of the port circumference assists in determining the correct length of the skin incision. All secondary ports should be directed through the fascia and peritoneum in a direct line with the planned surgical site. If this principle is followed during port placement, the sheaths will naturally point toward the surgical fields. This minimizes the amount of torque applied to the port site during manipulation of the instruments and reduces tearing of the peritoneum, which may cause CO_2 leakage. It also improves the surgeon's limited tactile sensation during intraabdominal handling of the tissues with the instruments. Using continuous laparoscopic monitoring, the secondary port is advanced through the fascia and peritoneum with a constant pressure and a slow, twisting action. The tip of the obturator will be seen laparoscopically to enter the abdominal cavity, and the safety shield will snap forward over the sharp obturator tip. Insertion of the port is continued until the shaft of the sheath is seen to protrude 1 to 2 cm inside the peritoneum.

The resistance of the abdominal wall may not allow the obturator to pass through the fascia and peritoneum without placing the sharp obturator tip dangerously close to the underlying viscera. To counteract this situation, sharp towel clips may be placed on the skin edges of the port site to elevate the abdominal wall away from the viscera. Also, after the sharp obturator point has passed through the fascia and peritoneum, the port can be redirected toward the laparoscopic lens for the remainder of the sheath insertion, thereby directing the sharp obturator point way from the viscera.

It is important to secure the port to the insertion site so that it does not become dislodged during instrument manipulation. Some ports consist of a self-retaining device, including (a) a Malecot flange system that will open on removal of the obturator or by opening a lever on the upper sheath; (b) inflation of a balloon at the distal end of the port sheath by injecting air through a side port; (c) a plastic retentive sleeve that is screwed down, over the sheath, through the fascia and peritoneum 1 to 2 cm, and tightened onto the shaft of the port; or (d) an integral screw edge on the outside of the port cannula. When using any of the retentive sleeves, it is essential to *never* use a plastic retentive sleeve in combination with a metal sheath because this can create a problem with electrosurgical capacitive coupling and subsequent bowel injury. Alternatively, the port may be sutured to the skin with a no. 2 Prolene suture; this technique has the advantage of allowing the port to be advanced farther into the abdomen, yet it cannot be inadvertently removed from the abdomen.

The first crucial function of the second inserted port is to facilitate examination and confirmation of accurate positioning of the primary port. Immediately following the securing of the second port, the laparoscope is transferred to the second port and the primary port is examined. This will ensure that no bowel or omental injury has occurred and that the port site has satisfactory hemostasis. The sheath of the initial port is then positioned so that 2 cm extends inside the abdominal cavity; a

retentive device or suture may be used to secure this port in this position.

The laparoscope is then returned to the umbilical port position, and the remaining secondary ports for the surgical procedure are inserted. It is important to place these other ports to facilitate traction and countertraction of tissues held in grasping forceps by the surgeon and assistant, respectively. The surgeon's electrocautery scissors should enter the abdomen from the same side and in a similar trajectory to the laparoscope to allow the surgeon to work with a “true” monitor image and manipulate or cut the tissue held between the two grasping forceps (Fig. 18.7B).

Instrumentation

The selection of laparoscopic equipment has increased exponentially over the past 4 to 5 years, reflecting how much laparoscopic surgery relies on the associated technology. Many of the instruments are available as disposable or nondisposable products. The nondisposable instruments have the advantage of representing a single monetary expenditure for the hospital, but the disadvantage of becoming dull or less efficient with repeated use. The disposable instruments are more expensive, which is of increasing concern in our present era of health care cost awareness. Until recently, disposable instruments have provided more versatility and specific functions than the more traditional nondisposable instruments. Presently, some instruments are being developed as “reposable” units: They have components (e.g., the blades of the scissors or jaws of a forceps) that can be discarded or replaced and that are mounted on a nondisposable shaft; this combination makes their use less expensive than classic disposable units while providing the surgeon with optimal instrumentation for each procedure.

Laparoscopy remains limited by the loss of 3D and wide-field vision perspective and the reduction of tactile sensation. Many features of the instrumentation of laparoscopy attempt to accommodate or compensate for these limitations. It is important for the laparoscopist to be familiar with the equipment used in each laparoscopic case and to determine which additional instruments will better facilitate the performance of a specific planned procedure. The intention of this review is not to provide an exhaustive list of available laparoscopic equipment, but rather to discuss the basic principles of the laparoscopic instrumentation available to surgeons and some of the more recent adaptations that may be useful in specific circumstances.

Grasping Instruments

Many grasping instruments are available for laparoscopy. These instruments vary in size from 3 to 12 mm and may be reusable or disposable. Grasping forceps are insulated, allowing them to be used for cauterization of the tissue they are grasping. The opening mechanism of grasping forceps may be single action, where only one jaw moves when the instrument is opened, or double action, with opening movement of both jaws. The double-action grasping forceps are usually preferable because they more closely approximate those used during open surgical dissection.

Grasping forceps may be locking or nonlocking. Two mechanisms have been developed to produce locking of the grasping forceps: the spring-loaded locking handle and the ratchet-style locking handle. The spring-loaded grasping forceps remains securely locked closed until the handle, which fits in the surgeon's hand, is firmly squeezed to open the jaws and release the held tissue. The ratchet-style locking grasper has a bar-type finger-activated ratchet that locks the jaws in the closed position with varying degrees of tension on the tissue. The jaws will not open until the ratchet lock is released.

The main difference between grasping forceps is the tip design. Grasping-forceps tips may be classified as traumatic or atraumatic. Atraumatic graspers have serrated grasping surfaces for gentle manipulation of tissues. The tip shape is variable and includes blunt, pointed (e.g., dolphin), straight (e.g., duck bill), curved, and right-angled. Traumatic graspers are designed to hold fibrous tissues securely and tightly and usually are toothed or clawed. The jaws of these instruments tend to be broader and longer. These instruments also include Allis, Babcock, and bowel clamps and may have tip-rotating and articulating functions to better access the operative site.

Cutting Instruments

Tissues can be transected using laparoscopic scissors, scalpels, electrosurgical probes, laser fibers neodymium:yttrium-aluminum-garnet (Nd:YAG) or potassium titanyl phosphate (KTP)], or high-speed ultrasonic instruments. Endoscopic scissors may be reusable or disposable and are available in a variety of shapes. Scissor blades may be straight or curved for dissection. Serrated tips are useful for cutting fascia, and a hooked tip facilitates transection of sutures. The scissors may be insulated to facilitate simultaneous electrocoagulation and transection of tissues. The ability to rotate or angulate the tips of the scissors, by turning a finger control knob, allows easier access to a variety of surgical sites. Scissors with angulating blades are useful for adhesiolysis between the bowel or omentum and the anterior abdominal wall. Curved electrosurgical scissors with rotating tip provide for excellent access to most surgical sites, rapid dissection of tissues, transection of tissues with mechanical (i.e., cold) cutting when near delicate structures such as the bowel, and electrical currents for incision and coagulation of tissues.

Laparoscopic scalpel blades are also available. These were initially developed for incising the common bile duct and have had limited applicability to laparoscopic urology. Recently, they have been used for incision of the urethra during a laparoscopic radical prostatectomy. Great care should be used when inserting, manipulating, or removing these instruments to avoid inadvertent intraabdominal injuries.

Electrosurgical currents may be applied to insulated instruments with needle-point, flat-spatula, or right-angled hook tips. A thin metal tip provides the greatest current density and the most efficient cutting. A needle electrode (i.e., Corson needle) creates a very fine incision of the peritoneum or tissues. A right-angle or hooked tip can be manipulated under tissues and used to draw the tissues away from underlying structures before electrical activation and incision of the tissue. The most common setting for cutting and coagulation currents on electrosurgical instruments is 25 to 50 W; the lowest setting necessary to achieve effective coagulation is recommended. It is imperative that the insulation material on the shaft of the instrument be completely intact to prevent inadvertent sparking of current between instruments or to adjacent tissues. Also, the entire active tip of the electrosurgical instrument should be visualized laparoscopically while being used, to avoid injury to adjacent structures (438). As previously noted, metal trocar sheaths should not be used in conjunction with plastic retention sleeves when electrocautery is being used. The plastic sleeve acts as an insulator and may allow electric charge to build up in the metal sheath. Inadvertent contact between the bowel and the metal sheath could result in a bowel injury or perforation.

The most effective electrocoagulation of small blood vessels is achieved by using an insulated grasper to grasp the tissue and oppose the walls of the vessel. Directly applying an electric current to the grasping forceps, or touching the tips of the forceps with an activated electrosurgical instrument in the coagulation mode, will coagulate the coapted vessel. Last, many electrosurgical instruments are combined with an aspirator-irrigator. This facilitates suctioning of the smoke generated during fulguration and cutting of tissues.

Monopolar electrosurgical instruments are most commonly used and require a remote ground so that the electric current applied to the tissues passes through the patient's body to the ground pad. Bipolar laparoscopic electrosurgical instruments are available. They incorporate both the live and ground contacts in the tip of the instrument; no ground pad is used and the electric current passes only between the two contacts. Less energy is required for bipolar electrocautery, as compared with monopolar; thus inadvertent injury to surrounding structures is reduced.

Laser probes, including KTP (532 nm) and Nd:YAG (1,064 nm), also may be used for cutting and fulgurating tissues. The KTP laser facilitates noncontact cutting and noncontact fulguration. The Nd:YAG laser provides contact cutting and noncontact fulguration. A 600-micron fiber is usually passed through an aspirator-irrigator instrument for stabilization. Wavelength-specific protective eyeglasses must be worn by all operating room personnel whenever laser energy is being used. In addition, a special filter is necessary on the camera to prevent disturbance of the image during laser firing.

A recent development in tissue cutting and hemostasis is the harmonic knife. This instrument uses high-frequency ultrasound to create rapid vibration of the tip of the instrument. Using different frequencies and the edge or flat portion of the spatula tip, the surgeon can selectively cut or coagulate tissues.

Retractors

Retractors often are required to expose a surgical site by retracting liver, spleen, or bowel, or to facilitate dissection by retracting the kidney to place the hilar vessels on slight stretch. Although many retractors have been developed, the simplest remains a blunt-tip grasping forceps in either a 5- or 10-mm size, depending on the available port site. These instruments can be used to elevate the liver or spleen or medially retract the bowel. Instruments specifically designed to be retractors possess a feature that, when opened, increases the surface area against which they are placed. This allows dispersion of the force of retraction over a larger surface of the retracted structure, thereby reducing the risk of visceral injury. Also, better visualization results because a large amount of tissue can be retracted. Retractors

include 5- and 10-mm instruments.

Fan retractors consist of three or four blunt-tip blades that can be opened after intraabdominal positioning. A variation of the fan retractor consists of two blades with an interposing V-hinge joint. When the V hinge is opened, the outer blades spread apart, creating a broad retracting surface. This retractor can be opened to the desired width and locked into position. Recently, the fan retractor has been modified by the addition of an inflatable balloon around the blades of the fan. After positioning the instrument into the abdominal cavity, the blades are opened. A syringe is attached to a side-arm connector, and the balloon covering the blades is inflated with 10 to 20 mL of air. This provides a larger surface area for retraction and thus better distributes the pressure applied to the tissues, potentially causing less ischemia and less chance of organ injury. Vein retractors are available in 5- or 10-mm diameter and consist of a broad, bluntly curved tip for gentle retraction of vascular structures. In addition, 14-gauge needle hook retractors are available; these are inserted separately into the abdomen, and the small hook end is advanced and secured on the peritoneal edge or tissue for retraction. A major advantage of this retractor is that it does not have to be passed through any of the ports.

There are several options for the surgeon to create his or her own retraction devices in the operating room. For example, a 24-inch length of umbilical tape, suture material, or vessel loop may be placed around the ureter or blood vessel for retraction purposes. The needle-pointed grasper of the Carter-Thomason device (see Exiting the Abdomen) can be used, through a small stab wound on the flank, to deliver and retrieve the ends of the tape, suture, or loop. A mosquito clamp on the abdominal wall side maintains tension on the retraction around the ureter or vessel, without using a port site for this purpose.

Sewing Instruments

Laparoscopic suturing and knot tying are two of the most challenging skills for the laparoscopic surgeon to acquire. Recent technologic developments have helped simplify some aspects of these techniques.

Laparoscopic ports used during suturing may vary from 5 to 12 mm in diameter. It is important to plan the surgical procedure and determine the most appropriate port size for each location according to the anticipated need for needle introducers, clip-appliers, or stapling devices. Reducer caps allow working instruments of smaller diameter (3.5 to 10.5 mm) to be used through larger laparoscopic ports (5 to 12 mm) without loss of the pneumoperitoneum. These reducers may be an integral part of the port or may be readily affixed to the top of the laparoscopic cannula.

Laparoscopic 5-mm needle-holders are used to grasp and manipulate needles during suturing of tissues. These devices may be single or double action. The single-action needle-holder has one fixed jaw and one moveable jaw, which is opened by squeezing the spring-loaded handle of the instrument. The double-action needle-holder more closely simulates the traditional needle-holder in that both jaws open when the ring handles are spread apart. The jaws may be serrated to provide a more secure grip on the needle. The hinge mechanism of the jaws should be flush with the shaft of the instrument when closed to facilitate intracorporeal knot tying; this design allows formed loops of suture to slide off the shaft easily without getting caught in the hinge mechanism.

Tissue graspers are usually 5 mm in diameter and should be atraumatic to facilitate grasping of the tissue to be sewn, to grasp the suture material without tearing it, and to assist in proper positioning of the needle within the needle-holder. It is helpful to have a locking feature on this instrument to facilitate these functions.

The suture introducer is helpful to allow introduction of the needle and suture without entanglement on the flap valve system of the port. The needle-holder securing the needle and suture within the introducer are moved as a unit through the designated port, and the needle-holder and suture with needle are advanced into the abdomen. Alternatively, if one is working through a 12-mm port, the suture can be grasped just behind the needle by the needle-holder; the flap valve is then inactivated and the entire assembly is passed through the port.

Knot-pushers facilitate delivery of extracorporeally tied knots into the abdomen; they may be independent or an integral part of the suture material. The independent knot-pusher is used to slide (Clarke-Reich) or to slide and cinch (Gazayerli) the knot into place. The integral knot-pusher is attached to a preformed knotted loop in the suture. After the loop is passed over the tissues to be secured, the plastic knot-pusher is snapped free of its terminal plastic base and used to deliver and secure the preformed knot within the abdomen.

The most significant advancement in laparoscopic suturing technology is the development of the EndoStitch device (U.S. Surgical Corporation, Norwalk, Connecticut). This device consists of a double-sided needle (9 mm, straight) with the suture attached to the midshaft of the needle, a built-in needle-holder on both jaws of the instrument, and a toggle mechanism that allows the needle to be transferred from one jaw of the needle-holder to the other. With the loading unit provided, the needle with the attached suture is loaded into the laparoscopic needle-holder. The needle's position is fixed on the needle-holder, eliminating the need for repositioning the needle. Closing the handles passes the needle through the tissue. A switch of the toggle lever secures the needle in the opposite jaw of the needle-holder, thereby completing passage of the suture when the handles are relaxed and allowing the jaws of the EndoStitch to separate (Fig. 18.8). This instrumentation has greatly facilitated reconstructive laparoscopic urologic procedures such as the pyeloplasty (4).

FIGURE 18.8. A: Automatic suturing device from U.S. Surgical Corp., Norwalk, Connecticut. The needle has a point on either end, and the suture is attached at midshaft. **B:** Either side of the jaws of the instrument alternately functions as the “needle-driver” to allow rapid back-and-forth passage of the needle, thereby providing the surgeon with a running suture. The same mechanism can be used to complete intracorporeal knotting of the ends of the suture.

Performing an intracorporeal knot is one of the more challenging skills for a laparoscopist to acquire. The vast array of techniques that have been described attests to the confusion and frustration that can be associated with learning this skill (256). Mechanical aids developed to facilitate or replace traditional surgical knots include, respectively, a polydioxanone (Vicryl) suture clip to secure a suture and metal clips or staples for occluding blood vessels, excising tissue, and reapproximating tissue edges (241).

The Lapra-Ty suture clip-applier (Ethicon EndoSurgery Inc., Cincinnati, Ohio) is a reusable device, and the Lapra-Ty (polydioxanone) suture clip is available in packets of six clips. The clips are individually loaded into the clip-applier and then positioned on a single strand of 0 Vicryl, 3-0 Vicryl, or 4-0 Vicryl. Tightly squeezing the handle of the clip-applier locks the suture clip onto the suture to act as a knot. Tensile-strength studies in the laboratory have shown that these suture clips, acutely, are as secure as a hand-tied surgeon's knot using the same suture materials. These suture clips may be used to secure the ends of the suture material when performing interrupted or running suture techniques laparoscopically. Used in conjunction with the EndoStitch device, these clips have further simplified reconstructive laparoscopy.

Laparoscopic clipping instruments are available in two forms: (a) occlusive for occluding blood vessels and (b) tacking for approximating tissue edges or securing various foreign materials (e.g., cadaveric fascia, mesh) to tissues. Occlusive clips come in lengths of 6, 9, and 11 mm. The applier is passed into the abdomen via a 10-mm port. The clip-applier may be either a single-load reusable type or a multiload, disposable type, which comes with 15 to 30 clips already loaded in the applier; the latter device, especially if it comes with a semiautomatic feed system, is capable of firing clips in rapid succession. The tips of the clip are approximated by the jaws of the clip-applier before closure of the body of the clip, thereby allowing the surgeon to slide a clip up or down along a given vessel before securing it in place (Fig. 18.9). The 9-mm clips are as secure as a hand-tied surgeon's knot of 0 silk on the renal artery when pressure tested (216). The tacking clips close in either a rectangular or B configuration, and the applier is passed into the abdomen via an 11-mm port (Fig. 18.10). All clip-appliers have a rotating shaft, and some allow

angulation of the working end, to help align the tip of the clip-applier with the structure to be clipped or tacked.

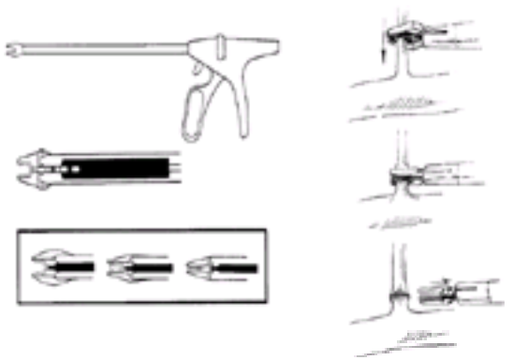

FIGURE 18.9. The clip-applier contains preloaded occlusive clips. After the jaws of a clip are placed around the suture to be clipped, the handle of the instrument is squeezed half-closed. This approximates the tips of the clip, which can be moved along the structure for precise placement. The handle is then fully closed, which securely closes the body of the clip on the structure. FIGURE 18.10. The tacking clips close in a rectangular or B configuration and are used to reapproximate tissue edges such as peritoneum to peritoneum or Marlex mesh to peritoneum. (Reprinted from Clayman RV, McDougall EM, eds. *Laparoscopic urology.* St. Louis: Quality Medical Publishing, 1993, with permission.)

Laparoscopic stapling devices are available only as disposable instruments and have rotating and articulating capabilities at the working end. Staple sizes range from 2.5 to 4.8 mm; smaller staples are used to occlude vascular structures, whereas larger staples are used to secure bulkier tissues. The length of each row of staples is 3 or 6 cm, and each cartridge delivers six separate rows of staples. As the staples are pushed into the tissues and closed, a knife simultaneously cuts the tissue between the third and fourth staple lines.

Developments in laparoscopic staplers (occlusive and reconstructive) have been most impressive. Indeed, bowel anastomoses can be readily performed laparoscopically using the same staple technology that was developed for open surgery. This technology has only begun to be transferred to urologic reconstructive surgery because of concerns over the potential of stone formation on the titanium staples that would be continuously exposed to urine within the reconstructed collecting system. However, in the bladder, titanium staples have apparently been well tolerated, and to date, there are no reports of stone formation on the staples used to secure a cuff of bladder during a nephroureterectomy (214,215).

Further advances in the realm of staple and clip technology will likely revolve around the development of extremely small absorbable clips. Already, absorbable clips have been developed for use in creating a right colon pouch for urinary diversion (138,312). Presently, these staples are too large to be used for the delicate reconstruction of the ureter or renal pelvis.

The recent development of fibrin glue is further expanding the range of reconstructive laparoscopic urology. The first clinically effective use of tissue glue was in 1972 by Matras and colleagues (249a), who used a fibrin glue to join peripheral nerves. At present, there are two commercially available preparations: Tisseel and Beriplast (120). These systems consist of fibrinogen (70 to 100 mg/mL) in one part of a dual syringe, and a second solution in the opposite chamber of the syringe. The second solution contains thrombin, factor XIII, fibronectin, and ionized calcium with or without aprotinin, an antifibrinolytic agent. In theory, the fibrinogen determines the strength of the glue while the amount of thrombin directly determines the speed of reaction, which may vary from 5 seconds to several minutes. Aprotinin prolongs the presence of the glue at the anastomotic site for 2 to 4 weeks. The glue used in combination with cellulose has been used to perform hand-assisted laparoscopic partial nephrectomy for tumor (194). This technique provides excellent hemostasis of the transected renal parenchyma. The glue has also been used experimentally to aid in the creation of anastomoses, such as tubal reconstruction, vasovasostomy, or ureteroureterostomy (117,237,271,306).

Miscellaneous

Other instruments and devices are available that facilitate specific laparoscopic functions. The organ entrapment sack is made of either a durable double layer of impermeable nylon and plastic or a single layer of thick-walled plastic. The sacks vary in size from 2 by 5 inches to 10 by 8 inches. The sack is tightly rolled over an introducing device and inserted through a 10-mm port. Within the abdomen the sack is unrolled, and the neck of the sack is triangulated open with traumatic grasping forceps placed on the three equidistant tabs on the sack edge or by a metallic band that causes the mouth of the sack to spring open when inserted into the abdomen. The surgical specimen is deposited into the sack, the neck of the sack is closed, and the neck of the entire sack is pulled out by its drawstring through a 12-mm port site. If just the neck of the sack is delivered, the tissue is fragmented and removed from the sack using forceps; a 10-mm, high-speed electric tissue morcellator [note that this morcellator can only be used with a LapSac (Cook Urological Inc., Spencer, Indiana)]; or a jaw-system mechanical morcellator. The morcellation process is monitored laparoscopically to ensure that sack perforation or incorporation of bowel or omentum into a fold of the sack does not occur. Landman and colleagues (229) recently reported their evaluation of the various tissue morcellators in the animal model. They determined that all three presently available morcellators were feasible for renal morcellation. The Steiner morcellator (Karl Storz Inc., Culver City, California) resulted in more rapid morcellation, larger morcellation products, and comparable safety in their experimental model.

Aspiration devices are necessary during laparoscopy, and combined aspiration-irrigation devices are preferable. The aspirating channel may be attached directly to an operating room vacuum and collection system. The aspirator consists of a 5- or 10-mm metal tube and trumpet valve. The irrigating channel is controlled with a one-way stopcock or trumpet valve. The irrigant must be pressurized to 250 to 700 mm Hg to allow adequate flushing of tissues and blood clots. The irrigation fluid most commonly used is saline and heparin (5,000 U/L); a broad-spectrum antibiotic (e.g., 500 mg of cephalosporin per liter) may be added to the irrigant. It is important for the aspirating tip of the instrument to have sideholes, in addition to the endhole, to maximize the suction ability of the instrument.

The development of laparoscopic ultrasound probes allows sonographic examination of tissues and Doppler detection of blood vessels during the surgical procedure. This may be useful in directing wedge resection of small renal lesions, identifying the testicular artery during laparoscopic varix ligation, or identifying the renal artery during a laparoscopic nephrectomy. The laparoscopic ultrasound probe is now articulating, which is helpful in performing intraoperative renal ultrasonography, especially during laparoscopic cryotherapy of renal lesions.

An argon beam coagulator may be used with 5- or 10-mm probes. This device uses argon gas (at a flow rate of 4 L per minute) to clear blood and fluid from the surgical field and deliver electrical current to a bleeding surface, thereby electrofulgurating the tissue. The surface temperature of the fulgurated tissue remains below 100°F, limiting the depth of injury to 1 to 2 mm (versus 5 mm, with standard electrocautery). This may be particularly helpful during wedge resection of the kidney or

for a partial nephrectomy.

Another device, which recently completed clinical trials, is the pneumodissector. This instrument applies brief blasts of CO_2 gas at a pressure of 50 psi to facilitate dissection of connective tissues. Animal studies have confirmed that the pneumodissector will not cause laceration of the liver, kidney, aorta, or vena cava, even at a maximum pressure of 100 psi (63). After sharp incision of the peritoneum, the pneumodissector effectively assists in dissection of the fatty tissues and exposure of the renal hilar vessels. It has been shown, in clinical evaluation, to be a safe and efficacious technique for rapid blunt tissue dissection (327).

There has been recent interest in hand-assisted laparoscopy (HAL) as a method for inexperienced laparoscopists to acquire the skills necessary for performing laparoscopic renal surgery. It also has particular relevance to procedures that require an incision to remove the surgical specimen intact, such as laparoscopic nephroureterectomy for upper tract transitional cell carcinoma or live donor nephrectomy (212,295,393). It may also facilitate the successful performance of laparoscopic partial nephrectomy (2).

For placement of a hand-assist device, it is necessary to first obtain a Veress needle pneumoperitoneum and placement of a primary port in the midclavicular line. Under laparoscopic visualization, a skin, fascial, and peritoneal incision, of 6 to 8 cm in length, is performed at the midline. For a right-hand–dominant surgeon, this incision is made overlying and just above the umbilicus for left renal surgery, and overlying and just below the umbilicus for right renal surgery. Various HAL devices are available, but essentially they all provide an airtight seal of the abdominal wall and allow the surgeon to insert the nondominant hand, through a plastic sleeve, into the abdominal cavity to assist with tissue dissection and retraction while maintaining the pneumoperitoneum. The presently available devices include Pneumosleeve (Dexterity Inc., Blue Bell, Pennsylvania), Intromit (Applied Medical Resources, Laguna Hills, California), and Hand Port (Smith-Nephew, Worcester, Massachusetts).

Exiting the Abdomen

At the conclusion of the laparoscopic procedure, it is essential to exit the abdomen in an organized and systematic manner to minimize the risk of complications. Intraabdominal pressure should be reduced to 5 mm Hg because this will allow any venotomy previously tamponaded by the 15 mm Hg pneumoperitoneum to be recognized. The surgical sites and all the port sites should be examined closely for hemostasis. The abdominal cavity should be scanned from the pelvic region to the upper quadrants to rule out any injury to abdominal viscera.

After satisfactory examination of the abdomen, the 10-mm laparoscope is removed and replaced by a 5-mm laparoscope through one of the secondary 5-mm ports. The primary 10-mm (or larger) port is removed from the abdomen under laparoscopic visualization. The assistant places a finger over the port site to maintain the pneumoperitoneum. If hemostasis of the port site remains satisfactory, the fascia is closed using a figure-of-eight of 0 absorbable suture under continuous laparoscopic observation. A small S-curved or Sinn retractor is used to retract the skin and expose the fascia. The fascia is grasped with a Kocher clamp or toothed forceps. The suture is passed through the fascia, and laparoscopic visualization ensures that the bowel or omentum is not incorporated into the stitches. This procedure of port removal and fascial closure is repeated for all the remaining ports larger than 5 mm.

Identifying the fascia for placement of a figure-of-eight suture is often difficult, especially in an obese patient. Several companies have developed devices to simplify this final step in the laparoscopic procedure. The device that we have found consistently to be the most useful and least expensive is the Carter-Thomason closure device (47) (Fig. 18.11). This device consists of two parts: a metal cone with two through-and-through oblique channels drilled in it and a needle-tip 2-mm grasping forceps. The two channels in the cone part of the device serve to direct the sharp, needle-pointed suture-grasper through the fascia and peritoneum; this is always performed under laparoscopic visualization. The suture chosen for closure should be a minimum of 12 inches in length. One end of the suture is grasped by the sharp, needle-pointed grasper. After removal of the port, the metal cone piece is placed into the port site; its tip is visualized by the laparoscope. The needle-point grasper is then inserted through one of the channels of the cone. Passage of the instrument through the fascia and peritoneum is monitored laparoscopically to avoid any intraperitoneal injury. When positioned well into the abdomen, the jaws of the needle-point grasper are opened to drop the suture. The jaws are then closed and the instrument is withdrawn from the working channel. The needle-pointed grasper is then inserted through the second channel, which directs the instrument through the fascia and peritoneum, 180 degrees from its initial insertion, on the opposite side of the peritoneotomy. After the needle-pointed grasper is positioned within the abdomen, the grasping jaws are used to secure the intraabdominal end of the suture and draw it out through the working channel. A 5-mm locking grasper can be used through another port to facilitate removal of the suture from the needle-grasper and for positioning the suture so that it can be easily grasped by the needle grasper on its second pass. The two ends of the suture should now lie on the abdominal wall, having passed through both sides of the fascia and peritoneum. The metal cone device is withdrawn from the port site and off the suture, which is tied down snugly to close the port site.

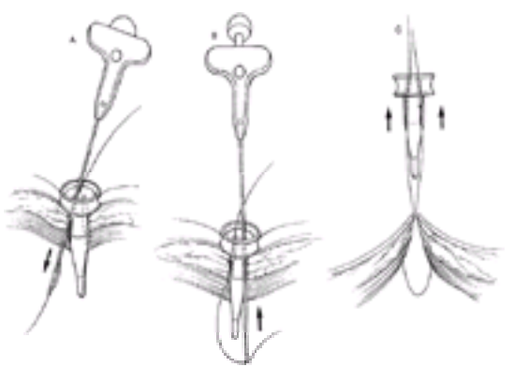

FIGURE 18.11. A: The Carter-Thomason laparoscopic wound closure device is inserted into the port site after removing the port. The suture end secured in the needle-pointed grasper is inserted through the channel, directing it through the fascia and peritoneum. **B:** The needle-pointed grasper is inserted through the second channel, is passed through the fascia and peritoneum opposite the initial suture insertion, and grasps the intraabdominal end of the suture. **C:** The two ends of the suture are tied down to complete the closure of the fascia and peritoneum.

After all of the sheaths larger than 5 mm have been removed and the fascia closed, all but the laparoscope-bearing 5-mm sheath are pulled from the abdomen under laparoscopic visualization. Fascial sutures are not necessary at these port sites if no bleeding is present from the sites; the only exception is in the child, in which case even the 5-mm ports require a fascial suture. If any bleeding is noted from a 5-mm port site, either electrocoagulation of the site or placement of a 0 absorbable suture is necessary.

The last sheath to be removed is the 5-mm sheath through which the 5-mm laparoscope has been passed. The pneumoperitoneum is maintained by having the assistant occlude the 5-mm port sites with a finger. The laparoscope is backed out until the tip is just protruding from the end of the port sheath. The last sheath and laparoscope are then slowly backed out of the abdomen as a unit. As the 5-mm laparoscope is withdrawn, the site of the peritoneotomy and fasciotomy are examined to rule out bleeding. If bleeding is noted, the site may be coagulated through the sheath, or if this fails, one of the other 5-mm port sites should be replaced. The bleeding port site may then be sutured with a 0 absorbable suture.

The CO_2 is allowed to escape from the 5-mm port sites. The skin incisions of the port sites larger than 5 mm are closed in a subcuticular fashion using a 4-0 absorbable suture. The skin incisions of all the port sites are closed and secured with sterile adhesive strips. This method of exiting the abdomen should obviate bowel or omentum becoming entrapped by the fascial sutures and eliminate herniation through any of the port sites.

Retroperitoneal Approach

Following balloon dilation or blunt-finger dissection access to the retroperitoneum, a Hasson-type cannula or 10- to 12-mm trocar is inserted. The 10-mm, 30-degree laparoscope is inserted and the retroperitoneal space is inspected. On initial examination, the psoas muscle and genitofemoral nerve should be clearly seen. Gerota's fascia and the ureter are typically visible, although this may be difficult in the obese patient or in those patients with any degree of scarring or fibrosis in the retroperitoneal space. A small amount of venous blood overlying the tissues is normal, but there should be no active bleeding.

Insertion of additional working ports is performed under endoscopic guidance. A 10- or 12-mm port is placed at the inferior lumbar triangle; a 5-mm port is placed at the level of the twelfth rib on the anterior axillary or midclavicular line; and a 5-mm port is placed at the level of the twelfth rib on the posterior line. The placement of the ports should form a T shape.

When a retroperitoneal approach is used, only minimal dissection in the area of the ureter is needed to completely expose this structure. Likewise, pulsations from the renal artery are often visible early in the case as the surgeon moves the endoscope up along the medial border of the psoas muscle. Instrumentation for the laparoscopic retroperitoneoscopic procedure is similar to that for the transperitoneal approach.

As with the peritoneal approach to renal surgery, it is important to systematically exit the retroperitoneal space. Following completion of the surgical procedure, the CO_2 pressure in the retroperitoneum is reduced to 5 mm Hg and the operative and port sites are examined to ensure adequate hemostasis. With the retroperitoneal approach, the port sites do not require a fascial suture closure because there is minimal risk of hernia formation. Therefore the ports are removed under direct visualization. The port sites are irrigated with saline and the skin is closed with a subcuticular 4-0 nonabsorbable suture.

Physiology of CO_2 Insufflation

Cardiopulmonary Function

There are two very nonphysiologic situations that occur during laparoscopy. The first is insufflation of the abdominal cavity with gas, usually CO_2, and the second is the elevation of intraabdominal pressure. Studies comparing the effect of insufflants on hemodynamic and respiratory function indicate that the type of gas used does not significantly affect cardiac output.

However, CO_2 gas may increase the central venous pressure and the mean arterial pressure (MAP). Likewise, argon gas can markedly increase cardiac afterload by elevating arterial pressures and systemic vascular resistance, even more so than CO_2 gas. In addition, CO_2 has been demonstrated to have a negative effect on respiratory function, whereas argon and helium do not appear to have these limitations. Thus it appears that the best alternative to CO_2 as an insufflant is helium because of the limited effect on hemodynamic function and essentially no effect on respiratory function (203). Wolf and colleagues (447) reported that conversion to helium insufflation was able to successfully reverse a significant respiratory acidosis caused by a CO_2 pneumoperitoneum in a patient with severe chronic obstructive pulmonary disease during a laparoscopic radical nephrectomy.

Aside from the choice of gas used for insufflation, the increased intraabdominal pressure itself can lead to unfavorable hemodynamic changes, which are essentially pressure dependent. Cardiovascular, pulmonary, and renal effects of elevated intraabdominal pressure have been extensively studied in the laboratory and clinical setting.

An elevated intraabdominal pressure has been shown to increase atrial filling pressures, increase systemic vascular resistance, decrease venous return, decrease cardiac output, and reduce stroke volume (70,223,269). Peak inspiratory pressures have been shown to increase in conjunction with the elevated abdominal pressure. These effects are pressure dependent, usually not becoming evident until pressures reach 14 to 15 mm Hg (269,439). In animal studies concerning the effects of laparoscopic surgery on hemodynamic responses, it has been shown that the changes are minimal when intraabdominal insufflation is performed in healthy, well-hydrated, and hyperventilated animals (173). Similarly, for healthy patients in the clinical setting, these hemodynamic changes do not appear to have any significant adverse effect (132,284). Clinically, the respiratory effect of the elevated intraabdominal pressure is monitored using pulse oximetry and capnography. The pulse oximeter saturation should be maintained at greater than 93% and the end-tidal CO_2 should be maintained between 35 and 45 mm Hg, which usually ensures that the $Paco_2$ is less than 50 mm Hg. Increasing respiratory rate and tidal volume can usually control these levels satisfactorily. Even in the face of moderate pulmonary disease, despite an elevation of the $Paco_2$ and respiratory acidosis, the impairment of pulmonary function usually causes no significant negative hemodynamic effect (85). However, in laboratory studies on septic animals, although laparoscopy could be performed, the hemodynamic compromise in the form of acidosis with cardiodepression was more apparent. Therefore the clinical application of laparoscopy in the septic patient should be approached with caution (141).

Renal Function

It is well recognized that a prolonged period of increased intraabdominal pressure is associated with decreased urine output, even to the point of anuria (269). This continues to be the most marked intraoperative renal effect observed from the pneumoperitoneum, and it is pressure dependent. In a human study, the use of a lower intraabdominal pressure (4 mm Hg), plus the aid of a retraction device, for performing the laparoscopic cholecystectomy led to no significant changes in urine output, effective renal plasma flow, or glomerular filtration rate (GFR) as opposed to the transient renal dysfunction that was noted with an intraabdominal pressure of 12 mm Hg (280). Although this transient renal dysfunction has been well documented, various mechanisms have been described to explain these changes: choice of insufflant, decreased cardiac output, ureteral obstruction, renal vein compression, renal parenchymal compression, and systemic hormonal effects (156,221). The choice of insufflant does not appear to have a direct affect on renal function (269). In animal studies comparing CO_2 to argon gas for pneumoperitoneum, no change in urine output was noted for intraabdominal pressures less than 15 mm Hg. For intraabdominal pressures of 15 mm Hg or greater, a similar impairment in urine output and GFR was seen for both types of gas.

The body of evidence also eliminates a decrease in cardiac output as a direct etiologic factor responsible for the renal dysfunction (221). Although cardiac output has been reported to decrease to as much as 37% of normal at 40 mm Hg, normalizing cardiac output with plasma expanders failed to improve the diminished renal blood flow and GFR (156).

In addition, ureteral obstruction resulting from extrinsic compression does not appear to play a role in oliguria (269). Placement of ureteral stents during pneumoperitoneum does not improve urine output. Likewise, intraoperative urograms in animals with decreased urine output during pneumoperitoneum confirm the absence of ureteral obstruction (221).

In contrast, changes in renal vein flow do appear to be linked to the oliguria associated with the pneumoperitoneum. To determine the etiology of oliguria, Kirsch and colleagues (221) subjected rats to intraabdominal pressures of 5 and 10 mm Hg. Urine output did not diminish until the pressure reached 10 mm Hg. At that level of pneumoperitoneum, vena caval blood flow decreased 92% and aortic blood flow decreased 46%, leading to the conclusion that the renal effect was due to renal vascular insufficiency from central venous compression. Similarly, McDougall and colleagues (269), using a porcine model, demonstrated a significant decrease in renal vein flow concomitant with a drop in urine output, but only at a pressure of 15 mm Hg or greater. Interestingly, renal vein flow and creatinine clearance remained diminished even after 2 hours of desufflation, although no long-term effects were noted (269). Subsequent animal studies, using MRI to provide a noninvasive evaluation of renal vessel blood flow and parenchymal perfusion, also demonstrated reduced cardiac output, reduced flow velocity in the renal vessels, decreased renal parenchymal perfusion, and a concomitant reduction in urine output. The changes seen in renal perfusion were similar in the cortex and medulla of the kidneys; these findings confirmed that a shunting phenomenon was *not* occurring in the renal parenchymal during the time of the elevated pneumoperitoneum pressure (258).

Although the renal vein compression hypothesis is supported to some extent by the foregoing studies, the most likely mechanism for oliguria during laparoscopy appears to be direct renal parenchymal compression, similar to that seen with a Page kidney. Razvi and associates (351) placed a pressure cuff around canine kidneys subjecting them to pressures of 15 mm Hg. This resulted in a decreased urine output of 63% in the treated kidney along with decreased GFR and reduced effective renal blood flow. As other investigators have observed, even after 2 hours of desufflation, renal blow flow did not return to baseline levels. The control kidney showed no significant changes in urine output or GFR.

From a hormonal standpoint, it is of note that aldosterone has been reported to be elevated during the oliguric period in the animal model, which correlates with the decreased urinary sodium and increased urinary potassium observed (56). It also supports the Page kidney effect as a significant component of the intraoperative oliguria observed during the pneumoperitoneum.

In healthy patients, this acute renal dysfunction appears to completely resolve postoperatively following desufflation; however, there is concern that in patients with preexisting renal disease, these transient changes may become clinically significant. To address this, Cisek and colleagues (59), in an animal model, performed renal reductive surgery to mimic chronic renal insufficiency. After being exposed to intraabdominal pressures of 20 mm Hg for 6 hours, simulating a complex laparoscopic procedure, a dramatic drop in urine output (80%), GFR (63%), and renal blood flow (20%) was noted, which did not return to baseline after 90 minutes of desufflation

postprocedure. An increase in the urinary *N*- acetyl-b-D-glucosaminidase (NAG) was observed, as was acute renal failure despite hydration and central venous pressure monitoring (59). However, at 1 week following the insufflation tests, the GFR returned to the baseline, chronic renal failure level, indicating that no long-term effect on the renal function from the acute insufflation was identified, even in the face of preexisting renal insufficiency.

The observed blood flow changes have suggested the possibility of renal tubular damage secondary to ischemia, as a cause of the oliguria associated with pneumoperitoneum. NAG is present in renal tubular cells and is released into the urine in response to tubular cell injury. Micali and colleagues (277) measured preoperative and postoperative NAG levels in 31 patients undergoing laparoscopic surgery compared with 28 patients undergoing conventional open surgery. No differences in NAG were noted between the preoperative and postoperative levels in either of the groups or between the groups. They demonstrated that pneumoperitoneum was not associated with the change in the urinary concentration of NAG. Similarly, there was no correlation between urinary NAG levels and the total operative time. This observation suggests that significant ischemic renal injury is not associated with laparoscopic-related oliguria. This biochemical finding has been confirmed histologically in animal models. In a rat study, after a 5-hour pneumoperitoneum at a pressure of 15 mm Hg, acutely and chronically, no significant histologic differences could be identified when compared with control rat kidneys (232). McDougall and colleagues (269), in the porcine model, also confirmed a lack of histologic abnormality in kidneys rendered oliguric at pressures of 15 mm Hg.

Elevated intraabdominal pressures may also act via stimulation of a variety of systemic hormones, which contribute to the hemodynamic and renal effects. Independent of the type of gas used, excessive intraabdominal pressures (20 mm Hg or greater) are responsible for increasing serum catecholamines (279). Likewise, endothelin, a potent vasoconstrictor, has also been shown to increase in response to renal vein compression and during pneumoperitoneum in animal models. In fact, compression of a unilateral renal vein leads to a decrease in GFR and urine output in both kidneys and is associated with elevated renal vein endothelin concentrations, thus implicating it as a contributing factor to the oliguria observed during long laparoscopic cases (151). In other animal studies, the administration of a vasopressin antagonist improved renal function when compared with control animals, suggesting that the endogenous release of arginine vasopressin also contributes to the oliguria seen with increased abdominal pressures (84).

Methods to improve urine output during pneumoperitoneum, which have included the use of ureteral stents, fluid hydration, and intravenous dopamine infusion, have been unsuccessful in changing urine output. However, altering the temperature of the insufflated CO_2 has been found to partially counteract the hemodynamic and renal effects of increased intraabdominal pressure. A comparison of the use of warm (37°C) versus room temperature CO_2 during prolonged (greater than 90 minutes) laparoscopic surgery demonstrated a higher core temperature, urine output, and cardiac index with warm insufflation, suggesting that local vasodilation in the compressed kidney may restore enough blood flow to maintain GFR and urine output (14).

In conclusion, oliguria is a recognized component of the physiologic effect of increased intraabdominal or retroperitoneal pressure. The etiology is multifactorial, emanating from vascular and parenchymal compression and associated with systemic hormonal effects. Ureteral obstruction does not play a significant role. These changes are pressure dependent and are usually not apparent until pressures reach 15 mm Hg or greater. Likewise, this effect is not associated with any histologic pathology or evidence of renal tubular damage. Following the release of the pneumoperitoneum or pneumoretroperitoneum, the renal function and urine output return to normal with no long-term sequelae, even in patients with preexisting renal disease. It is important for the entire operative team to have an understanding of the physiologic effects of CO_2 insufflation. This will allow appropriate intraoperative monitoring and management and minimize intraoperative and postoperative complications.

Pneumoretroperitoneum

For the most part, gas insufflation into the retroperitoneal or extraperitoneal space has been associated with greater CO_2 absorption and hypercarbia as compared with intraperitoneal insufflation, especially in the presence of subcutaneous emphysema (133,269,448). This, however, is not entirely without controversy. Other animal and human studies have demonstrated the opposite results. In a canine model, Wolf and colleagues (446) noted a higher increase in $Paco_2$ and a greater drop in serum pH in the intraperitoneal insufflation group compared with the extraperitoneal insufflation group. Conversely, risk of thoracic dissection of gas was greater during extraperitoneal insufflation than during intraperitoneal insufflation. Wright and colleagues (453), in a human study, noted a more rapid increase in the $Paco_2$ in the transperitoneal group than the extraperitoneal group, although no significant difference in the overall magnitude of the rise was demonstrated. Nonetheless, regardless of the method of laparoscopy, appropriate ventilatory management, with hyperventilation, usually avoids any adverse sequelae of hypercarbia.

The renal and hemodynamic effects of pneumoretroperitoneum are similar to those seen with a pneumoperitoneum. A unilateral pneumoretroperitoneum leads to elevated systolic and diastolic aortic pressures, although the effect is less than that seen with the pneumoperitoneum (55). In contrast, at 15-mm Hg pressure, the decrease in renal vein flow is similar to that seen with the pneumoperitoneum (269). An elevated retroperitoneal pressure also leads to oliguria, and when maintained for 2 hours, it leads to a gradual decrease in the contralateral kidney perfusion and a concomitant increase in the intraabdominal pressure (55). Likewise, this reduction in urine output is reversible after desufflation and leads to no identifiable pathologic renal abnormalities (269).

SPECIFIC LAPAROSCOPIC PROCEDURES

Laparoscopic access was initially applied within urologic surgery only for diagnostic purposes. Slowly, with advances in technology and skill, the indications for laparoscopic access have evolved such that diagnostic, ablative, and even complex reconstructive procedures are presently performed laparoscopically at academic centers throughout the world. The subsequent section is a comprehensive listing and description of the current state of the art of laparoscopic procedures in urology. The procedures have been stratified into diagnostic, ablative, and reconstructive designations and have been further subdivided into operations for either benign or malignant disease processes. For each procedure, a systematic review of the literature describing the indications, technique(s), efficacy, efficiency, equanimity, and economy is provided.

Benign Disease: Diagnostic Procedures

Renal Biopsy

Renal biopsy is often indispensable in the diagnostic evaluation of various kidney diseases. Since its original description by Iversen and Brun (188), the percutaneous approach has been the preferred procedure for sampling renal tissue for almost half a century. Percutaneous renal biopsy is indicated for patients with occult acute renal failure, nephrotic syndrome in an adult without signs of systemic disease, significant proteinuria, hematuria after urologic studies indicate no specific upper or lower tract causes, or systemic disease with suspected renal involvement (114,417). Valuable diagnostic and prognostic information can be obtained and treatment tailored to the patient based on biopsy results.

As a result of the efficacy and minimally invasive nature of percutaneous biopsy, biopsy under vision is reserved for patients for whom percutaneous biopsy is either unsuccessful or contraindicated. Percutaneous renal biopsy is sometimes difficult or impossible because of anatomic constraints such as mobility of the kidney, morbid obesity, positioning of the kidney high under the rib cage, spinal deformity, or the presence of impenetrable scar tissue or other organs around the kidney (e.g., a retrorenal colon). Absolute and relative contraindications for percutaneous renal biopsy vary among nephrologists. Reasons for referral for a renal biopsy under direct vision include failure of previous percutaneous biopsy attempts, inadequate tissue sample with the percutaneous biopsy, an uncooperative patient, marked obesity, a solitary functioning kidney, patients of the Jehovah's Witness faith, presence of renal artery aneurysm, calcific arteriosclerosis, or a coagulopathy (30,161,228,371).

Laparoscopic renal biopsy was initially described via a transperitoneal approach (396). Currently, however, the procedure is most commonly performed in a retroperitoneal fashion with the patient in the flank position under general anesthesia. Via a two-port approach, a pneumoretroperitoneum is obtained and the retroperitoneum is dissected bluntly. Renal biopsy is typically obtained with a single stroke of a laparoscopic cup forceps. Hemostasis of the biopsy site is then achieved with electrocautery or argon beam coagulation. The procedure has been described with mean operating room times ranging from 35 (115) to 90 minutes (131).

Diagnostic yield using this technique for laparoscopic renal biopsy has been high. Gaur and colleagues (115) described adequate tissue for diagnosis in 17 of 17 consecutive renal biopsies. Subsequently, other series have recorded 100% diagnostic yield in an additional combined total of 40 patients using either single or multiple biopsies under laparoscopic vision (53,131). These results are better than the reported diagnostic yield with percutaneous biopsy, which ranges from 80% to 95% (30,36,80,206,291).

Complications from laparoscopic renal biopsy have usually been minimal and self-limiting. Gaur and colleagues (115) reported 2 complications in 17 consecutive renal biopsies (12%). One patient required extension of a laparoscopic port site for hemostasis. The other patient had macroscopic hematuria, which resolved spontaneously after 2 days; this patient did not require a blood transfusion (116). In a series of 32 consecutive patients, Gimenez and co-workers (131) reported two complications (6%). An anticoagulated patient experienced postoperative pain, and evaluation revealed a perinephric hematoma. The hematoma resolved without intervention and the patient did not require transfusion. A single postoperative death was reported in this series. In this case, a female patient who underwent an uncomplicated biopsy and was found to have lupus nephritis was treated with high-dose steroids and experienced a perforated gastric ulcer. She was a Jehovah's Witness and refused blood transfusions, which ultimately resulted in her death. In a review of renal biopsy in eight morbidly obese patients, Chen and colleagues (53) reported no complications.

The overall frequency of complications after percutaneous needle biopsy of the kidney has been reported as 5% to 10% (114). In a comparison of percutaneous and open renal biopsies, Bolton and Vaughan (30) describe a 12% (20 of 171) complication rate for percutaneous biopsy and an 11% (11 of 100) complication rate for open renal biopsy. The severity of complications was similar, and transfusion requirements were equal at 3% for both the percutaneous and open renal biopsy group.

Convalescence from laparoscopic renal biopsy is rapid. Although Gimenez and colleagues (131) reported a mean hospital stay of 1.7 days (range 0 to 7 days), others have performed the procedure on an outpatient basis (53). Return to activity has been reported to be less than 2 weeks (116,131). Postoperative analgesic requirements are minimal, ranging from no parenteral medications (131) to an average of 3 mg of morphine (range of 0 to 8 mg) (53). Cost data on laparoscopic renal biopsy have not been published.

Evaluation of the Acute Abdomen: Posttraumatic and Postoperative

Exploratory laparotomy offers the greatest accuracy in the diagnosis of intraabdominal injury, but it is associated with significant morbidity. Laparoscopy may provide diagnostic capabilities equivalent to that of open exploration with less morbidity. Initial reports from the general surgery and gynecologic literature demonstrated the utility of laparoscopy in the diagnosis of the acute abdomen associated with trauma.

Laparoscopy was introduced as an alternative diagnostic modality for the evaluation of patients with abdominal injuries associated with trauma in the late 1970s (24,118). Since these reports, the diagnostic and therapeutic potentials of laparoscopy for the acute abdomen have expanded. Cuesta and colleagues (69) prospectively evaluated 65 patients with laparoscopic evaluation of their acute abdomen (excluding free-air and bowel obstruction) and were able to avoid exploratory laparotomy in 80%. In addition, these patients received smaller, more limited incisions for appropriate open surgical management of any laparoscopically defined problems. In a similar study, Chung and co-workers (58) prospectively evaluated 55 patients with an acute abdomen. They determined the accuracy of laparoscopic diagnosis to be the same as exploratory laparotomy. They managed 62% of patients laparoscopically, and these patients required significantly shorter hospitalization than matched controls treated by open operations. Morbidity was not increased by laparoscopy in patients who required conversion to open operation. The additional cost of the laparoscopic approach was not quantitated.

The urologic community is only beginning to explore the potential applications of laparoscopy in the setting of the acute abdomen. Bauer and colleagues (20) described the successful application of laparoscopic diagnosis and treatment of the acute abdomen in the urologic postoperative setting in three patients. In the first two patients, the laparoscopy revealed misplacement and malfunction of a suprapubic cystotomy tube and a gastrostomy tube, respectively. In the third patient, a large postoperative urinoma was managed by laparoscopic drainage and placement of a retroperitoneal drain and a suprapubic cystotomy tube.

Benign Disease: Ablative

Pelvis: Lymphocelectomy

The development of a lymphocele after surgical dissection was first documented by Mori in 1955 (286). The reported incidence of lymphoceles after pelvic lymphadenectomy for prostate cancer and renal transplant has ranged from 0.5% to 10% and 1% to 15%, respectively (304,310).

Small asymptomatic lymphoceles do not require treatment and may be followed with serial ultrasound evaluations. Spontaneous regression has been well documented, although absorption may take several months. Symptomatic or infected lymphoceles require intervention. Lymphoceles are most frequently symptomatic due to pressure exerted on one or more adjacent structures: the external iliac vein (edema of the lower extremity or venous thrombosis), lymphatics (lower extremity lymphedema), bladder (voiding symptoms), allograft ureter (renal dysfunction and obstruction of the collecting system), and anterior abdominal wall (pain and swelling).

The management of lymphoceles has evolved over the past two decades. Sterile lymphoceles have traditionally been managed by open transperitoneal marsupialization with or without omentoplasty. In 1983, Aronowitz and Kaplan (13) reported the first percutaneous drainage of a postoperative pelvic lymphocele. Lymphocele resolution was noted 3 weeks after insertion of a 9-Fr silastic pigtail catheter. More recently, the addition of sclerosing agents to percutaneous drainage has become increasingly popular. Tetracycline was initially used (270,387). Subsequently, successful management of lymphoceles with povidone-iodine has been described (38,130,413). In 1991, the first laparoscopic lymphocelectomy was performed by McCullough and colleagues (255).

Laparoscopic lymphocelectomy is accomplished via the transabdominal approach, and usually is performed with three trocar sites. After inspection of the abdominal cavity, the bluish-gray bulge of the lymphocele is identified in the pelvis (Fig. 18.12). If the lymphocele is readily identified, needle aspiration may be performed to further confirm the diagnosis. If the lymphocele is not readily apparent, decreasing the pressure of the pneumoperitoneum to 5 mm Hg may allow the lymphocele to appear more prominent. Alternatively, laparoscopic sonographic guidance can be used to identify the lymphocele. Failing this, transabdominal standard sonographic guidance can be used to allow for percutaneous puncture of the lymphocele, which can then be expanded with indigo carmine–stained saline. Occasionally, the location of the bladder relative to the lymphocele may be unclear. If this is the case, the bladder can be distended through the Foley catheter to help identify it relative to the lymphocele; the bladder should then be drained with an indwelling catheter.

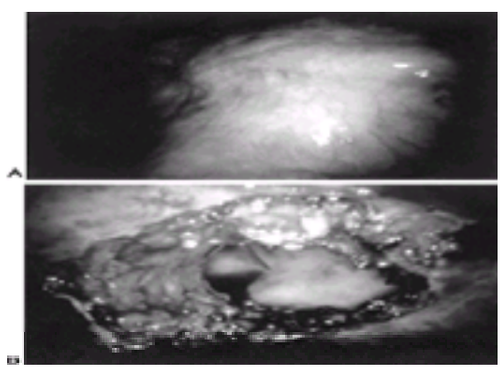

FIGURE 18.12. A: Laparoscopic inspection revealing the bluish-gray bulge of the lymphocele in the pelvis. **B:** Unroofed lymphocele with percutaneously placed needle visible within. See also Color Figure 18.12.

After confirmation of the lymphocele, using electrocautery scissors a 3- to 4-cm window is excised from the most translucent, thinnest portion of the lymphocele wall. Meticulous hemostasis about the edges of the peritoneal defect is obtained. The laparoscope is advanced into the lymphocele cavity, and intracystic loculations are disrupted by circular motions of the laparoscope. Complete decompression of the lymphocele can be further confirmed with intraoperative transabdominal or laparoscopic ultrasonography. If readily available, a pedicle of omentum may be advanced into the lymphocele cavity and anchored to the cut edge of the lymphocele with titanium clips.

Gill and co-workers (124) compared laparoscopic and open internal marsupialization of pelvic lymphoceles. This retrospective review compared three populations: 12

patients who underwent laparoscopic lymphocelectomy, 13 patients who had open surgery between 1990 and 1993, and 13 patients who had open surgery between 1980 and 1989. Baseline demographics were comparable among these three nonrandomized groups.

No patient managed laparoscopically experienced recurrence of a lymphocele. In contrast, 7 of the 26 patients (27%) managed with open surgery had recurrent lymphoceles. Although laparoscopic management required a longer operative time (177 versus 155 minutes), the patients who were managed laparoscopically had decreased blood loss (23 versus 68 mL), earlier resumption of oral food intake (0.9 versus 2.3 days), and an abbreviated convalescence (2.2 versus 5.6 weeks) (124).

Several other authors have addressed the issue of post–renal transplant lymphoceles and laparoscopic management. Bischof and colleagues (27) reported on 919 kidney transplants that were complicated by 63 (6.8%) symptomatic lymphoceles. Thirty-five of the 63 patients were drained percutaneously, with 47 aspirations (without associated sclerotherapy); 20 lymphoceles were drained by open surgery; and eight lymphoceles were drained laparoscopically. In both surgical groups, six patients each had previously been treated with percutaneous drainage, but reaccumulation of lymph fluid prompted more definitive management. The patients who underwent primary percutaneous drainage experienced local infection in 8 of 47 (17%) cases. One of these patients required open surgery after developing an abscess. Fourteen of 47 (30%) patients had recurrence. There was a single complication in the open surgery population: recurrence of a lymphocele that required a second open procedure. There were no complications and no recurrences in the population undergoing laparoscopic lymphocelectomy. Operative times were not reported. Similar excellent efficacy for laparoscopic lymphocelectomy has been reported by Melvin and co-workers (272) and by Shaver and colleagues (382), with eight and seven patients treated, respectively, without any recurrences.

However, not all reports have demonstrated superior efficacy with laparoscopic drainage. In a series reporting 59 lymphoceles associated with renal transplants, Gruessner and colleagues (142) reported recurrence rates of 48% (13 of 27), 22% (5 of 23), and 33% (3 of 9) for percutaneous, open, and laparoscopic drainage of lymphoceles, respectively. Patients drained laparoscopically had a shorter mean hospital stay than the patients treated with open surgery (3 versus 7 days). Operative time was not reported. Hospital costs for patients undergoing successful laparoscopic drainage were $8,300; for patients with primary open drainage, the costs were $15,680. In 36% (5 of 14), however, there was conversion from laparoscopic to open technique. Hospital cost for this population was $18,550. The only complication reported by the authors was intraoperative bleeding from the right inferior epigastric artery caused by a 5-mm trocar. The injury was repaired without conversion to open surgery (142). On the basis of this series, the authors concluded that posttransplant lymphoceles located lateroposterior and lateroinferior to the renal allograft were technically difficult to access, and may be better managed by open drainage.

Laparoscopic lymphocelectomy has clearly become a viable option for the management of lymphoceles after both renal transplant and pelvic lymphadenectomy. In cases of multiloculated and recurrent lymphoceles, the laparoscopic lymphocelectomy is the procedure of choice, offering patients excellent efficacy, low morbidity, and an expeditious and more comfortable convalescence. Although limited data are available, it appears that laparoscopic management of lymphoceles may have the additional benefit of reduced overall cost.

Pelvis: Varicocelectomy

Normally manifesting in the adolescent period, varicoceles are found in 15% of the male population (369); however, they are described in up to 40% of men seeking treatment for infertility (64). Most men with varicoceles are asymptomatic, but in some cases, patients may have testicular pain or signs of testicular atrophy (140).

Before 1990, clinically significant varicoceles were treated with either surgical ligation or a percutaneous approach using an occlusive transvenous technique under fluoroscopic guidance (414). Surgical ligation of the spermatic veins has been accomplished by an inguinal (187), retroperitoneal (321), or subinguinal approach (248). The laparoscopic varicocelectomy was first described by Sanchez de Badajoz and co-workers (364) and subsequently was developed in the United States by Winfield and Donovan (440).

Laparoscopically, the varicocele is typically managed via a transperitoneal approach. The ipsilateral internal spermatic vessels are identified and the peritoneum is incised laterally. A T-shaped incision is made by incising toward the iliac vessels. Having gained access to the retroperitoneum, the packet of testicular vessels is dissected from the psoas muscle. Testicular traction may be intermittently applied to aid in the identification of the spermatic cord. Dissection of the testicular veins from the testicular artery is then performed. Identification of the testicular artery is aided by intraoperative laparoscopic Doppler sonography or the topical application of 1% lidocaine or papaverine to the spermatic cord. Spermatic veins are isolated, interrupted with clips, and transected. In contrast, other authors have greatly simplified the laparoscopic varicocelectomy by proceeding to secure and divide both the testicular veins and the testicular artery. Interestingly, the positive impact on fertility has been similar with either approach.

Several studies have compared the results of the different modalities for management of varicoceles. Trials comparing the results of sclerotherapy, open varicocelectomy, and laparoscopic varicocelectomy are presented in Table 18.2. Abdulmaaboud and colleagues (3) retrospectively compared 301 patients with 417 varicoceles undergoing treatment with open surgery (131 cases), percutaneous retrograde sclerotherapy (163 cases), or laparoscopic varicocelectomy (123 cases). All three modalities were equally efficacious with regard to recurrence rate and improvement in semen parameters postoperatively. Specifically, the recurrence rates with open, percutaneous sclerotherapy, and laparoscopic treatment were 10.5%, 11.2%, and 9.1%, respectively. Comparison of semen parameters before and after treatment showed significant and equal increases in density and motility, as well as a significant reduction in abnormal forms in all groups. There was no significant difference in pregnancy rates with open surgery, sclerotherapy, and laparoscopy (37%, 41%, and 39%, respectively) (3).

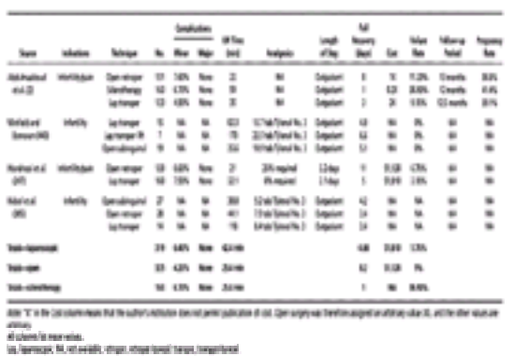

TABLE 18.2. VARICOCELECTOMY—COMPARATIVE TRIALS

However, the efficacy of percutaneous sclerotherapy is often overestimated; in the Adulmaaboud and colleagues (3) series, 26% of patients failed attempted percutaneous sclerotherapy due to technical difficulties. Problems resulting in failure of percutaneous management included perforation of the spermatic vein (4.3%), abnormal anatomy (10.4%), or spasm of the spermatic vein with failed catheterization (11.6%). If technical failures are included, the efficacy of percutaneous sclerotherapy decreases to 66%. This reported technical failure rate is consistent with most contemporary reports. In addition, although the overall success rate with left-sided varicoceles was 83%, the success rate with right-sided varicoceles was only 51% (3). Minor complications were associated with sclerotherapy; these included a groin hematoma, three femoral artery punctures, and minor contrast media reactions in seven patients. There were no operative complications reported in patients undergoing open or laparoscopic varicocele repair.

Sclerotherapy was carried out as an outpatient procedure performed under local anesthesia. Open surgery used a retroperitoneal approach and was performed with regional anesthesia in most cases, and laparoscopy was done under general anesthesia. Operative time for open surgery was significantly shorter than either sclerotherapy or laparoscopy. Open surgery required an average of only 22 minutes compared with 59 minutes and 35 minutes for management by sclerotherapy and laparoscopy, respectively. Patients undergoing sclerotherapy typically returned to normal activity within 1 day, significantly faster than the other management modalities. The open group experienced a significantly longer convalescence (8 days) than the laparoscopic group (3 days). Although not quantitated, the cost of sclerotherapy was reported to be one-fifth to one-fourth the cost of open surgery, and the cost of laparoscopy was approximately double that of open surgery (3).

In another large series, the relative merits of open and laparoscopic varicocele repair were prospectively evaluated by Mandressi and co-workers (247). Comparison of 120 patients managed by open surgery using Palomo's retroperitoneal technique with 160 patients who underwent laparoscopic repair revealed equal efficacy

regarding both recurrence and improvement in semen parameters. Recurrence rates of 6.7% (8 of 120) and 3.1% (5 of 160) were reported for the open and laparoscopic groups, respectively. Both populations manifested significant and equal improvement in postoperative semen parameters, including volume, sperm count, motility, and morphology. Pregnancy rates were not reported.

The mean total operative time for the laparoscopic group was 32 minutes, which was significantly longer than the open population, which had a mean operative time of 21 minutes. There were no intraoperative complications in either group. Minor postoperative complications occurred in 0.6% and 7.5% of the laparoscopic and open surgery groups, respectively. The only complication in the laparoscopic group was a case of shoulder pain that resolved spontaneously over 3 days. In the surgical group, two hydroceles (1.6%) and seven wound infections (5.8%) were recorded. The number of patients requiring postoperative analgesia was significantly higher in the surgical group. Only 6% of patients in the laparoscopic group required pain medications, whereas 26% of patients managed by open surgical venous ligation required pain medicines (247).

Hospital stay was significantly shorter for patients undergoing laparoscopic versus open varicocelectomy (2.1 days versus 3.2 days, respectively). On average, patients treated laparoscopically returned to normal preoperative activity within 5 days, whereas the patients treated surgically required 11 days. Overall costs were significantly more expensive for the laparoscopic than for the open procedure: $1,810 versus $1,130.

In contrast to a retroperitoneal open approach (i.e., Palomo technique), the subinguinal repair of a varicocele is thought to be less invasive and potentially less morbid. In this regard, Hirsch and colleagues (168) prospectively reported a comparison of open subinguinal and laparoscopic varicocele repair. Seventeen patients undergoing laparoscopic varicocele repair were compared with nineteen patients managed with the open subinguinal approach. Recurrence rates and changes in semen parameters were not reported. Average operating time was significantly longer for the laparoscopic group than for the open group (82 versus 36 minutes).

There were two reported complications in the open group: a minor wound infection and a subcutaneous hematoma. Both resolved promptly with conservative management. In the group treated laparoscopically, two patients failed laparoscopic management due to technical difficulties. In addition, two of the remaining 15 laparoscopically managed patients experienced complications that required overnight admission. One patient was observed after repair of laparoscopic trocar injury to the inferior epigastric vein. A second patient experienced nausea necessitating overnight observation (168).

All subinguinal cases were performed under local anesthesia with sedation; the laparoscopic group received general anesthesia. Postoperative analgesic requirements and convalescence were not significantly different for either management modality (168). Cost analysis was not performed in this study.

Nickel and colleagues (305) compared results of inguinal and subinguinal bilateral varicocele repairs with a published series of laparoscopic bilateral varicocele repairs. Twenty-seven patients underwent bilateral subinguinal repairs, and 28 patients underwent bilateral inguinal repairs. Results were compared with 14 patients undergoing laparoscopic bilateral varicocele repairs. Mean operative times for subinguinal, inguinal, and laparoscopic repairs were 39, 44, and 118 minutes, respectively. Pain medication was reported in number of pills of Tylenol with Codeine No. 3. Mean number of pills for subinguinal, inguinal, and laparoscopic bilateral repairs were 9.2, 7.5, and 8.4 pills, respectively. Mean time for return to work for the three groups was 4.2, 3.4, and 3.4 days, respectively. No advantage was noted for the laparoscopic approach.

To date, there does not exist a prospective, randomized trial comparing the efficacy of different modalities for varicocele repair regarding improvement in semen parameters or pregnancy rate. It seems clear, however, that percutaneous sclerotherapy provides an inexpensive, least invasive, and cost-effective first-line solution to the problem of a left varicocele. For those patients who do not respond to sclerotherapy, the next most reasonable option would appear to be a subinguinal open approach. Laparoscopic varicocelectomy, although feasible and safe, remains more costly and less efficient than either of the other two approaches; its use should be reserved for the rare patients in whom the percutaneous or subinguinal approach fails or when another laparoscopic procedure is to be accomplished concomitantly. Although only limited data are available, it appears that even when bilateral varicocele repair is required, laparoscopy should still not be the first line of therapy; indeed, in these patients, the subinguinal approach requires less operative time and results in equal postoperative discomfort and an equally expeditious convalescence.

Retroperitoneum: Adrenalectomy

Laparoscopic adrenalectomy was introduced by Gagner and colleagues (110) in 1992. Subsequent advances in minimally invasive surgery have allowed laparoscopy to become the technique of choice for management of the majority of surgical diseases of the adrenal gland. Indications for adrenalectomy include aldosteronoma, pheochromocytoma, adrenal cysts, adrenal myelolipoma, Cushing's disease, and Cushing's adenoma.

Although initially described as a transperitoneal approach, laparoscopic adrenalectomy can currently be performed using either a transperitoneal or retroperitoneal technique. The transperitoneal approach is performed with the patient in the flank position. Typically, for a right adrenal lesion, after achieving a pneumoperitoneum and placing four subcostal ports, a transverse incision is made in the posterior parietal peritoneum (i.e., hepatic posterior coronary ligament) parallel to and just below the inferior edge of the liver. The incision extends from the line of Toldt, laterally, to the inferior vena cava, medially. Dissection begins between the medial border of the adrenal gland and the lateral border of the vena cava (Fig. 18.13); Gerota's fascia is incised and the main adrenal vein is identified and secured with three clips. The adrenal vein is then divided, leaving two clips on the caval side. Superiorly, the gland is dissected free from the diaphragm, where the diminutive inferior phrenic tributaries to the adrenal are encountered and secured with electrocautery. Next, the inferior portion of the dissection is completed, staying well away from the renal hilum. Last, the gland is freed laterally, following which it is placed in a laparoscopic sack and removed. For much of the periadrenal dissection through the perirenal fat, the harmonic scalpel can be helpful.

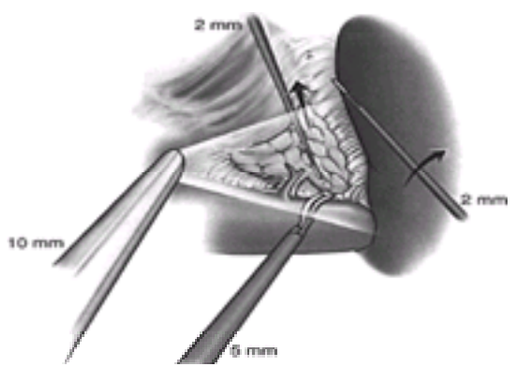

FIGURE 18.13. After incision of Gerota's fascia, the main adrenal vein is identified. (Reprinted from Spencer JR, O'Conor VJ Jr. Comparison of procedures for stress urinary incontinence. *AUA Update Series* 1987;18:259, with permission.)

Left transperitoneal adrenalectomy requires mobilization of the spleen and the splenic flexure of the descending colon; dissection of the latter also allows safe medial displacement of the tail of the pancreas. An incision in the peritoneum is made along the line of Toldt extending from the diaphragm caudal, past the splenic flexure of the descending colon; in doing this, any connections between the spleen and diaphragm are released (i.e., splenophrenic ligaments). A counterincision is then made perpendicular to the line of Toldt at the inferior border of the spleen; with this T-shaped incision, the splenic flexure of the colon is mobilized as the lienocolic ligament is secured and divided. Next, the kidney is further separated from the spleen by incising the lienorenal ligament. Occasionally, for a large adrenal mass, the tail of the pancreas must be identified and mobilized off the anterior surface of the adrenal gland.

At this time, the left renal vein may or may not be visible; if it is not, it may be necessary to trace the gonadal vein upward to identify its juncture with the left renal vein. In doing this, the anterior part of Gerota's fascia is incised. Dissection of the anterior and superior portions of the left renal vein allows identification of the left adrenal vein; it is secured with four vascular clips and divided. The medial dissection is then performed with any of the diminutive aortic branches to the adrenal gland being electrocoagulated. The gland is then freed laterally from the medial surface of the kidney. The specimen is placed into a laparoscopic entrapment sack for extraction.

Access for retroperitoneal laparoscopic adrenalectomy is gained via a 2-cm muscle-splitting incision in the midaxillary line just caudal to the tip of the twelfth rib.

Balloon or blunt dilation is used to create a working space, and insufflation to 12 mm Hg is performed. A second trocar is placed on the vertebral side of the first trocar. The peritoneum is mobilized medially, allowing for placement of a third trocar on the medial side of the first trocar. Gerota's fascia is opened, exposing the adrenal gland. At times, a laparoscopic ultrasound unit is helpful to demarcate the location of the adrenal gland, especially in patients with Cushing's disease. The gland is dissected circumferentially. The adrenal vein is clipped and divided during the final phase of the dissection. The specimen is then placed in an entrapment sack and removed.

Although a prospective study comparing the merits of laparoscopic and open adrenalectomy has not been performed, a number of authors have retrospectively compared these modalities. Trials comparing the results of open and laparoscopic adrenalectomies are presented in Table 18.3. In the following few paragraphs, studies have been selected in which transperitoneal open and laparoscopic, retroperitoneal open and laparoscopic, and transperitoneal laparoscopic versus open retroperitoneal approaches have been compared. In each comparison, the advantages of laparoscopy are apparent.

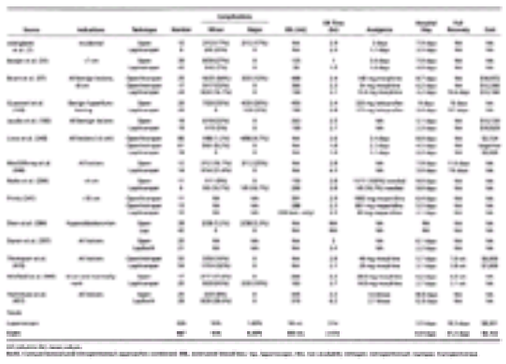

TABLE 18.3. ADRENALECTOMY—COMPARATIVE TRIALS

Guazzoni and co-workers (143) compared 20 transperitoneal laparoscopic and 20 open (both transperitoneal and retroperitoneal) adrenalectomies in the management of benign hyperfunctioning adrenal tumors. There were no conversions to open procedures. There was no significant difference in operative times noted, with laparoscopic and open adrenalectomies requiring 2.8 and 2.4 hours for completion, respectively (143). Estimated blood loss was significantly lower in the laparoscopic population at 100 versus 450 mL. Complications were encountered significantly more frequently in the open group (two patients experienced pneumothorax, two patients experienced wound infections, three patients required transfusion, two patients experienced postoperative ileus, and two patients had postoperative fevers greater than 38°C). In the laparoscopic group there was only one complication, a port site wound infection (143). Postoperatively, the patients treated laparoscopically experienced significantly less pain: 175 mg of ketoprofen compared with 320 mg of ketoprofen. Length of hospital stay and convalescence were also significantly shorter for patients treated laparoscopically: 3.4 days versus 9 days and 9.7 days versus 16 days, respectively (143).

Thompson and colleagues (415) retrospectively compared 50 patients managed with open retroperitoneal adrenalectomy to 54 patients managed by transperitoneal laparoscopic technique. Seven patients in this series required conversion to open adrenalectomy. However, experience significantly affected the conversion rate; the conversion rate of 12% in the first 11 patients was reduced to 4.5% in the last 43 patients. Operative times were 40 minutes less for patients managed via the open approach: 2.1 versus 2.8 hours. Complications in the laparoscopic group occurred in 10% versus 18% in the open group. Most interestingly, these authors also sought to document the incidence of late complications. Late complications in the open group occurred in 54% of patients, including chronic pain at the wound site, severe laxity of the abdominal wall musculature, and bothersome flank numbness. In contrast, no late complications occurred in patients managed laparoscopically. The laparoscopic approach tended to be more expensive than the open approach: $7,000 versus $6,000.

Adrenal tumors less than 7 cm in diameter managed with either open retroperitoneal or laparoscopic retroperitoneal technique were retrospectively compared by Bonjer and colleagues (32). Forty-two laparoscopic adrenalectomies were compared with thirty open procedures. Two laparoscopic adrenalectomies required conversion to open surgery. Complications were significantly less in the laparoscopic population, 7% versus 27% (32). Mean operative times were 30 minutes longer for the laparoscopic group (1.5 versus 1.0 hours). However, the laparoscopic group experienced significantly less discomfort, requiring an average of only 1 day as opposed to 3 days of pain medication. Hospital stay for the laparoscopic group was also significantly shorter: 4 days versus 7 days (32).

Whereas most authors have sought to compare open to laparoscopic techniques, Takada and associates (410) compared the two types of laparoscopic approaches to each other: transperitoneal (27 cases) versus retroperitoneal (11 cases). In four cases (36%), laparoscopic retroperitoneal exploration was converted to transperitoneal adrenalectomy because of difficulty during the retroperitoneal exploration in three cases and secondary to a pancreatic injury in one case. In contrast, with the transperitoneal approach, there were no conversions. Mean operative time for retroperitoneal adrenalectomy was 4.1 hours, which was not significantly longer than the 3.9 hours required for transperitoneal laparoscopic adrenalectomy (410). Similarly, there was no difference in time to oral intake and time to ambulation. However, the complications and length of stay associated with each technique were not reported.

Overall, the laparoscopic transperitoneal approach is preferred by some authors for left adrenalectomy and the retroperitoneal approach is preferred for the right adrenal due to the posterior insertion of the right adrenal vein into the inferior vena cava. Also, some authors prefer a transperitoneal approach in cases of Cushing's syndrome due to the large amount of fatty tissue surrounding the adrenal gland that can greatly impede a retroperitoneal dissection.

Of all the indications for adrenalectomy, none is more challenging than pheochromocytoma given its potential to cause a hypertensive crisis and volume-related problems. A drawback to the laparoscopic approach is that it precludes thorough exploration of the para-aortic region and the contralateral adrenal gland. However, scintigraphy with ^{131}I-meta-iodobenzylguanidine, CT scanning, and MRI of the abdomen are capable of localizing pheochromocytomas very precisely, thereby, in many centers, precluding the need for additional surgical exploration. Bonjer and co-workers (32) reported successful laparoscopic management of eight pheochromocytomas. In this series, intraoperative systolic blood pressure did not exceed 180 mm Hg, heart rate remained below 140 beats per minute, and cardiac arrhythmias were not encountered. Similarly, Gagner and co-workers (109) reported on 17 patients who had 23 pheochromocytomas; 6 patients had bilateral tumors. All cases were completed laparoscopically. Unilateral adrenalectomy required an average of 3.8 hours and bilateral cases required 6.3 hours for completion. Hypertensive crises with systolic blood pressures greater than 200 mm Hg or diastolic pressure greater than 100 mm Hg occurred in nine patients, and all were well controlled pharmacologically. Hypotension, defined as systolic blood pressure less than 80 mm Hg, occurred at induction or after venous clamping in three bilateral and six unilateral cases and was corrected with volume expansion or pressor agents (109). These findings are consistent with recent recommendations from The Cleveland Clinic demonstrating good blood pressure control in patients with pheochromocytomas with hydration and calcium channel blockers, thus obviating the use of a-blockers for a prolonged period preoperatively (424). Only 4 of 17 patients (24%) required continued antihypertensive medications postoperatively. Complications were noted in 6% of patients.

When all of the series are reviewed it becomes apparent that the laparoscopic approach, whether retroperitoneal or transperitoneal, provides the following benefits: less blood loss, less need for analgesics, shorter hospital stay, and more rapid convalescence. When comparing the laparoscopic transperitoneal and retroperitoneal approaches for adrenalectomy, no significant differences have been reported. In sum, at this time, the laparoscopic adrenalectomy, like cholecystectomy, has largely supplanted open surgery for adrenal disease.

Retroperitoneum: Renal Cyst Decortication—Simple Peripheral Cyst

Simple renal cysts are common incidental findings. They occur in at least 24% of all individuals older than 40 years of age and in 50% of individuals older than 50 years of age who are evaluated with abdominal CT scans performed for nonurologic indications (230). Simple cysts only rarely are discovered due to clinical manifestations. However, flank pain, abdominal pain, hematuria, recurrent infection, hypertension, and obstructive uropathy alone or in combination are the most common reasons that simple cysts require intervention (10).

Historically, open decortication was the treatment modality of choice for a symptomatic renal cyst. Although highly efficacious for eliminating cysts, one-third of patients undergoing open surgical management experienced perioperative complications, including wound infections, urinary retention, atelectasis, pneumonia, and venous thrombosis (227). Open surgical management is also associated with significant postoperative pain from the flank or abdominal wound and a postoperative

convalescence of 1 month or more.

The advent of minimally invasive urologic technologies engendered less invasive techniques for the management of renal cysts. Alternative techniques for ablation of renal cysts include percutaneous cyst aspiration with sclerosis, retrograde endoscopic cyst incision with marsupialization, and percutaneous resection with fulguration (172,178,210). The least invasive of these options is cyst aspiration with sclerosis. This is an easily performed procedure done with local anesthesia on an outpatient basis with a low morbidity rate. Sclerosis of the cyst can be performed with a number of agents: bismuth phosphate, isophendylate, ethanol, and autologous blood. Reports of aspiration and sclerosis have demonstrated varying degrees of success.

Holmberg and Hietala (172), using sclerotherapy with bismuth phosphate, reported elimination of 10% of cysts and decrease in the size of another 36% at 3 years follow-up among 54 cysts. Complications included eight (15%) patients with postprocedure pain, two patients (4%) with perirenal hematomas not requiring transfusion, and five patients (9%) with fever for 1or 2 days (172). Liatsikos and colleagues (239) reported a series of 24 patients with large symptomatic renal cysts. Treatment consisted of aspiration under ultrasound guidance and sclerosis with alcohol and tetracycline. Two patients experienced mild pain with alcohol injection, but the procedure was successfully completed. One patient reported severe pain with tetracycline injection necessitating termination of the procedure. This patient underwent surgical unroofing of the cyst 3 weeks later. With a mean follow-up period of 20 months, all patients remained asymptomatic. Follow-up ultrasound evaluations revealed resolution in 11 of 24 (46%) and small residual cyst cavities in 12 of 24 (50%). There were no complications in this series.

Aspiration and sclerosis should be the primary form of intervention for symptomatic renal cysts. It should be noted, however, that cyst puncture cytology has been shown to be only 80% to 85% sensitive in diagnosing renal malignancy (359,416); however, in the face of a Bosniak 1–type cyst with the aspiration of clear fluid and a negative cytology, the cyst is invariably benign.

Laparoscopic renal cyst ablation has been described using both transperitoneal and retroperitoneal approaches; it has been used as both a primary and secondary modality for cyst therapy, but as previously stated, it should be most commonly used only when percutaneous aspiration and sclerosis fails in the treatment of a documented, symptomatic benign cyst. The transperitoneal approach is performed with the patient in the lateral decubitus position. If the cyst is in close proximity to the renal collecting system, a ureteral catheter may be placed before laparoscopy to facilitate identification of the ureter and renal pelvis. Typically the procedure can be performed with three trocar sites: umbilical, below the costal margin in the midclavicular line, and infraumbilical in the midclavicular line. The line of Toldt is incised and the colon reflected medially to expose the kidney. The cyst is typically readily identified as a bulge in Gerota's fascia. The fascia and perirenal fat are dissected off of the cyst. The outer cyst wall is then excised and sent for histopathology. The cyst base is then carefully inspected; any mural nodule or lesion is biopsied at this time and sent for frozen section. If the cyst is peripheral and not in close contact with the collecting system, the argon beam coagulator can then be used to fulgurate the base of the cyst.

The laparoscopic retroperitoneal approach is performed with the patient in the lateral decubitus position. Access just behind the tip of the twelfth rib is performed with either balloon dilation or digital dissection of the retroperitoneal space. Two additional trocars are placed: one anterior and slightly superior and one inferior and slightly posterior to the original access site. Incision of Gerota's fascia and blunt dissection of the perirenal fat are performed to expose the cyst. As with the transperitoneal approach, a segment of the cyst wall is excised and the base of the cyst is treated in the same manner.

Jahnsen and Solhaug (191) first described laparoscopic management of the symptomatic renal cyst. Rubenstein and colleagues (359) subsequently reported a series of ten patients with symptomatic renal cysts that were managed laparoscopically. Six patients had simple cysts, two patients had polycystic renal disease, and there was a single case each of a peripelvic cyst and multiple simple cysts. The indication for surgery in all ten patients was chronic pain; six patients had undergone prior needle aspiration of their cyst. Two patients, both of whom had undergone a negative preoperative aspiration, were discovered to have renal malignancies at the time of surgery, and both underwent radical nephrectomy. The eight remaining patients were all asymptomatic without radiographic evidence of cyst recurrence at a mean follow-up of 10 months. Operative times ranged from 50 minutes to 4 hours (mean of 2 hours, 27 minutes), including one patient who underwent radical nephrectomy under the same anesthesia. There were no intraoperative complications and only two postoperative complications. Six patients did not require any postoperative parenteral narcotics. Median postoperative parenteral narcotic requirement was two tablets. Seven patients were discharged from the hospital on postoperative day 1, and overall mean hospital stay was 2.2 days. The mean interval to resumption of normal activity was 9 days. There were no long-term complications at a mean follow-up of 10 months (359).

Rassweiler and colleagues (347) reported experience with retroperitoneal management of 50 renal cysts. This report incorporated patients with septated or suspicious cysts, large simple cysts after failure of percutaneous aspiration and sclerotherapy, multiple renal cysts with deterioration of renal function, and simple hilar cysts that obstructed the collecting system. Operative time ranged from 30 to 130 minutes (mean of 80 minutes), and average hospital stay was 5.4 days. Mean opiate dose was 1.2 doses per patient. There were two (4%) complications, including one retroperitoneal hematoma requiring transfusion (347).

All of these studies suffer from the same problem: lack of long-term (i.e., longer than 1 year) objective follow-up and a uniform patient population. In this regard, because follow-up data are largely unavailable, no valid statements can be made regarding the need to fulgurate the base of the cyst, whether a transperitoneal or retroperitoneal approach is preferable, or whether it is necessary to place fat or omentum into the cyst cavity to prevent a recurrence.

Simple cysts are common and rarely have clinical manifestations. Although laparoscopic simple cyst decortication is feasible, safe, and effective, this type of intervention is rarely required. Initial management of symptomatic cysts should include aspiration and sclerosis for two reasons. First, this will largely preclude the unwelcome “surprise” of a renal cell cancer. Second, many simple cysts will respond well to sclerotherapy, thereby avoiding a more invasive, albeit laparoscopic procedure. As such, laparoscopic simple cyst decortication should be reserved for those patients who continue to suffer symptoms when percutaneous sclerotherapy fails.

Retroperitoneum: Simple Nephrectomy

Gustav Simon from the Medical School of Heidelberg University performed the first successful open nephrectomy in 1869. Despite technical modifications, this open surgical procedure remained essentially unchanged until the first laparoscopic total nephrectomy was performed by Clayman and colleagues in 1990 (61). The indications for simple laparoscopic nephrectomy parallel those of open nephrectomy and include any benign renal pathology resulting in sepsis, bleeding, pain, compression of surrounding structures, or hypertension that is difficult to control medically. Certain conditions, such as xanthogranulomatous pyelonephritis (XGP) or nephrectomy in patients with autosomal-dominant polycystic kidney disease (ADPKD), require special consideration (see sections on XGP and ADPKD).

Laparoscopic simple nephrectomy has been performed using either a transperitoneal or retroperitoneal technique (144). The transperitoneal procedure is performed in the lateral decubitus position. Twelve-millimeter trocars are placed at the umbilicus, in the midclavicular line under the costal margin, and 3 cm inferior to the umbilicus in the midclavicular line. Two additional 5-mm trocars are placed in the anterior axillary line at the tip of the twelfth rib and at the level of the umbilicus. Recent modifications have included elimination of one or both of the 5-mm trocars and reduction of one of the 12-mm trocars to 5 mm. At times, on the right side, an additional 5-mm trocar is placed just beneath the xiphoid process to aid in retraction of the liver during the hilar dissection.

Using monopolar electrosurgical scissors, the surgeon incises the line of Toldt from the hepatic or splenic flexure caudal across the iliac vessels until the ureter is identified. The ureter is dissected from surrounding tissues up to the level of the kidney. Gerota's fascia is entered and the dissection is continued on the renal capsule until the entire kidney has been freed from the perirenal fat (Fig. 18.14). The kidney can be retracted laterally and the renal hilum exposed. The renal vessels are carefully dissected. The renal artery is clipped five times and cut between the second and third clips (leaving two clips on the side of the specimen). Attention is then turned to the renal vein; it is secured with an Endo-GIA vascular stapler. The ureter is secured with four clips and divided; the kidney is then freed from any remaining retroperitoneal attachments. The specimen is then placed in an endoscopic sack and either morcellated with forceps or, after enlarging one of the port sites, the specimen can be removed intact.

FIGURE 18.14. Dissection template for simple laparoscopic right transperitoneal nephrectomy.

Access for retroperitoneal simple nephrectomy is gained by a 2-cm incision just posterior to the tip of the twelfth rib. After balloon or blunt digital dissection of the retroperitoneum around Gerota's fascia, a Hasson cannula is placed. Three additional trocars are placed: a 5-mm posterior trocar, located at the angle of the twelfth rib and the erector spinae muscle; a 5- or 12-mm trocar in the midaxillary line, 2 cm cephalad to the iliac crest; and a 5-mm trocar subcostal in the anterior axillary line, thereby describing a T configuration for the four ports. Attention is first directed to the renal hilum, and the renal artery and vein are sequentially controlled with clip ligation and the vascular Endo-GIA stapler, respectively. Gerota's fascia is incised and the kidney is dissected from the perirenal fat. The ureter is dissected from the surrounding tissues, clipped, and cut. The specimen may then be entrapped and morcellated.

Results of trials comparing open and laparoscopic simple nephrectomy are presented in Table 18.4. Parra and co-workers (323) compared 12 patients undergoing laparoscopic transperitoneal nephrectomy for benign renal disease with 13 patients managed with a traditional flank incision. All laparoscopic procedures were performed via a transperitoneal approach. One patient in the laparoscopic group required conversion to open surgery after injury to a lower pole artery with minimal blood loss. A second patient in the laparoscopic group experienced a bowel injury that was repaired laparoscopically. Both patients had had previous open abdominal surgery. There were no intraoperative complications in the open group. Mean specimen weights were similar: 169 g in the open group and 157 g in the laparoscopic group. Operative times for the open and laparoscopic procedures were similar (157 minutes and 145 minutes, respectively). Mean blood loss in the open population was twice that of the group treated laparoscopically: 141 versus 295 mL.

TABLE 18.4. SIMPLE NEPHRECTOMY—COMPARATIVE TRIALS

All parameters of convalescence favored laparoscopic simple nephrectomy. Patients in the open group had eight times the morphine equivalents for pain relief: 130 versus 14 mg. Mean hospital stay was 8 days for open simple nephrectomy and 3.5 days when the procedure was performed laparoscopically. Similarly, return to full activity was more expeditious in the laparoscopic group (16 versus 32 days, respectively). Postoperative complications included a wound infection and a urinary tract infection in the open group. No postoperative complications were reported in the patients treated with laparoscopic simple nephrectomy.

Rassweiler and co-workers (346) reported results comparing the open and the transperitoneal laparoscopic approaches and the retroperitoneal laparoscopic approach for simple laparoscopic nephrectomy. Results from 18 transperitoneal and 17 retroperitoneal laparoscopic simple nephrectomies were compared with the results of 19 open simple nephrectomies. Two conversions to an open procedure were required in the transperitoneal group, and one conversion was required in the retroperitoneal group. Mean operative times for laparoscopic transperitoneal and retroperitoneal nephrectomies were similar, and significantly longer than times required for open simple nephrectomy: 207 minutes, 211 minutes, and 117 minutes, respectively. Transfusion rates were lowest in the retroperitoneal group: 5.9% versus 17% in the laparoscopic transperitoneal patients and 16% in the open group (346).

All parameters of convalescence favored the laparoscopic approaches. Mean time for analgesia requirement for the transperitoneal and retroperitoneal laparoscopic groups was 2 days and 1 day, respectively, significantly shorter than the 4 days of analgesic administration that patients undergoing open simple nephrectomy required. Hospital stay reflected a similar pattern with transperitoneal and retroperitoneal simple nephrectomy requiring mean hospital stays of 6.6 and 6.3 days, respectively, versus 10 days in the open group. Time to complete recuperation was again similar for transperitoneal and retroperitoneal simple nephrectomy (24 and 21 days, respectively); both results were significantly shorter than the mean 40 days of recuperation time for open simple nephrectomy (346).

Overall complication rates were similar for the three approaches. Complication rates for transperitoneal, retroperitoneal, and open simple nephrectomy were 39%, 29%, and 26%, respectively. In the transperitoneal laparoscopic group, three patients experienced bleeding during dissection; one patient required conversion to open surgery. The other two were well controlled and did not require blood transfusion. There was also a bowel injury that was managed by conversion to open surgery. In addition, there were two cases of subcutaneous emphysema and a subcutaneous abscess, both of which resolved with conservative management. In the retroperitoneal laparoscopic group, there was also a conversion to open surgery as a result of intraoperative bleeding. One patient also required subsequent reexploration for a pancreatic fistula. As in the transperitoneal group, there was a single case of subcutaneous emphysema and a subcutaneous abscess, both of which resolved with conservative management. In the open population, two cases of intraoperative bleeding were reported that required blood transfusion. There was also a case of intercostal neuralgia that was managed with pain medications, a retroperitoneal hematoma that was successfully observed, and an incisional hernia that required surgical repair (346).

Eraky and colleagues (99) reported the largest experience with laparoscopic simple nephrectomy. In their report, 106 laparoscopic transperitoneal simple nephrectomies were performed for chronic pain (*n* = 73), recurrent urinary tract infection (*n* = 28), or hypertension (*n* = 5). All kidneys were entrapped in a LapSac and underwent manual morcellation with a blunt scissors and surgical clamps. Ninety-seven (92%) nephrectomies were successfully completed laparoscopically. Conversion was necessitated to overcome failure of entrapment in one patient, because of uncontrollable bleeding in three cases, and because of severe perirenal adhesions in five patients. Mean operative time was 186 minutes. When stratified by experience, however, the mean operative times were 217 minutes and 154 minutes, respectively, for the first 53 and second 53 cases. Twenty-four (23%) patients experienced minor complications consisting of low-grade fevers (less than 38 °C) and small asymptomatic hematomas. Four (3.8%) patients developed trocar site hernias. There were four (3.8%) major complications. These included a pulmonary embolism requiring anticoagulation, renal vein bleeding requiring reexploration, a colonic perforation requiring colostomy construction, and an infected hematoma that was drained percutaneously. Three of the four (75%) major complications and 17 of the 26 (65%) minor complications occurred in the first 53 cases. The mean hospital stay was 2.9 days, and mean follow-up period for the series was 14 months (range of 6 to 22 months). Analgesic requirements were not reported.

athletic activity.

McDougall and colleagues (264) also reported their initial experience, albeit with an extraperitoneal laparoscopic autoaugmentation, in a 26-year-old woman with a traumatic spinal cord injury. Urodynamic evaluation revealed poor compliance, a decreased leak point pressure, and a bladder capacity of 85 mL. An extraperitoneal laparoscopic seromyotomy autoaugmentation was performed using a 3-Fr right-angle Greenwald electrode. The bilateral detrusor flaps were sutured to Cooper's ligament bilaterally with 1-0 polyglactin suture. Operative time was 6.5 hours, and estimated blood loss was 75 mL. The patient was discharged on postoperative day 2 with bladder drainage in place. Bladder drainage was continued for 1 month, at which time a cystogram revealed no extravasation. At 6-month follow-up, the patient had a normal cystogram, good compliance, a bladder capacity of 285 mL, and improved leak point pressure. The patient had daytime and nighttime continence, and she was catheter-free voiding by Valsalva with a residual of 30 mL.

Subsequently, Poppas and co-workers (337) reported two cases of laparoscopic seromyotomy autoaugmentation that were performed with KTP laser assistance. Two children with myelodysplasia and high-pressure neurogenic bladders unresponsive to conservative management underwent laparoscopic autoaugmentation. The detrusorotomy was performed with the KTP laser. A right-angle backstop device was used for the final portions of the detrusorotomy after initial access to the urothelium had been achieved. There were no reported complications. Initial results were promising, with improvement in symptoms, decreased peak detrusor pressures, and increased bladder capacity in both cases. However, at 5 months, both cases failed and went on enterocystoplasty.

Autoaugmentation is an attractive, minimally invasive method for the treatment of the contracted, high-pressure bladder. Although the technique is amenable to a laparoscopic approach, there is little experience and inconsistent results. Further detailed studies in the laboratory and clinical arena are needed to determine the appropriate application and best technique for autoaugmentation surgery.

Ureteroureterostomy

The need for ureteral reconstruction is usually due to an intrinsic stricture (e.g., trauma, infection, stone impaction) or extrinsic compression (e.g., endometriosis, retrocaval ureter). Whereas the former can often be managed by endoscopic techniques, the latter usually requires a formal ureteroureterostomy for therapy. Several authors have described laparoscopic ureteroureterostomy in the management of ureteral pathology.

Nezhat and colleagues (301) reported the use of laparoscopic ureteroureterostomy for the management of ureteral obstruction secondary to endometriosis. Using laparoscopic techniques, the surgeon excised the diseased segment of the ureter and performed a ureteroureterostomy using four evenly spaced full-thickness 4-0 PDS sutures. The sutures were tied intracorporeally. Operative time was 117 minutes, with an estimated blood loss of less than 100 mL. The patient was discharged on postoperative day 1. Two months postoperatively, the ureteral stent was removed and intravenous urography revealed a patent ureter. Twenty-one months postoperatively, the patient was asymptomatic with a normal ultrasound evaluation of the kidney.

Laparoscopic ureteroureterostomy for retrocaval ureter was initially described by Ishitoya and colleagues (186) and later by Matsuda and co-workers (250) in 1996. Polascik and Chen (332) also reported ureteroureterostomy in the management of an obstructed retrocaval ureter. Using three trocars, the surgeon identified and mobilized the affected portion of the ureter. The ureter was divided at the most visible portion of the dilated proximal segment. The distal segment was spatulated for approximately 2 cm. The ureter was repositioned to lie anterior to the vena cava, and a previously placed stent was advanced into the renal pelvis. Anastomosis was performed using several interrupted 4-0 polyglactin sutures with an EndoStitch device. A double-J stent was left in position at the end of the procedure. Operative time was 3.75 hours. The patient was discharged on postoperative day 2. Analgesics were not required after the first day, and the patient resumed full activity on postoperative day 4. Retrograde ureteropyelogram performed 4 months after surgery revealed a patent ureter (332).

Laparoscopic ureteroureterostomy is feasible and has demonstrated good results in the few reported cases. The procedure is technically demanding, but future advances in laparoscopic tissue apposition may result in simplification. In a porcine model, Maxwell and co-workers (251) reported successful laparoscopic ureteroureterostomy using vascular closure staple (VCS) clips to perform the anastomosis. Operative times to perform the ureteroureterostomy were reduced from 39.7 and 39.5 minutes with hand suturing and EndoStitch suturing, respectively, to 22 minutes using the VCS clips. The procedure resulted in patent ureters without stones or encrustation at subsequent evaluation 12 weeks later.

Calyceal Diverticulum

Most calyceal diverticula remain asymptomatic. The incidence of calculi within calyceal diverticula varies from 10% to 50% (278). Options for management of these stones, when they become symptomatic, have included percutaneous extraction, ureteroscopic lithotripsy, and ESWL.

Gluckman and colleagues (134) reported the initial procedure of laparoscopic treatment of a stone-bearing, calyceal diverticulum. Subsequently, Ruckle and Segura (360) reported transperitoneal laparoscopic management of a stone-filled calyceal diverticulum. Later, Chen and colleagues (52) reported using a retroperitoneal approach for unroofing a calyceal diverticulum filled with milk of calcium.

Harewood and co-workers (154) described a series of three patients with calyceal diverticula that were managed by an extraperitoneal laparoscopic approach. All three patients had diverticula associated with calculi. All three cases were successfully completed laparoscopically with a mean operative time of 127 minutes. Blood loss was minimal in the first two patients, but hemorrhage was troublesome in the third patient, necessitating a transfusion of 3 units of packed RBCs. All calculi were eliminated, but there was a small recurrence of one (33%) of the diverticula. Patients received an average of six doses of meperidine and were discharged in 4 days. One patient experienced drainage from one of the trocar sites for 2 months that resolved without intervention. There were no other complications reported.

Hoznek and co-workers (175) reported results of retroperitoneal laparoscopic management of three patients with symptomatic calyceal diverticula. All procedures were successfully accomplished with a mean operative time of 80 minutes and minimal blood loss. The calyceal diverticular cavities were filled with surgical mesh impregnated with gelatin resorcinol formaldehyde glue. Average hospital stay was 6.7 days with patients requiring analgesics only during the first postoperative day. There were no complications reported. At 6 months, follow-up CT scan revealed no calculi or recurrence of the diverticula.

Laparoscopic calyceal diverticulectomy is a feasible procedure. However, for the most part, a laparoscopic approach is only considered first-line therapy by some endourologists for a large, anterior calyceal diverticulum, because all others can be expeditiously managed by percutaneous or ureteroscopic techniques.

Bladder Diverticulum

A urinary bladder diverticulum creates a separate, poorly contractile chamber and can lead to complications such as recurrent urinary tract infection, stone formation, ureteral obstruction, vesicoureteral reflux, and rarely, transitional cell carcinoma. Das (72) first described laparoscopic bladder diverticulectomy in 1992. Subsequently, there have been several reports regarding laparoscopic management of bladder diverticula.

Jarrett and colleagues (200) detailed their laparoscopic management of a large bladder diverticulum. After cystoscopic placement of a balloon catheter into the diverticulum, a transperitoneal approach was used to access the bladder. The peritoneum was reflected laterally and the diverticulum excised. The bladder was closed in a single layer with intracorporeal suturing expedited with Lapra-Ty clips. A cystotomy tube was left in position for bladder drainage, and Jackson-Pratt drains were left in position for drainage. Operative time was 6.5 hours. The retroperitoneal drain was removed on postoperative day 1. The patient was discharged on postoperative day 3. Analgesic requirement included 4 mg of morphine and 225 mg of intramuscular meperidine. On postoperative day 9, the patient had a cystogram that demonstrated no leakage and the Foley catheter was removed.

Iselin and co-workers (185) compared two laparoscopic urinary bladder diverticulectomies with four open cases. Patients in both groups underwent transurethral resection of the prostate followed by either laparoscopic or open urinary bladder diverticulectomy. Both laparoscopic diverticulectomies were performed successfully. Mean operative times for laparoscopic and open procedures were 4.2 and 1.7 hours, respectively. All cases had successful resolution of the bladder diverticula on follow-up. One complication occurred in the laparoscopy group: a pelvic hematoma was associated with a drop in hematocrit. The hematoma was observed and no blood transfusion was required. There were no significant complications in the open group. Hospital stay was 4.5 days in the laparoscopy group and 10.8 days in the open group. Mean time to full recovery was 2.5 weeks in the laparoscopic group and 8.7 weeks in the open population. The mean combined intraoperative and postoperative cost for the laparoscopic group was $9,800 versus $5,700 for the open group.

Laparoscopic bladder diverticulectomy is feasible, and the limited data available demonstrate that patients who undergo laparoscopic treatment of a bladder

diverticulum have less pain and a more expeditious convalescence. Hospital costs are a major deterrent; however, the financial impact of the markedly shortened convalescence should also be considered.

Malignant Disease: Diagnostic

Pelvic Lymph Node Dissection

The staging of a malignancy is of paramount importance before treatment. No noninvasive imaging modality or technique has proven adequate for determining lymph node status. Accordingly, surgical pelvic lymphadenectomy has been accepted as the most precise method to assess nodal disease in the setting of prostate, penile, urethral, and cervical cancers. Laparoscopic pelvic lymph node dissection (LPLND) was first described by Schuessler and colleagues (375) in 1991. It was this procedure, more than any other, that introduced laparoscopy into mainstream adult urology. Since then, LPLND has been evaluated as a less invasive alternative to the traditional open pelvic lymph node dissection at many centers.

Prostate cancer is the most common noncutaneous malignancy in men. The status of pelvic lymph nodes has a major impact on treatment and long-term prognosis in men with clinically localized prostate cancer. Clinical parameters including digital rectal examination, serum prostate-specific antigen (PSA) level, and Gleason's score can be used in conjunction with statistical tables to exclude the need for pelvic node sampling in patients with favorable characteristics (158,326). As such, the question arises as to which patients should be candidates for a lymph node dissection. We believe this is based on the potential therapy should the lymph node dissection reveal no metastatic disease. Specifically, when the risk of lymph node involvement is greater than 5% to 10%, staging pelvic lymphadenectomy is indicated if the treatment plan is for either perineal prostatectomy or radiation therapy. In contrast, among patients who are candidates for a radical retropubic prostatectomy, the threshold for performing LPLND is higher. These individuals should have upward of a 40% risk of nodal disease before proceeding with an LPLND because in this case, a positive LPLND will merely spare the patient a lower midline incision rather than avoiding needless extirpative perineal surgical or radiation therapy. Using these guidelines, fewer than 10% of patients with clinically localized prostate cancer are candidates for LPLND.

Transperitoneal LPLND is performed with the patient in the Trendelenburg position and rotated laterally. Peritoneal access and laparoscope insertion are through an incision at the umbilicus. Two additional trocars are placed bilaterally, lateral to the rectus abdominus muscle and approximately 2 cm inferior to the umbilicus. A fourth trocar is inserted in the midline above the symphysis pubis, thereby completing the “diamond” array of trocar placement. An incision is created in the parietal peritoneum just lateral to the medial umbilical ligament. The vas deferens is isolated and divided between clips or is electrocoagulated and cut. (In this regard, it is essential that each patient be told that following this procedure he will be infertile.) The external iliac artery is identified and dissected along its medial aspect; the external iliac vein is then identified and dissected anterior and medial along its length. The pubic ramus is identified medial to the external iliac vein and is dissected toward the midline. Next, the obturator space is carefully dissected, and the obturator nerve is identified and gently teased out of the nodal packet. The obturator vein can be divided if necessary, but the obturator artery should be preserved. The dissection is continued cephalad to the level of the bifurcation of the common iliac artery. All tissue bounded by the medial edge of the external iliac artery laterally, the pubis caudally, the obturator nerve and obturator vessels posteriorly, and the bifurcation of the common iliac artery cranially are removed. In those patients in whom there is a high suspicion for nodal disease, the dissection is “extended” by removing any nodal tissue along the common iliac artery up to the point where the ureter crosses the common iliac vessels; in addition, the nodal tissue in the presciatic (i.e., deep to the obturator nerve), presacral (i.e., medial to the hypogastric artery), and lateral/posterior to the upper portion of the external iliac artery areas may also be included in the dissection.

Another laparoscopic approach to LPLND, albeit less widely used, is extraperitoneal. This is performed by creating a 2-cm incision in the midline just below the umbilicus. After digital dissection, a balloon is used to expand the extraperitoneal space to 700 to 1,000 mL. Next, the balloon is deflated and removed; a Hasson-type trocar is placed into this incision. Three additional trocars are placed, in the same configuration as described for a transperitoneal pelvic lymph node dissection. The dissection proceeds laterally along the external iliac vein. Laparoscopic clips are used to control any lymphatics or venous branches visualized, in particular the inferior epigastric vein. All nodal tissue is taken from within the boundaries previously described.

Results of trials comparing open and laparoscopic LPLND are presented in Table 18.5. Schuessler and colleagues (373) reported results of 147 consecutive patients with localized carcinoma of the prostate undergoing LPLND. Initially, the laparoscopic procedure was performed in a limited manner; however, the final 86 patients underwent an extended LPLND (hypogastric, external iliac, and obturator lymph node dissection). Mean operative time was 2.5 hours, and mean estimated blood loss was 100 mL. Mean postoperative hospital stay was 2 days. Only 20% of patients required analgesics at the time of discharge from the hospital, and 85% of patients returned to full activity within 2 weeks after surgery. The overall complication rate was 31%. The reoperation rate among all 147 patients was 7% (11 of 147). Of 11 patients, 7 were reexplored laparoscopically. Reexploration was performed in five patients (3%) for hemorrhage, one patient (0.6%) for a bowel laceration, one patient (0.6%) for a ureteral injury, and four patients (3%) for lymphoceles. The mean number of lymph nodes removed was the highest in any series: 45 (range of 13 to 86); the overall positive nodal involvement rate was 23%.

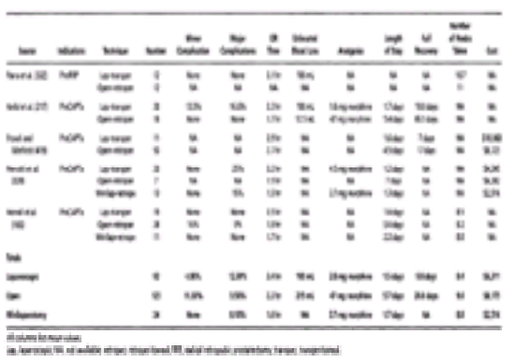

TABLE 18.5. PELVIC LYMPH NODE DISSECTION—COMPARATIVE TRIALS

Stone and co-workers (400) reported results of 130 LPLNDs performed for T_{1a} to T_{2a} carcinoma of the prostate. All LPLNDs were successfully performed laparoscopically. A median of five nodes per side was removed. Operative parameters were not reported. Five (3.8%) patients experienced major complications: two patients required transfusion of 1 unit of blood for injuries to an inferior epigastric vessel and an obturator vessel, respectively, one (0.7%) patient experienced a cerebrovascular accident, one (0.7%) patient experienced a bladder injury, and one (0.7%) patient required rehospitalization for intravenous antibiotics to treat an infected pelvic hematoma.

In a subsequent report, Stone and colleagues (401) compared standard, “limited” LPLND to extended LPLND for detection of carcinoma of the prostate. Thirty-nine patients underwent an extended LPLND that included obturator, hypogastric, common, and external iliac nodes. These results were compared with patients undergoing LPLND that included only the obturator and hypogastric lymph nodes. A mean of 9.3 nodes was removed during modified LPLND, compared with 18 nodes removed during extended LPLND. Extended dissection was positive in the extended area in only one patient (2.6%). Even when patients were stratified into high-risk groups based on PSA greater than 20 ng/mL, Gleason score 7 or higher, or stage T_{2b} or T_{3a}, patients in the extended LPLND group did not have a significantly higher node positivity rates: 30% and 26.4% ($p = .8$), 27% and 19% ($p = .4$), and 25% and 15% ($p = .17$), respectively. Of note, the extended LPLND was associated with a significant increase in complications: 14 of 25 patients (36%) undergoing the extended dissection had complications, compared with only 3 of 147 patients (2%) in the standard group. Complications in the extended group included 11 (28%) cases of scrotal or penile edema, 4 (10%) cases of lower extremity edema, and 2 (5%) cases each of obturator nerve palsies, pelvic abscesses, and urinary retention (401).

Kerbl and colleagues (217) compared 30 patients undergoing a standard limited LPLND with 16 patients undergoing open pelvic lymph node dissection during the same period. All laparoscopic procedures were successfully completed. Mean operative time was significantly longer for the laparoscopic group: 3.3 hours compared with 1.7 hours for the open group. However, postoperative analgesic requirement was markedly less in patients undergoing LPLND: 1.6 mg of morphine sulfate equivalents versus 47 mg in the open group. Major and minor complications occurred in 13% and 17% of patients in the laparoscopic group, respectively. No complications were reported in the open group. A learning curve was noted in the laparoscopic group, with all major complications occurring in the first 12 patients. Major complications included a bladder perforation, a pelvic hematoma, a pelvic collection requiring drainage, and a delayed bowel fistula. Minor complications

included subcutaneous emphysema in one patient, two instances of scrotal swelling, a scrotal hematoma, and one case of urinary retention. Hospital stay was 1.7 days in the laparoscopic group and 5.4 days in the open group. Similarly, return to full activity was expedited with the laparoscopic technique: 11 versus 66 days. Cost evaluation was also performed (217). Unilateral and bilateral LPLNDs cost $7,700 and $10,300, respectively. Open pelvic lymph node dissection was more cost-effective, with unilateral and bilateral procedures costing $6,600 and $8,200, respectively.

In 1994, Troxel and Winfield (419) performed a financial analysis comparing open and laparoscopic pelvic lymph node dissection. The total overall cost from hospital admission to discharge was $1,350 more for the laparoscopic approach. The same authors later performed a financial analysis comparing LPLND and open pelvic lymph node dissection during two separate time periods to evaluate the effect of the learning curve on overall cost (420). Cost analysis was performed comparing 50 men undergoing LPLND between 1990 and 1992 with 55 men undergoing LPLND between 1993 and 1994. Despite a decrease in preoperative and postoperative expenses (112% and 31%, respectively) in the laparoscopic group, the overall cost of the laparoscopic procedure remained unchanged because of increased operating room costs. Indeed, despite operative time decreasing by a mean of 19 minutes, the cost of surgical supplies increased $910 (104%), resulting in an increased overall absolute cost.

Ferzli and co-workers (104) compared 18 patients undergoing transperitoneal LPLND with 18 patients undergoing extraperitoneal LPLND in a nonrandomized, retrospective fashion. All prostate cancer patients received LPLND before brachytherapy or radical perineal prostatectomy. All laparoscopic procedures were successfully completed; one extraperitoneal procedure required open conversion due to dense adhesions from prior surgery. Mean operative time was similar between the two groups: 2.25 hours for transperitoneal laparoscopic LPLND versus 2.5 hours for the extraperitoneal LPLND. The mean number of lymph nodes removed was eight for both groups. Average length of stay was 3.2 days for the transperitoneal group and 2.7 days for the extraperitoneal LPLND group. The authors reported an increased complication rate in the transperitoneal laparoscopic group: 28% versus 0% in the extraperitoneal group. Complications included two patients (11%) requiring transfusions, one (5.5%) omental hernia, one (5.5%) prolonged postoperative ileus, and one (5.5%) infected lymphocele requiring percutaneous drainage. In the extraperitoneal population, there were no postoperative complications. However, one extraperitoneal procedure required conversion to open surgery and another procedure was converted to a transperitoneal laparoscopic approach when the peritoneum was entered during the dissection. Analgesic requirements and return to full activity were not reported (104).

Several groups have compared LPLND with mini-laparotomy incisions. Among these studies, two stand out. Both clearly favor the mini-laparotomy while also corroborating the benefits of LPLND as well as mini-laparotomy over a standard open surgical approach. Perrotti and co-workers (329) reported results comparing a standard open lower midline incision, a 6-cm mini-laparotomy incision, and LPLND. In their series, 7 patients underwent open lymphadenectomy, 13 patients underwent mini-laparotomy, and 20 patients underwent LPLND. Mean operative times for open and mini-laparotomy procedures were both 90 minutes. Mean operative time for LPLND was 190 minutes. Postoperative hospital stay for open, mini-laparotomy, and LPLND were 7, 1.3, and 1.2, respectively. Analgesic requirements were not reported for patients who underwent open pelvic lymph node dissection. However, patients in the mini-laparotomy and LPLND groups required a mean of 3.7 and 4.5 mg of morphine sulfate equivalents, respectively.

One (5%) patient in the LPLND group required conversion to open surgery for control of hemorrhage. In addition, one (5%) patient in the LPLND group experienced mild left lower extremity discomfort that resolved without intervention, one (5%) patient experienced self-limited abdominal discomfort and bloating 1 week postoperatively, and two (10%) patients experienced scrotal swelling for 4 days postoperatively. In the mini-laparotomy group, no intraoperative complications occurred and only two postoperative complications were seen: one (8%) patient complained of vague abdominal pain, and one (8%) patient experienced a small area of skin separation at the wound site. Complications for the open group were not reported. Operative costs for both mini-laparotomy and open lymphadenectomy were $1,311, compared with $2,100 for LPLND. Total costs for open lymphadenectomy, mini-laparotomy, and LPLND were $4,300, $2,500, and $4,200, respectively (329).

Herrell and colleagues (165) similarly compared three techniques for pelvic lymphadenectomy. In their series, 38 patients underwent open lymphadenectomy, 11 patients underwent mini-laparotomy, and 19 patients underwent LPLND. The mean number of lymph nodes removed for open, mini-laparotomy, and LPLND were 9.2, 8.8, and 8.5, respectively. LPLND required significantly more operative time (3.5 hours) than either open lymphadenectomy (1.9 hours) or mini-laparotomy (1.7 hours). Hospital stay was significantly longer for open lymphadenectomy: 5.6 days compared with 2.2 days for the mini-laparotomy group and 1.6 days for the LPLND group. No complications occurred in either the mini-laparotomy or LPLND groups. In the open lymphadenectomy group, there were several complications (22%): three (8%) cases of ileus, two (5%) patients with urinary retention, and one (3%) case each of a lymphocele, a deep venous thrombosis, and a pelvic abscess.

One major criticism of LPLND has been the concern that this approach may result in seeding of cancer cells in patients with positive lymph nodes. Problems of this sort have been noted in patients with ovarian and other gynecologic cancers, but usually these cases were complicated by malignant ascites or direct violation of the tumor's borders during the dissection. Nonetheless, because of this hypothetical problem, Cadeddu and colleagues (44) evaluated the effect of LPLND on the natural history of carcinoma of the prostate in 52 men with node-positive LPLND. There were three (5.8%) deaths from prostate cancer at 3.0, 3.5, and 4.0 years, respectively, after LPLND; however, at a mean follow-up of 3.1 years, none of the patients developed trocar site tumor implantation. Adjuvant radiation therapy was administered in 12 (23%) men. Of 45 men treated with androgen ablation, 19 (42%) demonstrated biochemical progression during the study period. Among these men with node-positive prostate cancer, the 5-year actuarial biochemical progression-free rate was 45%, similar to the results with open surgery. As such, LPLND appears to neither alter the natural history of stage D_1 carcinoma of the prostate nor lead to trocar site implantation.

LPLND is feasible and is an adequate staging modality for carcinoma of the prostate. When performed by experienced laparoscopic surgeons, LPLND offers patients the comfort, low morbidity, and rapid convalescence characteristic of most laparoscopic procedures. However, it must be stressed that in skilled hands mini-laparotomy provides patients an equally comfortable and expeditious convalescence at less cost. The choice of which less invasive modality to use for pelvic lymph node sampling is dependent on the experience of the individual surgeon; however, it is equally clear that either method remains far superior to a standard open surgical node dissection.

Retroperitoneal Lymph Node Dissection

Patients with nonseminomatous germ cell tumors are at risk for retroperitoneal lymph node involvement. Although noninvasive staging techniques are somewhat accurate, 20% to 25% of patients with clinical stage I disease are understaged when only clinical nonsurgical staging modalities are used. Laparoscopic retroperitoneal lymph node dissection (LRPLND) was originally reported by Hulbert and Fraley in 1992 (179) and has subsequently been performed in patients with stage I disease after orchiectomy and, rarely, in patients with stage IIb disease after chemotherapy.

Gerber and co-workers (119) reported results of 20 laparoscopic retroperitoneal lymph node dissections performed in men with stage I nonseminomatous germ cell tumors. A modified unilateral retroperitoneal lymphadenectomy was performed in all patients. Anatomic boundaries for the dissection included the renal hilum superiorly, ureter laterally, medial aspect of the vena cava or aorta medially (right and left dissection, respectively) (i.e., the interaortocaval lymph nodes), and level of the origin of the inferior mesenteric artery inferiorly; the dissection was extended to the bifurcation of the common iliac vessels on the ipsilateral side, and the stump of the spermatic cord was excised. The retrocaval and retroaortic nodes were not removed.

Of 20 cases, 18 (90%) were successfully completed laparoscopically. In two cases, conversion to an open procedure was necessitated because of bleeding from gonadal vessels. One of these two cases required transfusion. Two additional patients required blood transfusion in the postoperative period [total transfusions = three (15%) patients]. Median operative time was 6 hours, and median estimated blood loss was 250 mL. A median of 14.5 nodes were removed per patient, with 3 of 18 (17%) manifesting disease in the lymph nodes. Most patients required intramuscular or intravenous narcotics for less than 1 day. Hospital stay was 3 days, and patients returned to full activity in 2 weeks. Complications occurred in 6 of 20 patients (30%), including the 2 patients (10%) requiring conversion to open surgery. Other complications included two additional patients (10%) requiring transfusion in the postoperative period, one patient (5%) with myonecrosis that resolved with observation, and one patient (5%) with lymphocele. Of the 15 patients who successfully underwent retroperitoneal lymph node dissection and had no evidence of disease, none manifested retroperitoneal disease recurrence with a mean follow-up of 10 months. Of 15 patients, 1 (7%) presented with a lung nodule 4 months after retroperitoneal lymphadenectomy. CT scan demonstrated no evidence of retroperitoneal disease, and the patient received chemotherapy. There was no evidence of disease 9 months later. All 20 patients (100%) reported normal antegrade ejaculation.

Rassweiler and colleagues (348) reported results of 26 retroperitoneal lymph node dissections. Seventeen patients were managed for stage I disease, and the remaining nine patients underwent retroperitoneal lymph node dissection for stage II disease after chemotherapy. The procedure was successfully completed in 16 of 17 stage I patients (94%); however, it was successfully completed in only 2 of 9 stage II patients (22%). The stage I conversion resulted from bleeding that could not be controlled laparoscopically. Stage II conversions were all the result of difficult dissection attributed to the desmoplastic reaction associated with the disease process and chemotherapy. Mean operative time for stage I and stage II patients was 4.9 and 5.9 hours, respectively. Estimated blood loss was not reported. There were four (24%) postoperative complications in the stage I group. These consisted of a patient with a retroperitoneal hematoma who subsequently developed ureteral stenosis. This patient required ureterolysis 8 weeks later. Another patient developed a pulmonary embolism that was successfully managed with anticoagulation. In

addition, there was a single case of retrograde ejaculation. There was one (11%) postoperative complication in the stage II group, a lymphocele. Patients managed for stage I disease had a mean follow-up of 27 months. No patient manifested a regional relapse, but two patients had pulmonary metastases that were treated successfully with three cycles of chemotherapy. Histopathology in all nine cases of stage II cases revealed necrotic material only, and no patient had evidence of disease with a median follow-up of 29 months.

Janetschek and co-workers (196) have done the most extensive work in the area of LRPLND. They reported results of 105 patients undergoing laparoscopic retroperitoneal lymphadenectomy either for stage I nonseminomatous germ cell tumors after radical orchiectomy or stage IIb nonseminomatous germ cell tumors after chemotherapy. The procedure was successfully accomplished laparoscopically in 103 of 105 (98%) patients. Two (2%) patients required conversion to an open procedure because of bleeding. Mean operative time was 6.3 hours; however, the authors reported a “long and steep learning curve.” Operative time for the first 14 patients was 8 hours; this progressively decreased such that operative time for patients 45 through 64 was reduced to 3.7 hours. Minor postoperative complications were not quantitated but included a small asymptomatic lymphocele, transient lower extremity edema, and transient chylous ascites. Chylous ascites was noted in 21% of patients undergoing retroperitoneal lymph node dissection after chemotherapy. In all patients, the ascites improved with conservative measures, including low-fat diet or medium-chain triglyceride diet. No major complications were reported. Of the 64 patients managed for stage I tumors, 47 (73%) were negative for malignant disease. With a mean follow-up period of 25 months, one patient (1.5%) developed a retroperitoneal recurrence outside the surgical field. Retrospective review of this patient's specimen revealed that a positive lymph node had been missed on the original pathologic evaluation. In contrast, among the patients who received chemotherapy, LRPLND yielded necrotic tissue in 61% of cases and mature teratoma in 37%; active tumor was found in only one patient (2%). With a mean follow-up of 27 months, no recurrences were reported.

In a subsequent report, Janetschek and co-workers (197) expanded their series of retroperitoneal node dissection for stage I nonseminomatous testicular cancer to 73 patients. The operative time continued to decrease; the last 13 patients had a mean operative time of 3.6 hours. Mean estimated blood loss in this group was 156 mL, including one of the two conversions with an estimated blood loss of 2,600 mL. Postoperatively, antegrade ejaculation was normal in all patients. There were no major complications, and a single (1.5%) minor complication was reported. One patient experienced transient irritation of the genitofemoral nerve. Only patients with a minimum follow-up of 6 months were reported; as such, the mean follow-up for this group was 43.3 months. There was only one recurrence, as previously described.

In 1996, Janetschek and co-workers (195) reported comparison between open retroperitoneal lymph node dissection and an earlier portion of their series. This report included the initial 29 patients treated for stage I nonseminomatous testicular tumors. To demonstrate the effects of the learning curve, data for the laparoscopic group were stratified into two groups. Group 1 represented the first 14 cases, and group 2 represented the latest 15 cases. Mean operative times for the open population, group 1, and group 2 were 4.2, 8, and 5.1 hours, respectively. Mean decrease in hemoglobin for the open group, group 1, and group 2 was 2.5, 3.6, and 1.8 g/dL, respectively. Patients managed laparoscopically had a significantly shorter hospital stay. Mean hospital stay for open, group 1, and group 2 patients was 10.6, 5.5, and 4.0 days, respectively. Analgesic requirements and time to full recovery were not reported.

Cost analysis revealed significantly higher operative costs in the laparoscopic group ($3,200 versus $2,500). In contrast, the cost for hospital stay was less for the laparoscopic group. Overall, in Austria, laparoscopic retroperitoneal lymph node dissection was more cost-effective than open surgery ($4,000 versus $4,150). These calculations did not include cost of patient convalescence, which would have only added to the cost-saving benefits of the laparoscopic approach.

Laparoscopic retroperitoneal lymph node dissection is technically challenging but feasible, especially for staging of stage I nonseminomatous disease; for stage II postchemotherapy patients, a sanguine experience has been reported from only one center (197). The procedure offers these often very young patients the benefits of a minimally invasive approach, while accomplishing the goals of open retroperitoneal lymphadenectomy of effective lymphadenectomy and preservation of the sympathetic nerves responsible for ejaculation.

Malignant Disease: Ablative

Adrenalectomy

Laparoscopic adrenalectomy for malignant disease is highly controversial. Early reports have included removal of solitary adrenal metastases and smaller primary adrenocortical carcinomas. With small differences, the technique for laparoscopic adrenalectomy for malignant disease is essentially the same as previously described for benign adrenal pathology. However, in these cases, the dissection is more en bloc to include all of the periadrenal fatty tissue. On the right side, the borders of the dissection are the renal vein inferiorly, the line of Toldt and upper pole of kidney laterally, and the posterior coronary hepatic ligament superiorly. On the left side, the borders include the kidney laterally, the renal vein inferiorly, and the area of the lienorenal ligament superiorly. Gerota's fascia over the upper border of the adrenal is removed en bloc with the specimen.

Suzuki and co-workers (408) reported results of two patients who underwent laparoscopic adrenalectomy for malignant disease. The first patient underwent a transperitoneal laparoscopic adrenalectomy for what was thought to be a 5-cm cortisol-producing adenoma; however, the final pathology revealed an adrenocortical carcinoma. Despite removal of the tumor as an en bloc specimen, the patient presented with local recurrence and abdominal dissemination 19 months after surgery. The patient died 3 years after the initial procedure. In the second case, a patient with a 5.5-cm adrenal metastasis from poorly differentiated adenocarcinoma of the lung underwent a retroperitoneal laparoscopic adrenalectomy. The procedure required conversion to open surgery because of severe adhesions between the kidney and the adrenal tumor. The patient died of multiple metastases from lung cancer 8 months after surgery.

Elashry and colleagues (93) reported on two patients who underwent laparoscopic adrenalectomy for a solitary metachronous contralateral adrenal metastasis from renal cell carcinoma. The first patient presented 5 years after laparoscopic radical nephrectomy for T_2 disease; a 4-cm adrenal mass was detected during routine postoperative radiologic studies. The patient underwent an uncomplicated laparoscopic adrenalectomy. Operative time was 2.5 hours, with an estimated blood loss of 50 mL. Pathology of the specimen revealed metastatic clear cell renal cell carcinoma. The patient was without evidence of disease at 11-month follow-up. The second patient also presented 5 years after laparoscopic radical nephrectomy for T_2 disease; a 5-cm adrenal mass was detected during routine postoperative radiologic studies. CT-guided biopsy revealed malignant cells, and the patient underwent an uncomplicated adrenalectomy. Operative time was 4.3 hours and estimated blood loss was 75 mL. At 16-month follow-up, the patient remained free of disease. Both patients returned to full activity in 2 weeks.

Bendinelli and colleagues (22) reported results of six patients who underwent laparoscopic adrenalectomy for suspected solitary non–small cell carcinomas of the lung. The tumors ranged from 2.8 to 4.7 cm in diameter. In all cases, laparoscopic adrenalectomy was successfully performed without complication. There were no postoperative complications, and patients were discharged on postoperative day 2 or 3. Histology revealed metastatic disease in four cases and adrenal cortical adenoma in the remaining two patients. With a mean follow-up of 13.5 months, two patients were disease free. The remaining two patients with malignant disease died of other causes (myocardial infarct and trauma).

Because of the rarity of primary or resectable secondary adrenal cancer, to date, there are only a handful of reports of laparoscopic adrenalectomy for malignancy. The procedure is feasible and appears to be as effective as open surgery, but further evaluation is required before the long-term efficacy of laparoscopic adrenalectomy for malignant disease can be determined.

Radical Nephrectomy

Radical nephrectomy is the definitive surgical treatment for localized renal cell carcinoma as described by Robson and colleagues (354) in 1969. The procedure includes en bloc resection of the kidney and enveloping Gerota's fascia, along with the ipsilateral adrenal gland, proximal half of the ureter, and renal hilar lymph nodes. An important part of radical nephrectomy is early ligation of the renal artery followed by ligation of the renal vein. Recently, total nephrectomy rather than radical nephrectomy has been recommended for renal tumors occupying the middle or lower portions of the kidney, thereby sparing the ipsilateral adrenal gland (380,421).

Laparoscopic nephrectomy, as originally described by Clayman and co-workers (60) in 1991, was initially applied to a tumor-bearing kidney (i.e., oncocytoma) and was a total nephrectomy in that the adrenal gland was spared. Initial application of the laparoscopic technique for radical nephrectomy, by the same urologists, was controversial. However, its role in the management of renal malignancies has evolved over the past decade, and the laparoscopic approach is presently accepted as a management strategy for selected renal masses.

Recommended size limitations for laparoscopic management of renal masses has been quite variable. Most series report results for localized tumors that are 7 cm in greatest diameter. However, recently, Walther and co-workers (433) reported a series of laparoscopic cytoreductive radical nephrectomies for renal masses up to 15

cm in greatest diameter, and in an early series, the Washington University group (262) reported successful removal of a stage T_{3b} lesion involving the renal vein. With experience, all renal tumors, short of those involving the inferior vena cava or larger than 15 cm, are currently considered at major centers for laparoscopic removal.

The surgical technique for laparoscopic radical nephrectomy was originally described via a transperitoneal approach. The transperitoneal procedure is performed with the patient in the lateral decubitus position. Three 12-mm trocars are placed: at the umbilicus, in the midclavicular line under the costal margin, and in the midclavicular line 3 cm inferior to the umbilicus. Two additional 5-mm trocars are placed: in the anterior axillary line off the tip of the twelfth rib and in the anterior axillary line at the level of the umbilicus. At times, on the right side, an additional 5-mm trocar is placed in the midline, just beneath the xiphoid, to aid in retraction of the liver, during the hilar dissection.

Templates for laparoscopic right- and left-sided radical nephrectomy are presented in Fig. 18.19. Monopolar electrosurgical scissors are used to incise the line of Toldt from the hepatic or splenic flexure caudal to the iliac vessels and cephalad to the diaphragm. On the right side, this incision is continued cephalad to include division of the triangular ligament of the liver, whereas on the left side, the splenic attachments to the diaphragm are divided. Further dissection in the retroperitoneum on the right side takes the shape of a trapezoid: (a) the colon is dissected from the inferior surface of the kidney and the duodenum is dissected medially (i.e., Kocher maneuver) to reveal the surface of the inferior vena cava; (b) the posterior coronary hepatic ligament is incised from the line of Toldt, laterally, to the inferior vena cava, medially; and (c) the inferior vena cava is dissected from above the adrenal gland to the level of the insertion of the gonadal vein, and the gonadal vein is secured with two pairs of clips and divided. At this point, the hilar dissection can be accomplished by clipping and dividing the renal artery followed by stapling of the renal vein. The adrenal vein is then dissected, clipped, and divided. The ureter can then be dissected and divided, and the entire specimen can be moved onto the surface of the liver pending entrapment and morcellation or direct extraction by extension of one of the port sites or manually via a previously placed hand-assist device.

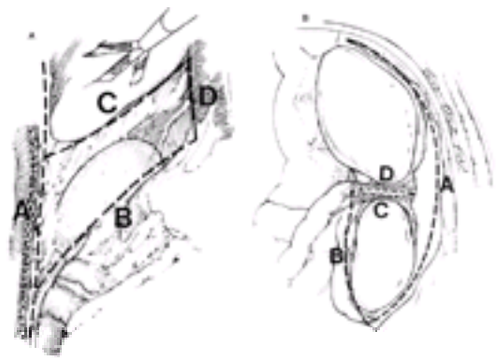

FIGURE 18.19. A: Trapezoid template for right-sided radical nephrectomy. *A,* The line of Toldt is incised from the hepatic flexure caudal to the iliac vessels and cephalad to the diaphragm. The incision is continued cephalad to include division of the triangular ligament of the liver. *B,* Reflection of colon and duodenum. *C,* Incision of posterior coronary hepatic ligament. *D,* Incision overlying the inferior vena cava from above the adrenal vein down to the insertion of the gonadal vein. **B:** Inverted cone template for left-sided radical nephrectomy. *A,* Incision of line of Toldt and medial through any splenophrenic attachments. *B,* Mobilization of the descending colonic mesentery off of Gerota's fascia. *C,* Incision of splenocolic ligament. *D,* Incision of splenorenal ligament.

On the left side, the dissection takes on the shape of an inverted cone: (a) the line of Toldt and splenophrenic attachments are divided; (b) the colon is dissected from the inferior surface of the kidney and Gerota's fascia and moved medially; and (c) the “opening” of the cone (defined as the splenocolic ligament) is divided anteriorly, and the splenorenal ligament, in the same plane, is divided posteriorly. The gonadal vein is then followed to its insertion into the renal vein where it is clipped and divided along with the ascending lumbar vein; the adrenal vein superiorly is likewise dissected, clipped, and divided. In this regard, the gonadal vein is the key to the entire subsequent dissection of the left renal hilum; tracing this vein cephalad reliably and safely leads the surgeon to the left renal vein. The renal artery is then dissected and divided followed by stapling and division of the renal vein. The ureter is then dissected, clipped, and divided. The entire specimen can be moved onto the surface of the spleen pending entrapment and morcellation or direct extraction by extension of one of the port sites or manually, through a previously placed hand-assist device.

Laparoscopic radical nephrectomy may also be performed via a retroperitoneal approach. Access to the retroperitoneum is gained with the Hasson technique through a 2-cm skin incision at the tip of the twelfth rib. After balloon or blunt dissection of the retroperitoneum outside Gerota's fascia, a second trocar (12 mm) is placed at the angle of the twelfth rib and the erector spinae muscle. Next, a third trocar (5 mm) is placed subcostally in the anterior axillary line and a fourth trocar (12 mm) is placed in the midaxillary line just cephalad to the iliac crest. Dissection is initiated around the renal hilum, with sequential control of the renal artery and vein with clip ligation and Endo-GIA stapling, respectively. Circumferential mobilization of the kidney within Gerota's fascia is performed. The adrenal gland may be spared depending on the size and location of the renal mass. The ureter is transected between clips. Next, off of one of the lower port sites, the incision may be extended horizontally to 8 to 10 cm, and the entire specimen retrieved intact; alternatively, an entrapment sack can be placed and the specimen can be secured in the sack. The latter approach often requires opening of the peritoneal cavity to provide sufficient space to maneuver the sack and the specimen. The specimen is then morcellated or removed intact depending on surgeon preference.

In an effort to simplify the technical aspects of laparoscopic surgery, hand-assisted techniques have been developed. This technique requires making a 7- to 8-cm transperitoneal incision over which one of a variety of wound-occlusive devices is affixed; the surgeon's hand and forearm are inserted through the secured “airtight” device into the peritoneal cavity while maintaining a pneumoperitoneum. Wolf and co-workers (449) detailed their technique for hand-assisted laparoscopic nephrectomy. Peritoneal access is gained via a 12-mm incision at the lateral border of the rectus muscle inferior to the umbilicus. A second 12-mm trocar is placed in the midclavicular line 2 cm beneath the costal margin. An upper midline incision is made above the umbilicus with its length in centimeters equaling the surgeon's glove size. One of the commercially available occlusion devices is then applied to the incision, allowing the surgeon's hand to be inserted into the peritoneal cavity. For a right-sided nephrectomy, the surgeon's left arm is placed through the hand-assist incision; for a left-sided nephrectomy, the surgeon's right arm is placed in the incision. The laparoscopic instruments are placed in the subcostal trocar site. Alternatively, the hand-assist device may be placed periumbilically; a 12-mm port is then placed in the midline, midway between the xiphoid and umbilicus, and a second 12-mm port is placed in the midclavicular line, subcostal. The laparoscopic instruments are again passed via the subcostal port.

With the hand-assist approach, radical nephrectomy proceeds as previously described. Tissues are picked up with the surgeon's hand and managed using routine laparoscopic techniques. The renal hilum may be identified by palpation, and retroperitoneal dissection of the kidney is greatly facilitated by blunt finger dissection. For suture ties, a “one-handed” knot can be created by using the intraperitoneal hand and grasping the free end of the suture with a laparoscopic instrument. At the termination of the case, the specimen is extracted via the hand-assist incision.

Results of trials comparing open and laparoscopic radical nephrectomy are presented in Table 18.6. To date, three large series have appeared in the literature, among which two directly compared laparoscopic and open radical or total nephrectomy techniques. In the largest published series, Barrett and co-workers (18) reported results from 72 attempted laparoscopic nephrectomies. Tumor size ranged from 1 to 9 cm (mean of 4.5 cm). The transabdominal approach and specimen morcellation were used in all patients. Eight patients underwent concomitant procedures, including six cholecystectomies, a tubal ligation, and a bowel resection.

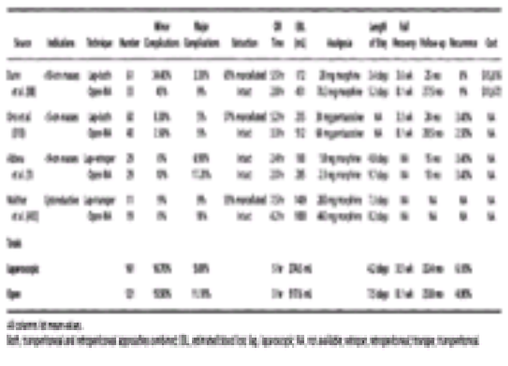

TABLE 18.6. LAPAROSCOPIC RADICAL NEPHRECTOMY—COMPARATIVE TRIALS

Of the 72 patients, 6 (8%) required conversion to open radical nephrectomy. The six conversions were the result of unrecognized tumor-associated venous thrombus, large parasitic veins servicing a large renal tumor, adhesions to the spleen, scarring of the renal hilum from prior infection, hilar bleeding, and a case of sudden hypoxia and suspected gas embolus. Sixty-six patients underwent successful laparoscopic nephrectomy with morcellation. Mean operative time was 2.9 hours, including the eight concomitant nonrenal laparoscopic procedures. There was a single (1.4%) intraoperative mortality. In this case, the patient suddenly became hypoxemic during the morcellation of the entrapped specimen; immediate open exploration failed to reveal a source of hemorrhage or other life-threatening surgical problem. Resuscitation attempts failed. At autopsy, extensive miliary lung disease was identified; the precise cause of death could not be determined. A gas embolus was suspected, but never proven.

Two patients (3%) required blood transfusion. Three patients (4%) experienced bowel complications, including one trocar site hernia. The hernia occurred at the extraction site in a patient who had undergone concomitant bowel resection. There was a single case each of a wound infection and transient unstable angina. Hospital stay for the 66 patients undergoing successful laparoscopic radical nephrectomy was 4.4 days. Fifty-seven patients had the diagnosis of a renal malignancy. With a mean follow-up of 21 months, there were no port site recurrences, no intraabdominal or retroperitoneal recurrences, and no evidence of metastatic disease. Analgesic requirements and time to full convalescence were not reported (18). Longer follow-up by this group has revealed one patient who developed a port site recurrence along with distant metastatic disease; of note, the port site recurrence was not at the site through which the tumor was morcellated. This occurred in a patient with a T_2 lesion with sarcomatous elements. This is the first and, to date, only report of seeding following radical nephrectomy (17a).

Dunn and colleagues (88) described the Washington University experience with radical nephrectomy. Clinical data on 60 consecutive patients undergoing laparoscopic radical nephrectomy for renal tumors 10 cm in diameter or smaller were compared with 33 open radical nephrectomies performed for tumors 10 cm in diameter or smaller. The majority of the specimens were morcellated. Two patients (3%) in the laparoscopic group required conversion to open surgery: one received 2 units of packed red blood cells because of intraoperative bleeding, which at the time of open conversion was found to be due to back-bleeding from the 1,100-g specimen, and the other patient had an injury to the superior mesenteric artery requiring repair. The overall transfusion rate was 12%. In the open group, the overall transfusion rate was 15%. Mean estimated blood loss was significantly less for laparoscopic nephrectomy: 172 versus 451 mL. Operative time was significantly longer for patients managed with the laparoscopic technique: 5.5 versus 2.8 hours. There were fewer major and minor complications in the laparoscopic group than in the open group: 3% versus 9% and 34% versus 45%, respectively.

Major differences in recovery were noted. Patients managed laparoscopically required significantly less analgesics for adequate pain control: 28 versus 78 mg of morphine sulfate equivalents. Resumption of oral intake was significantly faster in the laparoscopic group: 18 versus 59 hours. Hospital stay was also significantly reduced with the laparoscopic technique: 3.4 versus 5.2 days. Full recovery was expedited by the laparoscopic approach: 8 versus 29 weeks. The average follow-up in the laparoscopic group was 25 months (range of 3 to 73 months) among 44 patients with documented localized renal cell cancer; 91% were disease free. Among the three patients who failed therapy, two patients developed metastatic disease in the liver, lung, bone, or a paracaval node. Both patients subsequently died: one 52 months postoperatively, presumably due to metastatic disease, and the other 2 years later from aspiration pneumonia. A local recurrence occurred in the third patient; this patient developed recurrent disease in the ipsilateral ureteral stump, which was subsequently excised at open surgery. In the open group, the average follow-up was 28 months; 90% remained disease free, similar to the laparoscopic group.

A cost evaluation was also performed. Mean total operating room cost for laparoscopic radical nephrectomy was $6,300. Operating room cost for open radical nephrectomy was $4,400. The large discrepancy in operating room expenditures was not offset by the decreased hospital stay, such that overall cost for the laparoscopic procedure was $15,800; the open procedure required $13,700.

Ono and co-workers (314) reported results of 60 laparoscopic radical nephrectomies performed for renal masses less than 5 cm in diameter; the majority of specimens were morcellated. These results were compared with a contemporary series of 40 open radical nephrectomies. Forty-five patients (75%) underwent transperitoneal radical nephrectomy, and the remaining fifteen patients (25%) were managed via the retroperitoneal approach. Only one patient (2%) required conversion to an open procedure; this was prompted by uncontrollable bleeding from a left renal artery. Mean operative time for laparoscopic radical nephrectomies was significantly longer than open surgery: 5.2 versus 3.3 hours. Mean estimated blood loss, however, was significantly decreased in the laparoscopic population: 255 versus 513 mL. Patients undergoing laparoscopic radical nephrectomy required significantly less pain medication: 31 versus 68 mg of pentazocine. Hospital stay was not reported; however, mean time to full convalescence was significantly shorter in patients undergoing laparoscopic management: 3 versus 8 weeks (314). There was no significant difference in the complication rate between open and laparoscopic radical nephrectomy. Two patients (3%) in the laparoscopic group required intraoperative blood transfusions. There were five intraoperative complications, including the injury to the left renal artery. Other complications included a splenic injury, an adrenal injury, and bleeding from a periureteral artery. In addition, a duodenal injury was recognized on postoperative day 1; the patient was successfully managed by open duodenojejunostomy. In the postoperative period, there were two cases of paralytic ileus that resolved with conservative management and a pulmonary thrombosis that was managed by anticoagulation. There were only two intraoperative complications in the open population: an injury to the renal vein and a splenic injury. Postoperative complications in this population included a single case of paralytic ileus that resolved with conservative management. Three patients (8%) required blood transfusions.

All 60 patients in the laparoscopic group were alive with a median follow-up of 24 months. Of the 60 patients, 58 had no evidence of recurrence, metastatic disease, or trocar site seeding. The calculated 5-year survival was 95%. One patient had lung metastases discovered 3 months postoperatively by chest CT scan. The other patient had a right iliac bone metastasis, which was discovered 19 months postoperatively by CT scan and bone scintigraphy. Both patients were treated with a-interferon and were alive at the time of publication. Of the 40 patients managed by open radical nephrectomy, 39 (97.5%) were alive without evidence of metastasis or recurrence. There was no statistically significant difference in the calculated disease-free rates between the two techniques. One patient had both lung and bone metastases discovered 5 months postoperatively; a-interferon therapy was administered. The patient died of progressive disease after 11 months (314).

With regard to the retroperitoneal approach, Abbou and co-workers (1) reviewed 29 patients who underwent retroperitoneal laparoscopic radical nephrectomy and 29 patients who underwent open radical nephrectomy. A single laparoscopic procedure (3%) required conversion after a vascular staple was dislodged from the renal artery during specimen extraction. Mean operative time for the laparoscopic group was 2.5 hours, significantly longer than the 2 hours required for open radical nephrectomy. Mean hospital stay for patients managed laparoscopically was 4.8 days, significantly less than the 9.7-day hospital stay reported in patients undergoing open radical nephrectomy. There were two intraoperative complications in the laparoscopic group. The patient requiring conversion to open surgery was managed with transfusion of 2 units of packed red blood cells intraoperatively. Another patient experienced a colonic injury that was managed with a temporary colostomy. In the open population, eight complications (24%) in seven patients were reported: two cases of pneumonia, two cerebrovascular accidents, a case of phlebitis, a pulmonary embolus, a colonic injury, and an eventration. With a mean follow-up of 15 months, there was a single case of local recurrence and hepatic metastasis in the patient requiring conversion from laparoscopic to open technique. This patient had a 9-cm tumor with final pathology revealing a pT3b grade 2 renal cell carcinoma confined within the surgical specimen. The recurrence was noted 9 months postoperatively (1).

Ono and colleagues (314) compared transperitoneal and retroperitoneal laparoscopic techniques. Thirty-four transperitoneal laparoscopic nephrectomies with morcellation of the specimen were compared with 15 retroperitoneal laparoscopic radical nephrectomies. All but one transperitoneal (97%) and all (100%) retroperitoneal procedures were completed successfully using laparoscopic techniques. Mean operative times for the retroperitoneal and transperitoneal approaches were similar (4.9 and 5.1 hours, respectively). Estimated blood loss was also similar for the retroperitoneal and transperitoneal approaches (276 and 176 mL, respectively). Both procedures required the same amount of postoperative analgesia (29 mg of pentazocine), and the complication rate was similar.

With regard to the hand-assist approach, Wolf and colleagues (450) compared standard laparoscopic nephrectomy (8 cases) with laparoscopic nephrectomy performed with the hand-assist device (13 cases). The series consisted of 15 simple nephrectomies, 4 radical nephrectomies, and 2 nephroureterectomies. Mean operative times for hand-assist and standard laparoscopic nephrectomies were 4 and 5.4 hours, respectively ($p = .04$). Estimated blood loss for hand-assist and standard laparoscopic nephrectomies was 211 and 340 mL, respectively. There was no significant difference in hospital stay with hand-assist and standard laparoscopic nephrectomy patients: 3.1 and 3.0 days, respectively. Hand-assist patients required 57 mg of morphine sulfate in the postoperative period compared with 48 mg for the standard laparoscopic population ($p > .5$). The hand-assist patients returned to normal activity in 14 days, compared with 10 days for standard laparoscopic nephrectomy ($p > .1$). There was a single (8%) major complication in the hand-assist group, and there were three (38%) major complications in the

standard laparoscopy group.

The most important aspect of laparoscopic total or radical nephrectomy for renal cell cancer has to do with the long-term efficacy of the procedure. In this regard, Cadeddu and colleagues (42) reported results of a multicenter study encompassing 157 patients undergoing laparoscopic radical nephrectomy for pathologically proven renal cell carcinoma. Six patients (3.8%) required conversion to an open approach as a result of difficult dissection or hemorrhage. There were 16 (9.6%) perioperative complications in 15 patients and one intraoperative death. Mean follow-up was 19.2 months. There were no trocar site recurrences, and 151 patients (96%) had no evidence of disease recurrence at last follow-up. Four patients had progressive disease but were alive at the time of publication. All four patients had stage T_2 disease at the time of surgery. Three of four recurrences were at distant sites. One patient had a local recurrence in the ureteral stump 8 months postoperatively, as described in the Dunn series.

Another possible indication for laparoscopic nephrectomy has recently been examined by Walther and co-workers (433): cytoreductive surgery in patients with metastatic renal cell carcinoma before initiation of interleukin (IL)-2 immunotherapy. Patients with tumor thrombus, massive retroperitoneal lymphadenopathy, or liver invasion were excluded. Laparoscopically managed patients were stratified into two groups depending on whether the specimen was morcellated or removed intact. Results were compared with a contemporary group of open radical nephrectomies in similar patients. Open procedures were performed through a chevron incision extending from the midaxillary line of the ipsilateral side to the anterior axillary line of the contralateral side. After surgery, patients were randomized to treatment with either high- or low-dose IL-2.

Of the 11 patients, 3 (27%) in the laparoscopic groups were electively converted to open surgery because of tedious dissection. Transfusion requirements tended to be higher in the laparoscopic intact extraction group: 3.1 units (open group), 2.3 units (laparoscopic morcellated), and 5.2 units (laparoscopic intact extraction); of note, the estimated blood loss was greater in the laparoscopic intact extraction group (3,600 mL versus 1,300 to 1,600 mL in the other two groups). Patients in both laparoscopic groups had significantly longer operative times than patients undergoing open radical nephrectomy: 8.5 hours (laparoscopic morcellated) and 6.4 hours (laparoscopic intact) versus 4.2 hours for open removal. Postoperative complications occurred in four patients. In the laparoscopic group, a port site hernia and pressure necrosis of the skin occurred. In the open population, there was a pulmonary embolus and a small bowel obstruction. There was no significant difference in complications among the three groups.

Patients undergoing laparoscopic management of their tumors with morcellation were discharged from the hospital sooner (6.3 days) than patients undergoing open nephrectomy (8.2 days). Of note, patients with laparoscopic intact removal had a hospital stay similar to the open nephrectomy group: 9.2 days. Patients undergoing laparoscopic management with tumor morcellation had significantly less narcotic requirements (243 mg of morphine sulfate equivalents) than the laparoscopic intact removal group (332 mg of morphine sulfate equivalents) or the open surgery group (442 mg of morphine sulfate equivalents). Most important, the laparoscopic approach reduced time to treatment by almost 1 month; mean time to treatment with IL-2 for the open nephrectomy, laparoscopic intact, and laparoscopic morcellated groups was 11, 8, and 6 weeks, respectively. Time to full convalescence was not reported.

Overall, results comparing open and laparoscopic radical nephrectomy, by either a transperitoneal or retroperitoneal approach, are remarkably consistent. Patients treated laparoscopically undergo a procedure that respects the oncologic principles required for optimal management, while experiencing the benefits of a minimally invasive procedure. Specifically, patients managed by laparoscopic radical nephrectomy have significantly less pain, shorter hospital stays, and more rapid return to full activity when compared with patients undergoing an open procedure. These benefits are not associated with an increase in either intraoperative or postoperative morbidity. Tumor-free survival appears to be similar, in the short run (i.e., 2 years), between patients managed by open and laparoscopic approaches; 5- and 10-year data are needed. The expeditious convalescence associated with laparoscopic radical nephrectomy may be of value in patients with higher-stage malignancies. In this select group of patients, after a laparoscopic nephrectomy, adjuvant treatment can be initiated earlier.

Radical Nephroureterectomy

Laparoscopic radical nephroureterectomy for the treatment of upper tract transitional cell cancer was introduced by Clayman and colleagues in 1991 (62,261). Laparoscopic radical nephroureterectomy has been performed via both transabdominal and retroperitoneal techniques. Several techniques have been described for the management of the distal ureteral segment: transurethral resection (“pluck”), unroofing and stapled ureteral resection, intussusception, and needlescopic transvesical dissection. The usual recommendation for this procedure has been to proceed with any transurethral manipulation of the ureteral orifice and tunnel initially and then continue with the laparoscopic portion of the nephroureterectomy. However, because of concerns about possible local seeding of tumor cells, Clayman and colleagues (381) have recommended proceeding with the laparoscopic part of the procedure first, reserving any unroofing of the ureteral orifice and tunnel to the end of the procedure, thereby precluding any spillage of tumor cell–laden urine into the retroperitoneum.

Transurethral ureteral resection (“pluck” ureterectomy) is performed cystoscopically with the patient in a dorsal lithotomy position. The ureteral orifice, tunnel, and ureterovesical junction (UVJ) are transurethrally resected out to the perivesical fat. The ureter is thereby released from the bladder. Hemostasis is obtained and a urethral catheter is placed. If done early in the procedure, as soon as the laparoscopic portion of the procedure is initiated, the ureter should be isolated and clipped to prevent further leakage of urine into the retroperitoneum. After laparoscopic dissection of the kidney, the surgeon can “pluck” the ureter cephalad, thereby precluding any pelvic dissection of the ureter. The major drawback of this approach is concern about leakage of malignant cell–laden urine into the retroperitoneum until the ureter is laparoscopically occluded. Instances of seeding after an open “pluck” procedure have been reported by several urologists (12,167,201).

Ureteral unroofing and stapling is performed with the patient in the dorsal lithotomy position. A guidewire is placed in the ureter, and a 7-Fr ureteral dilating balloon (5-mm diameter, 10-cm length) is inserted over the guidewire. An Orandi electrosurgical knife is used to unroof the intramural ureter at the 12 o'clock position. The dilating balloon is then removed, and a 7-Fr 11.5-mm occlusion balloon catheter is inserted, inflated in the renal pelvis, and snugged down at the ureteropelvic junction. A roller electrode is used to fulgurate the cut edges and interior of the opened ureteral tunnel. Later in the procedure, after the kidney has been completely dissected laparoscopically, the ureter is dissected caudally until the detrusor muscle fibers at the UVJ are identified. The retrograde 7-Fr occlusion balloon is deflated and removed. An Endo-GIA stapler is applied to the cuff of bladder at the UVJ, thereby simultaneously incising and securing the bladder cuff and the UVJ specimen. For this portion of the procedure, an angulating Endo-GIA stapler is most helpful because it allows a more direct approach to the UVJ, thereby securing an ample cuff of bladder. If there is concern about the contralateral ureteral orifice or tunnel, this portion of the procedure can be monitored intravesically by having the assistant pass a flexible cystoscope while the bladder cuff is being secured.

Application of a needlescopic technique for management of the distal ureter was described by Gill and colleagues in 1999 (128). The patient first undergoes cystoscopy to rule out a concomitant bladder tumor and to ensure adequate bladder capacity. Diminished bladder capacity (less than 200 mL) increases the technical difficulty due to limited working space. Cystoscopy is performed with the patient in a 30-degree Trendelenburg position. Two needlescopic trocars (2 mm) are inserted suprapubically into the bladder under cystoscopic vision. A 2-mm Endoloop is inserted through the needlescopic trocar. A 6-Fr ureteral catheter is passed through the loop and into the affected ureter with the assistance of a guidewire. A 24-Fr continuous-flow resectoscope is then passed into the bladder alongside the ureteral catheter. A Collings' knife is used to electrosurgically score the urothelium circumferentially around the intramural ureter such that a 2- to 3-cm cuff is outlined. With use of a 2-mm grasper, the ureteral orifice and hemitrigone are retracted anteriorly and a full-thickness incision is made with the Collings' knife. In this manner, approximately 3 to 4 cm of ureter may be dissected free from surrounding tissues. The previously placed Endoloop is then positioned over the ureter and closed tightly, occluding the lumen as the ureteral catheter is withdrawn. The tail of the Endoloop is then cut with 2-mm laparoscopic scissors. The bladder edges about the excised ureter are then coagulated. All instruments are removed from the bladder and a Foley catheter is left indwelling. The laparoscopic nephrectomy is then performed, and the ureter is pulled up with the specimen via a 7- to 10-cm incision (128).

The intussusception technique is only used when the patient has transitional cell cancer of the renal pelvis; it cannot be used in patients with ureteral transitional cell cancer. In this approach, the ureterectomy is done after the laparoscopic nephrectomy portion of the procedure. A stone basket is passed retrograde up to the middle ureter. The ureter is occluded just proximal to the stone basket and incised, thereby allowing the stone basket to exit the ureterotomy site. The ureter is then incised vertically for a distance of 1 to 2 cm, to create two or three flaps; the stone basket is opened and the flaps of ureter are passed through the wires of the basket. The basket is then closed and pulled caudal while the surgeon holds the sidewalls of the middle ureter stationary; this results in the ureter intussuscepting. The surgeon then releases the sidewalls as they too become intussuscepted; the ureter is thus pulled through the ureterovesical junction and into or out the urethra, in males and females, respectively. The surgeon can then either continue to pull the ureter out, thereby avulsing it at the level of the trigone, or introduce a resectoscope to release the ureter at the ureteral tunnel (76).

Laparoscopic nephroureterectomy has been performed using either a transperitoneal or retroperitoneal technique; the former is more commonly described. The trocar placement is identical to that for a radical nephrectomy, except that for the transperitoneal approach an additional 12-mm trocar is placed in the midline 2 to 3 cm above the symphysis pubis for passage of the Endo-GIA stapler to secure the bladder cuff. For a hand-assist approach, placement of the hand-assist device is in the

lower midline so the surgeon's hand can be used to facilitate both the nephrectomy and ureterectomy portions of the procedure.

The nephrectomy portion, whether performed by a transperitoneal or a retroperitoneal route, is identical to that for a total nephrectomy. For the ureterectomy portion, if a pluck or needlescopic dissection was used, the ureter is simply pulled cephalad out of the pelvis; alternatively, if a ureteral unroofing approach is selected, the ureter is mobilized caudally into the pelvis, as described, and secured with the Endo-GIA stapler. The specimen is entrapped in an entrapment sack and removed intact.

Recently, Shalhav and colleagues (381) reported on 25 patients at Washington University who underwent transperitoneal laparoscopic nephroureterectomy; these patients were retrospectively evaluated, and the results were compared with those of 17 patients who underwent open nephroureterectomy during a similar time period. Operative time was significantly longer for patients treated laparoscopically: 7.7 versus 3.9 hours. However, estimated blood loss was significantly less in the laparoscopic group: 199 versus 441 mL. All measures of patient comfort and convalescence favored the laparoscopic group. These patients resumed oral intake in a mean time of 1 day, compared with 4.8 days for the open group. The laparoscopic group averaged 37 mg of morphine sulfate equivalents versus 144 mg of morphine sulfate equivalents for pain relief in the open group. Hospital stay was also significantly shorter for patients undergoing laparoscopic nephroureterectomy: 3.6 versus 9.6 days. Resumption of full activity was facilitated by the laparoscopic approach: 2.8 versus 10 weeks. Major and minor complications occurred in 8% (postoperative bleeding, adult respiratory distress syndrome) and 40% of the laparoscopic group, respectively, and in 29% (e.g., pneumonia, myocardial infarction, acute renal failure) and 29% of the open group, respectively. There was one death in the laparoscopic group and none in the open group. At a mean follow-up of 2 years and 3.6 years for the laparoscopic and open groups, respectively, the bladder recurrence rate of transitional cell cancer was 23% and 54%, respectively. Of note, at 2 years in the open group, the bladder recurrence rate was similar to that in the laparoscopic group. Cancer-specific survival in the two groups was 77%, albeit with longer follow-up in the open cohort.

Of concern in the laparoscopic group was the identification of two retroperitoneal recurrences in the pelvis; this occurred despite neither patient having had any identifiable gross extravasation of urine at the time of the procedure. Because of these two cases, the authors have changed their protocol such that the integrity of the bladder and the ipsilateral ureter and kidney are absolutely maintained throughout the procedure. Accordingly, transurethral unroofing of the ureter is now done at the end of the procedure, following dissection, entrapment, and removal of the entire specimen (i.e., kidney, ureter down to the ureterovesical junction, and periureteral cuff of bladder). At that time, using the resectoscope equipped with an Orandi knife, the ipsilateral ureteral orifice and tunnel are unroofed until the staple line is visualized; then the roller electrode is used to electrocoagulate the interior of the opened ureteral tunnel from the level of the incised orifice out to the staple line.

Recently, there has been increasing experience with the hand-assist approach to laparoscopic nephroureterectomy. The largest series to date is from Stifelman and associates (399), who presented 22 cases of hand-assisted laparoscopic nephroureterectomy for upper tract transitional cell cancer. The average operative time was 4.5 hours, with an estimated blood loss of 180 mL. Of note, there were no intraoperative complications. Mean narcotic requirements were 55 mg of morphine sulfate equivalents; the average hospital stay was 4.1 days with a convalescence of 2.7 weeks. At 13-month follow-up, bladder recurrences were noted in 18% and metastatic disease had developed in 9%. Compared with a pure laparoscopic nephroureterectomy, this approach markedly decreases the operative time with only a slight increase in the amount of pain medications required and a minimal increase in hospital stay. Data on the cost-effectiveness of the hand-assisted nephroureterectomy have yet to be compiled.

Laparoscopic radical nephroureterectomy is a viable option for the management of upper tract transitional cell carcinoma. The procedure respects the oncologic principles of the open procedure and does not appear to increase morbidity. Of note, the characteristic advantages of laparoscopy, including decreased pain and expedited convalescence, are particularly evident. The hand-assist approach appears to greatly facilitate laparoscopic nephroureterectomy while providing nearly similar benefits. However, concerns over retroperitoneal recurrence have discouraged the more widespread use of this approach. More long-term data are needed to realistically address these misgivings. Likewise, data are needed with regard to the best way of managing the distal ureter to minimize the risk of an extravesical recurrence. To this end, meticulous follow-up with pelvic CT scans is essential among these patients.

Malignant Disease: Ablative On the Horizon

Partial Nephrectomy and Renal Wedge Excision for Renal Tumors

Recently, several papers have revealed the excellent survival achievable with partial nephrectomy or, to a lesser extent, wedge excision among patients with small renal tumors (4 cm or smaller). The technical success rates and long-term patient survival with nephron-sparing surgery have been shown to equal results with radical or total nephrectomy for the management of stage I renal malignancies (103,148,259,309,442). Laparoscopically, renal wedge excision is technically much easier to accomplish than a formal partial nephrectomy. As such, it is not surprising that the initial experience with laparoscopic wedge excision was reported in 1993, but the initial successful laparoscopic partial nephrectomy for renal cancer was not reported until 1997 (97,263).

In general, only lesions of 2 cm or smaller that are predominantly exophytic are candidates for laparoscopic wedge excision. The basic method is to use a transperitoneal approach for anterior lesions and a retroperitoneal approach for posterior lesions. After renal mobilization, the lesion is identified either endoscopically or with an intracorporeal ultrasonographic probe. For the latter purpose, a flexible ultrasonic probe is most useful. Dissection around the lesion proceeds down to the renal capsule, being careful to keep the perinephric fat over the lesion undisturbed. If the fat overlying the tumor is displaced, it should be sent as a separate specimen for staging purposes.

After the lesion is well delineated, excision of the lesion with a margin of normal tissue is performed. Ultrasonic hook, ultrasonic shears, monopolar scissors, bipolar instruments, and other modalities have all been used for the wedge excision. To date, no transection modality has provided consistently reliable hemostasis. In this regard, a 5-mm argon beam coagulator is extremely useful to control small and medium-sized vessels and to stop parenchymal bleeding. Other hemostatic techniques include application of fibrin glue, gelatin formaldehyde resorcinol glue, bovine collagen, Surgicel (oxidized regenerated cellulose, Johnson and Johnson, Somerville, New Jersey), and Gelfoam (absorbable gelatin sponge, Pharmacia and Upjohn Co., Kalamazoo, Michigan). If the collecting system has not been violated, no drain is left.

Several techniques for laparoscopic partial nephrectomy have been described; however, these have largely been limited to single or several case reports. In general, these lesions are in the 2- to 4-cm size range. The approach is similar to the wedge excision with regard to locating the affected area of the kidney. No indwelling stent is placed. To try to prevent hemorrhage, a variety of devices have been employed: cable tie, double loop sling, and Endoloop suture occlusion (380a). More recently, hand-assist techniques have enabled the surgeon to use hand compression, thereby facilitating the transection of the affected area. The incision through the parenchyma is accomplished with any of the aforementioned modalities used for the wedge excision. Clayman and colleagues (97) have attempted to do this with an electrosurgical snare; however, their sanguine animal experience did not transfer into the clinical realm. Once the affected area is excised, the underlying incised parenchyma and collecting system can be most easily closed using a combination of fibrin glue and a hemostatic fabric. Alternatively, the collecting system can be sutured closed and parenchymal hemostasis can be obtained using a combination of the argon beam coagulator and the application of bovine collagen. By giving the patient an intravenous dose of furosemide (Lasix) and indigo carmine, the surgeon can make a final check to rule out any urine leak. A drain is left in the retroperitoneum.

McDougall and colleagues (266) reported results of nine partial nephrectomies and three wedge resections. The partial nephrectomies were for benign disease and have been previously reviewed. All three wedge resections were for small renal masses and were successfully completed laparoscopically. Mean operative time for these three cases was 3.5 hours. Mean estimated blood loss was 92 mL. Patients had a mean hospital stay of 2.7 days and required an average of 21 mg of morphine sulfate for pain control. Mean time for complete convalescence was 4 weeks, and there were no intraoperative or postoperative complications. Pathology revealed a renal cell carcinoma, an oncocytoma, and an old infarction. At 46 months, there was no recurrence of tumor in the one kidney with renal cell cancer (266).

Janetschek and co-workers (194) reported results of seven patients undergoing laparoscopic wedge resection for renal tumors up to 2 cm in diameter. Final pathology revealed five lesions to be renal cell carcinoma; the remaining two were multilocular cysts. All procedures were successfully completed laparoscopically. Mean operative time was 3.7 hours, and mean estimated blood loss was 311 mL. There was a single intraoperative complication: high abdominal pressures from the argon beam coagulator resulted in pneumothorax that resolved without the need to place a chest tube. No patient required analgesia after the second postoperative day. Mean hospital stay was 4.6 days, and patients returned to full activity between 7 and 21 days postoperatively. Long-term follow-up data were not available.

The initial laparoscopic partial nephrectomy for a renal cell cancer was reported in 1997 by Elashry and colleagues (97). This initial case required 5 hours; an electrosurgical snare was used to incise the renal parenchyma. The snare failed to provide satisfactory hemostasis; the argon beam coagulator proved effective in this

regard. The collecting system was closed using intracorporeal suturing. The procedure was complicated by a urinoma requiring percutaneous nephrostomy tube drainage; the patient was in the hospital for 5 days. Total analgesic requirement consisted of 60 mg of ketorolac. Long-term follow-up was not available in this case report.

Wolf and colleagues (451) reported results of ten laparoscopic nephron-sparing procedures performed in nine patients; eight of these procedures were completed using hand assistance. They compared their results with 11 open procedures. Of 11 tumors, 8 (73%) were malignant. There was no significant difference in operative time between the laparoscopic and open approaches (3.3 versus 2.7 hours). Estimated blood loss for the laparoscopic and open groups was 460 and 210 mL, respectively. This included a laparoscopic wedge resection complicated by a 1,860-mL blood loss. There were three complications in each group. Laparoscopic complications included a patient requiring a transfusion of 4 units of packed red blood cells and transient urinary retention in two patients. Complications in the open group included two transfusions of 4 units of packed red blood cells and an arteriovenous fistula requiring embolization. Patients managed laparoscopically required less analgesic medications (40 versus 105 mg of morphine sulfate equivalents). Hospital stay was 2.0 days for the laparoscopic group and 3.5 days for the open group. Return to normal activity was also more expeditious in the laparoscopic group (8 versus 23 weeks). Long-term follow-up data were not available.

Division of the laparoscopic procedures into polar nephrectomy, wedge resection, and enucleation revealed that the operative time and estimated blood loss are higher with a partial nephrectomy (445a). The operative times for laparoscopic partial nephrectomies, wedge resections, and enucleations were 4.2, 3.3, and 2.4 hours, respectively. Estimated blood loss for uncomplicated laparoscopic partial nephrectomy, wedge resection, and enucleation was 550, 300, and 300 mL, respectively. Mean length of stay for all three procedures was similar at 2 days.

Results for laparoscopic partial nephrectomy and laparoscopic wedge resection are frequently difficult to distinguish in the literature. Both procedures, although technically challenging with present technology, are feasible. Laparoscopic wedge resection has been described with results demonstrating the procedure to be effective, in the short run, and safe. Laparoscopic partial nephrectomy remains challenging, with the optimal technique yet to be developed. Both procedures suffer from a lack of cases and an absence of any long-term follow-up data.

Renal Cryoablation for Renal Tumors

The management of small renal masses continues to evolve with the progression from open radical nephrectomy, to open partial nephrectomy, to laparoscopic nephrectomy, and most recently to laparoscopic nephron-sparing surgery. Presently, the next step in minimally invasive therapy is just beginning to be explored: needle ablative therapy. Recently, cryotherapy has been used in the clinical management of small renal masses (Fig. 18.20). The ability of intraoperative laparoscopic ultrasound probes to accurately monitor the progression of the resulting ice ball has further stimulated interest in this modality. Other renal ablative modalities just beginning to be explored in the laboratory include wet and dry radiofrequency, photon irradiation, thermal rods, ethanol gel, and microwave therapy (Fig. 18.21).

Zegal and co-workers (458) performed cryotherapy in six patients with renal masses less than 4 cm in greatest diameter. The kidneys were accessed via open laparotomy incisions, and one to three cryoprobes were inserted into the renal masses under ultrasonographic guidance. Two cycles of cryoablation were applied to each tumor with a 1.5- to 2.0-cm ice ball margin created around each mass. All patients were successfully treated. During a follow-up period of 3 to 22 months, all patients were followed with CT scan, MRI, or both. There was no evidence of tumor recurrence during this relatively brief follow-up period.

Bishoff and co-workers (28) reported results of eight patients with T_1 renal tumors managed with laparoscopic-guided cryosurgical ablation. Mean tumor size was 2 cm. A transperitoneal laparoscopic approach was used to access anterior or medial tumors, and a retroperitoneal approach was used to access posterior and lateral tumors. A cryoprobe, 4.8 mm in diameter, was used for tumor ablation, and a double freeze cycle of 5 minutes with a single thaw cycle of 15 minutes was applied. Renal biopsies at the time of surgery revealed renal cell carcinoma in six patients and were indeterminate in two patients. There were no intraoperative or postoperative complications reported. Mean operative time was 3.7 hours, and the mean estimated blood loss was 87 mL. Hospital stay was 3 days. With a mean follow-up of 7.7 months, no patient had radiographic evidence of tumor recurrence.

Gill and colleagues (126) reported laparoscopic cryoablation of 11 exophytic renal tumors ranging in size from 1.5 to 3.0 cm. A 4.8-mm conical-tipped cryoprobe was used (Fig. 18.20A). All procedures were successfully completed via a retroperitoneal approach. Laparoscopic ultrasound guidance was used for probe placement and to monitor the ice ball (Fig. 18.20B). Mean surgical time was 2.4 hours, and estimated blood loss was 75 mL. Hemostasis was achieved using the argon beam coagulator and Surgicel (oxidized regenerated cellulose, Johnson and Johnson, Somerville, New Jersey). Mean postoperative analgesic requirements consisted of 21 mg of morphine sulfate equivalents. Nine of ten patients were discharged within 23 hours. One patient tolerated the procedure well but required an 8-day hospital stay for stabilization of his cardiac status and systemic anticoagulation therapy. Intraoperatively, there was a single complication (a small liver laceration that was coagulated). Postoperatively, the only complication was a perirenal hematoma. Mean follow-up was 5.5 months and consisted of CT scan and MRI radiologic evaluation. All lesions continued to decrease in size during the follow-up period. Three patients underwent follow-up CT-guided biopsy of the cryoablation site. There was no evidence of tumor on any of the three biopsies.

Follow-up data from The Cleveland Clinic series was subsequently presented by Levin and co-workers (236) in a patient group now expanded to 22 patients. Needle biopsies were performed in all patients 3 and 6 months after cryotherapy. No patient had recurrent disease on these biopsies. However, one patient with a negative biopsy at 6 months had a local recurrence at 12 months; laparoscopic radical nephrectomy was performed and revealed a 1.3-cm focus of renal cell carcinoma.

Laparoscopic cryoablation of small renal masses (less than 3 cm) under ultrasonic guidance is feasible. In small series of highly selected patients, the procedure has so far been safe and resulted in a rapid convalescence. However, follow-up has been relatively brief, and one case of oncologic failure has already been reported at less than 2 years postprocedure. Accordingly, at this point in time, renal cryosurgery for smallrenal masses remains a largely investigational technique pending further long-term (i.e., 3- to 5-year) follow-up.

The next decade will be of great interest as each of the forms of needle ablative therapy comes under clinical investigation. By the year 2010, effective needle ablative therapy may well become the norm for renal lesions in the 1- to 4-cm size range. With advances in this arena, nephron-sparing surgery, as we currently know it, may well begin to fade from the scene.

Radical Prostatectomy

Radical prostatectomy was performed for the first time by Proust (342) in 1901 via a transperineal incision. Developments in this form of surgery occurred slowly; indeed, it took more than 40 years before Millin (281) proposed a retropubic approach. Likewise, it took almost another 40 years for another major change to occur in this operation; in 1983, Walsh and co-workers (431) modified the retropubic approach to make it “nerve-sparing,” thereby preserving potency.

Laparoscopic transperitoneal radical prostatectomy was introduced by Schuessler and colleagues (374) in 1997. The technique has been subsequently modified and its application greatly expanded by Guillonneau and Vallancien (145). Recently, an extraperitoneal approach to laparoscopic radical prostatectomy has also been described by Savad and Ferzli (368).

Guillonneau and Vallancien (146) reported results of 120 consecutive patients undergoing laparoscopic transperitoneal radical prostatectomy. Mean operative time was 4.0 hours. The authors used a five-port array. The prostatectomy was done in the following order: infravesical mobilization of the seminal vesicles and division of the vasa, anterior dissection of the bladder, entry into the endopelvic fascia, suture ligation of the dorsal venous complex, incision of the bladder neck, take-down of the pedicles with bipolar electrosurgical coagulation, urethral dissection and incision, take-down of the rectourethralis, and entrapment of the specimen. The urethrovesical anastomosis was completed using completely intracorporeal sutures; six to eight individual sutures were placed and tied. When patients were stratified by thirds, operative times for the first, second, and third groups were 4.8, 4.1, and 3.9 hours, respectively. Mean estimated blood loss for all patients was 402 mL. When stratified by sequential experience, estimated blood loss was 534, 517, and 277 mL for the three groups, respectively. Conversion to an open procedure occurred in 7 (5.8%) patients, all of whom were among the initial 80 patients. Conversion resulted from bleeding in three cases and from difficult dissection in four cases. Twelve patients (10%) required transfusion; however, the transfusion rates decreased with experience: 15%, 12.5%, and 2.5% for the first, second, and third group of 40 cases, respectively.

There were three (2.5%) intraoperative complications: an epigastric vessel injury that was repaired laparoscopically, an obturator nerve palsy that resolved with conservative management, and a rectal injury that was repaired laparoscopically. Postoperative complications included two patients (1.7%) with a 5-day ileus and nine patients (7.5%) with leakage from the urethrovesical anastomosis. In seven of these nine patients, the leakage resolved spontaneously by postoperative day 5 with suction drainage alone. In one case, percutaneous aspiration of a urinoma was required, and one patient required anastomotic repair that was performed laparoscopically. One patient required open exploration for bleeding from an injured epigastric artery that was not appreciated intraoperatively. In addition, 14 patients (10%) experienced urinary tract infections, and three patients (1.5%) had transient urinary retention. Morphine sulfate was requested by only 9% of patients by postoperative day 1 and by only 2% of patients by postoperative day 2.

Definitive histologic examination revealed prostatic intraepithelial neoplasia in 2 patients (1.7%), stage pT2a disease in 37 patients (30.8%), pT2b in 68 patients (56.7%), stage pT3a in 7 patients (5.8%), and stage pT3b in 6 patients (5%). The overall positive surgical margin rate was 15%. With a mean follow-up of only 2.2 months, PSA levels were 0.1 ng/mL or less in 95% of the 94 patients studied. No instances of port site seeding were noted.

Mean postoperative catheterization time was 6.6 days. Catheterization times for the first, second, and third groups of patients were 7.9, 7.3, and 5.7 days, respectively. The 120 patients had a mean functional follow-up of 1.7 months. Eighty-five patients (71%) were completely continent (no pads), with 58% of patients regaining continence within 30 days. No patient had experienced a postoperative bladder neck contraction. Of the 60 patients with at least 6 months of follow-up, the continence rate was 73%.

Preservation of the neurovascular bundles was routinely performed only in the final 40 patients. Twenty of these patients (50%) were potent and sexually active before surgery. In 9 of these 20 (45%), spontaneous erections were reported postoperatively; however, only one patient (5%) reported rigidity sufficient for sexual intercourse. Of interest, the authors noted that the overall cost of laparoscopic radical prostatectomy in France was $1,237 less than that for an open retropubic radical prostatectomy (146).

The work of Abbou and co-workers (2) has been contemporaneous with that of Guillonneau and Vallancien (145,146). Laparoscopic transperitoneal radical prostatectomy was performed in 43 men. The approach was similar to that described by Guillonneau and Vallancien except that running sutures were used to effect the urethrovesical anastomosis. The median operative time for the first ten patients was 7 hours (n = 5) without lymphadenectomy and 8.6 hours (n = 50) with lymphadenectomy. After the first ten patients, the operative time for laparoscopic radical prostatectomy dropped to 4.3 hours in 21 patients without lymphadenectomy and 5.1 hours in patients with lymphadenectomy. Estimated blood loss was not reported.

Complications included two (4.7%) cases of prolonged lymphatic drainage, one (2.3%) rectal injury managed with open suture repair and colonic diversion, and four (9.3%) vesicoureteral anastomotic leakages that were managed by open surgery in three cases and laparoscopically in one case. One month after surgery, 36 patients (84%) were continent. Of the remaining seven patients (16%), five had only minor and occasional leakage during extreme stress; this population did not require use of pads. The remaining two patients wore only one pad daily for minor stress incontinence. With a mean follow-up of 6.3 months, all 43 patients had a serum PSA of less than 0.1 mg/dL. Positive surgical margins were identified in 12 (28%) specimens.

Laparoscopic radical prostatectomy is feasible. Subsequent modifications have made the procedure more expeditious, and initial results for both cancer control and patient morbidity are promising. At present, the procedure remains technically challenging as demonstrated by lengthy learning curves even in the hands of experienced laparoscopic surgeons. Long-term comparative data with open radical retropubic prostatectomy and with open perineal prostatectomy are needed to determine the role of the laparoscopic approach.

Radical Cystectomy

The first laparoscopic radical cystectomy and urinary diversion was reported by Sanchez de Badajoz and colleagues (365) in 1993. Denewer and co-workers (78) subsequently reported a series of ten patients who underwent laparoscopic radical cystectomy and continent pouch construction performed through a limited incision. Seven of the ten patients (70%) had received radiation therapy 1 to 4 months before laparoscopic cystectomy. Bilateral pelvic lymphadenectomy was performed. The rectovesicle pouch was sharply entered, and dissection of Denonvilliers' fascia was performed to mobilize the posterior portion of the bladder. Both bladder pedicles were secured with the laparoscopic stapler. A stapler or electrosurgical scissors dissection was used to separate the urethra at the pelvic floor. An 8-cm subumbilical midline incision was then used to create a sigmoid pouch with an intussusception antireflux valve. Individual ureteral anastomoses were also performed in an open fashion via the same 8-cm incision. In this series, the mean operative time was 160 minutes for cystectomy, and an additional 55 minutes was required for pouch construction. Mean intraoperative blood transfusion rate was 2.2 units of packed red blood cells per patient. Hospital stay was 10 to 13 days. A single intraoperative complication was reported: the external iliac artery was divided in one patient. The vessel was successfully repaired during the open portion of the procedure. Postoperative complications occurred in four patients (40%). These included a case of urinary leakage that resolved without any need for stenting or reoperation, a deep venous thrombosis, and a pelvic collection that required percutaneous drainage. One patient died postoperatively; this individual developed postoperative hemorrhage. Reexploration was followed by disseminated intravascular coagulation, multisystem organ failure, and death (78).

Puppo and associates (344) reported results of five laparoscopically assisted transvaginal radical cystectomies in women with invasive bladder cancer. A bilateral cutaneous ureterostomy was performed in the first case. In the remaining four cases, an ileal conduit was accomplished through a mini-laparotomy at the stoma site. The specimen was removed transvaginally in four cases. In one case, vaginal atrophy necessitated removal through a midline laparotomy.

All procedures were successfully accomplished laparoscopically. Mean operative time was 7.1 hours, and although estimated blood loss was not reported, three patients (60%) required transfusion (mean of 3 units of packed red blood cells). Analgesic requirements were not reported. Hospital stay was 10.6 days. No major

complications occurred intraoperatively. Two patients had significant lymphatic drainage for 1 week that resolved without intervention. All patients were reported to be alive with a mean follow-up of 10.8 months, but their disease status was not reported.

Gill and co-workers (123) reported results of two laparoscopic radical cystoprostatectomies with ileal conduits performed for invasive transitional cell carcinoma. In both cases, for the first time, the cystoprostatectomies and ileal conduits were constructed completely intracorporeally. Mean operative time was 11 hours, and mean estimated blood loss was 1,100 mL. Both patients resumed ambulation on postoperative day 2. Oral intake was resumed on postoperative day 4, and the patients were discharged on postoperative day 6. The two patients required 108 and 17 mg of morphine sulfate equivalents for analgesia, respectively. No intraoperative or postoperative complications were reported. Time to full convalescence was not reported. Long-term follow-up data were not available.

Laparoscopic cystectomy and diversion appears to be feasible. However, its application has been limited to very few institutions, and to date, there have been no large series and no direct comparisons with open cystectomy and diversion. Follow-up is too brief to comment on the long-term efficacy of this approach or to address concerns regarding possible seeding.

NEWER TECHNOLOGY

As the era of industrialization wanes, the age of computer-based information technology has become ascendant. Medical application of these advanced technologies will lead to major diagnostic and therapeutic advances. In this section, the impact of these newer technologies on laparoscopic surgery is presented. In this regard, the following areas are addressed: needle ablative therapy for renal tumor ablation, robotics, virtual reality as applied to laparoscopy, improvements in optics, newer laparoscopic tissue approximation techniques, and newer tissue dissection techniques.

Needle-invasive Ablation of Renal Tissue

Nephron-sparing surgery for renal tumors has become an established practice in select patients with a compromised global nephron mass and in patients with small tumors (less than 4 cm) (308). Within the past decade, minimally invasive techniques have been increasingly implemented for renal surgery. In keeping with these trends, various alternative energy sources for tumor ablation have also been developed. In urology, the majority of alternative treatments for solid organ tumors were originally investigated for treatment of benign and cancerous pathologies of the prostate. These treatments have now been adapted for renal surgery as well. The anatomic location and laparoscopic accessibility of the kidneys, as well as advances in imaging, have permitted accurate localization and ablation of renal tumors using these newer techniques. The various alternative energy sources described herein include cryoablation, radiofrequency ablation, microwave thermotherapy, high-intensity focused ultrasound (HIFU), and interstitial photon radiation energy.

Cryoablation

Uchida and colleagues (423) pioneered clinical renal cryoablation in 1995, using the percutaneous technique. Delworth and colleagues (76a) first reported open renal cryoablation, and Gill and colleagues (125) published the initial experience with laparoscopic renal cryoablation in 1996. At present, cryoablation is the most widely investigated and clinically used energy source for renal tumor ablation.

During renal cryoablation, tissue destruction is achieved by alternate cycles of freezing and thawing (108). Alternate freeze–thaw cycles are responsible for cell injury as a result of progressive metabolic failure secondary to extracellular and intracellular ice formation. As tissue temperatures approach the freezing zone, extracellular fluid is transformed into ice. Increased extracellular osmotic pressure relative to the intracellular compartment results, which draws water out of the cells. The ensuing increased intracellular solute concentration is detrimental to cell survival (254). Subsequently, intracellular ice formation occurs as a result of extension of extracellular ice directly, or as a result of continued rapid tissue cooling. The incorporation of minute blood vessels within the growing ice ball results in regional vascular occlusion that further accentuates tissue destruction. Profound tissue hypothermia inhibits tissue metabolism, adversely affecting cellular repair and survival following the cryotherapy insult.

During the thaw cycle, the osmotic effect is reversed. Extracellular ice melts, causing hypotonicity and thereby shifting water into the intact cells, causing cell swelling and disruption of cellular membranes. Thawing causes vasodilation and increased vascular permeability, tissue congestion, and edema. Platelet aggregation and microthrombi formation occur as a result of endothelial damage. Several small blood vessels are occluded following the thaw cycle. The microcirculatory failure and vascular stasis that result from cryoablation further augment the cytocidal effect of intracellular freezing. The resultant tissue anoxia is the basis of delayed cryoinjury. Repetition of the freeze–thaw cycle further potentiates tissue destruction (292). Sindelar and colleagues (392) proposed that an enhanced host cryoimmunologic response to the cryoablated tissue may be an additional mechanism of tissue destruction.

At the advancing edge of the ice ball, a 1- to 2-mm transition zone separates the zone of lethal destruction from the nontargeted normal renal parenchyma (296). This zone typically demonstrates a less pronounced and variable degree of cellular destruction.

Early to intermediate changes occurring a few weeks after cryosurgery include coagulative necrosis, which reduces the tubular cell remnants into proteinaceous aggregates, and variable amounts of chronic inflammation (273). The tubular basement membrane and collagenous network remain intact and form the framework for the subsequent deposition of fibrin. Late changes, occurring 3 months after surgery, include tissue destruction and autoabsorption within the lethal zone. Fibrin is laid down as part of the reparative process.

Chosy and colleagues (57) studied the lethal temperature required for renal cell destruction in the porcine model. Using thermosensors, a temperature of -19.4°C was found to be necessary for uniform cell death. This lethal temperature was achieved up to 3.1 mm inside the edge of the ice ball. Temperatures achieved at the tip of the cryoprobe are typically in the range of -140° to -180°C. Clinically, to ensure complete tumor destruction the freeze zone is extended approximately 1 cm beyond the edge of the tumor. To maximize the cold effect on tissues, concurrent renal artery clamping during the procedure has been suggested as a possible method for prevention of temperature conduction (the heat sink effect). However, Campbell and colleagues (45) demonstrated no significant advantage associated with this maneuver in the porcine model.

It is critical at all times to ensure that the ice ball is not in contact with any surrounding organ structure. Porcine studies have demonstrated deleterious effects such as small bowel obstruction and pelviureteral obstruction due to inadvertent injury caused by direct contact of these structures with the ice ball (45,125). However, Sung and colleagues (406) have recently demonstrated spontaneous watertight urothelial regeneration following intentional cryoinjury to the renal collecting system, thereby potentially paving the way for the cryotreatment of more centrally located tumors.

Percutaneous interventional MRI-guided cryoablation in 17 patients was recently reported by Shingleton and colleagues (386). The technique represents a less invasive form of renal cryoablation than the laparoscopic technique. Cryoprobes as small as 1.8 mm can be used. Short-term follow-up appeared promising.

Radiofrequency Interstitial Tumor Ablation

The role of hyperthermia in tumor destruction was noted initially by Busch (39) as early as 1866, in a patient with a sarcoma. Radiofrequency waves are low-frequency electromagnetic waves (frequency ranging from 0.5 to 1.0 MHz) that have the potential to alter the molecular kinetics of the tissues that they traverse. Radiofrequency waves cause ionic and molecular agitation, which results in a rise in kinetic energy. The resulting heat is the basis for thermotherapy (404). These low-frequency electromagnetic waves have greater tissue penetration than microwaves.

Clinical utility of radiofrequency ablation was established for the destruction of accessory cardiac conduction pathways responsible for arrhythmias (366). Radiofrequency ablation has also been employed for the treatment of hepatocellular cancer and osteoid osteomas and for performing neurotomy (75,244,357). In urology, transurethral needle ablation (TUNA) and transperineal radiofrequency interstitial tumor ablation (RITA) have been used for the treatment of benign prostatic hyperplasia and cancer of the prostate, respectively. Zlotta and colleagues (460) initially described RITA of a renal tumor in 1997. Their study included renal tumor radioablation before ipsilateral radical nephrectomy.

The size of the radiolesion depends on the length of the probe, the duration of contact, and the power used. Electrodes may be monopolar or bipolar. RITA induces vaporization and tissue charring in the immediate vicinity of the electrode tip. As a result, tissue impedance rises, thus limiting the size of the radiolesion. To overcome this problem, saline-infused RITA has recently been described using a probe through which hypertonic saline can also be infused (333). Radiofrequency waves spread along the interstitial saline infusion, minimizing tissue charring, thus resulting in larger radiolesions in an extremely short period of time; indeed, with

this approach, tissue impedance is reduced by upward of 66% at 1 minute. Hoey and colleagues (170) demonstrated lesions ranging from 2.5 to 22.8 cm^3 (mean of 8.5 cm^3) using this technique, compared with lesions of only 0.06 to 0.93 cm^3 (mean of 0.34 cm^3) when using the dry radiofrequency probe. Polascik and colleagues (333) produced lesions involving 25% to 50% of the rabbit kidney (i.e., up to 2- by 1.3- by 1-cm lesions) with a 30- to 45-second treatment with “wet” RITA at 50 W. Clinical trials using wet RITA for the treatment of renal tumors are yet awaited.

Microwave Thermotherapy

Microwaves are electromagnetic waves with high frequencies, ranging from 300 to 3,000 MHz. In 1979, Tabuse (409) initially reported using microwaves for tissue during hepatic surgery. Its initial application as a method of thermotherapy was described by Yerushalmi and colleagues (455) in 1982 for the treatment of prostate cancer. Transrectal and transurethral heat applicators have been described for treatment of patients with prostate cancer and benign prostatic hyperplasia, respectively.

Laparoscopic microwave thermotherapy has been described for the experimental destruction of rabbit VX-2 renal tumors (219). The needle electrode was 1 mm in diameter and 8 mm in length with a 5-mm coaxial cable. Microwaves (2,450 MHz) were generated at a maximum output of 110 W. Coagulative necrosis was achieved over a 5- to 6-mm radius around the probe. During microwave thermotherapy, temperatures of 84° ± 3.3°C were achieved at a distance of 5 mm from the electrode, and temperatures of 55° ± 1.6°C were achieved at a distance of 10 mm from the electrode. The procedure is rapid, with desired effects being seen within 30 seconds. An advantage of the coagulative effect of microwaves is that tissue hemostasis is achieved simultaneously. However, lesions of a limited size are produced, which may necessitate the placement of multiple probes. Furthermore, a considerable amount of steam may be generated during treatment, which may interfere with laparoscopic visualization. Clinical trials using microwave therapy for the treatment of renal tumors are pending.

High-intensity Focused Ultrasound

Several studies have investigated the effects of HIFU for treatment of prostate cancer. Tissue temperatures of 85°C and lesions 18 mm in size have been reported within a few seconds of initiating treatment. HIFU is performed with a 1- to 2.25-MHz ultrasound transducer. Low-intensity exposure (less than 500 W/cm^2) for longer than 1 second is typically associated with thermal coagulative damage of the targeted tissue, whereas higher-intensity exposure (greater than 3,000 W/cm^2) causes tissue cavitation resulting in punched-out lesions (87). Cavitation is induced by conversion of tissue water into vapor. The vapor bubbles absorb energy from the ultrasound waves and grow larger. Once the bubbles reach their resonance they collapse, releasing high pressure and temperature, which induces tissue destruction. Pressure and temperature as high as 28,000 bars and 10,000 K, respectively, may be generated. Ultrasound waves of intermediate intensities tend to produce changes, which include cavitation surrounded by an area of coagulative necrosis. However, the ultrasound waves must be accurately focused on targeted tissues. Misfiring or inaccurate focusing may result in destruction of nontargeted neighboring tissues.

Chapelon and colleagues (51) studied the effects of HIFU on renal tissues of rats and dogs. Subsequent human trials resulted in incomplete tumor destruction and production of superficial burns (436). Although studies to determine the true efficacy and safety of this developmental treatment modality are yet necessary, it has the potential to be a completely noninvasive ablative modality for destruction of renal tumors.

Interstitial Photon Radiation

The role of interstitial photon therapy for stereotactic ablation of brain tumors is well established. Radiosurgery has also been used for the treatment of brain metastasis from metastatic renal cell cancer. Chan and colleagues (50) studied the feasibility of using intracavitary photon radiation for renal ablation in dogs. A 3.2-mm-diameter probe was inserted into the renal parenchyma, and local radiation of 15 Gy was delivered. An average lesion of 2.5 cm was produced. The animals maintained normal renal function over a 6-month survival period. The exposed tissues demonstrated changes suggestive of coagulative necrosis with a sharply demarcated rim, signifying unaffected surrounding renal parenchyma.

Compared with the high intensity and high energy of external beam radiation and the low intensity and low energy of brachytherapy, interstitial radiation is associated with high intensity and low energy. Hence, it does not produce the excessive tissue destruction seen with external beam radiation, nor does it require the prolonged treatment time necessary with brachytherapy. Furthermore, interstitial photon radiation may be delivered percutaneously. The potential of this form of treatment has not yet been explored at the level of clinical urology.

Robotics

Advances in robotics in the fields of industrial and aerospace-related technology have led to the simultaneous growth of medical robotics (153). A robot is a programmable automated task performance system controlled by microprocessors. Telerobotic devices synergistically integrate machine and real-time remote human interactions via electronic interfaces. Surgical procedures performed in such a manner are referred to as telepresence robotic surgery.

Robotic surgery has triggered advances in microsurgery (including vascular surgery) and laparoscopy. For totally robotic procedures, the surgeon is seated at a control station from where the robotic arms can be telemanipulated (one arm holds the laparoscope, and two arms hold laparoscopic instruments) using two robotic ergonomically designed handles. A dedicated computer and coaxial cables link the two systems. For laparoscopic procedures, the robotic arms operate specially designed laparoscopic instruments that are inserted through standard laparoscopic ports.

AESOP (Automated Endoscope System for Optimal Positioning, Computer Motion, Goleta, California) is an example of a single robotic arm for control of the laparoscope (362) (Fig. 18.22). It was the first robotic system approved by the U.S. Food and Drug Administration (FDA) for laparoscopic intervention. The system obeys the surgeon's voice based on a preprogrammed voice card and voice recognition software. A safety feature incorporated into the AESOP arm is a mechanism that automatically releases the laparoscope from its clasp when any pressure in excess of 5 pounds is applied. A technical drawback of the current system is the inability to control telescopic zoom and angular rotation of forward-oblique laparoscopes.

FIGURE 18.22. AESOP robotic arm.

The Green Telemanipulator Surgical System (SRI International, Menlo Park, California) was originally designed as a remote operational system that could perform surgical tasks in the battlefield (139). The system consisted of robotic arms with four degrees of freedom. The da Vinci Surgical System (Intuitive Surgical, Inc., Mountain View, California) is a sophisticated robotic system developed from the Green prototype with 3D image capability (385). A feature unique to this system is the Endo-wrist technology of the robotic arms. The arms have six degrees of freedom of motion, and a seventh degree of motion is provided by distally located computer-enhanced joints designed to further accentuate surgical dexterity. The ARTEMIS (Advanced Robotic Telemanipulator for Minimally Invasive Surgery) and the Zeus Microsurgical Robotic System (Computer Motion, Goleta, California) are other robotic systems designed for minimally invasive surgery. The Zeus system may be used in conjunction with the AESOP laparoscopic manipulator and consists of robotic arms with six degrees of freedom. Newer robotic systems have been designed to provide force and tactile feedback to the operator. Currently, however, these haptic interfaces are still largely developmental.

Initially, clinical applications in urology included transurethral resection of the prostate and prostatic biopsy (74,358). Kavoussi and colleagues, in a comparison between human versus AESOP robotic laparoscopic control (eight laparoscopic pelvic lymphadenectomies and three laparoscopic Burch colposuspensions), concluded that the robotic system was more effective and accurate than human laparoscopic control (209a). In another study, Partin and colleagues (325) successfully performed 82% of 17 cases using one or two AESOP robotic arms with a single surgeon. Human intervention was warranted in the event of any intraoperative complications such as significant hemorrhage. At The Cleveland Clinic, experimental robotic-assisted laparoscopic pyeloplasty (405) and the initial study on completely robotic laparoscopic nephrectomy and adrenalectomy in the porcine model have been performed.

The Future of Robotics

During laparoscopy, a fulcrum is created on the shaft of the instrument at the site of entry into the body (the trocar). As a result, the surgeon's movements are inverted before being transmitted to the distal instrument tip. To eliminate this inversion, the Human Interface Technology Laboratory at the University of Washington is developing an immersive robotic interface (315). This futuristic system proposes to give the surgeon the perspective of being shrunk and immersed into the patient's body for direct control of the distal tips of the laparoscopic instruments. This would involve the use of robotics and virtual reality images and would eliminate the inversion effect produced during routine laparoscopy. Furthermore, this may improve precision while shortening the learning curve associated with laparoscopy. Current robotic surgery is based on a “master-slave” interaction in a telerobotic manner. The rapid developments in information technology and neural networks may well pave the way for completely automated robotic surgery performed independently. Using computer algorithms and artificial intelligence with sensory inputs from the environment, future robotic systems may be able to perform complex preprogrammed tasks without the need for any interference from the human “master.”

Remote Robotic Surgery

Advanced telecommunication technology has incredibly hastened the speed of data transfer over the past few years. Using high-bandwidth telecommunications, a surgeon can remotely control a surgical procedure being performed transcontinentally. Lee and colleagues (231) at Johns Hopkins University in Baltimore reported telementoring of a laparoscopic adrenalectomy performed in Innsbruck, Austria, 5,083 miles away, and telementoring of a laparoscopic varicocelectomy in Bangkok, Thailand, 10,880 miles away, in 1998. With further development of telecommunications and optics for data transfer, long-distance remote robotic surgery may become part of standard clinical teaching and practice.

Virtual Reality

Similar to flight simulators, which are designed to train pilots, virtual reality systems are being developed as a potential method for surgical training. Virtual reality systems seek to simulate real-patient situations by means of a series of synthetic computer-generated animations. Besides its potential use to train surgical residents, it will also enable more experienced surgeons to rehearse steps of a procedure before the actual operation. By entering patient-specific sophisticated imaging data into the simulator, a surgeon will be navigated through the area of interest. Such “enhanced” reality systems seek to augment reality with patient-specific images.

A laparoscopic virtual reality simulator comprises a manikin in which the laparoscopic instruments are manipulated. The surgeon wears a head-mounted display or alternatively uses a 3D video monitor. The system is equipped with a stereolaparoscope and auditory and haptic feedback (174). In addition, head, hand, and instrument-tracking technology is incorporated (435). A series of computer-generated images are relayed, consisting of representations of various anatomically correct cartoons. The images respond to movements of the surgeon by producing tissue deformation effects, bleeding, and other real-life physical situations (54). A state-of-the-art graphics computer with texture mapping capabilities is essential to generate these images. Alternatively, instead of the use of a manikin, systems are being developed that incorporate the use of a “dataglove.” The MIST-VR (Minimally Invasive Surgery Trainer—Virtual Reality) is an example of a developmental virtual reality system for laparoscopic training (171).

Optics

Image clarity and optimal visualization are key to the success of any laparoscopic procedure. Analog images are being replaced by higher-resolution digital images. Charge-coupled devices (CCDs) form the core of all digital and electronic cameras. A CCD chip is a light-sensitive solid-state silicon chip containing a series of pixels. Pixels are electronic sensors that discharge an electric charge when struck by light. When a photon strikes the CCD, an electrical potential is generated, creating a digital image. These images can be relayed, printed, or stored for future reference in computers or using optic computer disks. Current laparoscopic cameras may contain one to three CCD chips with 25,000 to 50,000 pixels. Higher-resolution triple-chip cameras function in a manner such that each chip is dedicated to one of the three primary colors: red, green, and blue (RGB). Images are transmitted employing RGB video channels. Advances in digital technology have enabled the production of cameras with several megapixels of image resolution. When clinically available for laparoscopic applications, these cameras will provide unparalleled visualization and definition.

In its present design, the laparoscopic camera is typically mounted to the proximal end of the laparoscope. An air interface exists between the laparoscope and the camera, which hampers image quality. Eliminating this air interface by directly mounting the CCD on the distal tip of the laparoscope would provide for clearer images.

Newer high-definition television monitors provide better sharpness and definition of displayed images. These monitors display up to 1,125 lines of resolution compared with 525 lines of resolution displayed by the ordinary television monitor. High-definition head-mounted displays incorporating liquid crystal on silicon microdisplays are available (OptiVu, Optimize, Los Gatos, California). Video images archived in the digital format are permanent, are easily retrievable, and can be stored on desktop computers that can be used for multimedia presentations. Digital video disc (DVD) technology with improved Moving Pictures Expert Group (MPEG-2)–quality images has resulted in crisp image storage and playback. Desktop and notebook computers with DVD cards and optimal memory capacity can store and display these high-quality movie images. Video imaging is a rapidly advancing field. Currently, MPEG-4 through MPEG-7 image qualities are being developed. In the years to come, these images will provide far superior resolution than current technology.

Stereoscopic Laparoscopy

Standard current laparoscopy involves 2D image technology. A disadvantage is the lack of depth perception. With increased operator experience, laparoscopic procedures are becoming more technically complex, necessitating superior visualization. Stereoscopic images have the potential to provide precise high-quality images with depth perception.

To produce 3D images, a video system must convey differing offset images to each eye. Stereoscopic images are obtained by using a stereolaparoscope, which consists of a laparoscope with two optical lenses. The laparoscope is equipped with a stereo camera containing two CCD chips. The surgeon wears a head-mounted device (HMD) with a liquid crystal display and active shutter glasses. Images are alternately cycled at 120 Hz to each eye (282). The right eye exclusively views the right image and the left eye the left image. While an image is provided to one eye, the shutter covers the opposite eye. Images cycled at less than 120 Hz cause perceptible flickering. Currently available HMDs are rather heavy and somewhat uncomfortable when worn for prolonged periods. Alternatively, a 3D monitor with lenticular lenses in front of the screen or passive-polarized glasses may be used. The left eye image is selectively displayed to the left eye and the right eye image to the right eye.

Widespread use of 3D technology in its current form has not gained popularity. In its current form, stereoscopic laparoscopy does not yet provide optimal depth perception. Moreover, trained laparoscopic surgeons attain a sense of depth perception over time, and hence may not feel the need for this expensive technology (166). Learned 3D vision is akin to watching 2D television or movies and yet being able to perceive depth efficiently. Nevertheless, advances in the field of optics such as the use of high-definition video displays with improved clarity and improvements in stereoscopic technology may render stereoscopic laparoscopy more useful.

Optics for Ergonomic Comfort

Laparoscopic surgery involves peering into a television monitor positioned straight ahead on a vertical rack for hours at end. Thus the surgeon's line of vision is away from the actual operative field. This dissociation of the surgeon's vision from the line of work may be associated with significant physical strain. This problem can be rectified by using an image projector and a sterile screen, which can be intraoperatively manipulated by the surgeon to provide a direct line of view of the surgical field at the patient's skin level, thereby eliminating the need to look up at the television monitor during the procedure (ViewSite, Karl Storz Inc., Culver City, California; and Inside View, LSI Solutions, Rochester, New York). The advent of flat screen technology will similarly enable the surgeon to view the laparoscopic field comfortably.

Techniques for Laparoscopic Tissue Approximation

Fibrin Glue

Fibrin glue is produced by mixing appropriate quantities of fibrinogen with thrombin. The latter cleaves fibrinogen into fibrin monomers, which crosslink with one another to produce a sealant (388). The initial use of fibrin glue was directed toward achieving tissue hemostasis. Currently, it is employed for tissue approximation as well. The ability to obtain fibrinogen concentrates in the 1970s led to the high-level production of fibrin glue; however, the risk of transmission of blood-borne viral diseases such as hepatitis and HIV led the FDA to withhold its use (120). Recently, autologous fibrin glue has been prepared using cryocentrifugation, cryofiltration, and ethanol precipitation methods, making it safer for commercial use (456). In addition, with recombinant DNA technology large quantities of safe blood products are becoming available.

Fibrin glue is commercially available in a double-barreled syringe containing fibrinogen and aprotinin in one barrel and thrombin admixed with calcium chloride in the other barrel. The fibrinogen content determines the strength of the glue, and the thrombin content determines the rate at which glue stabilizes. The addition of aprotinin protects against rapid resorption of the glue. Fibrin glue has been used for several reconstructive procedures, such as vasovasostomies, and for sealing splenic injuries (391,418). In laparoscopic urologic surgery it has been used to perform pyeloplasties and ureteral reanastomosis. McKay and colleagues (271) demonstrated the feasibility of performing laparoscopic ureteral reanastomosis with fibrin glue in pigs. Compared with the animals that underwent open ureteral reanastomosis, animals treated with fibrin glue had more pronounced inflammation and fibrosis. In another porcine animal study conducted by Wolf and colleagues (452), ureteral repair with fibrin glue was associated with better flow characteristics and histology than laparoscopic suturing. Eden and colleagues (90) reported the clinical use of fibrin glue for laparoscopic dismembered pyeloplasty.

Cyanoacrylate Glue

Cyanoacrylate glue, or superglue as it is known, is a heavy-duty adhesive. It has powerful hemostatic and adhesive qualities. It rapidly polymerizes on contact with any ionic medium, including blood or saline. Indeed, polymerization can be so rapid that iophendylate or glacial acid may need to be added to slow the reaction (48). It has been clinically used as a hemostatic agent in interventional radiology and as a skin sealant. Experimentally, it has been associated with some degree of fibroblast and human tendon cell cytotoxicity, and it has also been associated with a marked inflammatory response and fibrosis (100,202). Cyanoacrylate is nonabsorbable, and its effect on mucosal approximation must be studied in detail before its utilization for tissue approximation in urology.

Laser Welding

The use of lasers in urology for tissue ablation and for hemostasis is well established. The initial successful laser weld for achieving vascular anastomosis was performed by Jain and colleagues (192). The concept was derived from the use of electrocautery for closure of venotomies, described by Sigel and Acevido (389). The basis of tissue welding is the photothermic effect of lasers on tissue proteins. At approximately 60°C, collagen fibrils tend to uncoil and then crosslink (370). The ideal tissue-welding laser should have optimal tissue penetration and should be associated with a strong weld while limiting the thermal damage and lateral spread of heat. Advances in the field of laser welding include the use of laser solders, thermal feedback, and chromophore enhancement. In 1988, Poppas and colleagues (336) developed tissue solders for improving the strength of the weld and for limiting the lateral spread of heat by acting as a heat sink. The protein solder is effectively incorporated into the weld, thereby strengthening the tissue approximation (434). Albumin in concentrations of 40% to 50% is the most commonly used solder. The endpoint of laser welding may be determined by studying the color of the lased tissue. This is a rather inaccurate method that can lead to overheating of the tissues. The use of infrared thermal sensors (222) and chromophore enhancement with substances such as indocyanate and fluorescein may provide more accurate real-time thermal feedback and thereby prevent tissue damage. Nd:YAG lasers with a penetration of 3 to 5 mm and KTP lasers that penetrate up to 1 mm have been used for tissue approximation (335). Also, the use of the 1.9-mm diode laser for gastrocystoplasty in the canine model has been associated with good results; Bleustein and colleagues (29) demonstrated better results and less thermal damage with the use of the diode than Nd:YAG. The tensile strengths achieved with the diode lasers were comparable with that attained during tissue suturing (29). Laser welding appears to be an impressive and effective way of achieving sutureless tissue approximation.

Alternative Tissue Dissection Techniques

Alternative energy sources for laparoscopic tissue dissection include the use of ultrasound energy, pneumodissection, and hydrodissection. The harmonic scalpel (UltraCision) is driven by ultrasound vibrations. The power box is attached to forceps or a blade and vibrates at 55,500 cycles per second. The rapid vibration is associated with release of thermal energy, which facilitates simultaneous tissue coagulation. However, there is minimal risk of lateral spread of tissue coagulation (233).

Gardner and colleagues (113) reported the feasibility of high-pressure CO_2 for laparoscopic tissue dissection. Pneumodissection at 50 psi could be safely performed in the porcine model with a 5-mm pneumodissector. Short bursts of high-pressure CO_2 were used as a blunt dissector. The use of higher pressures (greater than 60 psi) was associated with splenic trauma when the pneumodissector was fired directly on the spleen. The same group presented their experience with the use of this technique in 20 patients (327). Acid–base imbalances were documented, although they were not statistically significantly different from the level of hypercarbia noted in patients undergoing a CO_2 pneumoperitoneum without use of pneumodissection. In their studies, gas embolism did not occur in either the animal or clinical cases.

Another tissue dissection technique involves the use of water under pressure. Hydro-jet dissection was employed to perform laparoscopic partial nephrectomy in the porcine model by Shekarriz and colleagues (383). An ultracoherent stream of normal saline, with a pressure of up to 30 atm, was used for dissection of the renal parenchyma during a partial nephrectomy. An average of 195 mL of saline was used per case. The saline stream effectively cut through the parenchymal tissue, preserving the intrarenal vasculature and collecting system.

Microlaparoscopic and Needlescopic Instruments

Instruments of smaller caliber than regular laparoscopic instruments have been developed to further decrease the morbidity and improve the cosmetic result associated with laparoscopic procedures. Needlescopic instruments are introduced through 2-mm (i.e., 14-gauge) trocars. A minute skin puncture results that needs no more than a single Steri-Strip for closure (129).

However, currently available mini-laparoscopic instruments are inferior in performance to larger 5-mm instruments. A 2-mm laparoscope does not provide the image clarity seen with a 10-mm laparoscope. Moreover, 2-mm clip applicators are not available and adequate suctioning cannot be performed. A judicious combination of conventional laparoscopic and mini-laparoscopic instruments is currently the best use of this technology. Significant advantages such as decreased pain and better cosmesis are noted when the 2-mm access is substituted for 5- or 10-mm ports. With further technologic development and improvement of instruments, it is possible that reconstructive procedures will be performed entirely via 2-mm ports.

CONCLUSION

With the incorporation of newer technologies, laparoscopic procedures of greater technical difficulty will be addressed in the future. More complex reconstructions and challenging ablations will be performed laparoscopically, with increasing confidence. Progressive technologic development is directed toward achieving increased efficiency, precision, and cost-effectiveness.

Computers in the 1950s were room-sized machines and had the storage capability equivalent to a few silicon chips of today's computers. Newer machines and instruments are smaller and yet vastly more powerful. We are presently in a transition from bulk technology to molecular technology. The future will witness progress in the fields of artificial intelligence and nanotechnology. A nanometer is one-billionth of a meter, and nanotechnology is the anticipated technology involving the use of molecular-sized devices. It has been envisaged that these micromachines will be able to perform a range of diagnostic and therapeutic procedures intracorporeally. When injected into the circulation, they will be able to find their way in a preprogrammed manner into the area of interest and intelligently execute the task for which they were programmed. Molecular-scale surgery and cell repair machines involving nanorobotics may be possible in the future. In the years to come, the role of the master surgeon may well be reduced to that of today's house officer: to just “put in a line.”

Conclusions
Chapter References

Although initially limited to calculous disease, today the span of endourology encompasses almost all types of maladies affecting the upper urinary tract. This is due to significant advances in the endoscopic and auxiliary instrumentation available to the urologic surgeon. Presently, rigid working endoscopes have become as small as 6 Fr, and their flexible counterparts are only 7.5 Fr. Despite the small size of these endoscopes, a working channel of 3 Fr or larger is available for the passage of myriad instruments, ranging from biopsy forceps to electrosurgical and laser probes.

As a result of these developments, diagnostic and therapeutic procedures, previously possible only through a large incision, now can be performed effectively endoscopically. From a diagnostic standpoint, a minimally invasive approach has been most beneficial in the upper urinary tract in the areas of lateralizing hematuria, filling defects, renal masses, and obstruction. Likewise, the therapeutic approach to many upper urinary tract disease entities has progressed from an open to an endourologic treatment. In the ureter, endourologic approaches have been used for treating strictures, transitional cell cancer, and ureterovesical fistulae. In the kidney, a minimally invasive approach has been used to deal with ureteropelvic junction (UPJ) and infundibular obstruction, calyceal diverticula, and transitional cell cancer. In addition, benign renal masses, including cysts and abscesses, have been treated successfully endourologically. Most recently, these same techniques have been used to resolve similar problems affecting a renal transplant. In these patients, both stricture and fistula problems have been managed successfully endoscopically. The endourologic approach also has been applied to perirenal processes, such as abscesses, urinomas, and lymphoceles.

DIAGNOSTIC RENAL AND URETERAL APPLICATIONS

Lateralizing Hematuria

In the diagnosis of lateralizing hematuria, an endourologic approach has become the final and definitive step in the diagnostic regimen (200). Among patients with macroscopic hematuria, the laboratory evaluation usually includes urine for cytology, urinalysis to rule out proteinuria associated with medical renal disease, coagulation studies, and when appropriate, a sickle cell preparation.

Aside from these basic studies, much has been written about examination of the morphology of the red blood cells in the urine in order to differentiate bleeding attributable to a glomerular problem (i.e., dysmorphic red blood cells) from bleeding caused by an anatomic lesion (i.e., normal-shaped red blood cells). Using interference microscopy, Tomita and associates (358) have identified five different red blood cell shapes indicative of a glomerular or nonglomerular (i.e., anatomic) site of bleeding. In patients with 15% glomerular red blood cells, the sensitivity and specificity of the test for glomerular bleeding was 90% and 98%, respectively. The accuracy of this study is further enhanced if the urine has a pH of less than 6.4 or is highly concentrated (osmolality greater than 400 mOsm/kg H_2O); likewise, identification of one subtype of the glomerular red blood cells (a doughnut cell) further increased the certainty of glomerular bleeding (196). Other reports have been less encouraging, with a sensitivity and specificity of 73% and 60%, respectively; however, these values were substantially improved when obvious causes of hematuria, such as urinary tract infection or urolithiasis, were eliminated from the data pool. Accordingly, in the patient with no obvious cause for lateralizing hematuria (i.e., negative radiologic studies), the appearance of deformed red blood cells on phase contrast microscopy or on a Coulter counter can be more than 90% accurate in diagnosing the presence of a glomerular, nonsurgical problem (4,270,311).

Also of interest are recent reports on detailed protein analysis of the urine among patients with hematuria of undetermined etiology. A nonglomerular source of hematuria is associated with an increase in high-molecular-weight proteins. Specifically, when the urine albumin exceeds 100 mg/L, the measurement of a_2-macroglobulin in the second voided morning specimen is recommended; if it is also elevated (i.e., a $_2$-macroglobulin-to-albumin ratio greater than 2.0×10^{-2}), a nonglomerular, postrenal site of bleeding is likely (127).

After the aforementioned studies, the next tests are usually radiologic and endoscopic: an intravenous urogram and cystoscopy. The intravenous urogram should clearly show the examiner all of the calyces and the entire length of the ureter; this might require additional radiographs and repositioning the patient to fill the entire ureter. Failure to image all of the calyces or the entire ureter necessitates completion of a retrograde ureterogram. If intravenous urography (IVU) fails to reveal an obvious cause for the hematuria (i.e., no filling defects, stones, or apparent renal masses) and cystoscopy reveals blood emanating from the right or left ureteral orifice, the next procedure is usually a computed tomogram or ultrasound (US) examination to rule out an occult renal mass that might have been missed on the IVU (227). If this study is unremarkable, there is some support for proceeding to a renal arteriogram to rule out an arteriovenous malformation or other large vascular anomaly; if discovered, the vascular abnormality can be embolized during the same angiographic session (Fig. 19.1).

FIGURE 19.1. Lateralizing essential hematuria: evaluation. CT, computed tomography; IVU, intravenous urography. (From McMurtry JM, Clayman RV, Perminger GM. Endourologic diagnosis and treatment of essential hematuria. *J Endourol* 1987;1:145, with permission.)

When radiographic studies have failed to identify an obvious cause for lateralizing hematuria, it is necessary to proceed with ureteroscopic evaluation of the ipsilateral urinary tract. The role of percutaneous nephroscopy in these patients is limited; indeed, this approach would be considered only in the rare event that ureteroscopic examination was not possible (e.g., patient with a cross-trigonal reimplantation) or was unsatisfactory (i.e., inability to closely examine the lower-pole calyces in the face of an otherwise negative examination).

Technique

Diagnostic ureteroscopy is performed routinely under intravenous sedation, thereby eliminating the more morbid effects and prolonged recovery time incurred by general or spinal anesthesia (368). The patient's urine culture must be sterile. In examining the upper urinary tract in a patient with lateralizing hematuria, it is essential that the examiner visualize each area of the ureter and renal collecting system *before it is traumatized by a guidewire or other blindly passed instrument.* Accordingly, the procedure is begun by examining the distal ureter with a short, rigid, less than 7-Fr ureteroscope. This endoscope is introduced directly into the affected ureteral orifice and slowly advanced up the distal ureter, being certain to visualize the full circumference of the ureteral lumen. The irrigant pressure is kept at or below 40 cm H_2O. At this point, no guidewire has been passed into the ureter. (In rare cases, it may be necessary to extend a 2- to 3-cm length of guidewire from the end of the ureteroscope to help open the ureteral orifice and to serve as a guide for the passage of the ureteroscope. However, this is done under direct endoscopic, not fluoroscopic, monitoring. Again, the goal is to see each area of the ureter before it is manipulated.)

The rigid endoscope is passed as far up the ureter as possible. However, if passage of the endoscope becomes difficult, a guidewire is introduced. The guidewire is passed only to the most proximal point of ureteroscopic examination. Under fluoroscopic control, the rigid ureteroscope is withdrawn; during this time, the examiner's eyes should be focused on the tip of the guidewire to make certain that while withdrawing the ureteroscope the guidewire is not inadvertently advanced up the ureter. A less than 10-Fr, or preferably less than 8-Fr, flexible ureteroscope is introduced over the solitary guidewire; the flexible ureteroscope is passed up to the point where the rigid ureteroscopic evaluation of the ureter ended (121). The guidewire is removed and the proximal portion of the ureter is examined carefully with the flexible ureteroscope up to the ureteropelvic junction.

Now the previously obtained IVU is examined carefully and each calyx is numbered. The endoscopist then proceeds to examine the renal pelvis, upper-pole calyces, middle calyces, and lower-pole calyces in sequence (Fig. 19.2A, Fig. 19.2B and Fig. 19.2C). Adhering to this sequence precludes the creation of iatrogenic lesions (i.e., bruising) along the os of the upper-pole infundibulum during flexion of the endoscope into the lower pole. As each calyx is entered, a small amount of dilute contrast is injected through the endoscope to determine the exact location of the endoscope; the assigned number of the entered calyx is then checked off. It is important to use minimum pressure on the irrigant flow during the ureterorenoscopic procedure (less than 40 mm Hg). Also, aspirating the upper collecting system through the flexible ureteroscope will reduce the volume of fluid and pressure within the upper collecting system and may help identify an area of venous bleeding. Any obvious lesion, such as a hemangioma, is treated directly with either neodymium:yttrium-aluminum-garnet (Nd:YAG) laser or electrocautery (via a 2-Fr electrode) (Fig. 19.2D); similarly, if a small tumor is noted, it is biopsied and then fulgurated.

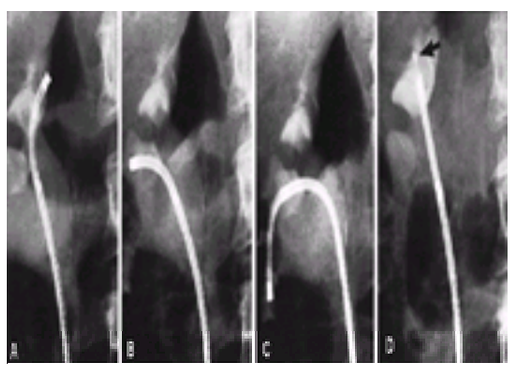

FIGURE 19.2. A–C: Flexible uteroscope examining collecting system of adult female patient with essential hematuria. **D:** Vascular lesion was identified and fulgurated with a 3-Fr electrosurgery probe *(arrow).*

After completely examining the collecting system, a guidewire is passed through the ureteroscope, and the ureteroscope is withdrawn. A 5- to 7-Fr indwelling ureteral stent is then placed, and the bladder is drained. The patient usually can be discharged on the same day (376). The stent is removed 3 days later in the office. Oral antibiotic coverage is given preoperatively and for 4 days after the procedure.

Results

Successful examination of the entire collecting system with the previously described approach is high. Bagley (12) noted that with a small (8.5-Fr), flexible ureteroscope, equipped with both primary and secondary deflection, the intrarenal collecting system could be examined satisfactorily in 92% of patients. The most difficult area to examine was invariably the lower-pole calyces.

Among patients coming to ureteroscopy for lateralizing hematuria of undetermined origin, approximately 50% are found to have a discrete vascular lesion that can be fulgurated. These vascular lesions (i.e., hemangioma or arteriovenous malformation) appear to be equally distributed throughout the kidney. Coagulation of the lesion results in an immediate successful outcome in more than 90% of patients; however, follow-up data at only 7 months reveals rebleeding in 12% of “successfully” treated individuals. This is not overly surprising given the finding that 12% of renal hemangiomas are multiple, thus implying that although the hemangioma that was bleeding may have been treated at the initial ureteroscopic session, a smaller, nonbleeding lesion may have been missed only to bleed at a later date (181). Nakada and colleagues (259) reported an average 58-month follow-up in 17 patients undergoing flexible ureteroscopy and intrarenal ureteroscopic therapy for lateralizing essential hematuria. Among 11 patients with a discrete lesion, only 18% subsequently rebled; however, for patients in whom no pathology or multiple bleeding sites were noted, the recurrence of hematuria was high (83%) (Table 19.1).

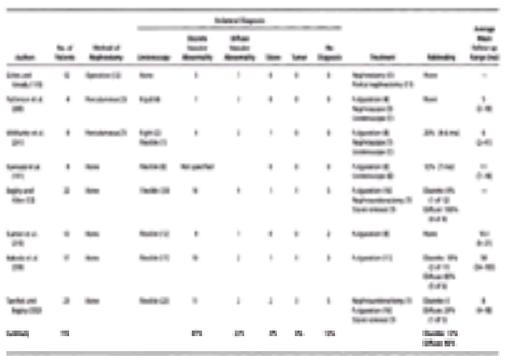

TABLE 19.1. ESSENTIAL HEMATURIA: DIAGNOSIS AND TREATMENT

In 5% to 10% of patients, despite a completely negative cytology and unremarkable radiologic evaluation, a renal calculus or small, upper tract transitional cell cancer will be detected. This usually can be treated at the same time as the diagnostic ureteroscopy, using ureteroscopic lithotripsy or electrical or laser lithotripsy, respectively (12,13,189,210,259,353) (Table 19.1).

In the remaining patients, multiple, putative sites of bleeding are noted; in these patients, the success rate of *in situ* endoscopic electrocoagulation is less effective. As an alternative, intrarenal instillation or systemic therapy may be attempted. Bahnson (17) reported instilling 10 mL of 1% silver nitrate into the renal pelvis via a retrograde ureteral catheter in three patients with lateralizing hematuria caused by sickle cell hemoglobinopathy; in all three patients, the bleeding ceased after one or two instillations. During an average follow-up of 13 months, no rebleeding was reported. Likewise, Stefanini and associates (342) noted that oral epsilon aminocaproic acid at a daily dose of 150 mg/kg divided into four 6-hour intervals, given for up to 3 weeks, appeared to control hematuria in the short term in four patients with upper tract hematuria caused by tumor or trauma.

Renal Mass

An endoscopic approach to a renal mass is rarely necessary. Modern imaging modalities, including US, computed tomography (CT), and magnetic resonance imaging (MRI), largely have supplanted the need to obtain a confirmatory tissue diagnosis.

All renal masses can be separated into three broad categories: cystic, solid, and indeterminant. The vast majority of renal masses are simple cysts. Renal US can definitively diagnose a renal cyst provided the lesion fulfills the diagnostic criteria of being anechoic at high and low gain and has a strong posterior wall. Similarly, CT criteria for a cyst are likewise reliable: a thin-walled lesion with a homogenous interior of low density [i.e., 0 Hounsfield units (HU)] is invariably a simple renal cyst (Fig. 19.3). If these criteria are not met, the lesion is considered indeterminant and further diagnostic studies are indicated.

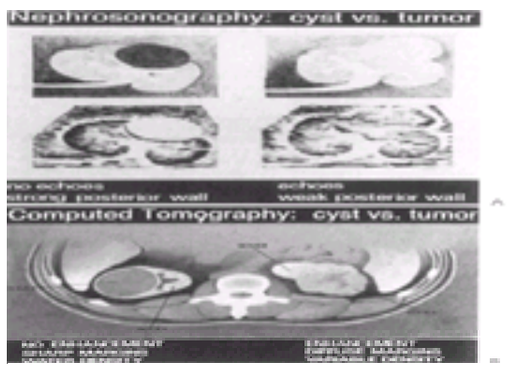

FIGURE 19.3. A: Characteristics of cystic *(left side)* and solid tumorous *(right side)* renal mass as each would appear on a renal ultrasound study. **B:** Characteristics of a cystic *(left side)* and tumor-bearing *(right side)* kidney as each would appear on a computed tomogram study. Numbers refer to Hounsfield units with and without *(in parentheses)* intravenous contrast administration.

For solid, noncystic lesions, the CT or MRI study is essential. One advantage of MRI is in the patient with renal insufficiency or a contrast allergy; in these patients the gadolinium-enhanced scan is of particular value (204,325). For the diagnosis of a solid lesion, the key point is to determine whether there is any fat within the lesion. If fat is found within the lesion, an angiomyolipoma is probably present; a solid lesion without any fat is more likely a renal cell cancer. The former, if smaller than 3.5 to 4 cm and asymptomatic, can be followed, whereas the diagnosis of a renal cell cancer leads to surgical ablation (269,363) (Fig. 19.4).

FIGURE 19.4. Diagnosis of renal cell cancer. CT, computed tomography; IVP, intravenous pyelogram; MRI, magnetic resonance imaging; US, ultrasound. (*If contrast allergy or renal insufficiency, substitute MRI for CT scan.)

Technique

Only in the case of an indeterminant lesion or a solid lesion in a patient with a known cancer (i.e., differential diagnosis of primary renal cancer versus a metastatic lesion) does it behoove the urologist to seek a more definitive diagnosis. In this regard, a US- or CT-guided puncture or biopsy of the lesion is indicated. If the contents are fluid, cytology, culture, and electrolytes can be obtained on the specimen; however, if the lesion has a solid component, an aspiration or needle biopsy can be obtained.

Needle biopsy of a renal lesion may be done either percutaneously or via a transrenal approach. The percutaneous approach to renal biopsy is by far the better-known procedure, having been used since 1950. The Vim Silverman needle and Tru-Cut needle have been the mainstays of percutaneous renal biopsy; however, recent advances in biopsy guns have provided the physician with much smaller 18-gauge, spring-loaded systems, which can be accurately guided to the lesion under US or CT imaging.

Leal (219) has described a transurethral, transrenal approach to renal biopsy. Using a torque control guidewire and 5- and 8-Fr catheters, the calyx closest to the parenchymal mass is accessed. The guidewire is pushed into the mass and the 8-Fr catheter is then advanced into the mass. The guidewire and 5-Fr catheters are removed, and aspiration is applied to the end of the 8-Fr catheter during fluoroscopic imaging. The 8-Fr catheter is then removed and the plug of tissue is flushed out and sent for histologic evaluation; an indwelling ureteral stent is placed.

If all of these methods fail to yield a definitive diagnosis, a retroperitoneal laparoscopic or open approach may be necessary, at which time both a diagnostic biopsy and definitive therapy can be accomplished (Fig. 19.4) (53).

Results

Overall, the vast majority of incidentally discovered renal masses are cysts. A simple renal cyst is identified during abdominal CT in 25% to 33% of patients more than 50 years of age. In contrast, Tosaka and colleagues (359) noted that among 46,000 adults undergoing US screening for renal masses, a mass was noted in only 1%. Among these masses, two-thirds proved to be a normal renal variant; cystic lesions (23%) greatly outnumbered renal cancers (5.4%). However, when the patient has a renal mass in association with macroscopic hematuria, flank pain, or a palpable flank mass, the chance of a renal cell cancer being present exceeds 50% (53). Other renal masses, specifically angiomyolipoma, renal pelvic tumors, and other benign lesions, are all relatively uncommon, accounting for approximately 5% of all renal masses among asymptomatic patients (359,363).

Complications from percutaneous renal biopsy with the larger 14-gauge needles occurred in 2% to 11% of patients; however, most of these problems were of a minor nature. The nephrectomy rate from renal biopsy is 0.06%, with a mortality rate of 0.08%. However, the advent of 18-gauge biopsy needles has resulted in the apparent elimination of major complications such as death or nephrectomies in some series; minor complications occur in only 5% (predominantly symptomatic perirenal hematoma or hematuria). The improved safety margin of this approach now has made it feasible to pursue a percutaneous biopsy even in the case of a solitary kidney (79,81,320).

Concerns about possible postbiopsy seeding of the needle tract are not sufficient to alter the course from percutaneous biopsy to renal exploration. Reported cases of seeding of the needle tract are few and are usually associated with unusual circumstances, such as multiple biopsies of a lesion over time, the use of large needles, or other extenuating circumstances (112,222,369).

Although the intrarenal biopsy method is of interest, it has been used successfully in only three patients, according to Leal's original report. Subsequent information has yet to be published. There is no information regarding complications from this approach. Overall, it remains significantly more invasive than currently available percutaneous biopsy techniques and thus would be of greatest value in those few patients in whom a percutaneous approach was unsuccessful or not feasible (e.g., massive obesity).

Diagnosis of Filling Defects Within the Upper Urinary Tract

As with the evaluation of a renal mass, the workup of the patient with a filling defect in the upper urinary tract should proceed in an orderly fashion from less invasive to more invasive studies. The patient's prior history and a fresh urinalysis with urine cytology and urine culture can help steer the clinician toward the correct diagnosis from the outset (Fig. 19.5). As such, patients with a history of stone disease or transitional cell cancer of the bladder are immediately suspect for similar upper tract conditions. Likewise, individuals with a history of diabetes, recurrent upper tract infections, analgesic abuse, or sickle cell disease may have papillary necrosis or an associated blood clot. Patients with a history of inflammatory bowel disease are at risk for developing a filling defect because of the presence of air in the collecting system from a ureteroenteric fistula. In addition, a long-term history of *Escherichia coli* urinary tract infection can be associated with malakoplakia or, in the diabetic patient, with emphysematous pyelonephritis. Pneumaturia may similarly indicate a fistulous bowel communication with the upper or, more commonly, lower urinary tract.

FIGURE 19.5. Radiolucent filling defect in the upper urinary tract: evaluation. CT, computed tomography; IVP, intravenous pyelogram; RBC, red blood cell; R/O, rule out; WBC, white blood cell. (*With a positive urine cytology, sterile urine, and a soft-tissue filling defect, a surgical procedure—that is, ureteroscopic confirmation versus surgical ablation—for suspected transitional cell carcinoma is reasonable.) (Modified from Resnick MI. Radiolucent filling defects. In: Resnick ME et al, eds. *Decision making in urology.* St Louis: Mosby, 1985:18, with permission.)

A complete urinalysis, performed by the urologist, is essential (Fig. 19.5). If the urine pH is above 6.5, the likelihood of a uric acid stone becomes remote. The presence of a significant amount of hematuria may indicate that the filling defect is secondary to a blood clot. A urine sample sent for cytology can be helpful if it is positive for malignant cells; however, the accuracy of this test is highly dependent on the skill of the cytologist. In one report, a false-positive cytology was noted in 17% of patients, and false-negative cytologies ranged from 10% to 80%, depending on the grade of the tumor (16,71,242,310,322). The urine culture also is helpful; the presence of fungi may indicate a fungal ball, whereas the presence of mixed aerobic and anaerobic bacteria would indicate a ureteroenteric fistula.

The next step in the diagnostic evaluation of a filling defect discovered on intravenous urography is either US or CT (Fig. 19.5) (301). US is safe, is relatively inexpensive, and has the ability to clearly show a larger stone because of its characteristic acoustic shadowing; however, the resolution of US is not as reliable as CT scanning (74). In Bagley's series, US evaluation of 14 patients with an upper tract filling defect failed to image 5 of 6 tumors and 4 of 4 stones. In contrast, CT imaged 57% of the stones (4 of 7) and 36% (5 of 14) of the transitional cell tumors (16).

When a stone is definitively identified, urinary alkalinization, high fluid intake, and if hyperuricemia is present, the use of a xanthine oxidase inhibitor are indicated (74). This should result in dissolution of the presumably uric acid stone within weeks to months. If, on subsequent radiographic studies, the stone persists unchanged in size, extracorporeal shock wave lithotripsy (ESWL) can be undertaken. Failing ESWL, a ureteroscopic or percutaneous approach is the next step.

When despite these studies the lesion remains indeterminant, retrograde ureterography and ureteroscopy are the next steps (Fig. 19.6). Even in the face of a positive cytology, given the 17% false-positive cytology rate in Bagley's series, a strong case can still be made for proceeding with diagnostic ureteroscopy and biopsy (16).

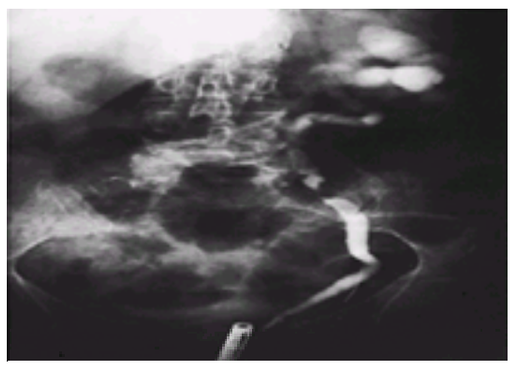

FIGURE 19.6. Retrograde uterogram reveals a midureteral filling defect with associated obstruction. The patient had macroscopic hematuria. Subsequent uteroscopy and biopsy established the diagnosis of a high-grade transitional cell cancer of the ureter.

Technique

In the past decade, the diameter of the rigid ureteroscope has decreased rapidly from 12.5 Fr to only 6 to 7 Fr; these diminutive endoscopes still contain working channels in the 3- to 4-Fr range. Their small size enables the urologist to perform ureteroscopy without the need to dilate the distal ureter. However, although these semirigid endoscopes can usually traverse the entire length of the ureter in the female, manipulation over the iliac vessels in the male may be difficult. As such, for upper ureteral lesions in the male or for lesions located in the renal collecting system, flexible ureteroscopy is necessary.

Like their rigid counterpart, the flexible endoscopes have undergone a significant decrease in size over the last 10 years, from 13 to 7.5 Fr. The latter endoscope still has a 3.6-Fr channel; thus it can usually be passed up the ureter without ureteral dilation and yet allows the urologist the ability to use a full range of instruments, including biopsy forceps, electrosurgical probes, and laser fibers. In addition, these endoscopes have an actively deflectable tip mobility of 170 degrees and passive secondary deflection, thereby facilitating their introduction into the lower-pole calyces (121). Also of interest are reports of even more diminutive, 2-Fr diagnostic passive flexible videoureteronephroscopes that can be passed through a 6-Fr guide tube to provide both vision and a 3-Fr working channel (380). However, experience with these endoscopes is limited.

Unlike in the case of lateralizing essential hematuria, the patient with a filling defect in the collecting system provides the endoscopist with an identifiable target. The endoscopist can approach the site of interest directly; however, in patients with suspected transitional cell cancer or stone, a systematic examination of the entire collecting system is still indicated to rule out other sites of stone or tumor growth. The normal saline irrigating fluid is kept at 75 mm Hg or less to prevent pyelovenous or pyelosinous backflow. Only when the biopsy forceps or a stone basket is in the endoscope's channel is the irrigant pressure increased to maintain flow (i.e., 150 mm Hg). As soon as the instrument is withdrawn, the irrigant pressure is lowered to 75 mm Hg.

After the ureter and renal collecting system are fully examined, the lesion can be addressed directly. If it is a stone, intracorporeal lithotripsy with a holmium:yttrium-aluminum-garnet (Ho:YAG) laser or a 1.9-Fr electrohydraulic lithotripsy probe through the flexible ureteroscope, or laser, electrohydraulic, ultrasonic, or pneumatic lithotripsy via the rigid ureteroscope, can be accomplished. If a cystic lesion is found, a biopsy can be obtained and the lesion unroofed and fulgurated (Fig. 19.7). If a tumor is discovered and a flexible ureteroscope is being used, the ureteroscope can be removed and an 8-Fr catheter and 10-Fr sheath can be introduced into the ureter. After withdrawing the 8-Fr catheter, a second guidewire is placed in the upper urinary tract. The 10-Fr sheath can then be replaced with a ureteral access sheath. This is passed over one of the guidewires, the dilator is removed, and the 12- or 14-Fr sheath is left in place. As such, when the ureteroscope is withdrawn during the biopsy process, the sheath maintains access to the ureter so the ureteroscope can be returned easily to the site of the lesion. If a rigid ureteroscope is being used, an access sheath is usually not placed.

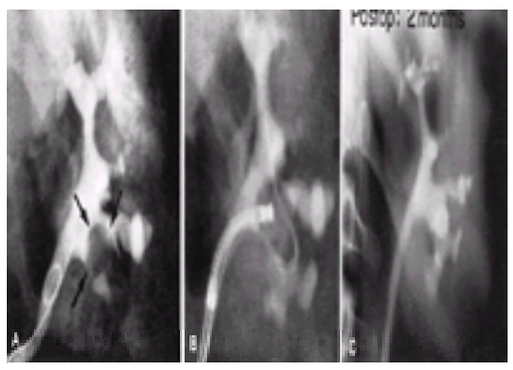

FIGURE 19.7. A: Filling defect *(arrows)* previously identified on an intravenous urogram is clearly delineated on this retrograde ureterogram. A guidewire has been passed up the ureter in preparation for introduction of the flexible ureteroscope. **B:** Via the flexible ureteroscope, a biopsy of the lesion was taken. It was found to be a benign cyst; accordingly, an electrosurgical probe was passed through the ureteroscope and the interior of the cyst was fulgurated. **C:** Two months later a follow-up intravenous urogram reveals no recurrence of the cyst.

When a suspected transitional cell tumor is viewed ureteroscopically, cytology samples are obtained immediately before any biopsies and just after the biopsy procedure via a saline irrigation directly in front of the lesion (186). Next, at least four to five biopsies are obtained. To do this, a 3-Fr biopsy forceps or a diminutive stone basket is passed. In the former instance, the opened biopsy jaws are advanced deep into the lesion; the jaws are then closed and withdrawn from the lesion by pulling the entire endoscope caudal (Fig. 19.8). Thus a larger piece of tissue may be obtained than if the closed biopsy forceps were pulled into the working channel, thereby shearing off the specimen. Alternatively, a stone basket may be opened at the site of the lesion and twirled into the lesion, thus entrapping a large amount of tissue; as the basket is twisted amidst the papillary fronds, tissue is detached and trapped on the wires of the basket. The partially closed basket and endoscope are then withdrawn as a unit, again to preclude shearing tissue from the basket. In Bagley's experience, the use of a biopsy forceps or stone basket produced equivalent results with regard to obtaining a definitive diagnosis, 68% to 76% (186).

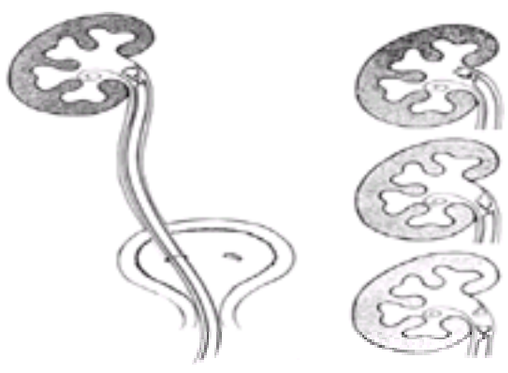

FIGURE 19.8. A 3-Fr biopsy forceps has been passed through the flexible ureteroscope in preparation for biopsying a papillary tumor. Once the jaws have been secured on the tumor, the entire endoscope with the biopsy forceps extended is pulled out of the ureter and urethra, thereby removing a large piece of the tumor. Note that a safety guidewire remains in the ureter. If the forceps is pulled into the endoscope, pieces of the tumor may be sheared off, thereby rendering the specimen too small for diagnostic purposes. Alternatively, a stone basket can be used to trap and avulse the tumor, thereby providing a large specimen for histologic analysis.

(From Clayman RV, Kavousi LR. Endosurgical techniques for noncalculous disease. In: Walsh PC et al, eds. *Campbell's urology,* ed 6. Philadelphia: Saunders, 1992:2254, with permission.)

Two of the biopsies can be sent for cytologic analysis, and the remaining biopsies are sent for routine histologic analysis. It is also helpful to have the pathologist come to the operating room so that the pathologist can appreciate the intact appearance of the lesion; this can be invaluable during the pathologist's subsequent histologic assessment of the diminutive biopsy specimens.

Following the procedure, an indwelling ureteral stent usually is placed; the stent is removed in the office 3 days later. Most of these procedures are completed on an outpatient basis under intravenous sedation. Antibiotic coverage may be given immediately before the procedure and continued orally for 4 days after the procedure.

With regard to antegrade nephroscopy via a percutaneous tract, this is a less desirable means for accessing the upper urinary tract, especially in the patient with a suspected transitional cell cancer. It is far more invasive and morbid than ureteroscopy and does not provide any more information than a ureteroscopic examination (282). As such, antegrade nephroscopy would be used only in the rare instance in which an upper tract lesion could not be visualized adequately, biopsied, or treated through the ureteroscope. In this regard, the nephrostomy tract is positioned as far from the lesion as possible while still remaining on a fairly direct line with the lesion. Accordingly, if the lesion is in the ureter, an upper-pole or middle-posterior-calyceal approach is chosen; however, if the lesion is in the kidney, a remote calyx is selected as long as the surgeon will still be provided with a sufficiently direct route to the tumor such that rigid endoscopic equipment can be used. In addition, concerns over seeding the nephrostomy tract from an unsuspected transitional cell cancer remain a valid albeit unlikely consideration. There has been only one report of such an occurrence (147).

Results

For the most part, the actively deflectable ureteroscopes are preferred to their passive cousins because they allow reliable access to most lesions and permit the examiner to perform a more complete examination of the entire collecting system. Endoscopes smaller than 7.5 Fr have been used usually for diagnostic purposes; these diminutive passive endoscopes are as small as 2 Fr. However, considerably more skill and patience are necessary. Nonetheless, Yoshida and colleagues (380) were able to obtain diagnostic information in 87% of their patients using a 2-Fr passive endoscope, positioned through a 6-Fr guide tube.

Among patients coming to ureteroscopy, a transitional cell cancer is diagnosed in 16% to 40%, and a stone is noted in 18% to 44% (121,181,295). The other common finding is that of a vascular impression or essentially normal urothelium in 16% to 24% (16,181). Less common diagnoses are blood clot, papillary necrosis, fibroepithelial polyp, inverted papilloma, intrarenal cyst, pyelitis cystica, “eccentric” papilla, fungal ball, submucosal hemorrhage, air, and malakoplakia (Table 19.2). In addition, on rare occasions, a renal cell cancer may produce a filling defect in the collecting system without a significant accompanying mass effect in the renal parenchyma (123).

TABLE 19.2. RADIOLUCENT FILLING DEFECTS IN THE UPPER URINARY TRACT: DIFFERENTIAL DIAGNOSIS

Obstruction of the Upper Urinary Tract

In evaluating the patient with upper urinary tract obstruction, the urologist needs to determine both the functional significance and the cause of the obstruction.

The diagnosis of functional obstruction is of primary importance because this, along with the patient's symptoms, helps determine whether the obstruction requires therapeutic intervention. In general, abnormal dilation of the upper urinary tract is initially diagnosed by renal US or intravenous urography. However, the presence of dilation does not mean that there is obstruction (e.g., congenital megacalycosis). Likewise, the presence of dilation may occur in the face of either functionally insignificant narrowing or longstanding obstruction to which the kidney has accommodated, such that the renal pelvis pressure is low and the threat to renal function is nil. Radiographic studies, such as retrograde ureterography or antegrade nephrostogram, provide only anatomic, not functional, information.

As such, once hydronephrosis is noted, the next and most important step is to determine if there is any functional impact. Today, urologists have three studies available to define the significance of narrowing in the upper urinary tract: duplex Doppler renal US, Lasix washout renal nuclear scan, and the antegrade pressure-flow study (i.e., Whitaker test). Of these, the simplest study is duplex Doppler renal US. In this study, an external Doppler US probe is used to determine peak systolic and end-diastolic velocity over the renal interlobar and arcuate arteries. The *resistive index* (RI) is defined as peak systolic velocity minus end-diastolic velocity, divided by the peak systolic velocity. In the face of functionally significant obstruction, the peak systolic velocity is blunted, and thus the RI rises. In general, a RI above 0.75 and a difference in resistive indices of 0.10 or more between the two kidneys is believed to be consistent with functionally significant obstruction. Values between 0.70 and 0.75 with a differential that is greater than 0.05 are equivocal (i.e., gray zone) (275,303,354). In these indeterminate cases, the administration of a diuretic followed by repeat determination of the resistive indices may help classify more accurately the nature of the obstruction (275). Resistive indexes less than 0.70 with a differential of less than 0.05 are normal. Using these parameters, Gilbert and co-workers (113) noted that the results with duplex Doppler renal US were similar to diuretic renography. Similarly, Rodgers and associates (303) noted that among 20 adults with acute renal colic caused by a ureteric calculus, the RI was elevated in 93%. However, other investigators have shown that renal RI measurements may not be valuable in detecting acute urinary tract obstruction. Older and colleagues (272) demonstrated, in 54 patients evaluated by renal RI, that although the mean RIs of the obstructed and nonobstructed patients were statistically different, the wide overlap of the values for each group precluded clinical usefulness for the individual patient. The sensitivity of RI was only 42%, with 11 false-negative results; specificity of RI for obstruction was 79%.

Diuresis renography is the major study used to determine the presence or absence of functionally significant obstruction; however, the test must be administered properly and a standard protocol must be followed in order to obtain meaningful data. Significant variables include the state of renal function, degree of patient hydration, fullness of the bladder at the time of the study, the amount of diuretic given, the type of radiopharmaceutical used, and the point in the examination when the diuretic is administered (235). In the adult, the diuresis renogram is accomplished using intravenous ^{131}I Hippuran (*o*-iodohippurate), ^{123}I Hippuran, or technetium-99m diethylenetriamine pentaacetic acid (DTPA). Renal imaging is done at 2, 5, 10, 15, and 20 minutes after giving the radionuclide with the patient in a supine position. At the 20-minute point, if it appears that the adult kidney may be obstructed, furosemide (40 mg) is given intravenously. In the normal unobstructed, two-kidney situation, half of the radionuclide tracer should drain from the kidney within 12 minutes. If it takes longer than 20 minutes, the kidney is considered obstructed (Fig. 19.9); results between 12 and 20 minutes are considered to be in a gray zone, and the test is deemed inconclusive. The presence of medical renal disease, renal artery disease, or massive hydronephrosis may blunt the response of the kidney to furosemide or alter the dilution of the excreted radionuclide, thereby resulting in a false-positive study; this occurs in 9% to 30% of diuretic scans. On the other hand, a false-negative diuretic scan is rare; hence, if a normal curve is obtained, the system is probably not obstructed. An equivocal result or suspicion of a false-positive result should lead to performance of a Whitaker perfusion test (vide infra) (231,277,278,349).

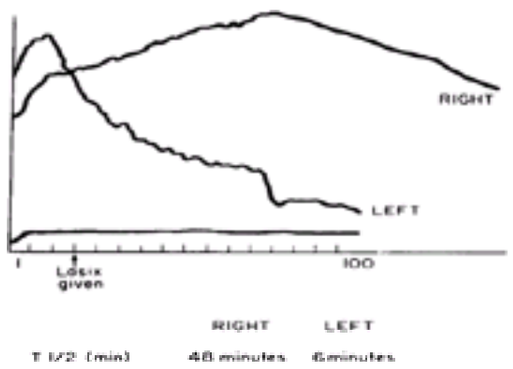

FIGURE 19.9. Lasix washout renogram performed in a patient with an obstructed right kidney. The right kidney shows an abnormal rising curve even before the Lasix is administered. On administration of the Lasix, the normal left kidney clears half of the radionuclide tracer in 6 minutes; however, the obstructed right kidney does not clear half of the tracer until 48 minutes, thus indicating its obstructed status. (From Clayman RV, Kavousi LR. Endosurgical techniques for noncalculous disease. In: Walsh PC et al, eds. *Campbell's urology,* ed 6. Philadelphia: Saunders, 1992:2269, with permission.)

In an effort to obtain more accurate information from diuresis renography, work by the Society for Fetal Urology and the Pediatric Nuclear Medicine Club of the Society of Nuclear Medicine has resulted in development of a standardized regimen for diuresis renography in children; as yet, a similar protocol is not available for adults (58). In the pediatric regimen, the bladder is catheterized; the patient receives intravenous hydration for at least 15 minutes before the study (15 mL/kg per 30 minutes); urine output response to the diuretic is measured; and the diuretic dose is standardized at 1 mg/kg of furosemide. The preferred radionuclide is 99m-technetium mercuroacetylglycylglycylglycine (^{99m}Tc MAG3) because it is rapidly cleared by the kidney and is primarily excreted by the tubules. The percent function of the affected kidney is determined; a half-life is calculated; and a clearance curve is generated. The curves can be divided into one of four groups: normal, obstructed, hypotonic pelvis, and equivocal (277). In general, a normal study would include renal function of 50% plus or minus 10% and a half-life of 10 minutes or less. If the half-life is 10 to 20 minutes, this is considered equivocal for obstruction, and a half-life greater than 20 minutes is compatible with significant obstruction (278,349).

In addition, other investigators have used the data accrued during diuretic renography to calculate a variety of other indicators that at times are useful in uncovering obstruction when the diuresis renogram is otherwise equivocal. These calculations include the normalized renal slope ratio, renal output efficiency, and calculations designed to relate renal volume to the rate of emptying of the collecting system (34,38,382). These other determinations are used to neutralize the two major causes of false-positive renal scans: compromised renal function and a dilated, phlegmatic renal pelvis. With use of these additional calculations, specificity could be increased from 85% to the 94% to 98% range using the normalized renal slope ratio, and accuracy rates of 94% were attained in patients with compromised renal function using the renal output efficiency formula. In another effort to overcome potential problems caused by a dilated system, Rossleigh and co-workers (305) have advocated obtaining an additional view after standard diuresis renography; this view is obtained after the child ambulates for 5 minutes or after the infant has been held upright for 10 to 15 minutes. In examining 12 children suspected of recurrent obstruction after a pyeloplasty; 64% of the postoperative patients who appeared to be obstructed on routine diuresis renography were not obstructed on the gravity-assisted drainage views. However, the gravity-assisted view was helpful in only 1 of 12 patients with suspected obstruction before a surgical procedure; for these children, routine diuresis renography was satisfactory. Upsdell and associates (361) have described giving furosemide 15 minutes before administering the radionuclide (the F-15 renogram); this results in a marked diuresis at the inception of the study. The authors found that this method of performing the renogram resulted in fewer equivocal results.

The Whitaker test is the most invasive means of determining the presence or absence of functionally significant obstruction in the upper urinary tract (374) (Fig. 19.10). This test is done in the interventional radiology area under fluoroscopic control with the patient in a prone position. Usually a 20- or 22-gauge nephrostomy needle or an 8-Fr catheter is percutaneously passed into the collecting system. A Foley catheter is placed in the bladder. Using a three-way stopcock, dilute contrast is infused through the nephrostomy tube until the collecting system is fully distended. Then the flow is increased to 10 mL per minute; pressure readings of the renal pelvis and the bladder are taken at 5-minute intervals until a steady state is reached. If the pressure differential between the renal pelvis and the bladder remains less than 15 cm H_2O, the test is negative for obstruction; if the differential pressure exceeds 22 cm H_2O, the test is considered positive. Differential pressures between 15 and 22 cm H_2O are in the gray zone. For patients with an indeterminate reading, the flow rate can be increased to 15 mL per minute; the differential pressure, once a steady state is reached, should not exceed 18 cm H_2O (262).

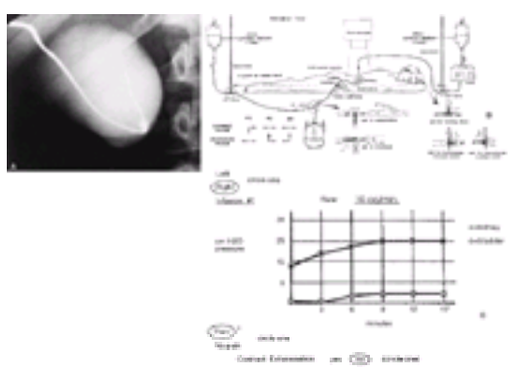

FIGURE 19.10. A: An antegrade nephrostogram reveals a hydronephrotic right kidney secondary to ureteropelvic junction obstruction. **B:** The setup for the Whitaker test consists of a pump to deliver fluid through the nephrostomy cannula, a pressure manometer connected to the nephrostomy cannula, a bladder catheter, and a pressure manometer connected to the bladder catheter. **C:** The values from the Whitaker test are plotted on a graph. In this patient, the pressure differential between the bladder and the kidney is 23 cm; the test indicates that there is a functionally significant obstruction at the ureteropelvic junction. (From Clayman RV, Kavousi LR. Endosurgical techniques for noncalculous disease. In: Walsh PC et al, eds. *Campbell's urology,* ed 6. Philadelphia: Saunders, 1992:2270, with permission.)

In contradistinction to the diuretic renogram, the most common problem with the Whitaker test is that of a false-negative study. This occurs because of inadequate filling of a large floppy renal pelvis, extravasation during the study, recording “final” pressures before a steady state has been reached, and renal intravasation caused by pyelovenous, pyelosinus, or pyelolymphatic backflow. Also, in some patients the UPJ obstruction is of an intermittent nature depending on the patient's position and the amount of urine output at a given point in time. As such, the obstruction actually may be relieved when the patient is lying prone; thus it may be necessary to repeat the Whitaker study with these patients in either a supine or sitting position.

The overall reliability of the Whitaker test is high. Laboratory studies by Ryan and colleagues (306) have confirmed the accuracy of the Whitaker test in detecting functional obstruction in a canine model. Clinically, Bouchot and co-workers (32) reviewed their findings with Whitaker tests and diuretic renograms in 47 children. They noted that the overall accuracy of the Whitaker test was 90.5% among children with hydronephrosis. However, the Whitaker and diuretic renogram studies were *not* in agreement in 43% of the cases. Again, most of the problems were due to false-positive or equivocal renogram curves. Similarly, O'Reilly (277) and Krueger and associates (206) independently noted that in 9% to 30% of cases in which the diuretic renogram was positive, the Whitaker test was negative for obstruction. However, in the same series, the Whitaker test was inaccurate in 15% of patients largely because of a false-negative result. Overall, the most diagnostically reliable situation occurs when both the diuresis renogram and the Whitaker test are positive; this occurs in only 40% to 60% of cases overall.

THERAPEUTIC URETERAL APPLICATIONS

Ureteral Strictures

With respect to ureteral strictures, from an endourologic standpoint, the ureter can be divided into three areas: proximal, middle, and distal. When discussing stricture

disease, the proximal and distal portions of the ureter are quite short: the proximal ureter is primarily the few centimeters of the ureter just below the UPJ, and the distal ureter stretches from the ureteral orifice to just above the ureterovesical junction. The middle ureter includes the ureter beginning just below the iliac vessels, crossing the bony pelvis, and the majority of the ureter lying in the soft tissues of the retroperitoneum. The predominant cause of a ureteral stricture is iatrogenic (i.e., ureteroscopy, gynecologic surgery, or ureteral surgery). The distal ureter is most commonly the site of stricture disease.

Endoscopic ureteral dilation was described initially in 1891 by Pawlick, when he used ureteral bougies cystoscopically to dilate strictures secondary to tuberculosis (249). In 1907, Nitze designed a catheter with a terminal inflatable balloon to dilate and occlude the ureter (264). In 1926, Dourmashkin (77,78) dilated the ureter with a series of rubber bags attached to hollow bougies. He regularly dilated ureters up to 20 Fr and, on occasion, up to 30, 46, and 54 Fr, enabling a stone expulsion rate of 68% in his patients. In 1978, Gruntzig (126) reported percutaneous transluminal coronary angioplasty using a dilating catheter with a 3.0- to 3.8-mm balloon at the tip; these balloons were later used to dilate ureteral strictures. The concomitant development of the 9- and 11-Fr ureteroscope by Perez-Castro and Martinez-Pineiro (289) led to a renewed interest by urologists in the endourologic treatment of ureteral strictures. With improved optical capabilities and smaller endourologic instrumentation came the advent of diagnostic biopsy and therapeutic incision of endoscopic ureteral strictures.

Technique

Catheter Dilation

Catheter dilation is performed over a guidewire with multiple tapered, ureteral dilators passed under fluoroscopic control. The 0.035-inch, floppy-tip guidewire is passed into the upper collecting system under fluoroscopic control. The 5-Fr angiographic catheter is passed over the floppy-tip guidewire to secure access to the upper collecting system, and the guidewire is exchanged for an Amplatz superstiff guidewire. The 5-Fr catheter is removed. The ureteral dilators are sequentially passed over the guidewires, progressing from a 5-Fr up to a 14-Fr dilator. Following the dilation, a 7- or 8-Fr ureteral stent is placed for 4 to 6 weeks (378). However, serial, rather than single, ureteral dilations may be necessary for stricture resolution.

Balloon Dilation

Since the introduction of transluminal balloon dilation by Gruntzig in 1978 (126), this concept has been accepted widely by urologic surgeons as a technique to dilate the ureteral orifice and intramural ureter before ureteroscopy. Balloon dilation also has been used in the management of stricture disease.

The technique of balloon dilation of the ureter involves four steps to complete the procedure: (a) access to the upper urinary tract, (b) placement of the dilating balloon catheter, (c) activation of the dilating balloon, and (d) placement of a ureteral stent. Fluoroscopy is essential to each of these steps to ensure appropriate positioning and activation of the dilating balloon catheter.

The patient is positioned in the lithotomy position, usually under general or regional (e.g., spinal or epidural) anesthesia. Cystoscopy is performed and a 0.035-inch Bentson guidewire is introduced into the ureteral orifice. Using fluoroscopic guidance, the surgeon advances the guidewire along the course of the ureter, past the stricture, and positions it with the floppy tip coiled in the renal pelvis.

When the Bentson guidewire will not traverse past the stricture, a Terumo guidewire may be used. The lubricated, hydrophilic polymer coating of this guidewire greatly facilitates its passage through the narrowest ureteral stricture. It is essential to keep the surface of this guidewire constantly moistened with water or saline to achieve the maximum reduction of surface friction. However, because of its slippery nature, once positioned in the upper collecting system this guidewire can fall out easily. Therefore, once this guidewire has been passed, a 5-Fr angiographic catheter is passed over it. The Terumo guidewire is exchanged for a 0.035-inch Bentson or a 0.035-inch Amplatz superstiff guidewire. The 5-Fr angiographic catheter is then removed, leaving the stiffer guidewire in position in the upper collecting system.

Ureteral dilating balloon catheters are available in a wide variety of sizes (5 to 12 mm) and balloon lengths (2 to 8 cm). For dilating ureteral strictures, an 8-mm-diameter, 4-cm-long balloon is usually used; the balloon should be rated to withstand pressures of greater than 10 atm. The dilating balloon exerts a radially distributed force perpendicular to the ureteral mucosa and is designed to be inflated with fluid. A pressure gauge is placed between the syringe and the balloon; the recommended pressure limit of the balloon should not be exceeded, or else the balloon may rupture within the ureter and cause significant ureteral damage.

The dilating balloon catheter is passed over the guidewire into the ureter under fluoroscopic monitoring. Proximal and distal metal markers on the balloon catheter indicate radiographically the borders of the balloon and allow it to be positioned accurately; the balloon should straddle the “contrast”-outlined stricture. Using a handheld pressure-generating syringe (e.g., LeVeen) with an incorporated pressure gauge, the clinician inflates the balloon with a 50:50 mixture of contrast medium and saline solution under fluoroscopic monitoring. The balloon is initially inflated up to 1 atm of pressure, following which it is inflated at a rate of 1 mL of contrast mixture per minute under fluoroscopic control until the waist in the balloon at the site of the stricture disappears. If the pressure rating of the balloon is reached and the waist is still present, an endoincision (vide infra) will be necessary. Once the waist disappears, the inflated balloon is maintained in position for 2 to 5 minutes before it is deflated; the balloon is then reinflated. If the stricture has truly been torn, the balloon should now fill out at a low pressure. In contrast, if the balloon fails to fill out at low pressure, the stricture has not been treated adequately and an endoincision (vide infra) will be necessary. Following deflation of the balloon, the catheter is removed from the ureter leaving the guidewire in position. An indwelling ureteral stent (either a 7- or 8-Fr or a 7-/14-Fr stent) is then placed fluoroscopically over the guidewire. The ureteral stent is maintained for 4 to 6 weeks.

Clayman and colleagues (50) studied the effects of rapid and slow balloon dilation of the distal ureter to 8 mm (24 Fr) in the pig model. They showed that dilating the ureter to 8 mm (24 Fr) was safe. Slow dilation, over a 10-minute period, produced less residual inflammation 6 weeks following dilation compared with the rapid-dilation (less than 10 seconds) group. However, both groups had similar epithelial denudation, inflammation, and submucosal hemorrhage immediately following the dilation. Selmy and colleagues (324) studied the effect of balloon dilation of the ureter on upper tract dynamics and ureteral wall morphology in the pig model. They found that 1 week after ureteral dilation there was circumferential edema in the lamina propria and thinning of the muscularis propria; this correlated with obstructive urodynamic changes and grade 2 reflux in one-third of the animals. Over a 6-week period, there was gradual resolution of the pathologic inflammatory changes, disappearance of the obstructive changes, and return to radiographically normal ureters. Their observations favor a 6-week stinting period.

Endoincision

The development of the smaller rigid ureteroscope (6.9 Fr), the smaller flexible ureteroscope (7.5 Fr), and accompanying ancillary instruments for use with these endoscopes has made visualization and manipulation of the ureter and upper urinary tract an easier and safer procedure. Cutting modalities for incision of a ureteral stricture include the cold knife, electrosurgical probes, and the Ho:YAG laser.

Strictures in the proximal ureter are incised using a technique similar to an antegrade endopyelotomy. A percutaneous nephrostomy tract is established such that there is a straight-line access to the UPJ region and ureter. The straight posterior or posterolateral incision in the ureteral stricture is full thickness until retroperitoneal fat is seen. The caudal extent of the incision should be 1 cm beyond the area of the stricture. The cephalic portion of the ureteral incision should be into the renal pelvis. Following the incision, an indwelling 7- or 8-Fr double pigtail or 7-/14-Fr endopyelotomy stent is placed in an antegrade fashion. A small 14-Fr nephrostomy tube and Foley catheter also are inserted postoperatively. A nephrostogram is performed 36 to 48 hours postoperatively.

When there is no evidence of extravasation at the site of the ureteral incision, the nephrostomy tube and Foley catheter may be removed. The ureteral stent is usually maintained for 4 to 6 weeks (88,183,318).

The middle ureteral stricture is the most difficult to manage endosurgically. Middle ureteral strictures may be approached in an antegrade or a retrograde fashion. The antegrade approach is identical to an antegrade endopyelotomy except that the cephalad extent of the incision travels 1 cm into normal ureter rather than entering the UPJ. The retrograde approach is similar to a retrograde endopyelotomy except that the proximal limb of the incision remains in the confines of the middle ureter, and in some cases, the short rigid ureteroscope with or without an insulated sheath may be used. In the retrograde approach, after securing a guidewire across the stricture and into the upper collecting system, the intramural ureter is balloon dilated to 15 Fr. This allows introduction of the 12-Fr ureteroscope, through which a cold knife may be passed. Alternatively, ureteral dilation may be omitted and the rigid 6.9-Fr or flexible 7.5-Fr ureteroscope may be introduced, through which a 3-Fr or smaller electrosurgical device or 200-micron holmium laser probe may be passed to perform the incision (Fig. 19.11). The stricture is incised posterolaterally if it lies above the iliac vessels, anterior if it overlies the iliac vessels, and anteromedially if it lies just below the iliac vessels; the full-thickness incision through the stricture is extended 1 cm above and 1 cm below the stricture region into normal-caliber ureter.

FIGURE 19.11. A: A benign, left ureteral stricture with hydroureter on intravenous pyelography. **B:** A guidewire has been passed retrograde into the upper collecting system. The ureteral dilating balloon catheter is filled to 1 atm pressure, and persistent waisting *(arrow)* of the balloon corresponds to the area of stricture. **C:** With the deflated dilating balloon catheter still in position, the short, rigid ureteroscope is inserted to the level of the stricture. A 3-Fr, right-angle electrosurgical probe is used to incise the stricture full thickness, extending the incision 1 cm above and 1 cm below the strictured region. **D:** Following incision of the stricture, inflation of the ureteral dilating balloon to 1 atm pressure demonstrates resolution of the area of waisting, confirming adequate incision of the stricture. **E:** A 7-/14-Fr double pigtail ureteral stent is positioned in the upper collecting system with the 14-Fr portion traversing the region of the ureteral incision.

In male patients, with a middle ureteral stricture above the iliac vessels, a 7.5-Fr flexible ureteroscope is recommended. A nonconducting Terumo guidewire is passed across the stricture, followed by passage of an 8-Fr dilator and 10-Fr sheath. The 8-Fr dilator is removed, and a side-arm adaptor is placed on the 10-Fr sheath; a retrograde ureterogram is performed to delineate the stricture, following which a second guidewire is passed by the ureter and into the renal pelvis. The 10-Fr sheath is removed. One guidewire is fixed to the drapes with a clamp, thereby becoming the safety guidewire. The flexible ureteroscope is passed over the second (i.e., working) guidewire. Once the ureteroscope is delivered to the ureter, the working guidewire is removed.

If the flexible ureteroscope buckles at the ureteral orifice or does not pass easily up the ureter to the site of the stricture, the flexible ureteroscope is exchanged for a ureteral access sheath. Once the 14-Fr end of the sheath is delivered well into the distal ureter, the 12-Fr dilator is removed. The flexible ureteroscope is then passed over the working guidewire through the 14-Fr sheath and into the ureter. The safety guidewire remains in place alongside the access sheath.

The flexible ureteroscope necessitates the use of a 2- or 3-Fr electrosurgical or less than 400-micron laser Ho:YAG probe. Periureteral damage from use of electrosurgical devices with a greater than 400-micron tip is similar to a cold-knife incision (75). Using visual orientation in combination with fluoroscopy in two planes, a full-thickness incision is made posterolaterally in the ureter above the iliac crossing, anteriorly in the ureter overlying the iliac vessels, or anteromedially in the ureter below the iliac vessels. Retroperitoneal or periureteral fat should be exposed by the endoincision, which extends 1 cm proximal and 1 cm distal to the ureteral stricture. After the stricture incision is completed, an indwelling ureteral stent (a 7- or 8-Fr double pigtail stent or a 7-/14-Fr endopyelotomy stent) is placed. When the 7-/14-Fr stent is used, it should be positioned such that the 14-Fr portion traverses the region of the ureteral incision. A Foley catheter is used to drain the bladder postoperatively. A cystogram 36 to 48 hours postoperatively usually confirms cessation of extravasation at the region of the ureteral incision, which permits removal of the urethral catheter. If extravasation is still present, the patient is discharged from the hospital with the urethral catheter still in place. An outpatient cystogram and catheter removal can be done 1 week later provided that a postoperative urine culture is sterile.

The distal ureteral stricture is usually at the ureteral orifice, the intramural tunnel, or just at or slightly above the ureterovesical junction. These strictures are incised such that the lower limb of the incision extends through the ureteral orifice (61). The retrograde approach is used most commonly for distal strictures. Cystoscopically, a guidewire is manipulated past the region of the stenosis and positioned fluoroscopically in the upper collecting system. An 8-mm, 4-cm-long ureteral dilating balloon catheter is passed over the guidewire after the cystoscope has been removed. Fluoroscopically, the balloon is positioned in the distal ureter such that the metal, lower radiopaque markers on the balloon lie just caudal to the ureteral orifice in the bladder. The balloon is inflated with a 50:50 mixture of contrast solution and saline stained with indigo carmine to a low pressure (i.e., 1 atm). The site of the stricture thus should be well outlined (i.e., a visible waist should appear in the balloon at the stricture site). A standard Iglesius resectoscope sheath is then inserted into the bladder. The proper positioning of the balloon catheter in the intramural ureter is confirmed visually. A right-angle, Orandi or Collins, electrocautery knife attachment is placed through the resectoscope sheath. Using 50 W pure cut, the surgeon begins the incision at the 12 o'clock position of the ureteral orifice and extends it cephalad through the ureteral orifice, ureteral tunnel, and for a distance of 1 cm cephalad to the area of stricturing. Following completion of an adequate incision, the 8-mm balloon should inflate fully at less than 1 atm of pressure. The dilating balloon is then deflated and removed. An indwelling 7- or 8-Fr double pigtail stent or a 7-/14-Fr endopyelotomy stent is placed over the guidewire; when the latter is used, the 14-Fr portion of the stent traverses the distal ureter. A Foley urethral catheter is used to drain the bladder. A cystogram 36 to 48 hours postoperatively is performed to confirm the resolution of any extravasation, following which the urethral catheter may be removed. The indwelling stent is removed on an outpatient basis 4 to 6 weeks following the stricture incision.

The Acucise cutting balloon device also has been used in the management of proximal and distal ureteral strictures (40) (Fig. 19.12). This technique involves placement of a nonconducting Terumo guidewire past the stricture and into the upper collecting system. The balloon catheter is positioned across the strictured region of the ureter under fluoroscopic control. In the proximal ureter above the iliac vessels, the cutting wire is oriented posterolateral, whereas below the iliac vessels the balloon cutting wire is directed anteromedially to avoid the branches of the internal iliac artery and vein, which are lateral to the ureter. *Strictures lying directly over the iliac vessels should not be approached with the cutting balloon device.* This type of ureteral stricture is better approached using direct ureteroscopic visualization and an electrosurgical probe because the surgeon can more accurately confirm visually the precise anterior location of the planned incision.

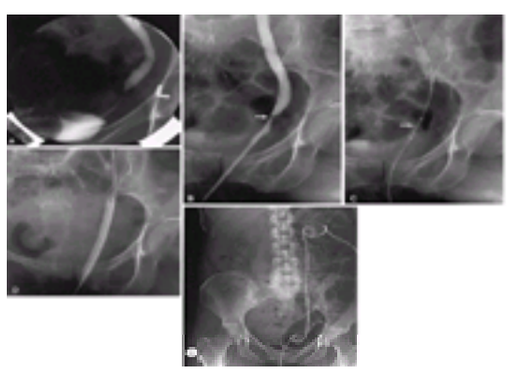

FIGURE 19.12. A: Distal left ureteral stricture with hydroureter on nephrostogram evaluation. **B:** Flexible cystoscopy is performed, and a 0.035-inch Terumo guidewire is passed through the strictured region *(arrow)* of the ureter in the upper collecting system. **C:** The cutting balloon catheter is passed over the guidewire and positioned with the cutting wire *(arrow)* oriented medially and traversing the region of the ureteral stricture. The radiopaque markers outline the exposed cutting wire, which is presented to the tissues as the balloon is inflated at a low pressure. **D:** Following incision of the stricture, a ureteral dilating balloon catheter inflated to 1 atm pressure confirms no residual waisting at the level of the stricture. **E:** A 7-/14-Fr double pigtail ureteral stent is positioned in the upper collecting system with the 14-Fr segment traversing the region of the ureteral stricture. The nephrostomy tube (placed preoperatively) and the Foley catheter are removed 24 to 48 hours postoperatively when a cystogram or nephrostogram indicates no residual extravasation at the site of the ureteral incision.

After positioning the cutting balloon catheter in the appropriate orientation, using two-plane fluoroscopy, the surgeon inflates the balloon with 2 mL of a 50:50 contrast solution and saline mixture while simultaneously activating the cutting wire with 75 to 100 W of pure cut electrical current. Inflation of the balloon carries the activated wire through the tissues. This portion of the procedure should take less than 3 seconds. The balloon is left inflated for 10 minutes, and then it is deflated and pulled retrograde. By affixing a side-arm adaptor over the guidewire and onto the cutting balloon catheter, a retrograde ureterogram can be obtained. This study should confirm extravasation from the site of the incision. The cutting balloon catheter is then removed. A 5-Fr angiographic catheter is passed over the Terumo guidewire

into the upper collecting system. The Terumo guidewire is exchanged for a 0.035-inch Amplatz superstiff guidewire, and the 5-Fr catheter is removed. An indwelling ureteral stent (a 7- or 8-Fr double pigtail stent or a 7-/14-Fr endopyelotomy stent) is passed over the guidewire and positioned fluoroscopically in the upper collecting system. The 7-/14-Fr endopyelotomy stent is positioned such that the 14-Fr portion of the stent traverses the region of the ureteral incision.

The more challenging problem, associated with ureteral stricture disease, occurs when the retrograde ureterogram reveals complete ureteral obstruction. A percutaneous nephrostomy tract is established. With the patient lying prone, the extent of the stricture can then be estimated through a combined antegrade nephrostogram and retrograde ureterogram. The latter is secured after using prone flexible cystoscopy to place the retrograde catheter; in some cases, the flexible ureteroscope can also be passed with the patient prone so a “cut-to-the-light” procedure can be done. A short (less than 1 cm) occlusion may be approached endosurgically. Bagley (11) has reported successful recanalization of complete ureteral obstructions up to 5 cm in length. However, in general, ureteral occlusions longer than 2 cm are better managed with an open surgical procedure.

The site of complete ureteral occlusion may be accessed antegrade by developing the percutaneous nephrostomy tract and passing a flexible nephroscope or short rigid ureteroscope down to the obstruction. Concomitantly, a flexible ureteroscope may be passed in a retrograde fashion to the distal end of the occlusion. If the ureteral stricture is short, the light from the retrograde endoscope may be identified and the tips of the two endoscopes may be aligned using fluoroscopy in an anteroposterior and then oblique projection. With a rigid ureteroscope passed antegrade, a direct incision using a cold knife may be performed onto the tip of the retrograde endoscope. Also, the surgeon can be guided by the light coming from the retrograde endoscope. In this case, the light through the antegrade endoscope is turned off. If the two endoscopes are properly aligned, a bright pink light should be seen through the stricture. As the incision is made toward the light, the light should become more white in appearance until the tip of the retrograde endoscope is clearly visualized. A 260-cm exchange guidewire is then passed through the retrograde instrument and retrieved by the antegrade endoscope. After establishing a guidewire across the stricture, the surgeon can complete the incision through full thickness of the scar and balloon dilation to 8 mm can be used to confirm the adequacy of the incision before placing a ureteral stent. When a flexible endoscope has been passed antegrade, an electrosurgical probe is used to incise the stricture. Alternatively, a stylet guidewire (e.g., rocket wire with a sharp tip from a Lawson retrograde nephrostomy kit) may be passed through the retrograde endoscope to create an indentation on the scarred ureteral tissue and to guide the incision by the antegrade instrument under direct visualization. Alternatively, this sharp wire can be passed, under fluoroscopic control, through the lower end of the stricture and retrieved proximally; the stricture can then be balloon dilated.

Following incision of the stricture, a long-acting steroid (e.g., triamcinolone 40 mg/mL) may be injected into the bed of the incised stricture (243). A 3-Fr Greenwald injecting needle catheter is passed via the rigid or flexible ureteroscope, and 3 to 5 mL of triamcinolone (40 mg/mL) is injected into any dense scar tissue bordering the ureteral incision. A pressure syringe (e.g., LeVeen) is helpful to inject the medication into this area.

Among patients with a particularly long stricture (i.e., longer than 2 cm), a rarely used alternative to open surgical repair is the placement of a free urothelial graft (49,243). With use of a 28-Fr Iglesius resectoscope equipped with an Orandi knife, a 2- to 4-cm-long piece of urothelium from the bladder is incised and carefully lifted off of the dome or base of the bladder. The donor site is cauterized with a roller electrode. The graft is meticulously defatted, following which the thin urothelial surface of the graft is sutured, facing inward, onto a 7-Fr ureteral stent using 5-0 chromic suture. Via a 14-Fr ureteral access sheath, the stent is fluoroscopically positioned in place so the graft-bearing portion of the stent traverses the area of the incised stricture; as the 14-Fr sheath is pulled retrograde, the stent-bearing graft is kept in place with a metal tip stent pusher. A urethral catheter is left in place and the patient is kept on bed rest for 48 hours. The urethral catheter is removed on postoperative day 7; the stent is removed after 6 weeks.

For totally occlusive strictures of the distal ureter, a percutaneous nephrostomy is placed. Through this site, a guidewire and ureteral dilating balloon catheter may be positioned into the distal ureter to the level of the obstruction. The balloon of the catheter should be constructed such that it is *flush* with the tip of the catheter. The balloon is inflated with a 50:50 mixture of contrast medium and saline solution stained with indigo carmine until a pressure of 1 atm is reached. An Iglesius resectoscope sheath is inserted into the bladder; after fluoroscopically aligning the tip of the Orandi electrosurgical knife over the balloon in two planes, an incision is made through the intervening tissue directly onto the inflated balloon. The balloon is thereby uncovered as the overlying sclerotic bladder and ureteral tissues are incised. A 260-cm exchange guidewire is passed through the balloon catheter and retrieved through the bladder. This through-and-through guidewire is then used to place a 7-Fr or 7-/14-Fr indwelling ureteral stent.

A Foley urethral catheter is inserted into the bladder to complete the procedure. A cystogram, 36 to 48 hours postoperatively, usually shows no evidence of extravasation, and the urethral catheter is removed. If extravasation persists, the catheter is maintained for another 7 days before repeating the cystogram. The indwelling stent is removed on an outpatient basis 4 to 6 weeks postoperatively.

Recently, Nissenkorn and Gdor (263) reported their experience with a nephrovesical stent for management of complete ureteral obstruction secondary to metastatic prostate or invasive bladder cancer (Fig. 19.13). The proximal end of a specially designed 7-Fr double pigtail stent is inserted into the renal pelvis via a percutaneous nephrostomy puncture. A subcutaneous tunnel is created from the flank to the suprapubic region, down which the distal end of the stent is passed. The stent is passed into the bladder through a suprapubic bladder puncture. This stent is changed every 4 months over a guidewire, using a small flank incision to access the subcutaneous nephrovesical stent.

FIGURE 19.13. A left, subcutaneous nephrovesical stent has been placed in this 32-year-old woman with complete obstruction of both distal ureters secondary to metastatic breast carcinoma.

Results

When evaluating the literature with regard to the management of ureteral stricture disease, it is important to review the cause of the stricture. Ureteral strictures secondary to radiation therapy or resulting from extraluminal metastatic malignancies, causing periureteral compression, respond poorly to endoureterotomy (216). In contrast, patients with a concomitant ureteral stone and an apparent ureteral stricture usually have resolution of the stricture following removal of the stone and alleviation of the inflammatory response to the stone; incising these strictures may falsely inflate the endoureterectomy success rate.

The development of high-pressure arterial balloon-dilating catheters allowed this technology to be applied to ureteral stricture disease. Several investigators have reported favorable results with balloon dilation of ureteral strictures. Success rates range from 48% to 88%, with an overall average of 55% in 271 patients (19,24,41,170,193,203,216,261,268) (Table 19.3). However, there appears to be limited consensus among the reports of balloon dilation on the optimal balloon size and technique to perform the procedure. In the literature, the dilating balloon size varies from 4 to 10 mm and the duration of balloon inflation ranges from 30 seconds to 10 minutes for anywhere from one to several inflation cycles. Also, there is no agreement on the size of stents or duration of stinting following balloon dilation; stent sizes range from 6 to 16 Fr, and stent duration ranges from 2 days to 12 weeks. In many of the reports, the success of the procedure is assessed on the basis of subjective relief of the patients' pain or symptoms. When objective studies are provided, they are often not more than 6 months after the procedure. These criteria are unreliable and could inaccurately inflate the success rate reported by 15% or more.

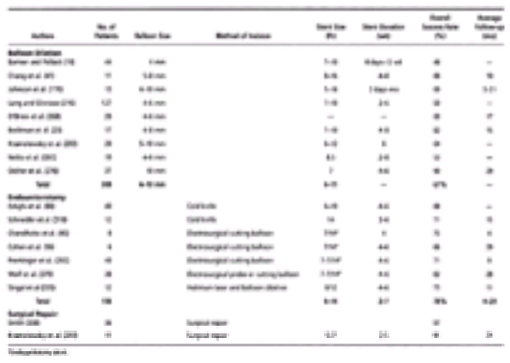

TABLE 19.3. MANAGEMENT OF URETERAL STRICTURES

Endoureterotomy, either endosurgical or fluoroscopic (i.e., cutting balloon), for middle and distal ureteral stricture disease appears to have good clinical results with success rates ranging from 66% to 88%. The overall success rate for 156 patients undergoing endoureterotomy is 78%, which appears to be better than the overall success rate of 67% noted for balloon dilation (Table 19.3). However, there is no apparent consensus on the ideal cutting modality used for the endoureterotomy. Cold-knife incision of the ureteral stricture appears to be as efficacious as electrosurgery and Ho:YAG laser in performing endoureterotomy (40,293,318,335). Figenshau and colleagues (95) investigated the acute tissue changes occurring in the pig ureter following balloon dilation (5 mm), cutting balloon, and endoscopic incision with a cold knife, Nd:YAG laser, or electrocautery as endosurgical management of ureteral strictures. This study used small 250- and 660-micron electrocautery probes. There was no significant difference in the degree of tissue injury among the various cutting modalities used except for the larger 660-micron electrosurgical probe. Unlike a ureteral incision balloon, dilation resulted in injury to the lamina propria but did not appear to split the muscularis and adventitial layers.

The optimal stent size and duration of stenting remain undetermined. Animal studies have shown that for middle ureteral stricture, the larger size stent (i.e., 14 Fr) provides similar results to a 7-Fr stent (247). Similarly, Kerbl and co-workers (187) could find no difference in the healing of ureteral strictures regardless of whether a 1-, 3-, or 6-week period of stenting was selected.

Although balloon dilation and endoureterotomy for ureteral strictures have impressive success rates, these do not duplicate the very high 91% to 97% success rate achieved with open surgical repair of ureteral strictures (203,261). There may be several reasons for the discrepancies noted in these comparisons. The success of any treatment modality may depend on the length of the ureteral stricture, the cause of the stenosis, and the location of the stricture; until now, strictures of similar nature have not been studied in an effort to cull from the general category of ureteral stricture those strictures that would best respond to an endourologic approach.

Several investigators have noted that long ureteral strictures tend to be associated with poorer success rates despite the use of balloon dilation or endoincision. Beckmann and colleagues (24) noted that in 25 patients with strictures shorter than 2 cm, balloon dilation was successful in 84%. Conversely, among eight patients with strictures longer than 2 cm, dilation succeeded in only 50%. Chang and colleagues (41) and Netto and colleagues (261) separately concluded that strictures longer than 1 cm rarely responded well to balloon dilation. The same observation has been noted in the literature on the use of incision of ureteral strictures. Meretyk and colleagues (243) found that the best results following endoureterotomy were in those patients with strictures less than 2 cm. Schneider and colleagues (318) reported that the longest stricture they treated by cold-knife incision was 2.5 cm in length, and this patient reobstructed 24 hours after removal of the ureteral stent. Therefore it would appear appropriate to apply endosurgical management to only patients with strictures less than 2 cm in length.

The cause of the ureteral stricture also has a significant impact on the success of the endosurgical treatment results. The most common cause (23%) of ureteral stricture in the Meretyk series was postoperative fibrosis following open pelvic surgery or a ureteroscopic procedure (243). These relatively nonischemic strictures respond better to endosurgical treatments than do poorly vascularized strictures (19,41,216,243,318). Other causes of ureteral stricture include intrinsic inflammatory processes, such as schistosomiasis, tuberculosis, or radiation injury (82,170,193,261,299,328). The ischemic stricture associated with radiation responds poorly to endoureterotomy.

Extrinsic processes resulting in ureteral stricturing include retroperitoneal fibrosis, endometriosis, and retroperitoneal malignancies (170,243,261). Those processes causing extrinsic compression of the ureter do not respond to balloon dilation or incision of the ureter. As such, ureteral strictures secondary to retroperitoneal fibrosis are more appropriately managed by releasing the ureter from the retroperitoneal fibrosis and transposing it into an intraabdominal position or treating the underlying disease process.

Likewise, for ureteral strictures associated with a malignancy, a nephrovesical stent or endoluminal metal stent (i.e., Wallstent) or a permanent nephrostomy tube is indicated (62,226,263,286). Lopez-Martinez and colleagues (226) have used the nephrovesical stent in eight patients with metastatic prostate cancer. The average duration of stent patency was 19 months (range of 1 to 48 months). Five patients reobstructed because of recurrent tumor, and in two patients additional stents were telescopically placed. Three patients died of metastatic cancer with the stent *in situ.* Six patients at risk at 12 months had patent stents compared with 3 of 5 at 24 months, 2 of 2 at 36 months, and 1 of 1 at 48 months. Nissenkorn and Gdor (263) have used the nephrostomy-diverting stent in eight patients with metastatic prostate and invasive bladder cancer. With a mean follow-up of 5.5 months, the stents functioned well and eliminated the percutaneous nephrostomy during the terminal stages of the patients' disease.

The anatomic location of the ureteral stricture also has been cited as a factor affecting the success of endoureterotomy. Smith (338) showed that in a series of 28 patients with ureteral stricture disease, all 4 patients with a middle ureteral stricture failed balloon dilation. Similarly, Meretyk and colleagues (243) noted a 25% success rate for endourologic incision of middle ureteral strictures compared with an 80% success rate for distal ureteral strictures. Likewise, proximal ureteral strictures, specifically secondary UPJ obstruction, respond well (i.e., 80%) to an endoincision. As such, marsupializing one limb of the stricture into the bladder or renal pelvis appears to provide a better success rate than strictures in the middle ureter, which by definition remain bound by normal ureter above and below the treatment region.

Contrary to earlier reports, it now appears that the duration of a ureteral stricture before treatment has no significant effect on the success rate of the therapy. When the factors of stricture length, location, and cause are controlled, the duration of the stricture does not alter the ultimate outcome. Successful endosurgical therapy has been reported in strictures ranging from 8 weeks' to 18 months' duration (261).

Clearly, the success of endosurgical treatment depends to some extent on the previously described characteristics of the stricture: cause, length, and location. Unfortunately, rarely do study reports subdivide the patient groups according to their stricture characteristics. This factor, when combined with the inconsistencies of the technique of balloon dilation or endoincision and the variability in posttreatment stent size and stent duration, results in a significant amount of clinical confusion such that cumulative data on the endosurgical management of ureteral stricture can only be judged in the broadest anecdotal manner.

Meretyk and colleagues (243) have described the use of long-acting steroid injection and free urothelial grafts in the stricture region to improve the results of endoincision of ureteral strictures. Triamcinolone injection appears to be clinically beneficial in patients undergoing incision of urethral and bladder neck contractures (65,92). One of the actions of triamcinolone is to block collagen formation. In three patients with recurrent stricture after endoscopic ureterotomy, Schmeller and colleagues (315) demonstrated that histologically the area of the ureterotomy consisted of collagen-rich connective tissue with few fibroblasts and a scarcity of smooth muscle fibers. Therefore the application of triamcinolone into the incised bed of the ureteral stricture may inhibit collagen formation and improve the success of endoureterotomy. Wolf and colleagues (379) demonstrated that a nonischemic etiology, more recent etiology (less than 24 months), shorter stricture (1 cm), use of a 12-Fr or larger stent, and injection of triamcinolone into the bed of the stricture were associated with better outcomes for ureteral strictures treated endosurgically.

Experimental results with free tissue grafts (i.e., tunica vaginalis) to repair the ureter have been inconsistent and complicated by hydronephrosis and graft sloughing (102,204,146). However, a free graft of bladder urothelium has worked well for urethral stricture disease (139) and could possibly be of value for ureteral replacement (124). In Urban's series, six patients underwent a free urothelial graft for ureteral strictures between 1.5 and 8 cm. Mean follow-up at 30 months revealed a patency rate of 83% (362). Presently, this time-consuming approach may be a reasonable procedure in high-risk surgical patients with strictures longer than 2 cm.

Several investigators have evaluated absorbable biocompatible materials as substitutes in the urinary tract (321). However, these have been unsatisfactory because

of urine leakage, shrinkage of the repair site, and stone formation. Improvement in cell-culture techniques have enabled some investigators to create a monolayer of urothelial cells on synthetic graft materials before implantation (179). These studies are encouraging for improved cellular lining, prolonged patency, and selective permeability of the graft, but follow-up is limited and clinical trials have yet to be instituted. Cussenot and colleagues (62) reported on the use of a flexible, expandable, tantalum wire stent in the management of four patients with ureteral stricture disease. All of the patients had complicated pathology, including periureteral malignancy and several failed endourologic balloon dilation attempts. Radiographic and endourologic follow-up showed mucosal hyperplasia of varying intensity in all four patients and recurrent obstruction in three (75%). This hyperplastic reaction to metal stent implantation also has been observed in the human urethra. In contrast, Pauer and Lugmayr (286) used a self-expanding, stainless steel alloy, 7-mm stent (Wallstent) to treat ureteral obstruction secondary to a metastatic retroperitoneal tumor in 12 patients; an indwelling double-J stent was used during the first 4 weeks of Wallstent placement. Hyperplasia and edema of the urothelium was observed in all cases during the initial 4 weeks of stent placement; however, the hyperplasia appeared to resolve after the initial 4 weeks. However, during an average follow-up of 27 weeks, 87% of the stents remained open. Two patients developed encrustation of the stent after 30 weeks.

In conclusion, endourologic management of ureteral strictures has not acquired the same degree of acceptance as endourologic management of UPJ obstruction. Overall, the endosurgical management of distal and upper ureteral strictures less than 2 cm and not associated with radiation or other ischemic injury is highly successful and results in minimal morbidity. Also, failure to establish patency does not preclude a subsequent open reconstructive repair. Strictures longer than 2 cm and those associated with radiation or ischemic injury or a middle ureteral location may be managed more appropriately by open reconstruction because of the high failure rate associated with this group of patients treated endosurgically. Further clinical studies are necessary to determine the long-term feasibility and success of adjuvant therapy, such as triamcinolone injection and free urothelial grafting.

Ureteroenteric Strictures

Ureteroenteric strictures are a late complication of urinary diversion. There is no predilection to the type of urinary diversion and the rate of development of stenosis at the ureteroenteric anastomosis, which ranges from 4% to 8% (128,316). The mechanism of stenosis is usually idiopathic. Compression of the ureter by recurrent tumor or inflammation secondary to radiation therapy is a rare cause of late stricture formation. The patient with ureteroenteric stenosis may have flank pain, urinary tract infection, sepsis, or fever. However, these strictures often may be asymptomatic, thereby leading to permanent renal damage. For this reason, it is important to follow urinary diversion patients annually with routine evaluation of the upper urinary tract to obviate silent, slowly developing, renal obstruction.

The standard therapy for a ureteroenteric anastomotic stricture is usually exploratory laparotomy and revision of the ureteroenteric anastomosis with reimplantation of the viable ureter into the conduit. The development of percuta-neous nephrostomy drainage and external ureteral stents initially provided a therapeutic alternative to the surgical approach, especially in patients with recurrent malignant disease (304,339). However, chronic nephrostomy tubes and ureteral stents are associated with considerable morbidity and must be exchanged at regular intervals to minimize the risk of obstruction (253,371). As such, in patients without recurrent cancer, this approach is only of a temporizing value. In 1979, Smith and colleagues (339) reported endoscopic dilation of ureteroileal strictures with Teflon dilators and insertion of a Gibbons ureteral stent. Subsequently, in 1988, Kramolowsky and colleagues (202) treated nine patients with ten ureterointestinal strictures with either balloon dilation or an endoureterotomy, followed by stent removal.

Technique

It is important to completely assess the patient with regard to the etiology of the ureteral anastomotic stricture and the location and extent of the stenosis before embarking on the endosurgical manipulation. As such, a CT scan and renal scan are helpful. If the stricture is complete or secondary to recurrent malignancy, the objective of endourologic therapy is to establish a retrograde external ureteral catheter, which may be changed on an outpatient basis every 12 to 16 weeks. If the stricture is totally occluding the ureter, a nephrostomy tube can be placed for a 4- to 6-week period. If, despite optimal drainage, the function of the affected kidney remains below the 15% level, nephrectomy may be the next best step provided the contralateral kidney is normal. Likewise, if the patient has evidence of urosepsis, a nephrostomy tube should be placed immediately.

For benign, partial ureteroenteric anastomotic obstruction of a well-functioning kidney, the goal is to reestablish a permanent, nonstinted, patent ureteral conduit. A percutaneous nephrostomy is placed. An antegrade ureterogram is performed in combination with a loopogram to determine the extent of the stenosis. The ureteroenteric stricture may be approached from an antegrade or a retrograde access or from a combined antegrade and retrograde approach.

The antegrade approach is commonly used for balloon dilation of the stricture. The patient is placed in a flank position, with the affected side superior. Both the stoma and flank are prepared and draped. Percutaneous access is easily established because the kidney is commonly hydronephrotic. After the percutaneous nephrostomy has been established, a guidewire is manipulated antegrade through the dilated UPJ and down the ureter. If the guidewire does not easily pass through the region of stenosis, a 5-Fr angiographic catheter is placed over the guidewire. The guidewire is exchanged for a Terumo guidewire, which because of its lubricity can usually pass through even the tightest stricture. The 5-Fr angiographic catheter is then advanced over the Terumo guidewire across the stenosis and into the conduit loop. The Terumo guidewire is then exchanged for a 260-cm exchange guidewire. A flexible cystoscope is passed into the conduit through the stoma, and grasping forceps are used to retrieve the end of the exchange wire from the stoma. The 5-Fr angiographic catheter is removed. An 8-mm, 4-cm-long, 7-Fr ureteral dilating balloon catheter is passed over the through-and-through guidewire under fluoroscopic control until it straddles the stricture. The balloon of the catheter should be rated to a minimum of 15 atm of pressure. A pressure syringe (i.e., LeVeen type) with an in-line pressure gauge is attached to the balloon inflation port and used to slowly inflate the balloon with a 50:50 contrast and saline mixture. The inflation is continued until the waist in the balloon at the level of the stricture disappears. The balloon is left inflated for 1 minute and deflated. This cycle of inflation followed by deflation may be repeated once or twice.

Following completion of the balloon dilation, the dilating catheter is removed. A 10- to 16-Fr nephroureteral stent is then placed antegrade, or preferably a single pigtail 12-Fr biliary urinary drainage catheter can be placed retrograde. The latter has sideholes only in the stent coil, which resides in the renal pelvis; the butt end of the tube exits the conduit stoma. A 2-0 Prolene suture is used to secure the shaft of the stent to the peristomal skin. The patient's urine collection device is passed over the end of the stent and secured in the usual manner to the peristomal skin. If a retrograde stent is placed, an 8- or 10-Fr nephrostomy tube also is positioned. On postoperative day 2 or 3, a nephrostogram may be performed, and if the collecting system is intact, the nephrostomy tube is removed. The nephrostent or retrograde ureteral stent is removed 4 to 8 weeks postoperatively.

Retrograde balloon dilation of ureteroenteric strictures also may be performed. However, this may be more difficult than an antegrade approach. Flexible cystoscopy of the conduit is performed through the stoma. If a nephrostomy tube is in place, indigo carmine–stained saline can be instilled to help identify the narrowed ureteroenteric anastomosis. Via the cystoscope, a Terumo guidewire is inserted into the ureter and advanced under direct endoscopic and fluoroscopic control. Once coiled in the renal pelvis, a 5-Fr angiographic catheter is passed over the guidewire through the strictured region and into the upper collecting system. The Terumo guidewire is exchanged for a 0.035-inch Amplatz superstiff guidewire, and the 5-Fr angiographic catheter and the cystoscope are removed. An 8-mm, 4-cm-long, 7-Fr ureteral dilating balloon catheter is passed over the guidewire until the balloon straddles the region of the stricture fluoroscopically. The same technique of balloon dilation and retrograde stent placement described for the antegrade approach is used for the retrograde approach (i.e., sideholes only in the renal pelvic coil of the stent). An indwelling ureteral stent should not be used because it may become occluded with mucus. This scenario may result in obstruction and fatal urosepsis (371). The stent is removed 4 to 8 weeks postoperatively under fluoroscopic guidance; a retrograde ureterogram is obtained.

Endoincision of a ureteroenteric stricture carries with it the risk of an inadvertent enterotomy or significant hemorrhage. Therefore these patients should receive a complete mechanical and antibiotic bowel preparation preoperatively. If the bowel is appropriately prepared, an enterotomy may be managed conservatively with an external ureteral stent and an elemental diet. In the situation of significant bleeding, an open procedure may be necessary; if the patient is stable, revision of the ureteroenteric anastomosis may be performed at the same time. In general, a left ureteral stricture that extends more than 1 cm above the ureteroenteric anastomosis site is a contraindication to an endoincision.

The endoscopic incision of the ureteroenteric stricture also may be approached in an antegrade or a retrograde fashion. In either case, the patient is placed in the flank position with the affected side superior, and both the stoma and posterior flank are prepared and draped.

To perform an antegrade endoincision of a ureteroenteric stricture, an 18-Fr nephrostomy tract should be established in a middle or upper posterior calyx to provide straight-line access to the affected distal ureter. The flexible 7.5- or 9.4-Fr ureteroscope, or 15-Fr nephroscope, is inserted through the nephrostomy tract into the renal pelvis, and under direct visualization the endoscope is delivered to the stricture. A 0.035-inch Terumo guidewire is visually passed through the stricture and into the conduit. A flexible cystoscope is passed via the conduit stoma and is used to retrieve the end of the Terumo guidewire. The flexible ureteroscope or nephroscope is removed, and a 5-Fr angiographic catheter is passed fluoroscopically over the Terumo guidewire until the tip is through the conduit. The Terumo guidewire is exchanged through the 5-Fr angiographic catheter for a 0.035-inch, 260-cm exchange guidewire. The 5-Fr angiographic catheter is removed. A 6- or 8-mm, 7-Fr ureteral dilating balloon catheter is passed retrograde over the guidewire until the balloon straddles the stricture. The balloon is inflated with dilute radiographic

contrast solution stained with indigo carmine, using a pressure syringe (i.e., LeVeen type) with an in-line pressure gauge, to 1 atm. With the balloon inflated, the flexible endoscope is introduced antegrade, and a 2- or 3-Fr straight-tip or right-angle electrosurgery probe is passed through the endoscope. A right-angle electrosurgery probe allows for highly accurate stricture incision. An incision is made in the ureter alongside the balloon using 50 to 100 W of pure cut energy. The incision is extended distally until the conduit is entered; the cut is made through the full thickness of the ureter until retroperitoneal fat can be seen. The ureteral dilating balloon should now expand to its full size; if the balloon was punctured during the incision, it is removed and replaced with a 10-mm nephrostomy dilating balloon. Visually and fluoroscopically, the balloon is positioned across the region of the incision. If the incision in the stricture is successful, the balloon should fully inflate at 1 to 2 atm without any evidence of a waist. If the scar tissue of the incised ureteral stricture appears to be particularly dense and no fat is seen, 3 to 5 mL of triamcinolone (40 mg/mL) may be injected into the bed of the incised stricture using a 3-Fr Greenwald needle mounted on a flexible shaft. A LeVeen pressure syringe is used to perform the injection into the dense scar tissue.

The balloon catheter and flexible endoscope are removed. A 12-Fr retrograde single pigtail catheter with sideholes only in the pigtail is inserted retrograde into the upper collecting system; the butt end of the catheter exits the stoma. A 14-Fr nephrostomy tube is inserted into the renal pelvis. A nephrostogram is performed on postoperative day 1 or 2, and if the collecting system is intact, the nephrostomy tube is removed. The external ureteral stent is maintained for 4 to 8 weeks postoperatively.

Retrograde endoincision is performed under direct vision with the Sachs urethrotome, 12-Fr, short, rigid therapeutic ureteroscope, or 15-Fr flexible cystoscope. The endoscope is inserted alongside the guidewire. An 8-mm ureteral dilating balloon catheter is passed retrograde, until the balloon straddles the area of the stricture. The balloon is inflated with 50:50 contrast material and saline in a pressure syringe (LeVeen type) with an in-line pressure gauge, to 1 atm pressure to delineate the stricture fluoroscopically. The balloon is then deflated and the area of the stricture is incised using a cold knife through the rigid ureteroscope. Alternatively, the balloon may be left inflated, and a 2- or 3-Fr straight-tip or right-angle Greenwald electrode may be used through the ureteroscope or flexible cystoscope to incise the ureter alongside the balloon. The incision should be extended through the full thickness of the ureter; ideally, periureteral fat should be seen. The incision is extended cephalad until the dilated normal ureter is identified. The ureteroscope is withdrawn and the 8-mm balloon is reinflated to confirm that the ureter is widely patent. A 12-Fr single pigtail ureteral catheter is passed retrograde as previously described. If on postoperative day 2 a nephrostogram shows no evidence of extravasation, the 8-Fr nephrostomy tube is removed. The retrograde catheter is removed 4 to 8 weeks postoperatively.

If the ureteroenteric obstruction is complete, a combined antegrade and retrograde approach is necessary. In the combined approach, the rigid endoscope is passed through the conduit, and the flexible ureteroscope or flexible nephroscope is passed through the developed nephrostomy tract. When the tips of the two endoscopes are fluoroscopically close (less than 1 cm), the light from the antegrade endoscope is turned off. The endoscopist then seeks the light coming from the rigid retrograde endoscope lying within the conduit, which will appear as a bright pink light transilluminating the intervening tissue. The C-arm fluoroscope is used in two planes of projection to further confirm the close alignment of the tips of the two endoscopes. At this point a cut-to-the-light procedure can be performed as previously described for treatment of the completely obstructing ureteral stricture (253). Alternatively, the light of the antegrade endoscope can be sought via the retrograde endoscope; a retrograde incision is then made (Fig. 19.14).

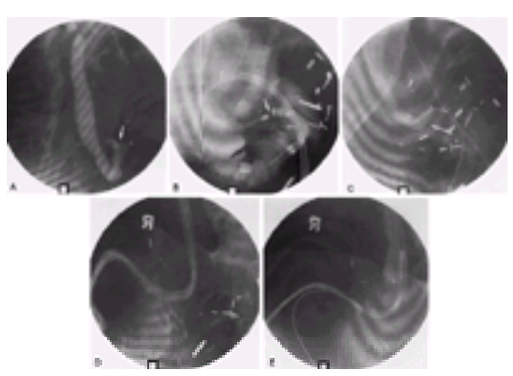

FIGURE 19.14. A: Right uteroenteric stricture *(arrow)* with moderate hydroureteronephrosis on antegrade nephrostogram. **B:** A flexible uteroscope has been passed antegrade to the level of the stricture. A flexible cystoscope is passed retrograde through the ileoconduit to the stricture. A cut-to-the-light technique is used by passing an electrosurgical cutting device through the cystoscope to incise the intervening stricture *(arrow).* **C:** After incising the stricture, a guidewire is passed antegrade and retrieved by the cystoscope to establish a through-and-through guidewire across the region of the stricture. **D:** A stent is then placed. In this case, two 7-Fr single pigtail catheters have been placed across the region of the incised stricture. Note: there are no sideholes in the shaft of the stents; the drainage holes are only in the pigtail portion. **E:** At the time of stent removal, ureteroscopy is performed through the ileal conduit to confirm patency of the incised stricture.

Once a guidewire has been established across the area of the stricture, the incision can be extended using an antegrade or retrograde technique to complete the endoincision. This incision should be performed slowly under direct endoscopic control to avoid inadvertent injury to an underlying artery or segment of bowel.

If the bowel is entered, a 10-Fr ureteral pigtail catheter is placed across the area of incision and into the renal pelvis. The fistula will usually close spontaneously over several weeks with the patient on an elemental diet (244). If an artery is incised, there will be immediate hemorrhage; a 10-mm balloon catheter or a Kaye catheter can be passed over the through-and-through guidewire to straddle the region of the incision, and the balloon is inflated to tamponade the bleeding site. The balloon can usually be deflated 2 days later. If bleeding recurs, the balloon is reinflated, and angiography followed by selective embolization or an open surgical repair is performed. If there is no bleeding, the balloon is exchanged for a 12-Fr single pigtail retrograde external ureteral catheter.

Results

The reported experience with ureterointestinal strictures is even more limited than that of UPJ and ureteral strictures. The largest single-center series used balloon dilation to treat 37 ureteroenteric anastomotic strictures in 29 patients (329). Most of these patients had undergone cystectomy and diversion for bladder or uterine/cervical carcinoma and had received adjuvant radiation therapy before cystectomy. All but three patients underwent diversion to an isolated segment of terminal ileum; in the remainder, a colon conduit was created. All of the ureteroenteric strictures were dilated in an antegrade fashion using a 4- to 10-mm dilating balloon catheter. The goal of the dilation was to eliminate the waist in the balloon at the area of the stricture; this required between one and three inflations at the same procedure. The balloon was left inflated for 1 to 2 minutes. Most of the ureters were stinted with an 8.3- or 10-Fr stent, although six ureters had stents ranging in size from 14 to 24 Fr. The stents were placed retrograde following the dilation and were maintained for 1 to 6 weeks. In short-term follow-up, only 30% of the cases were considered to be clinical successes. At 1 year of follow-up, only 6 of 37 strictures (16%) were patent. Half of the successful cases subsequently required repeat dilation and stent placement to maintain ureteral patency; these late restenoses occurred between 14 and 73 months following the initial dilation. These investigators were unable to identify distinguishing or predictive factors for success of balloon dilation of the ureterointestinal anastomotic strictures.

Several other investigators have reported on balloon dilation of ureterointestinal anastomotic strictures (6,24,41,170,268) (Table 19.4). There does not appear to be any consensus as to the size of dilating balloon to use, the size of the ureteral stent to place following the dilation, or the duration of stent placement. In these other series, the success rates for balloon dilation of ureterointestinal strictures range from 16% to 67%. Among all series, the overall average success rate was 29% at an average follow-up of 14 months. Of note, the highest success rate of 67% occurred among pediatric patients with a conduit and a benign etiology of the stricture (6). Many of these reports had short-term follow-up (less than 12 months) of their patients, and as Shapiro and colleagues (329) have demonstrated, longer follow-up significantly decreases the initially favorable results (Table 19.4).

TABLE 19.4. ENDOUROLOGIC MANAGEMENT OF URETEROINTESTINAL ANASTOMOTIC STRICTURE

The experience with endosurgical incision of the ureterointestinal anastomotic stricture also is limited. This procedure may be performed in an antegrade or a retrograde fashion, although most investigators have used the antegrade technique (5,40,59,109,224,335,379).

The largest single-center study was reported by Wolf and colleagues (379) and consisted of 30 ureterointestinal anastomotic strictures in 25 patients. Most of the patients (26 of 30) had an ileal conduit for transitional cell carcinoma or cervical carcinoma. Of 30 strictures, 16 occurred less than 24 months and 13 occurred more than 24 months from the time of the diversion procedure. A variety of approaches to the endoureterotomy were taken, including antegrade, retrograde, and combined antegrade and retrograde. The success rates of endoureterotomy for ureteroenteric strictures at 1, 2, and 3 years were 72%, 51%, and 32%, respectively. There was an improved outcome for right rather than left strictures (68% versus 17% 3-year success rates, respectively) and for strictures treated less than 24 months after the etiologic insult (37% 3-year success rate compared with 27% for those treated longer than 24 months after the insult). Stricture length, diameter, and previous treatment did not alter the results. Those strictures that were amenable to treatment in a purely retrograde fashion, as opposed to those requiring an antegrade or combined approach, tended to have a better outcome (75% and 18% 3-year success rates, respectively). More favorable results were also noted with the use of 12-Fr or larger stents (38% compared with 0% 3-year success rate when using smaller stents) and stinting longer than 4 weeks (35% compared with 26% 3-year success when stinting 4 weeks or less). The use of triamcinolone did not appear to affect the results. One of the patients in this series had a major postoperative complication. During incision with the cutting balloon device, a left ureteral–left iliac artery fistula was created. The bleeding was controlled with a high-pressure, 10-mm tamponade balloon catheter in the ureter. Angiography confirmed the presence and location of the fistula. Open surgical management was required. Overall, use of the cutting balloon for ureterointestinal strictures is advisable only if the stricture is at the ureteroenteric site and if initial attempts at an endoscopic incision have been unsuccessful.

Additional reports in the literature have shown an overall success rate of 52% for endoincision of the ureterointestinal anastomotic stricture (Table 19.4). A variety of cutting modalities have been used, including electrosurgical, cold knives of various sizes and configurations, and Ho:YAG laser (5,59,109,335,379). Following the endoincision, all patients have been stinted (10 to 20 Fr) for 3 to 8 weeks postoperatively. Kramolowsky and colleagues (202) compared their nine patients who underwent open surgical revision of a ureteroenteric stricture with their six patients who underwent endoscopic incision and balloon dilation of a ureterointestinal stricture. The ureter was patent with no ureteral stent in 89% of the patients treated with open surgical revision at 33 months and in 71% of patients undergoing the endoscopic incision at 18 months. Although the endoscopic procedure was less successful than the open surgical revision, it was associated with a significantly shorter hospitalization, decreased blood loss, reduced patient discomfort, and decreased cost compared with the open surgical procedure. Although the standard open surgical revision of a ureteroenteric anastomotic stricture is usually successful, it can be difficult to perform because of surrounding scar tissue or previous radiation therapy, making intraoperative and postoperative morbidity significant. Postoperative complications can occur in 30% of the open-surgery patients, and these problems often necessitate reoperation (202). Many patients with ureterointestinal strictures are poor surgical candidates because of age, longstanding urosepsis, or renal insufficiency. As such, the endoscopic incision of the ureterointestinal stricture provides a less invasive, less morbid approach that is successful in alleviating the problem in as many as 75% of otherwise surgical candidates (335).

In patients with known metastatic disease, the endoscopic approach allows placement of an external stent for drainage purposes. This may facilitate optimization of the patient's renal function before chemotherapy. All stents used in a ureterointestinal unit should have side drainage holes present only in the portion of the stent in the renal pelvis and at the end where the stent exits the stoma. No holes should be placed along the catheter where it traverses the conduit to preclude mucous obstruction and possible fatal urosepsis (371). Stents should be changed every 3 to 4 months as an outpatient procedure under fluoroscopic control.

Transitional Cell Cancer of the Ureter

Primary transitional cell carcinoma of the ureter (TCCU) represents only 2% of all urothelial malignancies seen in the urinary tract. Patients most commonly have hematuria, flank pain, or urinary frequency and dysuria, although lower abdominal mass, fever, or weight loss may be the presenting complaint. Batata and colleagues (20) demonstrated that 65% of ureteral cancer patients have cancer in other parts of the urinary tract concurrent with or before or after a diagnosis of ureteral cancer. The most common malignancy of the ureter is transitional cell carcinoma (93%); rarely, squamous cell carcinoma (5%) or mucoid adenocarcinoma (2%) may occur in the ureter. Most ureteral tumors occur in the distal ureter (65%), followed by the middle (17%) and upper (12%) ureter; the entire ureteral length is affected by malignancy in 7% of ureteral tumor patients (8).

Several investigators have evaluated prognostic factors in carcinoma of the ureter (30,140). As with transitional cell carcinoma of other areas of the urinary tract, ureteral transitional cell carcinoma has an excellent (greater than 90% survival rate at 5-year follow-up) prognosis if it is well differentiated and confined to the mucosa. Eighty-two percent of patients without muscle-invasive tumor survive 5 years. However, dissemination of the carcinoma into regional lymph nodes or beyond results in a 10% patient survival 5 years from the time of diagnosis. Local extension of the tumor into the periureteral tissues also has a poor prognosis, with only 29% of patients surviving 5 years (20,234).

The accuracy of clinical diagnosis of TCCU becomes crucial in predicting the patient's prognosis and determining the most appropriate therapy. Batata and colleagues (20) showed that 72% of ureteral tumors could be diagnosed reliably radiographically by intravenous pyelography (19%), retrograde urography, or ureteral catheterization (53%). However, that leaves more than one-fourth of the patients with indeterminate radiographic studies. Neither urine cytology nor flow cytometry is consistently reliable in diagnosing transitional cell carcinoma of the upper urinary tract. Although high-grade tumors often have an associated abnormal cytology, negative urine cytology is seen in as many as 10% of patients with high-grade lesions and in up to 60% of patients with low-grade lesions (310). Flow cytometry measures cellular DNA and RNA content. A false-negative flow cytometry may be seen in 66% of superficial papillomas and in 8% of invasive cancers (242). Blute and colleagues (31a) showed that imaging studies and cytology together correctly diagnosed a ureteral tumor in only 52% of 21 patients who eventually were found to have a ureteral malignancy.

In 1929, Young (381) performed the first recorded ureteroscopic examination when he inserted a pediatric endoscope into a dilated ureter and passed it up to the level of the renal pelvis in a child with posterior urethral valves. Fifty years later, Lyon and colleagues (229) reported on their experience with endoscopy of the distal ureter using pediatric instruments. Subsequently, Perez-Castro and Martinez-Pineiro (289) created the first custom-built ureteroscope; they described their experience in ureteroscopy, including initial examination of the ureter to the level of the renal pelvis in both men and women.

First-generation rigid ureteroscopes were developed with the goal of visualizing the distal ureter and generally measured 20 cm long with a diameter of 13 to 14.5 Fr. As indications were extended into the middle ureter, proximal ureter, and renal pelvis, working lengths increased and endoscope diameters decreased. Presently, rigid ureteroscopes are available in 6.9 Fr with working lengths up to 40 cm; these diminutive endoscopes also incorporate single (4 to 5 Fr) or dual (2.3 and 3.4 Fr) working channels to allow simultaneous passage of instruments and effective irrigation. Subsequently, flexible ureteroscopes with active deflection up to 180 degrees and a diameter of 7.5 Fr have been developed. The working channel size in these endoscopes is smaller (3.6 Fr) than in their rigid counterparts, hence the irrigant must be pressurized when using diagnostic or therapeutic instruments.

Presently, the indications for diagnostic ureteroscopy include radiographic filling defects or obstruction, unilateral malignant urinary cytology, or macroscopic, essential lateralizing hematuria (149). The indications for ureteroscopic treatment of upper tract tumors are less well defined.

Technique

Ureteroscopy is an adjuvant procedure in the diagnostic evaluation of the patient. Therefore all patients should have preprocedural evaluations, including a thorough history, physical examination, and radiographic evaluation. The urethra and bladder must be examined carefully with the cystoscope to eliminate the possibility of a lower tract tumor. If this is present, it should be resected and the surgical site allowed to heal completely before manipulation of the upper urinary tract to reduce the potential risk of tumor seeding and implantation (341).

The technique for ureteroscopy in patients with suspected upper tract TCCU involves no use of an initial ureteral guidewire to avoid inadvertent injury to the collecting system (259). The procedure is initiated by passing a small-caliber (6.9-Fr), short, rigid ureteroscope to study the distal ureter and rule out any pathologic condition. Through the ureteroscope, a guidewire is advanced to the uppermost point to which the 6.9-Fr ureteroscope was advanced, and the short rigid ureteroscope is removed. A small-caliber, actively deflectable flexible ureteroscope is passed over the guidewire and into the ureter under fluoroscopic guidance, being careful not to push the guidewire any higher in the ureter. If upper tract biopsies are anticipated, it is helpful to place a ureteral access sheath to the level of the ureter visualized with the rigid ureteroscope. This facilitates subsequent placement of the flexible ureteroscope, through the distal ureter, into the upper collecting system. In addition, following biopsy of a lesion, the ureteroscope can be removed without having to pull the biopsy device through the endoscope, which may shear off the tissue of the specimen within the scope. Multiple biopsies can be performed because the flexible ureteroscope can be easily reintroduced into the collecting system through the access sheath. Once the flexible ureteroscope is positioned at the upper level of the already examined ureter, the guidewire is removed. With the availability of smaller-caliber ureteroscopes, dilation of the distal ureter usually is not necessary.

Proximal ureteroscopy is performed, followed by examination of the renal pelvis. Systematic evaluation of the upper-, middle-, and lower-pole calices, in that order, is performed. This procedure prevents confusion due to contusion of the mouth of the upper-pole infundibulum caused by passive deflection of the shaft of the endoscope against this area during inspection of the lower-pole calices. Nonionic contrast medium is injected under fluoroscopic guidance to verify endoscopic entry into all calices of the renal collecting system. If a lesion is identified, its location is marked on the fluoroscope screen. After complete inspection of the collecting system, the lesion is addressed. The lesion is then biopsied by passing a 3-Fr biopsy forceps or a 3-Fr basket through the ureteroscope. The latter is twirled into the lesion and then closed; as it is withdrawn, the entrapped papillary fronds are detached from the tumor.

Brush biopsy catheters for the flexible ureteroscope are also available and may be of value if the biopsy material is not adequate. It is helpful to place a ureteral access sheath to facilitate passage of the flexible ureteroscope and removal of the biopsy specimen. After removal of the biopsied material, a 2- or 3-Fr electrosurgical probe or a 200- to 400-micron Nd:YAG laser probe (20 W) may be used to fulgurate the area; alternatively, if a large 12.5-Fr, rigid ureteroscope is being used, a resectoscope loop can be used to resect the tumor down to ureteral muscle (Fig. 19.15) (99). Last, the flexible endoscope is advanced into the renal pelvis, and the collecting system is systematically examined for any additional occult tumors. The aspirate and biopsy specimens should be sent immediately to the cytopathology laboratory, where they are evaluated by smear and cytospin. When any tissue fragments are visible in the specimen, a cell block is prepared.

FIGURE 19.15. This midureteral filling defect is a low-grade transitional cell cancer. The diagnosis and therapy both were completed using the ureteroscope. Follow-up over 2 years revealed no recurrence.

Following resection of the primary tumor, a withdrawal retrograde ureterogram should be performed to assess extravasation. The ureteroscope is removed, and an indwelling ureteral stent is inserted over the safety guidewire; a urethral catheter is also placed. If there is no extravasation, the urethral catheter is removed on the first postoperative morning. The ureteral catheter is removed 3 to 5 days later as an outpatient. In the event of extravasation, the urethral catheter is maintained for 2 or 3 days, at which time a cystogram is performed. When the extravasation has resolved, the urethral catheter may be removed. The ureteral stent is left in place for 4 to 6 weeks.

Results

Grasso and Bagley (121) used the small-diameter, actively deflectable, flexible ureteroscope to investigate 584 patients suspected to have urothelial malignancies. They were able to successfully complete the ureteropyeloscopy in 94% of the patients. Ureteral dilation was required in only 12% of procedures. Lower-pole access required secondary or passive deflection in 60% of procedures. Keeley and colleagues (185) performed diagnostic ureterorenoscopy in 92 consecutive patients with upper tract transitional cell carcinoma. Fifty-one open surgical procedures were subsequently performed, including distal ureterectomy in four and nephroureterectomy in forty-seven. Cytologic evaluation was positive for malignancy in 48 of 51 cases (94%). Grading of ureteroscopic specimens was possible in 42 cases (82%) (Table 19.5). Transitional cell carcinoma grade on ureteroscopy accurately predicted tumor grade and stage in the surgical specimens. There was no significant perioperative morbidity.

TABLE 19.5. ENDOSCOPIC MANAGEMENT OF PRIMARY URETERAL TRANSITIONAL CELL CARCINOMA

The success of intravesical agents in the treatment of superficial transitional cell carcinoma of the bladder has motivated some investigators to apply these agents in the management of upper urinary tract tumors (83,185,233). Among these reports a variety of topical chemotherapeutic agents have been used, including bacille Calmette-Guérin (BCG), mitomycin C, thiotepa, and interferon-a_2. There has been no standardization to determine which patients receive this adjuvant therapy, although it tends to be given to patients judged to be at high risk for recurrence. The therapy is usually administered via a ureteral catheter, after retrograde pyelography has confirmed no extravasation and good flow around the ureteral catheter. Keeley and colleagues (185) administered 40 mg of mitomycin C in three divided doses in the immediate postoperative period in 15 patients with no attributable toxicity. Seven patients received intravesical BCG with a ureteral stent in place; again with no significant toxicity. However, no attempt was made to randomize the patients; therefore little can be determined regarding the efficacy of either

treatment.

A low-grade, low-stage ureteral tumor may be associated with urothelial dysplasia and carcinoma *in situ* in other areas of the ureter in 50% and 9% to 13% of cases, respectively (140). Bloom and associates (30) reported ureteral stump tumors in 4 of 10 patients (40%) with primary ureteral carcinoma who underwent nephrectomy and partial ureterectomy. Strong and colleagues (346) had 5 of 13 patients (40%) with ureteral stump recurrences following segmental ureterectomy or incomplete nephroureterectomy for primary ureteral carcinoma. Therefore, when management other than radical surgical excision is chosen for a patient with transitional cell carcinoma of the ureter, ongoing surveillance of the entire urinary tract is mandatory. In most situations, this should follow the same regimen that is used among bladder cancer patients. Specifically, ureteroscopic examination of the ureter should be performed every 3 months for 1 year, then every 6 months for 1 year, and then on an annual basis. Although intravenous or retrograde urography and cytology may be substituted for the endoscopic evaluation, these studies may be less accurate in detecting early, diminutive, low-grade recurrences.

Kerbl and Clayman (188) described a method of transurethrally unroofing the ureteral orifice in two patients undergoing endoscopic management of upper tract transitional cell carcinoma. At presentation, neither patient had a history of bladder tumor. By creating a widely patent ureteral orifice, the clinician could perform flexible ureteroscopy (10 Fr) in the office without the need for dilation of the intramural ureter, without oral or parenteral analgesics, and without postureteroscopy stent placement. The entire length of the ureter and all of the calyces could be completely examined in this manner. These two patients have been followed for over 5 years. One patient has had a small, recurrent, superficial, papillary lesion in the renal pelvis treated with electrosurgical fulguration 4 years after the initial procedure; pathologic evaluation was not performed on this lesion. The other patient has had three small upper tract recurrences. Both patients have had grade I to II pathologic stage A bladder tumors during the 5 years of follow-up and have received intravesical BCG or interferon therapy following transurethral resection of the bladder tumor.

Incision of the intramural ureter creates low-grade asymptomatic reflux. Guthman and colleagues (133) have shown that sterile reflux in the adult does not impair renal function or result in increased urinary tract infections. The primary concern is whether reflux will result in more frequent upper tract recurrences in these patients because of seeding from the lower tract. Some investigators have shown that among patients with recurrent bladder tumors and reflux, the incidence of upper tract tumors may be as high as 20% (7,254). Long-term, clinical follow-up will be necessary to study this hypothetical concern.

A significant concern with regard to endoscopic management of patients with transitional cell carcinoma of the ureter is the potential for tumor implantation or tumor seeding. Soloway and Masters (341) have shown in an animal model that disruption of the urothelial cell layer by cauterization increased implantation of transitional cell tumors by fourfold. During balloon dilation of the distal ureter and passage of the ureteroscope, abrasion of the urothelium may occur. Kulp and Bagley (208) reported on 13 patients, all of whom underwent ureteropyeloscopy with biopsy and treatment one to four times before nephroureterectomy for TCC of the renal pelvis. Only one patient had vascular-lymphatic extension, and because of the tumor growth characteristics, extension was suspected before endoscopy. This patient had no intravascular-lymphatic free cells or clumps of cells noted on the final pathologic specimen. There were no local recurrences in the follow-up of the remaining patients, at 3 months to 6 years (average of 34 months).

Ureteral perforation and subsequent retroperitoneal tumor implantation are a concern during ureteroscopy for TCCU. Perforation is more likely to occur with electrosurgical resection of the ureteral lesion than with excisional biopsy and Nd:YAG laser fulguration of the tumor base. However, to date in none of the reports of ureteroscopic management of primary ureteral transitional cell carcinoma has there been a case of retroperitoneal seeding documented during clinical follow-up up to 21 months (83,86,122,151,187,233).

Nephroureterectomy or distal ureterectomy remains the treatment of choice in most patients with TCCU. For patients with a solitary kidney, renal insufficiency, or medical illnesses rendering them poor candidates for an open surgical procedure, endoscopic modalities for treatment of upper tract transitional cell carcinoma are reasonable alternatives for management. However, the overall long-term (i.e., longer than 5 years) efficacy of these endoscopic modalities remains unproven. Continued long-term follow-up of patients with ureteral transitional cell carcinoma managed with ureteroscopic excision and fulguration is essential to delineate the effectiveness and long-term complications and cost of this minimally invasive procedure.

Benign Ureteral Fistulae

The ureter may be damaged easily during abdominal or pelvic surgery because of its proximity to the peritoneum. Gynecologic operations are the primary cause of iatrogenic ureteral injury. The incidence of these lesions ranges from 0.5% to 1% for common pelvic operations and up to 10% for radical pelvic surgery (80). Ureteroscopy also can result in ureteral injury. In addition, ureteral fistulae to the peritoneal space, retroperitoneum, adjacent viscera, or skin may result from other benign (i.e., regional enteritis) disease. Perforation, resection, or ligation of the ureter leads to extravasation of urine, formation of a urinoma, and late development of ureterocutaneous or ureterovaginal fistulae. Many ureteric injuries are identified at the time of the surgical procedure and managed with repair or stinting without significant sequelae to the patient. Ureteric injuries that are not recognized intraoperatively or in the early postoperative period are complicated by periureteric fibrosis or epithelialization of the fistulous tract.

Technique

The approach to urinary fistulae is based on the principle that the urine must be diverted from the site of the extravasation. The placement of a percutaneous nephrostomy tube effectively diverts the urine away from the fistula; in addition, an indwelling ureteral stent, with sideholes only in the intrapelvic and intravesical pigtail, is positioned across the fistulous tract.

The stent may be passed antegrade or retrograde. The antegrade approach is performed more easily because of the dilation of the upper collecting system. If a guidewire cannot be manipulated across the ureter, a flexible ureteroscope can be passed antegrade, and the ureter can be cannulated under direct vision. Likewise, if a retrograde approach is chosen, ureteroscopy may be helpful to cannulate the ureter. Ureteroscopy is also helpful if the obstruction and fistula formation are the result of a prior surgical procedure. In this case, retrograde rigid ureteroscopy is advisable because any visualized obstructing suture can be incised with a ureterotome before placing a stent (198).

Results

Early diagnosis and treatment are key to the successful management of ureteral injuries. Endourologic techniques have a higher success rate when instituted as soon as possible following the ureteral injury (198). Successful endourologic treatment reduces the patient's hospitalization, incidence of complications, and postoperative discomfort. Placement of the ureteral stent seems to decrease stricture formation at the site of injury (212). Chang and colleagues (41) reported 12 patients with ureteral fistulae treated with percutaneous nephrostomy and 8- to 12-Fr ureteral stents. The stent was left in place for 4 to 6 weeks. In 10 of 12 patients (83%), the ureteral fistula healed without stricture formation or further intervention. One patient required continued stinting for recurrence of a pelvic malignancy. One patient had a persistent ureterovaginal fistula and required a psoas hitch and ureteral reimplantation. At the time of surgery, the ureter was noted to be angulated as a result of cicatrization and a chronic urinoma.

Malignant Ureteral Fistulae

The most difficult ureterovaginal or vesicovaginal fistulae to manage are those associated with incurable pelvic cancer. These patients often have been treated with radiation therapy, are terminally ill, and are not suitable candidates for open urinary diversion.

Technique

Nephrostomy tube drainage is usually instituted in these patients; although the drainage of urine is diminished, it is rarely stopped by this modality alone. Usually the ureter must be occluded to truly stop the leakage of urine. This can be accomplished with either of two antegrade approaches: electrocoagulation of the urothelium of the lower ureter or fluoroscopic placement of obstructing material in the distal ureter. Ureteral coagulation is performed through a flexible nephroscope introduced via the nephrostomy tract. Beginning approximately 6 to 7 cm below the ureteropelvic junction, the urothelium is circumferentially electrocoagulated using a 3- or 5-Fr round-tip or ball electrode. The procedure is continued until 4 to 5 cm of proximal ureter has been treated; the nephrostomy tube is then replaced. Alternatively, under fluoroscopic control, an antegrade angiographic catheter can be delivered to the fistulous site. A large sponge of Gelfoam (38 inches thick, 34 inches long, 14 inches wide) is instilled through the catheter; Gianturco coils also may be delivered to the fistulous site. These materials are superior to instillation of cyanoacrylate or placement of a detachable balloon for closing the ureter (129).

Results

Gunther and colleagues (130) first attempted to perform transrenal ureteral occlusion with the tissue adhesive butyl-2-cyanoacrylate. However, long-term follow-up showed that this substance softened in urine and was expelled by ureteral peristalsis. Subsequently, they adopted a detachable balloon filled with low-viscosity silicone rubber and released in the distal ureter (129). An advantage to the occlusion balloon is that the ureter is not irreparably destroyed should ureteral surgery or diversion become necessary at a later date. In their clinical report, five patients with urinary fistulae secondary to pelvic cancer and two patients with severe painful pollakisuria underwent ureteral occlusion with a detachable balloon (129). In all patients, urinary flow via the ureter ceased by ureteral balloon occlusion and combined nephrostomy drainage. Follow-up ranged from 1 month to 6 months. No complications occurred.

Kinn and associates (194) combined the insertion of nylon plugs with injection of polidocanol for ureteral occlusion in 15 patients with vesicovaginal fistulae. Urine leakage ceased in 73% of patients; however, the plug did migrate to the renal pelvis in six patients and was associated with pyelonephritis in one patient. More recently, a high success rate has been attained using Gianturco coils in combination with gelatin sponge material to occlude the ureter (103).

Reddy and colleagues (300) described the technique of percutaneous ureteral fulguration for occlusion of the ureter combined with nephrostomy drainage in three patients with urinary tract fistulae secondary to pelvic cancers. In their report, three patients were treated with percutaneous ureteral fulguration and nephrostomy tube drainage for lower urinary tract fistulae secondary to advanced pelvic malignancy. All patients were completely dry at the fistula site 4 to 10 days following the ureteral fulguration. Follow-up ranged from 1 to 21 months with stable renal function and no complications.

Arterial Ureteral Fistulae

Arterioureteral fistulae are rare, with less than 40 cases reported in the literature (72). The primary clinical presentation is massive hematuria, which may result in shock and cardiovascular arrest. In many cases the hematuria did not become apparent until the time of ureteral stent removal. In a review of the literature, Dervanian and colleagues (72) found that 57.5% of the arterioureteral fistulae reported in the literature were associated with prolonged (average of 5.6 months) ureteral catheterization. They hypothesized that the stent may result in ischemia of the ureter as it crosses the iliac vessels, thereby resulting in localized necrosis of the ureteral and arterial walls. Other factors that may contribute to arterioureteral fistula formation include primary iliac artery disease (e.g., mycotic infection, aneurysm), prior iliac artery surgery (e.g., endarterectomy, prosthetic graft), pelvic neoplasm, radiation fibrosis, postsurgical ischemia of the ureter, and endoureterotomy. Patients with known common iliac artery disease are poor candidates for chronic indwelling ureteral stents. In these patients, a permanent nephrostomy or a nephrovesical stent is a safer alternative.

Technique

Among patients with a chronic indwelling ureteral stent, it is advisable to remove the stent over a guidewire. This ensures the urologist's control over the upper urinary tract. The immediate treatment of sudden onset of hematuria after stent removal is to pass a 5- or 8-mm ureteral dilating balloon catheter over the guidewire until the balloon straddles the area of the common iliac vessels. On inflation, the fistulous tract is effectively occluded, thereby allowing time to stabilize the patient with intravenous fluids.

Treatment of the arterioureteral fistula is by embolization and bypass or by direct surgical repair. These fistulae are amenable to embolization. However, careful coordination between the interventional radiologist and vascular surgeon is essential to avoid lower limb ischemia. The advantage of this approach is that a femoral-femoral bypass can be performed, thereby obviating a major transabdominal procedure. The direct surgical procedure involves management of the blood vessel by ligation and bypass, direct suture repair, or patch repair. The urinary tract involvement may be managed with nephroureterectomy, cutaneous ureterostomy, ureteral resection and anastomosis, or ureteral ligation followed by percutaneous nephrostomy. The choice of surgical procedure depends on the local tissue conditions and the patient's overall medical status. However, the least invasive therapy is to embolize the common iliac vessel, proceed with a femoral-to-femoral bypass, and place a percutaneous nephrostomy tube.

Results

If an arterioureteral fistula is suspected, arteriograms and retrograde pyelograms should be performed (Fig. 19.16). Of the 33 cases in Dervanian's report, direct visualization of the arterioureteral fistula by retrograde pyelograms occurred in 27% and by arteriography in 23% of the patients studied. The common iliac artery was most often involved (55%); other vessels involved were the internal iliac artery (9%), external iliac artery (6%), inferior mesenteric artery (3%), and iliac patch angioplasty or anastomosis site (30%). The right ureter was involved in 58% of the cases and the left ureter in 42% of cases. The mortality rate of arteriovenous fistulae is approximately 15%. Knowledge of this rare problem and its efficient management are essential for all urologists.

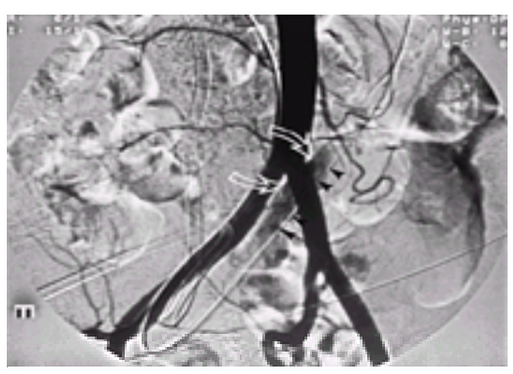

FIGURE 19.16. An arterial-ureteral *(curved arrows)* fistula is demonstrated on this flush aortogram. The arrowheads outline the ureter. This fistula developed 3 days following an endoureterotomy for a left ureteroenteric anastomotic stricture. This patient underwent an uneventful open repair of the left common iliac artery.

THERAPEUTIC RENAL APPLICATIONS

There are four areas in which endourology has a significant effect on the handling of noncalculous renal disease: obstruction, transitional cell cancer, cysts, and infection (e.g., abscess, fungal bezoar). In each of these areas, retrograde ureteroscopic and antegrade nephroscopic techniques are used. In this section, each of these four areas is reviewed from the standpoint of technique and results. Endourologic techniques as they apply to the transplant kidney are also reviewed.

Renal Obstruction

There are two types of stricture disease that affect the kidney: UPJ obstruction and calyceal abnormalities. In the latter category are the calyceal diverticulum and hydrocalyx.

Ureteropelvic Junction

Historical Aspects

Precedence in the surgical treatment of UPJ obstruction belongs to Friedrich Trendelenburg, who in 1886 performed the first recorded reconstructive procedure on the ureteropelvic junction. Unfortunately, the death of his patient probably tempered enthusiasm for this approach; it was not until 5 years later that Ernest Kuster accomplished a dismembered pyeloplasty unaccompanied by surgical mortality (257). Other innovative open surgical approaches to repairing the obstructed UPJ

soon followed: renal pelvis plication, Y-V flap advancement, straight flap insertion, and spiral flap repair.

In the early 1900s, faced with what appeared to be an inoperable situation, Joachim Albarran performed the first endopyelotomy when he incised an upper tract stricture and left a catheter in place. Surprisingly, the incised-but-not-reconstructed ureter healed and remained patent; Albarran termed this fortuitous occurrence a *ureterotome externe* when he first reported it in 1909. Subsequently, during a visit to Europe, Keyes learned of the technique and brought it back to the United States in 1915. However, it was not until the 1940s that David M. Davis, in the twilight of his career in urology, rediscovered Albarran's work. Between 1943 and 1948, Davis developed the technique of “intubated ureteroplasty.” He reported an 89% subjective and a 60% objective success rate at 1- to 2-year follow-up (67,68).

Much interest resulted from Davis' reports, and during the ensuing decade many laboratory studies were undertaken in an effort to better understand how the intubated ureterotomy worked. From these studies it became apparent that the urothelium covered the ureteral incision, usually within 5 days. Ureteral muscle appeared to regenerate and grow around the incised ureter between 6 and 12 weeks; contracture appeared to play less of a role with regard to the development of an intact circumferential muscle layer. In addition, peristalsis was noted to return across the area of the incision within 6 weeks (135,136,230,274,372). Despite these revelations, by the late 1960s intubated ureterotomy had become a rarely performed procedure, having been superseded by the more successful and aesthetically more pleasing plastic reconstructive procedures of the renal pelvis, specifically the Anderson Hynes dismembered pyeloplasty.

The 1970s brought an explosion in interest in percutaneous nephrostomy; in the late 1970s, this new method for minimally invasive access to the kidney rapidly replaced open nephrostomy first, and later, open urolithiasis surgery. It was in this environment that in 1983, Mr. J.E.A. Wickham developed the concept for performing a percutaneous intubated ureterotomy by incising the UPJ from inside out (i.e., “pyelolysis”). Wickham, working with Miller, Whitfield, and Ramsey, used a cold-knife urethrotome to incise the ureteropelvic junction. Via a preplaced nephrostomy tract, the kidney was traversed, and the UPJ was incised until periureteric fat could be seen. A nephrostomy tube was placed at the end of the procedure; an indwelling stent was maintained across the incised UPJ for 4 weeks. The reported success rate was 64% (287,298).

Subsequently, A.D. Smith brought Mr. Wickham's pyelolysis to the United States; he renamed the procedure *endopyelotomy.* Using a cold-knife endoscopic technique with a newly developed hook blade, Smith, Badlani, Karlin, and associates achieved success rates of 87.5% in patients with both primary and secondary UPJ obstruction (10,176,250). In their series, a 14-Fr tapered external nephrostent was left indwelling for 6 weeks. By 1993, they had expanded their series to 189 patients; overall success rate was 86% at 6 to 96 months' follow-up regardless of a primary or secondary type of UPJ obstruction (251).

The approach and method of UPJ incision are variable. The approach may be either antegrade by endoscopic means or retrograde by endoscopic, fluoroscopic, or combined means. Nonetheless, the classic antegrade percutaneous approach is still a very popular method for performing an endopyelotomy (Fig. 19.17). Via an upper pole or middle posterior calyx nephrostomy tract, the UPJ is visualized directly and incised with a cold knife until periureteric fat is seen clearly.

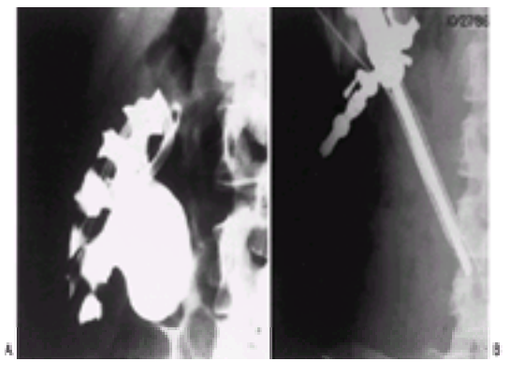

FIGURE 19.17. A: An antegrade nephrostogram reveals marked ureteropelvic junction obstruction. **B:** A cold-knife urethrotome has been introduced via the nephrostomy tract. A guidewire traverses the ureteropelvic junction. An incision in the ureteropelvic junction (UPJ) was then made along the lateral border of the UPJ.

Variations of the antegrade method include using a retrograde inflated balloon to invaginate the UPJ into the renal pelvis, using a wire-guided ureterotome blade, and a transpelvic approach. In the invagination method, the balloon is inflated just beneath the UPJ, provided the ureter has a low insertion into the renal pelvis. The inflated balloon is then pushed cephalad so that the UPJ is carried into the renal pelvis itself; as such, when the tissue overlying the balloon is incised, a double length of tissue is cut because the UPJ has been folded into the renal pelvis. This method should preclude any inadvertent incision of a crossing vessel and speeds the overall completion of the procedure (106,107). Alternatively, a wire-guided cutting instrument can be passed antegrade over the guidewire and through the narrowed UPJ, thereby incising it. This technique has been used successfully by both Korth and Schneider (201,318). Another technique is the transpelvic approach in which the renal pelvis is purposely incised along its lateral or posterolateral surface and the urethrotome is passed *outside* of the pelvis. The UPJ is then incised from the outside inward (273).

The retrograde approach varies from a purely fluoroscopic to an endoscopic technique. In 1987, Beckman and Roth (22) reported passing a retrograde angioplasty-type balloon to dilate the obstructed UPJ. Since then there have been few reports of a similar approach (Table 19.6). In general, an 8- to 10-mm dilating balloon catheter rated to 10 to 15 atm of pressure is passed retrograde until it straddles the obstructed UPJ. The balloon is then inflated until the obstruction disappears; the inflated balloon is left in place for a variable period of time (usually 1 minute). In some cases, the balloon is then deflated and reinflated for two more 60-second cycles.

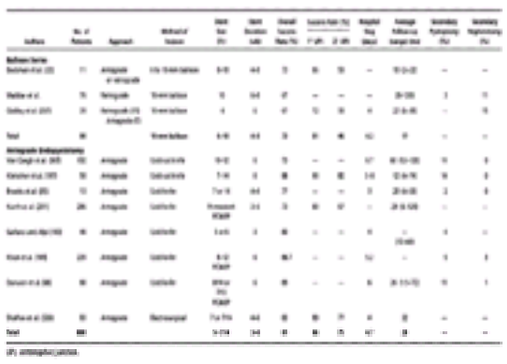

TABLE 19.6. ENDOPYELOTOMY: RETROGRADE BALLOON AND ANTEGRADE TECHNIQUE

At about the same time that Beckman and Roth described their retrograde fluoroscopic technique, Inglis and Tolley (160) reported a retrograde ureteroscopic approach to performing an endopyelotomy. In their approach, the rigid ureteroscope was passed up to the site of the UPJ obstruction, and the ureter was then incised with an electrosurgical probe until periureteric fat could be seen. Subsequently, several other urologists reported on a similar approach using electrocautery or a cold knife to make the incision (Fig. 19.18) (47). To facilitate delivery of the rigid or flexible ureteroscope, Thomas suggested stinting the ureter for 1 week before the planned endopyelotomy (356).

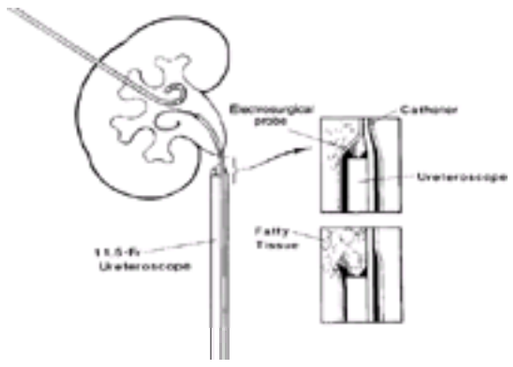

FIGURE 19.18. The 11.5-Fr long, rigid ureteroscope has been passed through the ureter; an electrosurgical probe tip can be seen protruding from the tip of the ureteroscope. The tip of the ureteroscope is covered with a nonconductive material. A nephrostomy rube remains from a preoperative Whitaker test. A safety guidewire and a 5-Fr nonconductive catheter have been placed up the ureter. The *inset* shows a close-up of the actual incision in the lateral aspect of the UPJ; the incision is continued until the full thickness of the ureteral wall has been cut and periureteral fat can be seen clearly. (From Clayman RV, Kavousi LR. Endosurgical techniques for noncalculous disease. In: Walsh PC et al, eds. *Campbell's urology,* ed 6. Philadelphia: Saunders, 1992:2277, with permission.)

A third variation on the retrograde approach was reported by Clayman and colleagues (52) in 1992. In this fluoroscopic technique, a 13-Fr electrosurgical wire-bearing, 8-mm balloon catheter is advanced over a guidewire until the balloon straddles the UPJ (Fig. 19.19). For primary UPJ obstruction before insertion over the guidewire, the balloon catheter is rotated until the electrosurgical wire faces laterally. The catheter is advanced halfway up the ureter, at which point a side-arm adaptor is placed on the throughput channel of the catheter. A retrograde ureterogram with dilute contrast is obtained, thereby defining the UPJ area. Next, the catheter is advanced across the UPJ; the electrosurgical wire should remain in a lateral orientation. The position of the electrosurgical wire is carefully checked with fluoroscopy (Fig. 19.20A,Fig. 19.20B). At this point, 0.5 mL of dilute contrast is placed in the balloon to define its position and to raise the electrosurgical wire slightly off of the catheter's shaft. Then the electrosurgical wire is simultaneously activated at 75 W of pure cutting current while the balloon is completely inflated to its full 2 mL volume (Fig. 19.20C). The inflated balloon is left in place for 10 minutes, and then it is deflated. There should be prompt extravasation from the incision site (Fig. 19.20D). If this is not the case, the cutting device can be activated one more time. If extravasation still is not appreciable, the cutting balloon catheter is deflated, pulled back to the midureter, and a retrograde ureterogram is repeated. If there is still no extravasation, the cutting balloon catheter is removed and a flexible ureteroscope can be passed to the site; if no incision in the ureter is seen, a cut can be made with a 2-Fr electrosurgical probe or a 360-micron Ho:YAG laser fiber passed through the flexible ureteroscope.

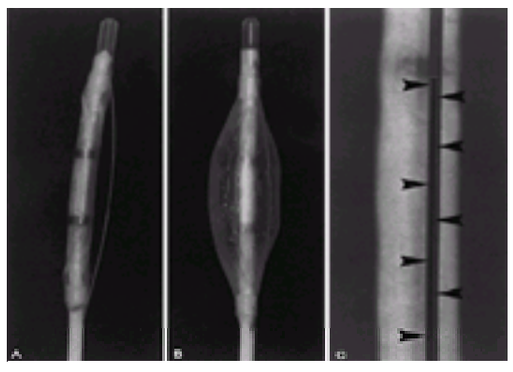

FIGURE 19.19. A: A cutting balloon (i.e., Acucise) is shown in its uninflated state. The cutting wire is clearly seen overlying the balloon. **B:** With the balloon inflated, the cutting wire is stretched over the balloon. **C:** A close-up of the cutting wire shows that the actual cutting surface of the wire *(arrowheads)* is only 150 microns in width but 2.8 cm in length.

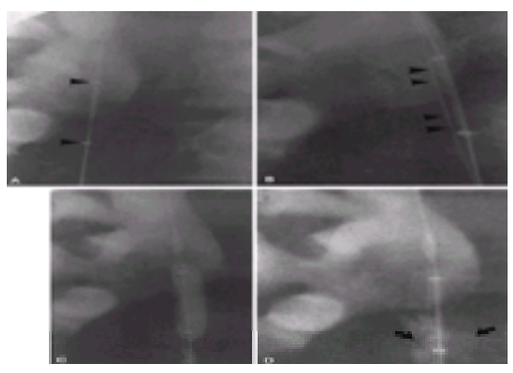

FIGURE 19.20. A: The cutting balloon has been passed up over the guidewire until the cutting wire straddles the ureteropelvic junction (UPJ) area. Note that the cutting wire lies between the two radiopaque markers *(arrowheads).* The cutting wire cannot be seen in this projection. **B:** The catheter has been turned so that the cutting wire is facing laterally *(arrowheads)* along the UPJ area. **C:** The cutting wire has been activated and the balloon has been fully inflated. **D:** As the balloon is deflated, extravasation of contrast *(arrows)* can be seen. Following this, the balloon is removed and an indwelling ureteral stent is placed along with a bladder catheter.

After the UPJ is opened, an external or internal stent varying in size from 8 to 14 Fr is placed. The stent duration is usually 4 to 6 weeks. A follow-up intravenous pyelogram (IVP) or Lasix washout renogram is obtained 1 to 2 weeks after stent removal and again at 3 months, 6 months, 1 year, and then annually for 5 years.

Results

The results of endopyelotomy, regardless of approach or method of incision, have been highly satisfactory. Although not quite equal to open pyeloplasty, the overall success rate has been high enough that, when combined with the minimal morbidity and short hospital stay associated with the procedure, endopyelotomy has become the preferred method of many urologists for treating adult UPJ obstruction.

The largest endopyelotomy experience to date is with an antegrade approach using a cold knife to incise the UPJ. Motola and colleagues (251) reported the initial large series of patients. Among 212 patients treated by antegrade endopyelotomy over an 8-year period between 1983 and 1991, the overall success rate was 89%. For patients followed 6 months or more, the success rate hardly changed: 86%. In addition, primary UPJ and secondary UPJ obstruction fared equally well (85% versus 86% success rate). Other urologists have independently reported success rates of 73% to 89% in series ranging from 13 to 286 patients (33,35,63,66,189,197,201,326,364). Overall, results for primary and secondary UPJ obstruction were comparable (Table 19.6).

In Motola and colleagues' (251) large series, operative time averaged 90 minutes with a hospital stay of 6.2 days. When compared with open pyeloplasty at their institution, they noted that endopyelotomy resulted in a shorter hospital stay (6.2 versus 10 days) and less operative time (90 minutes versus 106 minutes). Also, convalescence was much quicker in the endopyelotomy groups: 20 days versus 42 days. Brooks and colleagues (35) compared open and endourologic approaches with UPJ obstruction in 45 patients. Successful relief of obstruction was achieved in 100% of patients undergoing open and laparoscopic dismembered pyeloplasty,

78% undergoing Acucise endopyelotomy, and 77% undergoing antegrade percutaneous endopyelotomy. The Acucise endopyelotomy resulted in shorter convalescence (1 week) than the antegrade endopyelotomy (4.7 weeks), laparoscopic pyeloplasty (2.3 weeks), or open pyeloplasty (10.3 weeks). Complication rates were similar among all the groups.

Gupta and colleagues (132) reviewed 401 percutaneous endopyelotomy procedures performed over a 12-year period. Eighty-five percent of the failures occurred within 6 months of the endopyelotomy; although 2% failed as late as 5 years following the endopyelotomy. They noted that patients with high-grade hydronephrosis and poor initial renal function were much less likely to have a successful endopyelotomy than those with moderate hydronephrosis or good renal function. Other investigators have demonstrated similar results. The success rate for endopyelotomy in patients with UPJ obstruction caused by high insertion is similar to that reported for endopyelotomy in patients without high insertion (43,326).

Complications from endopyelotomy have been relatively few. Bleeding requiring transfusion has been noted in only 1% of patients in Smith's antegrade endopyelotomy series; however, others have noted significant hemorrhage in 8% to 9% of their cases (207,245). Cassis and co-workers (37) noted an overall major complication rate of 11%. Other serious complications have included ureteral avulsion, ureteral necrosis, and arteriovenous fistula formation (232,251,347). Urinoma, hematoma, and urinary tract infection also have been reported, albeit rarely.

For retrograde ureteroscopic endopyelotomy, success rates similar to antegrade endopyelotomy have been reported (Table 19.7) (44). An overall success rate of 80% was published by Meretyk and colleagues (245); however, in their series, there was a 16% incidence of intraoperative hemorrhage and a 20% incidence of distal ureteral strictures postoperatively. This resulted in their abandoning the retrograde endoscopic approach in favor of the antegrade technique. However, Thomas and colleagues (356) reported excellent results and low morbidity with a ureteroscopic approach, providing the ureter was stinted for 1 week before ureteroscopic endopyelotomy. In their series the success rate was 87%; one patient (2.5%) required urgent nephrectomy for acute bleeding. Of note, notwithstanding the early experience of Meretyk and associates (245), other urologists have reported an 82% to 90% success rate with the electrosurgical or Ho:YAG laser cutting modality (352,356). Interestingly, in two out of the three reports a dilating balloon is used following the incision at the UPJ to dilate the area. The overall experience with this approach remains small.

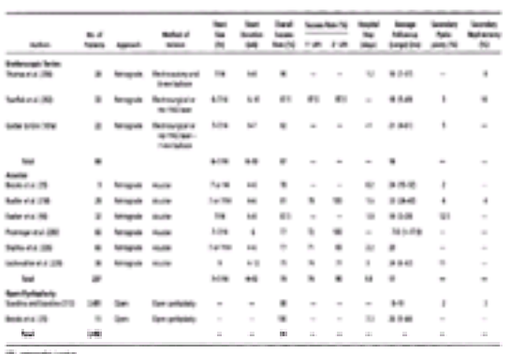

TABLE 19.7. RETROGRADE ENDOPYELOTOMY AND OPEN PYELOPLASTY

The retrograde, fluoroscopic approach to performing an endopyelotomy is the simplest method yet developed (Table 19.6 and Table 19.7). However, experience with either balloon dilation to 30 Fr or a balloon incision is less than with the antegrade approach. Although originally described by Kadir and colleagues (173) in 1982 in a patient with a secondary UPJ obstruction, balloon dilation of the UPJ did not undergo any significant testing until 1989, when Beckman and colleagues (23) and O'Flynn and colleagues (271) independently reported on its use in a series of 11 and 31 patients, respectively. After balloon dilation to 18 to 30 Fr, a 7- to 10-Fr stent was left indwelling for 4 to 8 weeks. Overall success rates of 68% to 73% were recorded at follow-up of 10 months. Of note, the procedure appeared to work better for primary (86% success rate) than for secondary (50% success rate) UPJ obstruction (23,173,271). Subsequently, McClinton and colleagues (236) expanded O'Flynn and colleagues' (271) original series and reported on 76 patients treated with endoballoon rupture of the UPJ using a 30-Fr balloon; follow-up of 8 months to 10 years revealed an overall success rate of 67%, with a re-treatment rate of 28%. With a single treatment, only 42% of patients had a durable successful outcome. Recent reports of balloon dilation of UPJ obstruction have used a 10-mm balloon catheter with reported success rates averaging 73%. Success with primary UPJ appears to be better than for secondary obstruction (Table 19.6). However, in a recent long-term follow-up, McClinton noted a durable response rate of only 52%.

Reports on the outcome of the endopyelotomy using a retrograde fluoroscopically guided cutting balloon are now available. In long-term follow-up of the Washington University series, at an average of 33 months' follow-up, the cure rate was 81% on diuretic renal scan evaluation (258). In this same group of patients, subjective analysis done with analog pain scales demonstrated that 61% had a favorable response with 36% totally free of pain and 25% markedly improved. Preminger and colleagues (293) reported a multiinstitutional clinical trial, with the cutting balloon catheter, in 66 patients with UPJ obstruction. With a mean follow-up of 7.8 months, the patency rate was 77% for the endopyelotomy, with 72% of the primary and 100% of the secondary UPJ obstructions remaining patent. Postoperative hemorrhage was the most significant complication, occurring in 3% of the patients, and controlled in both cases by embolization. Brooks and associates (35) compared the retrograde balloon incision to a standard antegrade endopyelotomy and to a laparoscopic pyeloplasty. The success rate for the antegrade and retrograde endopyelotomies was similar (77% to 78%) at 20 to 24 months' follow-up; however, the hospital stay (0.2 versus 3.0 days), analgesic use (1.2 versus 18 mg of morphine sulfate), and operative time (46 versus 145 minutes) were all less for the retrograde balloon incision. However, as with all of the retrograde approaches, there is no single series with more than 75 patients, and the number of published reports is limited.

Endopyelotomy: Unsettled Issues on Indication

In an effort to maximize the success rate of endopyelotomy, numerous investigations have been made into patient selection, procedural modifications, and the fate of endopyelotomy failures. Each of these areas is of vital importance because the answers to these questions may enable the urologist to preselect patients in whom endopyelotomy will have the best chance of working while providing the surgeon with the best instrumentation and appropriate guidelines necessary to maximize the chances of a favorable outcome. In addition, knowledge concerning the fate of endopyelotomy failures is essential so that urologists can provide their patients with accurate information on which to decide between an endourologic versus open procedure.

With regard to patient selection, concerns have been voiced regarding the use of endopyelotomy in the following seven circumstances: concomitant presence of renal calculi, children, the elderly, a high ureteral insertion, poor renal function, massive hydronephrosis, and a crossing renal vessel. First, it is important that the diagnosis of a UPJ be made in the absence of renal calculi. Szewcyzk and colleagues (348) have shown that patients with renal pelvic stones may appear to have a UPJ obstruction on preliminary testing. However, following percutaneous removal of these calculi, the associated edema in the area of the UPJ region resolves, indicating that the apparent UPJ obstruction was of a secondary, transient nature. Obviously, performing an endopyelotomy in this patient group or having a large number of these types of patients in an endopyelotomy series may result in an inflated success rate (348).

Pediatric endopyelotomy has been performed sparingly. In 1987, Towbin and co-workers (360) reported on the results of endopyelotomy for primary UPJ obstruction in three children, 11 to 18 years of age; the procedure was successful in two out of the three cases. Lingeman and colleagues (225) reported on seven children undergoing endopyelotomy for primary UPJ obstruction; in their series, a successful outcome occurred in 100% of children followed for an average of 13 months. More recently, Figenshau and colleagues (94) expanded Kavoussi and colleagues' (184) earlier report on pediatric endopyelotomy to 17 children ranging in age from 3 months to 17 years old. Endopyelotomy was performed for primary (eight cases) and secondary (nine cases) UPJ obstruction; at a mean follow-up of 25 months, the success rate in the primary group was only 62%, whereas the success rate in the secondary UPJ group was 100%. In two patients with a secondary UPJ obstruction, an additional percutaneous procedure was required to obtain a successful end result. All failures were found within the first year of follow-up. Schenkman and Tarry (312) compared 8 children undergoing endopyelotomy with a contemporary group of 20 children having an open pyeloplasty for UPJ obstruction. The endopyelotomy success rate at 1.5 years of follow-up was 88%. The open pyeloplasty success rate was 93%. The hospital stay was similar for the two groups (2.5 days versus 3.4 days for the endopyelotomy and open pyeloplasty, respectively). The operative time was longer for the endopyelotomy than for the pyeloplasty (220 versus 132 minutes, respectively), and this resulted in a higher average hospital cost for the endopyelotomy group ($8,474 versus $5,931, respectively).

At the other end of the age spectrum, endopyelotomy for primary and secondary UPJ obstruction in the geriatric population has proven quite successful. Horgan and colleagues (145) reviewed 18 patients ranging in age from 66 to 83 years; the success rate in these patients mimicked the success rate in the overall adult population:

88% for either primary or secondary UPJ obstruction. There were no intraoperative complications, and the average hospital stay was 6.3 days; these results were also identical to the hospital stay for their younger adult endopyelotomy patients.

Of ongoing concern to all urologists performing endopyelotomy is that the success rate is only 72% to 88%. In an effort to better identify ideal candidates for endopyelotomy, the following factors have been studied: high insertion, poor renal function, hydronephrosis, and the presence of a crossing vessel. Several investigators have determined that high insertion of the ureter has no adverse effect on outcome (43,327,364). In contrast, it was the opinion of Meretyk and associates (245) that poor renal function (i.e., less than 20%) augured a poor outcome; indeed, for these patients a nephrectomy was recommended. Gupta and colleagues (132) have similarly shown that patients with poor renal function were less likely to have a successful endopyelotomy (54% success rate if renal function is less than 25% versus 92% success rate if renal function is greater than 40%). With regard to hydronephrosis, Van Cangh and colleagues (365), Glinz and colleagues (117), and Gupta and colleagues (132) have each independently noted that massive hydronephrosis bodes ill. In Gupta and colleagues' (132) series, fully 89% of the failed endopyelotomies were among patients with severe or massive hydronephrosis. Similarly, Van Cangh and colleagues (365) noted a 76% success rate in patients with minimal hydronephrosis versus a 66% success rate in patients with grade 3 to 4 hydronephrosis. Glinz and colleagues (117) noted that among patients undergoing a successful endopyelotomy, the average volume of the renal pelvis was less than 60 mL.

The one area that has stimulated the greatest amount of debate regarding patient selection for endopyelotomy has been the issue of the crossing vessel (343). Cassis and associates (37) had first voiced concern about the potential importance of diagnosing the presence of a crossing vessel preoperatively; for this purpose the IVP was inadequate, and only an angiogram provided the necessary information. However, the seminal work on the impact of a crossing vessel on the outcome of an endopyelotomy was performed by Van Cangh and colleagues (365). They obtained preoperative angiograms in patients before endopyelotomy. The presence of a crossing vessel with either mild (grade 1 to 2) or severe (grade 3 to 4) hydronephrosis resulted in success rates of only 50% and 39%, respectively; whereas absence of a crossing vessel was associated with a successful outcome in 95% of patients with mild hydronephrosis and 77% of patients with moderate to severe hydronephrosis. In this series, the crossing vessel was the single most important prognostic factor (365). Including all series of open surgery, angiography, endoluminal US, and spiral CT, the incidence of crossing vessels in patients with UPJ obstruction averages 50% (33% to 79%) (131).

In the quest to diagnose a crossing vessel, the advent of two minimally invasive studies has been most timely. Today, endoluminal US and spiral CT provide the urologist with the ability to closely examine the UPJ area before proceeding with a given therapy (15,138). Endoluminal US involves the retrograde passage of a 7.2-Fr catheter over a 0.025-inch guidewire (Fig. 19.21). The tip of the catheter contains a 12.5- or 20-MHz US unit. The catheter is set up to scan 10 degrees from the perpendicular, providing a 360-degree cross section with a 1.5-cm radius. By slowly pulling the catheter through the UPJ area, the examiner can clearly identify any vein or artery crossing the UPJ and measure its size. Drawbacks to the technique, however, include the cost of the catheter (several hundred dollars), the invasive nature of the test, and the learning curve for the observer, which includes recognition of vessels, categorizing them as arteries or veins, and determining the anterior or posterior direction of vessel passage.

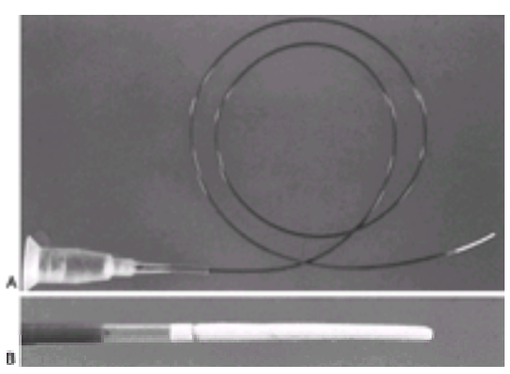

FIGURE 19.21. A: An endoluminal ultrasound catheter for intraluminal ultrasonography. The 7.2-Fr catheter passes over a 0.025-inch guidewire. **B:** The tip of the endoluminal ultrasound unit contains either a 12.5- or 20-MHz ultrasound unit capable of providing 360-degree scans of the ureter with a radius of 1.5 cm.

Nonetheless, using this method Tawfiek and colleagues (352) reported on 37 successful examinations in 27 patients with a primary UPJ obstruction and in 10 patients with a secondary UPJ obstruction. Crossing vessels were seen in 53%; the vessels crossed the UPJ anteriorly (16%), posteriorly (6%), anteromedially (9%), anterolaterally (19%), and anteriorly and posteriorly (3%); none were noted directly lateral (Fig. 19.22). This variation in vessel distribution is similar to that observed by Sampaio and Favorito (309) in their postmortem study of the normal UPJ, in which they noted 65% of patients had a crossing vessel at the UPJ; however, no vessels crossed the lateral surface. In Tawfiek and Bagley's report (352), the information gleaned from the endoluminal US study helped determine the site of endopyelotomy incision in 16 patients and changed the planned therapy in 5 patients.

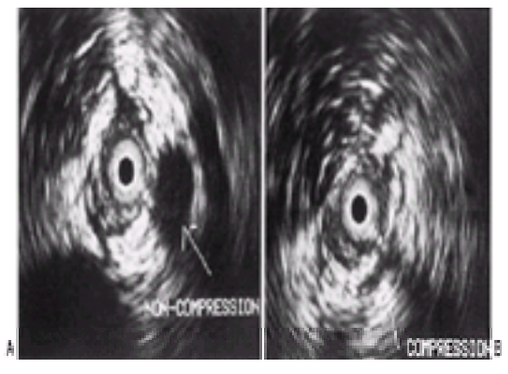

FIGURE 19.22. A: An endoluminal ultrasound study performed at the level of the ureteropelvic junction (UPJ) reveals a large vessel crossing the UPJ directly posterior *(arrow).* Noncompression refers to the conditions at the time of scanning: no manual pressure was put over the kidney area. **B:** By pressing down on the flank directly overlying the area of the scanning, the crossing vessel *(arrow)* can be compressed, thereby indicating its probably venous nature.

Spiral (helical) CT differs from the standard tomography the way a bread slicer differs from a potato peeler (138) (Fig. 19.23). In the former situation, only sections of the area of interest can be studied; although these sections can be made quite thin, an accurate reconstruction of the area is difficult. In the latter situation, a dynamic ongoing record of the entire area of interest is made; this continuous radiographic recording then can be reconfigured to provide the observer with views of the area from every conceivable angle. To accomplish this, during CT scanning the x-ray source undergoes rotation in a spiral pattern while the patient is moved through the CT scanner. With this arrangement, an entire scan of the area of interest usually can be done with a single breath hold (i.e., less than 25 seconds). Both the total amount of radiation exposure and the amount of image noise are reduced compared with conventional CT technology. With this technique, overlapping images at intervals as small as 1 mm can be obtained. The ability to detect small vessels around the UPJ is further improved by giving a bolus of intravenous contrast just before scanning. As such, vessels as small as 2 mm in size that cross the UPJ area can be detected. In addition, by reconstructing the renal pelvis, an accurate measurement of its size can be obtained, further enabling the surgeon to better determine the suitability of a given patient for endopyelotomy. Quillin and colleagues (296) imaged 24 consecutive patients, with symptomatic UPJ obstruction, with dual-phase, contrast-enhanced helical CT. Eleven (46%) of the patients collectively had 11 anterior and three posterior vessels (2 mm or greater in diameter) crossing the UPJ on helical CT. Laparoscopy and open surgery findings were in agreement with the helical CT angiogram for five of five patients in this study. Uncomplicated endopyelotomy was performed for 11 patients in whom no significant vessels were seen posterior or posterolateral to the UPJ.

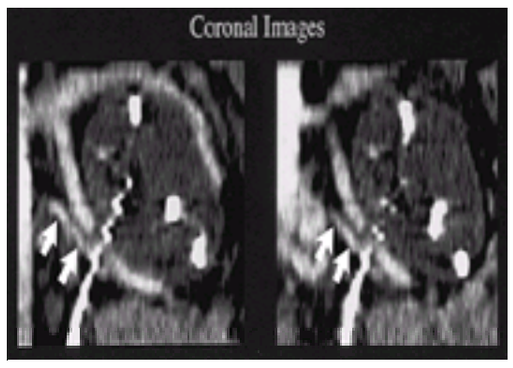

FIGURE 19.23. In this spiral computed tomography scan of a 34-year-old male patient with a UPJ obstruction, the coronal reconstruction reveals a vessel *(arrows)* crossing the UPJ posteriorly. The density of the vessel suggests that it is probably an artery.

Armed with endoluminal US and spiral CT, several investigators are seeking to corroborate Van Cangh and colleagues' (365) findings because many questions remain unanswered. Specifically, it remains puzzling that despite the presence of a crossing vessel, even in Van Cangh and colleagues' (365) series the endopyelotomy was still successful in approximately 50% of patients depending on the degree of hydronephrosis. Nakada and colleagues (260) demonstrated in 16 patients, who had undergone successful cutting balloon endopyelotomy for UPJ obstruction, with greater than 2-year follow-up, that six (38%) had anterior or posterior crossing vessels based on CT angiography. Could it be that only some and not other vessel configurations are directly responsible for the UPJ obstruction? Perhaps only an anterior crossing vessel causes problems or perhaps a crossing artery is of greater concern than a crossing vein. The next question arises that if a crossing vessel is found, what should be the next step: open pyeloplasty, laparoscopic pyeloplasty, laparoscopic exploration and incision of the vessel if it is not a major renal arterial branch, or laparoscopic exploration and incision of the vessel combined with endopyelotomy? Further clinical evaluation will be necessary to determine the significance and implication of the crossing vessel associated with UPJ obstruction. Ideally, appropriate laboratory and clinical studies will allow the urologist in the future to confidently select patients for endopyelotomy knowing that the procedure will then be as successful as its open surgical counterpart. In all respects, this continues to be the goal of each endourologic procedure: to offer the patient a minimally invasive approach of efficacy equal to, but with morbidity less than, a standard open surgical procedure.

Endopyelotomy: Unsettled Technical Issues

To what extent differences in the technical aspects of performing an endopyelotomy affect the ultimate success rate remains unknown. Controversy continues in several areas: the method of incision, the size of the indwelling stent placed after the endopyelotomy, and the period of time that the stent is left indwelling. From an incisional standpoint, although a cold-knife urethrotome continues as the preeminent method for opening the ureteropelvic junction, a variety of apparently equally efficacious methods have been described. Hulbert and colleagues (155) and Meretyk and colleagues (245) have independently reported on using a minute electrosurgical probe for making the incision; similarly, Chandhoke and colleagues (40) have reported on using an electrosurgical cutting balloon, whereas O'Flynn and colleagues (271) have written about using a 10-mm dilating balloon presumably to split the UPJ along its weakest point, and Tawfiek and Bagley (353), Gerber and Alsikafi (107b), and Renner and others (300a) have individually reported using the Ho:YAG laser to incise the UPJ stricture. As noted, the results with any of these techniques appear to be remarkably similar. Studies examining electrosurgical incisions have shown that when the cutting surface of the probe is less than or equal to 400 microns, the resulting incision and peripheral damage are indistinguishable from the incision achieved with a cold knife. However, probes that have a 1-mm or larger tip cause significantly more damage and should be avoided (75). With balloon disruption of the UPJ area, laboratory studies have shown that although the balloon splits the ureteral mucosa and muscularis, the adventitia usually remains intact, thereby precluding any significant retroperitoneal extravasation. The balloon at times splits the ureter along a single plane; however, the site of the split and the overall length of the tear are highly variable (288). With regard to other endoscopic cutting modalities, such as bipolar electrosurgical probes or special laser fibers (e.g., side-firing fiber with a KTP laser), data are unavailable.

Controversy continues over the size of the stent to leave indwelling after an endopyelotomy. For years, the notion has been that the stent serves as a mold around which the ureter heals. This philosophy was strongly endorsed in Davis's classic writings; based on his clinical experience, Davis recommended that as large a stent as possible should be placed following an intubated ureterotomy (68). As such, many urologists have advocated leaving a 14-Fr stent in place, in the hope that the healed UPJ will then assume the same size as a normal UPJ. These large stents have a dual taper so that the portion traversing the incised UPJ is 14 Fr, while the portion in the bladder is only 7 to 8 Fr. Both an external nephrostent and internal double pigtail design have been used. However, laboratory studies have challenged Davis's notion. Moon and colleagues (247) could show no difference in ureteral healing in a pig model after a cutting-balloon endoureterotomy whether a 7- or 14-Fr stent was used. Similarly, there have been a few clinical reports suggesting that the stent, rather than a mold, is actually serving as a *scaffold* along which the orderly growth of the urothelium and subsequent ingrowth of the ureteral musculature is guided, a concept attributed to Hinman (274). In several series, indwelling stents of 8 to 10 Fr have been placed; the outcomes have been highly favorable, with success rates of 83% to 88% reported (44,197,236). If stent size is ultimately shown not to affect the outcome of an endopyelotomy, the need to prestint the ureter before a retrograde endopyelotomy would be decreased, and the ease and safety of postendopyelotomy stent placement and removal would be facilitated.

Research has challenged the 6-week stent practice. Animal studies by Kerbl and colleagues (187) revealed that in a pig ureteral stricture model, stinting for 1 week with a 7-Fr stent provided results as good as stinting for 3 or 6 weeks. In the 1-week group, the results for endoureterotomy of longer strictures were statistically significantly better than in either the 3- or 6-week groups. Clinically, Kuenkel and Korth (207) noted in their series of 143 endopyelotomies that a stent for 3 weeks produced superior results to leaving a stent for 6 weeks. Abdel-Hakim (1) has noted that as short a stinting period as 4 days was successful in five patients, each of whom was stinted with a 7-Fr external ureteric catheter. However, maximum follow-up in this series was only 6 months. Kumar and colleagues (209) demonstrated that 2 weeks of stent placement were as effective as 4 weeks in the successful outcome of antegrade endopyelotomy. Obviously, in this regard we again have much to learn; prospective, randomized clinical studies of patients with similar types of UPJ obstruction are sorely needed to answer this and other questions regarding stinting after endopyelotomy.

Endopyelotomy: Fate of Failed Procedures

One last question regarding endopyelotomy is of paramount importance. Specifically, is the patient in whom an endopyelotomy fails placed at a disadvantage for subsequent surgical salvage? Certainly, if this is the case, one would be most hesitant to proceed with a minimally invasive procedure in which a failure rate as high as 30% could be expected. Kavoussi and colleagues (180) and Motola, Smith, and colleagues (252) have independently written on the fate of the failed endopyelotomy patient. Both reports noted that although salvage open pyeloplasty is at times a bit more difficult to perform than a primary pyeloplasty, the overall success rate was excellent. Among 15 patients in Motola and colleagues' (252) series and 5 patients in Kavoussi and colleagues' (180) report, all underwent a successful salvage dismembered pyeloplasty. Follow-up at 1 to 7 years revealed that all 20 patients had a successful outcome. Of note, in the Kavoussi and colleagues (180) series, one patient underwent a nephrectomy because of decreased renal function, whereas in the Smith series there were no subsequent nephrectomies.

Calyceal Diverticulum and Hydrocalyx

The calyceal diverticulum and the hydrocalyx are two entities related by the narrowness of their communication with the collecting system. Whereas in the former, there is no associated functioning renal tissue, in the latter, the relief of obstruction can have a potentially positive effect on renal function. As such, the endosurgical approach to these two conditions is quite different.

Calyceal diverticula are noted on 0.45% of intravenous urograms. Most commonly these outpouchings are unilateral and emanate from a minor calyx and are more of anatomic than clinical interest. Only one-third become symptomatic because of the development of urolithiasis, pain, hematuria, or recurrent infection (357).

Far more rare than calyceal diverticula is the hydrocalyx. This is usually an acquired condition caused by infection (e.g., tuberculosis, urolithiasis, prior intrarenal surgery). A congenital isolated hydrocalyx may be either developmental or associated with extrinsic compression from a crossing segmental renal vessel; the latter has been described most commonly in the upper pole of the kidney (Fraley's syndrome) (89,97). At times, the distinction between a hydrocalyx and a calyceal

diverticulum only can be made during nephroscopy; the absence or presence of a papilla differentiates between a diverticulum and a hydrocalyx, respectively.

Calyceal Diverticulum: Technique

For the few calyceal diverticula requiring surgical therapy, the standard approach has been to excise or marsupialize the diverticulum; the neck of the diverticulum is then closed with a suture. For a very large diverticulum, partial nephrectomy is performed. However, beginning in the late 1980s these lesions began to be managed successfully endourologically by percutaneous and ureteroscopic methods. There have also been a few case reports of successful laparoscopic treatment of a calyceal diverticulum (118).

When approached percutaneously, the diverticulum should be entered directly; the renal pelvis or normal part of the collecting system is not initially entered (Fig. 19.24) (158). Once inside the diverticulum, any stones are removed. Next, the opening of the diverticulum into the collecting system is identified and cannulated with a guidewire; the guidewire is then covered with a 5-Fr angiographic catheter. With use of a roller electrode, the entire inner surface of the diverticulum, except the neck of the diverticulum, is electrocoagulated. Following this, the neck of the diverticulum is enlarged by multiple electrosurgical (less than 400-micron tip) endoscopically guided, shallow (less than 2 mm in depth) incisions, balloon dilation to 12 to 24 Fr, and/or dilation with coaxial dilators to 26 to 28 Fr. Next, a nephrostomy tube is placed such that it traverses the diverticulum and terminates in the renal pelvis. This tube is usually removed 2 to 7 days later (48,157,171,211).

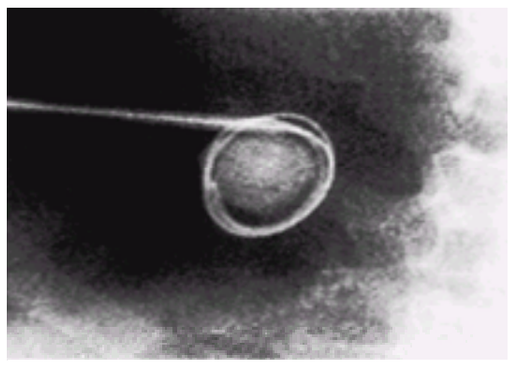

FIGURE 19.24. Direct percutaneous puncture of a stone-containing calyceal diverticulum. The wire has been coiled several times within the diverticulum to enable the urologist to dilate the tract over the stiff part of the guidewire. (From Hulbert JC, Reddy PK, Hunter DW, et al. Percutaneous techniques for the management of caliceal diverticula containing calculi. *J Urol* 1986;135:225, with permission.)

There are two alternatives to percutaneously cannulating and incising the neck of the diverticulum. In both situations, the neck of the diverticulum is not sought. In one technique, the entire inner surface of the diverticulum, including the presumably unidentified diverticular neck, is electrocoagulated under endoscopic control; a tube is left in the diverticulum for 2 to 3 days and then removed. The true collecting system of the kidney is never entered (323). In the other approach, a transdiverticular puncture into the collecting system is made; the interior of the diverticulum is either electrocoagulated as previously described or left intact. The neoinfundibulum is either dilated (12 to 18 Fr for 2 minutes), thereby creating a new drainage path, or is allowed to heal closed. In the former situation, an 8- to 10-Fr nephrostent is placed, whereas in the latter circumstance, the tip of the tube is placed only into the diverticulum. In Lang's (214) series, the stent was left in place for 4 weeks, following which it was exchanged for an indwelling stent of unspecified size and duration (27).

When approached ureteroscopically, the neck of the diverticulum is first identified, following which a safety guidewire may be passed into the diverticulum or into the renal pelvis. The lens of the ureteroscope is removed so that a 4-mm dilating balloon catheter can be passed over the guidewire through the sheath of the ureteroscope; the balloon is passed retrograde until it straddles the neck of the diverticulum. The balloon is then inflated, thereby dilating the neck of the diverticulum; the balloon is then deflated and removed. The ureteroscope's lens is replaced and the ureteroscope is advanced into the diverticulum. Alternatively, flexible ureteroscopy can be done and a nonconducting guidewire can be passed into the diverticulum. Next, a 2- or 3-Fr electrosurgical probe can be used to incise the neck of the diverticulum; several radial incisions (less than 2 mm) are made, and the ureteroscope is advanced into the diverticulum (Fig. 19.25). The calculus is then fragmented with laser or electrohydraulic energy, and the walls of the diverticulum can be treated with either electrocautery or Nd:YAG energy. An indwelling ureteral stent is placed in the collecting system; the stent does not transverse the diverticulum. Alternatively, following dilation of the neck of the diverticulum, the calculi may be treated by shock wave lithotripsy; however, in this case the diverticulum will probably remain intact (98,157,246).

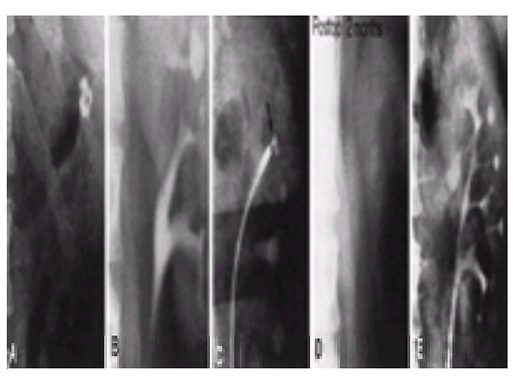

FIGURE 19.25. A: A plain abdominal radiograph reveals multiple calculi lying in the kidney just above the eleventh rib. **B:** An intravenous urogram reveals that the stones are lying in an upper pole calyceal diverticulum. **C:** The flexible ureteroscope has been advanced retrograde, and the neck of the calyceal diverticulum has been identified. With a 3-Fr electrosurgical probe, the neck of the diverticulum is incised, following which the stones are fragmented using laser lithotripsy. **D:** At 2 months after the operation, a plain abdominal radiograph reveals only a few stone flecks in the area of the diverticulum. **E:** The intravenous urogram at 2 months after the procedure reveals that the diverticulum has decreased markedly in size.

Another approach to treating the stone-bearing calyceal diverticulum is extracorporeal shock wave lithotripsy. Although this results in successful fragmentation of the stone in the majority of patients, in most cases, the stone fails to pass; however, many patients do become at least transiently asymptomatic. Of note, the diverticulum remains unaltered; hence, the potential for recurrent stone disease in the diverticulum remains a real risk. According to Streem and Yost (345), the ideal diverticulum for a primary ESWL approach is one in which the neck of the diverticulum is visibly patent on the pretreatment radiographs and the stone burden is less than 1.5 cm.

Hydrocalyx: Technique

In contrast to the calyceal diverticulum, the traditional approach to treating a hydrocalyx has been open partial nephrectomy or transposition of an obstructing vessel. Minimally invasive approaches to this problem have included both ureteroscopic and percutaneous therapy; however, the more common endourologic approach has been via a percutaneous route (165). With the endourologic approach, the goal is twofold: to open the narrowed infundibulum and to preserve the functioning calyceal tissue. A direct percutaneous approach into the hydrocalyx may be attempted. In this case, the technique is identical to that described for treating a calyceal diverticulum except that after incising or dilating the neck of the infundibulum (12- to 18-Fr balloon or 20- to 24-Fr Amplatz dilators), the walls of the hydrocalyx are not disturbed in an effort to preserve the function of the now unobstructed calyx (25).

In incising an infundibulum, it is important to limit the depth of any incision to only 2 mm in order not to injure any of the larger vessels that may surround the infundibulum (48). Anatomically, the vessels surrounding an infundibulum are most prevalent along its anterior and posterior surfaces; the superior and inferior surfaces of the infundibulum are less vascular. Based on anatomic studies, Sampaio (308) recommended that the initial incision should be on the superior surface of

the infundibulum; if need be, a counterincision can be made along the inferior surface. These surfaces in a middle calyx would be akin to the medial and lateral surfaces of an upper- or lower-pole calyx; in these cases, a lateral incision has been recommended (159). Again, anterior and posterior incisions should be avoided because they may result in significant hemorrhage.

Overall, the least invasive yet most effective form of therapy for a symptomatic, stone-containing calyceal diverticulum is a direct percutaneous approach with stone removal and obliteration of the walls of the diverticulum. Using this approach, up to 100% of patients can be rendered asymptomatic; more than 90% of patients become stone free; and in two-thirds or more of cases, the calyceal diverticulum is obliterated, thereby precluding recurrent urolithiasis or infection (Table 19.8) (89,154,171,318). In these cases, either cannulation and dilation of the true neck of the diverticulum or electrocoagulation of the entire diverticulum is recommended. In contrast, balloon dilation of a newly created drainage path from the diverticulum into the collecting system results in diverticular obliteration in only 20% of cases; however, in 70% of cases, the neoinfundibulum remains patent, thereby draining the calyceal diverticulum (214).

Authors	No. of Patients	Technique	Symptom Free (%)	Stone Free[a] (%)	Diverticulum Obliterated	Average Follow-up (range) (mo)	Catheter Duration

TABLE 19.8. CALYCEAL DIVERTICULA: PERCUTANEOUS APPROACH

The other endourologic methods for approaching this disease entity are less effective. With regard to ESWL, its success rate is highly variable dependent on how selective the physician has been (Table 19.9). In patients with a small stone burden (i.e., less than 1.5 cm) and with a patent diverticular neck on radiographic studies, Streem and Yost (345) achieved an 86% rate of asymptomatic or less symptomatic patients and a 58% stone-free rate; at follow-up 2 years later, 8% of these preselected patients had re-formed a stone in the treated calyceal diverticulum. Also, they noted that of nine patients treated in this manner who also had infection, recurrent infection occurred in 67%. Other urologists, using no selective criteria, have reported post-ESWL symptom-free rates of only 36% and stone-free rates of only 0% to 20% (101,171,294). A purely ureteroscopic approach was effective in only two of six patients treated by Mikkelsen and colleagues (246). In sum, percutaneous calyceal diverticulectomy with removal of the calculus and obliteration of the walls of the diverticulum remains the most definitive and long-lasting less invasive method of treating the symptomatic calyceal diverticulum. Other less morbid procedures are often less effective.

Authors	No. of Patients	Technique	Symptom Free (%)	Stone Free[a] (%)	Diverticulum Obliterated	Average Follow-up (range) (mo)	Catheter Duration

TABLE 19.9. CALYCEAL DIVERTICULA: EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY (ESWL)

Unlike with calyceal diverticula, there is scant experience in treating infundibular stenosis endourologically. Schneider and co-workers (317) reported on six patients with a hydrocalyx among whom a cold-knife incision was successful in 66%; the catheter was left indwelling for 3 to 6 weeks. The length of follow-up was not stated. Similarly, Lang (214) reported a 67% success rate in six patients with a hydrocalyx, treated by percutaneous infundibuloplasty (i.e., balloon dilation) who were followed for 2 to 7 years. In his series, the infundibulum was dilated with a 12- to 18-Fr balloon, which was left inflated for 2 minutes. Following this, an 8- to 10-Fr nephrostent was placed; the external stent was left in place for 4 weeks, after which it was exchanged for an internalized stent of unspecified size and duration. Hwang and Park (159) reported an 80% success rate with cold-knife infundibulotomy among 10 patients with tuberculous infundibular strictures followed for longer than 1 year after their percutaneous procedure.

Transitional Cell Cancer of the Renal Pelvis

Transitional cell cancer rarely affects the upper urinary tract: 94% of all transitional cell tumors occur in the bladder, whereas only 5% are found in the renal pelvis and 1% in the ureter (51,375). Traditionally, the therapy for all upper tract tumors has been an open surgical ablative approach. For the kidney and upper ureter, this has entailed a nephroureterectomy with excision of a cuff of bladder, whereas for the distal ureteral tumor, distal ureterectomy and ureteral reimplantation usually has been sufficient. The feasibility of an endosurgical approach to these tumors was championed by Gittes (114), who in 1980 questioned why low-stage, low-grade tumors of the ureter and renal pelvis could not be treated by local excision just as it is common practice for similar types of lesions affecting the bladder. For many years, the stumbling block to this approach remained one of access. However, with the advent of percutaneous and ureteroscopic techniques in the 1980s, this minimally invasive hypothesis could be examined more directly (383,384).

A major area of contention with regard to the endosurgical therapy of upper tract TCC is the appropriate indications for such therapy. On the one hand, some urologists believe this to be “heroic” therapy and thus would limit its application to individuals with a solitary kidney, with renal insufficiency, or who are a high surgical risk. On the other hand, other urologists believe equally as strongly that for low-grade, low-stage disease, an endosurgical excision should be offered to all patients as a simpler, less morbid, renal-sparing form of therapy. This controversy continues to grow because advances in endoscopic equipment and in electrosurgical and laser technology have greatly facilitated the ability of the urologist to access and treat superficial lesions anywhere in the upper urinary tract. As such, today an endosurgical approach would technically be feasible in approximately 40% to 50% of all patients (i.e., patients with low-grade and low clinical stage disease) with upper tract transitional cell cancer (375).

Technique

When approaching transitional cell cancer of the renal pelvis (TCCP), the ureteroscope may be most effectively used if the lesion is small (i.e., less than 1 cm). In males, except for the distal ureter, a flexible ureteroscope is commonly used, and the tumor, after excisional biopsy, is usually treated with electrocautery, the Nd:YAG laser, or Ho:YAG laser (314) (Fig. 19.26). In females, a rigid ureteroscope usually can be used to reach the renal pelvis and the upper-pole calyx, whereas a flexible ureteroscope is needed to approach lesions in the middle or lower calyces (14).

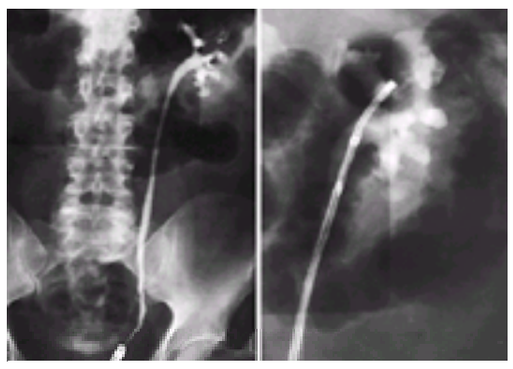

FIGURE 19.26. A retrograde ureterogram reveals poor filling of an upper-pole calyx. Flexible ureteroscopy revealed a papillary transitional cell carcinoma. The tumor was biopsied; however, because of its size and sessile nature, fulguration was not performed. The patient subsequently underwent a nephroureterectomy.

In all ureteroscopic cases, a nonconducting guidewire (i.e., Terumo or guidewire) is passed into the kidney to serve as a safety guidewire. This safety guidewire remains in place throughout the procedure and is used at the end of the procedure for the passage of an indwelling ureteral stent.

In procedures involving the upper ureter and renal pelvis, the distal ureter is dilated with a 4-mm balloon if a 9.4-Fr flexible ureteroscope is to be used or with an 8- to 10-Fr fascial dilator set if a 7.5-Fr flexible ureteroscope is available. If the patient previously has undergone diagnostic ureteroscopy and an indwelling stent was placed, the ureter usually will have dilated passively around the stent, precluding the need for active, acute dilation. Also in this situation, the surgeon is benefited by knowing the diagnosis such that the goal at the second session is therapy alone. If a preoperative diagnosis has not been obtained, the urologist will have to biopsy the lesion and then proceed with definitive therapy. In this circumstance, there is usually bleeding from the biopsy site, and subsequent therapy may be compromised because of impaired visibility. If this occurs, it is prudent to stop the procedure, place an indwelling stent, and plan to return on another day to therapeutically address the tumor.

If, during the procedure, the flexible ureteroscope cannot be easily advanced to the tumor site, the procedure should end. In the upper ureter, the ureteral wall is much thinner than in the distal ureter and it can be perforated easily. As such, it is not recommended to use a 4-mm balloon to dilate the upper ureter because ureteral perforation and possible retroperitoneal seeding may occur. In this case, it is far more prudent to place an indwelling ureteral stent and return in a few days to 1 week to perform the ureteroscopy. As previously noted, with an indwelling ureteral stent in place, the ureter will dilate passively, thereby facilitating subsequent ureteroscopy.

Throughout the ureteroscopic procedure, the irrigant pressure is kept below 100 mm Hg in order to preclude hypothetical renal backflow of any tumor cells. The only time the pressure on the irrigant is raised is when an instrument is passed through the working channel. In this situation, the pressure on the irrigant may be increased to 150 mm Hg; as soon as the instrument is removed, the irrigant pressure should be returned to less than 50 mm Hg. Furthermore, throughout the procedure it is important not to introduce air into the collecting system. Not only will the presence of air make it more difficult to work because of the air-fluid interface and the reflection of light off of the air bubble, but also it may set up a situation in which an explosion can occur during electrocoagulation, resulting in extravasation and possible tumor spillage (9).

The goal of the treatment either is to resect or to coagulate the entire tumor. In the former circumstance, the resection is carried down flush with the urothelium. With the rigid ureteroscope this can be done with a small electrocautery loop. With the flexible ureteroscope, the cold-cup biopsy forceps is used to tediously resect the superficial portion of the tumor and biopsy the tumor's base, following which the base of the tumor is electrocoagulated or treated with the Nd:YAG laser (20 W); alternatively, the tumor can be vaporized and the base coagulated with the Ho:YAG laser. At the end of the procedure, a retrograde ureterogram is performed in order to rule out any extravasation. An indwelling ureteral stent and a urethral catheter are placed. The urethral catheter is removed on the next morning. The ureteral stent is removed in 3 to 5 days, unless a significant perforation has occurred, in which case the stent is left in place for approximately 4 to 6 weeks; in this case, a cystogram is performed before removing the urethral catheter to rule out ureteral extravasation.

The percutaneous approach is reserved for larger tumors (i.e., larger than 1 cm) (350,351). The method of resection appears to be continually evolving. Initially, a retrograde ureteral catheter usually is placed. This can be a 7-Fr, 11.5-mm balloon occlusion catheter; the balloon can be inflated in the renal pelvis and snugged down at the UPJ to preclude any tumor fragments from traveling into the ureter. The puncture into the collecting system is made such that the urologist both will have a straight approach to the tumor and yet enter the collecting system as far from the tumor as possible (Fig. 19.27). The tract is dilated to 30 Fr with a high-pressure balloon, and then a 30-Fr Amplatz working sheath is placed. The irrigant is kept at a pressure of less than 100 mm Hg. The tumor is resected piece by piece with a standard 24- or 26-Fr resectoscope. With each pass of the resectoscope loop, the tumor fragment is evacuated from the collecting system. The base of the tumor is biopsied with a cold-cup forceps and fulgurated using the Nd:YAG laser (at 20 to 30 W for 3-second exposures) or electrocautery (50 W) (125). The occlusion balloon catheter is then deflated and removed; an indwelling nephrostomy tube is positioned in the renal pelvis. Two days after the procedure, a nephrostogram is performed; if there is no extravasation, the nephrostomy tube is removed. Alternatively, the nephrostomy tube may be left in place for 9 to 12 weeks, during which time instillation chemotherapy can be given on a weekly basis; similarly, by leaving the nephrostomy tube in place, second-look nephroscopy and tumor-base rebiopsy and fulguration can be accomplished at 6 or 12 weeks.

FIGURE 19.27. A: In a patient with a solitary kidney and hematuria, a retrograde ureterogram reveals a papillary filling defect at the level of the ureteropelvic junction. Subsequent ureteroscopy and biopsy showed the lesion to be a low-grade transitional cell cancer. **B:** A percutaneous nephrostomy was established via an upper-pole posterior calyx, thereby providing direct access to the tumor via a remote calyx. A standard resectoscope was then used to excise the tumor, and a nephrostomy tube was placed. (From Clayman RV, Kavousi LR. Endosurgical techniques for noncalculous disease. In: Walsh PC et al, eds. *Campbell's urology,* ed 6. Philadelphia: Saunders, 1992:2301, with permission.)

Results

The key question with regard to an endosurgical approach to TCCP is, To whom should this therapy be applied? Although there is consensus that for patients with low-grade, low-stage disease and with a solitary kidney, renal insufficiency, or high surgical risk that this minimally invasive approach is reasonable, there is significant concern about extending this approach to all patients with upper tract transitional cell cancer. In Table 19.10, series on the percutaneous treatment of TCCP are reviewed; the patients cited in these papers are also subdivided according to the grade or stage of their disease. What becomes clear is that even for low-grade or low-stage disease, the recurrence rate within the first 2 years after percutaneous resection is high: up to 33% (45,86,168,221,233,284). As such, multiple, subsequent endosurgical procedures can be expected. Also, among those patients with low-grade disease, approximately 75% underwent adjunctive therapy with iridium wires, instillation chemotherapy, or second-look procedures with further laser therapy to the tumor base. Despite all of this additional treatment, recurrences

were still noted in one-third of patients. Also during the same 2- to 4-year follow-up period, 23% of patients required a nephroureterectomy (45,86,168,221,233,284).

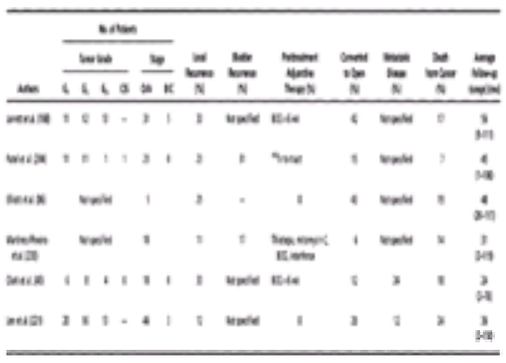

TABLE 19.10. UPPER TRACT TCC: PERCUTANEOUS ENDOSURGICAL THERAPY

The results of endosurgical therapy are only slightly better for patients with TCCP approached ureteroscopically; however, in most of these cases the tumors have been small (less than 1 cm) and usually low grade (G_1 to G_2) (Table 19.11). In 69 patients gleaned from various series with grade 1 tumors, there has been no report of local recurrence and no conversion to an open procedure at an average follow-up of 17 months; however, for 31 patients with grade 2 or 3 tumors, ureteroscopic resection was followed by local recurrence in up to half of the patients and conversion to an open procedure in 23% with an average follow-up of 32 months.

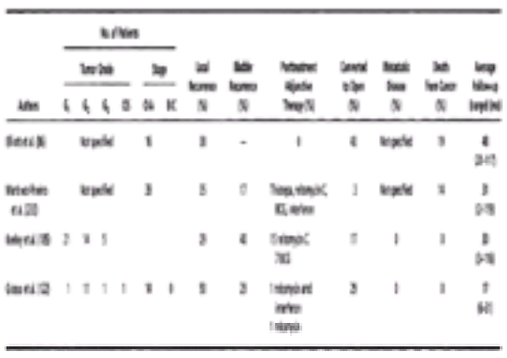

TABLE 19.11. UPPER TRACT TCC: URETEROSCOPIC ENDOSURGICAL THERAPY

Although some authors have been able to identify a patient population in whom recurrence in the short term is low, this has not been the case in other series. Most series incorporate topical chemotherapy, following the initial percutaneous resection, as the management protocol for upper tract TCC. Jarrett and colleagues (168), using this regimen, noted that among their 11 patients with a solitary, stage 0/A, G_1 lesion, there were tumor recurrences in two patients during a greater than 4-year follow-up period; one was treated by endoscopic resection and one by nephroureterectomy due to large volume disease. Clark and colleagues (45) reported a 33% recurrence rate in their similar stage and grade patients with percutaneous management and topical BCG for upper tract TCC. Orihuela and Smith (279) noted several risk factors for recurrence: lack of use of postoperative BCG instillation, a sessile lesion, a tumor larger than 2 cm in diameter, positive preoperative cytology, positive random upper tract biopsies, and a prior history of transitional cell cancer of the bladder (TCCB).

Lee and colleagues (221) retrospectively reviewed 110 patients with localized TCC of the upper urinary tract, all of whom had 13-year follow-up. In this group, the results of open nephroureterectomy (60) and percutaneous resection (50) were compared. Of the disease-specific deaths, 65% (17 of 26) were in patients with grade 3 lesions, with a mean cancer survival period of 15.2 months after the initial procedure. Disease-specific survival rates after open and percutaneous approaches for grade 2 disease were 53.8 and 53.3 months, respectively.

Tumor grade remains the most important prognostic indicator in patients with renal TCC regardless of the surgical approach. Grade 3 tumors are more aggressive, presenting in an advanced stage, and recurrences are more often associated with metastasis. Nephroureterectomy is the management of choice in the surgical candidate. Percutaneous management of upper tract TCC is usually reserved for patients with a solitary kidney, bilateral disease, or chronic renal insufficiency. Percutaneous treatment of grade 1 or 2 renal TCCU in healthy individuals with a normal contralateral kidney mandates strict and lengthy follow-up.

Endourology for Transitional Cell Cancer of the Renal Pelvis: Adjunctive Measures

The efficacy of endosurgical therapy of TCCP has been obfuscated by the myriad treatment approaches, as previously described, and by variations in the use of instillation therapy and postresection adjunctive measures. Regarding instillation therapy, various agents have been instilled using a variety of schedules in an effort to prevent tumor recurrence. For example, de Kock and Breytenbach (69) performed local open excision of an upper tract transitional cell cancer and followed this treatment with six weekly and then ten monthly retrograde instillations of 60 mg of thiotepa in 150 mL of normal saline over 30 minutes; the ureter was not occluded. Over a 5-year follow-up period, there was no recurrence. In other series, Eastham and Huffman (83), Streem and Pontes (344), Inglis and Tolley (161), and Grossman and co-workers (125) used mitomycin C in the upper urinary tract with no adverse side effects. In these reports, one to five instillations of 20 to 40 mg of mitomycin C or two instillations of 5 mg of mitomycin C were given in the immediate postoperative period either through a nephrostomy tube or a 7-Fr, 90-cm single-J ureteral catheter. In the percutaneous method, Eastham and Huffman (83) reported giving the mitomycin C as a continuous drip infusion at 50 mL per hour (40 mg of mitomycin C in 1,000 mL of saline) for 20 hours. Pressure in the renal pelvis was maintained at 15 cm H_2O or less. In contrast, infusion by the ureteral catheter consists of slowly instilling 5 mg of mitomycin C in 20 mL of saline into the ureteral catheter; the ureteral and urethral catheters are then clamped for a 30-minute period, after which they are opened to drainage. This is done on postoperative days 1 and 2. It is essential with both methods that before instillation an antegrade nephrostogram via the nephrostomy tube or a retrograde nephrostogram via the ureteral catheter be performed; there should be no evidence of extravasation or intrarenal backflow before instillation of any chemotherapeutic agent.

The largest experience with instillation chemotherapy in the upper urinary tract is with BCG (141,366). In their series, Jarrett and colleagues (168) reported using BCG in 19 of 33 patients treated endoscopically. The BCG was administered as 50 mL through the nephrostomy tube in six weekly instillations. They were unable to demonstrate any significant difference in survival curves between the patients who received BCG and those not receiving this adjuvant therapy. Other investigators have used similar regimens with BCG following percutaneous resection of the tumor and have not conclusively demonstrated any benefit from this adjuvant therapy (45,233). Sharpe and associates (330) reported on 17 kidneys with positive selective upper tract cytology but negative radiographic studies. In these patients, a 6-week course of weekly BCG (Pasteur strain, 120 mg in 100 mL of normal saline) was given; the solution was instilled slowly over 1 hour via an external ureteral catheter. The height of the solution was kept 20 cm above the patient, who was placed in a supine position. The patients voided 1 hour after the therapy. Overall, 75% of the patients had normalization of their urinary cytology at an average follow-up of 3 years. Complications with this approach were predominantly of a minor nature (dysuria and transient hematuria). There was only one major complication: fever with BCG bacteremia. Similarly, Bellman and colleagues (26) reported only minor side effects from percutaneous transnephrostomy BCG therapy; in their series, BCG instillations did not have to be stopped because of any complications. Of interest, subsequent rebiopsy of the renal pelvis revealed asymptomatic granulomas in 25% of their patients; the presence of granuloma formation had no influence on the success of the therapy. Mukamel and colleagues (255) also have documented the lack of significant adverse reactions from BCG in the upper urinary tract among 13 patients with documented vesicoureteral reflux. As of yet, there have been no deaths from using BCG in the upper tract; however, meticulous attention to detail before and during BCG instillation is essential. Specifically, a preinstillation nephrostogram should reveal an intact collecting system, there should be no hematuria at the time of instillation, the urine must be sterile, and the instillation should always progress at a low inflow pressure (i.e., 20 cm H_2O) (36,297).

Other adjunctive treatment variations have been reported. For example, Nurse and co-workers (266), Nolan and associates (265), and Patel and colleagues (284) placed a radioactive iridium 192 wire in the nephrostomy tract for 3 to 8 days in order to deliver 4,000 to 4,500 cGy at 0.5 cm from the wire. With this regimen they experienced no seeding of the nephrostomy tract. Taking a different approach, Orihuela and Smith (279) followed the initial tumor resection with a second-look procedure and laser application to the base of the tumor. Presently, it is difficult at this stage to select a given regimen that produces reliable high-quality results. Only through further study and careful reporting of data will the optimal endosurgical approach to TCCP become clear. However, there is a suggestion that adjunctive instillation therapy, especially with BCG, and second-look biopsy or electroresection of the tumor base may reduce recurrence rates.

Endourology for Transitional Cell Cancer of the Renal Pelvis: Unsettled Issues

In addition to the aforementioned problems of the impact of technique on outcome, four other clinical issues directly affect the efficacy of an endosurgical approach to TCCP: accuracy of diagnosis, tumor implantation, recurrence, and surveillance. Unlike for TCCU, the accuracy in diagnosis of TCCP by ureteroscopic means is disconcertingly low. Huffman (150) and Huffman and colleagues (152) noted that undergrading or understaging occurred in 60% of the renal pelvic tumors approached ureteroscopically. This is a significant problem because the procedure itself is primarily of benefit only for low-stage, low-grade disease.

Tumor implantation caused by local seeding of the upper urinary tract or retroperitoneal extravasation remains an ongoing, albeit largely undocumented, concern. With regard to local seeding, Grasso and co-workers (123) have reported one case of ureteral and urethral seeding of a renal cell cancer after a flexible ureteroscopic procedure (9.8 Fr). However, there have been no published reports of ureteral transitional cell tumors occurring after endourologic treatment of a renal pelvic transitional cell tumor. Clayman has noted a case of extensive ureteral tumors developing after a combined percutaneous and flexible ureteroscopic procedure to treat a grade 2 noninvasive transitional cell tumor in the renal pelvis of a solitary kidney. The latter patient had no prior history of transitional cell cancer. He eventually required a ureterectomy and autotransplantation with a pyelovesicostomy; no metastatic disease developed. Whether this situation resulted from tumor dissemination or the multifocal nature of his transitional cell cancer remains unsettled. To date, there have been no other reports of extensive seeding of the ureter following ureteroscopy in patients with TCCP. A second area of concern is the potential for seeding of the retroperitoneum should ureteral perforation occur during ureteroscopy or from extravasation during placement of the percutaneous nephrostomy tract. Both fears have been realized, albeit in only one case each to date. Martinez-Pineiro and associates (233) noted local tumor recurrence in a patient with TCCP T_1, G_2 who underwent a ureteroscopic procedure followed by subsequent nephroureterectomy. During the ureteroscopic procedure, the ureter was perforated; extension of the tumor into the retroperitoneum was noted at the subsequent surgical procedure, and this patient went on to develop distant metastases and died of the cancer. In another case, Huang and colleagues (147) reported seeding of a nephrostomy tract 5 weeks after percutaneous transnephrostomy (36 Fr) biopsy of a grade 3 midureteral tumor. Although these represent only isolated case reports, the small number of patients undergoing these procedures, coupled with the lack of follow-up CT scan data and the relatively short follow-up period in all series, makes one cognizant that the retroperitoneal appearance of TCCP caused by extravasation during the procedure may be significantly higher than what has been reported to date.

Another area of potential problems centers around the possibility of pyelorenal backflow and the subsequent development of distant metastases. Lim and colleagues (223) noted in one patient that following ureteroscopy the nephroureterectomy specimen revealed submucosal migration of tumor cells into the renal venous and lymphatic spaces. However, these authors were using irrigation pressures as high as 200 mm Hg. Despite this disconcerting finding, no metastatic disease developed over the ensuing 6 months in their patient. Kulp and Bagley (208) noted no problems of tumor cell backflow in 13 patients; however, in all cases, only gravity irrigation or gentle hand irrigation was used. It would appear that if the irrigation pressure is kept below 100 mm Hg, this problem may not develop.

The next concern with regard to the endourologic management of upper tract transitional cell cancer is the problem of tumor recurrence or new tumor development in the ipsilateral intact upper urinary tract. Realizing that when a ureteral stump is left after nephrectomy for TCCP the recurrence rate in the ipsilateral ureter is 40%, one can hardly be surprised by the 20% to 75% recurrence rate reported at less than 2 years after percutaneous or ureteroscopic therapy for TCCP (205,346). This is really no different than the 23% recurrence rate in the upper tract after conservative open surgical therapy for grade 1 tumors or the 54% recurrence rate after similar conservative therapy for high-grade lesions (256,370).

Given the high rate of recurrent or newly developed tumors in the ipsilateral ureter and renal pelvis, postresection surveillance of the affected upper urinary tract is of major importance. Just as most urologists believe that cytology and cystography are inferior to cystoscopy for following patients with superficial bladder tumor, cytology and intravenous urography in large part may prove to be less reliable than ureteroscopy for following patients with TCCP. In the series reported by Grossman and colleagues (125), among patients with a *known* upper tract lesion, the cytology before the lesion was endoscopically removed was positive in only 8% of patients with a grade 1 lesion and 50% with a grade 2 lesion. Similarly, in Blute's experience among patients with a radiographically identifiable upper tract lesion, the combination of intravenous urography, retrograde ureterography, and cytology diagnosed only 55% of all renal pelvic tumors, whereas ureteroscopic evaluation correctly identified all renal pelvic tumors. As such, given the poor track record of nonendoscopic studies when a lesion is present, the use of these same modalities for surveillance appears to be ill advised; periodic ureteroscopy appears to be essential.

Problems with a ureteroscopic surveillance protocol arise if a patient is going to require intravenous sedation, a formal outpatient surgical visit, and an indwelling ureteral stent every time surveillance ureteroscopy is completed. If current recommendations for bladder tumor surveillance are applied to transitional cell tumors of the upper urinary tract, this would include at least six examinations during the first 2 years and annual ureteroscopy thereafter (108,322). This certainly is not as simple or as inexpensive as office cystoscopy. In an effort to reduce the cost and complexity of surveillance cystoscopy, Kerbl and Clayman (188) have reported deliberately unroofing the ureteral orifice and tunnel with an Orandi electrosurgical knife in two patients undergoing endourologic management of upper tract transitional cell cancers. In both patients, the resulting refluxing ureteral orifice was sufficiently patulous to permit flexible ureteroscopy without dilation or sedation in the office. To date, both patients have undergone routine surveillance, office-based ureteroscopy, for over 2 years. In one patient, a total of three diminutive upper tract recurrences have been noted and subsequently treated on an outpatient basis. In the other patient, there has been one upper tract recurrence also treated in a similar manner. Of note, these tumors were too small to be imaged on either retrograde ureterography or intravenous pyelography. However, the potential negative impact of a refluxing ureter in a patient with upper tract transitional cell cancer may be of concern because approximately one-third of these patients subsequently will develop bladder tumors. This may further compound the risk of recurrent or new tumor development on the previously affected upper urinary tract. Conflicting reports regarding the potential risk of reflux in a patient with TCCB already exist in the literature; although some authors have noted no risk of upper tract TCC development in patients with TCCB and vesicoureteral reflux, others have reported as high as a 20% incidence of upper tract tumors over a 2- to 9-year follow-up period (73,205,281).

Although one might argue that if ureteroscopy can be done safely in the office, the follow-up for TCCP should become identical to the follow-up for TCCB. The natural corollary to this reasoning is that the minimally invasive approach could then be used in all cases of low-grade, low-stage TCCP. However, the impetus for conservative, endoscopic bladder surgery is largely due to the fact that the bladder is a solitary organ, the removal of which is a major surgical undertaking associated with significant operative morbidity, lengthy hospitalization, and major changes in a patient's quality of life. For TCCP, a similar situation pertains only in the patient with a functionally or anatomically solitary kidney (319). Only in that circumstance does ablative surgery carry similar quality-of-life issues to removal of the bladder, specifically long-term dialysis and renal transplantation. Furthermore, the extension of minimally invasive therapy for TCCP to patients with two kidneys has a high price. For the dubious benefit of preserving the affected kidney, the middle-aged patient with at least a greater than 34-year life expectancy will have to undergo at least 34 separate surveillance ureteroscopic procedures in addition to the likelihood of requiring at least three additional minimally invasive procedures to treat recurrent, low-grade TCCP and a 10% to 20% likelihood of eventual nephroureterectomy because of recurrent but now invasive, extensive, high-grade, or overly extensive disease. Based on these considerations and the previously cited review of the literature, minimally invasive surgery for TCCP should be reserved only for patients with a solitary kidney, renal insufficiency, or high surgical risk; for the patient who has two kidneys and normal renal function, a nephroureterectomy remains the most expeditious, probably least expensive, and most definitive means of treatment. The possibilities that TCCP or TCCU will metachronously involve the contralateral kidney (1% to 2.5%) or that the patient with a now solitary kidney will develop renal insufficiency are not sufficient arguments to change current surgical practice for this entity in the patient with two otherwise normal kidneys (205).

Simple and Peripelvic Renal Cysts

Renal cystic disease spans the pathologic spectrum, including benign and malignant processes, acquired and inherited conditions, and infectious and noninfectious etiologies. Renal cysts may occur within the renal cortex, within the medulla, or within the peripelvic region; they may have a simple, nonloculated or a complex, septated configuration.

The most commonly occurring renal cysts are of a simple, acquired, tubular origin. Simple cysts are noted in approximately 50% of the adult population at autopsy; meanwhile, 20% to 40% of patients 50 to 80 years of age have simple renal cysts sufficiently large to be detected on CT of the kidneys (217). The prevalence of cysts appears to increase with patient age; over two-thirds of patients older than 80 years of age will have a cyst detectable by CT (217). Simple cysts are lined by detached immature tubular epithelium capable of transepithelial secretion. As such, cyst fluid contains sodium and chloride that are secreted into the cyst lumen possibly by an

active transport mechanism; water osmotically follows the transfer of these ions. Fluid accumulation within the cyst also is determined by a host of pericystic regulatory factors: hormones (e.g., vasopressin, arginine), growth factors (e.g., epidermal growth factor), and other substances (e.g., prostaglandins E_1 and E_2) (120). In this framework, the growth and, in some cases, the “malignant degeneration” of renal cysts become understandable outcomes.

In the differentiation of simple renal cysts from other, more concerning, renal masses, the diagnostic accuracy of renal US or CT is sufficiently high to preclude further invasive or costly radiographic studies. Often, this is the end of the evaluation; however, some urologists prefer to obtain a single follow-up study in 1 year to look for any changes in the size or overall appearance of the cyst in order to further corroborate its benign nature. In this regard, it is relatively rare for simple cysts to increase in size; Richter and colleagues (302) noted that only 6% of cysts increased in volume over a 1- to 10-year follow-up period. Instead, the number of cysts in a kidney is more likely to increase with time; in the study of Dalton and associates (64), approximately one-third of the patients developed additional cystic lesions during a follow-up period of 3.5 years.

Overall, simple renal cysts rarely become symptomatic. Symptoms, such as flank pain, occur when the cyst obstructs a portion of the collecting system or because of the sheer size of the cyst. Macroscopic hematuria and hypertension are extremely rare signs attributable to a renal cyst. By the same token, only in the symptomatic patient is treatment of an otherwise simple cyst indicated. Similar criteria also have been used to treat some patients with adult polycystic kidney disease either by percutaneous drainage or open surgical reduction (28). For other cystic masses, treatment is indicated only if the cyst is thought to be the result of a more serious malady, such as infection or malignancy.

Technique

There are two minimally invasive strategies for treating simple renal cysts: drainage with sclerosis or drainage with ablation. Drainage with sclerosis is performed under local anesthesia using ultrasonographic or CT guidance. First, a sheathed needle is directed into the cyst and the cavity is drained. The fluid is sent for chemical, cytologic, and bacterial evaluation. Next, the sheath of the needle is left in the cyst cavity and contrast is introduced. This enables the radiologist to carefully examine the contours of the cyst wall and determine whether the cyst communicates with the collecting system. If the cyst is smooth walled, is not peripelvic in location, and is excluded from the collecting system, a sclerosant can be instilled into the cyst cavity.

A variety of sclerosants are available (e.g., 95% ethanol, bismuth phosphate, fibrin glue, hypertonic glucose); however, ethanol is the most popular and, possibly, the most effective agent. In this technique, approximately 25% of the cyst fluid is replaced with alcohol. The alcohol is left in place for 20 minutes, during which time the patient is moved into a variety of positions to ensure bathing of the entire inner lining of the cyst. The alcohol is then drained from the cyst and the sheath is removed (21,280,290).

Drainage with ablation of a simple renal cyst or of a peripelvic renal cyst can be done in either an antegrade (percutaneous) or retrograde (ureteroscopic) manner. In the percutaneous technique, the cyst can be approached in one of three ways: transcystic, transparenchymal, or indirectly through the collecting system. In each situation, the procedure begins with passage of a retrograde ureteral catheter. This will enable the urologist to instill an indigo carmine–stained mixture of contrast material and saline into the collecting system, thereby making it easy to differentiate between entry into the collecting system (i.e., blue fluid) and entry into the cyst cavity (i.e., clear to yellow fluid).

In the percutaneous transcystic method, the cyst is punctured with a nephrostomy needle (Fig. 19.28, parts 1A to 1C). The needle is then directed across the cyst and into the renal pelvis; entry into the renal pelvis is confirmed by aspiration of blue fluid. A guidewire is passed down the ureter or coiled in the renal pelvis. The point of entry into the cyst is dilated, and a standard 24- to 26-Fr resectoscope equipped with a roller electrode is introduced. At this point, the inner lining of the cyst is electrocoagulated in all areas except where the cyst abuts the renal parenchyma or renal pelvis. Now, with the safety guidewire covered by a nonconductive angiographic catheter, the opening into the collecting system, if thin-walled, can be widened using a cold knife or electrosurgery. A transcystic nephrostomy tube is placed at the end of the procedure, such that its tip lies well within the renal pelvis.

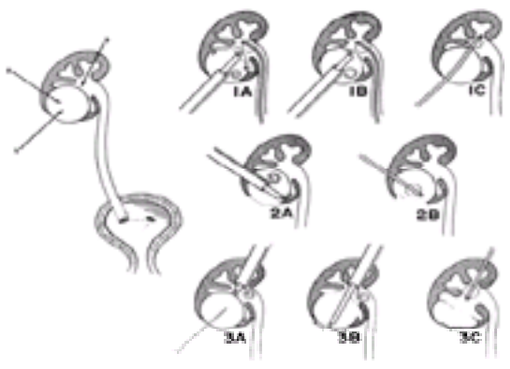

FIGURE 19.28. The three methods for percutaneously treating a renal cyst are depicted by the arrows: *1,* direct transcystic; *2,* direct transparenchymal; and *3,* indirect. **1A:** The cyst has been punctured directly and dilated; a 30-Fr Amplatz sheath has been passed, and through this a resectoscope has been introduced. The cyst wall abutting the collecting system is resected. Note that an occlusion balloon catheter has been passed up the ureter to assist in the recognition of the true collecting system. A safety guidewire catheter also has been placed in the cyst. **1B:** The remaining cyst wall is fulgurated with a roller electrode. **1C:** A transcystic nephrostomy tube is placed. **2A:** The parenchyma has been traversed in the process of entering the cyst. A 30-Fr Amplatz sheath is placed alongside a safety guidewire catheter. The outer wall of the cyst is resected, and other areas of the cyst wall are fulgurated. **2B:** A large-bore catheter is placed into the cystic cavity. The collecting system is not entered. **3A:** Via a remote calyx, the collecting system is entered and a 30-Fr Amplatz sheath is placed alongside a safety guidewire catheter. The presenting surface of the cyst is identified and resected. A needle has been placed into the cyst so that it can be readily drained and expanded, thereby aiding in its identification by the surgeon. Via the needle, normal saline stained with indigo carmine can be instilled into the cyst, thereby giving it a blue appearance and clearly delineating it from the normal collecting system. **3B:** The far wall of the cyst is fulgurated with a roller electrode. **3C:** A standard nephrostomy tube is placed in the collecting system.

In the percutaneous transparenchymal method, the cyst is entered by traversing the lateralmost portion of the renal parenchyma that overlies the cyst (Fig. 19.28, parts 2A,2B). Then a standard 24- to 26-Fr resectoscope is used to resect the outer, lateral cyst wall, thereby accomplishing a partial cyst decortication (148,291). The collecting system is never entered. If there is any bleeding at the end of the procedure, a catheter can be placed into the cyst cavity, thereby effectively tamponading the renal parenchyma.

In the percutaneous indirect method, a nephrostomy tract is placed in the kidney opposite the medial wall of the cyst (Fig. 19.28, parts 3A to 3C). A separate needle is passed percutaneously into the cyst cavity. By instilling an indigo carmine–stained mixture of contrast and sorbitol, the endoscopist is guided to the wall of the cyst that most closely abuts the collecting system and thus has a blue hue. With a resectoscope or a cold-knife urethrotome passed through the initial nephrostomy tract, the cyst wall is incised and the cyst is entered. Next, with use of a standard 24- to 26-Fr resectoscope equipped with a roller electrode, the far wall of the cyst is electrocoagulated. A nephrostomy tube is placed into the collecting system via the initial percutaneous puncture site, remote from the cyst cavity. This approach is of particular value when dealing with a peripelvic cyst (42,85,156,199).

The ureteroscopic approach to cysts is limited to smaller cysts (i.e., less than 2 cm) that have a section of their wall bulging into a calyx or that share a common wall with the renal pelvis (i.e., peripelvic cyst) (182). If this approach is selected, it is still helpful to preplace a small percutaneous tube into the cyst cavity in order to fill the cyst with an indigo carmine–stained mixture of contrast and sorbitol. Then, via the rigid or flexible ureteroscope, a Ho:YAG laser or electrosurgical knife can be used to enter the cyst. Next, the inner surface of the cyst can be coagulated using either electrocautery or Nd:YAG laser energy (20 W).

In the rare event when a cyst has reformed despite ureteroscopic or percutaneous methods, a laparoscopic approach (i.e., drainage and cyst decortication) can be used.

Results

Drainage and sclerosis is the least invasive form of therapy for simple renal cysts. Short-term success rates for ethanol ablation are the highest of any sclerosant treatment at 97% to 100% (21,280). Cysts as large as 600 mL have been treated successfully with this method. Other sclerosants result in cyst disappearance in less than 50% of cases, especially when follow-up was extended beyond 2 years (144,290). Of note, the follow-up after ethanol ablation generally is under 1 year. Clearly, long-term follow-up studies on the durability of ethanol ablation are sorely needed.

The endoscopic treatment of renal cysts is indicated predominantly for peripelvic cysts or as salvage therapy for simple renal cysts when drainage and sclerotherapy fail. The percutaneous approach is still relatively rarely performed and hence the experience is small. For the percutaneous approach, the long-term success rate (i.e., complete cyst ablation) has been only 50% according to Plas and Hubner (291). In their series, with a median follow-up of 45.7 months, approximately 30% of the cysts recurred. The ureteroscopic approach has been reported only once (182). In one patient, the procedure was successful; however, the follow-up was less than 6 months.

Renal Abscess and Fungal Collections

A localized renal infection may occur either in the renal parenchyma (e.g., lobar nephronia, an infected renal cyst) or within the collecting system (e.g., pyocalyx caused by obstruction). The infections are due to *E. coli* in approximately one-third of cases; another one-third of patients are infected with either *Proteus mirabilis* or *Klebsiella pneumoniae* (174,307). Today, *Staphylococcus aureus* accounts for less than 10% of all renal abscesses (96). On rare occasion, a fungus is the underlying cause: *Candida albicans, Mucormycosis, Aspergillus,* or *Torulopsis glabrata* (169).

Presenting symptoms most commonly include fever, flank pain, or chills (60% to 90% of patients). Symptoms usually are present for up to 2 or more weeks before the diagnosis of a renal abscess is made. The most common associated illness is the presence of diabetes mellitus; these patients, as well as individuals with immunosuppressive disorders, are at greatest risk for developing life-threatening sequelae from an unrecognized renal abscess (96).

Today, the diagnosis of a renal abscess can be made more easily because of the advent of renal CT and US (Fig. 19.29). Fowler and Perkins (96) noted that among 61 consecutive patients with renal abscesses, CT or US provided a diagnostic accuracy of 96% and 92%, respectively. On CT scan a renal abscess classically has a cystic, albeit thick-walled, appearance; the CT density of the abscess is usually greater than that of a cyst (134). On the other hand, the ultrasonographic appearance of an abscess is that of an irregular mass with echo-producing intralesional debris and a poorly defined back wall (373).

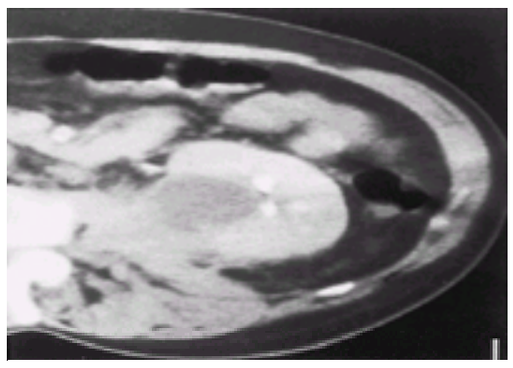

FIGURE 19.29. Computed tomography scan shows a cystic appearing lesion with debris. Puncture of the lesion confirmed the presence of a renal abscess. A drainage tube was subsequently placed inside the cavity as a therapeutic measure.

Technique

Although antibiotic therapy alone has been reported to cure the rare patient with a renal abscess, this approach has not been widely adopted. The consensus is that renal abscesses should be aspirated and, in most cases, percutaneously drained as soon as they are diagnosed. This is most easily done under US or CT guidance. Following a confirmatory diagnosis by needle aspiration, a 7- or 8-Fr self-retaining (e.g., Cope locking loop) percutaneous drainage tube is placed within the abscess cavity. An infracostal percutaneous route is selected in order to avoid any possible pleural contamination.

If the problem is one of a fungal bezoar, a standard percutaneous technique may be undertaken after the patient has been given parenteral amphotericin B and achieved appropriate serum levels. The urine at this point should be sterile. Via two retrograde ureteral catheters, the renal pelvis is irrigated with amphotericin B (5 mg/100 mL) to decrease the chances of retroperitoneal contamination by the fungus. Next, via an infracostal percutaneous approach, the fungal bezoar is removed with grasping forceps or suctioned from the kidney using the ultrasonic lithotripsy probe. At the end of the procedure, a nephrostomy tube is placed; one of the ureteral catheters is also left in place. Postoperatively, once a nephrostogram shows no extravasation and no remaining fungal bezoars, the collecting system is irrigated through the ureteral catheter with amphotericin B (50 mg/L at 50 mL per hour) for 2 to 3 days (31,137,175,377).

Results

Over the past few years, a few clinicians have reported limited success with antibiotic therapy alone for treating a renal abscess. Chakroun and colleagues (39) noted that this therapy worked in 25% of their patients, whereas Gelabert and associates (104) had only a single success among 12 patients.

Overall, the consensus remains that a renal abscess is best treated by aspiration combined with ongoing percutaneous drainage. Only in Chakroun and co-workers' (39) series was aspiration alone a viable treatment option; in this series of 12 patients, only three patients eventually required percutaneous drainage. However, for Gelabert and colleagues (104), as well as Janetschek and associates (166) and other clinical investigators, percutaneous drainage was the most definitive and effective means for treating a renal abscess. In several series, this form of therapy was effective in 82% to 88% of patients; in Fowler and Perkin's (96) extensive report of 57 renal abscess patients treated with percutaneous drainage between 1972 and 1988, the success rate was even higher at 97% (60,96,111,134,166,167). However, percutaneous drainage of a renal abscess is not an innocuous procedure; approximately 10% of patients develop hemorrhage, recurrent abscess, or urosepsis after this procedure.

Failed percutaneous aspiration and drainage of a renal abscess is fortunately rare. Most failures are due to a loculated abscess or are associated with a fungal infection. The patient with a loculated abscess can at times be salvaged percutaneously by the placement of multiple percutaneous drainage tubes. For the patient with a fungal abscess, irrigation of the abscess cavity with amphotericin B (50 mg/L at 50 mL per hour) is sometimes helpful in resolving the problem (134). However, for the most part when initial percutaneous therapy fails, the next step is open surgery, with manual fragmentation of any loculations followed by placement of large drains or, if the kidney is functioning poorly, nephrectomy; this open approach may be necessary in up to 9% of cases.

Because of the advances in antibiotic and endourologic therapy, the mortality rate from renal abscess has fallen to 7% to 9%. Today, most fatalities from renal abscess result from a delay in diagnosis rather than therapeutic failure.

As with the previously described parenchymally based renal abscesses, the best mode of therapy for infection of an obstructed portion of the collecting system (i.e., pyonephrosis or a pyocalyx) is percutaneous drainage. In these cases, a percutaneous nephrostomy tube is placed into the obstructed area of the collecting system. This results in immediate relief of obstruction and drainage of the infection. When combined with appropriate antibiotic therapy, nephrostomy tube drainage is highly successful. In Janetschek and colleagues' (166) collected series of 21 cases, all patients with these conditions responded well to a percutaneous approach. However, two patients, despite percutaneous drainage, ultimately required a nephrectomy because of failure of the kidney to recover function (166).

Before the advent of endourologic techniques, urinary tract fungal bezoars usually were the harbinger of ureteral obstruction, urosepsis, and death; up to 80% of

these patients succumbed. Today, however, successful therapy is achievable in the majority of these patients. A review of the endourologic literature reveals only a handful of cases of funguria with associated bezoar formation managed endourologically. In these cases, more than 80% of the patients have survived with an intact kidney following percutaneous drainage or extraction of the fungal mass (3,31,70,76,137,162,163,175).

Post–renal transplantation

In the renal transplant population, the frequency of a urologic complication is closely associated with the type of ureteral reimplant performed at the time of renal transplantation. Most of these complications are secondary to ureteral obstruction; the remaining, less common complications are due to urinary tract fistula formation, ureteral necrosis, and urolithiasis.

With the traditional Leadbetter-Politano reimplantation, urinary tract complications occur in 5% to 11% of patients (355). However, with the more recent adaptation of routine primary ureteral stent placement at the time of the operation or an extravesical technique for performing a ureteroneocystostomy, the incidence of urologic complications has fallen to below 4% (355). However, up to two-thirds of these problems are still due to ureteral obstruction. The obstruction may be either of an intrinsic (i.e., ureteral stricture) or an extrinsic (i.e., perirenal fluid collection, such as lymphocele, urinoma, abscess, or hematoma) nature. The development of strictures usually occurs early in the postoperative course, but in some cases ureteral stricture formation may occur as late as 5 years postoperatively (178,195,355).

When faced with a rising creatinine in the renal transplant patient, the clinician must determine whether the apparent compromise in renal function is prerenal (i.e., arterial stenosis, renal vein thrombosis, or alteration in fluid status), renal (i.e., rejection), or postrenal (i.e., obstruction or fistula). To evaluate for a ureteric or perirenal postrenal problem, a renal US study or a CT scan is of particular benefit. Either study can reveal the presence of hydronephrosis or an extrinsic obstructive lesion and assess for intrarenal filling defects. With regard to perirenal lesions, the diagnostic accuracy of the CT is slightly better than sonography; in one review, sonography detected 73% of perirenal fluid collections, whereas CT was correct in 87% of the patients (sensitivity of 64% and specificity of 94%).

An advantage of renal US is that it can be performed with duplex Doppler scanning. As such, the renal vascular RI can be determined. When the RI exceeds 0.75, the chances of an obstructive process are high. However, a normal RI argues for a nonobstructive process, such as transplant rejection or a fistula. In a study of 35 renal transplant patients with pyelocaliectasis by Platt and associates (292), the RI was elevated (average of 0.81) in 13 patients with proven obstruction; there were two false-negative diagnoses, but in both patients the obstruction was associated with a fistula. The latter problem was probably responsible for the apparently normal RI. After placement of a percutaneous nephrostomy in the obstructed patients, the RI fell to 0.67.

When obstruction is suspected, the next step should be an antegrade nephrostogram (177). This is of both diagnostic and therapeutic value. The site of obstruction can be delineated clearly; the presence or absence of an associated ureteric fistula can be determined; if need be, a Whitaker pressure study can be performed; and a percutaneous nephrostomy can be left in place after the study is completed. The Whitaker test can be most helpful in distinguishing between an anatomic and a functional narrowing. In one study, up to 25% of ureteric strictures were functionally insignificant; in these four patients, the rise in creatinine was subsequently shown to be due to rejection (177).

The other two major areas of complications following transplantation in which endourology has had an impact are ureteral fistulae and perirenal collections. The most common site of a ureteral fistula is either at the site of the ureteral reimplantation or, more rarely, along the renal pelvis. Diagnosis of this condition can be made most clearly either during an antegrade nephrostogram or a retrograde ureterogram. In either case, a ureteral stent can then be placed to “put the ureter to rest.” If an indwelling ureteral stent is placed retrograde, a urethral catheter also is indicated in order to preclude reflux and continued leakage at the fistula site. If the stent is inserted immediately after performing an antegrade nephrostogram, a percutaneous nephrostomy tube should be left in place to decompress the renal pelvis and prevent further passage of urine across the fistula.

Perirenal collections often produce symptoms of discomfort and a fullness in the lower abdomen; the usual sign is new-onset azotemia caused by ureteral obstruction. These collections may be due to one of four problems: urinoma, lymphocele, hematoma, or abscess. The CT scan is the most reliable method for diagnosing the presence of perirenal collection; at the same time the scan is done, the lesion can be drained and a self-retaining drainage tube can be placed. The obtained fluid can be sent for culture, cell blood count, and creatinine; these tests should effectively identify the nature of the collection.

Technique

The initial form of management for the majority of ureteral complications among renal transplant patients is placement of a percutaneous nephrostomy tube. Given the proximity of the transplanted kidney to the skin, the procedure can be accomplished rapidly and safely using either fluoroscopic or ultrasonographic imaging (336). The methods involved in dealing with ureteral strictures in the transplant kidney are the same as previously described for treatment of ureteral strictures in patients without a renal transplant. Likewise, the therapy for a ureteral fistula (i.e., placement of an indwelling ureteral stent) and for a perirenal collection (i.e., aspiration and drainage) do not differ from the techniques used to approach the same entities in patients with normal renal function and eutopic kidneys.

Results

Endourology has had a significant impact on the management of all types of ureteric and perirenal complications affecting the renal transplant patient. As previously noted, ureteric complications are usually due to either a ureteral stricture or a ureteral fistula. Ureteral strictures in the transplant patient have most commonly been treated with balloon dilation to 8 to 12 mm accompanied by ureteral stinting for 4 to 14 weeks with a 7- to 14-Fr ureteral stent. The success rate with this approach is 40% to 70% at an average follow-up of 2 years. Overall, strictures in the distal ureter or at the ureterovesical anastomotic site are more common than upper ureteral strictures and appear to respond better to endourologic management. In one study, the success rate with distal/ureterovesical junction (UVJ) ureteral strictures was 75%; however, only 16% of proximal ureteral strictures responded favorably to balloon dilation (93,172,177,192,283,333).

An alternative, albeit more invasive, approach to ureteric strictures is to endourologically incise the stricture. Conrad and colleagues (57) used a flexible wire-guided cold knife to endourologically treat 11 transplant patients with a ureteral stricture; all but two of the strictures were in the distal/UVJ portion of the ureter. An indwelling 14-Fr stent was placed for a period of 4 to 6 weeks. Success was achieved in 82% of patients with a mean follow-up of 28 months (2 to 61 months). Of interest, both UPJ obstructions and all six patients with very distal ureteral obstruction responded favorably to endoureterotomy; however, only two of four patients with middle or lower ureteral strictures had a favorable outcome. A similarly high rate of success has been reported by Youssef and associates (381a) using the Acucise device to cut the area of obstruction; a successful outcome was noted in five of six renal transplant patients. These data are similar to endoureterotomy data in the nontransplant patient population, among whom success rates for UPJ and distal ureteral obstruction are higher than for strictures lying in the lower or middle ureter that, after an endoureterotomy, have not been marsupialized into the renal pelvis or bladder, respectively. Overall, it would appear that an endourologic approach with balloon dilation or incision is a reasonable first step when dealing with posttransplant ureteral strictures, especially if the stricture involves the UPJ or UVJ area. Last, although endoureterotomy may be intrinsically more appealing to the urologic surgeon, at this point in time, given the small number of patients treated to date, there is no clear-cut difference in results between balloon dilation and endoureterotomy of distal strictures.

With regard to a ureteral fistula in the transplanted ureter, placement of an indwelling ureteral stent with either proximal (i.e., nephrostomy tube) or distal (i.e., urethral catheter) decompression is often effective. This is especially true if the leakage is associated with distal ureteral obstruction. However, ureteral fistulae are relatively rare, and experience with the endourologic management of this complication remains scant. In reviewing the available literature, the largest series of fistulae managed by stents was reported by Berger and co-workers (29); the procedure worked in only two of 12 patients. Subsequently, Hobarth and colleagues (143) and Irving and Kashi (164) independently reported an additional eight patients in whom either a ureteral stent or percutaneous nephrostomy was used to treat a ureteral fistula; a successful outcome was reported in five of the eight patients. One reason for the markedly improved results in the series of Irving and Kashi (164) is that these authors were careful to distinguish between a small ureteral fistula and total ureterovesical disruption as might occur with ureteral necrosis. In their series, patients with suspected ureteral necrosis were managed with direct surgical intervention. As such, endourologic methods were applied only to patients with small fistulae; among four patients with ureteral leakage unassociated with ureterovesical discontinuity, all were successfully managed endourologically.

Among perirenal collections, the most common type after renal transplantation is a lymphocele. In these cases, drainage may be followed by placement of a tube into the cavity; sclerotherapy with ethanol can be used if the lymphocele does not abut directly on the ureter or renal pelvis. Failing this, an open surgical procedure or, more recently, laparoscopic marsupialization can be performed. The latter has gained rapidly in popularity and today appears to be the treatment of choice should simple percutaneous drainage fail to resolve the problem (331). For other perirenal collections such as perirenal abscess, percutaneous drainage and appropriate antibiotic therapy is the first step. With regard to a nonexpanding hematoma, once the diagnosis is made, nothing further need be done unless the hematoma is causing extrinsic compression on the ureter. In this case, a ureteral stent can be placed until the hematoma resolves. Last, with regard to treating a perirenal urinoma,

percutaneous drainage is the first step. Following this, the site of the fistula must be identified and appropriate endourologic or surgical therapy instituted (vide supra).

EXTRARENAL APPLICATIONS

Perirenal Abscess

Perirenal abscess can result from rupture of an acute renal abscess into the surrounding fatty tissue inside Gerota's fascia. Perirenal abscess formation usually arises as a complication of pyelonephritis, urolithiasis, penetrating trauma, and prior urologic procedures in the retroperitoneum or the collecting system. Perirenal abscess also may occur because of a secondary nonrenal etiology: enteric fistula, pancreatic abscess, and lumbar osteomyelitis. Hematogenous spread to the kidney from a cutaneous infection or intravenous drug usage also has been responsible for perirenal abscess formation. A significant number of patients with perirenal abscess will have diabetes mellitus or other coexisting debilitating conditions, such as underlying malignancy or immunosuppression.

The clinical course of a perirenal abscess is often insidious. The symptoms and signs are usually vague and nonspecific. Most commonly present is fever (58% to 83%), followed by flank or abdominal pain (20% to 70%), and a palpable mass (9% to 13%). Advanced cases may manifest with malaise, weight loss, and a draining sinus. Leukocytosis with a left shift is a routine finding. Urine cultures are usually positive; however, the bacteria isolated from the urine may not reflect the organisms isolated from the abscess in 19% of the cases. *E. coli* and *P. mirabilis* are the most common causative organisms; however, when the abscess results from hematogenous spread, *S. aureus* predominates (84,332).

Abdominal plain films may show scoliosis, loss of the psoas shadow and renal margin, urolithiasis, and gas within a perirenal mass. Intravenous pyelography can reveal thickening of Gerota's fascia, mottling of the perirenal fat, delayed renal function or nonfunction, focal or diffuse renal enlargement, presence of a mass effect, renal fixation, or hydronephrosis. Chest radiographs may be abnormal in up to 41% of cases; pleural effusion, lower-lobe consolidation, and elevation of the hemidiaphragm are the most common findings (87). Renal US characteristically will show round or oval hypoechoic lesions. However, abscesses containing large amounts of gas may be mistaken for bowel. Abscesses that contain a large amount of echogenic debris or with septations may have characteristics that are indistinguishable from a tumor (367). CT is the imaging modality of choice because it provides better definition of the extent of the abscess and its relationships to other structures than can be obtained with US. Typically, the mass has a soft tissue density (less than 20 HU) and may have a “rind sign” caused by vascular enhancement of the abscess wall after the administration of intravenous contrast (110). Rarely, scintigraphy with gallium- or indium-labeled white blood cells may be useful in determining the presence of an abscess when the diagnosis is uncertain.

Technique

Patients routinely are given broad-spectrum parenteral antibiotics before abscess drainage. The abscess is localized by US or CT. The abscess is then punctured with an 18-gauge, thin-walled needle. The puncture should be extraperitoneal and extrapleural (i.e., below the twelfth rib) to avoid seeding of the abscess contents into the peritoneal and thoracic cavities, respectively, which can result in peritonitis, pleural effusion, pyopneumothorax, and empyema. Contents of the abscess are aspirated and sent for Gram stain, culture, and sensitivities. A guidewire is advanced through the 18-gauge needle puncture and coiled in the abscess cavity. The tract is dilated with semirigid dilators under fluoroscopic or US guidance. A drainage catheter is then positioned and secured. The size of the drainage tube depends directly on the viscosity of the initial aspirate. Tube sizes generally range from 8 to 14 Fr, or occasionally, a vanSonnenberg sump catheter will be used for a very viscous collection. If the abscess is loculated, two or more catheters may be percutaneously placed to provide adequate drainage. Mean drainage times are between 5 and 20 days (213). Prolonged drainage should alert one to the possibility of an enteric or urinary tract fistula.

Saline irrigation of the catheters may be started after 48 hours to help clear debris from the cavity and prevent catheter occlusion. Sinograms may be obtained at the discretion of the urologist to monitor the size of the abscess cavity and to identify any fistulous tract. Once the drainage from the catheter has ceased, a sinogram is repeated. If the cavity is now small (i.e., not much larger than the drainage catheter), the catheter can be removed. Alternatively, if a substantial cavity persists, 95% ethanol can be used to attempt to sclerose the cavity. In this case, one must be certain that there is no communication between the abscess cavity and the collecting system or other viscera. Sclerosis is continued on a weekly basis for 3 to 6 weeks until the abscess cavity has completely collapsed around the drainage catheter, at which time the catheter can be removed.

Results

Perinephric abscess is a very serious problem that carries a high mortality rate, especially when prompt drainage and broad-spectrum antibiotics are delayed (Fig. 19.30). Even with timely percutaneous drainage, mortality rates are as high as 13%. Initial percutaneous drainage is the procedure of choice in the management of perirenal abscess and in select cases may be the only intervention necessary. Elyaderani and Moncman (87) reported that 2 of 6 perirenal abscesses treated with percutaneous drainage resolved completely without further intervention. Lang (213) reported that 9 of 10 perirenal abscesses resolved with percutaneous drainage. These data are in agreement with results reported independently by Haaga (134) and by Gerzof and Gale (110).

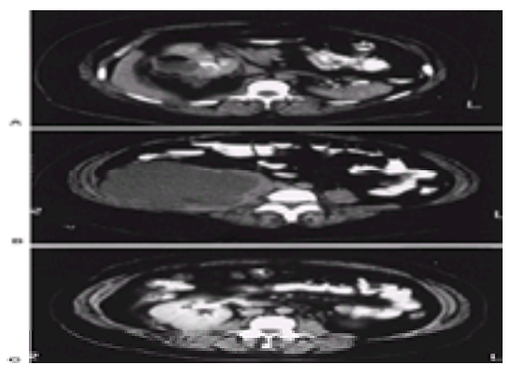

FIGURE 19.30. A: An obstructing upper-pole stone is present on this computed tomography scan. **B:** A large, retroperitoneal abscess caused by the obstruction and resulting infection. **C:** Three months after percutaneous stone removal and drainage of the abscess cavity, renal function has returned to normal and the abscess cavity has completely resolved.

Urinoma

A perirenal urinoma results from renal or ureteral trauma, urologic surgical procedures, or upper tract obstruction with associated ureteral or renal extravasation (e.g., neoplasm, surgical ligation, calculus disease). Extravasation of urine into the perirenal space is usually due to a forniceal rupture. When the amount of urine extravasated exceeds the capacity for lymphatic clearance, a perirenal fluid collection develops. Inflammation and fibrosis at the site of leakage can lead to ureteral obstruction, progressive hydronephrosis, and ultimately loss of renal function (215).

Clinically, the symptoms and signs of a urinoma include vague abdominal or flank discomfort and sometimes a palpable mass. There may be several months' delay between the causative event and presentation and diagnosis of the urinoma. In cases of a left-sided collection, one must be certain that the fluid-filled mass does not represent a pancreatic pseudocyst.

Plain films of the abdomen may reveal a mass if the urinoma is large. Findings on intravenous urography may include decreased renal function or absence of renal function on the affected side, cephalad and lateral displacement of the kidney, or contrast in the urinoma on delayed images. CT is the optimal study to define the extent and the relationship of the urinoma to surrounding structures. The wall of the urinoma may be thickened and smooth; the density of the urinoma is between -10 and +30 HU. Homogeneous enhancement of the urinoma implies a functioning kidney and presence of a communication between the urinoma and the collecting system (215). A retrograde pyelogram or antegrade nephrostogram is useful in identifying the level of obstruction and the point of extravasation.

Technique

Under US or CT guidance, a percutaneous drain is placed in the most dependent aspect of the fluid collection. The aspirated fluid is sent for creatinine determination, blood cell count, culture and sensitivities, and when indicated, amylase. The creatinine content of a urinoma should be similar to the high creatinine content of the urine.

A 10-Fr biliary urinary drainage or locking Cope loop catheter is placed. In instances where there is no longer a communication with the collecting system and no ongoing obstruction, drainage usually ceases after 48 to 72 hours. In cases of prolonged drainage, placement of an indwelling ureteral stent and urethral catheter or a percutaneous nephrostomy generally provides diversion sufficient for spontaneous closure of the fistulous tract. There are rare instances in which there is persistent drainage despite renal and bladder catheter drainage. In these cases, the urinoma drainage tract can be dilated. An endoscope can be used to identify the point of communication with the renal collecting system (156). Biopsies may be taken of the cavity to rule out malignancy. If the point of communication is small and well away from the normal collecting system, the entire urinoma cavity and especially the base of the urinoma can be electrocoagulated with a roller electrode. If there is a larger communication, however, the urinoma cavity again can be electrocoagulated, following which a nephrostomy tube can be passed across the fistula and into the collecting system. The now dry cavity usually will collapse and seal around the shaft of the tube. In traumatic cases where there is devitalized tissue, an open surgical approach may be necessary for debridement and closure of the fistulous tract.

When the drainage has ceased, a sinogram is helpful to document collapse of the cavity. If there is still a large cavity, but drainage has stopped, and there is no demonstrable communication with the collecting system, ethanol sclerotherapy or repeat electrocoagulation can be used to facilitate collapse of the cavity.

Results

More than 90% of urinomas related to obstructive processes respond to drainage and correction of the underlying causes of obstruction. Ball and co-workers (18) found similar success in treating four pediatric patients with urinomas; all four patients responded well to percutaneous drainage of the urinoma. In urinomas resulting from trauma, success with percutaneous drainage is dependent on the viability of the tissue and the vascular supply near the fistulous tract. Cases in which there is a large amount of devitalized tissue, such as those associated with major trauma, may require open debridement and closure of the fistulous tract (248).

Lymphocele

For the urologist, a lymphocele occurs most commonly following pelvic lymphadenectomy, retroperitoneal lymph node dissection, or kidney transplantation. There is a 5% to 10% incidence of symptomatic lymphocele development following pelvic lymphadenectomy for malignancy (119). Khauli and colleagues (190) reported a 36% incidence of perirenal fluid collections following renal transplantation; among those patients, 7% had symptomatic lymphoceles that required intervention.

It is hypothesized that lymphoceles form when transected lymphatic channels are allowed to drain into a nonepithelialized space. Lymph fluid is devoid of platelets and has low concentrations of clotting factors; thus meticulous attention to ligation of the lymphatic vessels is necessary to prevent lymphocele formation. Perioperative heparin therapy, diuretic use, and high-dose corticosteroids also have been implicated as contributing factors to lymphocele formation (142,190).

The symptoms caused by a lymphocele result from compression of adjacent structures, lower-extremity edema, abdominal or pelvic mass, or bowel and bladder problems. In the transplant patient, the lymphocele may result in ureteral obstruction and a rise in serum creatinine. In the postpelvic lymph node dissection patient, the first sign of a pelvic lymphocele may be deep venous thrombosis and associated pulmonary embolus caused by partial obstruction of the external iliac vein by the lymphocele.

US is most commonly used to evaluate suspected pelvic fluid collections. In transplant patients, the US may reveal, in addition to the lymphocele, hydronephrosis or a mass effect on the bladder, colon, or iliac vessels. CT studies provide similar information.

Technique

The fluid collection is punctured under sonographic or CT guidance. The initial aspirate is sent for electrolytes, creatinine, cell count, and culture sensitivities. Additional studies that may be useful are determination of protein and cholesterol content along with cytologic analysis. The typical lymphocele fluid will have creatinine and electrolytes similar to serum, but the levels of cholesterol and protein are usually lower than serum values. Culture of the fluid should be sterile. Usually an 8- to 14-Fr drainage tube is left indwelling. When the drainage is less than 10 mL per 24 hours, the cavity is studied by contrast injection. If the cavity has collapsed around the drainage tube, the tube can be safely removed. If, despite 1 week of drainage, large amounts of fluid continue to be collected, sclerosis of the lymphocele may be attempted with 95% ethanol, povidone-iodine, tetracycline, or bleomycin (54,55,191,240). Sclerosis may be repeated, if necessary, at weekly intervals for several weeks. For patients with persistent or recurrent lymphoceles, laparoscopic intraperitonealization of the lymphocele is usually successful and has far less morbidity than an open approach (91,237,337).

Results

Small lymphoceles may not require treatment or may be managed by simple aspiration. Khauli and colleagues (190) reported an 86% spontaneous resolution rate in the management of asymptomatic posttransplant lymphoceles. For symptomatic lymphoceles, percutaneous drainage with or without sclerotherapy has a reported success rate of 69%; however, drainage may persist for up to 4 months following initial tube placement (55). For patients who fail percutaneous drainage and sclerosis and who have uninfected lymphoceles, the standard of care has been surgical exploration and intraperitoneal marsupialization with or without placement of a tag of omentum into the lymphocele cavity.

Laparoscopic intraperitonealization of the lymphocele has become popular (91,237,337). Fahlenkamp and associates (91) have reported the largest series to date with five patients all successfully treated by a laparoscopic peritoneal window procedure, although one patient required an additional percutaneous drainage of an undrained loculated portion of the lymphocele. The enthusiasm for this procedure must be tempered by the small series of patients and the potential complications of a laparoscopic procedure. One case of division of a transplant ureter during laparoscopic lymphocele drainage has been reported (334).

In some cases, the patient's anatomy precludes intraperitoneal marsupialization of the lymphocele. Lucas and colleagues (228) have reported the successful use of an internalized Tenckhoff catheter to drain posttransplant lymphoceles in three patients with a mean follow-up of 5.3 years. In a fourth patient, the Tenckhoff catheter became occluded. At reexploration the catheter was found to be encased in omentum. Three Tenckhoff catheters were placed in tandem, and the patient has done well during a 3-year follow-up period.

Another approach to the postpelvic lymph node dissection patient with an anatomically unfavorable (i.e., not amenable to a laparoscopic approach), unresponsive lymphocele is endoscopic fulguration. McDougall and Clayman (239) reported using this approach in a patient with a refractory lymphocele after a pelvic node dissection. With the patient under intravenous sedation, a short, rigid ureteroscope could be passed into the cavity and the base of the lymphocele could be electrocoagulated. The drainage tube was not replaced, and drainage rapidly ceased; it has not recurred.

CONCLUSIONS

With the passage of time, endourology has come to encompass a means of diagnosis and treatment for a whole host of maladies formerly approachable only by open surgery. In this regard, percutaneous and, more recently, ureteroscopic methods have prevailed, the latter being far less invasive than the former. The work that remains to be done is to further refine each of these techniques until its respective success rate routinely equals or exceeds the outcome of its open or laparoscopic surgical counterpart. To this end, the urologist and the bioengineer need to work hand in hand to develop and then critically test each new, less invasive treatment modality as it becomes available.

Chapter References

Renal cysts are abnormal dilations somewhere along the renal tubule between the glomerular capsule and the collecting system or are diverticulum-like structures possibly in continuity with the nephron. All renal cysts originate from microscopic renal tubules by proliferation of renal epithelial cells to form a diverticulum from the tubule wall and accumulation within the cyst of fluid from either glomerular filtrate or net transepithelial fluid secretion (144). Renal cysts may develop by heritable, developmental, or acquired processes. Renal cystic disease can involve both kidneys diffusely as autosomal-dominant polycystic kidney disease (ADPKD), one particular area of both kidneys as medullary sponge kidneys, or just one kidney or part of it as multicystic kidney. Alternatively, a cystic tumor can replace normal renal parenchyma as in multilocular cyst. Finally, simple cysts can occur alone or together anywhere in the kidney.

Classification of cysts for the purpose of simplifying concepts does not necessarily provide a practical, clinical framework for such diverse cystic diseases. Hence, although the classification of Osathanondh and Potter (290), based on microdissection studies, brought a basis for future research on the pathogenesis of renal cystic disease, the clinician was not aided in making a diagnosis from history, physical examination, and radiographic studies. Meaningful clinical classifications of renal cystic disease based on clinical and radiographic features, genetic investigation, and morphology, such as those of Bernstein (28) and Gardner and Evan (127), honestly portray the diversity of renal cystic diseases, but they do not lend themselves to a simple conceptual framework. Table 20.1 gives the 1987 classification from the Committee on Classification, Nomenclature, and Terminology of the American Academy of Pediatrics Section on Urology that offers broad genetic categories but still displays adequately the diversity of renal cystic diseases (137). The advent of ultrasonography (US), magnetic resonance imaging (MRI), and computed tomography (CT) have drastically improved the clinician's ability to diagnose and differentiate the various renal cystic diseases. There has been rapid recent progress in identification or chromosomal localization of responsible disease genes, giving insights into the pathophysiology of the genetic renal cystic diseases. The importance of a careful family history is emphasized by the classification of renal cystic diseases into genetic categories. Table 20.2 shows the known linkages of genetic renal cystic diseases.

Genetic
Autosomal-recessive (infantile) polycystic kidneys (ARPKD)
Autosomal-dominant (adult) polycystic kidneys (ADPKD)
Juvenile nephronophthisis–medullary cystic disease complex (NMCD): Juvenile nephronophthisis (autosomal recessive) (NPH) Medullary cystic disease (autosomal dominant) (ADMCKD)
Congenital nephrosis (autosomal recessive)
Cysts associated with multiple malformation syndromes
Nongenetic
Multicystic kidney (multicystic dysplasia) (MCDK)
Cystic nephroma (multilocular cyst)
Simple cysts
Medullary sponge kidneys (<5% inherited)
Acquired cystic kidney disease in chronic hemodialysis patients (ACKD)
Caliceal diverticulum (pyelogenic cyst)

TABLE 20.1. CYSTIC DISEASE OF THE KIDNEY

Disease	Inheritance	Chromosome
$ADPKD_1$	AD	16p31.1
$ADPKD_2$	AD	4q13-q23
ARPKD	AR	6p21
NPH_1	AR	2q12-q13
NPH_2	AR	9q23-q31
$ADMCKD_1$	AD	1q21
$ADMCKD_2$	AD	16q12
MKS_1	AR	17q21-q24
MKS_2	AR	11q13
VHL	AD	3p25.5
TSC_1	AD	9q34
TSC_2	AD	16p13.3

AD, autosomal dominant; ADMCKD, autosomal-dominant medullary cystic kidney disease; ADPKD, autosomal-dominant polycystic kidney disease; AR, autosomal recessive; ARPKD, autosomal-recessive polycystic kidney disease; MKS, Meckel's syndrome; NPH, nephronophthisis; TSC, tuberous sclerosis; VHL, von Hippel-Lindau disease.

TABLE 20.2. GENETIC RENAL CYSTIC DISEASES—KNOWN LINKAGES

AUTOSOMAL-DOMINANT POLYCYSTIC KIDNEY DISEASE

ADPKD is the most common form of cystic disease of the kidney and is caused by mutations in any one of at least three genes: PKD_1 on chromosome 16 (accounting for 85% of patients), PKD_2 on chromosome 4 (accounting for 15%), and the unmapped PKD_3 (probably accounting for rare families unlinked to the other two sites) (Table 20.3). It is the third most common cause of end-stage renal disease (ESRD), contributing 6% to 12% of patients receiving chronic renal dialysis. Fifty percent of patients typically develop chronic renal failure by age 60 (119). The highest incidence rate of ESRD from ADPKD is 1.5 per 100,000 population, occurring between the ages of 45 and 64 years (99). ADPKD occurs in about 1 in every 1,250 live births and is characterized by bilateral cystic disease in enlarged kidneys with a retained reniform shape. It is a systemic disease, and subsets of patients may develop extrarenal manifestations such as liver cysts or cerebral aneurysms.

Disease	Inheritance	Chromosome	Gene	Mean Age Onset of ESRD (yr)	Gene Product
$ADPKD_1$	AD	16p31.1	PKD_1	54.3	Polycystin1
$ADPKD_2$	AD	4q13-q23	PKD_2	74	Polycystin2

AD, autosomal dominant; ADPKD, autosomal-dominant polycystic kidney disease.

TABLE 20.3. ADPKD—KNOWN LINKAGES

Clinical Features

Typically, for the first 10 years of life, the kidneys are normal in function and anatomy. From age 10 to 30 years, US may show the presence of cysts, although the patient is asymptomatic. However, from 30 to 40 years, the patient may be diagnosed because of symptomatic presentation such as palpable kidneys, microscopic or gross hematuria, urinary tract infection (UTI), flank pain, or renal colic from passing clots. Although elevation of creatinine may begin between 40 and 50 years of age, dialysis or renal transplantation for ESRD does not typically become necessary until after age 50. Without dialysis or renal transplantation, the mean age of death for ADPKD is 50 years (81) and patients die of uremia (59%), heart failure, and cerebral hemorrhage. However, more recent studies suggest that many patients today are being diagnosed as having ADPKD without symptomatic presentation because of modern imaging and that these patients may remain without ESRD, death, or symptoms until their seventies (73,89).

Polycystic Liver Disease and Extrarenal Cysts

Liver cysts are the most common extrarenal manifestation in patients with both PKD_1 and PKD_2 mutations. Although about 50% of ADPKD patients have liver cysts (241), liver function remains normal except in rare cases of severe massive cystic disease compressing the biliary tree, leading to biliary obstruction and obstructive jaundice (102). Unlike renal cysts, in women, liver cysts are more numerous, occur earlier, and are more extensive in women (408). Multiparity and postmenopausal estrogen therapy increase the risk of massive hepatic cystic disease (109,353). Hepatic cyst development requires somatic inactivation of the normal allele coupled to a germline mutation just as in renal cysts (401). Polycystic liver disease has rarely occurred as a genetically distinct event with no association with ADPKD (190). Liver cysts rarely have been found in children with ADPKD, although they have been described in an 8-month-old ADPKD patient (272).

Although massive hepatic cystic disease usually does not impair hepatic function, a minority of patients complain of symptoms such as abdominal swelling, intermittent attacks of pain, shortness of breath, pain on stooping, dyspnea, early satiety, nausea, heartburn, and regurgitation (280,390). When the symptoms are disabling, initial treatment can include percutaneous drainage and sclerosis or laparoscopic fenestration, especially if there is one or a small number of dominant cysts (381). However, if there are many cysts, part of the liver is spared, allowing treatment with combined hepatic resection and fenestration (280). Occasionally, symptoms remain despite fenestration procedures, at which time orthotopic liver transplantation is considered (with or without kidney transplant depending on dialysis dependency) (204). Hepatic cyst infections, although rare, can be confused with renal cyst infections and are best treated with percutaneous drainage and antibiotics that concentrate in the biliary tree, such as trimethoprim-sulfamethoxazole (TMP-SMX) and fluoroquinolones (136).

In addition to liver cysts, ADPKD patients have developed cysts in the pancreas, lung, ovaries, esophagus, testes, bladder, thyroid, uterus, spleen, pineal gland, subarachnoid space, epididymis, seminal vesicles, and prostate. The estimated prevalence of pancreatic cysts is 98.5% in ADPKD patients older than 20 years of age (377). Complications of pancreatic cysts in ADPKD are rare, but chronic obstructive pancreatitis has been reported (254). Polycystin 1 has been found in epithelial cells of the pancreas.

Until the advent of US, seminal vesicle cysts were not described in ADPKD. However, when male ADPKD patients were screened with transrectal ultrasound (TRUS), 60% were found to have seminal vesicle cysts and 11% had prostate cysts (84). Hendry and associates (170) noted that although the TRUS appearances suggested seminal vesicle cysts in six male ADPKD patients, vasograms revealed dilation of the seminal vesicles from atonicity or failure to effectively contract with no evidence of seminal vesicle cysts (170). Ovarian cysts are not more prevalent in female ADPKD patients than in the general population (408).

Aneurysms and Hernias

Intracranial aneurysm (ICA) rupture is the most feared extrarenal complication of ADPKD. From 0% to 40% of ADPKD patients have asymptomatic, unruptured cranial aneurysms on autopsy, prospective angiographic imaging studies, and prospective noninvasive imaging studies (35,52,64,188,368,393). Currently, the prevalence of ICAs is approaching 10% in ADPKD patients, as opposed to 2% in the general population. Familial clustering of ICA in ADPKD patients does occur (212,406), with a

prevalence of 16% in those families (408). ICAs have occurred in both PKD_1 and PKD_2 families.

The risk of rupture increases with the size of the aneurysm, with most aneurysms being less than 10 mm in size in ADPKD patients. Hence, the yearly risk of bleeding is low (0.5% to 2%) but the cumulative risk remains significant and depends on expected survival, which can be about 60 years in ADPKD patients (259). However, the average patient age when ICAs rupture in ADPKD is younger than in the general population and varies from 37 to 47 years of age (63). Although most acute neurologic events in ADPKD patients do not result from ruptured ICAs, these ruptured aneurysms can result in the potential sequelae of subarachnoid hemorrhage, with greater than 50% mortality and permanent disability; however, they are potentially preventable (63,259). Systematic screening of ADPKD patients with a positive ICA family history or previous aneurysmal rupture with MRI angiography beginning in the third decade of life is recommended (259). If angiography revealed an aneurysm, treatment with either microsurgical clipping or endovascular coiling should be recommended if the individual risk of rupture is higher than the risk of treatment. Such risk is dependent on the patient's age and health and the size and location of the ICA. In general, microsurgical clipping is still the treatment of choice, when feasible, because it is curative unless the patient is older, in which case endovascular coiling is a good alternative (259).

Cardiovascular abnormalities such as cardiac valve anomalies, dilation of the aortic root, dissections of the thoracic aorta, and coronary artery aneurysms have been reported to have an increased incidence in ADPKD patients (158,381). Routine echocardiography with Doppler analysis revealed 26% incidence of mitral valve prolapse, 31% incidence of mitral incompetence, 8% incidence of aortic incompetence, and 6% incidence of tricuspid prolapse in ADPKD patients (185). Symptoms of mitral prolapse (e.g., palpitations, nonexertional chest pain) are more common in ADPKD patients than in controls (119). PKD mutations may be responsible because polycystin 1 and polycystin 2 are strongly expressed in the medial myocytes of the elastic and large distributive arteries as well as in cardiac myocytes and valvular fibroblasts (149). Other nonrenal manifestations of ADPKD involve increased incidence of inguinal hernias, hiatal hernias, colonic diverticula, and cholangiocarcinoma. Polycystin 1 has been found in the epithelial cells of the intestine.

Pain

Pain is the most common presenting symptom of ADPKD, particularly in women (408). It antedates renal palpability and occurs in 59% of affected individuals (81). Pain usually occurs in the flank or lateral abdomen but may radiate to the epigastrium or suprapubic area. Acute pain can be secondary to cyst rupture or cyst hemorrhage. The more common dull pain increases as the disease progresses and cysts enlarge, and no etiology has been confirmed. Perhaps pain results from the stretching of the renal capsule, pressure on adjacent organs, or traction on the renal pedicle. Distinguishing this chronic dull pain from the pain of a simultaneous renal disease such as obstruction, hemorrhage, infection, or tumor is difficult but of great importance for the preservation of future renal function. These latter etiologies tend to cause pain of more recent onset. Abdominal pressure from massive hepatic cystic disease needs to be considered.

Hypertension

Mild to moderate hypertension antedates the onset of ESRD in about 60% of ADPKD patients. Before renal deterioration, ADPKD patients with hypertension have more renal cystic involvement than normotensive ADPKD patients (22). Cyst decompression can transiently lower blood pressure in hypertensive ADPKD patients until renal cystic volume increases again (103,115,384). Enlarging cysts could theoretically compress renal vessels, causing renal ischemia and thereby activating the renin-angiotensin-aldosterone system. Consequently, angiotensin-converting enzyme (ACE) inhibitors are widely prescribed as first-time agents for treating hypertensive patients with ADPKD. However, in hypertensive ADPKD patients with chronic renal insufficiency and massive cystic involvement, ACE inhibitor therapy can cause reversible renal failure (61). The mild to moderate hypertension in ADPKD responds well to drug treatment. Antihypertensive treatment may or may not retard the development of ESRD. Cardiovascular disease is the most common cause of death in ADPKD patients (408). Control of blood pressure is necessary to prevent accelerated hypertension and cardiovascular events. Mild to moderate hypertension in ADPKD patients may decrease on dialysis (326). PKD_1 patients have a fourfold increase in prevalence of hypertension compared with PKD_2 patients and have an earlier age of onset (34.8 versus 49.7 years) (376).

Hematuria; Flank Masses

Hematuria, gross or microscopic, is common, occurring in up to 64% of affected individuals (89). It is the presenting complaint in 35% (225). Hematuria can result from spontaneous or traumatic cyst rupture or concomitant calculi, infection, or neoplasm. An evaluation of hematuria in ADPKD patients should include all of these possibilities. Clots can cause renal colic and obstruction of the urinary tract. The most common inciting events precipitating hematuria in ADPKD patients are UTIs (42%), followed by sports or strenuous activity (20% in males and 11% in females) (225). Approximately 60% of ADPKD patients have palpable flank masses, of which one-third are bilateral and two-thirds are unilateral. However, it is a less common (15% of patients) finding at initial presentation.

ADPKD in Children

Less than 10% of cases of ADPKD present in the first decade of life (224). It is important to differentiate between children presenting at an early age with symptoms or complications leading to the diagnosis of ADPKD as opposed to those children of affected families in whom the diagnosis is made by family screening. Those identified in childhood by US family screening may have a benign early course (348), compared with those diagnosed *in utero* or by symptoms in the first few months of life, who have an estimated perinatal mortality of 43% with a 67% complication rate for the survivors by the age of 3 years (249). Children diagnosed as ADPKD *in utero* or in the first year of life have more severe renal cystic disease. In affected fetuses, oligohydramnios can occur earlier than in autosomal-recessive polycystic kidney disease (ARPKD) because the renal developmental abnormality occurs earlier in ADPKD than in ARPKD (154). Although most ADPKD infants survive, they have a more rapid decline in their renal function and more significant hypertension than their affected adult relatives. Of 24 children diagnosed with ADPKD prenatally or up to 1 year of life, 16 developed hypertension and required treatment at the mean age of 2.9 years; 3 of the 16 developed ESRD at the mean age of 2.8 years (249). Presenting symptoms in neonates include renomegaly in mild cases and respiratory distress or stillbirth in severe cases. Presenting symptoms after 1 year of age include renomegaly, hypertension, and hematuria.

Although simple renal cysts are common in adults, they are rare enough in children that any cyst on a renal US in a child at risk for ADPKD probably indicates the presence of ADPKD (121). When 106 children younger than 18 years of age who were at 50% risk of ADPKD were screened with US by these criteria as well as gene linkage analysis, 45% screened positive for ADPKD by both modalities. Fourteen children (13%) were positive for ADPKD by gene linkage analysis but had a normal initial US, although subsequent US examinations were positive for ADPKD during this analysis (121). The US false-negative rate was 25% using these criteria and highest in those children younger than 5 years of age. Since the development of present renal imaging techniques, the number of ADPKD cases discovered in childhood appears to be almost as high as that of ARPKD patients surviving the neonatal period (123).

Children with an early onset of severe ADPKD have a PKD_1 genotype and have an affected parent whose milder disease presented in adulthood. The increase in disease severity is limited to the kidney, which has a higher number of cysts and mostly glomerular cysts (289). Even though the child or fetus carries the same stable mutation as the affected parent, 45% of the subsequent gene carrier offspring have early-onset ADPKD, even with different partners (154). A modifying gene could be transmitted from the affected parent, which might alter the rate of somatic mutation at PKD_1 (289).

A less common cause of early onset of severe ADPKD occurs when both PKD_1 and TSC_2 [the more common gene causing tuberous sclerosis (TSC)] are both deleted, resulting in a phenotype with early-onset multiple renal cysts and/or early renal failure (50). This PKD_1–TSC_2 contiguous gene syndrome can occur because TSC_2 and PKD_1 are located a few nucleotides apart on chromosome 16. Patients may show findings of TSC [renal angiomyolipomas (AMLs), facial angiofibromas, and central nervous system (CNS) lesions resulting in mental retardation and/or seizures] before or after their early-onset severe renal cystic disease.

Morphology

On gross inspection, the ADPKD kidneys are huge because they are filled with hundreds of fluid-filled cysts (Fig. 20.1). Their surfaces are distorted by innumerable large cysts. However, unlike dysplastic kidneys, they retain their reniform shape. At autopsy, the mean combined kidney weight of clinically asymptomatic ADPKD patients was 512 g; of symptomatic patients, 930 g (165); and of ESRD ADPKD patients who came to renal dialysis, 2,600 g (23). The cut surface shows extensive parenchymal replacement of cortical and medullary cysts, which vary from a few millimeters to a few centimeters in diameter (Fig. 20.2). Cyst fluid varies from clear yellow to chocolate brown and from watery to gelatinous.

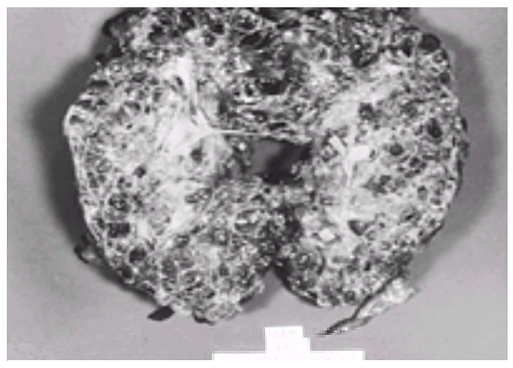

FIGURE 20.2. Autosomal-dominant polycystic kidney disease. Cut section reveals extensive parenchymal replacement by cortical and medullary cysts of varying sizes. (Courtesy of Dr. S.E. Mills, Department of Pathology, University of Virginia Medical School, Charlottesville, VA.)

On microscopic study, islands of normal renal parenchyma are found, although most parenchyma has been replaced with cysts. The cysts are lined by a single layer of flattened cuboidal or columnar epithelium, but glomerular and tubular cysts may also be recognized. Cysts involve all elements of the nephron and collecting ducts. Estimates suggest that only 1% to 2% of the 2 million renal tubules develop cysts (147).

Pathogenesis

Fewer than 5% of the nephrons develop cysts in patients affected with ADPKD. Although every cell in the kidney harbors the dominant mutations in patients with ADPKD genotypes, a “second hit” mechanism must disable the wild-type allele before a solitary tubule cell begins to divide until a microcyst is formed. When cysts become 2 mm in diameter, 70% of them separate from the tubule of origin and fill with fluid exclusively by transepithelial secretion of sodium chloride (NaCl) and fluid under central control of cyclic adenosine monophosphate (cAMP) (145). Transepithelial fluid secretion and extracellular matrix remodeling are secondary factors (143).

Hence, the rate-limiting step in a two-step process of cyst formation is inactivation of the remaining normal allele as an acquired, or somatic, mutation in patients with a germline PKD_1 mutation (319) or with a germline PKD_2 mutation (226,307,378). Epithelial cells lining the renal and biliary ducts cysts appear to have “forgotten” how big the tubule is supposed to be and continue to proliferate. Kidneys from patients with ADPKD exhibit high levels of apoptosis (programmed cell death) as well as cellular proliferation (276), just as in embryonal renal development. Cysts may be viewed as survivors of programmed cell death, whereas the surrounding tubular epithelium may be unusually susceptible to the forces that cause apoptosis (145). Cyst enlargement seems insufficient to account for development of ESRD in ADPKD, but cysts may adversely affect adjacent renal parenchyma, resulting in cystic fibrosis through paracrine and endocrine factors (407) and hence renal failure.

Genetics and Diagnosis

The mutant gene in ADPKD, either PKD_1 or PKD_2, is expressed in an autosomal-dominant pattern, with a 50% chance of inheritance. However, within a given family, there is variable penetrance and variable ages of onset. As many as 25% of patients have no family history for ADPKD (165) because (a) affected relatives died of other causes before their disease was diagnosed, (b) affected living relatives may not be aware of their diagnosis, (c) nonpaternity, or (d) spontaneous new mutations. Spontaneous mutations occur in less than 10% of ADPKD patients (119). The mutation rate for ADPKD has been observed to be high and has been estimated to be 6.9×10^{-5} (92). By the age of 30, 70% penetrance has been estimated, and 99% has been estimated by the age of 55 (92). Humans homozygous for ADPKD have not been described (143).

In 1985, Reeders and colleagues established a linkage of a PKD locus to the a-globulin locus on the short arm of chromosome 16 using reverse genetics. Now christened *PKD_1*, this gene on chromosome 16p13.3 (15) has been mapped, fully sequenced, and characterized. Mutations on this long gene (52 kb) account for 85% of ADPKD patients who have the more severe form of ADPKD (191). PKD_1's protein product, polycystin 1, among the largest reported, is predicted to function as a membrane glycoprotein involved in cell–cell or cell–matrix interactions. Both the size of the gene and its complicated genomic structure with highly homologous loci elsewhere on chromosome 16 prevent direct mutation testing for the purpose of screening at-risk individuals. Linkage-based testing is feasible, but complicated by the existence of two distinct loci (227).

PKD_2, the mutated gene in the milder ADPKD phenotype, has been localized to chromosome 4q 13-23 (222,311) and characterized (273). Polycystin 2, the PKD_2 gene product, and polycystin 1 may be involved in a common signaling pathway that links extracellular adhesive events to alteration in ion transport, possibly regulating transmembrane Ca^{2+} fluxes (273,339,383).

Because 15% of ADPKD patients were found to have no linkage to PKD_1 (297,412), a search for PKD_2 began that was far more expeditious than the PKD_1 search because the PKD_2 gene has a far less complex genomic organization. Therefore gene-based diagnosis in PKD_2 is simpler than in PKD_1. However, because only 15% of ADPKD families have this form of the disease, it is less clinically useful in the absence of effective PKD_1 gene-based mutation detection. PKD_2 has a milder renal phenotype compared with PKD_1 as judged by age at onset of hypertension, ESRD, and cyst appearance (163,297,331,376). The existence of PKD_3, a third unmapped gene, would explain why some linkage studies do not link a few ADPKD families to either PKD_1 or PKD_2 (9,85); however, evidence is inconclusive (301).

Both forms of ADPKD are caused by a second hit mechanism that disables the wild-type allele. Within PKD_1 and PKD_2 families, phenotypic variability may be explained partially by gender and partially by random somatic events (i.e., the second hits) that inactivate the normal PKD_1 or PKD_2 allele. Because familial clustering of such ADPKD complications as intracranial saccular aneurysm occurs, attempts to find genetic heterogeneity to explain variability between families has been explored in addition to PKD_1 or PKD_2 mutations. Hateboer and associates (164) found differences only in the prevalence of hypertension and hernias between PKD_1 families secondary to the different PKD_1 mutations segregating to each family within their study.

Separate modifying genes may also affect the ADPKD phenotype by altering the chance of somatic mutation such as the ACE genotype. PKD_1 patients homozygous for the ACE deletion allele are at increased risk for developing ESRD before the age of 50 years; however, they do not have a greater prevalence of hypertension (310). Another example of a modifying gene may be mutant cystic fibrosis transmembrane conductance regulator protein (CFTR) because patients with ADPKD and cystic fibrosis (CF) had less severe polycystic kidney and liver disease (normal renal function, smaller renal volumes, absence of hypertension, and no liver cysts) as

opposed to family members with only ADPKD (292).

Because of the technical demands and expense of both mutation detection and linkage analysis in ADPKD, identification of the genotype is not currently possible in most cases. There may be an exception in a subset of ADPKD families who reach ESRD late in life because this subset may be enriched for PKD_2 and gene-based diagnosis is simpler for PKD_2 (358). Gene-based diagnosis of PKD_1 is currently not practical because of complications engendered in detecting mutations in the reduplicated regions of the PKD_1 gene and because of the absence of recurrent mutations (358). Molecular genetic diagnosis of PKD_1 is best done by genetic linkage studies using intragenic and closely flanking polymorphic markers to overcome the problem of recombination.

Presently, the minimum requirement for the use of the test is the testing of two related clinically affected persons (120). Increasing the number of affected persons multiplies the degree of confidence in the recognition of the haplotype with which ADPKD is transmitted within each family. This requires large families, but in such a family, the predicated gene has a less than 5% error rate, which facilitates presymptomatic detection and prenatal diagnosis of ADPKD. When flanking markers for PKD_2 are used in conjunction with flanking markers for PKD_1, accuracy of diagnosis is improved. Individuals at risk for ADPKD who have less than two affected family members are dependent on US for diagnosis or potentially direct gene-based testing in PKD_2 families.

Although more accurate, molecular analysis of ADPKD is expensive and cannot be performed everywhere. US is the preferred method of diagnosis of ADPKD because it is highly sensitive, does not involve radiation or contrast material, and is widely available and inexpensive. The sensitivity of US for PKD_1 and PKD_2 patients older than 30 years of age is 100%. However, the sensitivity for PKD_1 patients younger than 31 years is 95.2%, and for PKD_2 patients younger than 31 years, it is only 66.6% (375). Therefore, for younger persons at risk in PKD_2 families, genetic testing is an option.

The early diagnosis of ADPKD facilitates improved genetic counseling and rational decision making about reproduction but will not necessarily lead to termination of an affected pregnancy. Linkage analysis can clarify gene status in potential living-related transplant donors. Many individuals at risk for ADPKD avoid presymptomatic diagnosis because of difficulty in getting life and medical insurance as well as future employment. A questionnaire-based study of ADPKD patients showed that 87% were concerned about the availability of health insurance, although 88% were covered. Fifty-seven percent of those with employer-based health insurance (83% of the total) had this availability determine their job choice (140).

Radiologic Findings and US Diagnosis

Contrast-enhanced CT scanning is the most sensitive diagnostic procedure for ADPKD. However, US has become the preferred diagnostic imaging method for children and adults because it is highly sensitive, does not involve radiation or contrast materials, and is widely available and inexpensive (Fig. 20.3). Renal US should pick up 95.2% of at-risk patients younger than 31 years of age in PKD_1 families and 66.6% in PKD_2 families (375). In those older than 30, US should pick up 100% of ADPKD because of the larger cyst size. The US diagnosis of $ADPKD_1$ depends on the patient's age. For patients aged younger than 30 years, two cysts, either bilateral or unilateral, must be present. Two cysts are necessary in each kidney for individuals aged 30 to 59 years, and at least four cysts are necessary in each kidney in individuals older than 60 years (322). A single cyst on US in an at-risk child is suggestive of ADPKD. Both US and CT are advantageous over intravenous pyelogram (IVP) because both allow a concomitant examination of the liver for cysts. IVP may reveal calyceal distortion on the pyelogram phase (mass effect), bilateral renal enlargement, and a Swiss-cheese appearance in the nephrogram phase (Fig. 20.4). Renal arteriography reveals stretching on vessels around avascular masses in large kidneys in the arterial phase and a mottled or Swiss-cheese appearance in the nephrogram phase (Fig. 20.5).

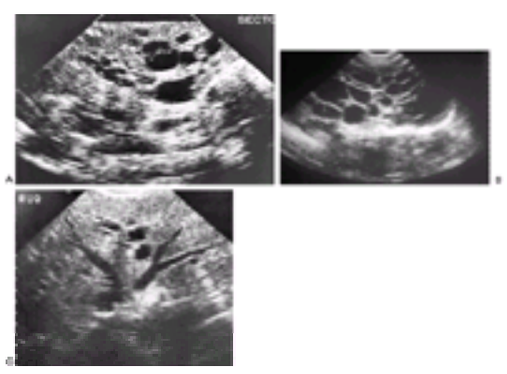

FIGURE 20.3. Autosomal-dominant polycystic kidney disease in two adults. **A:** Renal ultrasound (US) reveals multiple cysts of varying sizes in an enlarged kidney. US reveals a markedly enlarged kidney with numerous cysts of varying sizes **(B)** and two small cysts within the liver in a 37-year-old woman **(C).**

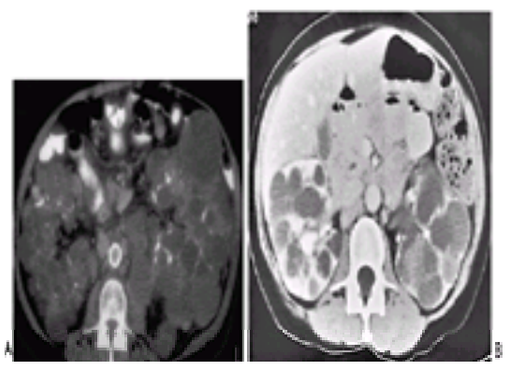

FIGURE 20.4. Autosomal-dominant polycystic kidney disease in two adults. **A:** Unenhanced computed tomography (CT) scan revealing calcifications in walls of multiple cysts in enlarged kidneys. **B:** Enhanced CT scan in a 51-year-old woman reveals bilaterally markedly enlarged kidneys with multiple cysts of varying sizes, shapes, and attenuation values. There is some enhancing renal cortical tissue remaining, but excretion into the collecting system is identified only with difficulty.

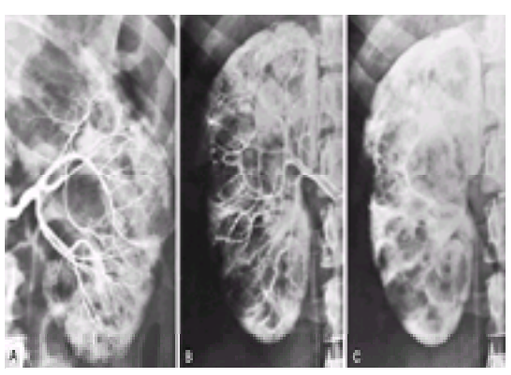

FIGURE 20.5. Autosomal-dominant polycystic kidney disease in two adults. **A:** The arterial phase of renal arteriography in a 23-year-old woman reveals stretching of the vessels around avascular masses in enlarged kidneys. **B:** The arterial phase of renal arteriography in a 30-year-old woman also reveals the intrarenal arterial branches to be stretched, elongated, and displaced by many cysts. **C:** The nephrogram phase of the same arteriogram reveals a mottled or Swiss-cheese appearance in both enlarged kidneys.

It is unfortunate that in a disease in which precise diagnosis of complications is crucial, the distorted anatomy of ADPKD kidneys often reduces the diagnostic accuracy of imaging procedures that are quite reliable in patients with normal kidneys (357). Contrast-enhanced CT scanning is the best technique for evaluating possible complications in ADPKD such as cyst or parenchymal infection, cyst hemorrhage, cyst calcifications, and renal calculi (242). Renal angiography can demonstrate renal cell carcinoma (RCC) in patients with ADPKD and can evaluate suspected renal hemorrhage and renovascular lesions. Both IVP and retrograde pyelography can localize the level of possible urinary tract obstruction in ADPKD. Retrograde pyelography should be avoided because of the high risk in ADPKD patients of introducing infection; however, it may be necessary when renal failure precludes satisfactory IVP and the level of obstruction needs to be localized. If intravenous contrast is contraindicated in an ADPKD patient, CT without contrast is the most useful test to rule out urinary tract obstruction (but not to find the level of obstruction) because US may not distinguish between parenchymal cysts and dilated calyces. Radiogallium scanning can help localize the cyst or parenchymal infection in ADPKD but false-positive and false-negative results may reduce the value of this test in individual patients. Indium-111 leukocyte scanning has potential to detect and localize infected cysts in patients with a polymorphonuclear leukocyte count greater than 2,000/mm ^{3} (49). MRI does not appear to offer advantages over CT, except perhaps to diagnose an acute renal hemorrhage.

Management

Therapy of ADPKD must be directed toward delaying and managing ESRD and toward managing the complications of ADPKD that occur before and after renal failure. Routine urologic diseases, such as urinary infections, calculi, and obstruction, can be very difficult problems in ADPKD patients and require special therapeutic consideration.

Renal Failure

Renal function is well preserved until late in ADPKD, at which time it decreases rapidly. Onset of renal failure is variable, but approximately 50% of ADPKD patients will have ESRD by 60 years of age (119). Time to development of ESRD in ADPKD patients is affected by genetic heterogeneity (PKD $_1$ versus PKD$_2$ mutations), random somatic events (second hits that inactivate PKD$_1$ or PKD$_2$ allele), and gender. A number of these factors predicting earlier ESRD in ADPKD patients can be identified early in ADPKD (206). For example, the median age of ESRD is 53 years for PKD$_1$ patients as opposed to 70 years in PKD$_2$ patients. Women had an additional 4 years until ESRD as compared with men (56 versus 52 years). Those patients diagnosed with ADPKD before age 30 developed ESRD at age 49 as compared with age 59 for those diagnosed after age 30. Hypertension does not appear to influence the rate of progression of renal failure in ADPKD, but the development of hypertension before age 35 reduced renal survival by 14 years compared with those developing hypertension after age 35. Earlier gross hematuria predicted earlier ESRD in ADPKD patients. Although female patients with ADPKD with three or more pregnancies had earlier onset of ESRD, Johnson and Gabow (206) also revealed that this effect was not significant independent of the patient's age at diagnosis and presence of hypertension.

The first sign of kidney failure in ADPKD is the inability to maximally concentrate urine. The renal concentrating defect in ADPKD can develop before glomerular filtration rate (GFR) decreases. There is loss of noncystic parenchyma replaced by fluid-filled cysts in a network of interstitial fibrosis, perhaps secondary to autocrine and paracrine factors (145). The noncystic nephrons compensate by increasing their function so that the GFRs are elevated very early in ADPKD; however, the compensatory mechanisms then fail, and other signs of renal failure follow.

General medical therapy for treatment of chronic renal failure includes low-sodium diets (326) and slowing of the development of osteodystrophy with aluminum hydroxide gel and treating metabolic acidosis. The Modification of Diet in Renal Disease (MDRD) Study revealed minimal benefit of a low-protein diet in ADPKD patients with moderate renal disease (GFR of 25 to 55 mL/min/1.73 m^2) but did suggest the benefit of protein restriction in advanced renal disease (GFR of 13 to 24 mL/min/1.73 m^2) (237).

Factors that predict a greater risk of renal failure include more severe proteinuria, UTIs in male patients, hepatic cystic disease in female patients, African-American race, and sickle cell trait in African-American patients (119). Management should include attempts to treat UTIs. Whether treatment of hypertension alters time of onset of ESRD in ADPKD patients is unknown, although control of blood pressure is necessary to prevent accelerated hypertension and cardiovascular events. Surgical cyst decompression does not slow progression of renal insufficiency in ADPKD (104).

Dialysis and Renal Transplantation

Fifty percent of ADPKD patients will eventually require dialysis or renal transplantation. Surprisingly, effective peritoneal dialysis has not been hindered by the large cystic renal and hepatic masses, hernias, or diverticulitis in ADPKD patients treated by continuous ambulatory peritoneal dialysis (157). When one takes into account ADPKD patients' older age at the time of dialysis, they do as well as other ESRD patients when receiving hemodialysis (18). When on hemodialysis, 5-year survival is 10% to 15% greater in ADPKD patients than in non-ADPKD patients, probably because of lower cardiac mortality in ADPKD patients (313). Long-term renal dialysis also markedly reduces blood pressure in hypertensive ADPKD patients (326). While on hemodialysis, the prevalence of renal pain, gross hematuria, and renal infection is significantly greater in ADPKD patients, but these complications are rarely severe (313). ADPKD ESRD patients do as well as nondiabetic ESRD patients undergoing renal transplantation in that patient and graft survival are similar (18,113,160). Although Florijn and co-workers (116) found that ADPKD patients are at risk for cardiovascular disease after renal transplantation and Andreoni and colleagues found that ADPKD patients are at risk for gastrointestinal (GI) complications after renal transplantation, others have found no increased risk of coronary events or GI complications in ADPKD after renal transplantation (313). Cysts do not develop in the transplanted kidney in ADPKD patients any more than in other patients after renal transplantation (113). Despite superior results with living-related transplantation for non-ADPKD patients, this has been somewhat limited for ADPKD patients because the disease is familial. However, if an ADPKD patient has two clinically affected family members and if the ADPKD phenotype links with the PKD$_1$ or less common PKD$_2$ locus, living-related donors can be found at any age with use of linkage analysis. For the remaining ADPKD patients, living-related donors can be identified by negative radiographic findings when 30 years of age or older or at any age with direct gene-based mutation detection in PKD$_2$ families. Bilateral pretransplant nephrectomies are not routinely indicated in ADPKD because of high morbidity and mortality (116), but they are indicated in situations of recurrent pyelonephritis, hematuria requiring blood transfusions, and large renal size causing vena caval obstruction or precluding placement of renal allograft into the true pelvis (24).

Urinary Tract Infections

Symptomatic UTIs are common, with an overall incidence of 53% and recurrence rate of 61% in ADPKD patients. Complicated UTIs are less common but difficult to treat. The incidence of renal infection in PKD$_2$ was half that of PKD$_1$ (163). Of 23 female patients who had symptomatic UTIs, 12 (52%) had pyelonephritis, of whom 3 developed perinephric abscess (89). Up to 90% of UTIs in ADPKD occur in female patients (357). Urine culture may or may not be sterile, depending on the location of the infection. Sklar and associates (357) divide ADPKD renal infections into three types: (a) acute bacterial interstitial nephritis (infection of the noncystic parenchyma with an unobstructed collecting system), (b) pyonephrosis (infection of upper collecting system, which may be obstructed by stone, blood clot, or compressing cyst), and (c) pyocyst (infected cysts). Although a urine culture should be positive in acute bacterial interstitial nephritis, it may be negative in pyonephrosis and in pyocyst because of the confined infection. Distinguishing between these is helpful in choosing a treatment course. A poor response to antibiotics should suggest either pyocyst or an obstructed urinary tract (pyonephrosis). Infected cysts can be successfully treated with cyst-penetrating antibiotics (333). Failure of prolonged systemic antibiotics to treat infected cysts may make percutaneous puncture and drainage (62,295), laparoscopic decortication and drainage (168), open surgical drainage, or even nephrectomy necessary because of the attendant mortality of infected cysts. The retroperitoneal route of laparoscopic cyst decortication and drainage prevents intraperitoneal contamination and can be guided by laparoscopic US (168). The incidence of serious infections complicating ADPKD seems to be decreasing because the rates of infection (26%), nephrectomy (45%), and death (7%) in a 1983 study of ADPKD patients are higher than the respective rates of 16%, 12%, and 0% in a similar 1996 study (132). Radiologic diagnosis or localization of a pyocyst can be extremely difficult. CT or gallium scan may help localize the infection to a cyst, but ^{111}In leukocyte scanning may prove to be more sensitive in detecting and localizing infected cysts in ADPKD in renal failure (49). In some cases, the presence of debris or echogenic material on CT or US aid in the diagnosis (295). ADPKD patients with renal calculi are three times as likely to have UTIs than those without calculi and the infections are more complicated (242). Obstruction should be ruled out to eliminate pyonephrosis.

Few antibiotics penetrate the cysts, and of those available, fewer still are effective against Gram-negative organisms, which cause the vast majority of UTIs in ADPKD patients. Lipophobic antibiotics such as aminoglycosides, ampicillin, and cephalosporins penetrate cysts poorly but have a favorable activity against Gram-negative enteric organisms (26). Lipophilic antibiotics penetrate all cysts but have varying ranges of activity; examples of such antibiotics include (a) clindamycin or metronidazole for anaerobes; (b) vancomycin or erythromycin for staphylococci or streptococci (357); and (c) chloramphenicol (346), cefotaxime (26), TMP-SMX (105), ciprofloxacin (333), and norfloxacin for Gram-negative enteric organisms. Gibson and Watson (132) advocate initial therapy of complicated UTI in ADPKD patients

with intravenous ampicillin and an aminoglycoside, realizing that failure to respond to these antibiotics would suggest a cyst infection because aminoglycosides do not penetrate cysts. Aminoglycosides should be withheld when renal function is compromised. Others recommend initial use of TMP-SMX and fluoroquinolones for infected renal cysts (408).

Urinary tract instrumentation (cystoscopy, retrograde pyelograms, and bladder catheterizations) should be avoided when possible in ADPKD patients because of the high association of infection and mortality despite sterile urine culture before instrumentation. Of 14 ADPKD patients who underwent urinary tract instrumentation, 6 (43%) developed symptomatic UTIs, of whom 3 had pyelonephritis that led to death in 2 despite parenteral antibiotic therapy (89). Most UTIs in ADPKD patients are believed to be ascending in origin and are more prevalent in women. With postmenopausal loss of estrogen protection, the vagina is colonized by Enterobacteriaceae instead of lactobacilli. Recurrent UTIs in postmenopausal women can be minimized by estrogen replacement therapy. Intravaginal estrogen cream may be helpful in postmenopausal ADPKD patients with recurrent UTIs if they do not have significant hepatic cystic disease.

Pain Management

Pain is reported in 61% of ADPKD patients (122) and must be evaluated to rule out obstruction, infection, neoplasms, and hemorrhage. If these causes are eliminated, chronic dull pain from ADPKD can be treated conservatively with analgesics such as acetaminophen. Nonsteroidal antiinflammatory drugs should be avoided because of their nephrotoxic potential. Pain clinics offer a multidisciplinary approach to help with this chronic pain. However, for those chronic pain ADPKD patients for whom such conservative methods have failed (usually a minority), cyst-decompression procedures are helpful. Percutaneous aspiration of three to five dominant superficial cysts under US guidance dramatically relieved pain in 11 narcotic-dependent ADPKD patients for 3 to 6 months (25). Percutaneous cyst aspiration accompanied by instillation with sclerosing agent results in a longer time period of cyst reduction than aspiration alone, but it also is likely to be limited to a lesser number of cysts decompressed as compared with open surgical drainage (384). Open surgical cyst decompression of 100 to 200 cysts per kidney in a 2- to 3-hour operation dramatically relieved pain in 80% of 26 narcotic-dependent ADPKD patients for 1 year and 62% for 2 years (104). Laparoscopic cyst decompression is limited to ADPKD patients with relatively few, but large, cysts because it provides inferior renal volume reduction compared with open surgical cyst decompression, although hospital stays and postoperative recovery are shorter (103). Cyst decortication and nephrectomy have been effectively performed laparoscopically for delayed recurrent pain after cyst aspiration and sclerosis, but only 1 to 62 cysts were decorticated at one sitting (101). Bilateral open transperitoneal cyst-reduction surgery for ADPKD allows drainage of 35 to greater than 1,000 cysts at one sitting with the option of simultaneous treatment of liver cysts by decortication or partial liver resection (115). Cyst-decompression procedures do not worsen or improve renal function in ADPKD patients long term (103).

Calculi

Flank pain in ADPKD can be secondary to obstruction of the urinary tract from clots, calculi, or cysts and is difficult to diagnose. Imaging studies must distinguish between obstructing calculi in the collecting system, renal parenchymal calcifications, and cyst wall calcifications. CT scanning with and without contrast best achieves these goals, and it can differentiate cysts from dilated calyces, which may not be possible on US (242). Levine and Grantham (242) found that CT scanning with and without contrast revealed 36% of ADPKD patients had renal calculi, whereas 25% had cyst calcifications. However, 20% of ADPKD patients were found to have nephrolithiasis when studied by review of IVPs and review of medical records, with nearly equal incidence in men and women (379). In this study, struvite was found in 10% of stones analyzed, although uric acid was found in 57% and calcium (phosphate, carbonate, and oxalate) in 77%; however, only 20% of the ADPKD stone patients had stones available for analysis. A common metabolic abnormality in ADPKD stone patients with normal renal function was hypocitricaciduria, whereas hyperuricemia was common in ADPKD stone patients taking diuretics or those with renal insufficiency (379). In all ADPKD patients (with or without calculi), hyperuricemia has been found in 71% (mean creatinine clearance of 69 mL per minute) and clinical gout in 24%, although the highest serum uric acid levels were found in ADPKD patients with the lowest GFR (268). Three times as many ADPKD patients with renal calculi have UTIs as those without renal calculi (242). There was no significant difference in the incidence of renal tract calculi between men and women or between PKD_1 and PKD_2 individuals (163). Obstructing ureteral and renal calculi have been successfully treated with extracorporeal shock wave lithotripsy (ESWL) (Fig. 20.6) in ADPKD. More than 82% of ESWL procedures were successful in ADPKD patients, but approximately half of them had residual fragments, which is higher than for patients without ADPKD (380). Retrograde procedures such as ureteroscopy with basket extraction, laser fragmentation, and ultrasonic fragmentation have been used successfully but can potentially cause ascending infections. Eighty percent of percutaneous procedures were successful in ADPKD patients (380). Alternatively, appropriate stone surgery can be done.

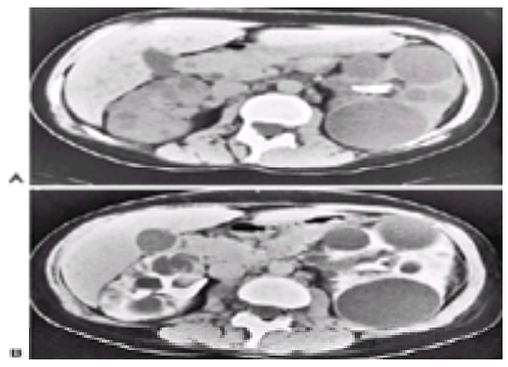

FIGURE 20.6. Autosomal-dominant polycystic kidney disease with left staghorn calculus treated by extracorporeal shock wave lithotripsy (ESWL) in a 31-year-old woman. **A:** Before ESWL, unenhanced computed tomography (CT) scan reveals a left staghorn calculus, bilaterally huge kidneys with multiple cysts of many sizes, and hepatic cysts. **B:** One day after ESWL, enhanced CT reveals no change in the renal cysts from ESWL. The residual gravel cannot be seen because of the contrast.

Obstruction, Hemorrhage, and Tumors

Obstruction of the urinary tract in ADPKD patients can also be caused by renal cyst compression, which can be treated by percutaneous, laparoscopic, or open surgical cyst decompression. Blood clots can also cause obstruction and can usually be managed conservatively. Bleeding in polycystic kidneys can usually be diagnosed by CT and treated with bed rest and observation. Cyst hemorrhage can be confined to the cystic space (causing acute pain), rupture into the collecting system (causing gross hematuria), and/or extend into the perinephric space. Intracyst hemorrhage has been treated successfully with desmopressin acetate and aprotinin administration (225). Severe hemorrhage can be treated by segmental renal artery embolization or percutaneous nephroscopic balloon occlusion of infundibuli to preserve some renal function in ADPKD patients. Alternatives to control hemorrhage include complete or partial nephrectomy.

RCC must be excluded in ADPKD patients with flank or abdominal pain, intrarenal hemorrhage, or hematuria. However, the risk of unilateral RCC in ADPKD patients is the same as the general population. However, ADPKD patients in renal failure who are receiving dialysis can develop acquired cystic kidney disease, which has a higher incidence of RCC. Both renal arteriography and MRI can help differentiate tumor from cyst (177) (Fig. 20.4).

AUTOSOMAL-RECESSIVE POLYCYSTIC KIDNEY DISEASE (INFANTILE TYPE)

ARPKD includes a spectrum of phenotypic appearances ranging from renal failure in infants to hepatic disease in older children. In addition, newborns with the severe common form of the disease can die of respiratory disorders within a few days after birth. Affected fetuses have bilaterally enlarged echogenic kidneys and oligohydramnios due to poor fetal urine output, usually after 20 weeks of gestation. These infants have the “Potter phenotype” (pulmonary hypoplasia, characteristic facies, and spine and limb deformities) because of their oligohydramnios. The incidence of ARPKD is about 1 in 20,000, with a heterozygosity frequency of 1 in 70 (417). ARPKD is characterized by bilateral cystic disease in enlarged kidneys with retained reniform shape. ARPKD is transmitted in an autosomal-recessive pattern only and is caused by a genetic defect on chromosome 6.

Clinical Features

The clinical picture of ARPKD covers a continuum of presentations of renal failure and hepatic disease developing at different ages and to different degrees.

Newborns and infants suffer more from renal failure. Children presenting after infancy are more likely to have liver disease, although a continuum exists.

More than 75% of ARPKD patients present in the newborn period, at which time the child has massively enlarged kidneys (up to ten times normal size) (80,143), causing respiratory difficulties as a result of diaphragmatic elevation and pulmonary hypoplasia. Vaginal delivery may be impeded by the massive kidneys. Most deaths occur in the first month of life and are due to pulmonary atelectasis and respiratory failure from oligohydramnios (351). Survival of all but the most severely affected neonates is now the norm. Approximately 86% of children born with ARPKD are alive at 3 months and 79% at 12 months (214). Oliguria and Potter's facies may be present, but renal failure is not the cause of death. If the child survives the newborn period, he or she most likely will have eventual renal failure and systemic hypertension, which can be particularly severe in the first year of life (123). Seventy percent of ARPKD children require drug treatment for hypertension, which is insufficiently treated in 31.2% of these patients because of its severity (416). Blood pressure elevation is intermittent during the course of the disease. After the first month, growth failure and congestive heart failure are usually the major clinical problems (232). Some patients have secondary effects of chronic renal insufficiency such as anemia, growth failure, and renal osteodystrophy (416).

After the first year of life, the clinical presentation of ARPKD is more variable because of the spectrum of renal failure and hepatic disease. As children with ARPKD grow, the renal cystic dilation can regress as the kidneys become smaller (38). These children can have either slowly progressive renal insufficiency or simply a mild renal functional impairment such as a mild inability to concentrate urine. The percentage of patients with severe renal insufficiency increases with age from 11% at 2 years to 32% at 5 years, 36% at 10 years, 43% at 15 years, and 100% at 20 years (123). Zerres and others (418) showed a statistically significant sex difference in terms of more pronounced progress in girls. Girls with ARPKD had shorter survival probability (82% at 1 year) compared with boys (95% at 1 year) and more girls had impaired renal function, developed ESRD, and showed growth retardation (418). Systemic hypertension is common, but b-blockers and converting enzyme inhibitors are effective (123). UTIs occur in 30% to 43% of ARPKD patients but are more common in girls (43%) than in boys (20%) and occur earlier in girls (418).

However, with time, these older children with ARPKD can develop more severe hepatic involvement. The hepatic disease in ARPKD is called *congenital hepatic fibrosis* (CHF) because the liver has an increase in the number of portal bile ducts and fibrosis of the periportal spaces. Hepatic US can be used to confirm the presence of “biliary dysgenesis” in at least half of ARPKD patients (123). CHF presents clinically as portal hypertension, which can result in massive upper GI hemorrhage from ruptured esophageal varices. More commonly, the children with ARPKD develop splenomegaly as their initial or only sign of portal hypertension due to hepatic fibrosis (317). There is no hepatocellular disease. Caroli's disease (gross cystic dilation of the intrahepatic biliary tree) is often associated with ARPKD, and the two diseases may be overlapping syndromes (416). In this older age group (older than 6 years), CHF, not the renal cystic disease, may be responsible for death. However, the continuum of renal failure and hepatic disease in older children with ARPKD also includes children symptomatic from both kidney and liver disease (266). The clinical cause and pathologic expression of renal disease can be entirely dissimilar within the same family (125,173,215).

Morphology

The gross and microscopic characteristics of ARPKD kidneys vary with the age of the child at the time of presentation, but the disease is always bilateral. In newborns with the severe form of ARPKD, gross inspection reveals the kidneys to be adult size and reniform (Fig. 20.7). The kidney surface is smooth and studded with 1- to 2-mm cysts. The cut surface shows a striking radial arrangement of thin-walled channels extending from the pelvis to the cortex. Microscopically, these channels are dilated collecting tubules and ducts, which are the fusiform cysts of ARPKD. Interstitial edema is severe.

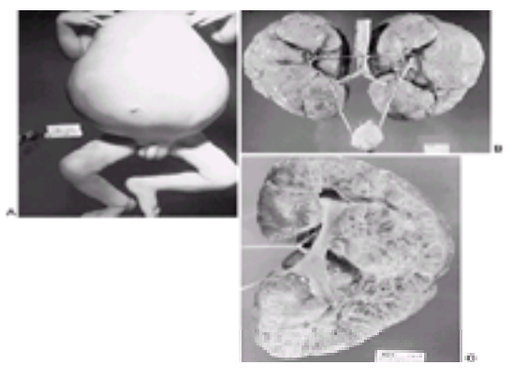

FIGURE 20.7. Autosomal-recessive polycystic kidney disease in a 7-month-old boy. **A:** Abdomen is markedly distended from the massively enlarged reniform kidneys **(B),** which have minute cysts studding the kidney surface. **C:** Cut section reveals radial arrangement of tubular-shaped cysts. (Courtesy of Dr. S. Bova.)

In children surviving the neonatal period, the kidneys become smaller, the collecting ducts become less dilated, and the remaining cysts are spherical as opposed to saccular (245). Also, variable degrees of corticotubular atrophy, basement membrane thickening, and interstitial fibrosis are present (173). These findings are also true for children who present with ARPKD after infancy. However, with time, these children are likely to develop CHF (317). Grossly, the liver in CHF is firm and enlarged with a granular surface. Microscopically, there are an excessive number of interlobular bile ducts. The liver is subdivided by bands of fibrous tissue in the periportal and interlobular spaces. Although portal hypertension is commonly attributed to a presinusoidal block because of the portal fibrosis or the portal vein abnormalities, a postsinusoidal block may be present in the same patients (31).

Pathogenesis and Genetics

The pathogenesis is unknown except that it is genetically transmitted as autosomal recessive. Heterozygotes are unaffected. Hence, a very careful family history covering at least three generations should be taken to exclude ADPKD. The ARPKD gene has been localized to chromosome region 6p21. The abnormal DNA results in the development of cysts in the renal collecting ducts, which expand to enormous size because of epithelial cell hyperplasia in the cyst walls and fluid accumulation within cyst cavities (143). Presenting newborns can have 80% of tubules involved, whereas patients presenting during adulthood have less renal involvement (10% of tubules) (351).

Because of the continuum of clinical presentation of ARPKD, four types were described by Blyth and Ockenden (40) with different ages of onset. Each type was to be transmitted as an autosomal-recessive allele and each type was to have occurred in all of the affected children of a family. However, further work has shown that not only do different clinical and pathologic courses occur within one family (125,173,215) but that ARPKD has a spectrum of phenotypic expressions and not just four genetically determined, rigidly defined subgroups (125,245). Deget and colleagues (87) revealed that intrafamilial variability of the clinical picture is small. Zerres and associates mapped the ARPKD gene locus to 6p21 codon in families with a mild ARPKD phenotype, and Guay-Woodford and associated (153) showed the severe perinatal form of ARPKD maps to the same chromosome. Together, these studies suggest there is a single ARPKD gene. Multiple allelism with only a few different alleles would account for the great variability of manifestations in different families and would also explain the relatively high intrafamilial concordance in manifestations (416).

Radiologic Findings

In infants with bilateral palpable abdominal masses, the initial study should be renal and abdominal US (Fig. 20.8). In newborns with the severe form of ARPKD, the kidneys are very large with diffusely increased parenchymal echogenicity. This increased echogenicity is caused by the sound beam bouncing off the innumerable dilated tubules. Some investigators have shown a more heterogeneous pattern with either “striped” or “pepper-and-salt” echoes (404), or a peripheral zone of normally echogenic cortex in some newborns (270). Occasionally, small cysts can be identified in the hyperechogenic medullary areas.

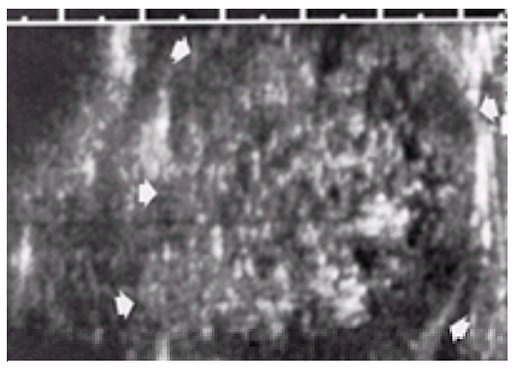

FIGURE 20.8. Autosomal-recessive polycystic kidney disease in newborn. Renal ultrasonography reveals marked renal enlargement with heterogenous pattern and myriad fine cysts. *Arrows* denote renal margin.

IVPs in infants with ARPKD may show only progressively dense nephrograms of these massive kidneys or may show the classic radial streaking of contrast in dilated collecting tubules. The collecting system is usually not seen, although contrast in the bladder may be seen on delayed films.

In the older child with ARPKD, the IVP pattern is less diagnostic because the kidneys are only somewhat enlarged and the renal pelvis and calyces are better visualized. The calyces may be blunted, or the pyramids may be opacified with a brushlike pattern. There may be an ectasia of the collecting tubules (215). US studies in the older child with ARPKD can demonstrate diffuse hyperechogenicity of the parenchyma or reveal a prominent rim of renal cortex with normal echogenicity surrounded by moderately echogenic medulla (270). Serial US studies in ARPKD patients surviving the neonatal period reveal that kidney size decreases (despite the child's linear growth) and echogenicity changed (38). Disseminated small cysts (less than 15 mm) are often visible and may be present from the neonatal period (123). US evaluation of the liver reveals increased echogenicity, dilated bile ducts, and no discrete cysts (173). CT of the kidneys in ARPKD can reveal accentuation of contrast material on the cortical layers and lacelike medullary cysts (211). CT without contrast commonly reveals bilateral renal calcifications in older ARPKD children with renal failure; however, these calcifications are not recognized on plain film (248). RARE-MR technique (rapid acquisition with relaxation enhancement) is a noninvasive imaging study that demonstrated the pathognomonic water-filled structures in all of eight ARPKD children evaluated (aged 3 months to 14 years) (219). Both magnetic resonance cholangiography (210) and hepatobiliary scintigraphy (400) have been used to diagnose Caroli's disease in ARPKD patients.

Diagnosis and Management

Families with a severely affected child carry a high risk that additional affected children will be severely affected as well, because intrafamilial variability of the clinical presentation is small (87). Because of the poor prognosis of the severe perinatal form of ARPKD, there is a strong demand for prenatal diagnosis. If a pathoanatomic examination of a previous affected child (liver biopsy or autopsy of fetus) is available, molecular linkage analysis is now feasible for prenatal diagnosis of subsequent pregnancies if DNA analysis of the parents and the one affected child has shown that markers linked to ARPKD are informative. Because direct mutation analysis in ARPKD is not available, correct clinical diagnosis of the first affected child is paramount for accurate prenatal diagnosis of subsequent pregnancies with molecular linkage analysis. The vast majority of families who meet these criteria were informative with the highly polymorphic markers of the ARPKD interval, with precise correlation between the genotype and the predicted phenotype (417). Mücher and co-workers (274) found that the large number of flanking polymorphic loci made genetic linkage-based prenatal diagnosis of ARPKD possible for more than 99% of the families that they analyzed.

In a prenatal differential diagnosis, ADPKD, Meckel's syndrome, and Bardet-Biedl syndrome should always be ruled out. Renal cystic changes can be seen in patients with CHF, which is also autosomal recessive. Adult ARPKD patients who present with mild renal failure can be diagnosed as ARPKD only if they have a negative family history and parents (older than 30 years of age) with normal renal US studies to exclude ADPKD. They can be diagnosed as having ARPKD if they have symptoms of portal hypertension or a liver biopsy revealing hepatic fibrosis (416).

The prenatal US picture of the enlarged kidneys and/or increased echogenicity is characteristic but not pathognomonic (415). Oligohydramnios occurs after 20 weeks of gestation in severe perinatal ARPKD. Related US measurements of kidney length may be the most useful parameter.

US (small renal cysts), liver biopsy (CHF), and family history (recessive inheritance) are usually sufficient to diagnose ARPKD (351). There is no known cure for ARPKD, but genetic counseling can inform parents that siblings of an affected child have a 25% chance of being affected and a 50% chance of being heterozygous carriers. Otherwise, treatment is supportive. Respiratory resuscitation and support may be necessary for newborns diagnosed with ARPKD. When the massively enlarged kidneys restrict diaphragmatic excursion, resulting in respiratory distress in addition to pulmonary hypoplasia, ARPKD newborns may require bilateral or unilateral nephrectomy. Unilateral nephrectomy may improve respiratory status and decrease feeding difficulties without inducing renal failure in ARPKD infants (20). Peritoneal dialysis can be instituted as they await renal transplantation (367). Older children may need antihypertensive medications for hypertension, digitalization for congestive heart failure, and alkali for metabolic acidosis to permit normal growth, as well as other supportive measures for treating renal failure in growing children. Chronic dialysis and renal transplantation may be necessary eventually, but liver involvement should be evaluated first. Jamil and co-authors (200) noted that liver disease did not progress rapidly after initiation of renal replacement therapy and did not subsequently present a clinical problem. Prophylactic portacaval shunting or combined liver–kidney transplantation was unnecessary. Portal hypertension may result from CHF in ARPKD and can be treated by portacaval shunting to treat esophageal varices. However, recurrent bleeding is controllable by sclerotherapy (200).

JUVENILE NEPHRONOPHTHISIS–RENAL MEDULLARY CYSTIC DISEASE COMPLEX

The juvenile nephronophthisis–medullary cystic disease complex (NMCD) consists of a group of hereditary diseases characterized by renal salt loss, renal cyst formation at the corticomedullary junction, and progressive renal failure. These diseases have different hereditary patterns and genetic heterogenicity but share similar clinical features and pathologic features. Both kidneys are small and reniform with small cysts at the corticomedullary junction. NMCD is uncommon, but it is the most common cause of renal failure in the adolescent.

Clinical Features and Genetics

Despite the genetic heterogeneity of NMCD, the pathologic and clinical features are similar except for the age of onset. The autosomal-recessive medullary cystic disease, juvenile nephronophthisis (NPH), affects mostly children and adolescents. The autosomal-dominant medullary cystic disease (ADMCKD) affects mostly adults. Finally, NMCD can rarely occur sporadically with no documented family history but consanguinity of parents should suggest the possibility of recessive inheritance.

NPH results in ESRD at about age 14 years and is the most common form of renal failure in adolescents (126). Because of severe salt wasting secondary to a severe defect in tubular function and the resultant inability to concentrate urine, children or adolescents present with polydipsia, polyuria, and secondary enuresis. Children can also present with growth retardation or skeletal deformity. The salt wasting occurs late in the disease and can be heralded by a decrease of already-present arterial hypertension. However, the polyuria and nocturia can be present for more than 10 years before ESRD occurs (54,60). Both sexes are affected equally. Urinary infections are not common.

Genetic heterogeneity exists within NPH (Table 20.4). Nephronophthisis type 1 (NPH_1, autosomal-recessive medullary cystic disease) has been mapped and localized to chromosome 2q12-13 (8). Within this region, the gene $NPHP_1$ was identified; this gene is deleted in more than 65% of patients with NPH_1 (175). NPH_1 is the most common type of NPH and NMCD. However, patients with the rare Senior-Løken syndrome (renal-retinal syndrome, autosomal-recessive medullary cystic disease, or NPH with retinitis pigmentosa) do not link to chromosome 2q12-13 (8). In addition, Gagnadoux and colleagues (124) described a group of infants who reached ESRD before 2 years of age with pathologic features similar to those of NPH. This disorder has been designated “infantile nephronophthisis” (NPH_2). Haider and associates (159) identified linkage of NPH_2 to chromosome 9q22-31 in a family with an autosomal-recessive mode of inheritance. Affected individuals developed hypertension, hyperkalemia, and rapid deterioration of renal function with ESRD by 3 years of age. There is emerging evidence that a third locus (NPH_3) exists for adolescence

onset recessive nephronophthisis (176).

Disease	Inheritance	Chromosome	Mean Age Onset of ESRD
NPH_1	AR	2q12-q13	13 yr
NPH_2	AR	9q22-q31	7.8 mo
$ADMCKD_1$	AD	1q21	62.2 yr
$ADMCKD_2$	AD	16q12	31.5 yr

AD, autosomal dominant; ADMCKD, autosomal-dominant medullary cystic kidney disease; AR, autosomal recessive; ESRD, end-stage renal disease; NMCD, juvenile nephronophthisis–medullary cystic disease complex; NPH, nephronophthisis.

TABLE 20.4. NMCD COMPLEX—KNOWN LINKAGES

The autosomal-dominantly inherited disease, medullary cystic disease, is less common than juvenile nephronophthisis and results in ESRD at about 32 years of age (126). Many ADMCKD patients are hypertensive at an early stage of the disease, but some later develop hypotension due to excessive salt wasting. Polyuria and polydipsia are less intense in ADMCKD than in NPH. Some ADMCKD patients have gout and/or hyperuricemia (362). Christodoulou and associates (71) localized a gene ($ADMCKD_1$) for ADMCKD to chromosome 1q21 in two large Cypriot families. Affected family members also had hyperuricemia and gout, with a mean onset of ESRD at 62.6 years of age. Scolari and colleagues (347) described a second locus for medullary cystic disease, $ADMCKD_2$, on chromosome 16p12 in a large Italian family. Affected family members had hyperuricemia, gouty arthritis, and an average onset of ESRD at age 31.5 years. Diagnostic criteria for ADMCKD include (a) autosomal-dominant inheritance; (b) defective urine-concentration with polyuria, isosthenuria, and relatively normal urinalysis results; (c) normal or small-sized kidneys with occasional small medullary cysts; and (d) renal pathologic findings characterized by tubular-interstitial fibrosis (347). A third locus ($ADMCKD_3$) is possible (176).

Landing and colleagues (232) were correct that *medullary cyst disease* is not the name of a specific disease but is a useful term for a lesion that occurs in the later stages of several different genetically determined and other types of tubulointerstitial disease.

Morphology and Pathogenesis

On gross inspection, both kidneys in NMCD are contracted and pale with granular subcapsular surfaces. On cut section, there is poor demarcation between the medulla and the attenuated cortex. The cysts are actually diverticula of the distal convoluted tubules. When the cysts are macroscopic, they are typically located on cut section at the corticomedullary junction. They can range from microscopic to 1 cm in size. Cysts are usually present but occasionally are not especially early in the disease. Cysts are more common in ADMCKD than in NPH.

Microscopic examination reveals glomerular sclerosis, tubular atrophy, and interstitial fibrosis with chronic inflammation. The tubular basement membrane is markedly thickened. Without the presence of cysts, the pathologic findings resemble those of interstitial nephritis. Indeed, NMCD has been considered a primary interstitial nephritis by some (53). Therefore a renal biopsy can be misleading if the corticomedullary cysts are missed in the biopsy specimen. Such biopsy specimens have been diagnosed as chronic interstitial nephritis initially but were changed because a later examination of the entire kidney from a subsequent nephrectomy or autopsy may show the medullary cysts (53,318). Renal biopsies may also not reveal the cysts if the biopsies are done early in the disease.

The pathogenesis of NMCD is unknown, except that it can be genetically transmitted. The gene product of $NPHP_1$, nephrocystin, may play a role in the protein–protein interaction (e.g., in signal transduction at focal adhesions, the contact points between cells, extracellular matrix). A defect in cell–matrix interaction would help explain the tubular membrane disruption in NPH (176). Perhaps a tubular basement membrane defect causes the early occurrence of the decreased urine-concentrating ability. Both NPH and ADMCKD may be the results of defects in the same developmental or metabolic pathway. Potential similarities in mutated genes may result in similar phenotypes (71).

Radiologic Findings and Management

Radiographic findings vary with the stage of progression of NMCD. Occasionally, an IVP early in the disease may reveal characteristic patterns either as streaky contrast enhancement or ring-shaped retention of contrast material in the corticomedullary region (288). More commonly, an IVP reveals normal findings early in the disease but shows bilaterally small kidneys later in the disease, at which time high-dose nephrotomography could reveal renal cysts (332). However, an IVP is of little value very late in the disease when renal function is greatly reduced. US has been shown to reveal cysts in the corticomedullary zone ranging from 2 to 10 mm in size in both patients with early and late NMCD (288). US reveals disappearance of the corticomedullary differentiation at all but the early stages of NMCD as well as small kidneys and increased parenchymal echogenicity (128,332). Although US may not show cysts until later in the disease (39), thin-section CT may (106). US, CT, or both could complement renal biopsy to diagnosis NMCD if the cysts were missed on biopsy but revealed by US or CT.

Treatment of NMCD is directed toward general therapy for renal failure. If salt wasting is present, it can be treated with salt supplementation. Control of hypertension and a low-protein diet may prolong normal kidney function if patients are diagnosed early as a result of linkage data and available flanking markers (71). Dialysis and transplantation are successful. However, recognition of genetic variants is vital to avoid selecting a living donor for transplant who is personally at risk of developing the disease (13). Molecular genetic diagnosis of NPH_1 can be performed by demonstration of the presence of deletions or point mutations of the $NPHP_1$ gene (176). In addition, if glomerular cysts are found on renal biopsy, the patient should undergo liver biopsy before renal transplant to rule out hepatic disease. Hepatic disease has occasionally been associated with juvenile nephronophthisis, more commonly if glomerular cysts are found on renal biopsy. Because hepatic fibrosis can lead to portal hypertension, hepatic biopsy should be considered before renal transplant (33).

RENAL CYSTS ASSOCIATED WITH MULTIPLE MALFORMATION SYNDROMES

Renal cystic disease, macroscopic to microscopic, has been found in some hereditary disorders. Knowledge of these disorders is important for genetic counseling.

Chromosomal Disorders

Patients with trisomy 21 (Down syndrome), trisomy 18 (Edward's syndrome), trisomy 13 (Patau's syndrome), and trisomy C can develop microscopic cysts, usually of the glomerular spaces of the renal cortex.

Autosomal-recessive Syndromes

Renal cystic disease is commonly found in Meckel's syndrome (MKS) or Meckel-Gruber syndrome (occipital encephalocele, hepatic fibrosis, renal cystic dysplasia, and polydactyly) (176), in Jeune's syndrome (asphyxiating thoracic dystrophy—small chest and renal dysplasia), and in Zellweger's syndrome (cerebrohepatorenal syndrome—high forehead and hepatomegaly). The prognosis of MKS is guarded in cases with onset of renal insufficiency in the neonatal period. Two gene loci have been mapped for MKS (Table 20.2). MKS_1 is localized in 17q21-q24 (294) and MKS_2 is localized on 11q13 (334). Zellweger's syndrome is associated with renal microcysts and an almost complete lack of peroxisomes in renal tubular epithelial cells and defects in several peroxisomal enzymes (370). Renal cystic changes have been less commonly reported in a few other autosomal-recessive syndromes such as Goldston syndrome (cerebral malformations), Majewsky and Saldino-Noonan types of short rib polydactyly, lissencephaly (microcephaly, smoothness of the brain, and cystic renal dysplasia), and the Elijalde syndrome (acrocephalopolydactylous dysplasia—gigantism and renal dysplasia).

X-linked Dominant Syndrome

Renal cystic disease occurs later in life in the orofaciodigital syndrome, type I, and somewhat resembles ADPKD.

Autosomal-dominant Syndromes

Tuberous sclerosis (TSC) and von Hippel–Lindau disease (VHL) are most likely to require the attention of a urologist as opposed to the other multiple malformation syndromes. Hence, both autosomal-dominant syndromes are described in detail.

Von Hippel–Lindau Disease

VHL (cerebroretinal angiomatosis) is caused by a genetic defect in the short arm of chromosome 3 and results in renal cysts and clear-cell renal carcinomas as well as retinal angiomas; cerebellar, medullary, and spinal hemangioblastomas; pheochromocytomas; islet cell carcinomas, cystadenomas, and cysts of the pancreas; cystadenomas and cysts of the epididymis; and endolymphatic sac (inner ear) tumors (133,244,258). The disease is inherited as autosomal dominant with a high penetrance of more than 90% by age 65 (252). Most manifestations of VHL do not become apparent until after the patient has reached the end of his or her second decade. However, retinal angiomatosis often is the earliest manifestation and has been found in an asymptomatic patient as young as 9 years of age (239). Cerebellar hemangioblastomas were once the most common cause of death in VHL. As more patients survive the cerebellar lesions as a result of improved treatment methods, the incidence of renal cysts and renal tumors in patients has increased (304), such that RCC accounts for 50% of deaths in VHL and is the most common cause of death (216). In one study, CT of the abdomen and brain and indirect ophthalmoscopy were done as screening examinations on family members at risk. Of those who were diagnosed as having VHL, 35% had RCC and 76% had renal cysts (239). RCC was found only in those patients who had renal cysts (118,239). Unlike RCC in patients who do not have VHL, RCC in patients with VHL occurs in younger patients, has an equal sex distribution, and is usually bilateral and multicentric (304). These RCCs can invade locally and distantly metastasize (31).

The VHL gene maps to chromosome 3p25-26 (233). The VHL gene functions as a recessive tumor-suppressor gene, and inactivation of both alleles on the VHL gene is the critical event in the pathogenesis of VHL neoplasms (79). The allele from the affected parent has been inherited as mutated, and the wild-type allele from the nonaffected parent has been sporadically inactivated in the VHL neoplasms. If one or both alleles are unaffected, the VHL gene encodes proteins responsible for negative regulation of cell growth. Mutations of both alleles results in loss of functions of the encoded proteins with resultant uninhibited cell growth and malignant transformation. The VHL protein (pVHL) inhibits the stimulatory effects of Elongin on transcription by binding to the Elongin B and C subunits of this protein (279). Mutated pVHL cannot compete for binding to Elongins B and C and therefore regulation of transcriptional elongation is lost resulting in tumor growth. The VHL protein downregulates vascular endothelial growth factor (VEGF) (414). The mutated VHL gene upregulates VEGF so that clear-cell renal carcinomas, hemangioblastomas of the eye and CNS, and papillary cystadenoma of the epididymis secrete large amounts of VEGF, causing new blood vessels to infiltrate these tumors, which become hypervascular (236,279). Wild-type VHL is required for exit from the cell cycle, so RCC cells with mutant VHL continue to proliferate because they cannot exit the cell cycle (414). The VHL protein also is responsible for proper assembly of the extracellular fibronectin matrix and regulates expression of carbonic anhydrases 9 and 10 (414). Chromosome 3p allele loss was found in RCC, hemangioblastoma, pheochromocytoma, and pancreatic tumors, suggesting a common mechanism of tumorigenesis in all types of tumors in VHL disease (79).

Renal Lesions of VHL

The renal cysts of VHL are multiple and bilateral and are lined by variably hyperplastic epithelium. Benign renal cysts with clear-cell cytologic features were found only in kidneys of VHL patients (395). By extrapolating from microscopic evaluation, VHL kidneys have an estimated 1,100 cysts with clear-cell lining and 600 clear-cell solid neoplasms per kidney (395). The mean volume of these renal lesions was 0.46 mm^3. Hence, a constant morphology exists as the cysts grow. Clear-cell renal lesions in VHL patients ranging from cysts to microscopic RCC to macroscopic RCC show the loss of the VHL gene (247). Nodular hyperplasia within the cyst walls have been observed progressing to clear-cell carcinoma (28). DNA quantitative studies reveal that both the RCCs and the atypical cyst lining cells have the same DNA indices in VHL, suggesting that the atypical cyst lining cells evolve into RCC (189). However, serial CT renal imaging of VHL patients revealed that the majority of solid RCCs appeared to arise *de novo* and were not initially cystic (68). Conversion from cystic to solid lesions did occur in this serial CT renal imaging study but was not the predominant sequence of events in the development of RCC in VHL.

Loss of function of the VHL disease gene may be the initial event in the renal cellular transformation that results in the development of clear-cell cysts and tumors. It is unknown whether benign cysts with clear-cell lining progress to RCC or if benign cysts with clear-cell lining, atypical cysts, and renal clear-cell carcinomas represent different accumulations of genetic defects (315).

Genotype–phenotype Correlations

Differences in phenotypes in VHL patients can be secondary to either variable mutations in the single VHL gene or the effects of other modifying genes but not mutations in genes other than the VHL gene on chromosome 3p25-26. Therefore allelic heterogeneity and not locus heterogeneity can account for differences in VHL phenotypes. VHL can be caused by many different mutations in the VHL gene, with more than 162 different intragenic mutations described (279).

VHL germline mutations can be divided into those that produce truncated VHL proteins (type I) or those that produce intact VHL proteins with a change in a single amino acid (missense mutations) (type II) (65). Type I VHL patients may have retinal angiomas, spinal and cerebellar hemangioblastomas, pancreatic cysts, and kidney cancer. This is the most common form. Type II VHL patients may develop pheochromocytomas in addition to the tumors in type I (65,398). Type II families represent 7% to 20% of VHL families and rarely have renal and pancreatic cysts. Type II can be subdivided into certain VHL mutations with a low risk of clear-cell renal carcinomas and CNS lesions (type IIa) and high risks of clear-cell renal carcinomas and CNS lesions (type IIb). Type IIb is least common. No specific germline VHL mutation is associated with retinal angiomas or endolymphatic sinus tumors (414).

However, even related VHL family members with identical germline mutation can have variation in disease severity. Other genes may modify the effects of germline VHL mutations, such as the number of retinal angiomas in VHL patients (402). In addition, the greater the number of retinal angiomas, the greater the problem with RCC and hemangioblastoma later on.

Diagnosis, Screening, Surveillance, and Management

If the patient has a family history of VHL, the diagnosis is made if an individual has a single manifestation of the disorder as clear-cell renal carcinoma, retinal angioma, or pheochromocytoma (414). Also, multiple pancreatic cysts are uncommon in the general population and would be satisfactory for a VHL diagnosis in an at-risk individual, unlike renal and epididymal cysts (253). If there is no VHL family history, the diagnosis of VHL should be considered in an individual with two or more retinal or cerebellar hemangioblastomas; a single hemangioblastoma and a visceral tumor; familial or bilateral pheochromocytoma; familial, multicentric, or early-onset clear-cell renal carcinoma; or bilateral endolymphatic sac tumors (253). Recently, the frequency of VHL germline mutations in individuals with a single VHL manifestation without a VHL family history has been investigated with the following results: 1.6% of patients with sporadic renal carcinoma had a germline VHL manifestation, as did 2.5% to 5% of patients with an isolated retinal angioma (414). Germline VHL mutations are rare in isolated cases of pheochromocytoma but occur in 50% of patients with isolated familial pheochromocytoma or bilateral pheochromocytoma with no VHL family history (327). Some had been misdiagnosed as multiple endocrine neoplasia type 2.

Genetic linkage analysis with microsatellite flanking markers has been widely used in presymptomatic diagnosis in VHL families but is not possible for relatives of isolated cases or in families where necessary samples are not available (327). The cloning of the VHL tumor-suppressor gene has enabled direct mutation testing for VHL families. Once a patient is diagnosed as being affected, all at-risk relatives should be tested for the mutation because early detection of RCC and retinal hemangioblastoma significantly reduces morbidity and mortality. Prenatal diagnosis is possible. Annual physical and ophthalmologic examinations begin in infancy in individuals diagnosed with VHL. About 50% of VHL patients will have only one manifestation of the disease. Imaging of the abdominal organs and brain and spine should be added in teenagers and adults.

Radiographic evaluation of renal lesions in VHL is useful for screening family members and for following patients once they have been diagnosed as having VHL. IVP can reveal several mass lesions, but it cannot differentiate cysts from tumors. CT can reveal solid mass lesions and many reveal renal cysts, but it cannot differentiate between a small cyst and a small tumor, nor can it find a small tumor in the wall of the cyst. Thin-section (3 to 5 mm) contrast-enhanced CT is mandatory, and spiral

geometry is desirable to decrease the chances a lesion is missed (69). US and, sometimes, angiography can fail to detect these small masses (239). US is critical to help determine whether a lesion is principally solid or cystic (69). CT scans can evaluate the adrenal glands for pheochromocytomas and the pancreas for islet cell carcinomas, cysts, and cystadenomas (186,244). Sequential CT studies are most sensitive in finding renal tumors before they become large enough to metastasize. However, a substantial proportion of renal lesions smaller than 1 cm were not detected by CT or US in VHL patients (201).

Annual studies are recommended once a diagnosis of VHL is made (216). MRI is especially useful in patients with renal failure in whom screening for RCC is still necessary (69). Contrast-enhanced MRI can be useful in determining whether a lesion is principally solid or cystic.

Annual CT renal imaging of VHL patients with renal lesions is recommended to determine the size and growth rate of the lesions and thus the appropriate management. Management can include continued observation, renal parenchymal sparing surgery, or nephrectomy. Bilateral nephrectomy can result in dialysis or renal transplantation. Walther and colleagues (397) noted no renal lesions 3 cm or smaller that metastasized in VHL patients. Renal parenchymal-sparing surgery was undertaken when the largest renal lesion reached 3 cm, at which time all visible tumors were resected from that kidney with use of intraoperative US to localize any additional tumors to be removed (397). Enucleation technique can be used because as many as 53 lesions have been removed from one kidney and lesions less than 3 cm have not been observed to penetrate this boundary, although they have invaded it (315). Because the remaining renal parenchyma in VHL patients has a high number of remaining microscopic lesions (395), these patients must be imaged annually with CT scans after renal parenchymal sparing surgery to detect when the largest residual renal lesion becomes radiographically evident and reaches 3 cm in size. At that time, nephrectomy or repeat parenchymal-sparing surgery can be considered. Excellent long-term survival is observed when partial nephrectomy is used to remove VHL renal lesions when technically possible regardless of lesion size (363). Despite a 51% local tumor recurrence in these VHL patients treated by partial nephrectomy when technically feasible, only 2 of 25 had concomitant metastatic disease and renal function was well preserved (363).

In VHL patients with renal lesions not amenable to renal parenchymal-sparing surgery or with local recurrence after such surgery, bilateral nephrectomy may eventually be necessary. Steinbach and others (363) noted that 23% of VHL patients eventually developed ESRD after treatment for localized RCC. Management options for ESRD in the VHL population includes dialysis or renal transplantation. Renal transplantation is attractive in these relatively young ESRD patients, but the risk of immunosuppression in VHL patients with multiple potential tumors must be considered. Goldfarb and associates (139) demonstrated no statistically significant difference in graft survival, patient survival, or renal function after renal transplantation in well-selected VHL patients compared with control patients without VHL. Of the 32 VHL patients, 3 died of metastatic RCC within 45 months of transplantation. For those VHL ESRD patients after bilateral nephrectomy for RCC with higher tumor stage (pT_3 and above) or large tumor burdens with a symptomatic presentation, waiting 2 years after nephrectomy to confirm that no metastatic disease develops before proceeding with renal transplantation seems reasonable. However, in VHL ESRD patients after bilateral nephrectomy for RCC that is low stage and was incidentally discovered, no waiting period may be necessary before renal transplantation.

Evaluation of living-related renal donors for VHL patients can now be performed with direct mutation testing to evaluate presymptomatic carriers of the VHL gene. A thorough evaluation is essential for all prospective living-related donors to VHL recipients.

Pheochromocytoma in VHL patients can be managed by either partial adrenalectomy or adrenalectomy (396).

Epididymal cystadenomas were found in 54% of VHL male patients screened by scrotal US (70). Two-thirds were bilateral. Their clinical course is benign, and scrotal US is useful for diagnosis (133). Surgical excision is necessary only if the lesions become symptomatic.

The care of VHL patients requires a multidisciplinary team and urologists need to be familiar with the nonurologic manifestations of VHL.

Tuberous Sclerosis

TSC is an autosomal-dominant disorder caused by a genetic defect on either chromosome 16 or 9; it results in the presence of hamartomas, which are benign tumors composed of cellular elements normally present in tissue. The CNS lesions of TSC include tubers (cortical dysplasia) in the cerebral cortex that can cause mental retardation, epilepsy, and autism. In addition, patients may have facial angiofibromas, renal AMLs, renal cysts, retinal hamartomas, ungual fibromas, bone tubers, and cardiac rhabdomyosarcomas. In patients with TSC, renal causes of death are second only to CNS causes (352).

Genetics

Although TSC is inherited as an autosomal-dominant trait with high penetrance, two-thirds of TSC patients have no family history of TSC and probably represent new mutations (sporadic cases from new mutations). Mutations in two different genes can result in the TSC phenotype, meaning that TSC exhibits locus heterogeneity. The TSC_1 gene is located at 16p13.3 and was cloned in 1993 (108). The TSC_2 gene is located at 9q34 and was cloned in 1997 (389). About 50% of TSC families link to TSC_1 and about 50% to TSC_2 (282,316). However, TSC_2 mutations are much more common in sporadic cases than TSC_1 mutations (12,229), so TSC_2 mutations are the more common genotypes. Most studies found no observable differences between TSC_1 and TSC_2 patients (229,282), although other studies found a higher incidence of mental retardation in TSC_2 patients than in TSC_1 patients (207) and a higher incidence of intellectual disability in TSC_2 sporadic cases than in TSC_1 sporadic cases (208). Complete clinical screening of the parents of supposedly sporadic cases reveals one of the parents to be a mosaic mutation carrier 10% of the time (391).

The TSC_2 gene encodes the protein tuberin, and the TSC_1 gene encodes the protein hamartin. Hamartin and tuberin directly interact, suggesting that they are components of a singular cellular pathway, which explains why TSC_1 and TSC_2 mutations have such similar phenotypes (389). Both TSC_1 and TSC_2 seem to act as tumor-suppressor genes because both germline mutations are inactivating and loss of allelic heterozygosity at 16p13 or 9q34 occurs in AMLs and rhabdomyomas in TSC patients (148,350). Loss of heterozygosity suggests that a TSC patient inherits (or spontaneously acquires through mutation) a deletion in one copy of the gene but develops lesions such as renal AMLs only when there is a somatic mutation in the other copy.

TSC_2, the more common gene causing TSC, and PKD_1, the gene causing 85% of ADPKD, are located a few nucleotides apart on chromosome 16 in a tail-to-tail orientation. Deletions involving both TSC_2 and PKD have been identified in a small subset of TSC patients with early-onset, multiple renal cysts and/or early renal failure (50). Thus the loss of TSC_2 and PKD_1 together describes a contiguous gene syndrome with a more severe infantile form of cystic disease than that found in TSC patients without loss of PKD_1 and a much earlier age of onset than normally found in ADPKD. Perhaps mutations of TSC_2 and PKD_1 have an additive or synergistic effect. The age of onset of renal failure in the TSC_2–PKD_1 contiguous gene syndrome sometimes varies significantly within the same family because of genetic mosaicism (338) (Fig. 20.9).

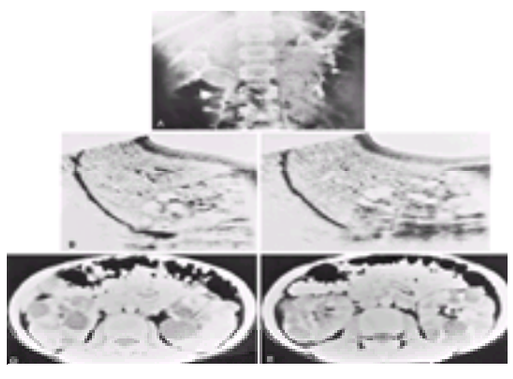

FIGURE 20.9. Tuberous sclerosis in a 10-year-old boy whose two brothers and mother were also affected. **A:** Intravenous pyelogram (IVP) reveals distortion of the collecting systems bilaterally. The splaying of the calyces could be secondary to either cysts or hamartomas. **B, C:** Renal ultrasonography reveals multiple cysts in both kidneys. **D, E:** Enhanced computed tomography reveals bilateral multiple renal cysts but no hamartomas. The presence of cysts can precede the presence of hamartomas. He had a seizure disorder, hypertension, and facial adenoma sebaceum. These radiologic findings in such a patient are typical for the TSC_2-PKD_1 contiguous gene syndrome.

Renal Manifestations of Tuberous Sclerosis

Renal disease is the second most common cause of death in TSC patients after CNS causes (352). Common renal lesions are AMLs and renal cysts. Less common renal lesions are RCC and malignant epithelial AMLs. ESRD has been reported in 1% to 15% of TSC patients (67,74,345).

Renal Angiomyolipomas. AMLs are benign tumors consisting of variable proportions of fat-containing cells, smooth muscle cells, and arterial vessels whose thickened walls lack normal elastic tissue. AMLs have been detected in 49% (78) to 47% (364) of TSC patients but are a rare finding in the general population. Of TSC patients with AMLs, 91% had multiple lesions and 84% had bilateral AMLs, unlike the solitary AMLs in the general population (78). The incidence of AMLs increases with age in TSC patients (78), which supports the "two-hit" genetic process because the chance of somatic mutation of the second allele increases with age. AMLs in both TSC_1 and TSC_2 phenotypes have been observed to demonstrate loss of heterozygosity, which supports the idea that TSC_1 and TSC_2 act like tumor-suppressor genes (148,350). Other factors such as hormones modify the development of AMLs because pregnancy can accelerate AML growth and has been associated with rupture and hemorrhage of renal AML (96). In addition, AMLs in the general population are more common in women, AMLs in girls have a greater propensity for growth than in boys, and the larger renal AMLs occur after puberty (110). Henski and associates (171) found that 48% of renal AMLs in TSC patients (3 men and 18 women) had progesterone receptor immunoreactive smooth muscle cells but none contained estrogen receptor immunoreactive cells. Pulmonary lymphangiomyomatosis (LAM) is rare and is associated with TSC. It can have estrogen receptor and progesterone receptor immunoreactive smooth muscle cells (27). Female TSC patients with LAM can present with pneumothorax and hemothorax. The activity of the pulmonary lesions of LAM patients varies with physiologic hormonal changes and hormonal manipulation, so hormonal treatment can prolong survival and pulmonary disease (42).

The elastin-poor vascularity of AMLs makes them prone to hemorrhage into the retroperitoneum. Increasing AML size correlates with higher risk of retroperitoneal hemorrhage (91,385). AMLs are usually symptomatic if larger than 8 cm, but they tend to be asymptomatic if smaller than 4 cm (91). Rare instances of spread of AMLs to regional lymph nodes or into the inferior vena cava have been described, but no patient has had progression to widely disseminated disease (96). With regular screening of TSC patients, the incidence of AMLs may increase because routine US surveillance of affected children revealed 57% (mean age of 6.9 years) to have AMLs (110).

Renal Cysts. Renal cysts have been found in 32% (78) to 43% (278) of TSC patients. When children with TSC were routinely screened with renal US, 10% were found to have renal cysts at initial screening (mean age of 6.9 years), but 17% were found to at follow-up (mean age of 10.5 years) (110). Simple cysts may appear or disappear in children with TSC (110). Renal cysts and AMLs tend to occur in the same patients with cysts antedating the AMLs (278). Renal cysts are usually asymptomatic. Features of TSC may present after or before the renal cysts. Although rare, renal failure in TSC is more likely to occur in patients with renal cysts (287). Children presenting with early-onset multiple renal cysts and/or early-onset renal failure may have the TSC_2–PKD_1 contiguous gene syndrome (50). When 60 children with TSC were screened with renal US, polycystic kidneys as in ADPKD patients were seen in only 1 patient. The histopathologic studies of renal cysts distinguish between TSC and ADPKD because the renal cysts of TSC have eosinophilic cells in their hyperplastic epithelium (361).

Renal Malignancies. RCC has been described at a higher incidence in TSC patients than in the general population. TSC-associated RCC occurs at a younger age, is more likely to be bilateral, and is more likely to occur in women as opposed to sporadic RCC in the general population (31,399). Bjornsson and colleagues (36) described loss of heterozygosity in both TSC_1 and TSC_2 RCCs, indicating that increased risk is associated with both genotypes. Pea and associates (303) found alleged cases of TSC-associated RCC that were incorrectly diagnosed and concluded that RCC is less common in TSC than previously thought. Some cases called *TSC-associated RCC* were probably malignant epithelioid AMLs, and they suggested that all reported TSC-associated RCCs be reevaluated.

Renal Failure. ESRD has been reported in 1% to 15% of TSC patients (67,74,345). ESRD in TSC is more common in females than in males (80% versus 63.1%) (74,345). Reduction in the amount of functioning renal parenchyma secondary to nephrectomy, partial nephrectomy, and/or arterial embolization to remove malignancies or control hemorrhage, as well as replacement of renal parenchyma by AMLs and RCCs, was thought to be contributory in 32% to 40% of patients (74,345). Renal failure more commonly occurs in TSC patients with renal cysts (287). Although renal failure occurs earlier in TSC_2–PKD_1 contiguous gene syndrome, age of onset of ESRD is variable, even within the same family, and may not occur before the third decade because of genetic mosaicism (338). Clarke and associates (74) noted that on imaging, 4 of 10 TSC patients with ESRD had polycystic kidney disease.

Pathology

The pathologic findings vary with the degree of cystic involvement in TSC. Grossly, the kidneys can be enlarged, with cysts projecting throughout the renal cortex bilaterally. On cut section, multiple cysts (microscopic to 5 cm) are found throughout the cortex and medulla. Microscopically, renal cysts of TSC are easily differentiated from other renal cysts because of their hyperplastic epithelium of eosinophilic cells (361). Microdissection shows that cysts develop from all parts of the nephron.

Radiologic Findings

An IVP can reveal calyceal distortion and renal enlargement resulting from either the renal cysts of TSC or from the renal AMLs (76). US can differentiate the cysts from the hamartomas (Fig. 20.9). The AMLs appear sonographically as regions of increased echogenicity because of the presence of fat. In contrast, the cysts appear as anechoic lesions varying in size from 2 mm to 2 cm with thin uniform posterior walls and posterior enhancement (278). However, US cannot differentiate the renal cysts of TSC from those of ADPKD (unless multiple hepatic cysts are demonstrated, which would confirm the diagnosis of ADPKD). CT scanning can also demonstrate both the AMLs and the cysts of TSC. Demonstration of fat within the AML on CT makes the diagnosis of AML possible. In small AMLs (4 mm), detection of fat is difficult to achieve because of volume averaging, which makes CT confirmation of AMLs difficult. The detection of fat on US is far easier. Because all lesions seen on CT are detected by US, US is the preferred screening procedure for renal lesions of TSC (278). The renal angiographic manifestations of TSC consist of multiple AMLs, multiple renal artery aneurysms, renal cortical cysts, or some combination of these.

Management

A majority of TSC patients develop renal involvement, and a minority have significant morbidity. A baseline renal US in all TSC patients should be routine. Cooke and others (78) suggest serial renal US in TSC patients with no renal lesions and every 1 to 2 years in TSC patients with renal lesions. If there is any concern about a lesion, CT or MRI scan is appropriate. If extensive renal involvement is noted, renal function should be evaluated.

Any female TSC patient with AMLs should be monitored closely during pregnancy with renal US evaluations to allow for early diagnosis and intervention in renal hemorrhage. Female TSC patients should be cautioned about pregnancy and hormone replacement therapies. AMLs larger than 8 cm should be treated electively with arterial embolization or partial nephrectomy because most will cause complications if left untreated (91). AMLs smaller than 4 cm can be serially imaged because they are usually asymptomatic (91). AMLs between 4 and 8 cm have an unpredictable natural history because they are symptomatic 54% of the time (91). Modifying factors such as pregnancy potential should be taken into account, and patient counseling to recommend serial imaging versus elective renal sparing therapy is needed. TSC patients presenting with acute retroperitoneal hemorrhage from AML should be offered immediate arterial embolization to spare renal parenchyma (161).

MULTICYSTIC KIDNEY (MULTICYSTIC DYSPLASIA)

Multicystic kidney disease (MCDK) is the most common cause of an abdominal mass in the newborn. Although present at birth, a unilateral multicystic kidney can be clinically silent throughout adulthood. However, bilateral MCDK is fatal at birth because of insufficient renal function. The involved kidneys do not maintain a reniform shape but are replaced by clusters of cysts with fibrotic tissue. MCDK is a form of renal dysplasia and is rarely a genetically transmitted disorder (360).

Clinical Features

A multicystic kidney is present from birth but may be detected as early as 15 weeks *in utero* by prenatal US (365). Prenatal US has made *in utero* diagnosis the most common presentation of a multicystic kidney. The second most common presentation is in newborns as an asymptomatic abdominal mass that is mobile, irregular,

and located in the flank and that may be transilluminated (394). Of those children diagnosed as having a MCDK, 90% were diagnosed before 1 year of age (365). A multicystic kidney is considered the most common or the second most common abdominal mass in the newborn, with congenital hydronephrosis as the alternative diagnosis (150). The widespread use of routine prenatal US has led to the observations that *in utero,* a multicystic kidney can involute and disappear. When the multicystic kidney disappears prenatally, the newborn is diagnosed as having unilateral renal agenesis, which may explain the cases of unilateral renal agenesis with an ipsilateral blind ending ureter (187). Postnatal follow-up US examinations in children with a unilateral multicystic kidney reveal that in the children followed 1 to 3 years, 47% of the kidneys decreased in size but were still detectable and 13% disappeared. In those children followed 3 to 5 years, 23% became undetectable on follow-up US (392). Over 4.5 years, White and associates (405) noted that 17% of MCDK kidneys involuted at a mean rate of 1.02 cm per year and 30% decreased in size at a mean rate of 0.38 cm per year, although they were still detectable. Twenty-six percent of MCDK kidneys grew at a rate of 1.16 cm per year over the 4.5 years. John and colleagues (205) noted that 48% of their MCDK patients had complete involution over 2.6 years, 32% had partial involution, and 4% (one child) had increase in size. Occasionally, a transient increase in size of a multicystic kidney would be followed by involution.

Contralateral compensatory hypertrophy has been noted in older MCDK patients regardless of whether or not the patient had a nephrectomy (151). When the length of the contralateral kidney is measured at birth in MCDK neonates, hypertrophy [defined as kidney length above 2 standard deviation scores (SDS)] was found in 24%, showing that hypertrophy starts *in utero* and continues throughout childhood (205). The other 76% of the MCDK neonates had renal lengths between mean and +2 SDS. All of the contralateral kidneys in MCDK children grew at a rate greater than normal (405). Length and volume of the contralateral kidney had the most remarkable increase during the first 6 months of life (205). The presence of abnormalities of the contralateral kidney did not affect the increased renal volume (205). Size increase, size decrease, or removal of the multicystic kidney did not alter the increased growth rate of the contralateral hypertrophy (405).

In older children and adults, a unilateral multicystic kidney can be found incidentally during radiographic study being done for unrelated reasons (230). A unilateral multicystic kidney can be entirely asymptomatic in these older patients or cause abdominal pain. Resultant imaging studies to evaluate the abdominal pain result in the diagnosis of MCDK (4,359).

Indications for Nephrectomy

Surgical exploration to confirm the diagnosis of a multicystic kidney is not necessary with the current use of renal US and radionuclide renal scans. Therefore indications for nephrectomy are controversial but include hypertension, infection, pain, increasing size, and malignancy. Renin-mediated hypertension in MCDK has been established. Of 441 cases reported to the multicystic kidney registry, no case has been documented with hypertension as a causative factor (392). Serial blood pressure measurements in MCDK patients followed for approximately 4 years revealed no cases of hypertension (205,405). Although hypertension is rare in MCDK, reported cases of hypertension in patients with MCDK who were treated by nephrectomy resulted in resolution of the hypertension in pediatric patients (7,107,202) and not in adult patients (4).

Rudnik-Schöneborn and colleagues (336) found that 6 of their 204 MCDK pediatric patients required treatment with antihypertensive drugs for their hypertension. Two of the children had hypertension secondary to concomitant cardiovascular diseases, two children had spontaneous resolution of their hypertension after 6 months, one developed hypertension after nephrectomy, and one had no resolution of hypertension after nephrectomy.

Nephrectomy has rarely cured hypertension of long or unknown duration. Therefore, if patients with a MCKD are to be managed by surveillance, evaluation for hypertension must be rigorous (107) so that patients with hypertension and a multicystic kidney may benefit from a nephrectomy.

Infection involving a multicystic kidney is very rare (392) and is therefore not an indication for a prophylactic nephrectomy. UTIs may occur in patients with a multicystic kidney because of associated vesicoureteral reflux, which is more often contralateral than unilateral (114). Neither nephrectomy nor conservative management prevented the predisposition to UTI as a complication of MCDK (336). Although exceedingly rare, nephrectomy is appropriate therapy for an infected multicystic kidney (324). Pain is an indication for nephrectomy in a symptomatic patient, but this is uncommon. If the unusual circumstance of extraordinary growth of the multicystic kidney is noted over significant time or if the enlarging kidney is causing discomfort or feeding difficulty, nephrectomy is recommended (405).

Although nodular renal blastoma has been reported in multicystic kidneys (283), the development of malignancy in multicystic kidneys is so rare that prophylactic nephrectomy is unwarranted (21,392). There is a threefold to tenfold risk of Wilms' tumor compared with that in the general pediatric population (309). The mean age of presentation of MCDK children with Wilms' tumor is younger than the typical 3 to 4 years in the general pediatric population, with a mean age of 25 months (309). Screening renal US studies every 3 months up to 8 years of age is recommended to adequately screen MCDK patients for Wilms' tumor.

The Contralateral Kidney

Bilateral multicystic kidneys are less common than a unilateral multicystic kidney and are incompatible with life. Approximately 23% of fetuses with a multicystic kidney diagnosed by routine prenatal US screening were found to have bilateral disease, which is a higher incidence than that reported of births with a multicystic kidney (3,235). Bilateral disease can be associated with Potter's syndrome in which facial dysmorphia, pulmonary hypoplasia, and amnion nodosa all result from prolonged hydramnios, which results from low urinary output (47).

Males are more likely to be affected in unilateral MCDK than females at a ratio of 2.4:1, but females are twice as likely to have bilateral MCDK (235). Rarely, MCDK can involve only a portion of a kidney, such as in a kidney with a duplicated collecting system, when the segmental MCDK typically occurs in the upper pole with atresia of the upper moiety of proximal ureter and reflux into the ipsilateral functioning lower moiety (203). Although rarely reported, ipsilateral cystic dysplasia of the testis has been associated with MCDK (329). However, because cystic dysplasia of the testis is asymptomatic and boys with MCDK do not undergo routine scrotal US screening, this lesion may be more common than is currently believed.

The prognosis of patients with a unilateral multicystic kidney depends on the status of the contralateral urinary tract, irrespective of the removal of the multicystic kidney (88). Current imaging of patients with a multicystic kidney reveal that 39% have contralateral abnormalities (vesicoureteral reflux, 18%; ureteropelvic junction obstruction, 12%), 6% have bladder wall abnormalities, and 6% have ipsilateral reflux (11). If voiding cystourethrography is routinely performed as part of the initial evaluation on all infants with a multicystic kidney, 18% to 28% are found to have contralateral vesicoureteral reflux despite a normal renal US of the contralateral kidney in most cases (114,405). Vesicoureteral reflux grades I through IV were present, with 50% spontaneous resolution or downgrading to reflux grade I in 50% of patients over 2 to 4.5 years (336). Therefore careful study of the contralateral kidney is most important in evaluating a patient with a unilateral multicystic kidney and should include voiding cystourethrography because the prognosis is otherwise excellent.

Morphology

A multicystic kidney can appear grossly as a disorganized patternless mass of variably sized cysts. The calyces and pelvis are not recognizably present grossly, and the reniform shape may not be evident. Usually, part or all of the ureter is atretic. The vascular pedicle may be atretic (93). Microscopically, immature ducts, ductules, and glomeruli, along with cysts and islands of cartilage, reside within fibrous stroma or cellular mesenchyme. Mature glomeruli may be present, although rare. The cysts are lined by low cuboidal epithelium. Contrast injection into the cysts reveals communication between the cystic spaces via tubular structures (138,344).

Pathogenesis and Renal Dysplasia

A multicystic kidney is a category of renal dysplasia in which the kidney is totally affected and cystic. Serial US examinations have revealed a multicystic kidney to decrease to a small noncystic mass (dysplastic kidney) or even to complete disappearance (aplasia) (365). The appearance by US changes from a predominant cystic dysplasia to predominant dysplasia as first the cysts involute and then the kidney decreases in size. Hence, these forms of renal dysplasia can be considered as a heterogeneous continuum of totally or segmentally involved kidneys, which may be cystic, solid, or both.

The diagnosis of renal dysplasia is made from recognizing histologic criteria thought to represent the aborted remnants of the ureteral bud or its poorly induced progeny (371). Such histologic findings include primitive glomeruli, ductules, tubules, cartilage, and primitive ducts. However, all of these features except for the primitive ducts can also be found near renal scars or in renal inflammation. Hence, primitive ducts are the only noncontroversial histologic evidence of embryonic renal maldevelopment (112).

An association exists between renal dysplasia and urinary tract obstruction. Is the cause of the obstruction (e.g., a malfunctioning ureteral bud or its branch) also the cause of dysplasia in the associated kidney or segment (371)? Support is found in the association of unilateral renal dysplasia with unilateral ureteral obstruction,

bilateral renal dysplasia with posterior urethral valves, and segmental renal dysplasia with segmental obstruction. Furthermore, although the severity of the renal dysplasia relates to the severity of obstruction, the severity of both could relate to the degree of malfunction of the ureteral bud.

A defect in the ability of the branching ureteric duct and the undifferentiated metanephric blastema to communicate appears to be the basic underlying principle for the formation of dysplasia (263). Cellular communication between the ureteric duct epithelium and the metanephric blastema cells involves cellular “cross-talk” using a network of ligands and receptors on both cell types. For example, hepatocyte growth factor is expressed predominantly in the metanephric blastema, while its receptor is localized in the ureteric bud epithelium, supporting the role of the ureteric duct as inducer of the metanephric mesenchyme (263). The multicystic dysplastic kidney likely begins with a normally determined stem cell population. Aberrant expression of genes involved in the cascade of renal differentiation could result in a renal malformation. A single gene mutation may alter the ability of the ureteric bud and metanephric blastema to communicate or to respond appropriately to their reciprocal signals (263). The final phenotypic expression of MCDK may be dependent on the dysregulation or altered expression of genes that have been affected by the primary gene defect.

The high incidence of contralateral renal defects associated with the isolated multicystic dysplastic kidney is more suggestive of a generalized defect in normal induction of kidney development than of an acquired unilateral insult (263). About 24% of MCDK fetuses diagnosed by prenatal US screening have bilateral disease (3,235), suggesting a common pathophysiologic mechanism. Numerous inherited syndromes with renal malformations, such as cystic dysplasia, have been described with known specific gene and protein defects. However, the variable penetrance of renal cystic dysplasia suggests that other genes may modify normal organogenesis (263). Associated nonrenal anomalies occur in up to 26% of unilateral MCDK patients and in 67% of instances of bilateral MCDK, suggesting an embryonic developmental field defect (235). Recent molecular techniques are expanding the understanding of the pathogenesis of MCDK.

Radiologic Findings

The frequency of the diagnosis of a multicystic kidney has increased because of the use of fetal US. A second-trimester US study is more likely to diagnose MCDK than late-trimester studies because the late-trimester studies may not identify the affected involuted kidney, thus altering the diagnosis to unilateral agenesis of unknown etiology (235). The accuracy of diagnosis in children has improved with the addition of radionuclide scanning to the point that the combination of US and renal scanning is so accurate that additional radiologic imaging is unnecessary. However, older patients may be diagnosed by other studies. A multicystic kidney appears as a nonfunctional mass on IVP. Contralateral compensatory hypertrophy occurs in 72% of children older than 2 years by US criteria (365). Because differentiation between a multicystic kidney and congenital hydronephrosis is necessary in evaluating an infant with a palpable abdominal mass, US features unique to a multicystic kidney have been described (366). The most useful criteria are (a) the presence of interfaces between cysts, (b) nonmedial location of the largest cyst, and (c) absence of an identifiable renal sinus (Fig. 20.10). Other confirmatory but not necessarily unique features on US are multiplicity of cysts that do not communicate and an absence of parenchymal tissue. Radionuclide scanning with Tc-99m DPTA reveals that 96% of multicystic kidneys demonstrate no uptake and that 4% have faint crescents of activity on delayed images (365). However, if Tc-99m DMSA is used as the tracer, 15% of MCDK kidneys show low-grade uptake, which correlates with the presence of mature cortical tissue found at nephrectomy (328). Renal angiography may show an absent or hypoplastic renal artery with no nephrogram (Fig. 20.11). Doppler US of the ipsilateral renal artery reveals marked abnormality of the waveform in a multicystic kidney (169). A retrograde urogram might reveal an atretic or absent ureter. CT is not commonly done on infants because of the requirement of prolonged periods of time without movement. However, when CT of a multicystic kidney in adults is performed, a small cystic kidney with or without calcifications can be revealed because the multicystic kidneys identified in adults tend to be smaller. Percutaneous injection of contrast material into cysts of multicystic kidneys in children has revealed communication between cysts (138,344).

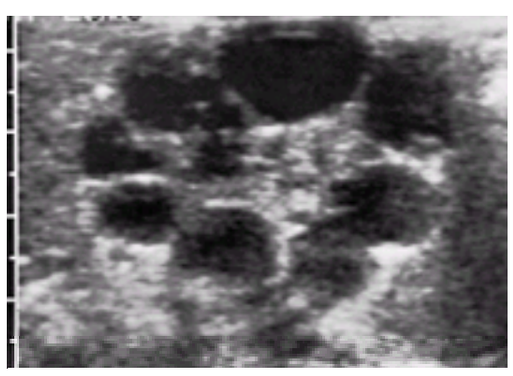

FIGURE 20.10. Multicystic kidney disease in female newborn. Renal ultrasonography at 1 week of age reveals multiple cysts in the right flank with septation between the cysts but no normal renal parenchyma. No communication was identified between the cysts, as would be present with hydronephrosis. The left kidney (not shown) was found to have ureteropelvic junction obstruction.

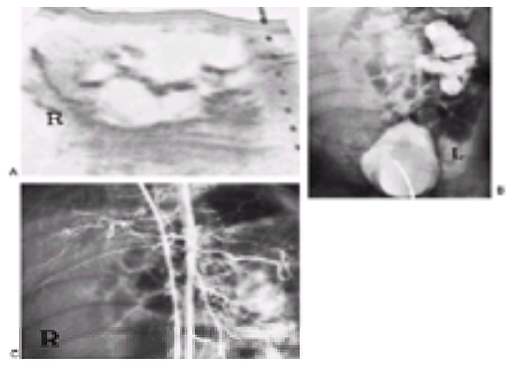

FIGURE 20.11. Multicystic kidney disease in female infant with ventriculoseptal defect and patent ductus. Although this 2-month-old had a right multicystic kidney and a left congenital ureteropelvic junction obstruction, only a right abdominal mass was palpated. **A:** Intravenous pyelogram reveals a hydronephrotic left kidney and nonfunction on the right. **B:** Midstream aortogram reveals no right renal artery. **C:** Midstream aortogram reveals no right renal artery.

Management

In the past, multicystic kidneys were routinely removed for pathologic diagnosis. However, the characteristic appearance on US plus nonfunction on radionuclide scanning allow for an accurate diagnosis without nephrectomy. Prophylactic nephrectomy is probably not indicated for pain, infection, hypertension, or malignancy because of the rarity of these disorders. However, surveillance by US and blood pressure measurements of these patients must be maintained to discover the rare cases of hypertension and malignancy.

Serial renal US studies every 3 months until age 8 have been recommended to make a diagnosis of Wilms' tumor at an early stage because of its fast growth rate (309). Monthly abdominal examinations by the parents may be as effective at diagnosing Wilms' tumor, with renal US examinations at 6 months and every 1 to 2 years thereafter until the multicystic kidney has involuted and the contralateral kidney is deemed normal.

Voiding cystourethrography should be performed as part of the initial evaluation in infants with multicystic kidneys to diagnose vesicoureteral reflux because of the risk of scarring in a solitary functioning kidney. Prophylactic antibacterial therapy is necessary until the reflux resolves spontaneously (at about 20 months of age in most of these patients) (114). Evaluation of the contralateral kidney is essential. Nephrectomy for the rare patient with pain, hypertension, malignancy, infection, or respiratory embarrassment is appropriate although US-guided percutaneous cyst decompression has been reported to definitively treat respiratory embarrassment

secondary to a multicystic kidney (181). Nephrectomy for the rare young patient with extraordinary growth of a multicystic kidney may be appropriate (405).

CYSTIC NEPHROMA (MULTILOCULAR CYSTIC KIDNEY)

Cystic nephroma (CN) is a very rare benign cystic tumor of the kidney that is usually unilateral and compresses the adjacent normal renal tissue. Hence, although CN is listed as a cystic disease of the kidney, CN does not diffusely replace normal renal parenchyma bilaterally; instead, it compresses normal renal tissue unilaterally. CN is rare, with fewer than 200 cases reported (2). Children and adults are affected with equal frequency. The cysts are limited to the area of the kidney involved with the mass and vary in size from a few millimeters to 5 cm. The tumor is completely cystic, with no solid nodules.

Clinical Features

Although children and adults are affected equally with CN, 73% of cases occurring in children younger than 4 years of age are in boys; in contrast, 89% of cases in patients older than age 4 are in females (251). Children present with a nonpainful abdominal mass, whereas adults present with a symptom such as abdominal pain or hematuria. When hematuria does occur, it is usually associated with herniation of CN into the renal pelvis. CNs often replace substantial portions of the kidney and commonly herniate into the renal pelvis (251) or renal sinus (220). The cystic mass has been observed to grow slowly in some patients (3 years) and rapidly in others (2 months) according to sequential physical examination (251). These lesions primarily occur in whites, males before age 24 months, and females between 40 and 70 years of age (59).

Eble and Bonsib (96) consider CNs in children as a different entity than CNs in adults, despite similar radiographic features. Their review concludes that tumors in young children that have been classified as CN as well as those classified as cystic partially differentiated nephroblastoma (a rare cystic benign-behaving type of Wilms' tumor) represent a single entity. Both should be considered highly cystic Wilms' tumors with little or no capacity for invasion or metastasis, and both should be classified as cystic partially differentiated nephroblastoma. Both are currently treated the same regardless of whether elements of Wilms' tumor are found, so there is no need to distinguish between the two entities. Hence, Eble and Bonsib (96) conclude that the diagnosis of CN should no longer be applied to young children.

However, CN in adults has no connection to Wilms' tumor but is a benign cystic tumor that may rarely become malignant with secondary development of a sarcoma (96). Distinguishing CN from other extensively cystic renal neoplasms is not possible from preoperative imaging studies or fine-needle aspirates of these neoplasms (34,96). Intraoperative frozen-section analysis cannot always reliably distinguish CN from cystic RCC (34). Multilocular cystic lesions of the kidney are classified as Bosniak class 3 complicated cysts (17) in which imaging cannot distinguish malignancy from benign cystic lesions. Only 12% of RCCs are predominantly cystic, but these cystic RCCs have a slower growth rate, are identified at earlier stages and lower grades, are associated with a better prognosis and longer survival, and are even more likely to occur in males (96%) than conventional RCC (34). Fortunately, partial nephrectomy and radical nephrectomy are both effective treatments for both CN and cystic RCC because preoperative imaging and fine-needle aspirates cannot distinguish between the two entities and intraoperative frozen-section analysis could not identify malignancy in 3 of 8 cystic RCCs (although permanent sections could) (34).

Morphology and Pathogenesis

The pathologic criteria for establishing a diagnosis of CN were reformulated in 1956 by Boggs and Kimmelstiel (41). The criteria include (a) a multilocular mass, (b) no communication between cysts, (c) cysts lined by epithelium, (d) no communication between the cyst and pelvis, (e) remaining kidney essentially normal, and (f) no normal nephrons in the septa of the cysts. Joshi and Beckwith (209) further reformulated the criteria by specifying that the (a) tumor is composed entirely of cysts and their septa; (b) CN is a discrete well-demarcated mass; (c) septa are the sole solid component and conform to the outlines of the cyst without expansive nodules; (d) cysts are lined by flattened, cuboidal, or hobnail epithelium; and (e) septa contain fibrous tissue in which well-differentiated tubules may be present.

Grossly, the multilocular cystic mass is well circumscribed by a thick capsule and compresses normal adjacent renal tissue. Bilateral lesions are rare. Cut surface reveals multiple noncommunicating cysts, varying from a few millimeters to 5 cm in diameter. Microscopically, the cysts are lined by flattened or cuboidal epithelium. All cases of multilocular cystic kidneys have shown uniformly benign behavior. In adults, stromal septa have pronounced cellularity with a spindle cell pattern sometimes seen. Sarcoma was found in the septal stroma in 4 of 21 adults, with 3 of them developing metastasis containing the stromal element (251). These patients might have had multilocular sarcomas of the kidneys (59). The chemical content of the cyst fluid is similar to that of serum (1). The pathogenesis of CN is not known except that there is no familial tendency and that it behaves like a tumor in its growth and local recurrence. CN is not of developmental origin but is a cystic neoplastic lesion. The lack of normal renal tissue in its septa distinguishes CN from contiguous simple cysts and from congenital renal cystic disease with multiple cysts.

Radiologic Findings and Management

IVP of CN usually demonstrates an intrarenal mass in a normally functioning kidney. US can well visualize the multicystic nature of the tumor when the septa are seen to divide the mass into multiple loculi of regular distribution and similar size (129). CT reveals a cluster of cysts with thick walls and calcifications. However, when the cysts are small, it is more difficult for CT to confirm the cystic component of the mass (298). The septa on CT enhance with intravenous contrast medium (Fig. 20.12). MRI with gadolinium enhancement reveals enhancement of internal septa in all CN patients studied (220). Renal angiography usually reveals a hypovascular mass, sometimes with a tumor blush and neovascularity (2,251). Cytologic evaluation of cyst fluid is of limited value (2). In general, thickening of the septum to more than 1 mm, the presence of a solid component, calcification in the lesion, and neovascularity are potent signs of malignancy when imaging cystic renal tumors (82). However, US, dynamic CT, and dynamic MRI could not reliably distinguish between malignant and benign cystic tumors (178). Renal angiography was the most reliable imaging modality in distinguishing cystic RCC from benign cystic lesions by the presence or absence of tumor vessels (178), but neovascularization has been found in 20% of CNs (251).

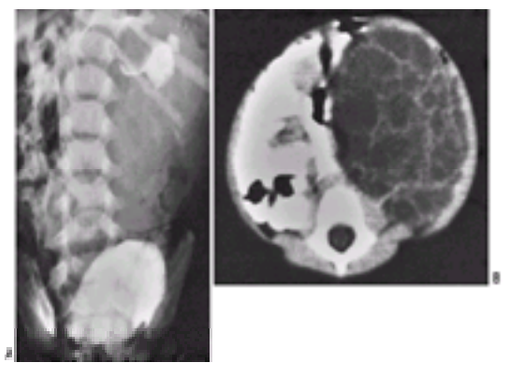

FIGURE 20.12. Cystic nephroma in a 4-year-old boy. **A:** KUB shows mass effect. **B:** Computed tomography scan with contrast reveals enhancing septa.

Therefore surgical intervention is the only effective method to differentiate CN from a malignant lesion of the kidney. A preoperative diagnosis of CN versus cystic partially differentiated nephroblastoma is of little importance because chemotherapy and radiotherapy are not used to treat either, renal-sparing surgery can be appropriate for both if technically feasible, and the two can be considered the same entity in young children (96). Nephron-sparing surgery did not result in local recurrence with 3-year follow-up (59). Complete excision of childhood CN or cystic partially differentiated nephroblastoma is possible as conservative surgery, but special care must be taken to excise the cystic lesion that penetrates the renal pelvis (66). Because radiographic methods cannot rule out malignancy, a partial nephrectomy is adequate only after the surgeon has confirmed there is no malignancy in the surgical specimen pathologically, although histopathologic confirmation by frozen section can be wrong (34,337). Cystic RCC has such a favorable prognosis that conservative surgery is appropriate, as it is for CN if technically feasible (34). Treatment by nephrectomy is appropriate after assessment of the status of the contralateral kidney although bilateral cases are rare (66).

SIMPLE RENAL CYSTS AND COMPLEX RENAL CYSTS

Although simple cysts are an entity in their own right, concern regarding simple renal cysts is usually directed toward their differentiation from neoplastic renal masses because they are so frequently discovered as an incidental finding on radiographic studies. Indeed, 24% of routine abdominal CT scans in one study (234) and 20%

in another (369) revealed unexpected simple renal cysts. Analyzing the data separately in both CT studies, 0% to 6% of patients younger than 40 years were found to have simple renal cysts, as opposed to 18% to 19% of patients 40 to 60 years of age and about 31% of patients older than 60. However, at autopsy, at least 50% of patients older than 50 years of age have grossly recognizable cysts of the renal parenchyma (223). Another autopsy study revealed a 39% overall incidence of renal cysts but a greater than 50% incidence in patients older than 50 (323). Forty-eight percent of patients had cysts less than 1 cm in diameter. These smaller cysts could have been missed by CT or US, which probably explains the discrepancy in frequency. By CT and US, the number of cysts per patient and the cyst diameter increased with the age of the patient (234,321). Such data suggest that simple renal cysts are acquired abnormalities, perhaps related to the aging process; however, the pathogenesis is unknown. They are not familial.

Renal Cysts in Children

Simple renal cysts are rare in children but may be detected at any age (373). A fetal simple renal cyst can rarely be identified by US in early pregnancy, but in the absence of associated anatomic or chromosome abnormalities, most fetal renal simple cysts will resolve during pregnancy without any sequelae (37). Before the routine use of IVP, US, and CT in children, the most common presentation of renal cysts in a child was that of an asymptomatic abdominal mass. However, in more recent series of pediatric patients, simple renal cysts were incidental findings on radiographic studies (19,141) with a reported frequency of 1 simple cyst for every 430 abdominal US studies performed (267).

Cyst Growth

Simple renal cysts are by definition unilocular, do not communicate with the collecting system, occur in a kidney that is otherwise normal, and have an epithelial lining that contains no renal elements. Grossly, cysts are tense and thin walled and vary in diameter from millimeters to 7 cm (Fig. 20.13 and Fig. 20.14). Microscopically, the cysts are lined with low cuboidal to attenuated flattened epithelium. Fluid of simple cysts has chemical features of an ultrafiltrate of plasma (223). A dynamic equilibrium exists between production and absorption of fluid in simple renal cysts such that the cyst fluid has levels of tritiated water that reach 73% of the serum level within 2 to 5 hours after an intravenous injection of tritiated water (199). Perhaps cyst growth is dependent on the ratio of fluid production to absorption. Serial US measurements of renal cysts reveal only 28% of cysts increased in size in a 2- to 3-year period. The size change was 1 to 2 cm, and 14% of the cysts decreased in size by 1 to 2 cm over 2 to 3 years (83). However, many US and CT studies reveal increasing prevalence of simple renal cysts with age (32,56,83,234,305) and increasing diameter of cysts with age (56,234,321).

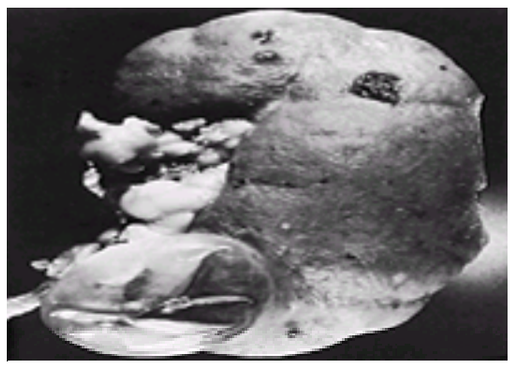

FIGURE 20.14. Simple cyst. A simple cyst is seen in the lower pole of this left kidney. Cyst was collapsed inadvertently at surgery. (Courtesy of Dr. S.E. Mills, Department of Pathology, University of Virginia Medical School, Charlottesville, VA.)

Radiology and Classification

Radiographic methods to diagnose a simple renal cyst have improved tremendously over the last decade. Because IVP cannot differentiate between a solid renal mass and a cystic renal mass, both of which distort the pyelocaliceal system (Fig. 20.15), renal US should be the next study. If the US requirements for a simple renal cyst are completely met on a study, investigation of a simple cyst is complete (19). The US appearance of a simple renal cyst is an anechoic mass with sharply marginated smooth walls and posterior wall enhancement (Fig. 20.16). However, if sonographic criteria for a simple cyst are not met or if lesions contain calcium, septations, or irregular margins, a CT examination is necessary (44). US is preferable as an initial study because it costs less, is less invasive, delivers no radiation, and does not require the pediatric patient to remain motionless for an extended time. The CT criteria for diagnosis of a cyst are (a) sharp margination and demarcation from surrounding renal parenchyma, (b) smooth thin wall, (c) water density content that is homogeneous throughout, and (d) no enhancement after intravenous administration of contrast material (44).

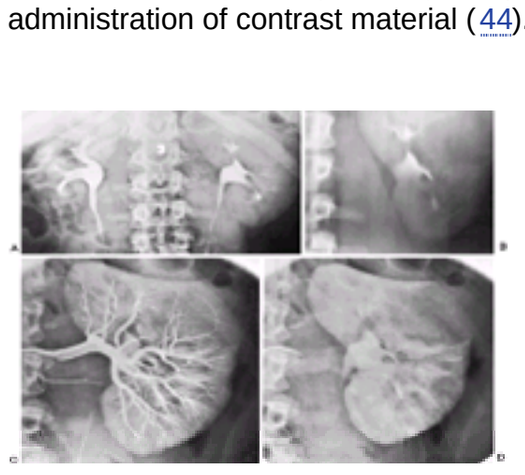

FIGURE 20.15. Simple cyst in a 36-year-old man. **A:** Intravenous pyelogram reveals bilaterally normal kidneys except for a spherical mass arising from the superolateral margin of the left kidney. **B:** Nephrotomography reveals the mass to be relatively lucent and to have smooth margins. **C, D:** Renal arteriography confirms the presence of a simple cyst by the draping of vessels around the mass, the lack of neovascularity, and its thin rim and “beaks” at its margin with the renal cortex.

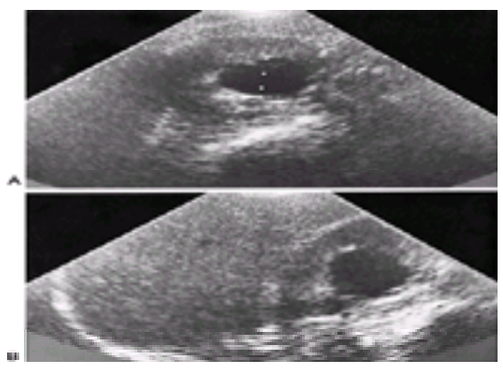

FIGURE 20.16. A, B: Simple cyst in 53-year-old woman. Renal ultrasonography reveals an anechoic renal mass with a smooth posterior wall and posterior wall enhancement.

CT scanning to evaluate a renal cyst or mass found on another imaging modality should include non–contrast-enhanced scans through the lesion as well as contrast-enhanced scans and should include 5-mm-thick sections of the lesion while there is a high level of contrast media in the blood, unless the lesion is large enough that 10-mm-thick sections are adequate. Bosniak (44) has classified cystic lesions of the kidney into four categories based on a combination of CT and US imaging to help make clinical management decisions and to approximate the risk of malignancy. *Category I* lesions are benign simple cysts diagnosed definitively by CT or US. *Category II* lesions are benign but are minimally complicated because of worrisome radiologic findings in septated cysts, minimally calcified cysts, infected cysts, and high-density cysts. Such lesions do not require surgical exploration but may need to be followed. *Category III* lesions may be malignant and are more complicated cystic lesions because of thick or irregular calcifications or irregular thick septa with solid elements at the cyst wall attachments. Such lesions require confirmation by surgery in patients without poor operative risks. *Category IV* lesions are malignant cystic lesions and have irregular margins or solid vascular elements. They require surgical excision. Hyperdense renal cysts are in category II because they are assumed to be benign, usually contain old blood, are isodense or hypodense with surrounding renal parenchyma after intravenous contrast administration, and can be followed by serial CT (44) because cystic RCC can simulate a benign hyperdense cyst (162).

Sixteen pathologically proven cystic renal masses were retrospectively reviewed using the Bosniak classification by Aronson and colleagues (10). All category II lesions were benign, all category IV lesions were malignant, and of the seven category III lesions, three were benign and four were malignant. Similarly, 70 pathologically proven cystic renal masses were reviewed by Siegel and associates (354), with 0% Bosniak I malignant, 13% of Bosniak II malignant, 45% of Bosniak III malignant, and 90% of Bosniak IV malignant. However, Wilson and co-workers (409), in a similar retrospective review of pathologically proven cystic renal masses, found a high rate of malignancy in Bosniak categories II (80%), III (100%), and IV (100%). In addition, Cloix and associated (75), in a similar retrospective review of pathologically proven cystic renal masses, found a RCC that had been classified as a Bosniak I. However, the Bosniak classification requires devoted renal CT studies with 5-mm cuts. Cloix and colleagues (75) used 10-mm slices in their study, and not all patients had devoted renal CT scans. Only 9 of the 20 patients in Wilson and colleagues' study (409) had undergone dedicated thin-section renal CT examinations both before and after intravenous contrast administration. Siegel and associates (354) suggest that intraobserver variation in distinguishing Bosniak II and III lesions may explain the differences between these studies. Bosniak (45) amended his original classification system by adding class 2F for minimally complicated cysts that are “somewhat suspicious” and require follow-up with serial CT scans to establish stability instead of immediate surgical exploration. Despite any shortcomings of the Bosniak classification, it is the best system currently available to classify complex renal cysts.

Spiral CT scanning eliminates respiratory misregistration; therefore the walls of cystic lesions can be visualized with great precision and specificity in the diagnosis of simple renal cyst is increased. However, small lesions can be missed by spiral CT if scanning occurs too soon after contrast injection (46).

Renal angiography is less important in the diagnosis of a simple renal cyst but would show an avascular mass with renal cortex compressed at the margins. Both contrast-enhanced power Doppler sonography and delayed CT have shown promise in demonstrating tumor vascularity/enhancement in complex renal cysts (221,261). Percutaneous cyst puncture for cytology and injection of contrast is not now as commonly needed because of the high quality of US and CT available. Of course, the diagnosis of suspected infected cysts or abscesses is benefited by percutaneous aspirate, Gram stain, and culture. MRI can help differentiate between a simple cyst and a hemorrhagic cyst (Fig. 20.17). In addition, gadolinium-enhanced MRI scans and non–gadolinium-enhanced MRI scans can be used in patients unable to receive injections of contrast media for CT. Nonenhanced and gadolinium-enhanced T_1-weighted and T_2-weighted MRI has been evaluated to determine whether imaging features could distinguish between benign and malignant complex renal cysts (16). Although mural irregularity and intense mural enhancement strongly predicted malignancy in complex renal cysts, appearances of benign and malignant lesions overlap.

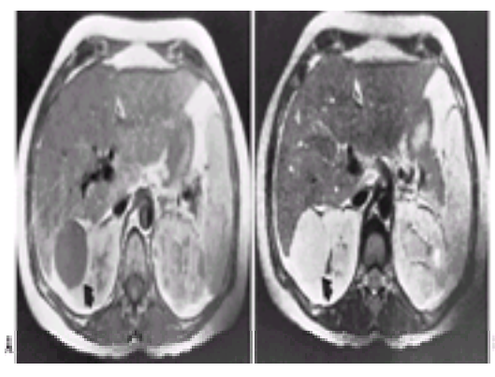

FIGURE 20.17. Simple cyst in a 44-year-old woman. **A:** Magnetic resonance imaging of a T_1-weighted image is characteristic of a simple right renal cyst *(arrow)* because of the distinct smooth margin and because of the low signal intensity (e.g., the cyst contents are very black). **B:** To confirm the diagnosis of a simple cyst, a T_2-weighted image demonstrates the cyst contents to have a high signal intensity (e.g., to be very white), which is consistent with water.

Renal Sinus Cysts

Cysts in the renal sinus deserve mention. Parapelvic cysts are usually single, larger cysts in the renal sinus originating from adjacent parenchyma and are simple cysts. Peripelvic cysts are multiple, confluent, irregularly shaped cysts that appear to arise in the renal sinus itself and that may develop from lymphatic ectasia secondary to blockage of renal hilar lymphatics (6). Autopsy studies show a 1.3% to 1.5% incidence of sinus cysts in the older population. If a sinus cyst of any size happens to be appropriately located, symptoms such as hypertension, hematuria, and localized hydronephrosis can result if a renal sinus structure is compressed, such as a vascular structure or the collecting system (6). On US evaluation, peripelvic or renal sinus cysts may be mistaken for dilated calyces and pelvis. This potential for false diagnosis may be the only clinical relevance of this condition (300).

Management of Simple Cysts

Usually, simple cysts are asymptomatic coincidental findings on imaging studies and require no treatment. However, they occasionally can present as flank or abdominal pain, infection, hemorrhage, hypertension, and impairment of renal function. Case reports elucidate the rare presentation of simple cysts as hypertension in children (14,179) and in adults (330). Increased renin release from the affected kidney has been demonstrated as well as normalization of blood pressure after open surgical or percutaneous elimination of the cyst (14,330). In ADPKD, the cause of hypertension has been proposed to be activation of the renin-angiotensin-aldosterone system by cyst compression of adjacent renal vessels causing ischemia (62). A similar mechanism may account for the hypertension in

the aforementioned case reports as well as hypertension in an aging population (305). More patients with simple renal cysts have hypertension (56). Not only are hypertension and simple renal cysts increasingly common with increasing age, but hypertension is significantly higher in individuals with cysts (305). Possibly, the association between simple renal cysts and higher arterial blood pressure arises from underlying renal disease causing both (306).

Approximately 6% of simple cysts hemorrhage, and although hemorrhagic cysts are extremely rare in children, they have been reported (325). Cyst hemorrhage can be spontaneous or secondary to trauma and may result in hematuria (296). Hyperdense renal cysts occasionally are incidentally found on CT imaging and are renal cysts containing old blood (44), suggesting minor cyst hemorrhage does not result in severe symptoms. Secondary cyst infections are rare but have been reported (131,256); these have been successfully treated with percutaneous drainage and systemic antibiotics (284). Acute urinary obstruction can cause extravasation of urine from the renal pelvis or calyces into a simple cyst (43). Except in rare cases when cysts cause calyceal or renal pelvic obstruction, simple renal cysts have no negative affect on renal function (184).

After the diagnosis of simple renal cyst has been made, no treatment is necessary except to treat symptoms such as abdominal or flank pain. Even though simple renal cysts are rare in the pediatric age group, once malignancy has been excluded appropriately by radiographic methods, no surgical exploration to confirm the diagnosis is necessary (141,320,355). Treatment of symptomatic renal cysts begins with percutaneous aspiration of the cyst to confirm that the symptom such as pain disappears. Cyst fluid can be analyzed cytologically as well as cultured to confirm diagnosis of simple cyst, but cyst fluid cytologic evaluation is not highly accurate. Twenty-four months after aspiration, cyst fluid will have reaccumulated, so there is no size difference between cysts that were aspirated and those that had no intervention (182). However, if the patient's symptom (pain) disappeared with aspiration and the cyst and symptom reoccurs, percutaneous aspiration should be repeated, followed by instillation of a sclerosing agent, such as urea cholohydrolactate, glucose, ethanol, phenol, tetracycline, bismuth phosphate, autologous blood, minocycline, Betadine (povidone-iodine), quinacrine, iophendylate, polidocanol, or ethanolamine (51,142,182,262,285,286,293,386). Cyst and symptom recurrence are significantly lower after aspiration and instillation of a sclerosing agent than after aspiration alone (182,285); however, long-term cyst reduction occurs in only 50% of cases (183). Repeated injections of a sclerotherapeutic agent over a few days into an indwelling percutaneous drain into the cyst had a higher success rate, though. Three repeated ethanol injections over 2 days into an indwelling percutaneous drain resulted in complete disappearanceof 97% of renal cysts at 3 months, with no recurrence during the mean 4-year follow-up (117). The drain was left to closed drainage between instillations.

Percutaneous resection of simple cysts is another treatment with the advantage of obtaining part of the cyst wall for pathologic analysis. Plas and Hubner (314) found that morbidity was minimal but that 50% of patients had residual or recurrent cyst tissue at 40 months, even though no patient had recurrence of their symptoms. Weichert-Jacobsen and others (403) described a modified percutaneous resection technique used only in patients with peripheral renal cysts and found no recurrence of cyst formation on US or symptoms at 19 months of follow-up. Laparoscopic excision of simple renal cysts has been reported through both abdominal and retroperitoneal approaches, with no evidence of recurrent cysts or symptoms in the initial series (155,275,281,335). Recurrence of a renal cyst but not symptoms has been reported after laparoscopic unroofing (217). A wide section of the cyst wall is obtained for pathologic review, as is the case for open surgical cyst excision. Open surgery does have the advantage of better control of bleeding.

Most symptomatic simple cysts can be effectively managed with percutaneous drainage and sclerosis. The repeat injections into an indwelling percutaneous drain have a high success rate. However, in those few simple cysts resistant to these techniques, the percutaneous resection is effective for peripheral simple renal cysts, as is laparoscopic decortication via either a transperitoneal or retroperitoneal approach or open surgical decortication.

Management of Peripelvic Cysts

Peripelvic cysts may lie between major hilar vessels and the renal pelvis. Sclerotherapy into peripelvic cysts is considered risky. Percutaneous sclerosis with multiple injections of povidone-iodine into an indwelling drain in four parapelvic cysts relieved symptoms in all patients with 7.2 months follow-up (312). Successful marsupialization of a peripelvic renal cyst using flexible ureteronephroscopy has been reported (218). Transperitoneal laparoscopic ablation of peripelvic cysts has been successful in alleviating pain but is technically challenging (180). Open surgical repair has succeeded after a failed retroperitoneal laparoscopic ablation of a peripelvic cyst (180).

Management of Complex Cysts

Bosniak category IV complex cysts can undergo partial or radical nephrectomy depending on the size and location of the complex cyst as well as the status of the contralateral kidney. Bosniak category III complex renal cysts can undergo open surgical exploration with preparedness to perform a partial nephrectomy (410). The cyst can be visualized directly while attempts are made to prevent tumor cell spillage, and the cyst fluid can be aspirated, and the external cyst wall and biopsies of the internal cyst wall can be sent for frozen analysis. Bosniak category IIF cysts can be followed by serial CT studies. Laparoscopic evaluation of 35 patients with Bosniak category II and III complex renal cysts revealed 5 patients (14%) with cystic RCC (341). At the time of laparoscopy, cyst fluid is aspirated and the cyst wall is excised and sent for pathologic evaluation, as are biopsies of the base of the cyst if suspicious. If the pathologist confirms malignancy, an immediate radical or partial nephrectomy can be performed (341).

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (MSK) is a relatively benign entity that is diagnosed by IVP. The diagnosis is usually made in adults who present for IVP for evaluation of calculi, hematuria, or infection. The male-to-female ratio is 2:1 (240). In MSK, the kidneys retain their reniform shape, and the incidence varies from 1 in 5,000 to 1 in 20,000 (228). Although described histologically to some extent in 1908 (100), it was the onset of IVP that made possible the description and classification of MSK as a disease by Cacchi and Ricci (55). Even today, IVP is the mainstay of diagnosis.

Clinical Features

MSK is most commonly diagnosed from 20 to 50 years of age, when patients have an IVP performed to evaluate their presenting symptom, which is either renal colic (50% to 60%), gross hematuria (10% to 18%), or UTI (20% to 33%) (228). Of those who have this radiographic diagnosis made, 60% will pass calculi at some time (228). However, an uncertain number are undiagnosed because they are asymptomatic. A small number of patients with MSK have been diagnosed when they were evaluated by IVP for other conditions, such as hypertensive screening, abdominal tumors, and so on. Hence, although 60% of patients diagnosed with MSK will pass calculi, it is uncertain what percentage of all patients with MSK will pass stones, have infections, and so forth. Nephrocalcinosis in MSK is clinically benign except that it leads to stone formation and passage of calculi. Of 70 kidneys examined in affected patients, 58 had intracavitary calculi ranging in number from one to infinity (100). Stone analysis reveals that calcium phosphate stones are the most common, with calcium oxalate stones making up most of the remainder.

In MSK, the medullary cysts are dilated collecting ducts in the pyramids and papillae. Urinary stagnation in these dilated or cystic tubules may be the cause of the calcifications found in these dilated ducts. Because metabolic disorders accounting for lithiasis are found less commonly in stone patients with MSK (60%) than in stone patients without MSK (93%), MSK may cause nephrolithiasis (134). Alternatively, perhaps the biochemical composition of the urine is altered in patients with MSK who have calculi (413). Defective urinary acidification might play an important role in the mechanism of hypercalcuria and hypocitraturia in MSK patients (291). From 40% to 90% of patients with nephrocalcinosis also have hypercalciuria (174). From 15% to 21% of patients with calcium stones were diagnosed as having MSK by IVP (299,413). Ginalski and colleagues (134) found MSK on 12% of IVPs in patients with nephrolithiasis and in 1% of IVPs of patients without nephrolithiasis and without a history of stones.

Progression of MSK, as evidenced by the size or location of the dilated collecting tubules on IVP, is uncommon (228). However, nephrocalcinosis in MSK is acquired (228). Sequential US studies on six children with MSK have revealed increasing echogenicity of the renal pyramids. This increasing echogenicity proved on CT to be calcifications, although the calcifications were too small to be seen on IVP (302). Three of these six children had hematuria, which was probably associated with their microlithiasis. Microlithiasis may be the cause of most of the hematuria seen in those MSK patients who have no demonstrable calcifications on IVP.

About 20% to 30% of patients with MSK have a UTI as their presenting symptom (228). UTI does not play a causal role in stone formation in most patients with MSK, most of whom have sterile urine (413); however, when present, infection has the potential of accelerating stone growth by alkalinizing the urine. Fortunately, infection in affected patients responds well to antibiotics, unlike in patients with ADPKD. In addition, patients affected with MSK have an incidence of hypertension similar to that found in the normal population. Occasionally, a mild urine-concentrating defect can be found in patients with MSK who otherwise have normal renal function.

Morphology, Pathogenesis, and Genetics

Grossly, the kidneys of MSK are of normal size or slightly larger and have kept their reniform shape. Cut surface reveals the larger of the dilated collecting duct cysts, which are present at the papillary tips of the renal pyramids (near the renal medulla). The smaller of the dilated collecting duct cysts may be visible only microscopically because they vary from 1 to 5 mm in diameter. Microscopically, the collecting ducts are lined by flattened epithelium, and the columns of Bertin are normal. As few as one or as many as all renal pyramids can have MSK and calcifications can be seen in the cysts clustered toward the papillary tips.

The pathogenesis of MSK is unknown, but it is probably congenital. Successive US studies in children with MSK show the progressive development of calcifications as the children grow as well as the presence of the disease in children (302). MSK has some basis for at least occasional genetic transmission because of documented family history in a few families (228) and its association with other congenital manifestations.

Radiologic Findings

The diagnosis of MSK is made by IVP (Fig. 20.18). The contrast medium stagnates in the dilated or cystic linear tubules in one or more renal papillae. These appear as linear radiations from the calyces and vary in shape from beads to strands. Whether a “pyramidal blush” is an early sign of MSK on IVP or is a normal finding is undecided. Calculi are located at papillary tips on a plain abdominal radiograph. US shows the medullary cysts only if they are large. However, in children, the renal medulla is better seen on US because there is less renal sinus fat and overlying muscle. As a result, hyperechoic areas of the pyramids are visualized and either represent ductal calcifications or dilated collecting ducts (302). On retrograde pyelography, the cysts or ectatic ducts either fail to fill with contrast or fill less prominently. The sensitivity of CT in the detection of MSK is markedly lower than that with IVP. However, CT is more sensitive than plain films and tomograms of IVP in the detection of the papillary calcifications of MSK (135).

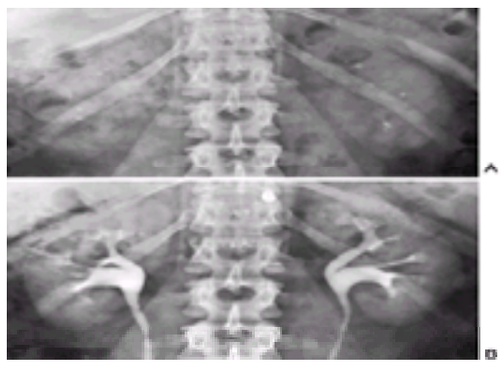

FIGURE 20.18. Medullary sponge kidney. **A:** A plain abdominal radiograph reveals bilateral nephrocalcinosis. The calculi are located at the papillary tips. **B:** An intravenous pyelogram in the same patient reveals linear radiations from the calyces. These radiations result from stagnation of contrast medium in the cystic or dilated collecting ducts.

Management

Some patients with MSK will have an asymptomatic course and require no medical intervention. Previously, 10% of the symptomatic patients had a poor prognosis because of recurrent renal calculi and infection (228), but with current therapies for infections and calculi, this number is probably lower. Infections in patients with MSK respond well to antibiotics. Prevention of stone formation can be attempted with increased fluid intake, thiazides, and inorganic phosphates (413). Urine alkalization may reduce the incidence of stone formation in these patients (90). Once calculi are formed, ESWL is effective in disintegrating symptomatic stones in the collecting system (90,277,387) but not in fragmenting the ductal (precaliceal) calcifications (90,387). Marked improvement in the frequency of renal colic and UTIs was noted after ESWL, perhaps secondary to the reduction in stone mass and the reduced incidence of obstruction in the upper urinary tract (90). Transurethral extraction of ureteral calculi is appropriate with ureteroscopy as needed. Appropriate antibiotic prophylaxis during the perioperative period should be used because of the high risk of obstruction in these patients from passage of more calculi.

GLOMERULOCYSTIC KIDNEY DISEASE AND GLOMERULOCYSTIC KIDNEYS

Glomerulocystic kidney disease (GCKD) is a rare congenital bilateral cystic disease in which Bowman's space is dilated and thus appears as a glomerular cyst. The cysts contain some sort of glomerular tuft or tuft remnant. These multiple cysts are confined to the renal cortex in these reniform but very large kidneys. The tubular portion of the nephron is structurally normal. The lack of tubular involvement distinguishes GCKD from other cystic renal diseases in which proximal or distal tubule dilation leads to cyst formation in both the cortical and medullary regions (57).

Glomerulocystic kidneys occur in (a) GCKD, (b) heritable malformation syndromes, and (c) dysplastic kidneys (30). Glomerulocystic kidneys are a major component of heritable malformation syndromes such as ADPKD, TSC, orofaciodigital syndrome, brachymesomelia-renal syndrome, trisomy 13, short rib–polydactyly syndrome, Jeune syndrome, and familial juvenile nephronophthisis, and is a minor component in Zellweger's syndrome. Glomerular cysts can be a minor feature in dysplastic kidneys such as diffuse cystic dysplasia and renal-hepatic-pancreatic dysplasia (30). In contrast, GCKD comprises nonsyndromal heritable and sporadic forms of severely cystic kidneys in young children and to a lesser degree in adults.

GCKD has a broad range of clinical manifestations from death in early infancy to survival in adult life, with little handicap and with successful marriage and reproduction. Patients more commonly present in infancy or early childhood and have bilaterally palpable flank masses (265,349,372). Renal function can deteriorate (265) or remain stable for an unknown amount of time (349). Glomerulocystic kidneys in young infants are a common expression of early onset ADPKD (32). Many of these newborns and young children have a family history of ADPKD, whereas others are sporadic. Because no differences are found between familial and sporadic cases, the sporadic cases are potentially new mutations of the same disease (30). Children with early onset of severe ADPKD have an affected parent whose milder disease presented in adulthood. The increase in disease severity is limited to the kidney that has a higher number of cysts and mostly glomerular cysts (289). Dedeoglu and co-workers (86) described an infant diagnosed with GCKD because of classic findings on his renal biopsy, normal renal US studies of his parents, and negative family history. Seven years later, his diagnosis was changed to ADPKD because a repeat renal US of his mother (30 years old) suggested ADPKD, pathologic examination of his kidneys after bilateral nephrectomies confirmed ADPKD, and gene linkage analysis was informative for the family for ADPKD. A positive family history can point the clinician in the right direction, which may be verified by linkage analysis. Glomerular cysts have also been identified in 40% of adult ADPKD kidneys examined for their presence (30).

Less commonly, GCKD is a cause of chronic renal insufficiency in older children (411). In rare instances, GCKD has been diagnosed in adults who can present with hypertension, flank pain, hematuria, mild chronic renal failure, and ESRD (57) or who can present as coincidental findings when patients undergo renal biopsies for another renal disease such as glomerulonephritis (58). Potentially, GCKD may be more common than realized because biopsies have not been performed on otherwise asymptomatic patients. GCKD in adults and older children may also be sporadic or familial. If familial, GCKD is dominant (269). Usually, patients progress to ESRD or stable chronic renal insufficiency (57). Poor prognosis may be related to extensive involvement with glomerular cysts at an early age. Survival beyond adolescence with only mild to moderate renal functional impairment and no associated congenital abnormalities appears to improve chances for maintaining adequate renal function (57). Another category of GCKD is hypoplastic GCKD, which is rare and dominant. Unlike other GCKD patients, these patients have small kidneys and abnormal pyelocaliceal anatomy. Amir and colleagues (5) suggest that GCKD may be acquired after hemolytic uremic syndrome.

GCKD kidneys are large and reniform, with cortical cysts that vary in diameter from a few millimeters to 7 cm (349). IVP demonstrates huge kidneys and can sometimes demonstrate calyceal distortion suggesting multiple renal cysts or masses (57). US demonstrates large kidneys and may show numerous small cysts, depending on cyst size (265). Therefore the kidneys appear strongly echogenic with cortical, subcortical, and subcapsular cysts (57). Selective renal arteriography can show intrarenal vessels stretched around numerous cortical cysts (349). A renal biopsy may be necessary to establish a diagnosis (57). MRI shows multiple cortical cysts and diffuse reduction of the intensity of the renal cortex with loss of the normal corticomedullary differentiation on T_1-weighted images (98).

Treatment is appropriate management of renal failure. Both dialysis and renal transplantation have been successful (265).

ACQUIRED CYSTIC KIDNEY DISEASE

Long-term maintenance dialysis therapy is now accepted therapy for patients with ESRD. However, dialysis has ushered in a new class of renal cystic disease called *acquired cystic kidney disease* (ACKD). ACKD was so named in 1977 by Dunnill and co-workers (95), who observed that 14 (47%) of 30 long-term dialysis patients had bilateral renal cystic disease at autopsy. None of these patients had renal cystic disease before beginning hemodialysis. Later studies revealed that hemodialysis patients and continuous ambulatory peritoneal dialysis (CAPD) patients have the same prevalence and severity of ACKD (196,343). Patients with longstanding renal insufficiency who have never been dialyzed also developed ACKD (48,72). In retrospect, ACKD was described in 1847 in patients with subacute glomerulonephritis causing such longstanding renal insufficiency (356). Because ACKD is asymptomatic in its early stages, ACKD can occur before ESRD is recognized. The uremic state promotes the development of ACKD, and dialysis extends the time that the cysts can develop. Serial CT scans of the kidneys of uremic patients suggest that cysts start to develop when serum creatinine is above 3 mg/dL (271). The incidence of ACKD in dialysis patients increases with the length of time the patient has received dialysis (241). Ishikawa and others (194) reported a 44% incidence of ACKD in patients who had undergone less than 3 years of hemodialysis, as opposed to an 80% incidence in patients who had more than 3 years. The reported prevalence rate of ACKD is increasing because of longer patient survival in dialysis therapies, higher rates of native kidney retention in transplant patients, and improved sensitivities of current imaging modalities (340). ACKD is bilateral, develops more quickly, and is more severe in men (77,198). The prevalence of ACKD in children undergoing CAPD and hemodialysis is just as high as that in adults (231,264).

Early on, ACKD patients are usually asymptomatic and are therefore not usually diagnosed unless screened radiologically as part of an evaluation for renal failure or transplantation. Alternatively, patients can present with severe intrarenal hemorrhage with or without gross hematuria. Among cases of ACKD with bleeding complications, only about 30% are related to tumor, whereas the rest are probably related to retroperitoneal hemorrhage due to rupture of a hemorrhagic cyst into the retroperitoneal space (130). Such hemorrhage can occur during anticoagulation therapy for hemodialysis, at which time patients may have such symptoms as sudden flank pain, hypotension, and decrease in hematocrit (192). Less commonly, ACKD patients may also develop a cyst infection, symptomatic distant metastases from RCC, matrix kidney stones (48), or increased erythropoietin production. The size increases of renal cysts over time in ACKD results in increased secretion of erythropoietin (97) and a rising hemoglobin (111).

Successful renal transplantation in dialysis patients can retard or lead to regression of established ACKD, as well as size reduction of the affected native kidneys (197,241), unless cyclosporine is used for immunosuppression (246). In cyclosporine-treated transplant patients, the prevalence of ACKD is essentially the same as that for hemodialysis patients. After a transplanted kidney undergoes chronic rejection, resulting in uremia, acquired renal cysts can develop in the grafted and native kidneys (195). The duration of uremia correlated with increased numbers of acquired renal cysts, just as prolongation of the dialysis period in ESRD increases not only the incidence of ACKD but also the number and size of acquired cysts.

Eighty-six percent of renal tumors in ACKD are asymptomatic and are found incidentally by imaging studies, although they can less commonly present with symptoms such as bleeding, pain, fever, hypercalcemia, or symptomatic metastatic disease. The prevalence of tumors increases with the duration of dialysis, just as kidney weight increases with duration. Increased kidney weight is secondary to increased cyst volume and epithelial proliferation, both of which can be considered premalignant. Cancer developed in 11% of tumors in ACKD kidneys weighing less than 150 g and 55.6% in ACKD kidneys weighing greater than 150 g. In addition, ACKD patients in the small kidney group did not have metastatic disease, whereas three patients in the large kidney group had metastatic disease (250). ACKD has an overall incidence of 43.6% of all dialysis patients surveyed. Renal tumors, usually multiple, are found in 7.1% of chronic dialysis patients but in 16.4% of the ACKD patients. Many of the tumors were small and were therefore considered adenomas, but 4.7% of the renal tumors had metastasized by the time of presentation (146). Considering only RCCs in ACKD, 20% are metastatic at presentation (260). In combined data from 13 studies, 4% of ACKD patients had RCC (defined as a tumor greater than 2 to 3 cm in diameter). However, this figure may be an underestimate because a pathologist will detect more tumors than a radiologist. The incidence of RCC in ACKD represents a fortyfold (in Japan) to fiftyfold (in the United States) increased risk of RCC compared with that of the general population (382).

RCC occurs at a younger age in ACKD than in the general population (45 versus 64 years) and has even higher male-to-female ratio in ACKD than the general population (6:1 versus 2:1). RCC is more common in African Americans than whites in the ACKD populations, but it is more common in whites than African Americans in the general population (260). In ACKD, RCC tends to be bilateral and multifocal, in contrast to solitary unilateral RCC in the general population.

Morphology, Pathogenesis, and Malignancy

Grossly, the renal cortex in ACKD is replaced by multiple, bilateral cysts; later, the medulla is involved to some extent. The kidneys are reniform and small initially as they decrease in size during the first 3 years of dialysis; however, they then increase in size secondary to acquired cyst development (260). Most cysts are 0.5 to 2.0 cm in diameter but can be 4 cm in diameter. Cyst fluid is clear to hemorrhagic.

Microscopically, few glomeruli remain. Microdissection studies reveal that the cysts mainly develop in proximal tubules that survive the sclerotic process leading to the end stage kidney (388). Most cysts are lined by low cuboidal or columnar epithelium. However, some cysts have atypical proliferations of columnar, multilayered living cells in papillary formation. Although epithelial proliferation in cystic kidneys does not invariably lead to the development of macroscopic tumors and malignancy, the relative infrequency with which adenocarcinomas are found in noncystic, compared with cystic, kidneys strongly suggests a causal relationship between epithelial hyperplasia and both cysts and tumors (31). The tumors found in ACKD can be categorized histologically into three groups: (a) papillary tumors that project into the cyst lumen without invading the cyst wall, (b) parenchymal tumors that reside adjacent to but not within the cyst, and (c) solid tumors that are sheets of less differentiated cells with either foamy or acidophilic cytoplasm. Central areas may have hemorrhage (94).

RCC in chronic dialysis patients has a papillary histologic pattern in 49% of cases, as opposed to 5% of the RCCs in the general population (193). Gains of chromosomes 7 and 17 and loss of Y have been observed in papillary RCCs in ACKD similar to sporadic papillary RCC, but the nonpapillary RCCs in ACKD patients did not show loss of chromosome 3p as in sporadic nonpapillary RCCs (152). Controversy exists over whether tumors less than 2 to 3 cm in size in ACKD patients should be called *adenomas* or *adenocarcinomas,* because there is no histologic difference and tumors greater than 3 cm had once to be less than 3 cm. Ishikawa and co-workers (193) suggest that all nonpapillary renal cell tumors in ACKD be diagnosed as RCCs and that the adenoma versus carcinoma question be limited to papillary renal tumors because of different genetic alterations and different natural histories. Specifically, a nonpapillary RCC can occur any time after starting dialysis, whereas papillary RCC and ACKD occur more frequently after long-term dialysis. Sant and Ucci (340) noted that renal neoplasms of 1.5 and 1.8 cm in native ACKD kidneys showed microscopic capsular invasion and suggested all renal adenomas be considered small adenocarcinomas with metastatic potential.

RCC can occur in the native kidneys in ACKD patients after successful renal transplantation (166,243,340). Renal transplantation reduces the frequency and severity of ACKD in ESRD patients but does not completely eliminate ACKD, even in all patients with good renal function, especially if the patient is treated with cyclosporine (246). Heinz-Peer and others (166) reported a 24.9% incidence of ACKD in native kidneys after successful renal transplantation and noted that 5% of the native kidneys with ACKD were found to have RCC. The genetic alterations in renal parenchymal cells undergoing epithelial proliferation during ACKD are important rate-limiting changes toward neoplastic growth. Therefore, although ACKD can be reversible in the native kidneys of individuals who have received functioning renal allografts, the final step in progression from cyst to adenoma to adenocarcinoma may not be reversible by correction of an uremic environment (144). The multistage process of oncogenesis may be beyond the bounds of physiologic control, so the malignant potential of ACKD may persist in renal transplant recipients, even after many years of normal function (166).

The pathogenesis of ACKD is unknown, but one theory involves the accumulation of biologically active substances such as cystogenic nephrotoxins that accumulate during hemodialysis, peritoneal dialysis, or chronic uremia. Such biologically active substances may cause kidneys to develop ACKD and renal tumors if these kidneys are exposed to the biologically active substance long enough. Support for this hypothesis lies in the fact that successful renal transplantation can result in regression of established ACKD. Because ACKD does occur in patients who have longstanding renal insufficiency before beginning dialysis, dialysate-leached chemicals are not believed to be the initiators of ACKD. Hence, this suggests that although hemodialysis and peritoneal dialysis prolong life, they are not complete kidney substitutes because they may allow some biologically active substance to accumulate (146).

Another theory suggests that the loss of functional renal mass such as a critical number of working nephrons increases production of renotropic factors that promote tubular cell hypertrophy and hyperplasia leading to cyst formation and, rarely, renal tumors (144,145). Hemodialysis and CAPD may fail to eliminate the substances that promote production of renotropic factors, although successful renal transplantation may retard or lead to the regression of ACKD. Increased expression of renotropic factors, epidermal growth factors, platelet-derived growth factor, and C-erb B-2 (a protooncogene) may be involved (172,260).

The hormonal theory offers another possibility for ACKD pathogenesis because ACKD occurs much earlier in male than in female patients. After 3 years of dialysis, ACKD incidence is 100% in males and 66% in females. Furthermore, after long-term dialysis, the severity of cystic transformation is far greater in male patients and the increase in renal volume in male ACKD patients is more than twofold that reported in female patients (77). However, the size of the kidney tends to plateau after 13 years of hemodialysis in male patients, whereas significant cystic changes developed in female patients receiving long-term (more than 18 years) hemodialysis (198). Perhaps the decreased androgen-to-estrogen ratio and the increased estrogen value could result in an estrogen receptor–mediated effect on tubular epithelial cell proliferation, which could be more pronounced in male tissues because they are less adapted to high estrogen values. In addition, androgen reduction (more severe in male patients) may upregulate epidermal growth factor (77).

Radiologic Findings, Screening, and Management

Because the incidence of ACKD increases with the length of time a patient has been receiving dialysis, asymptomatic dialysis patients should be screened after 3 years of dialysis treatment by either US or CT. A baseline predialysis renal US should be obtained for comparison purposes. If any US detects the presence of cysts, CT should be done to assess the presence of a renal tumor because ACKD patients are at increased risk for renal tumors. Unfortunately, it can be difficult for US to detect the small cysts of ACKD in these sonographically abnormal small kidneys of ESRD patients (146) (Fig. 20.19). Manns and others (257) were unable to identify 10% of the native kidneys in ACKD by US. Hence, if it were not for cost, contrast-enhanced CT would be preferable as a first test to diagnose ARCD as well as to diagnose tumor (Fig. 20.20). However, some authors have found US to be more accurate than CT to diagnose RCC in dialysis patients (374). If an ACKD patient becomes symptomatic with flank pain, hematuria, or any unexplained fever or systemic illness, appropriate imaging such as an enhanced CT scan is appropriate to evaluate for possible tumor, hemorrhage, or infected cyst. Annual CT screening of all long-term dialysis patients after 3 years would add $36 million to the Medicare budget, but data do not justify the expense (238). Screening ACKD patients on dialysis every 3 years by CT or US has been predicted to increase the 25-year life expectancy of a 20-year-old by 1.6 years but only increase the 5-year life expectancy of a 58-year-old by 4 to 5 days (342). More than half of the U.S. dialysis population would be unlikely to benefit from such screening because the median age of patients beginning dialysis is 62 years (342).

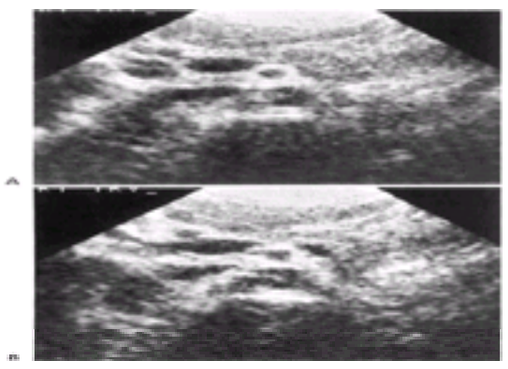

FIGURE 20.19. A, B: Acquired cystic kidney disease in a 52-year-old woman on chronic dialysis. Renal ultrasonography reveals small kidneys with increased cortical echoes as found in chronic renal disease. Multiple cysts are present and are of varying sizes.

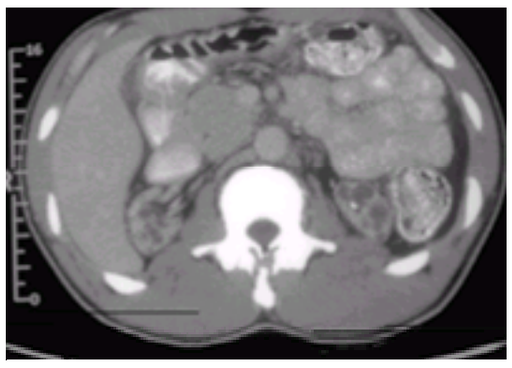

FIGURE 20.20. Acquired cystic kidney disease in a 46-year-old man on chronic dialysis who has had a left nephrectomy. Unenhanced computed tomography reveals a right small kidney with multiple cysts.

However, identification of subsets of ACKD patients most likely to benefit from annual screening is appropriate. For example, young patients with prolonged dialysis (255) and patients in good medical condition would benefit if annual renal imaging found localized RCC (238). In addition, subsets of ACKD patients with high-risk factors such as male gender (77) or large kidneys (250) would benefit. MRI is superior to US in depiction of simple and complex cysts of native kidneys in renal allograft recipients (167) but is not better than CT scanning even after gadolinium enhancement (382). The 1995 clinical practice guidelines of the American Society of Transplant Physicians for evaluation of renal transplant candidates do not recommend screening for ACKD and RCC because of the low frequency of cancer and reported regression of ACKD after transplantation (156). Gulanikar and associates (156) evaluated 206 consecutive adult patients for renal transplantation with a renal US and found 63 patients (30.6%) had ACKD and 8 (3.8%) had localized RCC (6 unilateral and 2 bilateral). Seven of the cancers were in the ACKD patients. Although US screening of the entire ESRD population for ACKD and tumors cannot be justified because of patient age and comorbidity limiting life expectancy, patients chosen for renal transplantation are younger and have less severe comorbidities. Given the expense and risk of renal transplantation, renal US screening for ACKD before renal transplantation is appropriate. Screening for tumors in native kidneys after transplantation with renal US may be justified in high-risk groups such as young men. Consideration should be given to scanning of native kidneys when a renal transplant patient undergoes US imaging of his or her graft (238).

In dialysis patients, renal tumors larger than 3 cm should undergo a radical nephrectomy unless the patient is a poor operative risk (382). Tumors less than 3 cm require radical nephrectomy if the patient is a transplantation candidate. Patients with tumors completely confined to the kidney can have a transplant immediately after the nephrectomy, but when tumors extend into the perinephric fat, a waiting period of 1 to 2 years is advised (308). Tumors less than 3 cm in the remaining ACKD patients require either radical nephrectomy or annual CT scans to access rate of growth to determine whether radical nephrectomy is appropriate. If a tumor is smaller than 3 cm and no rapid tumor growth is documented on serial imaging studies, but symptoms such as back pain or hematuria persist, nephrectomy is probably indicated because the tumor may be carcinoma and nephrectomy for intractable hematuria can reveal RCC that was not visualized preoperatively (130). Bilateral nephrectomy can be considered in ACKD-related RCC patients who are to undergo renal transplantation because posttransplant immunosuppression is a known risk factor for the development of renal neoplasms and because ACKD is a bilateral disease (382).

Chapter References

Hydronephrosis is the distention of the renal calyces and pelvis with urine as a result of obstruction of the outflow of urine distal to the renal pelvis. Prolonged hydronephrosis results in renal parenchymal atrophy. Elevated renal pelvic pressures and decreased renal blood flow are postulated to be mechanisms of injury and cellular atrophy. Obstructive uropathy progressively impairs all renal functions except urinary dilution. The longer and more complete the obstruction, the more severe the pathophysiologic changes become.

Significant changes in experimental hydronephrosis have occurred in three areas in the last 4 years. There is a better understanding of which factors and vasoactive substances cause the decreased blood flow after 24 hours of complete unilateral ureteral obstruction (UUO). There is more information on causative factors leading to tubular loss and interstitial fibrogenesis. The differences between the pathophysiology of obstructive nephropathy in the newborn and adult have been further delineated, showing that in addition to tubular atrophy and interstitial fibrosis, obstruction in the maturing kidney impairs renal growth and development.

Recent research shows a complex series of pathophysiologic events after ureteral obstruction involving more than the anatomic, pathologic, and physiologic changes previously described. A variety of vasoactive compounds, growth factors, and cytokines are activated in response to ureteral obstruction. These factors include platelet-derived growth factor, transforming growth factor-b (TGF-b), epidermal growth factor, insulin-like growth factor, clusterin, nitric oxide, endothelin, atrial natriuretic peptide, and angiotensin II. There are also factors that cause leukocyte infiltration, such as osteopontin and arachidonic acid metabolites (eicosanoids).

Recent excellent reviews by Gulmi and colleagues (76), Chevalier (19), Ricardo and Diamond (169), and Klahr and Morrissey (113) define current knowledge of these vasoactive mediators. My interpretation of these data is that the etiology, pathophysiology, and consequence of UUO is significantly different in the newborn and the adult. Obstruction of the maturing kidney impairs renal growth and development in addition to causing tubular atrophy and interstitial fibrosis. The renin-angiotensin system (RAS) in the maturing kidney plays a greater role in normal development and pathophysiologic response than in the adult. In adult UUO, there is a better understanding of the development of fibrosis and the presence of various vasoactive compounds. There also appear to be species differences in responses to ureteral obstruction.

PATHOPHYSIOLOGY OF OBSTRUCTIVE UROPATHY

Historical Aspects of Hydronephrosis

Hinman first studied experimental hydronephrosis systematically (87,89,90). These studies showed that infection plus obstruction caused severe and rapid renal damage (87). Histologic changes were noted after 1 week of obstruction, with some histologic recovery after release of 60 days of obstruction in rats (87). Denervation of the kidney did not alter the course of hydronephrosis (94). Renal arterial or venous obstruction accentuated the damage in hydronephrosis (89,92,93). Release after 2 weeks of complete ureteral obstruction with contralateral nephrectomy resulted in the return of most function to the previously obstructed kidney. The same experiment with 3 weeks of complete obstruction resulted in only a 50% return of function. The animals could not survive release of obstruction lasting longer than 2 or 3 weeks if the opposite kidney was removed at the time of release of the ureteral obstruction. The animals could survive release after 30 to 60 days of unilateral hydronephrosis if the opposite normal kidney was damaged gradually after release of the ureteral obstruction.

Pathology

Urinary tract obstruction causes proximal dilation with anatomic changes in the proximal ureter, renal pelvis, and renal parenchyma. Initially, the proximal ureter and renal pelvis react with muscle hypertrophy and hyperplasia. Production of connective tissue consisting of collagen and elastic tissue occurs later and is thought to impair myogenic impulse transmission and cause disturbance of peristalsis (42,48,65,70,116). An increase in collagen, which acts as an inelastic collar preventing distention, has been found in the obstructing segments of the ureteropelvic junction and in megaureters (77,151,152). Studies of infants with ureteropelvic junction (UPJ) obstruction showed an increase in the inner longitudinal muscle bundles, in collagen between muscle bundles, and in elastin in the adventitia (191).

Hydronephrosis eventually causes tubular dilation with cellular atrophy and interstitial fibrosis. Within 7 days, atrophy is seen in the distal nephron. By 14 days, there is progressive dilation of the distal tubules and atrophy of the proximal tubular epithelial cells. At 28 days, there is loss of 50% of the medulla with marked atrophy of the proximal tubules and thinning of the cortex. Glomerular changes are not noted before 28 days of obstruction. There is no evidence of microscopic changes in the arteries to account for the substantially reduced blood flow observed in hydronephrosis. Venous drainage is impaired, causing some of the renal damage (2,46,91,97,164,180,182,193). Urinary tract obstruction causes proximal dilation, blunting of the renal papillae after 2 to 3 days, and gradual atrophy and thinning of the renal tissue. Microscopically, the renal tubules dilate with cellular atrophy beginning in the distal nephron. In longstanding hydronephrosis, the glomeruli become sclerotic. During obstruction, there is increased cellularity of the interstitium with leukocytes, fibroblasts, and macrophages, which may have vasoactive functions. No

vascular obstruction is seen to account for the increased vascular resistance associated with chronic hydronephrosis.

Fluid Turnover in Hydronephrosis

Urine exits the renal pelvis in complete ureteral obstruction by extravasation, pyelolymphatic backflow, and pyelovenous backflow. Replacement glomerular filtration maintains the hydronephrosis. Thus there is an active turnover of urine in the hydronephrotic renal pelvis despite complete ureteral obstruction. Substances injected into the hydronephrotic renal pelvis have appeared in the systemic circulation, confirming the dynamic state of the hydronephrosis: strychnine (199), phenolsulfonphthalein (17), dye (138), and indigo carmine (96). Extravasation of urine first occurs through rupture of the fornix (10,96). Narath (146) and Olsson (155) studied urine backflow during ureteral obstruction. Initially, ureteral obstruction produces pyelocanalicular and pyelosinus backflow.

With acute obstruction and high pressures, as during retrogrades or with ureteral calculi, most of the fluid exits the renal pelvis by extravasation at the calyceal fornix. With low-pressure obstruction, much of the fluid exits into the lymphatic vessels. In chronic hydronephrosis, most of the fluid exits into the renal venous system.

Renal Counterbalance, Compensatory Renal Hypertrophy, and Renal Hypotrophy

The concepts of renal counterbalance, compensatory renal hypertrophy, and renal hypotrophy (disuse atrophy) were first introduced by Hinman in 1922 (88) and later summarized in 1926. The theory of renal counterbalance is based on the premise that there is a mechanism to monitor total renal function and that the function of each kidney can be modulated up or down as appropriate. Thus, if one kidney is removed or rendered nonfunctioning by obstruction, the opposite kidney would undergo compensatory hypertrophy. If additional renal tissue is added by release of unilateral obstruction or transplantation of additional kidneys, some mechanism would modulate total renal function downward by renal hypotrophy. Renal hypertrophy and hypotrophy involve changes in function. Some misunderstandings and controversy have resulted from efforts to comprehend renal counterbalance in terms of renal mass instead of function.

Studies have provided new information about compensatory renal hypertrophy. Two forms of renal growth have been postulated: obligatory growth thought to be under the stimulus of growth hormone and compensatory growth under an unknown humoral stimulus. Compensatory renal growth includes both hypertrophy and hyperplasia (161) and is not as great in older animals (84). After unilateral ureteral obstruction, there is a bilateral increase in renal mass the first week, followed by atrophy in the obstructed kidney and continued hypertrophy in the opposite unobstructed kidney. The increased mass in the obstructed kidney may be a local response to injury (229) or a response to the unknown humoral factor. In most models, the renotrophic factor is present in anephric animals. Renotrophic factor stimulates three forms of growth: embryonic growth, wound repair compensatory growth, and neoplastic growth (159). The renotrophic factor is thought to be humorally mediated and must be continually present to maintain compensatory growth (126). Similar renotrophic factors are present in urine and serum (80). During compensatory hypertrophy, glomeruli increase in size but not in number. Diabetes and pregnancy cause renal hypertrophy.

Chronic UUO in fetal sheep impairs growth of the obstructed kidney and stimulates compensatory growth in the contralateral kidney. The developing kidney is more susceptible to the effects of ipsilateral UUO. Adaptive growth of the contralateral kidney is also enhanced. Compensatory growth is reversible (187), whereas normal growth is not. Angiotensin acts as a growth factor in normal renal development and is not necessary in neonatal mouse. Insulin-like growth factor-1 plays a role in neonatal (but not adult) compensatory renal growth (143).

Renal hypotrophy (atrophy) is most easily understood in terms of function. When a hypertrophied kidney is experimentally transplanted into a recipient with a hypertrophied kidney, both kidneys return to their previous size (187,189). When two additional kidneys were transplanted into male rats with normal kidneys, there was no change in the size of either the two transplanted kidneys or the two normal kidneys. However, total renal blood flow and glomerular filtration showed no increase over normal conditions (170). Silber (187,189) found that after transplanting an additional kidney there was an increase in total renal mass and a 50% increase in total renal blood flow and glomerular filtration rate (GFR).

Studies in our laboratory showed that with release of unilateral complete obstruction, the obstructed kidney regains function over the next 4 months. Compensatory hypertrophy persists in the contralateral kidney during that time. Total renal function is not fully recovered to control values at 4 months. Studies in Chevalier's laboratory have confirmed the compensatory hypertrophy in the contralateral kidney in the neonate (19). These studies suggest both a humoral and a neural mechanism.

Return of Function After Complete Ureteral Obstruction

Recovery of renal function after release of complete ureteral obstruction varies with the species, total time of obstruction, presence or absence of infection, degree of pyelovenous and pyelolymphatic backflow, and whether the renal pelvis is intrarenal or extrarenal. In the dog with a normal contralateral kidney after release of 2 weeks of obstruction, the GFR can recover up to 46% of control function in 3 to 4 months. After release of 4 weeks of total ureteral obstruction, there was recovery of the GFR to 35% of control by 5 months. No return of function was noted with release after 6 weeks of total ureteral obstruction in the dog (201).

How long the human kidney can be completely obstructed and still regain function after release is not known for certain. Reports in the literature have been difficult to evaluate because the length and completeness of obstruction and the return of renal function are difficult to document adequately. With greater use of renal scanning and renal ultrasound and better awareness of possible ureteral obstruction after pelvic surgery, better documentation should be possible. The cases with the longest period of complete ureteral obstruction meeting the aforementioned criteria and showing some recovery of function are 56 and 69 days (74,120,166).

Prediction of Recovery Potential Before Release of the Obstruction

To make the right decision about nephrectomy or correcting an obstruction, the urologist needs to know whether the kidney will regain function after the obstruction is released. The two best means of assessing recoverability before surgery are the placement of temporary ureteral stents or nephrostomy tubes and the use of renal scans with sophisticated analysis. The simplest method is to place percutaneous nephrostomy tubes to relieve the obstruction and monitor creatinine clearances. If the previously obstructed kidney has not regained at least a 6 to 10 mL minute creatinine clearance by 2 to 3 months, I do not think it merits repair if the other kidney is normal.

Prediction of recoverability with the renal scans is more difficult and has not been successful in many studies. Evaluating cortical zones of interest by arbitrary mathematical analysis, however, has been successful: technetium (^{99}Tc) pentetic acid, diethylene triamine pentaacetic acid (DTPA) (121), ^{99m}Tc DMSA (dimercaptosuccinic acid) (132), and iodohippurate sodium labeled with iodine 131 (^{131}I hippuran) (66,108). That the different scanning agents measure various renal functions has not seemed to be as important as the method of quantitative analysis of the results. ^{131}I hippuran measures renal blood flow and correlates with the GFR. ^{99m}Tc DMSA accumulates in the cytoplasm of proximal tubular cells and is used to assess functioning cortical tissue. ^{99}Tc DTPA is eliminated by glomerular filtration and correlates with cortical renal blood flow. MacNeily and associates (125) believe it is important that measurement of the radioactivity be made between 1 and 3 minutes when the radioactivity is confined to renal blood vessels and functioning parenchyma. Before 1 minute, the radioactivity can be extrarenal; after 3 minutes, the accumulation of radioactivity in the renal pelvis can cause confusion.

Intrapelvic and Renal Tubular Pressures

Normal

Normal renal pelvic pressure is 6.5 mm Hg, which slightly exceeds the intraperitoneal, bladder, and ureteral pressures. Normal proximal tubular pressure is 14 mm Hg (134).

Unilateral Ureteral Obstruction

Ureteral and renal pelvic pressures after complete unilateral ureteral obstruction rise abruptly and then decrease within 24 hours to 50% of the peak values (202). Ureteral pressures continue to decline over the next 8 weeks to 15 mm Hg despite the continued completed obstruction (202). Thus static ureteral pressure measurements have never been helpful in determining the degree of ureteral obstruction.

The peak ureteral pressures with acute complete ureteral obstruction vary with hydration, osmotic diuresis, degree of ureteral contractions, and amount of

reabsorption. The maximum pressure from filtration is the stop-flow pressure of 15 to 20 mm Hg [glomerular capillary pressure (60 mm Hg) minus capillary oncotic pressure (25 to 30 mm Hg) minus hydrostatic pressure in Bowman's capsule (15 mm Hg)]. The higher pressures measured during acute obstruction are a result of filtration pressure and active muscle contractions in the ureter and renal pelvis. Ureteral pressures of 50 to 70 mm Hg have been measured after acute ureteral obstruction in humans (5,97,130,134,144,153,196). Ureteral pressure after obstruction can be further increased to 100 mm Hg by saline or mannitol diuresis (158,201).

Pressure transmitted back to the renal pelvis varies with the conditions of the obstruction. In acute unilateral obstruction in nondiuretic rats, the ureteral and proximal tubular pressure rises to 14 mm Hg, which is normal proximal tubule pressure (72,73). In diuretic rats, the maximum pressure in the ureter and proximal renal tubule rises to 40 mm Hg (72,73). Further elevation of ureteral pressure by injecting fluid to 80 mm Hg fails to transmit and does not raise proximal tubular pressure above 40 mm Hg, presumably because of compression of papillary foramina (72).

Within 24 hours, the elevated proximal tubular pressure is below normal as a result of afferent arteriole constriction (49,72). Another consequence of elevation of ureteral pressure is that the proximal and distal tubules become leaky to creatinine, mannitol, and sucrose. Studies have shown that the aqueous junctional complexes of membranes of adjacent cells are disrupted. The permeability is restored when tubular pressures return to normal (16,122).

When unilateral ureteral obstruction persists, ureteral pressure slowly declines to reach normal levels in 3 to 4 weeks (202). Michaelson (134) found an average decrease of intrapelvic pressures of 6.6 mm Hg after follow-up of six patients with partial obstruction for 8 weeks. Although ureteral and pelvic pressures decrease toward normal ranges with chronic obstruction, they must continue to be slightly elevated because something is sending signals maintaining the alterations seen in renal function during obstruction. Because relief of the obstruction promptly reverses the process, another possible explanation would be that the distention and increased tension are sending signals initiating the physiologic response.

Alterations of Renal Function During Unilateral Obstruction: Short-term Effects

Glomerular Filtration Rate

As previously described, within minutes of ureteral obstruction, the hydraulic pressure of the fluid proximal to the obstruction rises. As the proximal tubular pressure rises, the GFR falls. The decrease in the GFR is attributable to both the rise in tubular pressure and the decrease in the area of filtering membrane when the afferent arteriole constriction begins after 5 hours of obstruction. The GFRs in rats with complete obstruction were 52% at 4 hours, 23% at 12 hours, 4% at 24 hours, and 2% at 48 hours (79,162).

Renal Blood Flow

Ipsilateral renal blood flow and ureteral pressure have a triphasic relationship during the first 24 hours of acute unilateral ureteral obstruction (Fig. 21.1) (137). The initial transient (112-hour) response is an increase in renal blood flow and ureteral pressure, indicating a preglomerular vasodilation. Pretreatment with prostaglandin (PG) inhibitors prevents this vasodilation, indicating that PGE_2 and PGI_2, which dilate vessels and are produced in the kidneys, may be responsible (1,64,101,175). Nishikawa and associates (149) and Needleman and co-workers (147) measured increased production of the vasodilating prostaglandins during acute ureteral obstruction. The increase in renal blood flow caused by acute ureteral obstruction appears to be limited to cortical blood flow, with the inner cortex having the greatest increase (190). The transient increase in renal blood flow is thought to be the result of a vasodilating prostaglandin release.

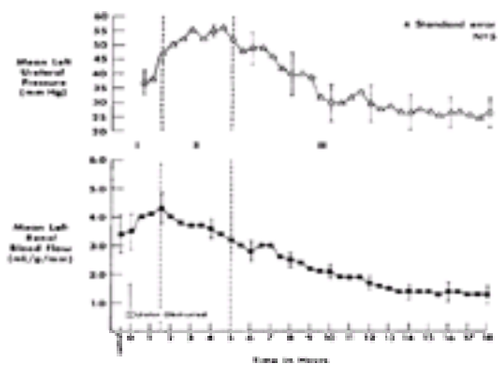

FIGURE 21.1. Triphasic relationship between ipsilateral renal blood flow and ureteral pressure during 18 hours of left complete ureteral obstruction in the dog. In phase I, both left renal blood flow and ureteral pressure increase. In phase II, left renal blood flow decreases, while ureteral pressure continues to increase. In phase III, left renal blood flow and ureteral pressure decline together. (From Vaughan ED Jr, Sorenson EJ, Gillenwater JY. The renal hemodynamic response to chronic unilateral complete ureteral occlusion. *Invest Urol* 1970;8:78, with permission.)

The second vascular phase, which consists of a decrease in renal blood flow with continuation of rising ureteral pressures, occurs 5 to 112 hours after the obstruction. The postulated mechanism is a rise in postglomerular vascular resistance.

During the third and chronic phase (5 to 18 hours), renal blood flow and ureteral pressure decrease. This fall in renal blood flow and ureteral pressure continues chronically (202). Preglomerular vasoconstriction causes the decrease in renal blood flow and lower ureteral pressure. Similar preglomerular vasoconstriction is seen in a single nephron with tubular obstruction (4).

Sheehan and associates (181) found reduced renal blood flow and thromboxane A_2 synthesis in dogs with partial ureteric obstruction. Increased renal blood flow to the nonobstructed side was associated with elevated PGE_2 formation. Elevated angiotensin I levels corresponded to maximal increases in prostaglandin synthesis.

Hemodynamic Changes in UUO

The role of vasodilator eicosanoids in phase I has been confirmed since the initial studies by Allen and associates (1), showing that pretreatment with indomethacin prevented the initial vasodilation seen with UUO. Studies have confirmed the role of vasodilator prostaglandin in causing the increased renal blood flow immediately after UUO (61,139).

The role of eicosanoids after phase III UUO is not as well established. Yarger and colleagues (227) showed a decrease in renal vasoconstriction in UUO after the administration of imidazole, a thromboxane A_2 synthesis inhibitor. Indomethacin, which decreases synthesis of both vasodilator and vasoconstrictor eicosanoids, did not increase renal blood flow.

The mechanism of the chronic preglomerular vasoconstriction in hydronephrosis has received the most experimental attention in the last 10 years. Unilateral ureteral obstruction results in decreased renal blood flow to the ipsilateral kidney and increased blood flow to the unobstructed contralateral kidney (56). The ipsilateral vasoconstriction is in part caused by thromboxanes, angiotensin, endothelin, and mesangial-cell contact (29,62,103,115,118,139,140,185,227). Increased production of vasodilators as prostaglandins opposes the vasoconstriction in the ipsilateral kidney and, in part, causes the vasodilation of the contralateral kidney (101). Chronic UUO in the guinea pig increases angiotensin-dependent renal vasoconstriction independent of renal nerves (31). Vasodilation of the opposite kidney may be mediated by the renal nerves or contralateral renal renin suppressors (32,37). Thromboxanes have been shown to act as modulators of renal vascular resistance in UUO (78,227). Vasodilator prostaglandins appear to contribute to vasodilation of the intact opposite kidney (223).

Fern and co-workers (57) studied UUO mice with no to four functional copies of the angiotensin gene and found that angiotensin regulates at least 50% of the renal interstitial fibrotic response and that a functional renal-angiotensin system is not necessary for compensatory growth. UUO was also reported by Kinter and colleagues (112) to reduce renal antioxidant enzyme activities, including those seen with sodium depletion, thus contributing to the progression of renal injury in

obstructive nephropathy.

Nitric oxide, an endothelial-derived relaxing factor (EDRF), is increased in the ipsilateral vasoconstricted rat kidney but not in the vasodilated contralateral kidney (33). Endogenous nitric oxide has a marked systemic and renal vasodilatory effect in the unobstructed normal rat (6,198,205,209,228).

Haung (82) has pointed out that in normal renal physiology nitric oxide regulates local arteriolar tone, tubular sodium handling, and mesangial-cell proliferation and causes decreased synthesis and increased degradation of matrix protein. This suggests that nitric oxide may serve as an antifibrotic in the kidney. Administration of L-arginine before UUO resulted in nearly complete restoration of renal blood flow and GFR after release of obstruction and infusion of nitric oxide synthase (NOS) inhibitor before release of the obstruction resulted in complete loss of renal function in the affected kidney. Administration of L-arginine significantly decreased the infiltrating of macrophages into the interstitium of the obstructed kidney and improved GFR (82).

Glomeruli from the contralateral vasodilated kidney produce increased PGE_2 and 6-keto PGF_{1a} (223). The increased injury to the renal medulla in obstructive uropathy has been postulated to be due to reduced O_2 as a result of reduced nitric oxide formation (13,33).

Studies from Chevalier's laboratory at the University of Virginia have shown the following:

1. In neonatal obstruction, *in situ* localization of renin and mRNA was increased with ureteral obstruction (53). In contrast, adult rats with chronic unilateral ureteral obstruction of 24-hour and 4-week duration did not manifest an increase in the distribution of immunoreactive renin or renin mRNA in the obstructed kidneys (54).
2. In chronic unilateral ureteral obstruction in newborn rats studied by El-Dahr and co-workers (53), the renal sympathetic nerves modulated renin gene expression, which leads to increased renin distribution along afferent glomerular arterioles in both kidneys.
3. EDRF modulates basal arterial blood pressure, renal vascular resistance, GFR, and effective renal plasma flow in normal rats and in rats with unilateral release of bilateral ureteral obstruction of 24-hour duration (167).
4. Neonatal unilateral ureteral obstruction in newborn rats stimulates increased renin secretion in the obstructed kidney. The increased renin secretion is from recruitment of more renin-secreting renal cortical cells and is not blocked by chemical sympathectomy (150).

The pathophysiology of obstructive nephropathy in the newborn was recently reviewed by Chevalier (19) as summarized and partly quoted here. Obstruction to urinary flow results in a complex response by the developing kidney, manifested by impaired nephrogenesis, including delayed maturation of the renal vasculature, glomeruli, tubules, and interstitial cells. In the adult, UUO stimulates renal cell proliferation. These changes may result from a combination of factors, including loss of epithelial cell polarity, a reduction in the oncoprotein bcl-2 and epidermal growth factor (EGF), and increased expression of the fibrogenic cytokine TGF-b_1. UUO in the neonate causes impaired renal growth, renal tubular dilation, tubular atrophy, and interstitial fibrosis. Recent studies have focused less on the hemodynamic effects of obstruction and more on renal cellular response and the role of growth factors (18).

The developing kidney responds differently to chronic UUO than the adult kidney (18). The RAS plays a greater role in UUO in the neonate than in the adult kidney. In the neonate, there is enhanced activity of the entire RAS, which contributes to the very high renal vascular resistance during development, which normally gradually decreases. Chronic UUO in the neonatal rat results in a marked increase in renal renin gene expression, distributed along the length of the afferent arteriole and intratubular artery rather than being localized to the juxtaglomerular region. Angiotensin II is now recognized as a vasoconstrictor and an important growth factor that can stimulate proliferation or hypertrophy of renal tubular cells. Renal renin gene expression following UUO is ten times higher in the neonate than in the adult rat. Inhibition of angiotensin markedly reduces the progression of interstitial fibrosis and apoptosis (18). Compensatory renal growth in the neonate is primarily hyperplastic, whereas that in the adult is hypertrophic (47).

Activation of the RAS stimulates the expression of a variety of fibrogenic compounds, including TGF-b_1, platelet-derived growth factor, adhesion molecules, and a-smooth muscle actin. The functional consequences of obstructive nephropathy in early development are hyperfiltration by remaining nephrons, followed by a progressive decrease in the glomerular filtration rate that may only develop in later life.

Chronic UUO in the developing kidney slows renal maturation. There are similarities between the renal response to UUO and cystic kidney disease, possibly in part because of the constriction of the nephron in cystic kidneys. The progressive increase in renal expression of TGF-b_1 contributes to progressive interstitial fibrosis. In response to urinary tract obstruction, renal tubular cells lose their polarity. The EGF receptors normally located on the basal surface in the adult become localized to the apical surfaces (18).

In another laboratory, Gulbins and associates (75) found that in hydronephrotic rat kidneys physiologic control of basal vascular tone in larger preglomerular arterioles is modulated by an endothelium and EDRF. Efferent arteriolar tone is predominantly controlled by EDRF. Reyes and colleagues (167) state, “The role of some vasoconstrictors and vasodilators in altered renal hemodynamics occurring during ureteral obstruction [has] been studied. Angiotensin II (163), thromboxane A (113), and antidiuretic hormone (168) decrease GFR and ERPF. Prostaglandins and platelet-activating factor (PAF) tend to maintain GFR and ERPF. Inhibition of vasoconstrictors angiotensin II (163), thromboxane (113), and antidiuretic hormone (168) or giving platelet activating factor increases GFR and ERPF but not to normal levels indicating other nonactive factors are involved.” Renal macrophages have been identified as the cellular source of prostanoids in hydronephrotic kidney (176).

The role of macrophages and reactive oxygen species in experimental hydronephrosis has recently been reviewed by Ricardo and Diamond (169). Reviewing the role of the infiltrating renal macrophage as a mediator of interstitial fibrosis after UUO, they postulate that “the mechanical disturbance of the proximal tubule resulting from complete ureteral ligation, elaborates a florid pro-inflammatory and pro-fibrogenic response. The initial injurious states results in the release of an array of chemoattractant signals by the tubular epithelium, including ICAM-1, osteopontin, and MCP-1, which lead to the facilitation and recruitment of macrophages into the renal interstitium. One of the many macrophage-derived products is TGF-beta, which promotes fibrogenesis by stimulating the synthesis of extracellular matrix proteins in parallel with the downregulation of matrix metalloproteins and the upregulation of matrix metalloprotein inhibitors” (169).

The role of growth factors, cytokines, and vasoactive compounds was recently reviewed by Klahr and Morrissey (113), who found that “renal interstitial inflammation and fibrosis occurs after ureteral obstruction. Fibrosis most likely develops as a consequence of an imbalance between extracellular matrix synthesis and deposition and the degradation and removal of matrix. Angiotensin II in turn upregulates other factors (TGF-b, tumor necrosis factor-a, nuclear factor-k B and several adhesion molecules and chemoattractants). Blockade of angiotensin II synthesis or inability of this peptide to bind to its receptor lessened the increased levels of mRNA for TGF-b and collagen-IV. Increased levels of angiotensin II have a major role in the development of tubulointerstitial fibrosis after ureteral obstruction” (113). The predominant physiologic alteration after 24 hours of ureteral obstruction is renal vasoconstriction. This may be due to an imbalance between vasoconstrictor and vasodilatory substances. Important vasoconstrictors include angiotensin II, thromboxane A_2, endothelin, and antidiuretic hormones. In bilateral ureteral obstruction, the leukotrienes have a vasoconstrictive effect. Vasodilators that may have a role include L-arginine (a precursor of nitric oxide), platelet-activating factor, and atrial natriuretic peptide. A decrease in these substances could cause vasoconstriction (113).

Recent studies in the research laboratory of Felsen and Vaughan have further explored the pathophysiology of UUO. The mouse kidney obstructed for 2 weeks expressed significantly more TGF-b, exhibited more tubular apoptosis and fibrosis, and had less inducible nitric oxide synthase (iNOS) expression and less total NOS activity than the contralateral unobstructed kidney. Treatment with the monoclonal antibody to TGF-b (ID11) significantly decreased tissue TGF-b concentration, tubular apoptosis, and fibrosis (136). Decreased nephrosis was accompanied by decreased p53 and increased bcl-2. Furthermore, iNOS expression in the obstructed kidney was restored by ID11 treatments, and tubular proliferation in both kidneys was significantly increased by ID11. These data suggest the possibility that ID11 can preserve the obstructed kidney in UUO.

The results using nitric oxide knockout mice demonstrate that nitric oxide appears to be protective against the apoptosis of UUO (135). Nitric oxide protects against the fibrosis of UUO (98). An *in vitro* study demonstrated that angiotensin II and mechanical stretch release NO and TGF-b from a renal tubule cell line and TGF-b is a negative regulator of NOS. In dogs, the nitric oxide system is activated during late UUO (177).

Experimental Studies of Postnatal Urinary Obstruction

Unilateral severe partial ureteral obstruction in the neonatal guinea pig results in renal growth arrest by 2 to 4 weeks (28). Three weeks after the obstruction in these animals, renal blood flow was decreased 50% and the GFR was decreased by 80%. The mechanism is thought to be ischemia caused by vasoconstriction from

angiotensin II (29). Prostaglandins and thromboxane do not seem to mediate the vasoconstriction in this experimental model (26). The reduced GFR is thought to be the result of decreased renal blood flow, raised intratubular pressures, and reduced glomerular ultrafiltration coefficient. If the contralateral kidney is impaired or removed, there is less reduction of ipsilateral renal blood flow and some compensatory hypertrophy occurs in the partially obstructed neonatal kidney (21,28). The younger the age, the more compensatory hypertrophy of the contralateral unobstructed kidney is observed (195). Factors influencing the amount of injury from partial ureteral obstruction are age at the time of obstruction, severity of obstruction, and duration of obstruction. Brief (10-day) unilateral partial ureteral obstruction in the neonate results in permanent reduction of function in that kidney. If the obstruction is relieved at 5 days, there is less impairment of function than is seen after 10 days of obstruction (22,30).

Recovery of renal function in urinary obstruction is best achieved by early relief of obstruction. A few studies in experimental animals test whether some drugs further enhance recovery. Infusion of imidazole (a thromboxane inhibitor) or captopril (an angiotensin-converting enzyme inhibitor) significantly increased GFR and renal blood flow after release from 24 hours of complete ureteral obstruction in the adult rat (227). Long-term administration of captopril improved inulin clearance and renal mass after complete unilateral ureteral occlusion of 1- to 3-week duration in adult rats. Administration of indomethacin resulted in slight improvement of GFR but not of renal mass. McDougal (131) concluded from these studies that angiotensin II production and possibly thromboxane synthesis contribute to a loss of renal function after release of obstructive uropathy in adult rats.

Chevalier and Peach (29) found in the neonatal guinea pig that administration of enalapril during ureteral obstruction significantly lowered vascular resistance. After release of neonatal unilateral chronic partial ureteral obstruction, enalapril reciprocally altered angiotensin-mediated vascular tone of both kidneys. In those experiments in neonatal guinea pigs, enalapril (angiotensin-converting enzyme inhibitor) was administered after release from 5 to 10 days of unilateral partial ureteral obstruction. Vascular resistance was not reduced in the obstructed kidney to a greater extent than systemic vascular resistance. However, vascular resistance in the intact kidney was reduced after release of the obstruction in the opposite kidney. These studies suggest that the vascular tone of the intact kidney is increased after release of obstruction on the opposite side.

Tubular Function

In partial acute ureteral obstruction, urine volume decreases, osmolality increases, and urinary sodium concentration is reduced (86,194,219). These changes result from a slower rate of tubular flow caused by a decreased GFR and higher pressures. If the ureteral pressure is elevated to 70 mm Hg, there is a 50% reduction in maximum tubular clearance of glucose and *p*- aminohippuric acid (127). After complete acute ureteral obstruction, there is an additional decrease in the glomerular filtration rate and decreased sodium concentration in the distal tubule. After release of acute ureteral obstruction of 5 to 60 minutes at a pressure of 75 to 120 mm Hg, there is a temporary concentrating defect (58,106,110).

Summary

After acute ureteral obstruction ureteral and pelvic pressures rise as high as 50 to 70 mm Hg, depending on the diuretic state. This is a higher pressure than the 20 mm Hg net filtration pressure, indicating a component of muscle contraction. Renal blood flow and ureteral pressure relationships respond in a triphasic pattern to acute ureteral obstruction. The first phase (lasting 112 hours) is renal vasodilation from vasodilating prostaglandins associated with a rise in ureteral pressure. The second phase (5 to 112 hours) consists of a continued increase in ureteral pressure associated with a decrease in renal blood flow, indicating postglomerular vasoconstriction mediated in some unknown manner. The third and chronic phase exhibits both decreasing ureteral pressure and renal blood flow, as a result of preglomerular vasoconstriction mediated in part by thromboxanes and angiotensins. During acute complete ureteral obstruction, the GFR decreases and tubular function becomes impaired. With acute partial obstruction, tubular pressure rises and the GFR decreases with a resultant decrease in urine volume because of better reabsorption, increased osmolality, and lowered urine sodium concentration.

Long-term Effects of Partial Obstruction

Studies have been performed during chronic partial obstruction in patients and experimental animal models. Evaluation of renal function during the obstruction is important because there is a different environment after release of the obstruction. Studies by Suki and associates (194), Olesen and Madsen (154), Stecker and Gillenwater (192), and Wilson (213) show significant impairment in renal functions during mild degrees of obstruction. These studies during chronic unilateral partial ureteral obstruction show reductions in renal blood flow, GFR, concentrating ability, hydrogen excretion, and sodium reabsorption. Because tubular transit time is increased, sodium reabsorption must be impaired more than the filtration rate and tubule flow rate to account for the increased urinary sodium concentrations.

Most patient studies during partial obstruction have been with bilateral ureteral obstructions. All studies have shown impairment of urinary concentration (7,9,50,51,67,129,142,200,217,218,230). Impairments of all phases of acidification (ammonia excretion, titratable acidity, and bicarbonate absorption) have been reported (7,9,51,67,129,217,218,230).

Long-term Effects of Complete Obstruction

Ureteral and Tubular Pressures

Ureteral pressures peak 3 to 5 hours after complete unilateral ureteral obstruction and within 24 hours decrease to 50% of peak values. Ureteral pressures continue to decline over the next 6 to 8 weeks to approximately 15 mm Hg (202). Proximal tubular pressure may return to normal (4) or to 70% below normal (104,225). Numerous collapsed tubules are observed on the kidney surface (81,104). Glomerular capillary pressure is reduced (43).

Renal Blood Flow

Renal blood flow measured by flow probes during continued complete unilateral ureteral obstruction shows progressive decreases that are caused by afferent arteriole constriction. Measurement showed renal blood flow to be 70% of control at 24 hours, 50% at 72 hours, 30% by 6 days, 20% by 2 weeks, 18% at 4 and 6 weeks, and 12% at 8 weeks (137,202) (Fig. 21.2). Blood flow is decreased most in the outer cortex and inner medulla (186,190,226). The mechanism of the afferent arteriole vasoconstriction is discussed earlier in this chapter.

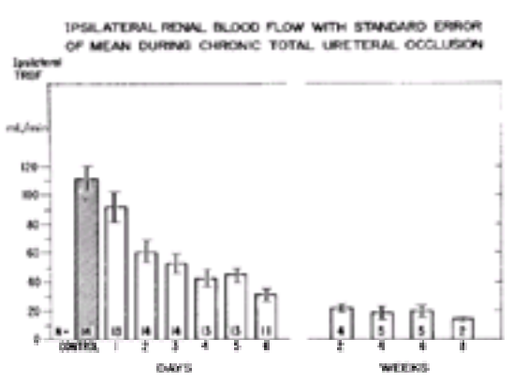

FIGURE 21.2. Changes in left renal blood flow with chronic total left ureteral occlusion in 14 dogs with chronic indwelling blood flow probes. TRBF, total renal blood flow. (From Moody TE, Vaughan ED Jr, Gillenwater JY. Relationship between renal blood flow and ureteral pressure during 18 hours of total unilateral occlusion. *Invest Urol* 1975;13:246, with permission.)

Glomerular Filtration Rate

Measurements of the GFR decrease progressively during complete ureteral obstruction in the dog, to 1.74 mL per minute at 1 week and 0.4 mL minute at 5 weeks of occlusion (145). The fluid exiting by pyelolymphatic, pyelovenous, and pyelotubular backflow is replaced by the continuing glomerular filtration. Immediately after

ureteral obstruction is released, there is minimum urine flow. One week after release from 2 weeks of obstruction, the GFR was 15% of control; maximum recovery of the GFR after release from 2 weeks of obstruction was 46% of control (200). After release from 4 weeks of ureteral obstruction, the GFR was 3% and recovered to 35% of control at 5 months (201). No return of glomerular filtration was noted in dogs after 6 weeks of obstruction with a normal contralateral kidney.

Tubular Function

All tubular functions studied, with the exception of urinary dilution, are progressively impaired by complete ureteral obstruction. Perhaps urinary dilution is unimpaired because it is not a system that requires energy. Concentrating ability is severely impaired immediately after release. This tubular function is one of the first to be injured. Recovery of concentrating ability can be complete after release from 2 weeks of complete obstruction. After release from 4 weeks of obstruction, concentrating ability is permanently impaired.

During short partial ureteral obstruction, urine osmolality is higher because of slow tubular transit times in the obstructed kidney. When the partial obstruction is released, urine osmolality falls (106).

Other tubular functions that have been shown to be impaired by chronic unilateral ureteral obstruction are maximum tubular excretory capacity of *p*-aminohippuric acid and glucose, potassium excretion, sodium reabsorption, and urinary acidification (8,36,109,201).

The main tubular effect is in concentrating ability. After release of up to 24 hours of obstruction, there is a normal flow rate of dilute urine with no sodium-losing tendency (214).

Contrasting Conditions During Ureteral Obstruction

Physiologic changes are different depending on whether the ureteral obstruction is unilateral or bilateral. With bilateral ureteral obstruction, the uremic state starts with retention of substances that are normally excreted, and one or more of these substances apparently affect renal hemodynamics and tubular function. Better understanding of clinical problems, such as postobstructive diuresis, has resulted from the study of this situation.

The surface tubules in rats look normal after 24 hours of bilateral ureteral obstruction, in contrast to the poorly perfused and filtering nephrons with collapsed tubules observed in unilateral ureteral obstruction. Proximal and distal tubular pressures are elevated in bilateral ureteral obstruction but are lower than normal in unilateral ureteral obstruction. Afferent arteriole pressure is increased in bilateral ureteral obstruction and decreased in unilateral ureteral obstruction. Glomerular capillary pressure increases to higher levels when both ureters are obstructed than when ureteral obstruction is unilateral. Renal blood flow is reduced to one-third of the control value after release of both bilateral and unilateral ureteral obstruction (24 hours). The single-nephron GFR is 40% of normal in bilateral ureteral obstruction. The reason for the decreased single-nephron GFR is the elevated tubular pressure because the glomerular capillary pressure is normal.

The explanation for the differences between the renal vascular responses in unilateral and bilateral ureteral obstruction is not known (44,81,105,133,197,206,213,214,226).

Contrasting Studies After Release of Ureteral Obstruction

The contrast in the physiologic effects of chronic (24 hours or greater) unilateral and bilateral ureteral obstruction has provided a better understanding of postobstructive diuresis. The major difference is the significant natriuresis and diuresis occurring after release of bilateral ureteral obstruction. Through different mechanisms, renal blood flow and GFR are reduced to 33% of control in both unilateral and bilateral ureteral obstruction after release from 24 hours of obstruction. In unilateral ureteral obstruction, there is afferent arteriole constriction with abnormal distribution between the cortex and the medulla, with a shift of blood flow from the outer cortex to the inner cortex and medulla (104,105). In bilateral ureteral obstruction, there is efferent arteriole constriction and normal distribution of blood flow. The reduced GFR in unilateral ureteral obstruction is caused by the afferent arteriole constriction, and the reduced GFR in bilateral ureteral obstruction is the result of the increased proximal tubule pressure. After release of bilateral obstruction, the tubular pressure returns toward normal and the GFR remains low because of new afferent arteriole constriction (172,221). Wright (220) postulated that the new afferent arteriole constriction after release of bilateral ureteral obstruction is caused by the macula densa feedback mechanism responding to increased distal delivery of tubule fluid.

The role of nitric oxide is not the same in UUO and bilateral ureteral obstruction (BUO). Following release of BUO, renal nitric oxide synthase activity is decreased (167). Following UUO, NOS activity is increased, thereby counteracting the vasoconstrictor responses (33).

Urine flow is increased up to ten times that of control after release of bilateral ureteral obstruction, in contrast to the low rates of flow and solute excretion after release of unilateral ureteral obstruction. The excretion rates of potassium, phosphate, and urea are significantly increased. After release of bilateral ureteral obstruction, diuresis occurs despite the withholding of fluid and food during the period of obstruction. The diuresis persists for several days until sodium balance is restored. The concentrating defect persists several days longer than the salt loss. The impaired sodium reabsorption occurs in both the proximal and distal tubule (14,15,133). The mechanism of the postobstructive diuresis is not known, but cross-perfusion studies have shown a buildup of a natriuretic factor in the plasma of animals with bilateral ureteral obstruction (215). Wright and Howards (222) postulated that postobstructive diuresis results from two factors: (a) distention and damage to the collecting ducts by increased luminal pressure and (b) inhibition of proximal tubular sodium reabsorption by an unidentified factor that is normally excreted in the urine.

After release of 24 hours of unilateral ureteral obstruction, the previously obstructed kidney has a normal urine flow rate of dilute urine with no natriuresis. These conditions result from reduced renal blood flow and GFR, slightly impaired sodium reabsorption, and severely impaired concentrating ability.

Leahy and associates (117) studied renal injury and recovery in partial ureteric obstruction. Creatinine clearance after release of partial ureteric obstruction showed 8% of control with 60 days' obstruction, 31% of control with 28 days' obstruction, and normal function after 14 days' obstruction. Methyl-methacrylate extrusion casts of the renal microvasculature confirmed arteriolar constriction.

Clinical Postobstructive Diuresis

Patients rarely have a severe, life-threatening diuresis after release of urinary tract obstruction. Generally, diuresis occurs only if all nephron units were obstructed in a way similar to the animal studies described previously. Excellent reviews have been published by Goldsmith (68), Howards (100), Vaughan and Gillenwater (200), Wilson and Klahr (216), Klahr and Morrissey (113), Yarger (224), and Wright and Howards (222). A diuresis generally occurs after release of bilateral obstruction. The diuresis is physiologic, usually mild, and self-limiting. Patients with bilateral obstruction have a retention of sodium and water, and the diuresis is just restoring normal fluid and electrolyte balance (142).

The postulated mechanisms for the rare pathologically significant postobstructive diuresis are (a) impaired urine concentrating ability, (b) impaired sodium reabsorption, and (c) solute diuresis caused by retained urea or administered glucose. Transient peak urine flow rates of up to 69 mL per minute, with an average of 30 mL per minute, and cases of diabetes insipidus unresponsive to vasopressin have been reported (51,171).

In the clinical situation, a patient could develop major fluid and electrolyte problems if he or she had the rare pathologic sodium or water diuresis and it went unrecognized. Our plan of management after release of obstruction is to have the patient weighed and blood pressures recorded in the upright and supine positions and ask that the physician be notified if urine volume exceeds 200 mL per hour. The thirst mechanism will correct any abnormal water loss in the conscious and alert patient. Pathologic sodium loss with resultant contraction of extracellular fluid volumes can be recognized by orthostatic hypotension. Pathologic sodium loss can be replaced by 0.5N saline solution, initially at 50% of output to avoid perpetuating a possible salt and water overload. Pathologic diuresis from nephrogenic diabetes insipidus can be recognized from urine having a specific gravity value ranging from 1.000 to 1.004. Urine from patients with impaired sodium reabsorption should be isotonic.

Relationships of Hypertension and Hydronephrosis

There are two known mechanisms whereby hypertension can result from obstructive uropathy. During acute unilateral ureteral obstruction, renin-angiotensin-aldosterone secretion is increased, with an associated hypertension (208). Also, chronic partial or complete bilateral ureteral obstruction is

associated with sodium, water, and urea retention, which produce a volume-related hypertension. In both types, the hypertension is corrected shortly after release of the obstruction. Vaughan and Sosa (203) have reviewed the subject extensively.

The incidence of hypertension with hydronephrosis is variable and not well documented. Most patients with bilateral chronic ureteral obstruction have a mild volume overload–related component to the hypertension, which is corrected by the postobstructive natriuresis and diuresis (200). In acute unilateral ureteral obstruction, patients had a 30% incidence of hypertension (178). In this same study, Schwartz (178) found the incidence of hypertension in patients to be 1.35% in chronic unilateral ureteral obstruction. Other studies have reported a 13% to 20% incidence of hypertension in chronic unilateral ureteral obstruction (12,207).

Thus most patients with chronic unilateral hydronephrosis are normotensive. Any hypertension is usually coincidental in most patients with chronic unilateral hydronephrosis. If significant, the kidney obstruction should be corrected to preserve renal function. In attempting to relate the hypertension and hydronephrosis, Vaughan and Sosa (203) point out that the patient's workup can be similar to renovascular hypertension if renin secretion is studied, contralateral renin suppression is shown, and a positive captopril test is obtained.

Fetal Hydronephrosis

Changing concepts in diagnosis and subsequent management of antenatal hydronephrosis were reviewed by Shokeir and Nijman (184). The increased use of ultrasonography for fetal–maternal screening has detected genitourinary abnormalities in 2 to 9 per 1,000 births, with a male-to-female ratio of 2:1. The major abnormality identified was hydronephrosis. A false-positive error rate of 9% to 22% is reported in the antenatal diagnosis of hydronephrosis. Explanations for the spontaneous resolution of antenatal hydronephrosis include the four- to six-times greater fetal urine flow rate than after delivery, fetal folds, and the increased compliance of the fetal ureter. The high fetal urine flow rate is attributed to differences in fetal renovascular resistances, GFR, and concentrating abilities. UPJ obstruction is the most common cause of antenatal hydronephrosis. Reflux is later diagnosed in 25% to 35% of cases.

The management of fetal hydronephrosis is controversial (184). Once hydronephrosis is diagnosed, ultrasound is repeated near term. If bilateral hydroureteronephrosis and a dilated bladder is diagnosed, ultrasound is recommended every 4 weeks. Other diagnostic tests available are amniocentesis, periumbilical blood sampling, chorionic villous sampling, and fetal urine sampling. None of these tests can accurately predict the degree of renal injury or predict the recoverability of renal function prenatally or postnatally. Prenatal intervention to relieve the obstruction has not been proven yet for routine use. Theoretically, the best opportunity would be in cases of urethral valves causing bladder outlet obstruction with progressive oligohydramnios. Shunting the urine from the obstructed bladder to the amniotic cavity should relieve the urinary obstruction and prevent the pulmonary hypoplasia associated with oligohydramnios. There are no large successful series showing the practicality of this procedure.

Screening for hydronephrosis shows a 2% incidence, with 21% of these having significant structural abnormalities requiring postnatal follow-up. Prenatal intervention for hydronephrosis gives similar outcomes as postnatal detection (39,60).

Congenital obstructive nephropathy is the principal cause of renal failure in infants and children. In the maturing kidney, urinary tract obstruction permanently impairs renal development (20).

Postnatal management of suspected hydronephrosis involves doing ultrasound several days after delivery. Unless serious abnormalities such as bilateral hydroureteronephrosis are detected, further ultrasounds are deferred until 1 month of life. Neonatal oliguria the first few days of life can mask hydronephrosis, which can be detected on the studies 4 weeks later. Diagnosis and management of the various conditions causing fetal urinary tract obstruction is dealt with in another chapter.

Glomerular Development

Chronic UUO interferes with both nephrogenesis and terminal maturation of glomeruli. Human fetuses with severe obstructive nephropathy have a reduced number of glomeruli (63). In experimental animals, relief of obstruction at 10 days does not increase the number of perfused glomeruli, but under certain conditions, GFR returns to normal, indicating that the remaining nephrons have hyperfiltration (23).

The effects of UUO on the developing tubule are profound, including suppression of proliferation, stimulation of apoptosis, and the maintenance of an immature phenotype by tubular epithelial cells. Expression of transforming growth factor-b $_1$ and clusterin are increased. Maturation of interstitial fibroblasts is delayed. Progression of tubular atrophy and interstitial cystitis results in part from continued activation of the RAS and oxygen radicals. Unlike in the adult, in the neonate, suppression of proliferation and stimulation of apoptosis are mediated at least in part through angiotensin II receptors (35).

Obstruction in the neonatal rat is attenuated by EGF (24). EGF stimulates renal tubule epithelial cell proliferation and maturation and reduces apoptosis in the neonatal rat kidney subjected to chronic UUO (25). During the critical period of nephrogenesis, impairment of the obstructed kidney and growth of the contralateral kidney are directly proportional to the duration of obstruction; thus earlier relief of obstruction may allow greater ultimate preservation of renal mass (34). However, after 5 days of obstruction in the neonatal rat, relief of obstruction does not reverse renal vascular, glomerular, tubular, and interstitial injury. Hyperfiltration and residual tubulointerstitial damage in the postobstructed kidney are likely to lead to deterioration of function in later life (27).

SURGICAL MANAGEMENT OF HYDRONEPHROSIS

All operative techniques for correction of ureteropelvic junction obstructions strive to achieve dependent drainage with an unobstructive anastomosis of the ureter to the renal pelvis. Attempts must be made to avoid parenchymal loss or ligation of any of the renal vessels. It must be remembered that any anastomosis heals by scar tissue, which will contract by about one-third of its original diameter as it matures. End-to-end or end-to-side anastomoses without spatulation of the ureter are doomed to failure.

Diagnostic Tests of Upper Urinary Tract Obstruction

Evaluation of the upper urinary tract is done (a) to determine whether it is dilated, (b) to determine whether the dilation represents a clinically significant obstruction, (c) to determine the effect of the obstruction on renal function, and (d) to determine the potential recoverability of function.

The tests used to diagnose upper urinary tract obstruction are ultrasonography, intravenous urography, diuretic renography, retrograde and antegrade pyelography, the Whitaker perfusion test, computed tomography (CT) scans (including helical CT scans), and magnetic resonance imaging with or without contrast agents. These tests have been recently reviewed by Shokeir (183).

Ultrasonography is often the first test used to screen for upper tract dilation. It is quick, noninvasive, accurate, readily available, and relatively inexpensive. The diuretic ultrasound has had limited usefulness to determine whether an obstruction is significant or not. Using Doppler ultrasound to determine the resistive index has been advocated by Platt and colleagues (160) to differentiate obstructive from nonobstructive dilation in adults. The resistive index is defined as peak systolic velocity minus lowest diastolic velocity divided by peak systolic velocity. A resistive index above 0.70 is used to differentiate obstruction from nonobstruction. In our hands, this test has not been very discriminatory.

Intravenous urography accurately depicts the anatomy of the calices, renal pelvis, and ureters but is not as accurate in quantitating the significance of any obstruction.

Diuretic renography was introduced by O'Reilly and associates in 1978 (157) and has since become an established method of diagnosing and evaluating upper urinary tract obstruction. In the diuretic renogram, an isotope is administered, and at a given time, a diuretic is administered intravenously. The ideal time activity curves under conditions of nonobstruction and obstruction are shown in Fig. 21.3. Adequate function is essential, and urethral catheters are necessary in most children. False-positive results from this test are seen in patients with poor renal function, in grossly dilated systems in which the rate of washout decreases even without obstruction, and when dehydration flattens the curves. False-negative results can occur in patients with a highly compliant (small volume, tight) renal pelvis, or when there is a forced diuresis. Accuracy is reported to be improved by deconvolutional analysis of the renogram with calculation of parenchymal transit time (212). The half-time of isotope drainage ($t_{1/2}$) after a diuretic is commonly used for evaluation. Kidneys with a $t_{1/2}$ of less than 10 minutes are considered unobstructed, and kidneys with a $t_{1/2}$ of greater than 20 minutes are considered obstructed. Those in between are equivocal. In my opinion, the accuracy of this technique is highly

variable, depending on the institution where it is performed.

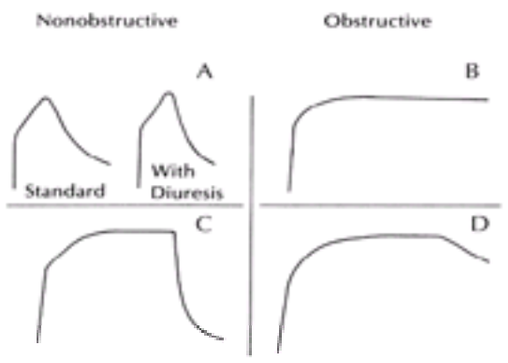

FIGURE 21.3. Typical diagrammatic diuresis renograms. *D* is where diuretics were administered; *A* is nonobstructive; *B* is obstructed with no washout; *C* is nonobstructive after diuresis; *D* is obstructive with no washout after diuresis. (Modified from Lupton EW, Richards D, Testa HJ, et al. A comparison of diuresis renography, the Whitaker test, and renal pelvic morphology in idiopathic hydronephrosis. *Br J Urol* 1985;57:119, with permission.)

Connolly and associates (38) reviewed the variability of diuresis renography interpretation resulting from the different methods used for determining postdiuretic renal pelvic clearance half-times. They found a 27.8% variation between the four methods of $t_{1/2}$ determinations, emphasizing the individual variations of studies in different institutions.

Retrograde pyelography is rarely used except to define the anatomy better in certain situations. Rapid emptying of the contrast indicates no obstruction. If a percutaneous nephrostomy tube is inserted, antegrade pyelography should be done to help define whether the system is obstructed and the site of the obstruction.

The technique and interpretation of the Whitaker test (210) requires the collecting system to be filled completely before beginning the test. Other sources of error are urine leaks when there are high urine outputs and not using a urethral catheter. Koff and colleagues (114) classified the pressure-flow patterns as simple or complex. This procedure, properly done, will help define obstruction in equivocal cases such as massively dilated systems with poor function. The obvious disadvantage is the invasiveness of placing a nephrostomy tube.

The unenhanced helical CT has become the test of choice to diagnose acute urinary tract obstruction from kidney stones and can give valuable information in other conditions with dilated upper urinary tracts.

Accuracy of the Various Tests

The available literature regarding the accuracy of these tests to determine whether an upper urinary tract dilation represents a significant obstruction was reviewed by Lupton and associates (124) and O'Reilly (156). In general, there is good correlation of the tests when there is clear-cut severe obstruction or clear-cut nonobstruction. On the equivocal cases, however, there is much disagreement.

Two studies (40,124) showed excellent correlation between diuresis renography and mean transit time through the renal parenchyma. Studies comparing diuresis renography with perfusion pressure flow studies have reported variable results, with reported correlations of 86% (179), 84% (83), 67% (124), 53% (211), and 54% (69).

Studies comparing diuresis renography with renal pelvic morphology report an 87.5% correlation between the two tests (55,71,123). Israel (102) reported a 100% correlation between diuresis renography and synchronous intrapelvic pressure measurements.

Equivocal washout studies present clinical problems. If the kidney has good function and the patient is well hydrated, O'Reilly (156) thinks an equivocal response indicates partial obstruction. When renal function is impaired, it is difficult to distinguish whether an equivocal response is caused by obstruction or by the renal impairment itself. By O'Reilly's analysis (156), 15 of 188 patients (8%) had obstruction on the diuresis renograms but normal perfusion-pressure studies. O'Reilly stated that two cases had intermittent obstruction and the other 13 had gross hydronephrosis, poor renal function, or both. Of the 188 cases, 48 (25%), including 32 previously reported by Hay and colleagues (83), had normal diuresis renograms but abnormal perfusion-pressure studies. possible explanation put forward by O'Reilly for the discrepancies is that the systems tolerated lower flow rates but not the 10 mL per minute used in the perfusion-pressure studies.

The intrarenal resistive index is a physiologic parameter that indirectly reflects the degree of resistance in the intrarenal vasculature. In a review of the literature, Rawashdek and associates (165) concluded that the intrarenal resistive index measurements are still in a developmental phase and that this technique has yet to be recognized as a dependable parameter to determine whether a dilated renal pelvis represents significant obstruction.

Indications for Surgery

The major indications for surgical repair of hydronephrosis are relief of pain or relief of significant obstruction that will destroy renal function. Intermittent hydronephrosis classically occurs during a marked diuresis and is best demonstrated by radiologic studies during the symptomatic episodes (148). Determination of whether a mild partial obstruction is significant is more difficult. The best studies are the intravenous urogram to demonstrate calyceal clubbing and dilation, diuretic renograms, Whitaker renal perfusion studies, retrograde pyelograms with washout studies, or longitudinal follow-up urograms showing progressive dilation of the renal pelvis and calyces. When an individual case is first seen with mild to moderate dilation of the renal pelvis, it is not always possible to forecast its natural history.

Ryan and associates (172) have reported that *in situ* double-J stents impair upper urinary tract motility and experimental calculus transit time and may delay passage of ureteric calculi.

Forty-one kidneys in infants and newborns were studied with diuretic renography, showing partial obstruction or dilation with obstruction that washed out with diuretics. Twelve-month follow-up showed deterioration to significant obstruction in 20%. The deterioration was more likely to occur in the markedly hydronephrotic units (99). Bilateral hydronephrosis detected antenatally was followed for up to 7 years in 26 children. Operations were never performed on 34 kidneys, and operations were performed on 18 kidneys. There was no consistent difference in final filtration rates of the two groups (107).

I have seen patients whose previous radiologic studies showed a mild hydronephrosis, presenting with significant hydronephrosis that had progressed over periods of 1 to 10 years. Thus ureteropelvic junction obstruction is progressive in some patients.

A 17-year follow-up of 36 adults with UPJ obstruction managed without surgery showed little change in function or worsening of hydronephrosis. Forty-seven patients who had pyeloplasty (and presumably more hydronephrosis) showed split function of the obstructed kidney from 40.8% to 47.1% of total function after pyeloplasty, but total GFR did not improve (111).

Lennon and associates (119) studied *in vitro* the pharmacologic options for the treatment of acute ureteric colic. Morphine was confirmed to have a spasmogenic effect on ureteric activity, which was unaffected by naloxone. Both indomethacin and diclofenac produced an abrupt inhibition of ureteral contraction, which, because of spasmolytic effects, may be indicated as therapy for the acutely obstructed ureter.

Selection of Operative Procedures

All of the operative techniques provide a dependent and progressive funneling of the ureteropelvic junction. The two basic techniques are the use of some type of

pelvic flap (41,59,173) and the dismembered pyeloplasty (3,59). Recently, balloon dilations have become popular, and they were 80% successful in 40 cases (128). Endopyelotomies have been successful as well (86%) (141). The most commonly used surgical procedure is the dismembered pyeloplasty. All the operations work, and one should not be dogmatic in declaring that one or another of the operations is best.

Meticulous care and delicate handling of the renal pelvis and ureter are essential for the success of the pyeloplasty. Small, sharp scissors and fine vascular forceps are essential to prevent crush damage of the tissues. Tissues that are frequently lifted or held should have sutures placed for traction, or skin hooks should be used. Tissue must be approximated with fine sutures (I prefer chromic catgut 4-0 or 5-0 wedged on an atraumatic needle). Knots should be placed on the outside. I prefer to use interrupted sutures beginning at the apex to avoid a “dog-ear” in this location.

I agree with Blandy (11) that too much time has been wasted arguing over whether to use stents or nephrostomies. Any urologist should know how to use both. Stents should be used if the anastomosis appears likely to kink or is obstructed by edema during the first few days. Nephrostomies are needed if renal function is unclear or if there is a high likelihood of leakage or obstruction. I generally favor using both stents and nephrostomies. In bilateral hydronephrosis, if one side is infected, that side should be repaired first. In uninfected hydronephrosis, if one side has poorer function, that side should be repaired first.

Ureteral strictures in association with ureteropelvic junction obstruction are uncommon in my experience. Ureteral strictures can be corrected during the pyeloplasty. The Davis intubated ureterotomy (45) or end-to-end anastomosis can be used.

Foley Y-plasty

The Foley Y-plasty (59) was designed for the correction of an obstructive, congenital high insertion of the ureter into the renal pelvis (Fig. 21.4). The pelvis and ureter must be dissected free. Careful planning of the pelvic incisions is essential. The anterior and posterior pelvic incisions and the ureteral incision should be approximately the same length. I have found it helpful to mark the end of each planned incision with a 4-0 silk suture. The anterior pelvic incision is started at the ureteropelvic junction and extended laterally and downward toward the hilum of the kidney. The posterior incision is then similarly made, completing the V portion of the Y incision. The ureteral incision is then made down the lateral margin (the side facing the renal pelvis). The sharp tip of the pelvic flap is rounded off. Before closure, the nephrostomy tube and stent are placed, if they are being used. Interrupted 4-0 or 5-0 chromic catgut is used for closure, starting at the tip to avoid leaving a dog-ear in the renal pelvis. I drain the area with two drains. All tubes and drains are brought out the posterior part of the wound, because it has less sensation than the anterior portion. The Foley Y-type ureteropelvioplasty can be combined with a Davis intubated ureterotomy (45) when the ureteral structure is longer than can be corrected with the Foley Y-plasty alone (Fig. 21.5). Use of stents is essential in the Davis intubated ureterotomy to provide scaffolding for new growth. I usually place several sutures loosely from the edges across the catheter to ensure that the sides lie flat and do not curl up. Davis states that the healing by secondary intention requires 6 weeks. When exposing the ureter, there should be minimum dissection to preserve the blood supply. Careful nontraumatic handling of the tissues is essential.

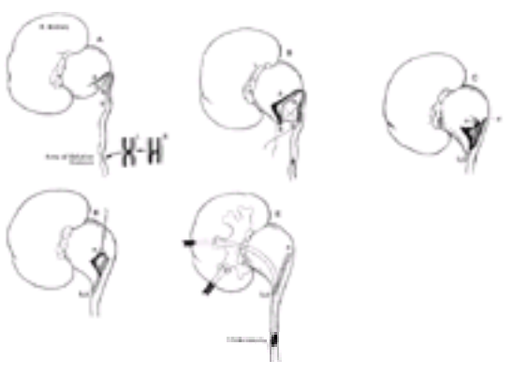

FIGURE 21.4. Classic Foley Y-plasty. **A:** Anterior and posterior pelvic incisions should be the same length as the ureteral incision. **B:** The tip of the flap and the lower end of the ureterotomy should be approximated first. **C**, **D:** The closure is started at *(b,b')* and extended upward to *(a,a')*. A dog-ear may form at point *a. I* and *II* illustrate the infrequent relative narrowing of the ureter, which is occasionally seen lower in the ureter. **E:** If there is a narrow segment, it can be treated by a ureterotomy or dilation. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH et al, eds. *Campbell's urology,* ed 4. Philadelphia: Saunders, 1979, with permission.)

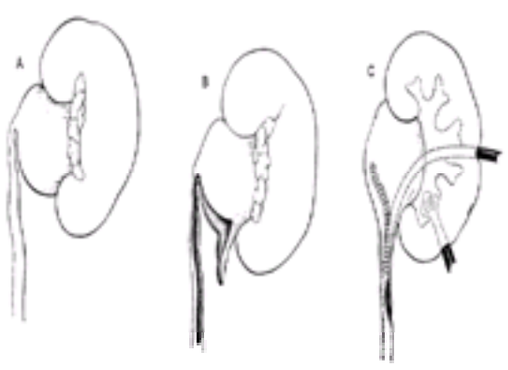

FIGURE 21.5. The classic Foley Y-plasty for high ureteral insertion with a long obstructing ureteral defect. **A:** The high insertion of the ureter into the renal pelvis. **B:** The long ureterotomy and funneling flap in the renal pelvis. **C:** The closure of the renal pelvis with the lower portion of the ureteral incision left open as a Davis intubated ureterotomy.

Dismembered Ureteropyelostomy

The operation first described by Foley in 1937 (59) and Anderson and Hynes in 1949 (3) is the most commonly used pyeloplasty and works well in most situations. The operation consists of suturing a spatulated ureter to a generous V-shaped pelvic flap. The pelvic flap is essential to provide the funneling. The kidney and ureter are dissected free, noting carefully whether there are any lower pole vessels. It is important to know how long the narrow upper ureteral segment is to plan the pelvic flap. If needed, additional length can be gained by mobilizing the kidney. Preoperative evaluation should have provided information about the length of the narrowed ureteral segment. If additional information is needed, one can open the renal pelvis and pass down a calibrating ureteral catheter or bougie à boule.

Before opening the pelvis, I plan and map out the incision, the pelvic flap, and any excess renal pelvis I am going to remove, placing marking sutures or using a marking pen. I always mark the lateral edge of the ureter where I plan to do the spatulation to prevent rotation and cutting the ureter in the incorrect place. Proper orientation is essential. It is easy to misplace the anastomosis and cause rotations or angulation if one does not pay attention, stay oriented, and properly mark the tissues. A nice aspect of this operation is that it can be used with either an intrarenal oran extrarenal pelvis. There are several ways one can fashion the renal pelvic flap (Fig. 21.6,Fig. 21.7,Fig. 21.8 and Fig. 21.9) (11).

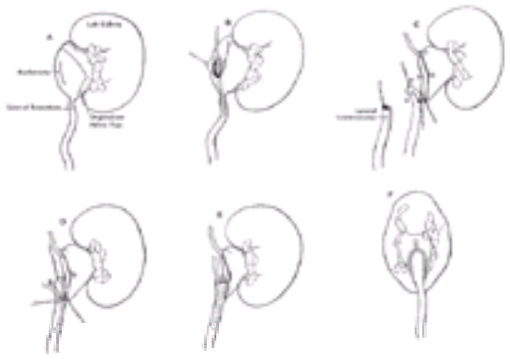

FIGURE 21.6. Dismembered Foley Y-plasty operation. The obstructing segment is excised and a dependent funneling of the pelvis is achieved. **A:** The pyelotomy and ureterotomy incisions are planned and marked. **B:** The pyelotomy incision is started. **C:** The lateral ureterotomy is done and ureteral stent passed after excising the ureteral segment. **D:** Suturing with 3-0 or 4-0 absorbable sutures is started on the posterior surface at the apex. **E:** Traction sutures are used to approximate the edges. It is important not to crush the tissue with heavy forceps. The tip of the flap is sewn to the ureterotomy. It is important to start at the apex. **F:** The funnel is completed, and any redundant pelvis can be resected. The pelvis is reconstituted. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH et al, eds. *Campbell's urology,* ed 4. Philadelphia: Saunders, 1979, with permission.)

Ureteropelvic obstruction in children. *Surg Gynecol Obstet* 1974;139:873, with permission.)

Ureterocalyceal Anastomosis

The ureterocalyceal anastomosis can be used when there seems to be no other option for anastomosing the kidney. This anastomosis is most useful when the renal pelvis cannot be dissected out or used. The procedure is more difficult and will have a higher failure rate than other procedures. The two different methods are removing a button of renal parenchyma over the lower calyx (Fig. 21.10) or opening the lower calyx by incising down to the calyx in the medial portion of the lower pole of the kidney (Fig. 21.11).

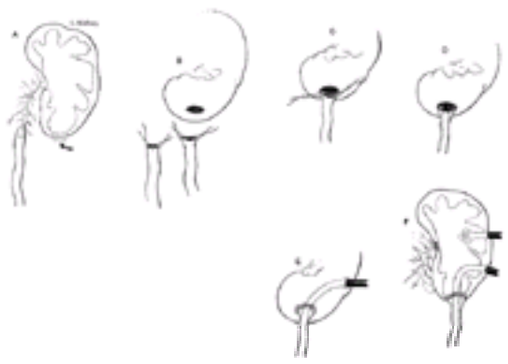

FIGURE 21.10. Ureterocalyceal anastomosis for difficult situations in which anastomosis to the pelvis is impossible. **A:** The scar tissue is excised. The renal pelvis is closed after placing a stent and nephrostomy tubes. **B:** Ureterotomies are done after orientation sutures are placed in the ureter. The ureteral opening is enlarged, ready for the anastomosis. An elliptic segment of renal parenchyma is excised. The dimensions of the opening should be the same as those of the ureter to be anastomosed. **C:** Ureter is sutured to calyceal mucosa with interrupted 3-0 or 4-0 absorbable sutures. **D:** Ureteral stent is passed after posterior anastomosis is complete. **E:** Anastomosis is completed. **F:** Diagram of funneling. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH et al, eds. *Campbell's urology,* ed 4. Philadelphia: Saunders, 1979, with permission.)

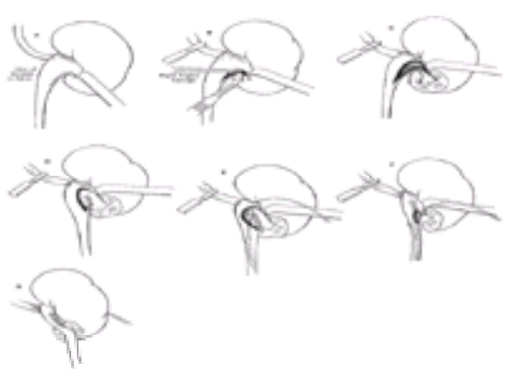

FIGURE 21.11. Ureterocalicostomy. **A:** Line of incision from ureter to renal pelvis to lower calyx. **B:** Cutting into the calyx and the lower pole parenchyma. **C:** The calyx is open and hemostasis obtained. **D:** Posterior anastomosis of the ureter to the calyx. **E:** A Cumming nephrostomy tube is used to stent the anastomosis and drain the renal pelvis. **F:** Anterior anastomosis is begun. **G:** Anterior anastomosis is completed. (Modified from Blandy J. *Operative urology.* Oxford: Blackwell Scientific, 1978, with permission.)

In ureterocalyceal anastomosis, one usually is not able to adequately dissect out the renal pelvis because of scar tissue. Usually, there is a longer narrowed segment of ureter. The ureter is cut back to normal tissue and spatulated on the lateral border. If the renal pelvis can be entered, I pass a sound down to the lower calyx and cut out an adequate button of renal parenchyma, marking the mucosal edges of the calyx for later anastomosis. If the renal pelvis cannot be entered, a guillotine type of procedure will provide access to the lower calyx.

The other type of procedure that can be used in some circumstances is the ureterocalicostomy. This procedure was devised to correct a narrow infundibulum. The renal pelvis is opened and a right-angle clamp is passed into the lower calyx. Before making the cut it is advisable to place a bulldog clamp around the renal artery, because bleeding from large veins can be tremendous. The parenchyma is cut, including the mucosa of the lower calyx. The ureter is cut on its lateral border and sutured with 3-0 or 4-0 chromic sutures to the calyceal mucosa. The sutures should be interrupted at the apex. Nephrostomy tubes and stents should always be used, because these operations have a higher risk of failure.

Extrinsic Vascular Obstruction

The Hellstrom vascular relocation procedure (85) is a simple technique for correcting renal outlet obstruction from a crossing vessel (Fig. 21.12). This procedure should be used solely when there is extrinsic obstruction only. One has to be careful that there is no intrinsic obstruction. I have operated on at least six hydronephrotic kidneys with intrinsic obstruction that previously had been thought to have only extrinsic obstruction. Intrinsic obstruction cannot be ruled out by passing a catheter through the area in question. Some of the obstructions are caused by impaired function, not intrinsic or extrinsic scarring. If there is any doubt about an area of intrinsic obstruction, I think it should be corrected at the time of surgery. In the Hellstrom procedure, the anterior herniation of the renal pelvis is placed behind the vessels, and the vessel is fixed to the renal pelvis to relieve the extrinsic obstruction.

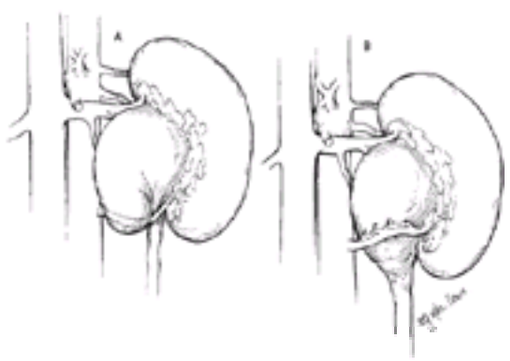

FIGURE 21.12. Hellstrom technique. The obstructing vessel is moved to a nonobstructing position. An intrinsic defect should be carefully ruled out by perfusion studies on the operating table. **A:** Anterior herniation of the renal pelvis over an obstructing renal vessel. **B:** Fixation of the renal vessels in a nonobstructing position. (Modified from Smart WR. Surgical correction of hydronephrosis. In: Harrison JH et al, eds. *Campbell's urology,* ed 4. Philadelphia: Saunders, 1979, with permission.)

Hydronephrosis in a Horseshoe Kidney

Hydronephrosis can occur in horseshoe kidneys. The obstruction is usually ureteropelvic junction obstruction and is not from pressure where the ureter crosses the kidney. The isthmus is usually medial to the obstruction and is not causing the obstruction. The problem with routine cutting of the isthmus is that one can injure major renal vessels or enter the collecting system. In my experience, most pyeloplasties can be accomplished without having to divide the isthmus. If the isthmus is thin, it should be divided with lateral placement of the lower poles.

The pyeloplasty can be done like any other pyeloplasty. The dismembered pyeloplasty is usually the preferred procedure. To expose the horseshoe kidney, one needs to make a midline or paramedian incision. The bowel is mobilized medially. The kidney usually lies in the region of the bifurcation of the aorta. Renal vessels come from the aorta and iliac arteries.

Hydronephrosis from Retrocaval Ureter

The retrocaval ureter is a congenital anomaly in which the right ureter passes behind the vena cava, causing obstruction (Fig. 21.13). The abnormality is caused by persistence of the posterior cardinal vein as the major portion of the infrarenal inferior vena cava. The kidney is approached through a flank or an abdominal incision. The renal pelvis is dissected down to where the ureter passes under the vena cava. The ureter can be cut here. The normal ureter is located as it crosses anterior to the vena cava and is cut. One then spatulates the distal ureter segments and does an anastomosis with a U-shaped flap of the renal pelvis.

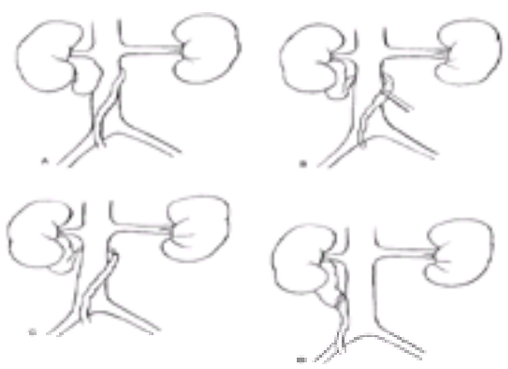

FIGURE 21.13. A: Retrocaval ureter. **B:** The renal pelvis is dissected down to where the ureter passes under the vena cava. **C:** The ureter can be cut here; the normal ureter is located as it crosses anteriorly to the vena cava, and is cut. **D:** The distal ureter segment is then spatulated, and an anastomosis with a U-shaped flap of the renal pelvis is performed.

Results of Renal Transplantation
Chapter References

Recent years have witnessed an explosive growth in the number of patients experiencing end-stage renal disease (ESRD), as well as the number of centers providing therapeutic modalities such as hemodialysis, peritoneal dialysis, and renal transplantation. Data from the United States Renal Data System (303) reveals an annual growth in the prevalent population of ESRD patients of more than 10% (Fig. 22.1), with many treated by center hemodialysis. Currently, more than 220,000 patients with ESRD require treatment. There is an age-dependent increase in the incidence of new patients with ESRD (Fig. 22.2). The mean age is 61 years, and more than half are older than 65 years. The continued aging of the U.S. population will undoubtedly ensure continued growth of the ESRD population.

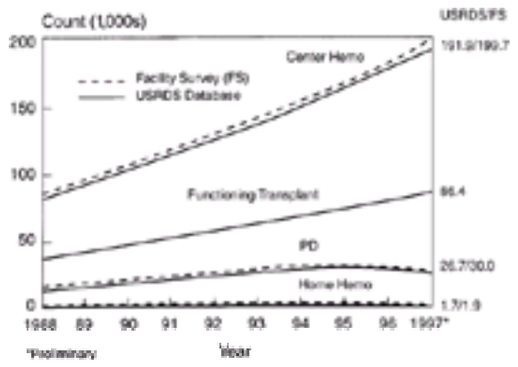

FIGURE 22.1. Point prevalence counts of patients with end-stage renal disease alive on December 31, by treatment modality and year, 1988–1997. Medicare patients only. PD, peritoneal dialysis. (From United States Renal Data System 1999 Annual Data Report. III. Treatment modalities for ESRD patients [Review]. *Am J Kidney Dis* 1999;34[2 Suppl 1]:S53, with permission.)

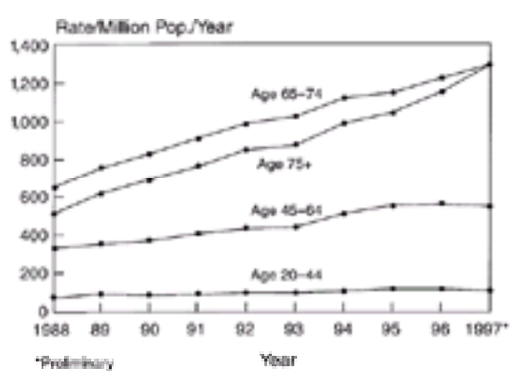

FIGURE 22.2. Incidence rates of treated end-stage renal disease per million population, by age group, 1988–1997. Medicare patients only. (From United States Renal Data System 1999 Annual Data Report. II. Incidence and prevalance of ESRD. *Am J Kidney Dis* 1999;34[2 Suppl 1]:S45, with permission.)

Although there has been continued improvement in patient survival for both dialysis and transplantation (Fig. 22.3), the mortality rate of the ESRD population continues to be approximately 20% per year. Patients with ESRD enjoy only 20% to 25% of the life expectancy of the general population (8.8 years versus 31.8 years, respectively, at ages 45 to 49). Cardiovascular events are the most common cause of death in patients with ESRD. As Fig. 22.4 indicates, death rates for dialysis patients increase dramatically for each cause among patients older than 65 years of age.

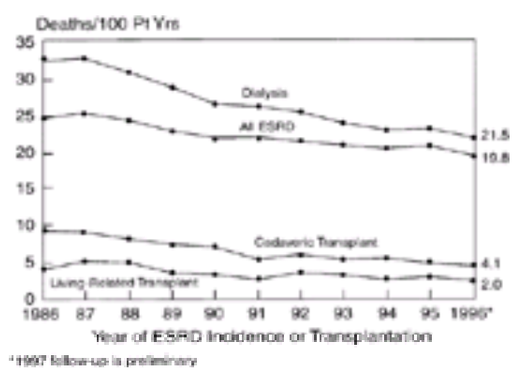

FIGURE 22.3. Death rates based on estimates from proportional hazards regression models by modality and year of end-stage renal disease *(ESRD)* incidence or of first transplantation. For each category, death rates are adjusted by age, race, sex, and diabetes to the average patient in a corresponding standard population.

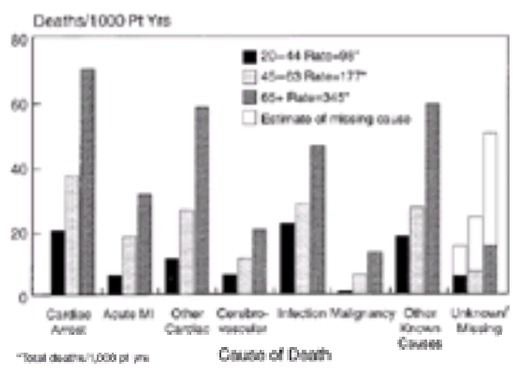

FIGURE 22.4. Cause-specific death rates for all dialysis patients by age, 1995–1997. The categories are collapsed from a death notification form. Patients younger than 20 years of age are excluded. MI, myocardial infarction. [From USRDS 1999 annual data report. *Am J Kidney Dis* 1999;34(2 Suppl 1):S88, with permission.]

The annual cost for the ESRD population in 1997 was more than $15 billion (Fig. 22.5). This is more than $43,000 per patient, with approximately 75% of this cost being absorbed by the federal Medicare program and additional amounts paid by state medicaid programs and private sources. These figures significantly underestimate the true expense because costs related to lost time from work and other expenses are not reflected.

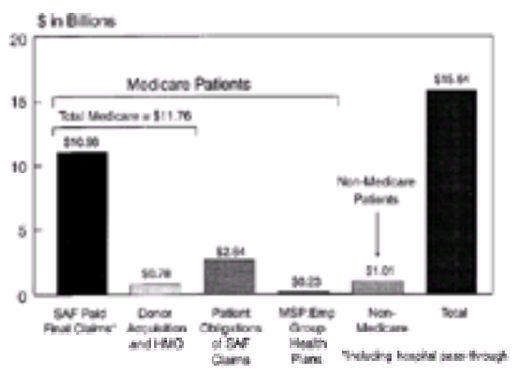

FIGURE 22.5. Estimated total direct monetary cost of treating end-stage renal disease in the United States, 1997. Separate estimates of cost are reported according to eligibility for Medicare insurance. HMO, health maintenance organization; SAF, Standard Analysis Files. [From USRDS 1999 annual data report. *Am J Kidney Dis* 1999;34(2 Suppl 1):S128, with permission.]

As a result of economic considerations, quality of life, and outcomes, renal transplantation has emerged as the preferred treatment modality for most patients with ESRD (67). However, the number of transplants performed has not kept pace with the ESRD population growth (Table 22.1), and more than 42,000 patients are now awaiting transplantation (9). As apparent from Table 22.1, the number of kidney transplants has increased over 10 years by one-third from about 8,600 to 12,000 per year. However, this has been inadequate to meet the rising number of waiting patients, which has increased more than 250% during the same period. Although there have been slight increases in the number of cadaveric organ donors, this has been attributed to an increased use of older donors (older than age 60) and those with extended criteria of organ quality (e.g., ischemia, hypertension). There has been a doubling in the number of live donor transplants in the last decade, as improved immunosuppression has permitted the use of more distant relatives and even unrelated (spouses) individuals (Fig. 22.6). Experimental work on the use of animal xenografts as a source of donor organs remains many years away from being a clinical reality (13,224), but it continues to represent the best hope to resolve the worldwide organ donor shortage problem. The severe shortage of available donor organs has had more marked implications in extrarenal (e.g., heart, liver) transplants as numerous patients awaiting transplantation die each year, and significant concerns have arisen with respect to assurance that available organs will be allocated to needy recipients in a fair and equitable manner. Federal legislation created the National Organ Procurement and Transplant Network, and the United Network for Organ Sharing (UNOS) was awarded the federal contract to develop policies for equitable organ distribution.
