Complications of intravesical thiotepa mainly are related to systemic absorption, a function of thiotepa's small molecular weight (MW = 189 Da), which facilitates transepithelial passage. Myelosuppression is the most prominent systemic manifestation, and presents as leukopenia or thrombocytopenia. Monitoring of hematologic parameters, including platelet and leukocyte counts, is recommended for patients on thiotepa therapy. Other complications include bladder irritation from a chemical cystitis. This typically manifests as urinary frequency and dysuria. The leukemogenic potential of systemic thiotepa is documented and, although no definitive causative relationship has been established, several cases of nonlymphocytic leukemia–myelodysplastic syndrome have been reported in patients following intravesical thiotepa administration (315).

Mitomycin C

Mitomycin C (MMC) is an alkylating agent capable of binding to DNA, inhibiting its synthesis and initiating strand breakage. MMC initially was reported to be effective in the treatment of bladder cancer in 1967 (312). Using a tri-weekly instillation protocol, investigators demonstrated the ablative effects of MMC. Commonly used doses for intravesical MMC are 20 to 40 mg diluted in 20 to 40 mL of sterile water. MMC can be given as a single, postresection instillation or combined with weekly instillations for 6 to 8 weeks. Monthly or quarterly maintenance protocols have also been used for prophylaxis.

MMC instillations have demonstrated efficacy in the treatment of residual, superficial transitional cell carcinoma of the bladder, or as prophylaxis following complete resection of intermediate- or high-risk lesions. Studies using various intravesical MMC protocols have demonstrated its therapeutic efficacy at treating residual T_a or T_1 disease, with most series reporting approximately a 40% complete response rate (229,272,330). A comparative study of thiotepa and MMC for the treatment of residual disease demonstrated the superior efficacy of MMC over thiotepa (39% versus 26% complete response, respectively) (128). MMC also may be used as a second-line agent for the treatment of residual superficial disease after failed thiotepa therapy (128). The National Bladder Cancer Group reported on 117 thiotepa-refractory T_a, T_1, and T_{is} lesions, in which a 27% complete response (negative cystoscopy, cytology, and biopsy) was observed. Others have reported a 20% to 50% complete response for residual disease in patients who have failed thiotepa as first-line treatment (128,150,272,349).

The effectiveness of intravesical MMC as a prophylaxis to decrease recurrences and prevent tumor progression has been studied in a multitude of randomized and nonrandomized studies. The majority of series confirm the short-term benefit of MMC in reducing recurrences following resection by approximately 40% (33,128,146,272,330,358,380). As with other intravesical chemotherapeutic agents, the benefit decreases as the follow-up period lengthens. Tolley and associates (358) reported on a randomized Medical Research Council trial, which included 447 patients with superficial bladder cancer, to evaluate the effects of a single postresection dose or multiple postresection instillations of MMC. After a median follow-up of 7 years, a 20% sustained decrease in recurrence rate was noted in the MMC-treated groups over controls. Interestingly, no statistically significant difference was observed between patients who received a single postresection dose of MMC and those who received multiple doses. A combined analysis of six randomized studies (1,157 patients) with MMC noted an overall 9% benefit in recurrences, with only two studies demonstrating a statistically significant reduction (190). The ability of MMC to prevent tumor progression was suggested initially following a report by Huland and co-workers (146), in a low-risk group of patients receiving long-term MMC instillations following complete resection and negative pretreatment

cytologies. Disease progression (stage or grade) was reported in 38% and 6% of controls and MMC-treated patients, respectively. However, multiple other studies (5,171,243,358) have failed to confirm the ability of MMC to prevent either stage or grade progression, to improve overall patient survival, or significantly decrease recurrence rates to the same degree reported by Huland and others.

Systemic complications of intravesical MMC are uncommon and related to its larger molecular weight, which leads to poor absorption. Most complications associated with MMC are local in nature and consist of irritative symptoms related to the development of a chemical cystitis. A unique skin rash consisting of a palmar desquamation also has been reported and appears secondary to a delayed hypersensitivity reaction. Infrequent complications reported with MMC use include decreased bladder capacity and myelosuppression.

Ethoglucid

Ethoglucid (Epodyl), a derivative of podophyllin, is an alkylating agent that arrests cellular division. Dosing of ethoglucid as a prophylaxis usually consists of four weekly instillations followed by monthly treatments for up to 1 year. Treatment of residual superficial disease with ethoglucid leads to a complete response in approximately 45% of patients (286). Intravesical ethoglucid has been shown to decrease short and intermediate recurrence rates compared with endoscopic resection alone. At 3 years, a 27% improved recurrence rate was observed in the etoglucid-treated group compared with controls (181). In the same study, randomized comparison of intravesical ethoglucid with doxorubicin demonstrated a similar ability of both treatments to decrease recurrences (181).

Systemic side effects, such as myelosuppression, are less common with ethoglucid compared with thiotepa secondary to its slightly larger molecular weight (262 Da). However, local irritation consisting of a chemical cystitis has been reported more frequently with ethoglucid.

Doxorubicin

Doxorubicin hydrochloride (Adriamycin) is an anthracycline antibiotic with antitumor activity. Through its ability to intercalate between bases within the DNA, doxorubicin can inhibit DNA replication and protein synthesis. Doxorubicin has been used as an intravesical agent against superficial bladder cancer in varying doses and schedules. Doses of doxorubicin that have been used range from 30 to 80 mg, usually dissolved in saline, to deliver a final drug concentration of 1 mg/mL. Schedules have ranged from a single postresection dose delivered immediately after resection to multiple weekly doses followed by a maintenance schedule. Doxorubicin has demonstrated efficacy in the treatment of residual superficial disease. Following a weekly regimen for 16 weeks, Lundbeck and co-authors reported a complete response of 52% in 64 patients, the majority of whom had T_a, grade 2 disease (201). However, with increased follow-up, only 39% of doxorubicin-treated patients remained tumor-free at 5 years (200).

Prophylactic use of doxorubicin has been studied in trials using early versus delayed treatment (single or multiple instillations) with or without maintenance. As a single postresection dose, doxorubicin was shown to decrease by 39% short-term recurrences in patients with moderate-risk disease (multifocal, low-grade recurrent papillary tumors) (396). The benefit of early exposure to doxorubicin was further confirmed by a study of the EORTC Group (30832), which suggested that early administration of doxorubicin may be of benefit over delayed therapy in low- or intermediate-risk patients (33). The same group demonstrated that maintenance therapy with doxorubicin provides no additional long-term protection against subsequent recurrence (33). In a pooled analysis of five large, controlled studies evaluating doxorubicin as a prophylaxis, three achieved a significant decrease in recurrence rates with an overall benefit of 15% (190). Comparative studies have not demonstrated a superior effect of doxorubicin when compared with other intravesical chemotherapeutic agents including thiotepa, MMC, and epirubicin. In contrast, BCG has been shown to be a more effective intravesical agent compared with doxorubicin (169,187). Currently no evidence is available to suggest a role for doxorubicin in the prevention of disease progression for superficial disease.

Doxorubicin is a high-molecular-weight molecule (580 Da) with limited systemic absorption. Systemic complications of intravesical doxorubicin are rare, whereas local complaints are more common. Chemical cystitis is the most common adverse side effect (40%), and can lead to withdrawal of therapy and/or bladder contractures.

Epirubicin

Epirubicin (4'-epidoxorubicin), an anthracycline derivative of Adriamycin, was developed in hopes of providing a drug for intravesical use with improved cytotoxic activity and decreased systemic and local side effects. Studies have demonstrated the effectiveness of epirubicin as both a treatment and prophylaxis for superficial bladder tumors. As a treatment for residual disease, 59% of patients demonstrated an initial complete response following eight weekly instillations of epirubicin (183). Longer follow-up revealed that only half of complete responders maintained a disease-free status (182), similar to outcomes reported with Adriamycin (200). The EORTC completed a randomized trial of 399 patients with low-risk disease (solitary T_a, T_1 lesions), comparing a single, immediate postresection, 80-mg dose of epirubicin with controls (saline instillation) following complete endoscopic resection (254). After an average follow-up of approximately 2 years, a 50% reduction in tumor recurrences was observed in patients with both low- and high-risk lesions. Cystoscopy at 5 to 7 weeks after treatment demonstrated a significant early benefit in the prevention of tumor recurrences, providing additional evidence that immediate exposure to epirubicin after resection can effectively treat residual occult disease as well as possibly inhibit tumor cell implantation (254). This study also provided evidence that, in low-risk patients, a single postresection dose was as effective as longer, multiple-dose regimens. Alternative protocols using multiple instillations have confirmed the beneficial prophylactic effect of epirubicin. Comparative studies have evaluated epirubicin versus doxorubicin with contradictory results, demonstrating either an improved outcome with epirubicin (7), or no advantage (254). The overall superiority of BCG over epirubicin in preventing recurrent disease, particularly in higher-risk patients (T_1, grade 3), has been observed (66,224).

The side effect profile of epirubicin appears improved compared with doxorubicin. Chemical cystitis in up to 10% of patients may occur and lead to cessation of therapy. Allergic skin reactions also have been reported as a rare complication. Similar to doxorubicin, epirubicin is associated with minimal systemic side effects.

Immunotherapy

The importance of the immune system as a surveillance mechanism capable of recognizing and eliminating tumor cells led to the development of strategies that centered on immune system stimulation to both augment cancer cell recognition and promote tumor cell–specific cytotoxicity. Several concepts emerged from experimental immunotherapeutic evaluations: (a) that cancer cells have the ability to evade immune system recognition as an important survival mechanism, (b) that most tumor cells can be made susceptible to immune effector cell–mediated killing following modulation of the immune system, and (c) that modulation of the immune system via supplementation *in vitro* or *in vivo* of appropriate cytokines can mimic immune stimulation leading to tumor-specific cytotoxicity.

Bacille Calmette-Guérin

Mycobacterium bovis BCG is an attenuated strain of mycobacterium developed at the Pasteur Institute by Albert Calmette and Camille Guérin. Its most common use has been as a vaccine for the prevention of tuberculosis (TB). Initial observations that the immunomodulatory effects of BCG may induce antineoplastic activity suggested a possible role in the treatment of cancer. Direct experimentation with BCG as an antineoplastic agent was initially suggested from work on leukemia (218). Although this early excitement led to its investigation as a treatment for a variety of neoplasms, poor efficacy and complications with its administration limited its acceptance.

The use of BCG in the treatment of bladder cancer was strengthened by the work of Coe and Feldman (55), who demonstrated in a pig model that the bladder was able to mount a delayed hypersensitivity-type reaction. In 1976, Morales and associates (234) reported on the results of a successful trial evaluating the prophylactic activity of intravesical BCG to prevent recurrent superficial bladder cancer. Over the next two decades, BCG emerged as the most effective intravesical treatment for superficial transitional cell carcinoma of the bladder, including CIS (50,216,217). Many of the available substrains of BCG (TICE, Frappier, Connaught, Pasteur) have demonstrated activity against superficial tumors. Standardization of treatment regimens using BCG remains controversial. Selection of the optimal strain has been difficult, because different strains have demonstrated variations in mycobacterial viability and/or titer and overall immunostimulatory activity. These variations have contributed to the inability to accurately compare reported trials. Studies on the routes of administration (intravesical, intralesional, with or without intradermal dosing) have established that intravesical exposure alone is adequate to elicit the needed immune response and provides an improved margin of safety compared with intratumoral injections (189).

In contrast to chemotherapeutic agents in which the observed cytotoxic activity typically occurs in a dose-dependent manner, immunotherapeutic substances reach a threshold response beyond which additional exposure may result in the activation of immune regulatory mechanisms that limit the effectiveness of the agent. Immune system stimulation of intravesically administered BCG occurs after binding of the mycobacterium to the bladder via an interaction with the extracellular-matrix protein, fibronectin (50). Fibronectin–BCG interaction (mediated by specific, high-affinity receptors expressed on the mycobacterium cell surface) facilitates uptake of the

mycobacterium by the cellular components of the bladder (tumor, epithelial, and immune) and leads to intracellular processing of mycobacterial proteins. These are presented subsequently to immune effector cells, which initiates the production of cytokines capable of nonspecific immune system stimulation via macrophages, natural killer (NK) cells, and lymphocytes (355,397). Experiments characterizing *in vivo* BCG activity demonstrate the absolute requirement for an intact immune system, including sufficient CD4+ and CD8+ T-cell function, so that a delayed-type hypersensitivity reaction can be generated (279). Antigen-specific CD4+ cell stimulation leads to the release of a Th_1 (cell-mediated) cytokine profile, many of which can be detected within the urine of BCG-treated patients, and may serve as a marker of antitumor activity (31). CD8+ cytotoxic T-cell and macrophage activation occurs following cytokine release and serves as the effector cells of tumor antigen–specific and nonspecific cytotoxic activity. Interaction with concomitantly administered agents or drugs that interfere with BCG binding (anticoagulants that effect fibronectin formation) or mycobacterial viability (antibiotics such as isoniazid, trimethoprim-sulfamethoxazole [TMP-SMX]) should be avoided to maximize mycobacterial-bladder interaction, immune system stimulation, and subsequent antitumor effects of intravesical BCG.

Protocols for the use of intravesical BCG have been determined empirically and the optimal regimens have yet to be determined. Differences in biologic activity (mycobacterial titer and viability) among the various available strains of BCG, as well as variations in dosing and duration of the instillation protocol, have made it difficult to establish a standardized regimen. A wait period of at least 1 week, but usually 2 to 4 weeks, after endoscopic resection before the initiation of an induction phase (consisting of weekly instillations for 6 weeks) is common to all BCG regimens. Unlike chemotherapy, in which a beneficial response may be observed by eliminating tumor cell implantation following TURBT, immediate use of BCG will enhance systemic absorption of the mycobacterium and subsequent complications, including life-threatening sepsis. Maintenance therapy with BCG following induction treatment remains controversial. Studies have been reported that demonstrate no benefit to maintenance BCG therapy (21,145); however, the number of patients evaluated may have underpowered these studies, limiting their ability to detect a reasonable difference in recurrence. Several studies also have reported significantly improved outcomes in patients who had received maintenance instillations of BCG, albeit at the expense of additional side effects. The Southwest Oncology Group (SWOG) randomized 384 patients with CIS, T_1, or multifocal and/or recurrent T_a tumors. Following complete resection, all patients received 81 mg of Connaught BCG intravesically and 0.5 mL percutaneously weekly for 6 weeks. Upon completion, 192 were randomized to receive maintenance therapy, consisting of three weekly instillations and percutaneous treatments at 3 and 6 months and every 6 months for 3 years. A significant improvement in the time to recurrence (36 versus 77 months) was noted in the observation and maintenance groups, respectively. However, no significant benefit in overall survival was observed following maintenance BCG treatment (188).

Several clinical uses for BCG therapy in the management of superficial bladder cancer have been established, and include the eradication of CIS, T_a, or T_1 disease, and as a prophylaxis against disease recurrence and tumor progression following complete endoscopic resection. BCG has demonstrated the ability to eradicate residual superficial papillary disease (T_a/T_1) as well as CIS, but should not be used in place of definitive endoscopic resection (37,61,69,235). A complete response rate of 50% to 60% has been reported using BCG on residual T_a and T_1 lesions. BCG may be used successfully to treat superficial transitional cell carcinoma of the prostatic urethra (35,141,300). Tumor that lies outside of contact with the BCG (tumor involving the prostatic stroma or acini, as well as invasive disease into the muscle layer of the bladder wall) will not be treated effectively with intravesical BCG. Similarly, upper tract tumors also will not be treated effectively with intravesical BCG. Direct instillation of BCG into the upper portions of the collecting system can be used to manage superficial, upper tract transitional cell carcinoma, although this experience is limited (226).

Patients with CIS of the bladder are at high risk for disease progression and require either effective intravesical therapy or cystectomy to eliminate tumor progression. Although many chemotherapeutic agents exhibit activity against CIS, BCG has emerged as the most effective therapy. Overall, approximately 70% to 75% of patients with CIS experience a complete response following an initial exposure to intravesical BCG (61,69,135,137,185,187,188,191). Studies have shown that an initial induction course (six weekly instillations) of BCG will effect a complete response in 31% to 88% of patients. Of those that fail after an initial course of BCG, 39% to 58% can be treated effectively with a second course of BCG immunotherapy (49,120). The timing of the follow-up evaluation after BCG treatment may be of importance in characterizing a lesion as nonresponsive. Herr and colleagues (133) demonstrated that nearly one-third of patients with clinically detectable disease at 3 months after exposure to induction BCG subsequently will demonstrate no evidence of residual disease at 6 months with further observation only. Despite the favorable initial responses to BCG, disease ultimately will recur in many patients, and a significant number will progress in stage and grade. Nadler and associates (240) reported the long-term outcome of 104 patients who had received either one or two courses of BCG for high-risk lesions. With a median follow-up of 65 months, only 25% of patients treated with one course, and 41% of patients treated with two courses, were without disease. Of great importance was the significant number of failures that occurred after a 5-year disease-free interval. Many of the BCG failures demonstrated progressive disease, mandating that long-term follow-up be performed. The rapid recurrence of CIS following BCG treatment portends a more aggressive outcome (34) and may identify a particularly high-risk group of patients who should proceed to additional, aggressive therapy such as early cystectomy.

Extensive experience has been reported comparing the relative efficacy of intravesical chemotherapy and BCG in the treatment of superficial papillary lesions and CIS. A growing body of data now suggests the superiority of BCG as primary therapy for CIS and high-risk papillary lesions over other intravesical agents. Overall, a 20% to 25% improvement in complete responses are observed in patients treated with BCG as a prophylactic compared with patients who received intravesical chemotherapy. Furthermore, long-term evaluation of disease control appears to be maintained following BCG exposure. In contrast, the observed long-term outcomes following intravesical chemotherapy demonstrate that less than 20% of patients with CIS remain disease-free. Although many studies directly comparing MMC, thiotepa, and Adriamycin with BCG suggest a superior response with BCG (70% compared with 30%, 45%, and 40% complete response rates for thiotepa, doxorubicin, and MMC, respectively), conflicting studies have been reported. Witjes and co-workers (379) reported the long-term results of an EROTC randomized trial comparing MMC (30 mg weekly for 4 weeks, then once monthly for 5 months) and BCG (BCG RIVM 5×10^8 bacilli weekly for 6 weeks). Data on 344 patients (median follow-up of 7.2 years) demonstrated no advantage for BCG in reducing recurrences, disease progression, or overall survival. The results of this study contrast with the SWOG study comparing MMC (only 20 mg in 20 mL) to TICE BCG (50 mg in 50 mL) given in six weekly administrations followed by monthly maintenance for 1 year. Overall, 377 patients at relatively high risk for a disease recurrence were evaluable. Early closure of the study was ordered after an interim analysis revealed a 40% recurrence in the BCG-treated patients compared with a 57% recurrence in the MMC-treated group (185). Lundholm and associates (202) reported an MMC and BCG randomized comparison involving 261 high-risk patients (T_{is} and T_1). At a median follow-up of 39 months, 49% of BCG patients were free of disease compared with 34% of the MMC-treated patients. Studies have also demonstrated improved activity for BCG treatment as a prophylaxis compared with Adriamycin (187,217). Lamm and co-authors (217) reported a 37% improvement in disease-free survival in patients with CIS treated with BCG compared with patients who received Adriamycin. In addition, the superiority of BCG therapy over thiotepa has been documented.

Although most studies have demonstrated the ability of BCG to decrease recurrence rates, the ability of BCG to delay or prevent tumor progression and improve overall survival remains controversial. Most studies evaluating the therapeutic outcome of BCG on superficial bladder tumors have not observed a decrease in disease progression following treatment. This may be due, in part, to a large percentage of relatively low-risk lesions included in most reported studies. Despite high rates of tumor recurrence, the well-documented low risk of progressing to invasion limits the statistic power of most studies to identify a significant difference in disease progression. However, Herr and associates (138) have reported the long-term follow-up of 86 high-risk patients with refractory T_a and T_1 disease (most with associated CIS) who were randomized to receive early intravesical BCG or observation followed by intravesical treatment at the time of failure. At 10 years, progression-free survival was significantly better in the early BCG treatment group (62%) compared with the control group (37%), more than 50% of whom received delayed BCG therapy. In addition, 10-year disease-specific survival was improved in the early BCG–treated group compared with TURBT alone (75% versus 55%, respectively).

The toxicity of BCG therapy remains a major concern when considering treatment options for superficial disease. In general, toxicity of BCG increases with the intensity of the regimen. The route of administration, number of injections, and dose of mycobacterial organisms used affect the type and extent of adverse reactions. Comparisons of toxicity between BCG and chemotherapy suggest a worse profile for BCG. The variability of dose and mycobacterial viability among strains and specific lots has made it difficult to identify and quantitate the toxicity differences between the various strains of BCG. Patients with lowered immune responses are at higher risk for complications from BCG exposure. Patients with active TB, immunologic deficiency syndromes (including human immunodeficiency virus [HIV] positivity), leukemias, or Hodgkin's disease should avoid BCG exposure. Similarly, pregnant patients and transplant recipients on immunosuppressive therapy are not appropriate candidates. Patients with active urinary tract infections should undergo a complete course of antibiotic therapy before BCG exposure to decrease the possibility of systemic absorption of mycobacterium and limit local complaints. Antibiotics administered for cystitis simultaneously with intravesical BCG may decrease viability of the mycobacterium and limit its efficacy.

Toxicities may be categorized as local or systemic, as well as minor and severe. Local symptoms following intravesical BCG are most common (more than 90%) and consist of irritative symptoms. These irritative symptoms are thought to be secondary to a chemical cystitis, but may represent the clinical manifestation of the desired immunostimulatory response. The lack of local symptoms following repeated BCG exposures may signify an inadequate stimulation of an immune response within the bladder. Symptoms consist of dysuria and frequency, and typically begin after the third dose and worsen with subsequent exposures. Pyridium, diphenhydramine, and anticholinergics are recommended for symptomatic relief. Hematuria (43%) may occur in combination with the cystitis and seldom is severe. Gross hematuria, when present, may be problematic and require endoscopic intervention to clear. Subsequent treatments should be postponed until the hematuria clears, to limit the possibility of increased systemic absorption and sepsis. Severe local complications including ureteral obstruction (0.3%) and contraction of the bladder (0.2%) are

rare and can be self-limiting after cessation of exposure. Both require postponement of further BCG exposure and long-term anti-TB therapy. Granulomatous prostatitis is a more common local complication following intravesical BCG (0.9%). Prostate examination and prostate-specific antigen (PSA) determinations should be obtained before the initiation of therapy, because both may change following BCG exposure and simulate cancer of the gland. Most cases of granulomatous prostatitis are asymptomatic; however, acute inflammation and urinary tract obstruction may ensue, which requires treatment consisting of isoniazid and rifampin for 3 to 6 months.

BCG is delivered as a live mycobacterial solution and, although its virulence has been attenuated, under the correct circumstances it may disseminate and continue to proliferate as an established mycobacterial infection. It is thought that the dose of BCG used in intravesical protocols should include at least 10 million organisms to be efficacious, a lethal dose if given systemically. Systemic side effects of BCG include fever, chills, influenza-like symptoms, malaise, pneumonitis, hepatitis, rash, arthralgia, renal abscess, cytopenia, and sepsis. Fevers are encountered frequently (28%) and can be accompanied by chills and malaise. Low-grade fevers (less than 38.5°C) usually are self-limiting and responsive to antipyretics and hydration. Subsequent BCG doses should be postponed until all symptoms resolve, and pretreatment with isoniazid should be given at least 1 day before BCG exposure and continued for 3 days or until symptoms resolve. Higher fevers typically resolve within 48 hours; however, they cannot be distinguished from early, progressive systemic infections. Patients with high fevers that do not resolve within 12 hours should be hospitalized, placed on isoniazid and rifampin with the addition of ethambutol (1,200 mg daily) if patients become critically ill, and closely observed for signs of progressive sepsis. The increased risk of subsequent severe reactions with additional exposures must be weighed carefully against the risks of bladder cancer before recommending continuation of therapy. Granulomatous hepatitis or pneumonitis have been reported in 0.7% of cases, and when they are identified, BCG therapy should be stopped and isoniazid, rifampin, and ethambutol administered for 3 to 6 months. Sepsis following intravesical BCG is the most serious complication encountered. It was reported in 0.4% of patients and can be fatal if not quickly recognized and effectively treated. Intravascular absorption of BCG through the bladder is the common finding in patients experiencing sepsis. Traumatic catheter placement at the time of BCG instillation, active cystitis, and recent endoscopic tumor resection or biopsy may facilitate intravascular absorption. It is recommended that treatment be postponed if a traumatic catheterization is suspected to have occurred before BCG administration. In addition, a minimum of 1 week, and preferably 2 to 4 weeks, should pass after endoscopic biopsy or tumor resection before BCG instillations are initiated.

The diagnosis of BCG sepsis must be made early so that treatment may begin without delay. The association of high fevers, shaking chills, hypotension, mental confusion, coagulopathy, or other signs of sepsis following BCG exposure warrant immediate hospitalization and treatment. Isoniazid, 300 mg, and rifampin, 600 mg daily, along with 1,200 mg of ethambutol daily is recommended. Corticosteroids (prednisone 40 mg per day) may be added in critically ill patients and is recommended over the use of cycloserine. Most recommend 6 months of treatment following a severe systemic complication, although others suggest that a shorter, 6-week course will suffice.

Interferons

Although BCG has proven to be an effective treatment for superficial bladder cancer, its potential for significant adverse effects and intolerance by some patients has led to the search for alternative immunotherapeutic agents. Interferons, a class of naturally occurring glycoproteins, demonstrate a myriad of *in vivo* functions including antiproliferative, immunoregulatory, antiangiogenic, and antiviral activities. The antitumor effects of interferons are thought to occur by both direct and indirect mechanisms. Interferons enhance tumor-antigen expression, which can improve immune cell function and tumor clearance. Interferons have direct antiproliferative effects on tumor cells and have been identified as potent inhibitors of endothelial cell activation, a necessary step in tumor-induced angiogenesis. Both animal studies and clinical trials have demonstrated the antitumor activity of interferons against bladder cancer cells.

The clinical efficacy of interferons for the treatment of residual superficial bladder tumors has been studied in several prospective trials. Although several routes of administration have been used, including intramuscular, intralesional, and intravesical, it appears that intravesical delivery may be most effective. As with other forms of intravesical therapy, comparing published studies of interferon therapy is problematic due to the differing doses and schedules used. Intravesical interferon therapy effects a response in treating residual papillary tumors or CIS in 0% to 67% of patients. In one of the larger multiinstitutional trials evaluating the ability of interferons to treat CIS, Glashan (109) reported a 65% overall response rate (43% complete response, 23% partial response) in patients who had received 100 million units of recombinant interferon-alfa weekly for 12 weeks followed by monthly maintenance for up to 1 year. This study demonstrated that, although interferon therapy was less effective than BCG as front-line therapy for CIS, it was able to eradicate disease in patients who had previously failed BCG therapy. Although no large studies quantitating the effectiveness of interferons on chemotherapy have been published, smaller reports document the ability of interferon therapy to salvage such patients. The results of a larger experience evaluating the ability of interferon to rescue patients with recurrent or persistent disease after BCG treatment are available. Approximately 20% of patients who are either BCG intolerant or with BCG-resistant disease will have a complete response with high-dose interferon treatment.

Several trials designed to study the ability of interferons to serve as a prophylaxis have been completed. Although long-term data are available, short-term recurrence rates of 20% to 60% have been reported. Randomized studies comparing chemotherapy and BCG with interferon treatment also have been reported. A multicenter Italian trial compared MMC with interferon alfa-2b therapy in patients with T_a or T_1 primary tumors. In 287 patients, an 11% advantage in the short-term recurrence rate was found in MMC-treated patients compared with those who received interferon. Randomized studies comparing BCG with interferon consistently have demonstrated responses in favor of BCG treatment. In addition to second-line treatment, combination therapy that includes interferon along with either BCG or chemotherapy may be effective. Animal studies using murine models of bladder cancer have demonstrated a synergistic response when interferon is combined with an intravesical chemotherapeutic agent or BCG.

These observations are supported by mechanistic data suggesting that interferons work to enhance the immunologic response initiated following BCG exposure.

Bropirimine

Bropirimine is a small-molecular-weight, aryl pyrimidine with immunomodulatory activity. Its antitumor effects are thought to be secondary to its broad-ranging stimulation of the immune system. Bropirimine is capable of stimulating B-cell proliferation, macrophages, NK cells, and lymphokine-mediated T-cell activation, leading to increases in both humoral and cell-mediated responses. As an oral agent, bropirimine has demonstrated efficacy in treating residual superficial transitional cell carcinoma. Most reported trials have used a dosage of 3 g per day for 3 consecutive days each week for up to 1 year. Sarosdy and co-authors (298) reported the results of a phase II trial in which a 61% response rate was observed in 33 evaluable patients with CIS of the bladder. Of the 12 patients who had failed prior BCG therapy, 6 (50%) responded to bropirimine therapy. Upper tract CIS also has been reported to respond to bropirimine. Toxicities include headaches, rashes, arthralgia, and transient hepatic enzyme elevations. Despite initial promising reports, bropirimine has not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of superficial bladder cancer.

Other Immunologic Agents

Keyhole limpet hemocyanin (KLH) is a highly immunogenic protein found in the primitive mollusk, megathura crenulata. KLH serves to enhance immune system function by stimulating a nonspecific and perhaps tumor-specific (by means of cross-reacting antigens) immunologic response. KLH has been shown to decrease bladder tumor growth and prolong animal survival using the murine MBT2 model system. Patients treated with KLH demonstrate an intense inflammatory reaction not unlike the immune response observed following exposure to BCG.

Clinical trials evaluating the efficacy of KLH as a treatment for superficial bladder cancer have demonstrated response rates comparable with those seen for BCG, however with significantly less toxicity. Intravesical KLH was found to provide improved disease recurrence rates when compared with mitomycin or Epodyl. Jurincic and associates (164) reported a 39% versus 14% recurrence in 44 patients treated with MMC 20 mg monthly, or KLH 1 mg subcutaneously, then 10 mg intravesically monthly, respectively. Lamm and co-workers (186) reported a 66% overall response rate in 51 patients treated with KLH for residual disease, noting that patients with CIS responded most favorably. The particular advantage of KLH over BCG is low toxicity associated with intravesical KLH. Indeed, some studies have reported no toxicity associated with intradermal or intravesical KLH, making it a desirable alternative to BCG.

Specific mediators of the immune response also have been used directly to modulate both T- and B-cell antitumor responses. Tumor necrosis factor (TNF) has been evaluated as an intravesical agent in a small group of patients with superficial bladder cancer by the Eastern Cooperative Oncology Group. No long-term responders to TNF therapy have been reported.

Interleukin-2 (IL-2), an immunomodulator used as part of therapy for melanoma and renal cell carcinoma, has been tested as an antitumor agent against superficial bladder tumors. Both intravesical and intralesional IL-2 induced responses; however, further phase 2 trials are needed to establish its clinical efficacy and

comparative activity to currently available agents.

Hematoporphyrin Derivatives

Photodynamic therapy consists of the systemic administration of a photosensitizing compound that can be activated following exposure to light of the proper wavelength. The proposed mechanisms by which photodynamic therapy exerts its cytotoxic activity include the production of oxygen singlet and superoxide radicals that produce vascular endothelial and bladder epithelial damage, tissue hypoxia, generation of a nonspecific immune reaction, and intense local inflammatory cell infiltration.

Photodynamic therapy holds promise as a treatment for superficial bladder cancer because, theoretically, it has the ability to treat the entire bladder surface with a single treatment. Prout and colleagues (274) reported that nearly half of 19 patients treated with photodynamic therapy for residual superficial disease had a complete response. Second-line treatment for BCG-refractive or BCG-resistant CIS has been another proposed application of photodynamic therapy. In a recent multicenter study, 36 patients with CIS who had received at least one prior cycle of BCG were treated with a single whole-bladder treatment of porfimer sodium and red laser light (630 nm). At the initial 3-month evaluation, 58% were free of disease; however, at 12 months only 31% remained without evidence of disease (248). The intense inflammatory reaction and subsequent hypoxia secondary to endothelial cell damage leads to a postphotodynamic therapy syndrome consisting of pain, urinary frequency, urgency, and nocturia. A severe adverse consequence of photodynamic therapy is contraction of the bladder, which has been reported in 4% to 20% of patients. Based on the lack of long-term follow-up data on patients treated with photodynamic therapy, and that 11 of 14 patients in the aforementioned study who failed photodynamic therapy and underwent cystectomy had evidence of extravesical disease, caution must be practiced before recommendation of such therapy in this high-risk group of patients.

Radiation

For those cases of superficial bladder cancer in which transurethral resection and intravesical therapies have failed, definitive treatments such as radiation therapy or radical cystectomy have been used. Experience with radiation therapy as a definitive treatment for superficial disease has not been studied extensively. The available evidence from uncontrolled studies suggests that, overall, radiation therapy is not an effective long-term treatment for T_a disease or CIS. Although some report an initial high response for T_a lesions to radiation, nearly 90% will demonstrate a recurrence within 5 years. Careful evaluation for the presence of associated CIS should be sought in patients under consideration for radiation, because complete responses in patients with CIS are rare. The response of superficially invasive T_1 lesions is related to grade. Higher-grade lesions respond better to radiation as compared with grades 1 and 2 lesions. Some have advocated radical radiation as a treatment for T_1G_3 disease, reporting a 55% to 64% 5-year survival.

Cystectomy

The role of radical surgery in the management of superficial disease is reserved for high-risk patients who are not candidates for intravesical therapy, who have failed attempts at disease control with intravesical therapy, and who have superficial lesions not amenable to endoscopic resection alone. Failure of intravesical therapy manifests as persistent superficial disease, progressive disease with worsening grade or evidence of invasion of the muscle wall, or the development of metastatic disease. For patients with high-risk lesions (T_1, high-grade, CIS), long-term progression rates may be as high as 50% to 80%. The aggressive behavior of high-grade lesions, superficially invasive (T_1) tumors, and CIS must be considered carefully when additional intravesical agents are recommended for patients who have failed initial or second-line intravesical therapy. BCG, recognized as the most effective intravesical agent for high-risk disease, clearly delays the development of progressive disease, but has not demonstrated definitively the ability to prevent the long-term risk of progression. Although studies with shorter-term follow-up documented a decreased progression rate following BCG therapy, long-term follow-up demonstrates no difference in progression in patients treated with or without BCG following resection. Indeed, up to one-third of high-risk patients treated conservatively with BCG will die of bladder cancer if followed for more than 10 years (132).

Radical cystectomy rarely is required for managing superficial bladder cancer; however, when used in properly selected patients, it provides survival rates that are similar to age-matched controls. Freeman and co-workers (94) reported on patients with refractory superficial disease, noting that up to one-third of the high-risk patients who presented for radical cystectomy were understaged. Of the patients with upstaged lesions, 50% demonstrated evidence of extravesical extension or metastasis to the regional lymph nodes. The high rates of extravesical and metastatic disease found at the time of cystectomy in patients with high-grade T_1 tumor and CIS, who failed previous attempts at intravesical treatment, underscore the importance of prompt intervention at the earliest sign of refractory or progressive disease. The advances in continent and orthotopic lower urinary tract reconstructive options has improved patient acceptance of cystectomy and provides an improved quality of life to patients needing early radical intervention.

MANAGEMENT OF INVASIVE BLADDER CANCER

The successful management of invasive bladder cancer requires a careful understanding of its natural history and recognition of histologic features obtained from the initial biopsy to predict behavior and appropriately direct the use of a variety of therapeutic options available to the urologic oncologist. Histologic grade of the initial bladder cancer remains the single most important predictor of behavior for any individual bladder cancer (163,319).

The natural history of bladder cancer assumes its origin from transitional epithelium. The histologic grade is the most significant predictor of tumor invasion. In general, low-grade tumors (1 and 2) present as superficial disease confined to the mucosa. These tumors have a tendency to recur, but rarely invade, and can be managed conservatively by transurethral resection (TUR). However, high-grade tumors (3 and 4) often present with evidence of deep invasion, are often associated with adjacent or remote CIS, and are associated with an adverse prognosis regardless of presenting stage. Marshall and associates (215) illustrate the 5-year survival for patients with high-grade transitional cell carcinoma (transitional cell carcinoma) managed by segmental resection according to the presenting stage (Table 30.1). At 5 years, there is virtually no difference in survival for patients who present with high-grade tumors, despite being initially diagnosed with superficial disease. Others have reported similar results for patients with high-grade superficial tumors treated by TUR (8,24,90,131,132,151,203). The natural history of high-grade bladder cancer is to invade sequentially the lamina propria and the muscularis propria, to gain access to lymphovascular spaces, and to invade into the perivesical fat and contiguous structures. As the depth of invasion increases, so does the incidence of metastatic disease to the pelvic lymph nodes and beyond. Important prognostic factors should be obtained at the time of initial biopsy. These include the presence or absence of invasion into the muscularis propria, an assessment of normal-appearing epithelium adjacent to and remote from the primary tumor to detect CIS, or the degree of epithelial dysplasia (8). The degree of involvement of the lamina propria significantly impacts on prognosis for tumors not showing invasion of the muscularis propria (144). Invasion deep into the lamina propria or invasion of the muscularis mucosa implies an ominous prognosis similar to those tumors invading the superficial muscularis propria (130). The presence of lymphovascular invasion also significantly impacts on prognosis. Molecular markers will undoubtedly be used in the future to guide management. Currently, evidence suggests that tumors with a p53 mutation or deletion (based on immunohistochemical staining) show a far greater propensity for progression than similar tumors that have a wild-type or normal p53 gene (81). Other markers such as p21, p16, and RB have been shown to adversely impact on behavior (134,341).

TABLE 30.1. SURVIVAL FROM FIRST SYMPTOM OF PATIENTS WITH HIGH-GRADE BLADDER CANCER REGARDLESS OF STAGE

Therapeutic options for management of invasive bladder cancer range from conservative measures (endoscopic resection with or without the use of intravesical pharmacotherapy) to more aggressive procedures, ranging from segmental resection to definitive radiation therapy, or the combination of extended TUR with chemotherapy/radiotherapy, and finally, radical cystectomy. Selection of the optimal treatment requires a careful weighing of the consequences of undertreatment, as well as the therapeutic efficacy and side effects related to each form of therapy.

Perhaps the biggest dilemma confronting the urologic oncologist regarding bladder cancer is the limitation of current clinical (T) staging. For example, of the patients thought to have primary transitional cell carcinoma confined to the lamina propria (T_1), 30% will be found to have muscle-invasive disease at the time of cystectomy, and half of those patients already have extension of cancer outside the bladder (96). In general, current clinical staging with IVP, CT, MRI, and the information derived from cystoscopic evaluation and bimanual examination results in at least a 40% understaging (P>T) and a 10% overstaging (P<T) (364). These facts need to be considered carefully when advising the individual patient regarding treatment options. The ultimate goals in management should be to cure the disease and to prevent local progression and development of metastatic disease. Unlike other malignancies (such as prostate cancer), patients who fail the initial treatment of an invasive bladder cancer will likely die of their disease, usually within 3 years of presentation. Furthermore, although efforts have been made to improve treatment of metastatic bladder cancer with chemotherapy, the prognosis is generally poor, underscoring the need for definitive therapy early at the curable stage.

Herr and associates (134) reported the best 5-year survival rates for patients with muscle-invasive transitional cell carcinoma who were managed by systemic neoadjuvant chemotherapy and TUR. In a small group of highly selected patients with documented muscle invasion, 28 achieved T_0 status following TUR and methotrexate, vinblastine, Adriamycin, and cisplatin (MVAC) chemotherapy and refused definitive surgery. Of those 28 patients, 17 (61%) remained alive with an intact bladder at 10 years. Most series using TUR as primary management for high-grade, invasive bladder cancer report survival rates ranging from 20% to 45% (24,90,130,144,151,203).

Segmental resection is an attractive option for many patients and physicians, because it implies bladder preservation with surgical removal of the affected part of the bladder. In the properly selected patient, segmental resection appears to provide results that are equal to or better than those achieved by cystectomy (136,247,320). However, great caution must be exercised in recommending segmental resection in the management of high-grade, invasive bladder cancer. In fact, very few candidates are appropriate for segmental resection. In the two largest series reporting the results of segmental resection, fewer than 5% of more than 5,400 patients who presented with a primary invasive bladder cancer were deemed appropriate candidates for this option, and there have been no substantial series reporting results in the last 20 years (320,364). The problem with segmental resection is the reality that the epithelium remote from the primary cancer is under the same carcinogenic influence that resulted in the primary cancer. The probability of recurrence or understaging the initial cancer places patients who choose segmental resection at great risk for recurrence and ultimate death from metastatic disease. Appropriate candidates for partial cystectomy are those with grade 2 muscle-invasive disease, whose primary cancer is more than 2 cm from the bladder neck with multiple selected biopsies remote from the primary tumor showing no epithelial atypia. Selected patients with small urachal mucinous adenocarcinomas may be appropriate candidates, but in general, these patients are still best managed by cystectomy with orthotopic diversion to the urethra. In highly selected male patients, prostate-sparing cystectomy with orthotopic urinary diversion to the prostatic urethra seems preferable to segmental resection (334). This provides preservation of sexual and urinary function, including ejaculatory function and fertility, while providing a better cancer operation and segmental resection with little added morbidity.

In the 1950s, radical cystectomy emerged as the standard form of therapy for patients with high-grade, invasive bladder cancer. However, the morbidity of the operation, the need for an ileal conduit for urinary diversion, and the fact that early results indicated that only approximately 50% of these patients were cured led many patients to opt for less effective alternatives or to defer cystectomy until the disease was no longer curable. During the 1960s and 1970s, in an effort to improve survival, various protocols of preoperative radiation therapy before cystectomy were attempted but failed to provide any benefit to survival (11,322,327,374,375 and 376).

For the past 30 years, the primary alternative to radical cystectomy has been definitive radiation therapy. Table 30.2 shows the best contemporary published results achieved by radiation therapy, with reported 5-year survival being less than 50% in all series, and few patients ever becoming candidates for salvage by cystectomy (70,110,152,212,310). These results are clearly inferior to those reported in cystectomy series, and places patients at significant risk for recurrence and disease progression.

TABLE 30.2. MUSCLE-INVASIVE BLADDER CANCER: BLADDER SPARING—RADIATION THERAPY ALONE

Recently, a growing interest in bladder-sparing protocols have evolved using a vigorous TUR of the primary tumor, followed by chemoradiation therapy (75,166,306,354). Results achieved by these various protocols appear in Table 30.3. It is noteworthy that the number of patients treated in the bladder-sparing protocols are few, and despite only short-term follow-up in all series, 5-year survival remains less than 50%, with fewer than one-third of these patients maintaining a functional bladder at 5 years. Importantly, two of the five referenced groups reporting results have subsequently abandoned the bladder-sparing protocol (75,107). None of these groups have addressed the issue of toxicity or true bladder function following the chemotherapy/radiotherapy protocol. In addition, the overall treatment burden of these bladder-sparing protocols is considerable, requiring nearly 6 months of treatment with repeated cystoscopies and biopsies, and with a treatment-related mortality that equals that of radical cystectomy.

TABLE 30.3. MUSCLE-INVASIVE BLADDER CANCER: BLADDER SPARING (TURBT + CHEMOTHERAPY + RADIATION)

To reiterate, the primary goals of any treatment of high-grade, invasive bladder cancer should be (a) tumor-free survival, (b) avoidance of pelvic recurrence or metastatic bladder cancer, and (c) quality of life. The development of metastatic bladder cancer following failure of local treatment is nearly uniformly fatal with few

durable complete responses from any form of systemic chemotherapy.

Clinicians at the University of Southern California (USC), have developed an aggressive surgical approach for patients with high-grade, invasive transitional cell carcinoma of the bladder, which includes an en bloc cystectomy with bilateral pelvic iliac lymph node dissection and continent urinary diversion (342). Improvement in medical, surgical, and anesthetic therapy have clearly reduced the morbidity and mortality associated with contemporary surgery. This, coupled with the evolution of continent urinary diversion, especially orthotopic lower urinary tract reconstruction to the native urethra, has now provided both male and female patients a more acceptable means to store and eliminate urine, lessening the impact of cystectomy on quality of life.

In 2001, Stein and colleagues (342) reported the results achieved in patients undergoing radical cystectomy for the management of high-grade, invasive bladder cancer. In this group of 1,054 consecutive patients, 69% were without evidence of disease with an overall survival of 62% at 5 years (Fig. 30.27) (342). Nearly all deaths from bladder cancer occurred during the first 3 years following cystectomy. After 3 years, few patients died as the result of bladder cancer. However, in all bladder-sparing protocols, patients continued to be at significant risk and to die of metastatic bladder cancer as long as the bladder remained *in situ.* The 5- and 10-year recurrence-free and overall survival reported in this study is believed to represent the gold standard for which other therapy should be compared and judged.

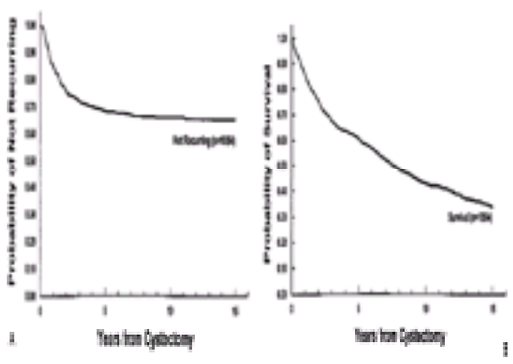

FIGURE 30.27. A: University of Southern California (USC)/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of nonrecurrence. **B:** USC/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of survival.

The importance of pathologic stage as it relates to recurrence-free and overall survival is shown in Fig. 30.28 (342). In addition, certain pathologic subgroups have been identified, which stratify patients into different prognostic categories that help dictate the need for adjuvant therapy following cystectomy (Fig. 30.29). The recurrence-free survival rate of 85% at 5 years is noteworthy, as is the 82% survival rate at 10 years for patients with organ-confined, lymph node–negative disease. No survival difference was observed when comparing superficially noninvasive (P_{is},P_A), lamina propria–invasive (P_1), and muscle-invasive (P_2–P_{3A}) tumors as long as the tumor was confined to the bladder (342). Similar results for organ-confined transitional cell carcinoma treated by cystectomy have been reported by others (105,267).

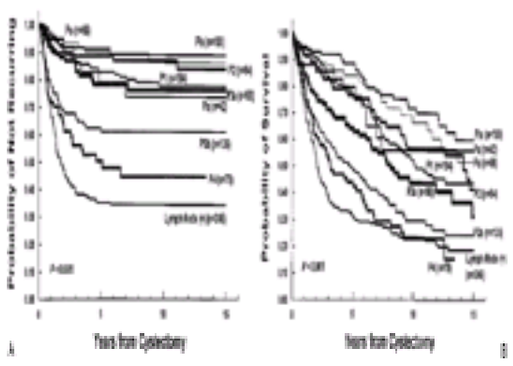

FIGURE 30.28. A: University of Southern California (USC)/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of not recurring by pathologic stage. **B:** USC/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of survival by pathologic stage.

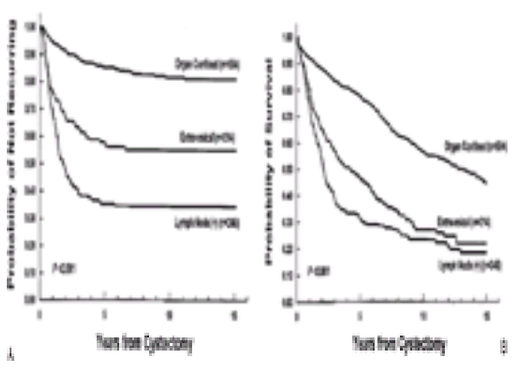

FIGURE 30.29. A: University of Southern California (USC)/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of not recurring. **B:** USC/Norris Bladder Cancer Experience in 1,054 patients undergoing cystectomy: probability of survival according to pathologic groups.

However, once the transitional cell carcinoma escapes the confines of the bladder, prognosis changes. The 5- and 10-year recurrence-free survival for patients with P_{3B},P_4 tumors is only 59% and 56%, respectively, despite being lymph node negative (342). Those patients with extramural tumor demonstrated a significantly higher recurrence rate and worse survival compared with those with organ confined disease. This suggests that patients with extravesical bladder tumor are at increased risk of recurrence and progression and should be considered for adjuvant forms of therapy following surgery.

Despite an early and aggressive attitude toward high-grade, invasive bladder cancer, approximately 25% of patients undergoing cystectomy for invasive bladder cancer in the USC series were found to have metastatic disease to the pelvic lymph nodes (342). This underscores the virulent and metastatic capabilities of high-grade, invasive bladder cancer. However, it has been shown that an aggressive surgical approach with en bloc pelvic iliac lymph node dissection can cure nearly 35% of these patients. The prognosis in patients with lymph node–positive disease can be further stratified by the number of involved lymph nodes and by the stage of the primary bladder cancer (P stage). It has been reported that patients with fewer than five positive lymph nodes following an appropriate pelvic lymphadenectomy at cystectomy had a 40% recurrence-free survival at 10 years, compared with 23% of patients with five or more involved nodes. The extent of the primary bladder tumor also impacts on recurrence for patients with positive lymph nodes. Patients with lymph node–positive disease, whose primary bladder cancer was organ confined (P_A–P_{3A}), had a significant recurrence-free survival advantage (45%) compared with those whose primary tumor extended outside the bladder (P_{3B}–P_4) (342). Similar observations have been reported by others (105,195,267,368). Although patients with lymph node involvement have the highest recurrence rates, a substantial number of patients who will clearly benefit from a meticulous lymph node dissection remains (267). Nonetheless, patients with lymph node involvement are at high risk for recurrence and should be considered for adjuvant treatment strategies.

Improved medical, surgical, and anesthetic techniques have dramatically decreased the mortality and morbidity of radical cystectomy. In more than 1,054 patients in Stein and associates' series (342), a 2.5% mortality rate has been reported, which is comparable with other contemporary series of patients undergoing radical cystectomy (93,105). The reported early complication rate at 27% included all complications within the first 4 months of surgery, most of which could be appropriately managed conservatively without further sequelae. This early complication rate is similar to that reported by others (93,105,267). The addition of preoperative therapy (radiation and/or chemotherapy) or the form of diversion performed (continent versus incontinent) did not significantly alter the mortality or morbidity rate in this large group of patients (342). Strict attention to perioperative details, meticulous surgery, and a team-oriented surgical and postoperative approach are critical to minimize morbidity and mortality, and to ensure the best clinical outcomes following radical cystectomy in these patients.

Radical cystectomy provides the best local control for the treatment of high-grade, invasive bladder cancer (342). An overall local pelvic recurrence rate of 7% has been reported. Patients with organ-confined, lymph node–negative tumor demonstrate only a 4% pelvic recurrence, those with node-negative extravesical extension (P_{3B},P_4) demonstrate a 10% pelvic recurrence, and patients with lymph node–positive disease had an 11% pelvic recurrence following cystectomy (342). Currently, no other form of therapy for high-grade, invasive bladder cancer provides comparable local control.

The use of high-dose, short-course preoperative radiation therapy does not reduce the risk of pelvic recurrence regardless of pathologic stage. Local recurrence following radical cystectomy is a highly lethal problem. Few patients can be salvaged by any combination of chemotherapy and/or radiation therapy, with nearly all dying of disseminated disease within 2 years. Patients have been treated who developed local pelvic recurrence as their first site of failure following cystectomy with aggressive combination chemotherapy (MVAC). Some also received radiation therapy and further surgical resection. Only three (10%) became long-term survivors, with a median survival of 9.1 months for the entire group. Patients who failed with distant disease, and who also demonstrated local recurrence did even worse. Patients whose initial failure showed both local pelvic recurrence and distant metastatic disease with aggressive combination chemotherapy (MVAC) also have been treated. There were no long-term survivors, and the median survival was 5.7 months. There were 175 patients treated whose initial failure was outside the pelvis. Only 11 (6%) were cured by aggressive combination chemotherapy (MVAC or cisplatin, methotrexate, and vinblastine [CMV]), with a median survival of 6 months.

These data clearly underscore the lethality of a tumor recurrence following cystectomy. The dismal prognosis of tumor recurrence following cystectomy raises important considerations in the technical performance of radical cystectomy. Traditionally, the operation widely resects the neurovascular bundles leading to loss of erectile function. Some authors advocate nerve-sparing cystectomy in an effort to preserve erectile function (302). However, the best results have reported an efficacy of preserving erectile function of only approximately 35%, and the risk of increasing the incidence of pelvic recurrence remains unclear. Because the lymphatics draining the trigone and posterior bladder wall run along the neurovascular bundles, these patients are best served by radical cystectomy that widely resects the neurovascular bundles and placement of a penile prosthesis that will restore good and effective erectile function without risking increased pelvic recurrence. It also should be noted that clinical staging and preoperative predictor factors currently fail to clearly identify appropriate patients for nerve-sparing techniques.

Development of orthotopic lower urinary tract reconstruction has dramatically reduced the impact of cystectomy and the quality of life issues following removal of the bladder (77,78,343,345). Orthotopic diversion has lessened the need for a cutaneous stoma, eliminated the urostomy appliance, and limited the need for intermittent catheterization. Continence rates following orthotopic diversion are excellent, providing patients a more natural voiding pattern per urethra. Currently, more than 90% of female patients are considered candidates for orthotopic diversion with a low risk of tumor recurrence following reconstruction (343,345). It is believed that the only contraindications to orthotopic urinary diversion are the presence of tumor within the urethra or extension to the urethral margin, compromised renal function (creatinine greater than 3.0 mg/dL), or the presence of inflammatory bowel disease. Even for patients with locally advanced disease, orthotopic urinary diversion can be employed without concern about subsequent tumor-related reservoir complications (124). The option of lower urinary tract reconstruction to the urethra also has been shown to decrease physician reluctance and to increase patient acceptance to undergo early cystectomy for bladder cancer when the disease may be at a more curable stage (124). Whether patients enjoy a better quality of life following cystectomy or bladder-sparing protocols, which require significant prolonged treatment to the bladder with increased potential for tumor recurrence, remains an issue. However, the argument for bladder-sparing protocols has diminished with the availability and successful application of orthotopic urinary diversion following cystectomy.

Age is another important consideration in management options for patients with high-grade, invasive bladder cancer. It is better to provide the best therapeutic options for older patients with high-grade, invasive bladder cancer rather than temporizing or being conservative because of the age of the patient (86). In these patients, a high-grade, invasive bladder cancer is more likely to shorten the life span of elderly patients than other medical age-related problems that can occur as a result of the operation. Four hundred four patients older than 70 years of age (including 52 patients older than 80 years) who underwent radical cystectomy for the management of high-grade, invasive bladder cancer were studied and compared with 762 patients younger than 70 years of age who underwent the same operation (86). The operative mortality rate was 2% in patients younger than the age of 70, 3% in patients ages 70 to 79, and 0% for patients 80 or older. There were no differences in the early complication rate between the three groups. The median hospital stay following cystectomy was 10 days in patients younger than 70 years, compared with 11 days for those patients older than 70 years. In patients older than 70 years, 60% survived more than 3 years without tumor recurrence. Older patients are also appropriate candidates for orthotopic lower urinary tract reconstruction, although continence rates may be less than those achieved in younger patients. Results showed that a total of 85% of patients older than 70 years of age achieved good (52%) or satisfactory (33%) urinary continence. *Good* was defined as requiring no protection, and *satisfactory* was defined as requiring three or fewer pads over 24 hours. In patients younger than 70 years of age, 88% achieved a similar level of continence, but a greater number (73%) judged their continence as good and 15% as satisfactory (78). These findings support the notion that it is better to treat older patients according to their physiologic age rather than chronologic age, and high-grade, invasive bladder cancer remains a lethal disease in patients of all ages.

Perhaps the greatest advantage to radical cystectomy over any other form of therapy is the fact that it pathologically stages the primary bladder cancer and regional lymph nodes. This histologic evaluation provides important prognostic information and, together with the development of molecular markers, helps identify high-risk patients who could benefit from adjuvant therapy (341). Patients with extravesical tumor extension, or with lymph node–positive disease, are at high risk for recurrence and should be considered for adjuvant treatment strategies. In addition, recent information regarding molecular markers such as genes p53, p21, and RB provides additional information that may help identify patients who will truly benefit from certain chemotherapy drugs and indicate those patients who will not benefit from these drugs and can be spared the toxicity (341).

EN BLOC RADICAL CYSTECTOMY AND PELVIC–ILIAC LYMPHADENECTOMY

Surgical Technique in Male and Female Patients

Preoperative Preparation

Patients undergoing radical cystectomy are admitted the morning before surgery for a mechanical and antibacterial bowel preparation and IV hydration and to be evaluated and counseled by the enterostomal therapy nurse. A clear-liquid diet may be consumed until midnight, at which time the patient takes nothing by mouth. A standard modified Nichols bowel preparation (242) is initiated the morning of admission: 120 mL of Neoloid orally at 9:00 AM; 1 g of neomycin orally at 10:00 AM, 11:00 AM, 12:00 PM, 1:00 PM, 4:00 PM, 8:00 PM, and 12:00 AM; and 1 g of erythromycin base orally at 12:00 PM, 4:00 PM, 8:00 PM, and 12:00 AM. This regimen is well-tolerated, obviates the need for enemas, and maintains nutritional and hydrational support. IV crystalloid-fluid hydration is begun the evening before surgery, and maintained to ensure an adequate circulating volume as the patient enters the operating room.

Patients older than 50 years of age routinely undergo prophylactic digitalization before cystectomy unless there is a specific contraindication. Digoxin is given orally, with dosages of 0.5 mg at 12:00 PM, 0.25 mg at 4:00 PM, and 0.125 mg at 8:00 PM. Evidence suggests that preoperative digitalization may decrease the risk of perioperative arrhythmias and congestive heart failure in the elderly patient undergoing an extensive operative procedure (40,264). In addition, IV broad-spectrum antibiotics are administered en route to the operating room, providing adequate tissue and circulating levels at the time of incision.

Preoperative evaluation and counseling by the enterostomal therapy nurse is a critical component to the successful care of all patients undergoing cystectomy and urinary diversion. Currently, approximately 90% of male and female patients requiring cystectomy for bladder cancer are appropriate candidates for orthotopic diversion (77,339). Patients considered to be appropriate candidates for orthotopic reconstruction are instructed how to catheterize per urethra, should it be necessary postoperatively. All patients are site marked for a cutaneous stoma, instructed in the care of a cutaneous diversion (continent or incontinent form), and instructed in proper catheterization techniques should medical or technical factors preclude orthotopic reconstruction. The ideal cutaneous stoma site is determined only after the patient is examined in the supine, sitting, and standing positions. Proper stoma-site selection is important to patient acceptance and to the technical success of urinary tract reconstruction should a cutaneous form of diversion be necessary. In general, incontinent stoma sites are best located higher on the abdominal wall, whereas stoma sites for continent diversions can be positioned lower on the abdomen (hidden below the belt line), because they do not require an external collecting device. The clinicians at USC also have found the umbilicus to be an excellent site. This cutaneous site allows for easy catheterization and the stoma, if properly

placed at the base of the umbilicus, is completely camouflaged and nonvisible.

Patient Positioning

The patient is placed in the hyperextended supine position with the iliac crest located just below the fulcrum of the operating table (Fig. 30.30). The legs are slightly abducted so that the heels are positioned near the corners of the foot of the table. In the female patient considering orthotopic diversion, the modified frogleg position is used, allowing access to the vagina. Care should be taken to ensure that all pressure points are well padded. Reverse Trendelenburg position levels the abdomen parallel with the floor and helps keep the small bowel contents in the epigastrium. A nasogastric tube is placed, and the patient is prepped from nipples to midthigh. In the female patient, the vagina is fully prepped. After the patient is draped, a 20-Fr Foley catheter is placed in the bladder, and left open to gravity. A right-handed surgeon stands at the patient's left side of the operating table.

FIGURE 30.30. Proper patient positioning for cystectomy. Note that the iliac crest is located at the break of the table. (From Skinner DG, Lieskovsky G. *Diagnosis and management of genitourinary cancer.* Philadelphia: WB Saunders, 1988, with permission.)

Incision

A vertical midline incision is made extending from the pubic symphysis to the cephalad aspect of the epigastrium. The incision should be carried lateral to the umbilicus on the contralateral side of the marked cutaneous stoma site. The anterior rectus fascia is incised, the rectus muscles are retracted laterally, and the posterior rectus sheath and peritoneum are entered in the superior aspect of the incision. As the peritoneum and posterior fascia are incised inferiorly to the level of the umbilicus, the urachal remnant (median umbilical ligament) is identified, circumscribed, and removed en bloc with the cystectomy specimen (Fig. 30.31). This maneuver prevents early entry into a high-riding bladder, and ensures complete removal of all bladder remnant tissue. Care is taken to remain medial and avoid injury to the inferior epigastric vessels (lateral umbilical ligaments) that course posterior to the rectus muscles. If the patient has had a previous cystotomy or segmental cystectomy, the cystotomy tract and cutaneous incision should be circumscribed full-thickness and excised en bloc with the bladder specimen. The medial insertion of the rectus muscles attached to the pubic symphysis are slightly incised, maximizing pelvic exposure throughout the operation.

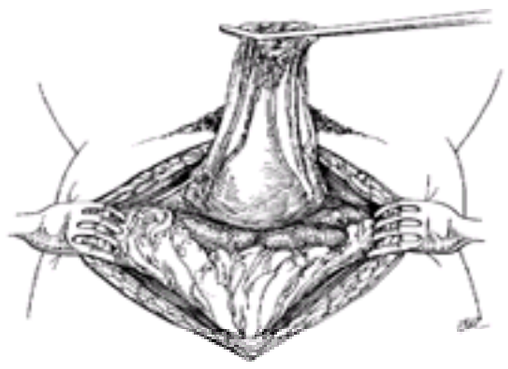

FIGURE 30.31. Wide excision of the urachal remnant en bloc with the cystectomy specimen. (From Walsh, Retik, Stamey, et al., eds. *Campbell's urology,* 6th ed. Philadelphia: WB Saunders, 1992, with permission.)

Abdominal Exploration

A careful systematic intraabdominal exploration is performed to determine the extent of disease and to evaluate for any hepatic metastases or gross retroperitoneal lymphadenopathy. The abdominal viscera are palpated to detect any concomitant unrelated disease. If no contraindication exists at this time, all adhesions should be incised and freed.

Bowel Mobilization

The bowel is mobilized starting with the right colon. A large right-angle Richardson retractor elevates the right abdominal wall. The cecum and ascending colon are reflected medially to allow incision of the lateral peritoneal reflection along the avascular/white line of Toldt. The mesentery to the small bowel is then mobilized off its retroperitoneal attachments cephalad (toward the ligament of Treitz) until the retroperitoneal portion of the duodenum is exposed. Combined sharp and blunt dissection facilitates mobilization of this mesentery along a characteristic avascular fibroareolar plane. Conceptually, the mobilized mesentery forms an inverted right triangle; the base is formed by the third and fourth portions of the duodenum, the right edge is represented by the white line of Toldt along the ascending colon, the left edge is represented by the medial portion of the sigmoid and descending colonic mesentery, and the apex is represented by the ileocecal region (Fig. 30.32). This mobilization is critical in setting up the operative field, and facilitates proper packing of the intraabdominal contents into the epigastrium.

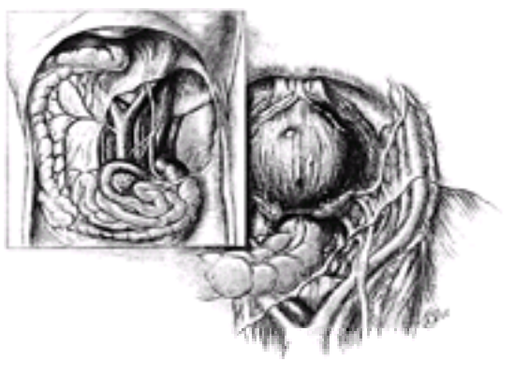

FIGURE 30.32. View of the pelvis from overhead, after the ascending colon and peritoneal attachments of the small bowel mesentery have been mobilized up to the level of the duodenum. This mobilization allows the bowel to be properly packed in the epigastrium and exposes the area of the aortic bifurcation, which is the starting point of the lymph node dissection.

The left colon and sigmoid mesentery are then mobilized to the region of the lower pole of the left kidney by incising the peritoneum lateral to the colon along the avascular/white line of Toldt. The sigmoid mesentery is then elevated off the sacrum, iliac vessels, and distal aorta cephalad to the origin of the inferior mesenteric artery. This maneuver provides a mesenteric window through which the left ureter will pass (without angulation or tension) and for the ureteroenteric anastomosis to the urinary reservoir at the terminal portions of the operation, and it also facilitates retraction of the sigmoid mesentery while performing the lymph node dissection (Fig. 30.33). Care should be taken to dissect along the base of the mesentery, which prevents injury to the inferior mesenteric artery and blood supply to the sigmoid colon.

FIGURE 30.33. View of the pelvis from overhead, after the ascending colon and small bowel have been packed in the epigastrium. Note that the sigmoid mesentery is mobilized off the sacral promontory and distal aorta up to the origin of the inferior mesenteric artery.

Following mobilization of the bowel, a self-retaining retractor is placed (these authors prefer a Finochietto retractor). The right colon and small intestine are carefully packed into the epigastrium with three moist lap pads, followed by a moistened towel rolled to the width of the abdomen. The descending and sigmoid colon are not packed, and are left as free as possible, providing the necessary mobility required for the ureteral and pelvic lymph node dissection.

Successful packing of the intestinal contents is an art and prevents their annoying spillage into the operative field. Packing begins by sweeping the right colon and small bowel under the surgeon's left hand along the right sidewall gutter. A moist, open lap pad is then swept with the right hand along the palm of the left hand, under the viscera along the retroperitoneum and sidewall gutter. In similar fashion, the left sidewall gutter is packed, ensuring that the descending or sigmoid colon are not incorporated. The central portion of the small bowel is packed with a third lap pad. A moist, rolled towel is then positioned horizontally below the lap pads, but cephalad to the bifurcation of the aorta. Occasionally, before placement of the first moist lap pad, a mobile, greater omental apron can be used to facilitate packing of the intestinal viscera in a similar fashion to the lap pad. After the bowel has been packed, a wide Deaver retractor is placed with gentle traction on the rolled towel to provide cephalad exposure.

Ureteral Dissection

The ureters are identified most easily in the retroperitoneum just cephalad to the common iliac vessels. They are dissected into the deep pelvis (several centimeters beyond the iliac vessels) and divided between two large hemoclips. A section of the proximal cut ureteral segment (distal to the proximal hemoclip) is then sent for frozen section analysis to ensure the absence of CIS or overt tumor. The ureter is then mobilized cephalad and tucked under the rolled towel to prevent inadvertent injury. Frequently, an arterial branch from the common iliac artery or the aorta needs to be divided to provide adequate ureteral mobilization. In addition, the rich vascular supply emanating from the gonadal vessels should remain intact and undisturbed. These attachments are an important blood supply to the ureter that ensure an adequate vascular supply for the ureteroenteric anastomosis at the time of diversion. This is particularly important in irradiated patients. Leaving the proximal hemoclip on the divided ureter during the exenteration allows for hydrostatic ureteral dilation, and facilitates the ureteroenteric anastomosis.

Pelvic Lymphadenectomy

A meticulous pelvic lymph node dissection is routinely performed en bloc with radical cystectomy. When performing a salvage procedure following definitive radiation treatment (greater then 5,000 rads), a pelvic lymphadenectomy usually is not performed because of the significant risk of iliac vessel and obturator nerve injury.

Generally, the lymph node dissection is initiated 2 cm above the aortic bifurcation (superior limits of dissection), and extends laterally over the inferior vena cava to the genitofemoral nerve, representing the lateral limits of dissection. The cephalad portion of the lymphatics are ligated with hemoclips to prevent lymphatic leak, whereas the caudal (specimen) side is ligated only when a blood vessel is encountered. Frequently, small anterior tributary veins originate from the vena cava just above the bifurcation, which should be clipped and divided. In men, the spermatic vessels are retracted laterally and spared. However, in women the infundibulopelvic ligament along with the corresponding ovarian vessels are ligated and divided at the pelvic brim.

All fibroareolar and lymphatic tissue are dissected caudally off the aorta, vena cava, and common iliac vessels over the sacral promontory into the deep pelvis. The initial dissection along the common iliac vessels is performed over the arteries, skeletonizing them. As the common iliac veins are dissected medially, care is taken to control small arterial and venous branches coursing along the anterior surface of the sacrum. Electrocautery is helpful at this location, which allows the adherent fibroareolar tissue to be swept off the sacral promontory down into the deep pelvis with the use of a small gauze sponge. Significant bleeding from these presacral vessels can occur if not properly controlled. Hemoclips are discouraged in this location because they can be dislodged easily from the anterior surface of the sacrum, resulting in troublesome bleeding.

Once the proximal portion of the lymph node dissection is completed, a finger is passed from the proximal aspect of dissection under the pelvic peritoneum (anterior to the iliac vessels), distally toward the femoral canal. The opposite hand can be used to strip the peritoneum from the undersurface of the transversalis fascia, and connects with the proximal dissection from above. This maneuver elevates the peritoneum and helps define the lateral limit of peritoneum to be incised and removed with the specimen. In male patients, the peritoneum is divided medial to the spermatic vessels, and lateral to the infundibulopelvic ligament in female patients. The only structure encountered is the vas deferens in the male, or round ligament in the female; these structures are clipped and divided.

A large, right-angled rake retractor (Israel) is used to elevate the lower abdominal wall, including the spermatic cord or remnant of the round ligament, to provide distal exposure in the area of the femoral canal. Tension on the retractor is directed vertically toward the ceiling, with care taken to avoid injury to the inferior epigastric vessels. This provides excellent exposure to the distal external iliac vessels. The distal limits of the dissection are then identified: the circumflex iliac vein crossing anterior to the external iliac artery distally, the genitofemoral nerve laterally, and Cooper's ligament medially. The lymphatics draining the ipsilateral leg, particularly medial to the external iliac vein, are carefully clipped and divided to prevent lymphatic leakage. This includes the lymph node of Cloquet (also known as *Rosenmuller*), which represents the distal limit of the lymphatic dissection at this location. The distal external iliac artery and vein are then circumferentially dissected and skeletonized, with care taken to ligate an accessory obturator vein (present in 40% of patients) originating from the inferomedial aspect of the external iliac vein.

Following completion of the distal limits of dissection, the proximal and distal dissections are joined. The proximal external iliac artery and vein are skeletonized circumferentially to the origin of the hypogastric artery (Fig. 30.34). Care should be taken to clip and divide a commonly encountered vessel arising from the lateral aspect of the proximal external iliac vessels coursing to the psoas muscle. The external iliac vessels are then retracted medially, and the fascia overlying the psoas muscle is incised medial to the genitofemoral nerve. On the left side, branches of the genitofemoral nerve often pursue a more medial course and may be intimately related to the iliac vessels, in which case they are excised.

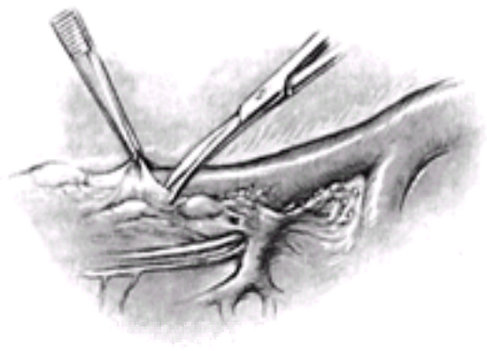

FIGURE 30.34. Technique of skeletonizing the external iliac artery and vein.

At this point, the lymphatic tissues surrounding the iliac vessels are composed of a medial and lateral component attached only at the base within the obturator fossa. The lateral lymphatic compartment (freed medially from the vessels and laterally from the psoas) is bluntly swept into the obturator fossa by retracting the iliac vessels medially, and passing a small gauze sponge lateral to the vessels along the psoas and pelvic sidewall (Fig. 30.35). This sponge should be passed anterior and distal to the hypogastric vein, directed caudally into the obturator fossa. The external iliac vessels are then elevated and retracted laterally while the gauze sponge is carefully withdrawn from the obturator fossa with gentle traction using the left hand (Fig. 30.36). This maneuver effectively sweeps all lymphatic tissue into the obturator fossa and facilitates identification of the obturator nerve deep to the external iliac vein. The obturator nerve is best identified proximally and carefully dissected free from all lymphatics. The obturator nerve is then retracted laterally along with the iliac vessels (Fig. 30.37). At this point, the obturator artery and vein are entrapped between the index finger laterally (medial to the obturator nerve) and the middle finger medially of the left hand. This isolates the obturator vessels exiting the obturator canal along the pelvic floor. These vessels are then carefully clipped and divided, being sure to stay medial to the obturator nerve. The obturator lymph node packet is then swept medially toward the sidewall of the bladder, ligating small tributary vessels and lymphatics from the pelvic sidewall, and removed en bloc with the cystectomy specimen.

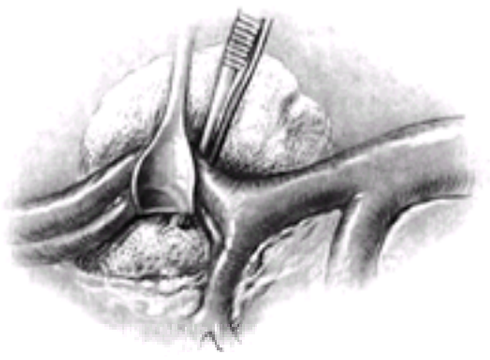

FIGURE 30.35. Technique of passing a small gauze sponge lateral to the external iliac vessels and medial to the psoas muscle.

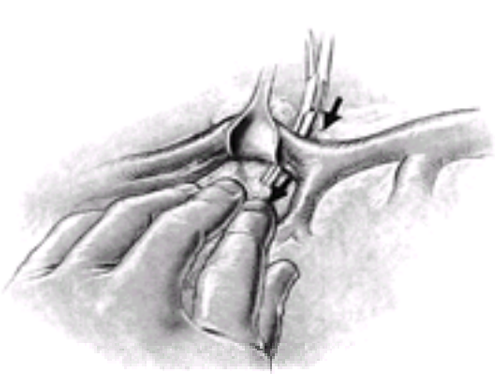

FIGURE 30.36. Technique of withdrawing the gauze sponge with the left hand. This aids in dissecting the obturator fossa, sweeping all fibroareolar and lymphatic tissue toward the bladder.

FIGURE 30.37. Obturator fossa cleaned. This allows proper identification of the obturator nerve passing deep to the external iliac vein.

Ligation of the Lateral Vascular Pedicle to the Bladder

Following dissection of the obturator fossa and dividing the obturator vessels, the lateral vascular pedicle to the bladder is isolated and divided. Developing this plane isolates the lateral vascular pedicle to the bladder, a critical maneuver in performing a safe cystectomy with proper vascular control. Isolation of the lateral vascular pedicle is performed with the left hand. The bladder is retracted toward the pelvis, placing traction on the anterior branches of the hypogastric artery. The left index finger is passed medial to the hypogastric artery, and posterior to the anterior visceral branches. The index finger is directed caudally toward the endopelvic fascia, parallel to the sweep of the sacrum. This maneuver defines the two major vascular pedicles to the anterior pelvic organs: (a) the lateral pedicle, anterior to the index finger, which is composed of the visceral branches of the anterior hypogastric vessel, and (b) the posterior pedicle, posterior to the index finger, which is composed of the visceral branches between the bladder and rectum.

With the lateral pedicle entrapped between the left index and middle fingers, firm traction is applied vertically and caudally. This facilitates skeletonization of the anterior branches off the hypogastric artery (Fig. 30.38). The posterior division of the hypogastric artery including the superogluteal, iliolumbar, and laterosacral arteries are preserved to avoid gluteal claudication. Distal to this posterior division, the hypogastric artery may be ligated for vascular control, but should not be

divided, because the lateral pedicle is easier to dissect if left in continuity. The lateral pedicle is then divided between large hemoclips down to the endopelvic fascia, or as far as is technically possible. With blunt dissection the index finger of the left hand helps identify this lateral pedicle and protects the rectum as it is pushed medially. Large, right-angle hemoclip-appliers are ideally suited for proper placement of the clips. Each pair of hemoclips is positioned as far apart as possible to ensure that 0.5 to 1 cm of tissue projects beyond each clip when the pedicle is divided. This prevents the hemoclips from being dislodged, resulting in unnecessary bleeding. Occasionally, in patients with an abundance of pelvic fat, the lateral pedicle may be thick and require division into two manageable pedicles. The inferior vesicle vein serves as an excellent landmark, because the endopelvic fascia is just distal to this structure. The endopelvic fascia just lateral to the prostate may then be incised, which helps identify the distal limit of the lateral pedicle.

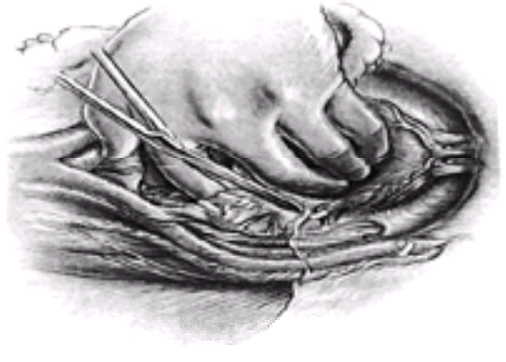

FIGURE 30.38. The left hand is used to define the right lateral pedicle, extending from the bladder to the hypogastric artery. This plane is developed by the index finger (medial) and the middle finger (lateral), exposing the anterior branches of the hypogastric artery. This vascular pedicle is clipped and divided down to the endopelvic fascia. Traction with the left hand defines the pedicle, allows direct visualization, and protects the rectum from injury.

Ligation of the Posterior Pedicle to the Bladder

Following division of the lateral pedicles, the bladder specimen is retracted anteriorly, exposing the cul-de-sac (pouch of Douglas). The surgeon elevates the bladder with a small gauze sponge under the left hand, while the assistant retracts on the peritoneum of the rectosigmoid colon in a cephalad direction. This provides excellent exposure to the recess of the cul-de-sac and places the peritoneal reflection on traction, which facilitates proper division. The peritoneum lateral to the rectum is incised and extended anteriorly across the cul-de-sac to join the incision on the contralateral side (Fig. 30.39). It should be emphasized that the anterior and posterior peritoneal reflections converge in the cul-de-sac to form Denonvilliers' fascia, which extends caudally to the urogenital diaphragm (Fig. 30.40, *large arrow*). This important anatomic boundary in the male separates the prostate and seminal vesicles anterior to the rectum posteriorly. The plane between the prostate and seminal vesicles, and the anterior sheath of Denonvilliers' fascia, will not develop easily. However, the plane between the rectum and the posterior sheath of Denonvilliers' (Denonvilliers' space) should develop easily with blunt dissection. Therefore the peritoneal incision in the cul-de-sac must be made on the rectal side rather than the bladder side (Fig. 30.40, *small arrow*). This allows proper and safe development of Denonvilliers' space between the anterior rectal wall and the posterior sheath of Denonvilliers' fascia (Fig. 30.41). Employing a posterior sweeping motion of the fingers, the rectum can be carefully swept off the seminal vesicles, prostate, and bladder in men, and off the posterior vaginal wall in women. This sweeping motion, when extended laterally, helps thin and develop the posterior pedicle, which appears like a collar emanating from the lateral aspect of the rectum. Care should be taken as this posterior plane is developed more caudally, because the anterior rectal fibers often are adherent to the specimen and can be difficult to bluntly dissect. In the region just cephalad (proximal) to the urogenital diaphragm, sharp dissection may be required to dissect the anterior rectal fibers off the apex of the prostate to prevent rectal injury at this location.

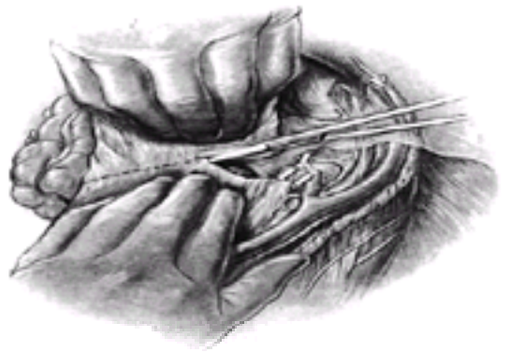

FIGURE 30.39. The peritoneum lateral to the rectum is incised down into the cul-de-sac and carried anteriorly over the rectum to join the opposite side. Note that the incision should be made precisely so the proper plane behind Denonvilliers' fascia can be developed safely.

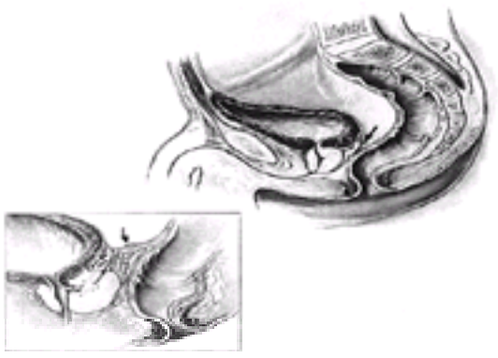

FIGURE 30.40. Illustration of the formation of Denonvilliers' fascia. Note that it is derived from a fusion of the anterior and posterior peritoneal reflections. Denonvilliers' space lies behind the fascia. To successfully enter this space and facilitate mobilization of the anterior rectal wall off Denonvilliers' fascia, the incision in the cul-de-sac is made close to the peritoneal fusion on the anterior rectal wall side, and not on the bladder side.

FIGURE 30.41. After the peritoneum of the cul-de-sac has been incised, the anterior rectal wall can be swept off the posterior surface of the Denonvilliers' fascia. This

effectively defines the posterior pedicle that extends from the bladder to the lateral aspect of the rectum on either side.

Particular mention should be made concerning several situations that may impede the proper development of this posterior plane. Most commonly, when the incision in the cul-de-sac is made too far anteriorly, proper entry into Denonvilliers' space is prevented. Improper entry can occur between the two layers of Denonvilliers' fascia, or even anterior to this, making the posterior dissection difficult, increasing the risk of rectal injury. Furthermore, posterior tumor infiltration or previous high-dose pelvic irradiation can obliterate this plane, making the posterior dissection difficult. To prevent injury to the rectum in these situations, dissection of this plane can be facilitated by combining an initial perineal approach from below with sharp dissection from above. If a rectotomy occurs, a two or three layer closure is recommended. A diverting proximal colostomy is not required routinely unless gross contamination occurs, or if the patient has received previous pelvic radiation therapy. If orthotopic diversion or vaginal reconstruction is planned, an omental interposition is recommended to prevent fistulization between suture lines.

Once the posterior pedicles have been defined, they are clipped and divided to the endopelvic fascia in the male patient. The endopelvic fascia is then incised adjacent to the prostate, medial to the levator ani muscles (if not done previously) to facilitate the apical dissection. In the female patient, the posterior pedicles, including the cardinal ligaments, are divided 4 to 5 cm beyond the cervix. With cephalad pressure on a previously placed vaginal sponge stick, the apex of the vagina can be identified and opened posteriorly just distal to the cervix. The vagina is then circumscribed anteriorly with the cervix attached to the cystectomy specimen. If there is concern about an adequate surgical margin at the posterior or base of the bladder, then the anterior vaginal wall should be removed en bloc with the bladder specimen, subsequently requiring vaginal reconstruction postoperatively if sexual function is desired. If orthotopic diversion is planned, some surgeons prefer to spare the anterior vaginal wall. This eliminates the need for vaginal reconstruction and helps maintain the complex musculofascial support system and prevent injury to the pudendal innervation to the rhabdosphincter proximal urethra, both important components to the continence mechanism in women. The anterior vaginal wall is then sharply dissected off the posterior bladder down to the region of the bladder neck (vesicourethral junction), which is identified by palpating the Foley catheter balloon. At this point, the specimen is attached only at the apex in men and at the vesicourethral junction in women.

Anterior Apical Dissection in the Male Patient

This technique of apical dissection in men undergoing orthotopic diversion has been modified recently, based on the excellent functional results observed in female patients undergoing the same form of diversion. These women retain their continence mechanism almost immediately following removal of the urethral catheter, which has been attributed to the limited dissection performed anterior to the urethra along the pelvic floor. The continence mechanism in men may also be maximized if dissection in the region of the anterior urethra is minimized. This has led to a slight modification in the technique of the apical dissection in the male patient undergoing orthotopic reconstruction.

All fibroareolar connections between the anterior bladder wall, prostate, and undersurface of the pubic symphysis are divided. The superficial dorsal vein is identified, ligated, and divided. With tension placed posteriorly on the prostate, the puboprostatic ligaments are identified and divided just beneath the pubis and lateral to the dorsal venous complex, which courses in between these ligaments. Following transection of the puboprostatic ligaments, the levator muscle fibers are mobilized laterally off the prostate. The apex of the prostate and membranous urethra now becomes palpable. Several methods can be performed to properly control the dorsal venous plexus. An angled clamp may be passed beneath the dorsal vein complex, anterior to the urethra. The venous complex can then be ligated with a 2-0 absorbable suture, and divided close to the apex of the prostate. If any bleeding occurs from the transected venous complex, it should be oversewn with an absorbable (2-0 polyglycolic acid) suture. In a slightly different fashion, the dorsal venous complex may be gathered at the apex of the prostate with a long Allis clamp and a figure-of-eight 2-0 absorbable suture placed under direct vision anterior to the urethra around the venous complex. This maneuver avoids passage of any instruments between the dorsal venous complex and rhabdosphincter, which could potentially injure these structures and compromise the continence mechanism. After the complex has been ligated, it can be sharply divided with excellent exposure to the anterior surface of the urethra, which is now visible. The urethra is then incised just beyond the apex of the prostate, and a series of 2-0 polyglycolic acid sutures are placed in the urethra circumferentially, carefully incorporating the edge of the rhabdosphincter and levator muscle laterally and rectourethralis muscle posteriorly or the caudal extent of Denonvilliers' fascia. The Foley catheter is then clamped with a curved Kocher clamp and transected distal to the specimen removed.

Alternatively, the dorsal venous complex can be sharply transected without dividing the puboprostatic ligaments or without securing vascular control. Cephalad traction on the prostate elongates the proximal and membranous urethra, and allows the urethra to be skeletonized laterally by dividing the so-called lateral pillars, which are extensions of the rhabdosphincter. The anterior two-thirds of the urethra is divided, exposing the urethral catheter. The urethral sutures are then placed under direct vision. Six equally spaced 2-0 polyglycolic acid sutures are placed into the urethral mucosa and lumen anteriorly. The rhabdosphincter, the edge of which acts as a hood overlying the dorsal vein complex, is included in these sutures if the venous complex is sharply incised. This maneuver compresses the dorsal vein complex against the urethra for hemostatic purposes. The urethral catheter is then drawn through the urethrotomy, clamped on the bladder side, and divided. Cephalad traction on the bladder side with the clamped catheter occludes the bladder neck, prevents tumor spill from the bladder, and provides exposure to the posterior urethra. Two additional sutures are placed in the posterior urethra, incorporating the rectourethralis muscle or distal Denonvilliers' fascia. The posterior urethra is then divided and the specimen is removed. The urethral sutures are tagged appropriately to identify their location and are placed under a towel until the urethroenteric anastomosis is performed. Bleeding from the dorsal vein is usually minimal at this point. If additional hemostasis is required, one or two anterior urethral sutures can be tied to stop the bleeding. Frozen section analysis of the distal urethral margin of the cystectomy specimen is then performed to exclude tumor involvement.

If a cutaneous form of urinary diversion is planned, urethral preparation is slightly modified. Once the dorsal venous complex is secured and divided, the anterior urethra is identified. With cephalad traction, the urethra is stretched above the urogenital diaphragm, a curved clamp is placed across the urethra distal to the apex of the prostate, and the urethra is divided distal to the clamp. Care must be taken to avoid rectal injury with this clamp. This is prevented by placing gentle posterior traction with the left hand or index finger on the rectum and ensuring the clamp is passed anterior. The specimen is then removed. The levator musculature can then be reapproximated along the pelvic floor to facilitate hemostasis.

Anterior Dissection in the Female

When considering orthotopic diversion in female patients undergoing cystectomy, several technical issues are critical to the procedure to maintain the continence mechanism in these women.

When developing the posterior pedicles in women, the posterior vagina is incised at the apex just distal to the cervix. This incision is carried anteriorly along the lateral and anterior vaginal wall, forming a circumferential incision. The anterolateral vaginal wall is then grasped with a curved Kocher clamp. This provides counter traction and facilitates dissection between the anterior vaginal wall and the bladder specimen. Careful dissection of the proper plane will prevent entry into the posterior bladder and also reduce the amount of bleeding in this vascular area. Development of this posterior plane and vascular pedicle is best performed sharply with the use of hemoclips, and carried just distal to the vesicourethral junction. Palpation of the Foley catheter balloon assists in identifying this region. This dissection effectively maintains a functional vagina. Furthermore, an intact anterior vaginal wall helps support the proximal urethra through a complex musculofascial support system that extends from the anterior vagina. The vagina is then closed at the apex and, in the past, was suspended to Cooper's ligament to prevent vaginal prolapse or the development of an enterocele postoperatively. Currently, a colposacralplexy incorporating Marlex mesh, which fixates the vagina without angulation or undue tension, is being performed.

Alternatively, in the case of a deeply invasive posterior bladder tumor with concern of an adequate surgical margin, the anterior vaginal wall should be removed en bloc with the cystectomy specimen. After dividing the posterior vaginal apex, the lateral vaginal wall subsequently serves as the posterior pedicle and is divided distally. This leaves the anterior vaginal wall attached to the posterior bladder specimen. Again, the Foley catheter balloon facilitates identification of the vesicourethral junction. The surgical plane between the vesicourethral junction and the anterior vaginal wall is then developed distally at this location. A 1-cm length of proximal urethra is mobilized, and the remaining distal urethra is left intact with the anterior vaginal wall. Vaginal reconstruction by a clam-shell (horizontal) or side-to-side (vertical) technique is required. Other means of vaginal reconstruction may include a rectus myocutaneous flap, detubularized cylinder of ileum, a peritoneal flap, or an omental flap. Regardless, a well-vascularized omental pedicle graft is placed between the reconstructed vagina and neobladder, and secured to the levator ani muscles to separate the suture lines and prevent fistulization.

It is important that no dissection be performed anterior to the urethra along the pelvic floor in women considering orthotopic diversion. This prevents injury to the rhabdosphincter region and corresponding innervation, which is critical in maintaining the continence mechanism. Anatomic studies have demonstrated that the innervation to this rhabdosphincter region in women arises from branches off the pudendal nerve that course along the pelvic floor posterior to the levator muscles

(56). Any dissection performed anteriorly may injure these nerves and compromise the continence status. Some reports suggest that a sympathetic nerve–sparing cystectomy is important in maintaining continence in these women. The autonomic nerves coursing along the lateral aspect of the uterus and vagina have been sacrificed routinely, and the pudendal innervation of the rhabdosphincter region has been relied upon for continence; excellent continence has been observed in women undergoing orthotopic diversion with this technique. Fluorourodynamic studies in women undergoing orthotopic diversion also have identified the rhabdosphincter region as the area that provides the continence mechanism in these women (116). It is possible that preservation of the sympathetic nerves may contribute to the high incidence of hypercontinence and urinary retention requiring continuous intermittent catheterization (124).

When the posterior dissection is completed (ensuring dissection just distal to the vesicourethral junction), a Statinski vascular clamp is placed across the bladder neck. With gentle traction, the proximal urethra is divided anteriorly, distal to the bladder neck and clamp. The anterior urethral sutures are placed as described in the male patient. The distal portion of the catheter is then drawn into the wound through the urethrotomy and divided. The Statinski vascular clamp placed across the catheter at the bladder neck prevents any tumor spill from the bladder. Gentle cephalad tract on the clamped catheter allows placement of the posterior urethral sutures. The posterior urethra is then transected and the specimen is removed. Frozen section analysis is performed on the distal urethral margin of the cystectomy specimen to exclude tumor.

If a cutaneous diversion is planned in the female patient, the posterior pedicles are developed as previously mentioned. Attention is then directed anteriorly and the pubourethral ligaments are divided. A curved clamp is placed across the urethra, and the anterior vaginal wall is opened distally and incised circumferentially around the urethral meatus. The vaginal cuff is closed as previously described and suspended to Cooper's ligament.

Following removal of the cystectomy specimen, the pelvis is irrigated with warm, sterile water. The presacral nodal tissue, previously swept off the common iliac vessels and sacral promontory into the deep pelvis, is collected and sent separately for pathologic evaluation. All nodal tissue in the presciatic notch, anterior to the sciatic nerve, is also sent for histologic analysis. Hemostasis is obtained and the pelvis is packed with a lap pad while attention is directed to the urinary diversion. The pelvis is drained by a 1-inch Penrose drain for 3 weeks and a large suction Hemovac drain for 24 hours. A gastrostomy tube 18-Fr Foley catheter is routinely placed using the Stamm technique. This provides a simple means to drain the stomach and prevents the need for an uncomfortable nasogastric tube while the postoperative ileus resolves.

MANAGEMENT OF THE URETHRA IN PATIENTS WITH BLADDER CANCER

Indications for Urethrectomy in the Female Patient

In the past, urethrectomy was performed routinely in all women undergoing cystectomy. However, with a better understanding of the continence mechanism in women (56), coupled with sound pathologic criteria in which to safely select appropriate female candidates for orthotopic diversion, urethrectomy is currently performed in those female patients who are not suitable candidates for an orthotopic reservoir, or who would prefer an alternative form of diversion. Currently, 90% of women undergoing cystectomy at the authors' institution undergo orthotopic diversion (339,340). The clinical and functional results in these women undergoing orthotopic urinary diversion has been excellent.

Urethrectomy is performed at the time of cystectomy in women with a high risk for urethral tumor involvement, in those with known urethral tumor involvement, or in patients who prefer a cutaneous form of diversion. An extensive analysis of female cystectomy specimens removed for transitional cell carcinoma of the bladder demonstrated that tumor involving the bladder neck is an important risk factor for urethral tumor involvement. All cystectomy specimens with carcinoma involving the urethra had concomitant tumor involvement at the bladder neck. However, not all specimens with tumor involving the bladder neck demonstrated urethral tumor involvement. This is an important issue because, although bladder neck involvement with tumor is a risk factor for urethral tumor involvement, approximately 50% of patients with tumor at the bladder neck will have a urethra free of tumor. In this situation, the female patient may be considered an appropriate candidate for orthotopic diversion.

Intraoperative pathologic evaluation of the proximal urethra has been found to be the most critical determinant for orthotopic diversion in women (339). Intraoperative frozen section analysis of the distal cystectomy margin (proximal urethra) has been demonstrated to be an accurate and reliable method to prospectively evaluate the proximal urethra for tumor involvement. Furthermore, because of the potential risk of injuring the continence mechanism with a preoperative biopsy of the bladder neck and urethra in women, coupled with a reliable method to evaluate the proximal urethra intraoperatively, intraoperative frozen section analysis of the proximal urethra is now primarily relied upon for proper patient selection in women considering orthotopic lower urinary tract reconstruction.

Indications for Urethrectomy in the Male Patient

With the increasing familiarity and application of orthotopic diversion, the management of the urethra in the male patient undergoing cystectomy for bladder cancer is of particular importance. Urethral recurrences develop in approximately 10% of male patients following cystectomy for bladder cancer (95). The greatest risk factor for urethral recurrence is tumor involvement of the prostate in the radical cystectomy specimen, with prostatic stromal invasion more ominous than either ductal or mucosal involvement. Patients considering orthotopic diversion traditionally have undergone precystectomy screening of the prostate by means of a deep transurethral biopsy at the 5 and 7 o'clock positions adjacent to the verumontanum, which have been suggested to be the most common sites of involvement of the prostatic urethra, ducts, and stroma with transitional cell carcinoma (295,382).

Recently, the incidence of urethral recurrence in male patients undergoing a cutaneous form of diversion has been evaluated and compared with the urethral recurrence rate in men undergoing an orthotopic diversion (97). Interestingly, the estimated probability of a urethral recurrence at 5 years following cystectomy was significantly increased in male patients with a cutaneous diversion, compared with those undergoing an orthotopic diversion (10% versus 4%, respectively). Even those patients with high-risk pathology (prostate involvement) diverted by means of an orthotopic diversion had a lower probability of urethral recurrence compared with patients with similar pathology undergoing a nonorthotopic form of diversion. The 5-year risk of recurrence in these patients with prostate involvement was only 5% in the orthotopic group compared with 24% for the nonorthotopic group. Although the exact etiology is unknown, it has been suggested that the orthotopic form of diversion may provide some protective effect, perhaps by the mucus or some other secretory product of the intestine, that prevents the development of cancer in the retained urethra (65).

In summary, the current indication for urethrectomy (contraindication to orthotopic diversion) in male patients is believed to include those demonstrating CIS or overt carcinoma of the urethral margin detected on intraoperative frozen section analysis. En bloc urethrectomy is performed at the time of cystectomy in male patients with known tumor involving the urethra. A delayed urethrectomy is performed after patients have undergone a cutaneous form of urinary diversion when prostatic stromal tumor involvement was demonstrated on final pathologic examination of the cystectomy specimen. Patients with prostatic stromal involvement of tumor demonstrated in the cystectomy specimen and who underwent an orthotopic diversion are closely monitored postoperatively with urethral wash cytology for recurrence purposes. Furthermore, a preoperative biopsy of the prostate is no longer performed, because orthotopic diversion is contraindicated only in those patients with overt tumor of the urethra diagnosed on intraoperative frozen section analysis.

CHEMOTHERAPY IN THE MANAGEMENT OF ADVANCED UROTHELIAL CANCER

In the past 50 years, the progress in the management of advanced bladder cancer has been slow and steady. Objective response rates as high as 65% to 75% have been recorded in the past decade, in contrast to single-agent response rates of less than 10% to 15% in the first recorded series of chemotherapy for bladder cancer. Twenty years ago, sustained response to chemotherapy for metastatic bladder cancer was so uncommon that it allowed reporting only of isolated cases of prolonged survival. Over this period, median survival figures initially increased from 3 to 4 months to 12 months (with the introduction of the MVAC regimen) (197,278) and more recently have been as long as 18 to 20 months, with long-term survival of 20% to 30%, depending on the characteristics of the patients receiving treatment.

Although only 20% of incident cases of bladder cancer are clinically advanced at first presentation, many patients with superficial or invasive disease eventually develop recurrence or metastases, thus the management of advanced, inoperable cancer of the urinary tract is a much more common problem than suggested by the published incidence figures for advanced bladder cancer. Despite improvements in survival, more than 80% of such cases still will result in death from cancer, and more effective strategies of treatment therefore are still required.

Biology of Advanced Bladder Cancer

A biologic continuum exists between superficial and advanced bladder cancer, but little information is available regarding the specifics of the biology of advanced

disease. In general, advanced disease is associated with less differentiated histology, aneuploidy, and advanced T stage of the primary tumors. Whereas loss of heterozygosity of chromosome 9 appears to be associated with the initiation of bladder carcinogenesis in superficial disease, advanced cancer appears to require the presence of aberrations of P53 in most instances, with changes mapping to chromosome 17. Similarly, aberrant expression of the epidermal growth-factor receptor (EGFR), transferrin receptor, and the Rb gene are associated with more advanced presentations or with the risk of progression to more advanced disease.

The common sites of metastasis include regional and distant lymph nodes, bone, lung, skin, and liver, and less frequently brain, meninges, vagina, and other intraabdominal sites (18,58,277). The initial presentation depends on the sites of involvement, but also may reflect the nonspecific constitutional features of advanced malignancy, such as asthenia, weight loss, malaise, and fatigue.

When planning treatment, it is important to recognize that the distribution of metastases correlates with prognosis. More prolonged survival is seen in patients with lymph node and soft tissue disease, and a substantially worse prognosis is expected in those with liver, brain, and bone metastases (103,197,299).

This issue is also of importance when attempting to set different series into context. The use of different staging technologies may contribute to different volumes or sites of cancer being included in different series (the phenomenon of stage migration) (85). For example, in the early series of the 1970s and 1980s, clinical examination and relatively crude imaging techniques led to the identification of metastatic disease of a substantially larger volume than is usually found today. Thus entry into treatment programs for metastatic bladder cancer essentially represented “high-volume” disease. By contrast, in more recent series, CT or MRI scans (with a much higher resolving power) may identify tiny metastatic deposits, which may be confirmed as being malignant by biopsy or positron emission tomography (PET). This, in turn, leads to entry into chemotherapy trials of patients with metastatic disease with a much smaller tumor burden and a concomitantly better prognosis. These factors are of real importance when attempting to assess the true benefits of novel treatment programs compared with conventional chemotherapy, and they justify the importance of using randomized trial design to achieve this (276).

There are also clear differences in the results of treatment of transitional cell carcinoma as compared with the nontransitional cell types (adenocarcinoma and squamous carcinoma) of metastatic uroepithelial cancer (197,345). The nontransitional histologies appear to be much less responsive to conventional chemotherapy. For example, in the Intergroup Trial that compared the MVAC combination chemotherapy regimen with single-agent cisplatin (see subsequent discussion), the response rate for nontransitional cell histology was less than one-third that observed for transitional cell carcinoma. Novel compounds (such as paclitaxel) also appear to give lower objective response rates for schistosomiasis-associated nontransitional cell bladder cancer than for transitional cell carcinoma (167).

If a metastatic deposit is biopsied, the most likely histology is transitional cell carcinoma, but there is considerable occult heterogeneity within the individual deposits of transitional cell cancer. This applies with respect to histology, growth kinetics, DNA content, gene expression, and markers of cytotoxic response and resistance; this may affect the outcome of chemotherapy (38,278). Furthermore, the concept that bladder cancer has a stem cell of origin is becoming increasingly respected (38), and may be an important cause of the difficulty of curing this disease. This also may explain the presence of mixed populations of transitional cell cancer and nontransitional histologies within individual metastatic deposits and even within primary tumors.

It also has become increasingly clear that specific determinants of response to chemotherapy can be identified in bladder cancer cells, including p-glycoprotein (38,263,278) and glutathione (262). Recent data have also suggested the possibility that altered expression of P53 may correlate with increased resistance to combination chemotherapy regimens such as MVAC (33). However, it has been shown previously in bladder cancer cell lines that the expression of P53 itself may be upregulated by exposure to chemotherapy. Other determinants of cytotoxic responsiveness, such as expression of thymidylate synthase and the EGFR, also may be relevant to this discussion.

Conventional Chemotherapy

Chemotherapy has been used for metastatic bladder cancer for the past 40 years. However, in the early reported studies, the reproducibly quantifiable response rates were low, and long-term survival was uncommon (45,384). Most conventional single cytotoxics yield true objective responses in approximately 10% to 20% of cases, including complete responses in less than 5% to 10% (45,384,387).

The most rigorous assessment of response has been documented in randomized clinical trials. Thus a paradoxic decrease was seen in reported objective response rates in some series from the 1960s to the 1980s, largely as a result of the increased precision of reporting and the reduced level of observer bias in randomized studies, although this decrease was also accompanied by the availability of more effective chemotherapy regimens. Response rates also were associated with apparent improvement in overall outcomes, as measured by median and long-term survival, probably due to different case selection and stage migration, although more effective regimens may have been an important factor. Furthermore, the improved outcomes also may have reflected the improvements in supportive care or an increased willingness to treat patients aggressively.

Most randomized trials of single-agent chemotherapy have produced responses of less than 3 to 4 months, with median survival rates of approximately 6 to 8 months. The most active “standard” single agents against transitional cell carcinomas include cisplatin, methotrexate, vinblastine, MMC, and doxorubicin (45,278,384,387).

In the 1980s, combination regimens were developed in an attempt to increase response rates and duration of survival. Initially, the use of combination regimens appeared to improve response rates without a corresponding increase in survival, as reviewed in detail elsewhere (278). Typical combination regimens that increased toxicity without a significant improvement of survival compared with single-agent therapy included cyclophosphamide, doxorubicin, and cisplatin (168,360) and methotrexate and cisplatin (139).

With the development of regimens combining methotrexate, vinblastine, and cisplatin (with or without doxorubicin), higher response rates with more durable remissions were achieved (122,346). At the Memorial Sloan-Kettering Cancer Center in particular, the MVAC regimen was even shown to yield complete pathologic remissions in patients with liver and bone metastases, with long-term survival reported in more than 60% to 70% of complete responders (347).

A multicenter, randomized trial that compared single-agent cisplatin with the MVAC regimen demonstrated for the first time a survival benefit from the combination regimen (197). Cisplatin alone produced a median survival of 8 months, whereas the MVAC regimen gave a median survival of 12 months, similar to the follow-up experience from the Memorial Sloan-Kettering Cancer Center and other nonrandomized trials (Table 30.4) (196). The tail of the survival curve at 2 years confirmed the superiority of the combination regimen, but a long-term follow-up study showed that the majority of patients in both arms died within 5 years (299). However, it should be emphasized that most of the long-term survivors were in the group treated by the MVAC regimen.

Series	No. of Patients	Response CR (%)	Category Total (%)	Median Survival (mo)
Sternberg et al. (347)	121	26	72	13.4
Tannock (276)	13	43	100	
Logothetis (198)	55	35	65	11.0
Bouton-Lamuze (276)	67	19	57	13.0

MVAC, methotrexate, vinblastine, Adriamycin, and cisplatin.

TABLE 30.4. INTERNATIONAL EXPERIENCE WITH MVAC REGIMEN AND STAGE MIGRATION[29]

Another randomized trial (198) confirmed the superiority of the MVAC regimen, in this instance compared with the combination of cyclophosphamide, Adriamycin (doxorubicin), and Platinol (cisplatin) (CAP). The superiority of MVAC was anticipated, given the lack of difference between CAP and single-agent cisplatin in earlier randomized trials discussed previously.

The MVAC regimen justifiably has been viewed as a standard of care, with several series from the 1980s producing objective response rates in the broad range of 40% to 70%, but with reproducible median survival rates of approximately 1 year (Table 30.4). However, more recent experience suggests that the median survival achieved with the MVAC regimen may have increased by as much as 50% (221), presumably due to the impact of stage migration, case selection, or changes in supportive technologies. This calls into question the definition of what constitutes “standard of care” in 2000.

NEW AGENTS FOR BLADDER CANCER

In the past decade, several newer cytotoxics have been shown to be active against transitional cell carcinoma, and now are being tested in combination chemotherapy trials. Several of these drugs have objective single-agent response rates of 25% to 30% in previously untreated patients, or have demonstrable anticancer effect in patients who have previously received chemotherapy for metastatic disease. Some of the more promising innovations include ifosfamide (381), paclitaxel (290), docetaxel (220), and gemcitabine (232,265,336). Of particular interest is the apparent reduction in toxicity compared with more established agents, especially for gemcitabine, ifosfamide, and the taxanes, suggesting the possibility of incorporation into combination regimens without enhancement of toxicity.

However, some previously applied novel drugs have not fulfilled their early promise. For example, trimetrexate, mitoxantrone, and gallium have not found their way into “routine” management of advanced bladder cancer after many years of clinical trial experience, because of either lack of efficacy or unanticipated toxicity. Even the early promise of carboplatin has recently come under a cloud in view of the disappointing single-agent response rates (64) and the disappointing median survival rates of approximately 9 months achieved from the doublet of paclitaxel and carboplatin in several phase II clinical trials (281,366).

It is important to note that the paclitaxel-carboplatin regimen found its way into routine clinical practice without having been validated in any randomized trial, presumably because of reduced toxicity. This occurred despite the fact that the reported median survival (approximately 9 months) appears inferior to that found in current studies with the MVAC and ifosfamide taxol-platinum (ITP) regimens (approximately 15 to 18 months). At present, the ECOG is formally comparing the MVAC regimen against the paclitaxel-carboplatin doublet, but this issue is of great importance in illustrating the danger of future introduction of new regimens into clinical practice without validation in comparisons against established standards of practice.

A proliferation of new combination cytotoxic regimens has been developed, incorporating the taxanes and gemcitabine, in particular, with new and established agents. Phases I and II clinical trials have clearly shown anticancer activity and varying profiles of toxicity from such combinations as gemcitabine-paclitaxel-cisplatin, gemcitabine-paclitaxel-carboplatin, ifosfamide-paclitaxel-cisplatin alternating with doxorubicin-gemcitabine, and many others. To date, no regimen has been proven superior, and it must be remembered that the phenomenon of stage migration may be confounding the interpretation of these new trials.

Thus it is of real importance that novel cytotoxics be validated in well-structured clinical trials, and in particular that randomized comparisons be carried out against standard treatments. For this purpose, the MVAC regimen has been viewed as the gold standard, because it has remained the one regimen proven to yield a survival benefit in randomized trials.

However, as noted previously, what constitutes a “standard” result from the MVAC regimen in the year 2000 must be considered carefully. In past experience, as reviewed in Table 30.1, patients treated with the MVAC regimen were able to expect a median survival of approximately 12 months. However, in more recent experience from the Memorial Sloan-Kettering Cancer Center, it appears that a more realistic median survival is in the range of 16 to 18 months (220). At present, it is not clear whether this apparent increment is a result of stage migration, improved supportive care, case selection, or other factors.

Recently, the combination of ifosfamide, paclitaxel, and cisplatin has produced preliminary results with a response rate of nearly 80% and a median survival of approximately 18 months (220). Although encouraging, these data must be taken in the context of the contemporary Memorial Sloan-Kettering experience with the MVAC regimen. Thus before the ITP regimen can be accepted as a significant step forward, it must be tested against the MVAC regimen or another appropriate standard.

Several groups have demonstrated that gemcitabine can be administered effectively in combination programs with agents such as cisplatin and paclitaxel (206,233,337).

At the Annual Scientific Meeting of the American Society of Clinical Oncology (New Orleans, May 2000), the formal presentation of data from randomized trials comparing the MVAC regimen against the combination of gemcitabine-cisplatin (sponsored by the Eli Lilly Company) was presented. In this study comparing outcomes in approximately 200 cases, a statistically significant reduction in toxicity was observed, with comparable survival figures. Although the study was not designed to demonstrate equivalence, it was clear that no large difference would be observed between the two survival curves, although final confirmation of this observation will require several years of follow-up.

In addition, ECOG is currently comparing the MVAC regimen against the paclitaxel-carboplatin regimen. These phase III trials will clarify what should constitute the standard of care in the first decade of the 21st century.

CHANGING ROLES FOR CHEMOTHERAPY IN LOCALLY ADVANCED, CLINICALLY NONMETASTATIC DISEASE

In the past two decades, several studies have attempted to incorporate systemic chemotherapy into regimens that include definitive primary treatment, with the aim of reducing the symptoms and size of the primary tumor (thereby facilitating surgery or radiotherapy) and controlling occult systemic metastasis (278). The major approaches for combining systemic and local therapies have included the use of neoadjuvant (first-line) chemotherapy, adjuvant chemotherapy after treatment of the primary tumor, and the use of concurrent chemoradiation therapy or schedules of perioperative chemotherapy. These strategies have been reviewed in detail elsewhere. In brief, phases I and II trials initially used single agents, such as cisplatin or methotrexate, in combination with definitive radiotherapy or surgery, and showed objective response rates of 40% to 75% in primary tumors assessed endoscopically or at cystectomy. Randomized clinical trials failed to demonstrate a survival benefit from single-agent regimens. Combination regimens, such as MVAC, were also used, confirming high response rates (301); however, nonrandomized long-term follow-up studies did not suggest the occurrence of increased cure rates.

Despite the publication of many promising phases I to II clinical trials, most randomized assessments have failed to demonstrate any survival benefit from strategies of neoadjuvant cytotoxic chemotherapy. Some years ago, a meta-analysis of the early randomized trials confirmed this observation (104). However, it should be noted that most of the trials considered for this analysis used single-agent chemotherapy.

More recently, the first reports of large trials conducted by the EORTC-MRC (Medical Research Council) Intergroup (14a) and by the Radiation Therapy Oncology Group (RTOG) (313) have shown that initial chemotherapy with the combination of cisplatin-methotrexate-vinblastine does not substantially improve long-term survival. In fact, the EORTC-MRC collaboration did demonstrate a small difference in outcome, but it should be noted that the demonstration of this difference required randomization of nearly 1,000 cases. The results of the North American Intergroup Trial, which compared neoadjuvant MVAC followed by cystectomy versus cystectomy alone, have not yet been reported. It seems unlikely that this trial will alter the evolving paradigm in view of the many other trials that have not shown a clinically important difference when neoadjuvant chemotherapy is used for invasive bladder cancer.

Another approach that has been tested extensively is the use of chemoradiation therapy, with the intention of sparing the bladder and thus improving quality of life. Pilot and phase II trials have demonstrated objective (endoscopic) response rates of 50% to 80%, with a high level of bladder sparing in the early years of follow-up, although long-term survival figures have not been truly comparable with those achieved by surgery. However, an important caveat to this statement is that the chemoradiation trials have used clinical staging, compared with surgical staging in the cystectomy series. The most promising approach tested in the phase II setting was developed by Housset and colleagues (144a), and used a complex regimen of a repeated combination of cisplatin, 5-fluorouracil, and radiation. These investigators reported a high rate of bladder preservation and impressive 5-year actuarial survival figures. This approach has also been tested by the RTOG in a nonrandomized fashion, and high initial response rates have also been demonstrated. A randomized trial is required to demonstrate the true safety of this approach. Some clinicians believe that, with the present state-of-the-art options, radical cystectomy (with or without chemotherapy) offers a more reliable means of cure, notwithstanding the aforementioned caveats of stage migration and the limitations of comparing clinically and surgically staged cases.

Apart from a single, randomized trial (conducted by the National Cancer Institute of Canada) demonstrating improved local control from the combination of cisplatin plus radiotherapy versus radiotherapy alone (62), no randomized trials have demonstrated improved overall survival from this approach. In the National Cancer Institute of Cancer trial, the survival trend was in favor of combined modality therapy, but case numbers were insufficient to achieve statistic significance. However,

Shipley (313), one of the primary innovators in the field of bladder-preserving chemoradiation for bladder cancer, has argued that chemoradiation should be used to improve local control only, and that it remains for systemic chemotherapy to change overall survival. At present, most studies appear to be concentrating on improving schedules of delivery and combination of chemotherapy and radiation, rather than focusing on the important issue of whether this approach truly confers a survival benefit (275).

Strategies of adjuvant cytotoxic chemotherapy have also been tested. An early randomized trial from the USC was reported as showing a survival benefit from the use of adjuvant cyclophosphamide-doxorubicin-cisplatin (318), although the true utility of this approach has been heavily challenged on the basis of statistic and methodologic flaws. This trial continues to be the subject of interesting debate at USC. More recently, statistically underpowered randomized trials have shown improved disease-free survival from the use of adjuvant CMV or MVAC, but have not shown an overall survival benefit (98,348). The latter trial did suggest a trend in favor of an overall survival benefit, but the study, with less than 100 randomized cases, produced a result that failed to achieve statistic significance.

At present, it is most likely that survival will be improved by the use of adjuvant therapy after resection of the primary tumor. Led by investigators at the USC and Baylor College of Medicine, this hypothesis is being tested in a multicenter, randomized trial in which the molecular prognosticator, P53, determines eligibility for chemotherapy for patients with invasive bladder cancer (stages T_1 and T_2) who have negative lymph nodes after surgery and lymphadenectomy. Patients are randomized to an observation arm or to adjuvant chemotherapy with the MVAC regimen (as the more novel paclitaxel- and gemcitabine-containing regimens have not yet been tested in the context of invasive disease). This study will answer important questions regarding the use of molecular prognostication, as well as defining the true use of adjuvant chemotherapy for patients with invasive, node-negative disease.

With the availability of the various new cytotoxics discussed previously, it is likely that investigators will begin to address the role of these agents in the treatment of locally invasive, clinically nonmetastatic disease. The reduced profile of toxicity lends itself to multimodality combination approaches, especially because this may facilitate early use after radical surgery. Caution will be required in combining the potent radiosensitizers, paclitaxel and gemcitabine, with radical radiotherapy. These authors believe that it is not appropriate to introduce regimens that have not yet been validated in the context of metastatic disease into front-line, unstructured programs of neoadjuvant or adjuvant chemotherapy. For example, it is possible that paclitaxel-carboplatin, or even gemcitabine-cisplatin, will prove to be less effective than the MVAC regimen for invasive bladder cancer, and thus could constitute ineffective adjuvant treatment for bladder cancer. Thus it will also be important in this setting to complete the appropriate clinical trials (such as the current adjuvant trial of the ECOG) before attempting to modify standards of care in the community.

Current clinical results of patients undergoing radical cystectomy provide the best survival and the lowest local recurrence rates for patients afflicted with high-grade, invasive bladder cancer (342). Orthotopic lower urinary tract reconstruction has improved quality of life for patients following cystectomy and these data provide a standard to which other treatment alternatives must be compared in the future.

Radical cystectomy remains the most effective treatment for muscle-invasive or recalcitrant high-grade bladder cancer. Despite advances in chemotherapy and irradiation, no study has demonstrated their equivalence to surgery with respect to survival or locoregional tumor control. Urinary diversions are a necessary component of the modern oncologic or reconstructive urologic surgeon's armamentarium. Over the years, established urinary diversion techniques have been further refined. With improved antibiotics and better perioperative care, the morbidity rates associated with radical cystectomy and urinary diversions have been greatly reduced. Enhanced understanding of urinary, gastrointestinal, and continence physiology has led to the evolution of continent urinary diversions that more closely mimic the native bladder's function. Development of tissue regeneration techniques promises the advent of even better, more physiologic urinary diversions in the future. Today's urologic surgeon can offer myriad options to a patient faced with the need for urinary diversion. This chapter highlights the surgical techniques, caveats, and potential short- and long-term complications associated with the most common urinary diversions performed today.

The surgical techniques have been grouped into three major headings:

1. Incontinent urinary diversions
2. Continent heterotopic urinary diversions
3. Continent orthotopic urinary diversions

PATIENT SELECTION

The most important factors in selection of the appropriate urinary diversion for a patient include the patient's informed desires, the patient's physiologic function and physical capacity, and the surgeon's familiarity and comfort with different types of urinary diversions. In general, for patients with renal or hepatic dysfunction, or short or diseased bowel, an incontinent procedure using the shortest segment of bowel is used to minimize the metabolic abnormalities associated with prolonged exposure of the bowel segment to urine and to maximize the length of remnant bowel. For patients with functional limitations, incontinent urinary diversions are similarly performed. For all other patients, the various continent and incontinent options are discussed thoroughly. The potential social and functional implications for each procedure are highlighted. The patient's motivation and personal desires will ultimately dictate the type of urinary diversion performed. Before reconstruction, the upper urinary tract anatomy and function are assessed thoroughly with laboratory examinations and radiologic imaging. In older patients, the colon should also be evaluated before its use in reconstructive surgery.

INCONTINENT URINARY DIVERSIONS

Cutaneous Ureterostomy

Cutaneous ureterostomy is a particularly useful method of providing urinary diversion in patients with vesical dysfunction and associated ureteral dilation. It has certain applicability as a temporary measure in infancy and childhood before definitive corrective surgery in such conditions as urethral valves, severe bladder outflow obstruction, megacystis, high-grade refluxing ureters, ureteral adynamic segments, and hypoplastic abdominal wall muscles. It can be used with a more permanent intent in situations where bowel anastomoses or reabsorption of urinary constituents by bowel mucosa must be avoided.

The only patients who are truly suitable for a permanent cutaneous ureterostomy are those with at least one grossly dilated thick-walled ureter. The acutely dilated thin-walled ureter may have poor peristaltic power and a potentially compromised vascular supply, compared to a ureter with a thickened muscularis that is generously vascularized by collaterals (94). Cutaneous stomal stenosis, which is a major problem of this technique, is also less likely.

Technique

In general, bilateral cutaneous ureterostomy should be avoided because of the requirement of two separate stoma sites with the attendant requirement of separate urinary appliances. If both ureters are dilated, a double-barreled stoma site can be used. If one ureter is dilated and the other is of normal caliber, a proximal transureteroureterostomy can be performed by spatulation of the normal-caliber ureter to the side of the dilated ureter. The recipient ureter is brought to the skin level as a single-barreled stoma. Externalized stenting should be bilateral.

A considerable length of ureter must be mobilized from the retroperitoneum to traverse the distance to the anterior abdominal wall. Sufficient attention must be directed at avoiding devascularization of the distal ureter by excessive dissection in its periadventitial vascular tissue. Following ureteral mobilization for a doubled-barreled cutaneous ureterostomy, one ureter is brought extraperitoneally to the opposite side. Both ureters are then brought through a small cruciate fascial incision to a predetermined skin site and prepared for stoma creation. The opposing walls of each ureter are spatulated approximately 2 cm, and then the incised edges are anastomosed to each other with interrupted or running absorbable sutures (Fig. 31.1A). To create a projecting ureterostomy nipple, the edges of the common lumen are then everted via a subtle “rosebudding” suture technique (skin edge to 1-cm proximal serosa to mucosal edge) with interrupted absorbable suture (Fig. 31.1B) (24).

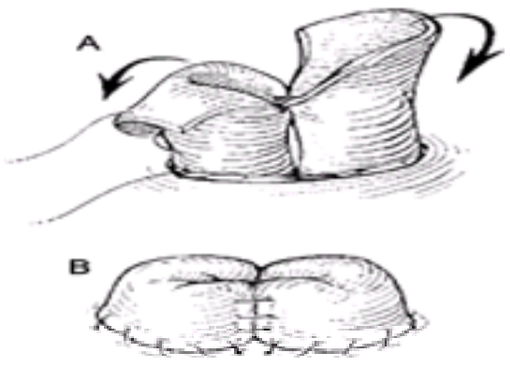

FIGURE 31.1. Double-barreled ureterostoma. **A:** The medial aspects of both ureters are spatulated and joined by interrupted or running 4-0 absorbable sutures. A subtle “rosebudding” suture technique is performed. **B:** Conjoined ureteral terminus everted on itself to create a projecting ureterostoma nipple.

V-flap widening of either the double-barrel or single-lumen ureterostomy stoma may be required in situations where the degree of terminal ureteral circumference is marginal or inadequate for eversion (Fig. 31.2) (115). Similarly, V-flap technique is helpful even in cases of a dilated single-barreled ureterostomy to ensure a sufficient stomal lumen.

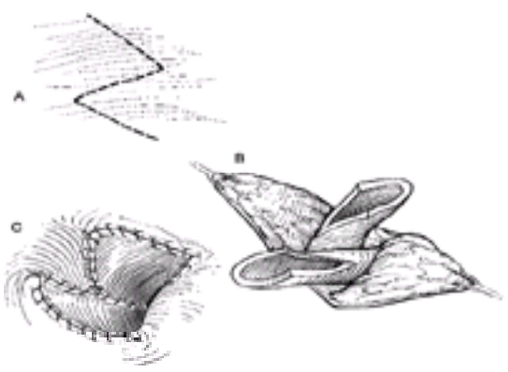

FIGURE 31.2. A–C: Double V-flap ureterostomy stoma.

If possible, the transperitoneal course of the ureters should be covered by anterior and posterior peritoneum sutured together to prevent internal bowel incarceration (115). Suction drainage is advised at the site of a transureteroureterostomy if one has been performed.

Complications and Results

The most serious early complication is necrosis of the ureterostomy stoma. This can result from compromise to the vascular supply because of excessive mobilization or rough handling, too tight an opening in the abdominal wall muscle or skin, or tight eversion of the ureter to form a stoma. There is usually insufficient ureter to resect the necrotic section and to produce an adequate stoma; therefore conversion to an enteric conduit must be performed.

Late complications include stomal stenosis and stomal retraction. Stenosis is usually due to an inadequate terminal lumen circumference, either fashioned or de novo, and may occur in as many as 50% of cases within 7 years (34). Retraction results from inadequate ureteral length initially or shrinkage subsequently. Similar to early necrosis previously described, conversion to an enteric conduit is usually necessary.

Initial results have been reasonable, more so in patients who require only temporary cutaneous ureterostomy. However, because of the high rate of stomal complications (36), the procedure is seldom appropriate for permanent diversion.

Conduits

The first to attempt diversion of the urinary stream into an isolated segment of ileum and ascending colon was probably Verhoogen in 1908 (127). Because of the prohibitive mortality rate, the technique was soon discarded, and ureterosigmoidostomy became the standard method of urinary diversion. With the development of pelvic exenteration as a therapeutic procedure for advanced pelvic malignancies, Bricker (16) was faced with the problem of “what to do with the ureters, since the sigmoid colon and rectum are not available as a receptacle.” For these patients he developed a separate ureteroileocutaneous diversion to which an external urinary reservoir was attached. He initially tried to achieve continence of the abdominal stoma by surrounding it either with imbricated fascia of the external oblique muscle or with a fascial sling. Although continence was achieved to some degree over a period of time, none of the patients remained continent. At about the same time, Gilchrist and associates (42) reported on the use of an ileocecal segment as a bladder substitute with an appliance-free continent urinary stoma dependent on the antiperistaltic activity of the terminal ileum and the action of the ileocecal valves. This success was not reproduced by other authors, and the concept was largely abandoned until recently.

Ileal Conduit

Some 50 years after Bricker's first description (in 1950), his ileal urinary diversion remains the most popular form of urinary diversion after cystectomy. Refinements in the operative technique and advances in the field of antibiotics, stomal appliances, and enterostomal therapy over the years have contributed to improved results both in terms of renal function and quality of life (13). Although not without long-term complications, most immediate postoperative complications can be prevented by meticulous surgical technique, a short ileal segment, adequate preoperative bowel preparation, use of perioperative prophylactic antibiotics, construction of a well-vascularized everted stoma, and use of delicate nontraumatic ureteral stents.

Technique

The success of Bricker's operation depends on preserving the vascular supply to the ileal segment and the ureters. Decreased vascularity, the cause of most major short-term complications, is due either to technical errors or to previous radiotherapy. A short segment of ileum, about 12 cm long, should be used. Adequate bowel preparation with antibiotic and mechanical bowel cleansing is essential to prevent infectious complications. In the classic Bricker procedure, the left ureter is brought under the base of the sigmoid mesocolon, without angulation, torsion, or tension, to a point close to the right ureter. The proximal end of the ileal segment either has been closed with a staple line or is sutured with absorbable sutures. Each ureter is spatulated and sutured to a small opening in the lateral aspect of the ileal conduit with absorbable sutures (Fig. 31.3).

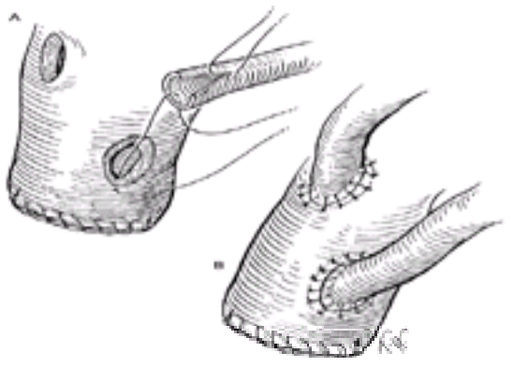

FIGURE 31.3. Bricker procedure for ureteroileal anastomosis. **A:** One-centimeter staggered, elliptoid incisions are made in the ileum. Following spatulation of the ureter, 4-0 absorbable apical sutures are placed at the 6 and 12 o'clock positions. **B:** Additional sutures are placed in an interrupted fashion.

The ureteroileal anastomosis according to Wallace (128) differs from Bricker's technique in that the spatulated ureters are anastomosed to each other before connecting the ureters to the open end of the isolated ileal segment (Fig. 31.4). First, both ureters are trimmed to a convenient point so that the anastomosis is out of the pelvis in the event that radiotherapy becomes necessary at a later date. Shortening of the ureters also will prevent subsequent kinking. Both ureters are then spatulated on the anterior surface for about 1.5 cm, with care taken not to interfere with the blood supply, and joined together with running 4-0 absorbable sutures. The conjoined ureters are sutured to the proximal, open end of the isolated ileum in a similar fashion. The theoretic advantage of the procedure is that the conjoined ureters afford a larger anastomosis to the ileum, thereby decreasing risk of ureteral anastomotic stenosis, and the ability to visualize the ureteral orifices at the end of the isolated segment in case of retrograde instrumentation of the upper urinary tract (40). Its utility is apparent in cases of dilated ureters requiring larger areas of ileal segment for individual anastomosis. But the surgeon must be aware that the contralateral ureteral anastomosis could be in jeopardy if a kidney and ureter must be removed.

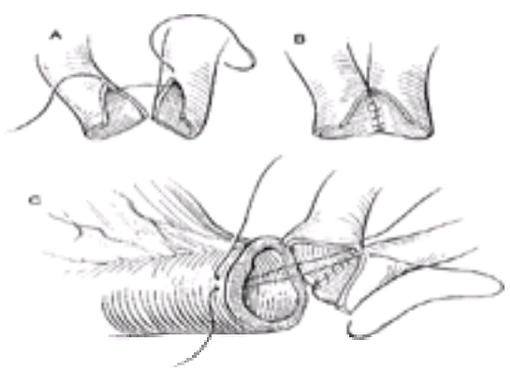

FIGURE 31.4. Wallace procedure for ureteroileal anastomosis. **A, B:** Medial walls of spatulated distal ureters are joined with a continuous, 4-0 absorbable suture. **C:** Conjoined ureters are sutured to the proximal, open end of the isolated ileal segment with similar suturing technique.

Clinical results of a new nonrefluxing ureteroileal anastomosis have been described. The so-called Hammock anastomosis should prevent ureteroileal reflux caused by a retrograde peristalsis of the conduit (59). It replaces the submucosal tunnel used in ureterocolonic anastomoses, which is not feasible in the thin wall of small bowel. The ureters, conjoined in a fashion similar to the Wallace technique, are anastomosed to the side wall at the proximal end of the ileal segment. The conjoined ureteral orifice is then buried into the intestinal wall made elastic and supple by multiple longitudinal and transverse seromuscular incisions. The ureteroileal anastomosis either can be stented with polyethylene stents brought out through the abdominal stoma and removed on the fifth to seventh postoperative day, or left unstented. We invariably use stents.

Proper construction of the stoma should prevent most short- and long-term problems. The site of the stoma should be tailored to the patient's specific anatomy in supine, sitting, and standing positions and should be identified and marked preoperatively by the surgeon or a stomal therapist. A circular opening about 2.5 cm in diameter is made in the skin at the site of the marking and continued bluntly to the fascia. The anterior fascia is opened by a 2-cm cruciate incision (Fig. 31.5). The rectus muscle is separated and the posterior fascia is likewise opened in a cruciate incision sufficient to allow free passage of two fingers. To prevent herniation, the conduit must be passed through the rectus muscle and not lateral to it. The mesenteric margin of the segment should be oriented toward the left shoulder to avoid any tethering, tension, or torsion of the mesentery that may cause vascular compromise to the conduit. Eversion of the stoma for about 1 to 2 cm is accomplished by the “rosebudding” suture technique. Sutures of 2-0 PGA are passed from the skin edge of the stoma site through the serosa of the conduit 2.5 to 3 cm proximal to the distal end of the ileal segment and then full thickness through the end of the segment (Fig. 31.6A). Two to three interrupted 3-0 absorbable sutures are placed from skin edge to ileal edge between each quadrant suture to complete the ileal rosebud (Fig. 31.6B). No suturing is required at either fascial level. The everted stoma allows a careful and accurate fitting of the stomal appliance and prevents leaks, as well as severe skin changes and stomal stenosis, in most patients. Before closure, the posterior rectus fascia portal should be examined. If the opening is in excess of what is required for the conduit, a few nonabsorbable sutures are used to close any large defect and prevent parastomal bowel herniation. Finally, the proximal end of the ileal conduit should be anchored tension-free to either the sacral promontory or the fascia of the psoas muscle with nonabsorbable suture.

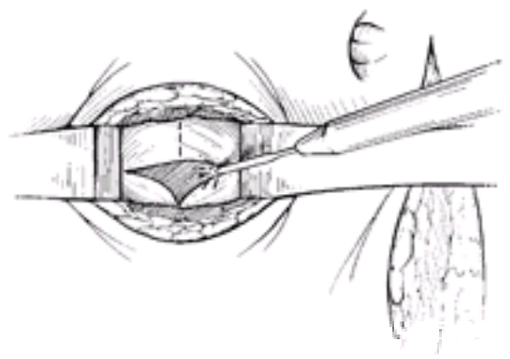

FIGURE 31.5. Construction of the diversion stoma. Following excision of a skin button representative of the conduit, subcutaneous tissues are separated down to the anterior rectus fascia. A cruciated, fascial incision is created in alignment with the skin button.

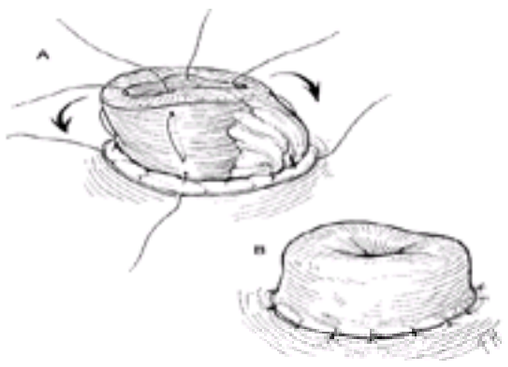

FIGURE 31.6. Rosebud suture technique of stoma. **A:** Four absorbable 2-0 PGA quadrant sutures are passed from the skin edge of the stoma site through the serosa of the conduit 2.5 to 3.0 cm proximal to the distal end of the ileal segment, then passed full thickness through the end of the ileal segment. **B:** Two to three interrupted 4-0 absorbable sutures per quadrant are placed from skin edge to ileal edge.

Complications

Experience and time have documented a significant incidence of both early and late complications following ureteroileocutaneous diversion. Among the early complications, wound infection and wound dehiscence were noted in 13.8% to 25.3% of patients (31,63,64,122) and intestinal obstruction in 6.1% to 23.6% of cases (62,122). Most obstructions respond to conservative treatment, with only 3% requiring surgery. The incidence of urinary leakage from the ureteroileal anastomosis may be as high as 11.3% (70), but most series report an incidence of 2.5% to 4.4% (26,64,122). The incidence of urinary leakage has been reduced by routine use of ureteral stents. Investigators have indicated that these stents reduce the incidence of urinary extravasation to 1% to 3% (8). The rate of early complications is higher in patients who have been irradiated. A high incidence of wound infection, drainage from the anastomosis, and prolonged ileus was reported in patients who received irradiation therapy before surgery (26,70,82,123). The mortality rate subsequent to ureteroileal diversion was about 20% in the early series (17,43), decreasing to 2.0% to 3.3% in more recent series (15,31,70). Among the recognized causes of death are pulmonary embolism, myocardial infarction, and infections.

Late complications are encountered in both children and adults (Table 31.1). Insight into delayed effects of urinary diversion on the kidneys, which may appear many years after surgery, has been reported mainly from studies on children followed for 10 years or longer (79,86,104,105,110). These studies demonstrate that renal deterioration visible on pyelography occurs in 18% to 56% of patients. The incidence of renal damage is directly related to the status of the upper tract at the time of diversion and to the length of follow-up. The longer the time interval, the higher the incidence of renal damage. Further renal deterioration in abnormal systems is more common than in normal kidneys (83,86,110). Smith (110) showed that subsequent to diverting a normal upper tract, 7% of the renal units at 5 years, 10% at 10 years, and 23% at more than 10 years showed deterioration. In the initially abnormal systems, additional deterioration was documented in 16%, 20%, and 45%, respectively, at the same time intervals. Further renal injury to already damaged kidneys may cause serious or fatal complications (86,92). For these reasons, some authors believe that ureteroileal diversion should not be performed when severe renal insufficiency is present, but rather other modes of urinary diversion without interposed bowel should be used (29,92,93).

TABLE 31.1. COMPLICATIONS AFFECTING THE KIDNEYS IN PATIENTS WITH URETEROILEAL

Obstructions of the stoma, the conduit, or the ureters are major factors leading to renal damage. The incidence of stomal obstruction in adults is about 5% (63,64,122), and in children it ranges between 12% and 52% (93,110). Stomal obstruction may cause back-pressure, affecting the upper urinary tract with impairment of urine flow from the loop. In these cases the loop is elongated, acting not as a conduit but as a reservoir containing varying amounts of residual urine. Early diagnosis and revision of stomal stenosis are mandatory to prevent severe, irreversible renal damage. Obstruction may involve not only the stoma but any part of the loop, and on rare occasions the whole loop may become fibrotic and stenotic, the so-called pipe-stem loop. This late complication was reported in 2.0% to 6.3% of children. Its etiology is not clear, but various factors, including ischemia and infection, have been suggested as possible causes. The loop is noncompliant throughout its length with impaired peristalsis and resultant proximal upper tract deterioration. Attempts to balloon dilate these stenotic loops have been unsuccessful. The only effective management has been replacement of the entire conduit (67). Stoma complications commonly seen include stomal excoriation and urea dermatitis of the surrounding skin. These conditions are usually related to a poorly fitted or improperly placed stomal appliance.

Ureteral obstruction occurring chiefly at the ureteroileal anastomosis was noted among 7.7% to 17.7% of adults and 2.0% to 22.3% of children, typically on the left side, where the left ureter is brought behind the sigmoid mesentery. Intravenous pyelography, antegrade pyelography, and retrograde pyelography in the form of a loopogram study can help localize the site and extent of the obstruction or stenosis. In adult patients who have had diversion for bladder cancer, tumor recurrence at the site of anastomosis or along the ureter is a possible cause of obstruction. Urine cytology and brush histology of the ureter may establish the diagnosis. Initially, endoscopic attempts should be made to manage ureterointestinal anastomotic stenosis not associated with malignant recurrence. Retrograde or antegrade laser incision of the anastomotic stricture is our first approach. The success of this approach is dependent on the length of the ureteral stricture. Strictures of less than 1 cm in length are most amenable to this form of treatment. Open reoperation, although a more invasive intervention, is somewhat more dependable, with a reported lower restricture rate. Any obstruction subsequent to ileal conduit diversion incurs greater risks of stone formation and urinary infection. Stones develop in approximately 4% of adult patients and in approximately 10% of children, and acute episodes of pyelonephritis, in children and adults, occur in 10% to 20% of patients.

In approximately 15% of patients with renal deterioration, no obstruction can be detected. The deterioration in such patients is attributed to infected refluxing urine (79). Experimental studies by Richie and Skinner (90) have shown that infected refluxing urine in dogs with urinary diversion produces pyelonephritic changes in most of the kidneys examined. Because of the increased risk of renal deterioration, all patients with ileal conduits should have periodic urine cultures, serum creatinine assay, and imaging of the upper tract every 6 months for the first 2 years and annually thereafter.

The question of the significance of refluxing contaminated urine from the conduit to the upper urinary tracts has prompted the recommendation for antireflux implantation into the ileum. Although this is technically feasible, the thin-walled ileum does not adequately support the antireflux tunnel, and this procedure has not gained wide acceptance.

Although rarely encountered, parastomal herniation can occur after ileal conduit diversion (50). This complication is best avoided by “defatting” the mesentery that is to be drawn through the fascia window, devascularizing the terminal 1 to 2 cm of the ileal loop, and directing the conduit path through the body of the rectus muscle instead of at its lateral margin. These maneuvers would allow a more limited window to be created in the fascial and peritoneal layers, thereby preventing parastomal hernia formation through a broad fascia defect.

Perspectives

Although the ileal conduit may not be the ideal bladder substitute, it has stood the test of time and is well suited to the bladder cancer patient after cystectomy. With the use of bowel staplers, the ileal segment can be rapidly isolated and ureteral anastomoses accomplished easily and accurately. Most immediate postoperative complications can be prevented by meticulous surgical technique, adequate preoperative bowel preparation, use of perioperative prophylactic antibiotics, construction of a well-vascularized everted stoma, use of a short ileal segment exiting directly through the rectus abdominis muscle, and meticulous anastomosis of the ureters. We further believe that routine use of ureteral stents for postoperative drainage minimizes the risk of anastomotic urinary leaks. Long-term complications remain a problem but are less difficult in adult patients with bladder cancer than in the pediatric group. It is important to note that severe short-term complications requiring reoperation are rare in the hands of the experienced surgeon (2% to 3% at our institution), and patients can be fitted easily with a reliable appliance that requires changing only every 5 to 7 days. Even though such patients must tolerate wearing an ostomy appliance, they do not need to catheterize a reservoir and usually resume almost all normal activities. For these reasons, the ileal conduit remains the most popular and frequently used method of urinary diversion subsequent to cystectomy for cancer. However, because of the increased success of continent urinary diversions, fewer conduits may be performed in the future.

Jejunal Conduit

In general, construction of a jejunal conduit should be contemplated only for selected cases in which alternative bowel segments are less attractive. Such instances may become apparent in patients with bladder, cervix, uterine, or rectal malignancy who have received significant radiotherapy to the pelvic cavity. Jejunum is typically avoided to prevent the often severe metabolic complications associated with its use for urinary diversions.

If jejunum is selected, the length of the segment should be as short as possible to minimize the potential for metabolic complications by limiting the degree of contact of urine with the jejunal mucosa. This may become a factor when positioning the stoma in that a more cephalad location is usually required, as compared with the stoma site for an ileal conduit. Ureteral stents should be used to divert the urine from contact with the mucosa, thereby lessening the potential for electrolyte disturbance during the initial postoperative period. Otherwise the technical aspects of constructing a jejunal conduit are similar to those of an ileal segment.

Specific considerations concerning postoperative care involve assessment of the patient's electrolyte status. Hyponatremia can be substantial and may lead to the development of secondary hyperaldosteronism. Therefore each patient should be monitored routinely at frequent intervals and evaluated for salt replacement. More than half the patients who undergo this type of diversion ultimately require salt replacement, usually in the form of sodium chloride tablets (44).

Colonic Conduits

Although it was thought that the isolated ileal conduit would eliminate most of the problems previously encountered with ureterosigmoidostomy, the long-term results proved otherwise, and colonic conduits were devised to improve the results of urinary diversion in certain situations. Using colon as a urinary diversion has several advantages. First, the large lumen provides an excellent stoma, which rarely undergoes stomal stenosis. Stomal stenosis and hyperkeratosis are both major problems in childhood urinary diversion. Second, a segment of colon can be chosen that is well outside previous pelvic radiation fields. Third, an antirefluxing ureterocolonic anastomosis can be created by either using the ileocecal valve or implanting the ureters into the tenia of the colon.

Virtually every portion of the colon, based on the colonic arterial arcade, has been used as an isolated urinary conduit. The preferred segment of colon seems to be the proximal sigmoid (3). One must be aware that the colonic wall has no longitudinal branches of collateral vessels, and therefore all the vasa recta must be preserved. In contrast, the microcirculation of an ileal or jejunal submucosal plexus can support a segment of small bowel that has been deprived of its vasa recta. An important aspect of any colonic diversion is the need to demonstrate a normal colon either radiographically or by colonoscopy or both.

Ileocecal Conduit

The ileocecal conduit has certain anatomic advantages over other colonic conduits. The blood supply is abundant and constant; the segment is rarely involved in compromising disease, such as diverticulitis; and its right lower quadrant location facilitates a tension-free right lower abdominal stoma. The ureters are attached to the ileal segment so that the ileocecal valve serves as an antireflux barrier. Libertino and Zinman (68c) described a method of reinforcing the ileocecal valve by wrapping the redundant cecum around the distal 4 to 8 cm of the terminal ileum. Late complications in their series of 150 patients included stomal prolapse requiring operative repair in 4%, ureterointestinal strictures requiring surgery in 3%, parastomal hernias requiring surgical repair in 2%, and small bowel obstruction after 6 months to 2 years in 1.3% of patients.

Transverse Colon Conduit

The transverse colon is well out of the field of any pelvic and lower-abdominal radiation. The main indication for transverse colon conduit is in patients after pelvic radiation with significant radiation changes to the ileum and rectosigmoid. The ends of the transverse colon segment approximate the kidneys on both sides and can be directly anastomosed to the renal pelvis if the ureters cannot be used. The conduit must be constructed so that the distal (left) end emerges as the stoma in an isoperistaltic fashion (Fig. 31.7). The ureters are anastomosed either directly or by an antirefluxing method. In patients with a complete destruction or severe fibrosis of both ureters, the colon can be directly connected either end-to-end to the right renal pelvis or end-to-side to the left renal pelvis. Stomal position may be either right or left upper or lower quadrants and should be marked preoperatively. Schmidt and Buchsbaum (101) published their long-term results and technical alterations. In their experience in 50 patients over a period of 15 years, they encountered an operative mortality in two (4%) and stable or improved renal function in 48 (95%) of their patients. Significant complications, most of them requiring surgical repair, occurred in almost one-third of the patients. These included parastomal hernia, stomal prolapse, ischemic ureteral stricture or ureteral obstruction attributable to recurrent tumor, nephrolithiasis, conduit stone formation, recurrent ureteral fistula, and incisional hernia.

(From Schmidt JD, Hawtrey CE, Buchsbaum HJ. *J Urol* 1975;113:308, with permission.)

Ravi and colleagues (87) reviewed their experience in 30 patients, all of whom received pelvic radiation of 65 Gy or more. They encountered no operative mortalities, and 25 (83%) had normal or improved renal function following the diversion. Complications were seen in 11 (37%), half of which required surgical correction. Although at substantial risk for obstruction at the ureterocolonic anastomosis, only three patients (10%) were found to have strictures. They attributed this lower-than-expected rate to resecting the ureter proximally and performing the anastomosis at a level of the midureter.

Sigmoid Colon Conduit

The most common indication for a sigmoid urinary diversion is the young patient who requires a diversion for benign neurogenic disease (65). The redundancy and

mobility of the sigmoid and its location in the left lower abdomen offer several advantages for its selection as a conduit. Patients with malignant pelvic tumors are not good candidates for a sigmoid conduit because of the diminished blood supply to the rectosigmoid after cystectomy and the possibility of previous pelvic irradiation. In the patient undergoing total pelvic exenteration, however, a sigmoid conduit can be used because the distal blood supply for healing of a colorectal anastomosis is of no concern. In most centers, sigmoid conduits tend to be limited to patients undergoing total pelvic exenteration because an intraabdominal bowel anastomosis can be avoided.

The construction of the distal colonic conduit is similar to that of other colonic conduits (Fig. 31.8). A tunneled ureterocolonic antireflux mechanism similar to the Leadbetter technique is preferred despite the increased chance of ureteral stenosis and hydronephrosis. The everted, protruding abdominal stoma is usually located in the left lower quadrant, but placement on the right side is also possible if previous operative scars or other deformities preclude the left side.

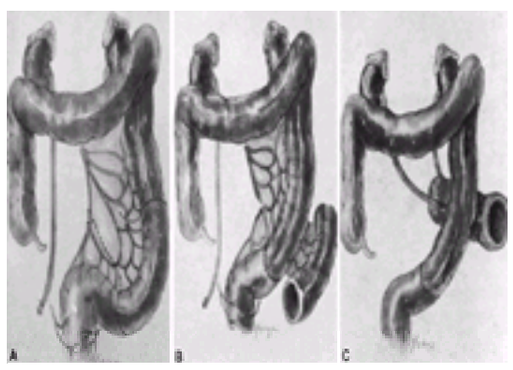

FIGURE 31.8. Sigmoid colon conduit. **A:** Isolation of a suitable sigmoid segment for sigmoid loop urinary diversion. Note that the distal sigmoid mesentery is divided all the way to the sacral promontory, including division of the superior hemorrhoidal artery. This provides maximal mobility of the loop and allows it to function in an isoperistaltic manner. **B:** Division of the proximal mesentery should be quite short, and care should be taken to avoid injury to venous drainage from the segment. The proximal end of the isolated segment is closed, and standard bowel anastomosis is performed medial to the isolated segment. **C:** The right ureter is brought under the sigmoid mesentery. (From Richie JP, Skinner DG. Ureterointestinal division. In: Walsh PC et al, eds. *Campbell's urology.* Philadelphia: Saunders, 1986:2612, with permission.)

The early postoperative complications are similar to those observed with the ileal conduit and other colonic conduits. Late complications are usually due to a failure of the ureterocolonic antireflux mechanism, with hydronephrosis and renal deterioration due to reflux or obstruction (3,35).

Complications

The deleterious effect of ileal conduit diversion on the kidneys has been attributed to the high rate of stomal stenosis and to free reflux of urine from the loop to the kidneys. The colon segment was introduced to achieve nonrefluxing ureterocolonic anastomosis and to avoid stomal complications. Early reports on colon conduits were encouraging, showing a low incidence of stomal complications (3,81). Stomal stenosis occurred in 0% to 2.8% of patients, pyelonephritis in 7.1% to 17%, and renal deterioration in 8.6% to 22.4% (Table 31.2). However, most patients included in these studies were followed for a short period. Longer follow-up on patients in other series revealed a higher incidence of complications. Elder and associates (35) noted in a group of 41 children followed from 9 to 20 years (average, 13.2 years) a 61.5% incidence of stomal stenosis, a 22% incidence of ureterocolonic stenosis, and a 48.4% incidence of renal deterioration. These data suggest that late stomal and renal complications are not prevented by using a colon conduit.

TABLE 31.2. COMPLICATIONS OF COLON CONDUIT DIVERSION

Perspectives

The use of the colon conduit as a urinary diversion in children provides a different set of criteria than does its use in adults with bladder cancer, as discussed in this chapter. In the adult, the problem of stomal stenosis is not major, and it can usually be avoided by creating a well-vascularized everted stoma. Therefore prevention of reflux remains the major attribute of the colon conduit. As noted, the value of the antirefluxing ureteral reimplantation is unclear. The paucity of long-term results makes it impossible to discern an actual advantage of antirefluxing procedures versus standard ureteral implantation, even though a theoretic advantage may exist. Ureteral stenosis increases after antireflux reimplantation, although the impact of this problem in adults may not be significant. The undisputed indication for the colonic conduit occurs in the patient who has had extensive pelvic irradiation with radiation damage to the distal ileum. The transverse colon is the preferred urinary diversion in this situation because it is less likely to be injured by radiation and has been found to have the lowest incidence of associated ureterocolonic anastomotic leakage or stomal complications (7,87,101).

CONTINENT URINARY DIVERSIONS

Urinary Diversion into the Rectosigmoid

Ureterosigmoidostomy

With the development of continent urinary diversion techniques using the Mitrofanoff principle, ureterosigmoidostomies have been less commonly performed. However, fueled by its simplicity, ureterosigmoidostomies remain popular with many contemporary urologic surgeons. Patient selection is paramount for successful continent diversion by ureterosigmoidostomy. Because of the high risk of potentially severe long-term complications, most would avoid this procedure in younger individuals. Relative contraindications include those patients with neurogenic bladder dysfunction, prior bowel disease or dilated ureters, renal impairment, pelvic irradiation, or hepatic dysfunction. Patients with neurogenic bladder dysfunction may have associated bowel or anal sphincteric dysfunction; thus, if ureterosigmoidostomy is to be considered, it is imperative that an evaluation and assessment of anal sphincter integrity be performed to avoid fecalurial incontinence (114). Patients with prior bowel disease, such as diverticulitis or colon polyps, should be avoided because of the risk of bowel fistula and colonic malignancy postoperatively. Implantation of dilated or tapered ureters into the large bowel is difficult and is associated with a higher risk of subsequent long-term renal deterioration (48).

Patients with established renal impairment are poor candidates for ureterosigmoidostomy or any continent intestinal diversion because of the inherent likelihood of exacerbations of electrolyte and acid–base disturbances with subsequent progressive renal deterioration. Patients with prior extensive pelvic irradiation also are not

favorable candidates because of the condition of the irradiated bowel or distal ureters (4,114). Patients with hepatic dysfunction are at certain risk for ammonia intoxication following ureterosigmoidostomy or any continent diversion because of the intestinal reabsorption of ammonium (106).

Technique

The most distal portion of the rectosigmoid is the preferred site for the ureteral anastomosis. After freeing both ureters, they are led through a submucosal tunnel into the bowel lumen. In the Leadbetter technique, the left ureter is brought through the sigmoid mesentery (Fig. 31.9). The anterior tenia is opened at two sites to expose the underlying mucosa, and each ureter is placed into a 3-cm-long trough. Two small openings are made in the mucosa to which each spatulated ureter is carefully anastomosed with fine 4-0 chromic sutures. The muscularis of the tenia is then closed over each ureter with interrupted silk sutures to form the submucosal tunnel.

FIGURE 31.9. Leadbetter's combined technique of ureterosigmoidostomy. Note that the left ureter is brought through the sigmoid mesentery and implanted on the anterior tenia. The rectosigmoid is fixed to the lateral pelvic wall of psoas muscle in the region of the right ureterocolonic anastomosis. (From Richie JP, Skinner DG. Ureterointestinal diversion. In: Walsh PC et al, eds. *Campbell's urology.* Philadelphia: Saunders, 1986:2602, with permission.)

Goodwin (45) promoted a transcolonic technique for the ureterocolonic anastomosis (Fig. 31.10). This differs from Leadbetter's method in that the rectosigmoid is opened anteriorly, and the ureters are brought through separate submucosal tunnels in the posterior wall into the bowel lumen. The ureters, either separately or conjoined to form a single lumen, are sutured to the mucosa from inside the bowel lumen.

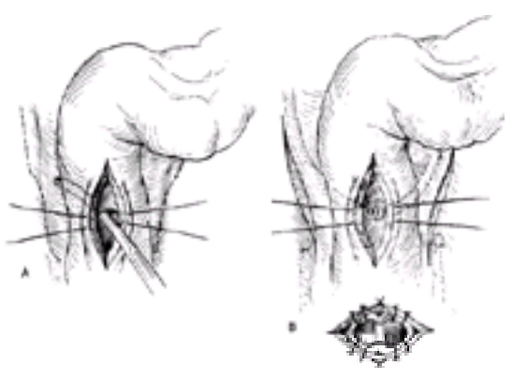

FIGURE 31.10. Goodwin's transcolonic technique of ureterosigmoidostomy. **A:** Note that both ureters are brought through individual submucosal tunnels in the posterior rectal wall. **B:** The ureters are then sewn together medially before they are secured to the colonic mucosa circumferentially. (From Richie JP, Skinner DG. Ureterointestinal diversion. In: Walsh PC et al, eds. *Campbell's urology.* Philadelphia: Saunders, 1986:2603, with permission.)

Results and Complications

Nonrefluxing techniques for ureterocolonic anastomoses have improved the long-term results for ureterosigmoidostomy by decreasing the incidence of ureteral reflux and ureteral obstruction (130,133,134). Comparison between the refluxing and nonrefluxing techniques reported by Wear and Barquin (130) showed fewer episodes of pyelonephritis and renal damage with the latter technique, although the incidence of acute pyelonephritis and renal deterioration remained high, ranging from 20% to 57% and from 13% to 35%, respectively (33,60,133,134) (Table 31.3). Because all patients undoubtedly have exposure of the reconstructed urinary tract to fecal flora, most investigators recommend long-term antibacterial therapy (33,114).

TABLE 31.3. COMPLICATIONS OF URETEROSIGMOIDOSTOMY

Early complications after ureterosigmoidostomy are encountered in about two-thirds of patients undergoing this procedure. Wound infection, wound dehiscence, and prolonged ileus are common (134). However, the most serious complication is urinary leakage from ureterocolic anastomosis or from the colotomy incision. The incidence of this complication can be minimized by a watertight ureterocolic anastomosis, the use of ureteral stents, and continuous drainage of the rectal contents. Proper drainage can be achieved by using two rectal tubes that have multiple perforations. Stents and tubes should be irrigated every 4 hours to ensure patency. Although minor leaks usually seal spontaneously without further treatment, major leaks involve a high incidence of complications, such as prolonged ileus, severe acidosis, and electrolyte imbalance. In patients in whom a major leak develops, immediate reoperation with reanastomosis or cutaneous diversion should be performed, and in life-threatening conditions, nephrectomy is indicated.

Electrolyte or acid–base imbalances, encountered in as many as 50% of patients, are caused by reabsorption of urine from the bowel. Reabsorption takes place not only in the sigmoid colon but also throughout the entire colonic mucosa (129). Characteristic laboratory findings in the serum subsequent to ureterosigmoidostomy include high urea levels with normal creatinine, high ammonium and chloride levels, low potassium levels, and metabolic acidosis. To improve acidosis and electrolyte imbalance, it is imperative to avoid prolonged contact between urine and the colonic mucosa. All patients should be instructed to evacuate the rectum every 2 to 3 hours during the day and at least once or twice at night. A lifelong low-chloride diet and supplemental solution of 10% potassium citrate should be prescribed for most

patients.

The association between ureterosigmoidostomy and colonic tumors has been confirmed by numerous studies since the first report by Hammer (49). In reviewing the literature, Leadbetter and associates (68a) found 45 patients with tumors at the site of the ureterocolonic anastomosis, of which 31 were adenocarcinoma, 4 were transitional cell carcinoma, and 4 were benign colonic tumors. It has been estimated that the incidence of colonic carcinoma associated with ureterosigmoidostomy is 500 times higher than in the normal population. The mean lag period for development of carcinoma of the colon for patients following ureterosigmoidostomy after age 40 years was 8.7 years (range, 5 to 14 years), whereas for those who were younger than 40 years, the lag period was 21.4 years (range, 14 to 50 years). The etiology of these tumors is obscure. Mechanical irritation by the fecal stream at the site of the ureterocolic anastomosis (95), the carcinogenic effects of the mixture of urine and feces (30), and the presence of large amounts of carcinogenic nitrosamines in the rectal urine (119) have been suggested as possible etiologic factors.

All patients with ureterosigmoidostomy should be examined for occult blood every 6 months and undergo a yearly intravenous pyelogram and colonoscopy starting 5 years postoperatively (39). Barium enemas are relatively contraindicated because of the potential for reflux of this material to cause associated septic events (133). If a colonic tumor is found, segmental resection of the bowel and cutaneous urinary diversion should be performed.

Ureteroileosigmoidostomy

The principle of interposition of an ileal segment between ureters and functionally intact colon had been suggested by Goodwin (46), who proposed a “ureteroileal undiversion” into the sigmoid. Several methods using a segment of ileum or an ileocecal segment interposed between ureters and sigmoid have been proposed with the intent of reducing the risk of cancer development associated with ureterosigmoidostomies and to improve the ureteral antireflux mechanism. However, currently neither sufficient data nor long-term results exist to suggest that the creation of a low-pressure colonic reservoir with ileum will reduce ureteral reflux with its associated complications. Likewise, it is not established that the interposition of an ileal segment between ureters and sigmoid will prevent the formation of colonic tumors.

CONTINENT CUTANEOUS (HETEROTOPIC) URINARY DIVERSIONS

Because of the shortcomings of ureterosigmoidostomy and the ileal conduit, continent urinary diversion to the abdominal wall has gained increased popularity among both patients and physicians. In 1950, Gilchrist and associates (42) reported for the first time the use of an ileocecal segment as an appliance-free continent urinary diversion. Continence was based on the antiperistaltic function of the terminal ileum and the action of the ileocecal valve. Since then, various other methods have been proposed, but none of them has proved to be perfect and free of complications when applied clinically.

Most of the techniques have a reported complication rate of more than 10%, the most common being failure of the continence mechanism (73,109). The reservoir usually is continent at low filling, but larger volumes and high intermittent tension of the bowel wall can result in urine leakage (71). All of these methods rely on the coapting ability of bowel under the influence of imbrication, tapering, or intussusception to achieve a suitable closing pressure, but they differ in terms of where this valve is placed—inside or outside of the reservoir. In postmortem studies of isolated ileocecal segments and in vivo barium enema studies, Ashken (5) found that the ileocecal valve was incompetent in more than 50% of the cases. He therefore used a spout of ileum sutured into the open end of the cecum or ascending colon as the valve mechanism of an ileocolic urinary reservoir. Prolapse of the ileal spout with incontinence and difficulty in catheterization required reoperation in 40% of his patients. A variation using an invaginated segment of ileum sewn into the open end of the cecum was described by Benchekroun (10), who named it the “inkwell valve.” As with other cecal reservoirs, the most common complications were prolapse of the inkwell valve and ischemic necrosis with subsequent urinary leakage from the cecal reservoir.

Reinforcement of the ileocecal valve has been attempted in several ways: by imbricating or tapering the terminal ileum, by burying the terminal ileal segment with redundant cecum, or by intussuscepting the ileum either outside the reservoir or through the ileocecal valve and placing the continent nipple into the lumen. Continence of the intraluminal valve was compared with continence of a form of reinforced ileocecal valve, and the intraluminal continence mechanism was more successful (118). The issue of long-term continence remains a central focus in current attempts to popularize continent cutaneous diversions.

Kock Pouch

Kock's (67a) description of a continent ileostomy with its intussuscepted intraluminal valve mechanism eventually led to the development of an intestinal pouch used as a continent urinary reservoir. It is used in many centers worldwide but has been replaced by more simpler methods in most areas of the United States.

Technique

Approximately 80 cm of ileum has to be isolated. Distally, the mesentery and bowel are divided along the avascular plane between the superior mesenteric artery and the ileocolic artery. The division of the mesentery should extend to the base of the mesentery to ensure sufficient mobility of the efferent limb of the pouch. Before the proximal end of the isolated bowel is closed, several centimeters of the proximal ileum together with a small triangular wedge of mesentery are discarded to enhance the mobility of the reservoir and the small bowel anastomosis. Staples or the conventional technique using two layers of interrupted 4-0 silk sutures can be used to reestablish bowel continuity. The median portion of the detached ileum consisting of two 22-cm-long segments is opened on the antimesenteric border, formed into a U-shaped plate, and sewn together side-to-side with a 3-0 PGA suture (Fig. 31.11A and Fig. 31.11B). The proximal and distal valves are then created by intussuscepting about 12 cm of ileum at each end. For this purpose the mesentery is divided at a length of 7 to 8 cm on each side flush with the serosa of the ileum. The tubular ileum on each end is then intussuscepted with the help of Allis clamps to form two nipples lying in the open pouch. Three to four parallel rows of 4-mm staples, each 5.5 cm long, are used to maintain the intussusception. To prevent late slippage or desussception of the nipple valve mechanism, a folded 2-cm-wide PGA mesh is passed through a small separate window in the mesentery and sewn with seromuscular stitches to the bowel wall to secure the intussuscepted nipple from outside. The mesh of the efferent nipple is also fixed to the abdominal wall to facilitate catheterization of the pouch (Fig. 30.11C and Fig. 30.11E). Both ureters are spatulated, anastomosed end-to-side to the free portion of the afferent nipple, and stented with infant feeding tubes. The pouch is then closed with a single layer of interrupted 3-0 PGA running sutures. Some authors have promoted a two-layer suture to ensure watertightness of the closure. Before the closure is completed, a Medina tube is passed through the efferent nipple into the pouch. The efferent limb of ileum is brought through the abdominal wall, and a flush stoma is created. Posteriorly, the pouch is attached to the sacral promontory with several interrupted PGA sutures.

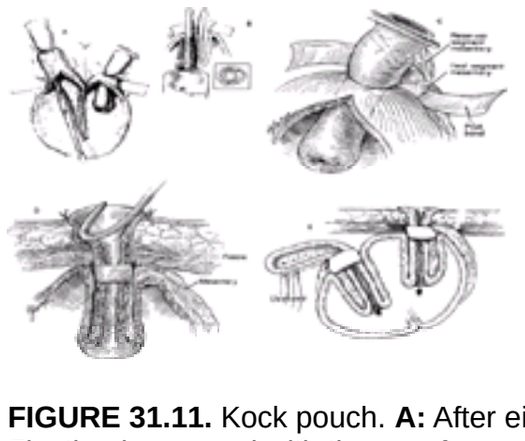

FIGURE 31.11. Kock pouch. **A:** After either defatting the mesentery or dividing it, proximal and distal valves are created by intussusception of the ileal segment. **B:** Fixation is secured with three or four rows of GIA staples. **C:** The PGA strip is passed through a small window in the mesentery of the reservoir and then through a similar window in the mesentery of the adjacent ileal segment. This traps the valve and helps prevent disintussusception. **D:** Improper fixation of the terminal segment makes catheterization difficult, and the catheter does not easily enter the valve. A short segment, fixation of PGA to the external fascia, and fixation of the reservoir to the abdominal wall minimize difficulties with catheterization. **E:** The distal segment is made as short as possible and secured flush with the abdominal wall. Then the PGA mesh must be pulled into the abdominal wall and sutured to the external fascia. The reservoir is then fixed to the abdominal wall with several circumferentially placed sutures. (**A, B:** From Kock NG, Nilson AE, Nilson LO, et al. *J Urol* 1982;128:469, with permission. **C–E:** From deKernion JB, DenBesten L, Kaufman JJ, et al. *Am J Surg* 1985;150:84, with permission.)

Results and Complications

Despite increasing experience and many modifications, the Kock pouch still has a high complication rate. Although the principle of the afferent intussuscepted nipple is highly effective in the prevention of ureteral reflux and has been used in various other diversions (66,120), the intussuscepted efferent nipple remains a source of complications. Skinner and co-workers (109) reviewed their experience in 531 patients undergoing a Kock pouch diversion between 1982 and 1988. Early complications occurred in a total of 86 patients (16.2%), resulting in an operative mortality rate of 1.9% (10 of 531). The late complications encountered in 489 patients were stratified according to the technical changes made over the years. Even in their last series of 239 patients, the overall incidence of late complications was still 22%. Leakage occurred in 15% of the patients, requiring one or several reoperations in the majority of those, and it remained the primary late complication even after modifying the efferent valve fixation. Although this complication rate seems to be lower than that originally reported for the Kock pouch, the number of patients is much smaller.

Mainz Pouch

The Mainz pouch was first described in the English literature by Thuroff and colleagues in 1986 (125). Since then, this principle has been used as a continent cutaneous diversion, as well as bladder augmentation or orthotopic bladder substitution, by an increasing number of urologists worldwide.

Technique

For the continent urinary diversion, 10 to 30 cm of cecum and ascending colon and approximately 50 cm of terminal ileum are isolated (Fig. 31.12A). The colon and about 30 cm of the adjacent ileum are detubularized at the antimesenteric border and sewn together side-to-side with a single layer of running sutures to create an intestinal plate (Fig. 31.12B and Fig. 31.12C). The ureters are brought into the pouch through a 5-cm submucosal tunnel along the posterior tenia of the colon. The ileal mesentery of the tubular portion of the ileum designated for the creation of the continence mechanism is then freed from the ileal wall. The ileum is intussuscepted and stabilized with two rows of staples (Fig. 31.12D and Fig. 31.12F). The intussuscepted segment of ileum is then brought through the natural tunnel of the ileocecal valve and fixed to it with TA-55 staples from inside and outside (Fig. 31.12G and Fig. 31.12H). After stenting of the ureterocolonic anastomosis and insertion of the suprapubic catheter through a separate stab incision in the pouch and abdominal wall, the anterior wall of the reservoir is closed with a single row of through-and-through running sutures (Fig. 31.12I).

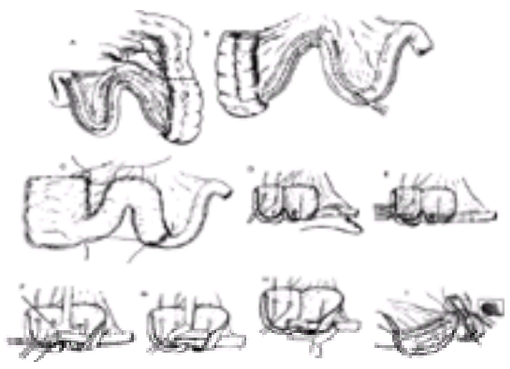

FIGURE 31.12. The Mainz pouch. **A:** The intestinal segment to be isolated for the Mainz pouch continent urinary diversion. **B:** Antimesenteric splitting of the intestinal segment used for the pouch and nipple. **C:** Side-to-side anastomosis of the colon and detubularized ileal loop to create an intestinal sheet. **D:** Ileoileocecal intussusception. The ileocecal valve remains intact. Six to eight cm of proximal ileum are freed from the mesentery. **E:** With Allis clamps, the ileum is pulled through the natural tunnel of the ileocecal valve. **F:** Stabilization of the intussusception by two rows of 4.8-mm staples. **G:** Staple fixation of the intussusception at ileocecal valve (4.8-mm staples). **H:** Staple fixation of the intussusception at the posterior wall of the ileocecal valve (4.8-mm staples). **I:** The efferent loop is anastomosed to the abdominal wall. The preferred site of the Mainz group is the umbilicus (as shown here). (From Thuroff JW, Alker P, Riedmiller H, et al. *J Urol* 1986;136:18,20; and Thuroff JW, Alker P, Riedmiller H, et al. *J Urol* 1988;140:285, with permission.)

Several methods to form a continent cutaneous stoma have been used: abdominal stoma to the left or right lower quadrant, alloplastic prosthesis at the skin level, and an umbilical stoma. All the alloplastic stoma prostheses had to be removed because of infection and were changed to a continent abdominal or umbilical stoma. The best functional and cosmetic results were accomplished with the umbilical stoma, and it is currently the method preferred by the Mainz group.

Results and Complications

A mean capacity of 620 mL, resting pouch pressures between 23 and 31 cm H_2O, and peak pressures up to 43 cm H_2O are reported in the continent diversion patients. Thuroff and co-workers (126) reported their experience with the Mainz pouch in the first 100 consecutive patients (51 of those underwent a cutaneous continent diversion). No operative mortality and seven major perioperative complications requiring reoperation in three cases were encountered in the total group. Late complications after a mean follow-up of 23 months included valve prolapse or incontinence in 11 patients, all of them in the early series, whereas none of these problems occurred in their series after modifying the technique of fixation and stabilization of the intussuscepted ileocecal valve.

Authors' Modification (UCLA Pouch)

We have experimented with various forms of urinary diversion at our institution. Our initial experience with the Kock pouch was disappointing because of the high early failure and reoperation rates (32). Subsequently, several forms of detubularized right colonic reservoirs were attempted with varying success. We currently use the detubularized ileocecal reservoir and achieve continence by preserving the ileocecal valve and by tapering and compressing the ileal segment.

Technique

The entire right colon up to the hepatic flexure and approximately 12 cm of the terminal ileum are isolated with their blood supply (Fig. 31.13A). The colonic segment is detubularized along the anterior tenia down to the area of the cecum. At this point, the incision is turned upward to terminate at the junction of the ileum with the cecum (Fig. 31.13B). Creation of the continent valve is a critically important step in the procedure. The segment of terminal ileum is tapered over a 14-Fr Foley catheter with an absorbable gastrointestinal anastomosis (GIA) stapler. Fixation of the ileal limb is probably the most important step in preventing postoperative incontinence. Based on the studies by Raz (88,89), a technique was developed that is different from prior procedures in that the ileal limb is fixed against the wall of the continent pouch in a trough created in its serosal layer with 2-0 absorbable sutures (Fig. 31.13C). Intraluminal pressure is transmitted to the ileal limb, causing compression of the catheterizable portion.

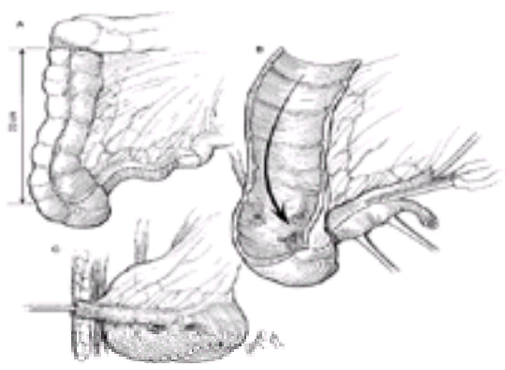

FIGURE 31.13. UCLA pouch. **A:** Right colon to the hepatic flexure and 12 cm of terminal ileum are isolated. **B:** The colonic segment is detubularized along the anterior tenia. The terminal ileum is tapered with an absorbable GIA stapler; the staple line is reinforced with interrupted 2-0 PGA ligatures, and the ureterocolonic anastomoses are performed. **C:** A trough is created in the serosa of the constructed reservoir. The catheterizable limb is fixed to the reservoir in that trough with the interrupted 2-0 PGA sutures. The pouch is closed and the stoma site on the skin surface is prepared accordingly. The pouch is then fixed to the posterior rectus fascia and anterior abdominal wall with a few 2-0 PGA suture ligatures.

Ureterocolonic anastomoses are carried out in a LeDuc fashion (Fig. 31.14). The pouch is created by folding down the ascending colon and suturing it to cecum with running absorbable suture material. Ureteral stents are positioned and a suprapubic tube is brought through the left lower abdominal wall. At a previously determined site, a 1-cm buttonhole is created in the skin, anterior fascia, and posterior fascia. The distal segment of the catheterizable ileal limb is advanced between the rectus muscle. The mesentery of the limb is inspected for tethering or tension. Excess ileal limb is removed, and a flush skin stoma is created that has a somewhat flared configuration to allow easier catheterization (Fig. 31.13C). The skin and limb edges are sutured with interrupted 3-0 PGA suture material. The 14-Fr Foley is left in place. The pouch is then fixed to the posterior rectus fascia and anterior abdominal wall with a few 2-0 PGA suture ligatures.

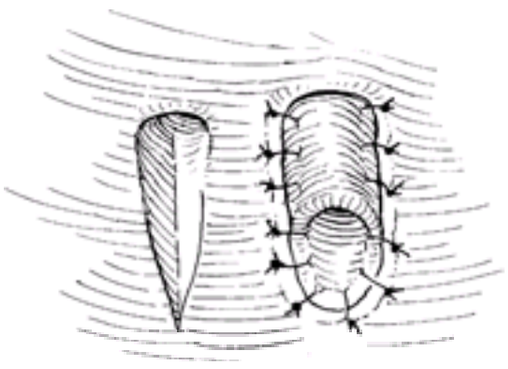

FIGURE 31.14. LeDuc ureterocolonic anastomosis. A 2- to 3-cm mucosal trough is created *(left).* The spatulated terminal ureter is brought through the apex and rested in the trough. Full-thickness 4-0 PGA sutures are placed from the distal posterior ureteral edge to the distal apex of the trough. Mucosal edges of the trough are tacked to the ureteral wall with interrupted sutures *(right).*

The patient returns in approximately 3 to 4 weeks for contrast studies of the reservoir. The ureteral stents and the 14-Fr Foley are removed and the patient is taught the catheterization technique. If no problems are noted, the reservoir drainage tube is removed.

Results and Complications

Thus far this procedure has been performed in 25 patients. The results at 4 years are gratifying (89). No patient has required reoperation for incontinence, stomal obstruction, or parastomal hernia formation. Two patients had temporary difficulty with catheterization but have not required reoperation. The operative time is only slightly greater than that of the ileal conduit and markedly decreases with experience. The relative ease of the procedure and the excellent early results have prompted us to recommend the operation more widely and with much more enthusiasm than we had for prior methods of cutaneous diversion.

Indiana Pouch

One of the first continent cutaneous pouches to gain wide acceptance in the urologic community was the Indiana pouch developed at Indiana University by Rowland and co-workers (97). The major contribution of this pouch was the creation of a reliable continence mechanism. The pouch has remained popular because of all the continence mechanisms used in continent cutaneous diversions, this mechanism is one of the least technically demanding to construct.

Construction of the mechanism initially relied on the concept of buttressing the ileocecal valve with a double row of imbricating sutures taken to the entire ileal segment (96,97). However, because pressure profiles demonstrated that the continence zone was confined to the region of the buttressed ileocecal valve, it became apparent that the imbricating sutures were necessary only in the region of the ileocecal valve (9).

Technique

In this form of continent diversion (97), approximately 20 to 25 cm of cecum and ascending colon are isolated along with 15 to 18 cm of terminal ileum (Fig. 31.15A). The colon is detubularized about three-fourths of its length starting from the distal end. The ureters are anastomosed through a tunnel along the posterior colonic tenia. The continence mechanism consists of plicated terminal ileum, which reinforces the ileocecal valve (Fig 31.15B). The ileal plication consists of two rows of Lembert sutures 8 to 10 mm apart beginning at the ileocecal valve and extended 3 to 4 cm proximally and reinforced by a second layer of continuous silk sutures (Fig. 31.15C). The remaining ileum can be tapered over a catheter and excess ileum removed by a GIA stapler. The pouch is created by folding down the opened cecum in a Heineke-Mikulicz configuration and closed with continuous 2-0 PGA suture material (Fig 31.15B). Ureteral stents are positioned, and a suprapubic tube is taken through the lower abdominal wall. A 1-cm buttonhole is made in the skin, anterior fascia, and posterior fascia. The catheterizable ileal limb is advanced between the rectus muscle. Excess ileum is removed. A flush skin stoma is created by sewing the ileal edges to the skin edge with interrupted absorbable suture material. The postoperative care of a patient with an Indiana pouch is similar to that for other right colon continent cutaneous diversions. Cecostomy tube removal and self-catheterization instruction should occur at 3 weeks after surgery.

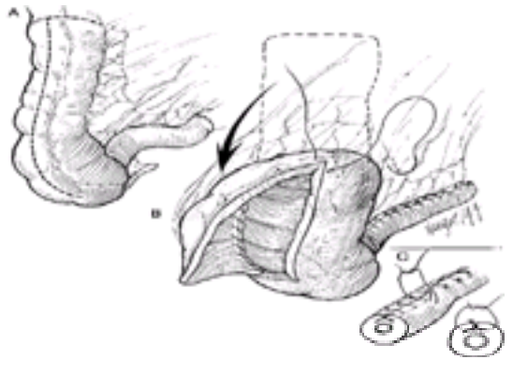

FIGURE 31.15. Indiana pouch. **A:** From 20 to 25 cm of cecum and ascending colon are isolated along with 15 to 18 cm of terminal ileum. The colon is detubularized about three-fourths of its length starting from the distal end. The ureters are anastomosed through a tunnel along the posterior colonic tenia. **B:** The continence mechanism consists of plicated terminal ileum, which reinforces the ileocecal valve. **C:** The ileal plication consists of two rows of Lembert sutures 8 to 10 mm apart beginning at the ileocecal valve and extending 3 to 4 cm proximally, and is reinforced by a second layer of continuous silk sutures. The remaining ileum can be tapered over the catheter and excess ileum removed by a GIA stapler. The pouch is completed by folding down the opened cecum in a Heineke-Mikulicz configuration **(B)** and closed with continuous 2-0 PGA suture material.

Results and Complications

In Rowland and associates' (97) first 29 patients, the average amount of catheterized urine was 291 mL, the average of the greatest volume of urine was 508 mL, and intraluminal pouch pressures did not reach more than 20 cm H_2O. In a report on 91 patients with a minimum follow-up of 6 months, 85 (93%) of the patients had daytime continence, and 69 (76%) of the patients had nighttime continence (99), but most of these patients had to catheterize themselves once at night to remain continent. The reoperation rate, mainly caused by complications with the efferent limb, was 26%. The advantages of the Indiana pouch are its relatively simple construction and an acceptable length of time for the operation. However, endoscopic studies on dogs at our institution have shown that the ileocecal valve, although reinforced by imbrication, undergoes anatomic changes after several months. The ileocecal valve changes to a permanent opening surrounded by a fibrotic ring, and it is unlikely that the actual valve is responsible for the urinary continence (118). Long-term results will show if incontinence will develop in patients after several years.

Florida Pouch

The distinguishing feature of the Florida pouch, described by Lockhart (68e), is the amount of colon used and the manner in which it is reconfigured.

Technique

The entire ascending colon and right third or half of the transverse colon is isolated, along with 10 to 12 cm of ileum. The proximal portion of the large bowel segment is mobilized and rotated laterally to form an inverted U (Fig. 31.16A). The entire large bowel is then detubularized along its antimesenteric border, and the medial limbs of the U are joined with continuous absorbable suture material (Fig. 31.16B and Fig. 31.16C). The ureters are implanted in the posterior plate in standard fashion. Construction of the catheterizable ileal segment continence mechanism is performed in a fashion similar to that for the Indiana pouch. One exception is that Lockhart suggests the application of opposing Lembert sutures, being taken on each side of the terminal ileum, to buttress the ileocecal valve. The standard drainage tubes are positioned and the large bowel plate is then closed side-to-side. The catheterizable limb is then brought through the skin and a stoma is created as previously described for the Indiana pouch.

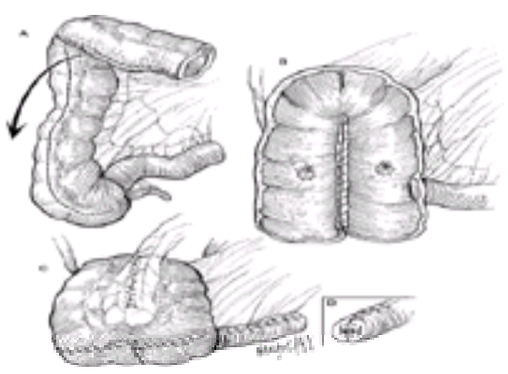

FIGURE 31.16. Florida pouch. **A:** The entire ascending colon and proximal third or half of the transverse colon are isolated, along with 10 to 12 cm of ileum. **B:** The proximal portion of the large bowel segment is mobilized and rotated laterally to form an inverted U. The entire large bowel is then detubularized along its antimesenteric border, and the medial limbs of the U are joined with continuous 2-0 PGA suture material. The ureters are implanted in the posterior plate in standard fashion. **C:** Construction of the catheterizable ileal segment continence mechanism is performed in a fashion similar to that for the Indiana pouch. **D:** Opposing Lembert sutures buttress the ileocecal valve.

Results and Complications

Urodynamics performed on 28 patients revealed pouch capacities of 500 to 1,200 mL, with intraluminal pressures at capacity ranging from 10 to 58 cm H_2O. In more than 100 patients, the overall reoperation rate was reported to be 7%. Seventy patients experienced hyperchloremia, but only four patients, including those with preexisting renal disease, required treatment.

Gastric Pouch

In certain circumstances, the use of stomach to create a urinary reservoir has become an attractive option. A most unique feature of stomach, when compared with the small and large bowel, is its consistent inability for electrolyte reabsorption. This property allows stomach to be considered the preferential reservoir for individuals with preexisting renal insufficiency. In addition, not only does stomach possess an inherent barrier against absorption of chloride and ammonium, but it also has the ability to actively secrete chloride ions (85). Therefore the hyperchloremic acidosis seen with other urinary intestinal diversions is avoided with gastric diversions. Other instances in which gastric diversions are viable alternatives include patients with prior entire lower-bowel irradiation or in whom shortening of the bowel is expected to lead to degrees of malabsorption. In any case, the technical feasibility of its use and its theoretic advantages have promoted clinical trials with gastric pouches, particularly in the pediatric population (2).

Technique

An 8- to 10-cm wedge-shaped segment is isolated from the greater curvature of the stomach. The section is then mobilized on a gastroepiploic vascular stalk by dividing the short gastric vessels proximal to the segment (Fig. 31.17A). The stomach is then closed with continuous 2-0 PGA sutures followed by interrupted simple ligatures at 1-cm intervals. The isolated segment is refashioned into a sphere by folding it back on itself and suturing the edges with a similar suturing technique (Fig. 31.17B). Ureteral implantation is performed in an antireflux fashion bilaterally. A Mitrofanoff cutaneous conduit can be created if the appendix permits. Otherwise, a proximal transureteroureterostomy can be performed with the ipsilateral distal ureter tunneled into the reservoir and its distal extent brought to a catheterizable site.

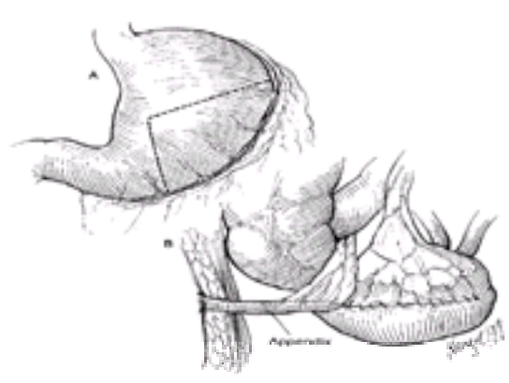

FIGURE 31.17. Gastric pouch. **A:** An 8- to 10-cm wedge-shaped segment from the greater curvature of the stomach is isolated. By dividing the short gastric vessels proximally to the fundus, the vascular pedicle preferably used is the left gastroepiploic artery. **B:** Ureterogastric anastomoses are performed, and the isolated wedge is fashioned into a sphere by folding it on itself and suturing the edges with continuous 2-0 PGA material. Either a patent appendix or native distal ureter is tunneled into the reservoir and then brought to the skin to serve as a catheterization portal.

Results and Complications

Mean pouch capacities of 245 mL and mean end-filling pressures of 35 cm H_2O have been reported (2). The most common side effect of gastric pouches is a dysuria and hematuria syndrome caused by aciduria. This condition is often amenable to acid-reducing therapies such as the use of proton pump inhibitors. Experience with gastric pouches is still limited.

Perspectives

The major short-term complications and the early reoperation rates of continent cutaneous diversions have diminished with further experience and refinements of technique. Improved experience with continent diversions has also resulted in shorter operative times for such procedures. Given the lack of need for external appliances, and continued urinary continence over time, continent diversions have become the diversions of choice for most patients. The associated differences in quality of life associated with continent and incontinent urinary diversion techniques must be addressed and evaluated.

URINARY DIVERSIONS TO THE URETHRA (ORTHOTOPIC)

The ideal bladder replacement should mimic the function of the native bladder. For example, the neobladder should be able to store an adequate volume of urine at low pressures, have minimal absorption of its stored contents, completely empty volitionally, provide resistance to bacterial translocation, and have a low propensity for mucus production or stone formation. None of the urinary reservoirs in clinical use entirely achieves these goals. With the attempt to develop a satisfactory bladder replacement, many complications were encountered with the outlet of the reservoir. Several variations of intestinal neobladders attached to the urethral remnant in male patients have been introduced. These offer several advantages: no physical or psychologic problems caused by an abdominal wall stoma; continence in most patients, at least during the daytime; the ability to store and empty urine often without the need of a catheter; and an improved body image, resulting in more self-confidence and better sexual performance (13). Initially, a major shortcoming of urinary diversion to the urethra was that high intraluminal pressures existed in the contracting intestinal reservoir. Persistent peristaltic contractions of the intestinal bladder, particularly during sleep, create pressures high enough to overcome the urethral closure pressure and cause incontinence.

To reduce the high-pressure contractions seen in tubular portions of continent urinary diversions, antimesenteric disruption of the circular smooth musculature (detubularization) of the isolated bowel segments has been recommended. Detubularization reduces the frequency and strength of the peristaltic pressure waves and increases neobladder compliance. Detubularized bowel also offers several advantages for reconfiguration necessary to create a neobladder (58,100). Folded detubularized ileum or colon leads to a neobladder with a larger diameter. Volume increases by the square of the radius, and the newly formed neobladder therefore has a much larger capacity than the unopened tubular intestinal segment of the same length. The larger diameter of the reconfigurated neobladder also will also accommodate larger volumes of urine at lower pressures.

Only certain patients are eligible for a urinary diversion to the urethra. Carcinoma *in situ* or an invasive tumor at the bladder neck or anywhere in the urethra is a contraindication. Nevertheless, 8% to 12% of patients with bladder cancer develop a recurrence in a urethra free of dysplasia at the time of cystectomy.

Three basic tenets should be adhered to when considering construction of a continent diversion to the urethra:

1. It is essential that adequate mobilization of the bowel segment and ureters be performed for a sufficient tension-free urethra anastomosis. If tension exists on the urethral anastomosis, the patient is at increased risk of anastomotic leakage and possibly anastomotic disruption. Most important, this tension may be transmitted to the neobladder mesentery, resulting in compromise of its vascular supply, which could ultimately result in ischemia, necrosis, and loss of the entire bladder substitute (1).
2. The second tenet applies to surgeon familiarity with and ability to perform a variety of different diversions. Depending on the integrity of the bowel segment intended to be used, the surgeon may have to resort to an alternative bowel segment or an entirely different type of diversion. Unforeseeable conditions, such as bowel malignancies, anatomic variability, patient instability, or urethral involvement with tumor, may contraindicate neobladder construction. Therefore familiarity with continent cutaneous diversion and incontinent diversion procedures is imperative.
3. Preservation of the intrinsic external urethral sphincter determines the degree of continence. All periurethral tissue must be intact and the entire length of urethra preserved (72).

Ileal Neobladders

Camey Procedure

For years, the Camey or similar procedures were the most popular urinary reservoirs to the urethra. In 1979 Camey and LeDuc (19) reported their positive experience with 90 patients who underwent construction of an ileal bladder after radical cystectomy. In 1984, Lilien and Camey (68d) reported on their long-term results in 25 patients. More than 90% of their patients achieved continence if they adhered to an interval of voiding every 2 to 3 hours. However, the operative mortality rate in 84 patients approached 5% (4 of 84 patients), and in 15% of the patients the procedure was not feasible because of a short or fatty mesentery. Patients were usually incontinent at night unless they emptied their reservoir every 2 to 3 hours. Prolonging daytime intervals of urine evacuation or placement of an artificial urinary sphincter around the urethra resulted in distention of the neobladder and marked hydronephrosis. Others reported daytime incontinence rates as high as 20%. In some of our patients with significant daytime incontinence after a Camey procedure, the measured intraluminal pressure in the reservoir reached 80 cm H_2O. This dampened enthusiasm for the procedure, but the new understanding of the principle of detubularizing and reconfiguring the bowel to lower pressure preserved the role of the ileal neobladder in urology.

The simplest form of reconfiguration is transverse folding of a detubularized bowel segment. In his theoretic deliberations on intestinal neobladders, Hinman (58) demonstrated the gain in volume by reconfiguring detubularized bowel. A 40-cm intact ileal segment, as used for the original Camey urinary reservoir, will hold approximately 160 mL. The same segment folded once and retubularized will hold around 320 mL. If it is folded on itself again, as done for example by Goodwin and associates (47) or Kock and colleagues (67a), its volume will increase to 660 mL.

A modification of the original Camey procedure, the Camey II operation, uses this principle of bowel detubularization to prevent neobladder peristaltic activity and its resultant complications (18). A major component of the Camey II procedure, as in other orthotopic neobladders, is the careful dissection of the urethra from the apex of the prostate. This preservation of an intact urethral stump allows earlier restoration of continence.

Technique

A 60-cm ileal segment is selected that can reach the region of the membranous urethra without tension. Following isolation of the segment and restoration of bowel integrity, the ileal segment is incised along its antimesenteric border throughout its length (Fig. 31.18A). In the region of the ileourethral anastomosis, the incision is spatulated to curve toward the mesenteric border. The entire detubularized segment is folded over itself in the form of a transverse U, with the medial borders of the U sutured together with an absorbable running 2-0 absorbable suture. Both ureters are brought into the lumen through a separate stab incision. For the ureteroileal anastomosis, an antireflux technique described by LeDuc (68b) is used. A 1-cm opening is made in the ileal wall at the site selected for the ileourethral anastomosis. The remaining ileum is closed by folding the segment to complete the neobladder construction. Closure is achieved with running sutures of similar absorbable material (Fig. 31.18B). The ileal sheet is then advanced into the pelvis and the anastomosis to the urethra is performed with six to eight previously placed absorbable sutures. It has been recommended to suture the posterior aspect of the ileal neobladder to the fascia to reduce tension on the anastomosis.

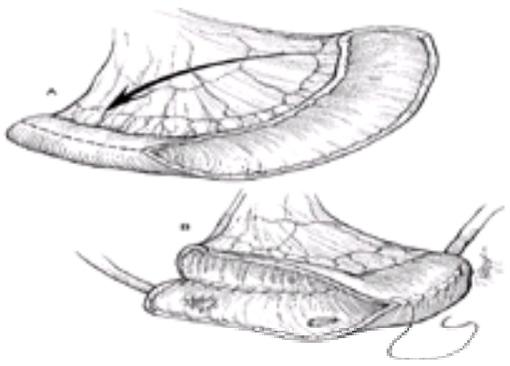

FIGURE 31.18. Camey II neobladder. **A:** Selection of 60-cm ileal segment with appropriate vascular supply and antimesenteric splitting of ileum are shown. **B:** Ileal plate is folded into a transverse U with its medial borders sutured together with continuous 2-0 PGA suture. A site is chosen and a 1-cm opening is made in the ileal wall in preparation for the ileourethral anastomosis. Following the urethral anastomosis, the ureteroileal anastomosis is performed in a LeDuc fashion. The remaining ileum is closed by suturing the anterior wall of the neobladder (following completion of the anastomosis).

Postoperatively, uninterrupted urine drainage must be maintained. Copious mucus formation can obstruct the catheter and subsequently can lead to disruption of the ureteroileal anastomosis. Therefore, as with other types of continent diversions, early irrigation is advised. Otherwise, no substantial differences are noted in the postoperative care of these patients compared with other continent diversions.

Results

The Camey II modification has resulted in improved continence. Intraluminal reservoir pressures have been found to be in the acceptable range of 10 to 40 cm H_2O during filling and at capacity, and nocturnal continence rates of 60% to 75% have been reported.

Studer Neobladder

Studer and co-workers (120) reported on clinical results of an orthotopic ileal bladder replacement using an ileal reconfiguration similar to the cup-patch technique described by Goodwin and associates (47). The antireflux mechanism consisted of simply attaching the ureters to an isoperistaltic proximal limb of 20 cm. This neobladder has particular utility in cases where limited ureteral length is a factor during implantation into the neobladder. The afferent isoperistaltic limb can be extended cephalad to accommodate a shortened right or left ureter.

Technique

A 60-cm ileal segment is isolated approximately 25 cm proximal to the ileocecal valve. The distal 40 to 45 cm of the segment is opened along its antimesenteric border, leaving the proximal 15 to 20 cm intact (Fig. 31.19A). The proximal portion is then rotated 180 degrees counterclockwise on its mesentery, so this portion lies in the right retroperitoneum. The detubularized portion is then folded in half and its medial walls are connected with a running 2-0 PG suture, thereby constructing the posterior plate of the segment. Anastomosis of the urethra to a 1-cm opening in the most dependent portion of the reconstructed ileum is completed over a urethral catheter with five to six previously placed urethral sutures. Standard ureteroileal (Bricker) anastomoses are performed in proximity to the apex of the isoperistaltic proximal limb (Fig. 31.19B). Ureteral stents are brought out through the neobladder and a separate abdominal incision; a suprapubic tube is positioned, and perianastomotic drainage is provided.

FIGURE 31.19. Studer neobladder. **A:** An ileal segment measuring 60 cm is isolated 20 cm from the ileocecal valve. The distal 40 cm is detubularized along the antimesenteric border and folded in a transverse U configuration. The posterior plate is completed by joining the medial walls with continuous 2-0 PGA suture. **B:** Anastomosis of the posterior plate of the ileum to the urethra is performed with several urethral sutures. Standard ureteroileal (Bricker) anastomoses are performed at the apex of the proximal limb.

Results and Complications

Postoperative bladder capacity initially ranged from 150 to 250 mL. Within 6 months, mean pouch capacity was reported to be 450 mL with intraluminal pressures varying from 20 to 40 cm H_2O (20). In recent patients, daytime incontinence was rare, but nighttime incontinence was seen in almost half the patients (20). The need for surgical revision was rare in both their initial and recent patients. Electrolyte disturbances were seen rarely, although they were more evident when longer segments of ileum were used. Vitamin B_{12} deficiency has not been seen clinically, probably because of preservation of a reasonable segment of distal ileum. According to radiographic studies, the integrity of the isoperistaltic proximal limb prevents the deleterious effects of any reflux from the resting, filling, emptying, or storage pressures of the neobladder (120).

In a more recent review, Cancrini and colleagues (20) reported on 96 patients who underwent Studer ileal orthotopic neobladders for invasive bladder carcinoma. The mean follow-up was 28 months. Overall, a 6% perioperative death rate and a 6% early postoperative complication rate, all directly related to the procedure, were reported. Of their patients, 24% had late complications requiring hospitalization, and overall, 10% required a second operation. The rate of ureteral strictures was 7%. The cohort's daytime continence rate was 98% at 2 years (97% at 1 year), although 22% exhibited occasional stress urinary incontinence. The nighttime continence rate was 74% at 1 year and 83% after 2 years. The average neobladder capacity was 350 cm^3 at 2 years (330 cm^3 at 1 year), with an associated neobladder pressure at capacity volume of 10 to 20 cm H_2O.

Hautmann Neobladder

To further increase the volume of the ileal neobladder, an M-shaped reconfiguration was introduced by Hautmann and associates (53).

Technique

Approximately 60 to 80 cm of terminal ileum is detubularized and arranged to an M-shaped ileal plate (Fig. 31.20A and Fig. 31.20B). The ureters are implanted directly into the neobladder using LeDuc's antireflux technique (Fig. 31.20C). The urethra is connected to a separate opening in a small, U-shaped ileal flap created by displacing the detubularizing incision from the antimesenteric border to a more anterior position for a length of 5 cm. The neobladder is completed by rolling the

ileal sheet around the longitudinal axis and closing it with a single row of through-and-through 4-0 polyglactin 910 running sutures (Fig. 31.20D).

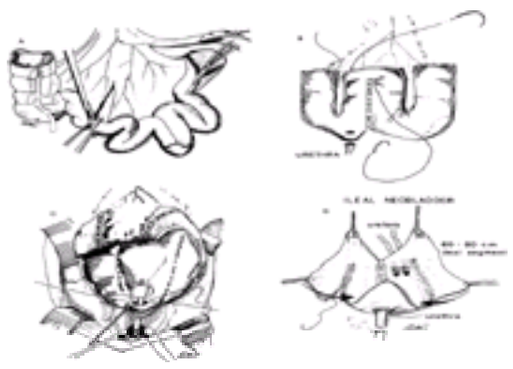

FIGURE 31.20. Hautmann neobladder. **A:** Selection of ileal segment with appropriate vascular supply and antimesenteric splitting of ileum are shown. **B:** A creation of an ileal sheet by side-to-side anastomosis of incised ileum following arrangement in an M (or W) shape. Note position of U-shaped flap for ileourethral anastomosis. **C:** Anastomosis of ileal sheet to urethral remnant with six mattress sutures tied from inside the neobladder (anterior view). **D:** Ureteral implantation into the ileal sheet through separate incisions in the posterior wall similar to the technique described by Le Duc. The urethral remnant has been anastomosed to an opening in the U-shaped bowel flap, and the pouch can be completed as denoted by the arrows. (From Hautmann RE, Egghart G, Frohneberg D. *J Urol* 1988;139:39, with permission.)

Hollowell and colleagues (61) describe using an ileal chimney modification to the Hautmann pouch. For this adaptation, the most proximal 10 cm of the isolated bowel segment is not detubularized. The remnant 50 to 70 cm of ileum is otherwise fashioned as originally described by Hautmann. Instead of implanting the ureters into the pouch, the ureters are anastomosed to the proximal, nondetubularized (chimney) segment.

Results and Complications

A follow-up of the first 100 patients showed promising results. The average maximum capacity was 821 mL, with a mean resting pressure at maximum filling of 26.4 cm H_2O, and maximal pressure amplitudes of 30 cm H_2O (52). In a review of more than 200 patients (56), total day and nighttime continence was seen in 85% at 3-year follow-up. Intermittent catheterization was required in 4% for postvoid residual urine volumes greater than 100 mL. There were five perioperative deaths, an overall complication rate of 7.5%, and a neobladder-related complication rate of 6.5%. Of the patients, 32% required either rehospitalization or reoperation for postoperative problems, such as ileus, abscess, coloreservoir fistula, hydronephrosis, ureteral obstruction, and ureteroileal anastomotic structure.

Hemi-Kock Neobladder

Clinical results with an ileal U neobladder with or without intussusception of the afferent ureter-containing limb have been reported (57). This neobladder has less capacity than, for example, a Kock neobladder, but it is technically simpler to create and requires less time. The hemi-Kock neobladder offers the advantage of an adequate urine storage with acceptable low intraluminal pressure at maximal filling. Basically the same technique as for the cutaneous Kock pouch is used.

Technique

A 45-cm segment of ileum is isolated 30 to 50 cm proximal to the ileocecal valve, detubularized on the antimesenteric border, folded, and sutured together on one side to create a U-shaped intestinal plate, which is then folded transversely to create the reservoir. The same antireflux mechanism as for the cutaneous Kock pouch is used. The urethra is anastomosed to an opening left in the most dependent portion of the suture line uniting the reconfigured ileum.

Results and Complications

In a small series of 16 patients with a relatively short follow-up, Kock and co-workers (67c) demonstrated neobladder capacities of 300 to 500 mL, intraluminal pressures of less than 40 cm H_2O, daytime continence in all, and nighttime continence in 85%. No hydronephrosis has been reported so far, and no reoperation was necessary. Skinner and colleagues (108) reported daytime continence in 94% and nighttime continence in 84%. Early complications were seen in 11%.

Ileocolonic Neobladders

The ileocecal segment in various reconfigurations has been used to form a variety of neobladders. The cecal portion requires mobilization from its fixed position for urinary reconstruction. It has a larger diameter than the ileum and can usually be mobilized without difficulty into any area of the abdomen or pelvis. The orthotopic Mainz (*M*ixed *A*ugmentation *I*leum' *N*' *Z*ecum) neobladder, the ileocolonic neobladder (Le Bag), and the authors' adaptations all offer the advantage of a larger intraluminal volume with a shorter segment of bowel than is necessary for an ileal orthotopic reservoir.

Mainz Neobladder

The orthotopic Mainz neobladder is a variation of the continent cutaneous catheterizable version of the Mainz. Both share the common principle of using the cecum and a folded ileal segment to create a broad sheet of intestine, which can then be closed in a spherical fashion (124,125).

Technique

Following isolation of a 10- to 15-cm segment of cecum with a 20- to 25-cm segment of ileum, an ileoascending colostomy is performed to restore intestinal continuity, and the mesenteric defect is closed (Fig. 31.21A). The entire segment is detubularized along its antimesenteric border, sacrificing the ileocecal valve. It is sewn together side-to-side in the shape of an incomplete W with a single layer of running absorbable sutures to create an intestinal plate. The ureters are brought into the pouch through a 5-cm submucosal tunnel along the posterior tenia of the colon, anastomosed to the mucosa and stented (Fig. 31.21B). An appendectomy is performed, and a buttonhole incision is created at the base of the cecum, which serves as the site of the urethrointestinal anastomosis. The lateral portions of the intestinal plate are then rotated anteriorly to the right side; urethral and suprapubic catheters are positioned, and the neobladder is closed (Fig. 31.21C).

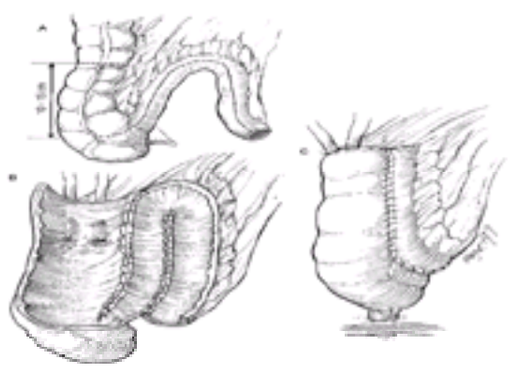

FIGURE 31.21. Mainz neobladder. **A:** From 10 to 15 cm of cecum and ascending colon with 20 to 30 cm of ileum are isolated. **B:** The entire segment is marsupialized along its antimesenteric border, and a broad posterior plate is created by suturing the apposing edges of the limbs to create an incomplete W. Tunneled ureterocolonic anastomoses are performed. **C:** A buttonhole incision is created at the base of the cecal portion for the urethrointestinal anastomosis. The neobladder

is closed by folding the lateral limbs anteriorly and suturing in a continuous fashion.

The postoperative care of the Mainz neobladder is similar to that of ileal voiding diversions with an added emphasis on prevention of intraluminal mucus accumulation. Diversions with cecal segments may be found to require more frequent irrigation during the initial postoperative phase because of a propensity for greater mucus production, as compared with diversions that are solely composed of ileum.

Results and Complications

Daytime continence is reported to be greater than 90%, and nighttime continence, with two or three scheduled voids, is noted in 75%. Intraluminal pressures of 31.40 cm H_2O have been noted at mean capacities of 500 mL (126). Late complications primarily consisted of incontinence and urethral anastomotic strictures. Of 34 orthotopic diversions, 4 required either an open or endoscopic reoperation for such complications (126).

Le Bag Neobladder

The Le Bag neobladder is primarily a derivative of the Mainz neobladder that uses a single segment of ileum along with cecum. It consists of two variations of urethral anastomosis.

Technique

Approximately 20 cm of cecum and ascending colon are isolated with a corresponding length of terminal ileum (Fig. 31.22A). The entire segment is detubularized along its antimesenteric border, folded, and the free ileal colonic borders are sewn to one another side-to-side (Fig. 31.22B and Fig. 31.22C). The initial variant of this operation preserved an intact tubularized proximal 3 to 4 cm of ileum, which was then anastomosed to the urethral stump by rotating the neobladder 180 degrees into the pelvis (Fig. 31.22D). This maneuver was subsequently abandoned because it was thought that the intact ileal segment may contribute to postoperative incontinence by its retained peristalsis. The technique was therefore modified to create the urethral anastomosis to a dependent cecal buttonhole. Once the final position of the neobladder has been secured, a small hiatus in the anterior suture line is left open to perform the ureteral implantation (according to the previously described Goodwin technique for ureterosigmoidostomy). Postoperative care is similar to that for other types of orthotopic colonic diversions.

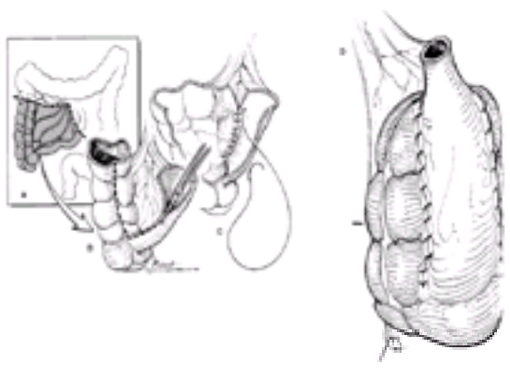

FIGURE 31.22. LeBag ileocolonic neobladder. **A:** Selection of ileocolonic segment with single vascular pedicle. **B:** Commencement of incision along antimesenteric border to create two flat sheets of bowel. **C:** Suturing of ileal and colonic segments. The outer two edges are sutured first. The inner edges are only sutured partially, so that the urethra can be anastomosed through the residual opening (see text). **D:** The completed pouch before 180-degree rotation to enable anastomosis to the urethra. (From Light JK, Engelmann UH. *J Urol* 1986;136:27, with permission.)

Results and Complications

Kolettis and colleagues (68) described their updated experience with the Le Bag orthotopic urinary diversion. Between 1990 and 1995, the Le Bag construction was used in 38 patients with bladder cancer. With a mean follow-up of 14 months, they describe a 21% incidence of perioperative and early complications. The late complication rate was 34%. Of their patients, 29% required reoperations, with 21% requiring open procedures and 8% requiring endoscopic procedures. The rate of ureterointestinal anastomotic strictures was 8%. Overall, the daytime continence rate was 91%. The nocturnal continence rates were not as high, with 46% of their patients being completely continent at night, and an additional 34% exhibiting only mild nocturnal incontinence. Overall, three patients required clean intermittent catheterization for inability to spontaneously empty their urinary pouch. The median pouch capacity was 600 mL, and the mean postvoid residual was 90 mL. Mild hypochloremic acidosis was noted in nearly all of their patients.

UCLA Neobladder I and II

The UCLA, the orthotopic Mainz, and the Le Bag neobladders share the common principle of configuring cecum and ileum together to function as a capacious, low-pressure, continent, spherical, urinary diversion to the native urethra (89,126). In general, the technique of our institution and the recent variant of the Le Bag differ from one another in only a few features, predominantly the technique used for ureteral implantation.

We have recently also applied the concept described by Studer and co-workers (120) of using an intact proximal ileal limb for ureteral anastomoses. When positioned in the right retroperitoneum, this limb can function as an extension or bridge from the diversion to the ureters. This modification has been of significant value in situations where limited ureteral length has placed a ureterocolonic anastomosis in jeopardy of being under tension.

Technique (UCLA I)

A bowel segment consisting of 10 to 15 cm of cecum and ascending colon, as well as 20 cm of terminal ileum, is sufficiently mobilized, assessed for its ability to reach tension-free to the urethra, and then isolated (Fig. 31.23A). An ileoascending colostomy is performed to restore intestinal continuity, and its mesenteric trap is closed. The right colon-cecal portion is detubularized through its anterior tenia down to the ileocecal valve. The ileocecal valve is sacrificed, and the entire ileal segment is detubularized through its antimesenteric border (Fig. 31.23B). This specific detubularization technique prevents medial redundancy and “bunching” of the distal posterior wall of the neobladder. A broad, posterior plate is created by suturing the opposing medial walls of the cecum and ileum with running 2-0 polyglactin suture (Fig. 31.21C). All suture lines are reinforced with interrupted ligatures at 1.5-cm intervals.

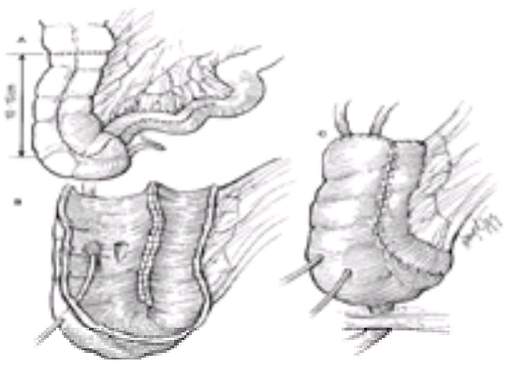

FIGURE 31.23. UCLA I neobladder. **A:** From 10 to 15 cm of cecum and ascending colon with 15 to 20 cm of terminal ileum is isolated. **B:** The right colon-cecal portion is detubularized through its anterior tenia down to the ileocecal valve. The ileocecal valve is sacrificed, and the ileal segment is detubularized through its antimesenteric border. A broad plate is formed by suturing the opposing medial walls with continuous 2-0 PGA sutures. A 1-cm buttonhole incision is created in the most dependent cecal portion of the neobladder. **C:** The urethrocolonic anastomosis and the ureterocolonic anastomoses (Le Duc technique) are performed, and the neobladder closure is completed.

A routine appendectomy is performed, and a 1-cm incision is made in the most dependent area of the cecal portion of the neobladder for a tension-free anastomosis to the urethra. Five to six previously placed 2-0 PGA urethral sutures are then brought full thickness through the incision at the base of the cecum. A urethral catheter is positioned and the sutures are tied.

Ureterocolonic anastomoses are carried out in a Le Duc fashion (Fig. 31.14). The ureters are brought through separate openings in the posterior wall of the midcecum. Instead of creating an antireflux tunnel, the mucosa is simply incised at a length of 2 cm, creating a small trough. The ureters are then spatulated, and three full-thickness 4-0 PGA sutures are placed from the distal posterior ureteral edge to the distal apex of the trough. The mucosal edges of the trough are then tacked to the intact ureteral wall with a few 4-0 PGA sutures. Each ureter is stented with a polyethylene stent, which then can be passed through a small stab wound in the ileum and brought out through the abdominal wall. The neobladder construction is then completed; a suprapubic tube is placed, and perianastomotic drainage is provided.

Technique (UCLA II)

A 10-cm-longer (compared with the UCLA I) ileal segment is isolated with the cecum and ascending colon. The proximal 10 cm of the ileum is left tubularized (Fig. 31.24A and Fig. 31.24B). Otherwise, the neobladder is constructed in a similar fashion until the ureteral anastomosis is performed. The intact proximal ileal limb is rotated to the right retroperitoneum, and Bricker ureteral anastomoses are performed and stented (Fig 31.24C). The remainder of the procedure is the same as that described for the UCLA I. No alterations in postoperative care pertain to either neobladder.

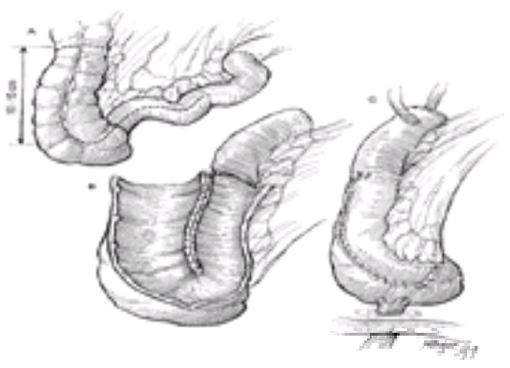

FIGURE 31.24. UCLA II neobladder. **A:** A 10-cm-longer (compared with the UCLA I) ileal segment is used. **B:** The proximal 10 cm is left intact; the medial walls of the detubularized portion are sutured with continuous 2-0 absorbable sutures. **C:** Bricker ureteral anastomoses are performed, and the urethrocolonic anastomosis and neobladder closure are the same as described for the UCLA I neobladder.

Results and Complications

Upon review of our initial experience (10 patients), mean capacities of 450 mL were noted with intraluminal pressure ranges of 20 to 45 cm H_2O. In a review by Raz and associates (89), the clinical, urodynamic, and metabolic results of the UCLA I neobladder were assessed for 19 patients. Follow-up protocol for each patient included an intravenous urogram, serum chemistries, and cystoscopy at 3 months, then every 6 months for 2 years, and then yearly thereafter. Videourodynamics were performed at 6 months after surgery. Mean follow-up was 23 months, with a range of 6 to 42 months. The ability to void to completion was seen in 17 of 19 (89%), with 2 of 19 (11%) requiring intermittent catheterization for postvoid residuals of 400 to 500 mL. Complete daytime continence was noted in 17 of 19 (89%), and stress urinary incontinence requiring protection was seen in the remaining 2 patients. Nocturnal incontinence was noted in 6 of 19 (32%), but 4 of these 6 patients preferred not to wake through the evening to void.

Renal function was stable in all 19 patients. Serum sodium, potassium, chloride, calcium, vitamins B_{12} and D, and folate levels were normal in all patients. Mild metabolic acidosis was seen in 7 of 19 patients (37%). Upper urinary tract radiologic studies demonstrate mild pelvocaliceal dilation in 2 of 19 (11%), both of whom were asymptomatic.

Urodynamic studies revealed normal compliance in all patients and filling pressures less than 20 cm H_2O. Phasic contractions were seen in 9 of 19 (47%). Mean capacity was 575 mL with a range of 350 to 1300 mL. Of the 19 patients, 17 were able to empty their neobladders via pelvic floor relaxation and abdominal straining at acceptable voiding pressures.

No early complications were noted in these 19 patients or 6 others. No subsequent upper tract infections requiring rehospitalization were seen. Late complications were found in 2 of 19 (11%), both of which were ureteral anastomotic strictures that required intraoperative incision. No urethral anastomotic procedures have been required. No chronic diarrhea or osteomalacia has been seen. The authors conclude that this ileocolonic neobladder provides a compliant, capacious reservoir with good functional, urodynamic, and continence results without major complications.

Perspectives

Despite the problems associated with urethrointestinal anastomosis, the neobladder approach theoretically remains the best method of postcystectomy urinary diversion. When combined with sparing of the corporeal nerves to the penis, the best possible result can be achieved, with complete restoration of the patient's body image and retention of sexual function. However, the operation must be used with caution in patients with carcinoma in situ and tumors near the bladder neck or the prostatic urethra. The high incidence of nighttime incontinence with some methods has been unacceptable to many patients and may represent the major deterrent to the wide adoption of the procedure. Long-term follow-up is not available, and the true incidence of stones, retention, and upper tract deterioration is as of yet unknown. Judicious modifications of the procedure, combined with use of an external artificial sphincter in some instances, may improve acceptance of these procedures, representing a major advance in achieving quality of life for the bladder cancer patient. Our success with the procedure has encouraged us to offer it to most patients with bladder cancer, unless contraindicated. However, some patients still prefer the simpler ileal conduit.

Orthotopic Urinary Diversions in Women

Until the past decade, the concept of orthotopic neobladder construction in women undergoing radical cystectomy had not been extensively entertained. Concerns about risk of urethral tumor involvement, compromising the cancer surgery, and the potential for postoperative urinary incontinence were major reasons orthotopic neobladder construction in female bladder cancer patients had not been evaluated more enthusiastically.

Rationalizations that absence of the “buffering” prostate and prostatic urethra in the female inherently place the female bladder cancer patient at higher risk of primary or secondary urethral transitional cell carcinoma (TCCa) had been raised. However, studies demonstrate results to be different than previously speculated. Ashworth, in a study in which all patients with bladder tumors were cystoscopically evaluated, noted that 4.1% of men had concomitant urethral involvement, as compared with

only 1.4% of women with bladder cancer. Retrospective pathologic evaluation of bladder and urethral specimens of women undergoing radical cystourethrectomy for advanced or high-risk TCCa revealed the overall histologic incidence of urethral involvement in patients with TCCa of the bladder to be 2% to 13% (28,112,116). This rather large range of urethral involvement highlights the differences in demographics of each reported group. However, subset analysis of each study reveals a similar finding: No urethral involvement was noted in any case where the bladder neck was not concomitantly involved with tumor. More specifically, Coloby and colleagues (28), Stein (112), and Stenzl (116,117) describe bladder mapping evaluations of women undergoing cystourethrectomy for TCCa. In each study, approximately 21% to 32% of patients had bladder neck involvement. Whereas Stenzl described a 16% incidence of concomitant urethral involvement when bladder neck involvement was noted, Colomby and Stein revealed 33% and 50% incidences of urethral involvement, respectively. Again, in these three large series, in the absence of bladder neck involvement, no urethral involvement was noted at the time of cystourethrectomy. Interestingly, of patients with urethral involvement, 33% to 66% have pT4 disease, suggesting that a significant number of urethral involvements are due to extravesical extension of the tumor and infiltration into the pelvic structures (including the urethra).

Based on the published series, it is suggested that the risk of urethral involvement at the time of cystectomy without any evidence of bladder neck involvement is low. Therefore, based on bladder cancer mapping studies, 68% to 79% of patients would be of relatively low risk for having urethral involvement at the time of radical cystectomy. But what is the long-term recurrence rate of TCCa in the spared urethral segment? This rate, in selected female patients, may be as low as 2% with a 20-year follow-up (117). However, further studies are necessary to validate these results. One reason for this relatively low recurrence, as compared with the urethral recurrence rates noted in male patients undergoing urethra-sparing cystectomy, may be that the female urethra is not only shorter than the male urethra, but the distal one-third to one-half of the female urethra is composed of a squamous histology. This squamous epithelium progresses cephalad with increasing age and decreasing estrogen levels (113,131,132). Therefore, in essence, the risk of urethral involvement at the time of cystectomy or with follow-up for women with bladder cancers not involving the bladder neck is relatively low. Based on these findings, a urethra-sparing procedure can be acceptable from an oncologic standpoint.

The second main concern to address is the risk of postoperative stress urinary incontinence in women undergoing resection of their bladder necks and a portion of their proximal urethra. Anatomic evaluations suggest that preservation of the distal two-thirds of the urethra, the pubourethral ligaments, the pelvic floor musculature, and the urethral rhabdosphincter and its associated innervation (pudendal nerve) is adequate for preservation of urinary continence in women (27,112,117). In fact, most large series reveal that daytime postoperative urinary incontinence in women with orthotopic neobladders is a less common event than expected and may often be caused by inadequate storage pressures or storage volumes rather than inadequate urethral resistance. In smaller series by Cancrini (21), Blute (12), and Hautman and colleagues (55), daytime continence rates ranged from 90% to 100%, and evening continence rates ranged from 70% to 80%. To achieve and maintain these evening continence rates, patients are often required to void or empty their neobladder two to three times per evening to avoid incontinent episodes during the night. In the largest series of orthotopic neobladders in women undergoing radical cystectomy for TCCa, Stein (111) describes an 88% daytime continence rate and an 82% evening continence rate in 34 patients treated at their center.

Interestingly, postoperative urinary retention, or “hypercontinence,” is a more common problem than previously anticipated. Approximately 15% to 20% of women undergoing orthotopic neobladder construction will require clean intermittent catheterization (CIC) for inability to void spontaneously or because of high postvoid residuals (54,135).

Clearly, orthotopic neobladders can be performed in properly selected female bladder cancer patients without compromising the cancer surgery, while achieving acceptable continence levels. But does this procedure provide a better quality of life for women? Anecdotally, surgeons performing orthotopic neobladders state that their neobladder patients are much happier and better off than their other patients who have not undergone orthotopic neobladder constructions. However, the published female neobladder series are still relatively small, and no validated quality-of-life evaluations have been performed to scientifically answer this question.

However, quality-of-life surveys in male bladder cancer patients undergoing incontinent cutaneous diversions versus orthotopic neobladders do not demonstrate any dramatic quality-of-life benefit for the neobladder group. More quality-of-life studies are anticipated and are needed to better answer this question.

Special Considerations for the Female Neobladder Candidate

After the female patient is evaluated from an oncologic, a gastrointestinal, and a renal standpoint, as previously outlined for all patients being considered for a cystectomy and urinary diversion procedure, particular attention should be paid to the following points:

1. Absence of bladder neck involvement
2. Patient's motivation to perform timed voiding to minimize incontinence or neobladder overdistention
3. Patient's understanding and acceptance of up to 20% diurnal and up to 30% nocturnal incontinence rates
4. Patient's acceptance of 15% to 20% risk of hypercontinence with associated need and ability to CIC per urethra
5. Patient's sexual function

The patient's bladder neck should be biopsied preoperatively to preclude bladder neck involvement. Although some advocate only intraoperative frozen histologic evaluations of the bladder neck and proximal urethra (111), we think that preoperative evaluation of the bladder neck will allow both the surgeon and the patient to have a more concrete surgical plan, rather than deferring the decision to the intraoperative frozen section. The preoperative activity of the patient should be considered, and, when possible, vagina-sparing approaches or surgery for the sexually active patient should be attempted, if the cancer operation will not be compromised.

The most important factor to consider is the motivation of the patient. Is the patient willing to accept the risks of CIC? Is the patient able to learn to perform CIC with the possibility that she may need to CIC several times a day in 15% to 20% of the cases? Is the patient willing to accept the risks of daytime and especially nighttime incontinence? Furthermore, is the patient willing to awaken several times a night to void to minimize her nocturnal incontinence rates? These are not trivial points, and they should be thoroughly discussed with the patient preoperatively to optimize the realistic expectations of the patient and to best select the optimal candidates to achieve the highest level of patient satisfaction postoperatively.

Special Considerations: Preoperatively Incontinent Patients

The surgeon should determine whether the incontinence is due to detrusor hyperactivity, low bladder outlet resistance, or both. Given a low-pressure orthotopic neobladder, urethral pressures of approximately 30 cm H_2O are often adequate for postoperative continence. Routine prophylactic urethral or bladder neck suspension at the time of neobladder construction should be discouraged because this maneuver is associated with a high incidence of postoperative urinary retention.

Surgical Technique

The standard cystectomy in the female patient is modified to account for the following points:

1. Maximizing vaginal preservation without compromising the cancer surgery
2. Optimizing continence preservation by preserving the pubourethral ligaments, the rhabdosphincter, and the pelvic floor diaphragm
3. Creating a high volume–low pressure neobladder
4. Preventing urinary outflow obstruction by preventing “pouchocele” formation (angulation of the neobladder at the neobladder-urethral junction) and by avoiding mucosal folds near the neobladder outlet
5. Preventing enterocele or rectocele formation by reinforcing the endopelvic fascia at the pouch of Douglas
6. Preventing enterovaginal fistulas by interposing omentum between the neobladder and the vagina

Excellent discussions of the surgical technique have been published (12,54,80,113). A brief summary of the procedure follows.

The patient should be positioned in a low lithotomy position with maximal flexion of the operative table at the superior anterior iliac spine. The vagina should be completely prepped and accessible to the surgeon. After the peritoneal reflection is incised along the pouch of Douglas, the bladder can be sharply dissected off of the anterior vaginal wall down to the bladder neck–urethral junction. This maneuver may be facilitated by placing a sponge-stick in the vagina to better delineate the vaginal wall. After the posterior vaginal wall is incised, Allis clamps can be placed on each corner and the vagina can be placed on stretch, thereby increasing the

ease of bladder dissection along the anterior vaginal wall. If there is any concern about leaving cancer, the anterior vaginal wall should be resected with the bladder.

The pedicles on each side are taken down to the level of the proximal urethra and bladder neck (the bladder neck is identified by palpation of the Foley balloon with the Foley catheter placed on slight traction). Once the proximal urethra and bladder neck are reached, attention should be turned to the anterior segment of the urethra. The pubourethral ligaments should be spared because they provide major support to the midurethral complex and are integral to female urethral continence. The rhabdosphincter and pelvic floor musculature should be preserved by avoiding dissection beyond the endopelvic fascia. The urethra just distal to the bladder neck should then be clamped and the urethra transected no more than 1 cm beyond the bladder neck.

Regardless of which type of orthotopic neobladder is to be constructed, several key points should be observed:

1. The bowel should be detubularized and an adequate length should be used to ensure an adequate reservoir volume and low storage pressures. Occasionally, postoperative incontinence is secondary to low neobladder storage volumes or high storage pressures.
2. During creation of the neobladder, care must be taken to prevent mucosal folds near the neobladder outlet to prevent outlet obstruction and urinary retention postoperatively.
3. The anatomy of the neobladder should be evaluated to ensure that it is not kinking or folding on itself. Occurrence of such a kink or severe fold can account for postoperative urinary retention. Some authors advocate placing an omental segment between the neobladder and the vagina to support the posterior aspect of the neobladder and to prevent it from folding on itself (117).
4. The pudendal nerve provides the major innervation to the rhabdosphincter and is therefore integral to urinary continence, but the importance of the autonomic innervation to the urethra for continence is debatable. Some authors meticulously preserve the autonomic nerves by preserving the lateral vaginal walls (12,54,55,80); others deliberately transect these nerves as part of their dissection (107,113). No apparent difference in continence rates is reported by the two schools of innervative philosophy.
5. Placing an omental segment between the neobladder and the vagina will also help decrease the rate of neobladder-vaginal fistulization.
6. With the uterus and bladder removed, the pelvis is at increased risk of developing an enterocele. This occurrence can be minimized by anchoring the vaginal apex to the endopelvic fascia and plicating the cardinal ligaments and endopelvic fascia cephalad to the vaginal apex. This maneuver increases the tensile strength over the urogenital diaphragm and prevents herniation (enterocele formation).
7. Routine “neobladder suspension” to the pubis or Cooper's ligament (maneuvers aimed at preventing or minimizing postoperative urinary incontinence) should be avoided because these maneuvers may dramatically increase the incidence of postoperative urinary retention (54).

Metabolic Complications of Urinary Intestinal Diversion

The pathophysiology of metabolic complications caused by intestinal segments continuously exposed to urine has been studied extensively. Complications include electrolyte abnormalities, recurrent infection, calculus formation, altered hepatic metabolism, abnormal drug metabolism, growth retardation, osteomalacia, and cancer. The causes of these complications can best be described as multifactorial. Many of these sequelae are influenced by the degree to which solute absorption occurs across the intestinal segment. The factors that affect solute absorption include the type of intestinal segment used and its absorptive surface area, duration of bowel contact with urine, concentration of solutes in the urine, pH and osmolality of the urine, renal function, and possibly the time since surgery.

Electrolyte Disturbances

Serum electrolyte complications and the type of electrolyte abnormalities that can occur are primarily dictated by the particular type of bowel used. The electrolyte abnormality that occurs with ileum and colon is a hyperchloremic metabolic acidosis. It can be found in most patients who undergo ileal or colonic interposition to the urinary tract but is generally of a minor degree. The mechanism has been postulated to involve bicarbonate secretion, ammonia absorption, chloride absorption, or impaired distal tubule hydrogen ion secretion. Approximately 70% of patients with ileal conduits have been shown to have some degree of acidosis (23,69), and it can be seen as a severe problem in 10% (102). Similarly, most patients with continent diversions from ileal segments have elevated serum chloride and depressed serum bicarbonate levels (6,76). Up to 80% of patients with a ureterosigmoidostomy will demonstrate and may require therapy for a metabolic acidosis (37). A lower but significant incidence of acid–base disturbances has been reported for other continent diversions, such as the Mainz pouches (65%) and those continent diversions made of ileum (10% to 15%) (14,124).

Symptoms associated with prolonged acidosis include anorexia, weight loss, fatigability, and lethargy. If allowed to persist, the condition could lead to more significant metabolic complications with potentially lethal outcomes (34).

The treatment of hyperchloremic metabolic acidosis involves use of alkalizing agents and chloride transport blockers either in combination or as monotherapy. Alkalinization can be accomplished with oral agents, such as sodium bicarbonate, Bicitra, or Polycitra. These medications may exacerbate preexisting cardiac or renal disease because of the sodium content. In patients in whom excessive sodium loads are undesirable, chlorpromazine or nicotinic acid may be given to limit the degree of acidosis. Of interest is the report of Thuroff and associates (126) on 100 patients with Mainz pouch. Initially, most required alkalization agents to correct a hyperchloremic acidosis, but 6 months after surgery, only half needed these agents, and at 12 months none required therapy.

Electrolyte abnormalities resulting from jejunal interposition for urinary diversion include hyponatremia, hypochloremia, hyperkalemia, azotemia, and acidosis. These result from an excessive secretion of sodium chloride coupled with an increased reabsorption of potassium and hydrogen ions. Dehydration may develop because of subsequent water loss resulting in hypovolemia, renin secretion, and secondary hyperaldosteronism. Symptoms typically seen include lethargy, nausea, vomiting, muscular weakness, and elevated temperature. The treatment for the disorder involves rehydration with sodium chloride and alkalinization with sodium bicarbonate. Long-term supplementation may be needed. If this disorder remains untreated and is allowed to persist, the patient may become obtunded and subsequently succumb.

Patients with urinary intestinal diversion may be found to have hypokalemia and depletion of total body potassium. Frequently seen with ureterosigmoidostomies and rarely with ileal conduits, this depletion is most often caused by renal potassium wasting from renal damage and osmotic diuresis. Moreover, ileal segments, when exposed to high concentrations of potassium in the urine, reabsorb some of the potassium, whereas colon is less likely to do so. Therefore those with ileum interposed probably partially compensate the potassium loss by the kidney, whereas those with colon do not. This explains why total body potassium depletion is seen more commonly in patients with ureterosigmoidostomy and ureterocolonic diversion. One must be cognizant that if hypokalemia is associated with severe acidosis, treatment should involve potassium replacement concurrently with correction of the acidosis. Correction of the acidosis without appropriate potassium replacement may cause a progressive severe hypokalemia with resultant flaccid paralysis and significant morbidity.

Hypocalcemia and hypomagnesemia are primarily the result of renal wasting and acidosis. Although infrequently manifested clinically, severe deficits of either or both cations can result in neuromuscular dysfunction, altered sensorium, seizures, and death. Treatment should involve supplementation either parenterally or orally depending on the severity.

Bacterial Infections/Sepsis

Patients who have urinary intestinal diversion are known to have an increased incidence of local and systemic infections. The cause is unclear, but there is evidence to suggest that bowel interposed in the urinary tract does not have the ability to prevent local bacterial growth, which then serves as a potential source of local infection and systemic dissemination. Bacteriuria is common in patients with a conduit or continent diversion. It has been shown that up to 80% of patients with conduits have some degree of bacteriuria, with 15% to 20% experiencing at least one septic event (104). Similarly, patients with continent diversion have a 5% to 20% incidence of septic episodes within 1 year of reconstruction (74). The mechanism by which the septic episodes occur is thought to involve ischemic breakdown of the mucosal barrier attributable to overdistention. This mucosal breakdown permits colonized luminal bacteria access to the systemic circulation. Another possibility is that reflux of lumenal bacteria has unimpeded access to the renal parenchyma, resulting in implantation of pathogenic bacteria in the upper urinary tract. Because of the propensity for infection in these patients, proper measures to prevent substantial bacterial colonization or urine stasis should be adhered to. In addition, some favor chronic administration of antibacterials in certain situations.

Calculi

An increased risk of urinary tract calculi exists in patients with intestinal diversions. Patients with an ileal conduit have a 20% incidence, if followed 20 years or more (76). Continent pouch calculi have been noted in up to 30% of patients, depending on the type of continent diversion. Possible etiologic factors contributing to stone

development include acidic renal tubule fluid, increased calcium excretion, and persistent urinary tract infection with urease producing bacteria. Inspissated mucus and foreign bodies, such as sutures or staples, may also have a role. Management is dependent on site, stone burden, and underlying cause. Upper tract stones can often be managed similar to patients without urinary intestinal diversion. Pouch or neobladder stones may require an open or percutaneous procedure. In patients with continent cutaneous diversions, stone manipulation through the continent stoma should be avoided because of the potential for damage to the continence mechanism.

Nutritional Disturbances

Nutritional disturbances can be seen when significant portions of the bowel are removed from the enteric tract for urologic reconstruction. Alterations of absorptive processes in particular are seen when small intestine is used, which can result in nutritional deficiencies and their sequelae. Loss of the distal ileum can impair vitamin B_{12} absorption. Chronic vitamin B_{12} deficiency usually results in megaloblastic macrocytic anemia and possibly neurologic deficits. Decreased bile salt absorption, fat malabsorption, and a decrease in absorption of the fat-soluble vitamins can also be seen with distal ileal loss. This may result in severe diarrhea caused by bile acid irritation of the colonic mucosa. In general, the surgeon should be aware of the potential for these deficiencies and should address them by prompt investigation and supplementation, if needed. Loss of portions of the large intestine are usually well tolerated and cause few nutritional problems. However, diarrhea may be severe if extensive portions of the large bowel are removed with the ileocecal valve, potentiating nutritional deficiencies.

Altered Metabolism

Altered sensorium may occur as a consequence of drug intoxication or abnormalities in ammonia metabolism caused by altered hepatic metabolism. Patients with urinary intestinal diversion are more likely to experience this when administered drugs that can be absorbed by the gastrointestinal tract and excreted unchanged by the kidney. Toxic metabolites of drugs capable of intestinal absorption can be problematic, if not rapidly cleared from the blood by the kidney or liver. This has been reported for phenytoin and certain antibiotics that are secreted in the urine unchanged (98). In patients with normal hepatic reserve, acute changes in ammonia loads usually do not result in significant alterations in serum ammonia and ammonia intoxication. However, when hepatic metabolism has been compromised because of sepsis, cirrhosis, and other chronic hepatic diseases, encephalopathy may become apparent. Hyperammonemic encephalopathy has been reported commonly in patients with a ureterosigmoidostomy because of an increased ammonia load coupled with the potential for translocation of bacteria from the intestinal lumen to blood. Treatment of hyperammonemic encephalopathy or ammoniagenic coma involves draining the urinary intestinal diversion, either with a rectal tube, in the case of ureterosigmoidostomy, or a Foley catheter in those with a continent diversion or conduit. These maneuvers prevent urinary ammonia exposure to the intestinal mucosa for extended periods of time. In addition, systemic antibiotics to treat underlying sepsis are recommended. In severe circumstances, arginine glutamate may be given to complex with ammonia forming an inert substrate. Lactulose can be given orally or rectally.

Bone Demineralization

Bone demineralization and osteomalacia are potential long-term complications of urinary diversion with intestine. Chronic acidosis and renal wasting of calcium and phosphate seem to play a role in this condition. These abnormalities can cause calciuria, decrease calcium-phosphate remineralization, and interfere with vitamin D metabolism, the results of which lead to subtle bone mineral content changes in the majority and severe abnormalities of bone mineral content in a few (75). Correction of acidosis with bicarbonate and administration of vitamin D are useful in such situations. Because bicarbonate and vitamin D are essential for normal bone growth and because these two substances administered in the animal model have been shown to prevent bone demineralization, it would be reasonable to consider administration of an alkali and vitamin D to all patients with urinary diversion and any evidence of bone demineralization. If remineralization does not occur with these measures, calcium supplements and the activated form of vitamin D should be considered.

Quality of Life

Great strides have been made in surgical techniques for performing urinary diversions. As a result, the modern urologic surgeon has several surgical options in his or her armamentarium to perform urinary diversions. However, apart from the surgeon's capability to perform different urinary diversions, the most important factor in deciding which type of urinary diversion to perform should be based on the patient's satisfaction.

An ileal loop diversion has been decreed by many urologic surgeons as inadequate because it promises indefinite need for stomal care and “condemns” patients to “wearing a bag.” Meanwhile, orthotopic neobladders have been embraced by many surgeons for more closely functioning as the native bladder, with better body image and physiologic function. However, the perceptions of the surgeon and the patient are often discrepant. The question is therefore raised: Does the urologic patient enjoy a better quality of life with a neobladder or with an “antiquated” ileal loop diversion? Furthermore, what physical and psychologic impact do urinary diversions have on patients undergoing urinary diversions? Understanding the factors most important to the patient will help physicians better counsel their patients and develop modalities to best address the priorities of patients undergoing these procedures. The importance of quality-of-life issues cannot be overemphasized.

To perform an adequate quality-of-life study, the questionnaire used should be validated. Optimally, all patients evaluated in the given study should have had the diversions performed for similar disease processes. For example, the psychologic point of view of a cancer patient with a urinary diversion may be extremely different than that of a patient with a neurogenic bladder who undergoes a urinary diversion procedure. The baseline and preoperative function and quality of life of patients undergoing these procedures should also be known and available for evaluation. Furthermore, quality-of-life issues at several time points postoperatively should be assessed to better determine the quality-of-life outcomes over time for the patients in question.

In reference to the optimal quality-of-life study, few studies have to date been performed with validated questionnaires, and even fewer studies evaluate homogenous groups (e.g., only bladder cancer patients, only neurogenic bladder patients, only interstitial cystitis patients) in their studies. No study has obtained or described the study population's baseline (preoperative) quality of life, psychologic health, and physical health. Despite these drawbacks, several interesting observations have been made. First, most patients undergoing urinary diversions are satisfied with their quality of life. Up to 95% of patients report an overall good to excellent quality of life regardless of the type of urinary diversion performed (51). Similar results are reported in regard to overall satisfaction with composite body image (51). Overall, 70% of patients describe no limitations on their activities (121), 15% complain of problems with recreational activities, and 24% complain of problems with athletic activities. The areas of greatest dissatisfaction are related to sexual function and sexual satisfaction, with nearly half of all patients complaining of high levels of sexual dissatisfaction (51).

Common problems described by patients include the following:

1. For ileal loop diversions: stomal skin irritation (30%); difficulty caring for stoma and applying device, appliance care or caring for collection device (57%)
2. Continent cutaneous diversions: occasional to frequent problems with stomal catheterization (28%)
3. Orthotopic neobladders: daytime incontinence (23%), nocturnal incontinence or need to awaken to void (56%)

As described, regardless of these areas of dissatisfaction, the general satisfaction of patients with urinary diversions is high.

Quality-of-Life Differences Between Incontinent Cutaneous, Continent Cutaneous, and Orthotopic Continent Urinary Diversions

The results of the few validated studies addressing this question are interesting. Bjerre and colleagues (11) evaluated the quality of life with respect to body image, partner relationships, and global life satisfaction in patients undergoing ileal incontinent cutaneous urinary diversions and patients undergoing orthotopic Kock pouches. No difference was reported between the two groups. Filipas and colleagues (38) similarly evaluated the quality of life of 56 patients undergoing continent versus incontinent urinary diversions. Again no difference in satisfaction was noted between the two groups in regard to friends, social life, health, income, job, living situation, family life, or quality of life. Gerharz and colleagues (41), likewise, noted no difference between two nonrandomized groups (continent cutaneous reservoir or ileal conduit patients) in overall satisfaction or mental well being. McGuire and colleagues (78) evaluated the quality of life of 92 patients undergoing urinary diversion (ileal loop, Indiana continent cutaneous pouch, or Hautmann ileal neobladders) and compared each group's quality of life to published quality of life of age-based population norms. Interestingly, no physical quality-of-life difference was noted between any of the three urinary diversion groups and age-based population norms. Mental quality-of-life results proved differently. While the quality of life of continent cutaneous and orthotopic neobladder patients was no different than that of age-based population norms, the mental quality of life of ileal loop patients was slightly, although statistically significant, lower than that of the age-based population norms.

Overall, it can be generalized that most patients undergoing urinary diversion procedures will fare well from a quality-of-life standpoint, and that to date, with the

relatively few quality-of-life studies performed on urinary diversion patients, no significant difference in quality of life is noted among patients undergoing continent versus incontinent or heterotopic versus orthotopic urinary diversions.

The prostate, the major accessory sex gland of the male, has an exocrine but no established endocrine secretory function. Its secretion provides fluid that constitutes approximately 15% of the ejaculate. Aside from producing a volume-expanding vehicle for sperm, no definitive clinical function in reproduction has been identified for the prostate. The prostate, the prostatic urethra, and the bladder neck play a critical role in normal delivery of sperm in the sexual act. However, the major clinical interest in the growth and function of the prostate has resulted from the frequency with which it is the site of benign and malignant neoplasms and infection. The intimate anatomic relationship of the gland with the bladder neck and urethra increases the importance of these pathologic changes. The current status of our knowledge with regard to benign prostatic hyperplasia (BPH) is summarized in this chapter.

ANATOMY

Embryology

The prostate gland develops from the pelvic portion of the urogenital sinus at a fetal crown-rump length corresponding to a 10- to 12-week gestation (12). The prostate arises after the development of numerous endodermal buds, which initially proliferate throughout the entire length of the primitive urethra. Ultimately, the most extensive areas of proliferation into and about the prostatic anlage occur adjacent to the areas of the ejaculatory ducts and the verumontanum. These areas correspond to the points of termination of the mesonephric duct and its müAdullerian counterpart, respectively (194). The endodermal buds next invade the abundant surrounding urogenital sinus mesenchyme, which is responsible for the development of the connective tissue and muscular constituents of the definitive prostate (Fig. 32.1). Although this process continues throughout the life of the fetus, the gland is well differentiated by the end of the fourth month (12). Normal development of the wolffian and müllerian ducts and urogenital sinus-derived structures is dependent on the testosterone and müllerian-inhibiting secretions of the fetal testis. Conversion of testosterone to dihydrotestosterone, which occurs in both stroma and epithelium, is critical for the development of the prostate. An understanding of the role of growth factors and embryonic control mechanisms in organogenesis in general and in the prostate is currently the subject of intense investigation, as is the phenomenon of so-called imprinting (58,288).

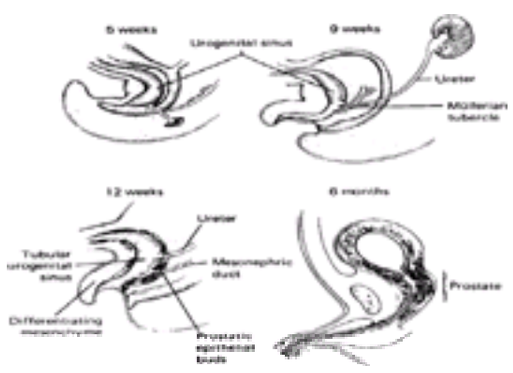

FIGURE 32.1. Embryogenesis of the prostate gland. The prostatic anlage develops from the pelvic part of the urogenital sinus. By the end of the third month,

numerous epithelial outgrowths emanate from the prostatic urethra above and below the mesonephric duct. Note the proximity of the surrounding mesenchyme to the invading endodermal buds. Gross Anatomy

General Considerations

The prostate is a compound tubuloalveolar gland whose base abuts the bladder neck and whose apex merges with the membranous urethra to rest on the urogenital diaphragm (386). The intact adult gland resembles a blunted cone, weighs approximately 18 to 20 g, and measures about 4.4 cm transversely across its base, 3.4 cm in length, and 2.6 cm in its anteroposterior diameter (208). The urethra enters the prostate near the middle of its base and exits the gland on its ventral surface above and in front of its apical portion. The ejaculatory ducts enter the base on its posterior aspect and run in an oblique fashion to emerge and terminate adjacent to the verumontanum. The capsule of the prostate gland is an inseparable condensation of stromal elements that is incomplete at the apex; it does not represent a true capsule (13). Fibrous septa emanate from the capsule, pierce the underlying parenchyma, and divide it into multiple lobules (386). These glandular units drain into branched tubules, which lead into 20 to 30 prostatic ducts. Most of these ducts empty their contents into the prostatic urethra adjacent or distal to the verumontanum (235). These and other relationships are depicted in Fig. 32.2 and Fig. 32.3.

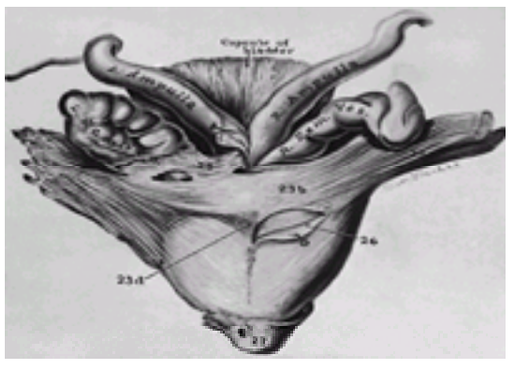

FIGURE 32.2. A dorsal view of the prostate gland, ampulla, seminal vesicles, and bladder. A median sulcus divides the prostate into halves and receives bandlike projections from the retrospermatic branch of the prostatic cord *(23d).* The dorsal capsule of the prostate *(26)* is synonymous with the anterior layer of Denonvilliers' fascia. Note the caplike investment *(27)* of the urogenital diaphragm on the apex of the prostate. (From Uhlenhuth E. *Problems in the anatomy of the pelvis: an atlas.* Philadelphia: Lippincott, 1953, with permission.)

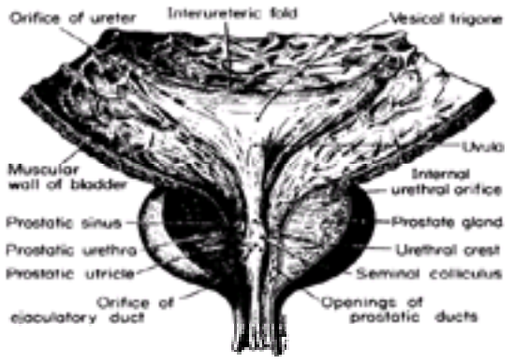

FIGURE 32.3. A frontal view of the bladder and prostate gland. The prostatic utricle sits atop the verumontanum (seminal colliculus) and represents one of two müllerian duct remnants in humans, the other being the appendix testis. Note that the majority of prostatic ducts drain adjacent or distal to the verumontanum. The area extending from the trigone to the termination of the prostatic urethra constitutes the internal urethral sphincter or bladder neck mechanism. (From Woodburne RT. Pelvis. In: Woodburne RT, ed. *Essentials of human anatomy.* New York: Oxford University Press, 1978, with permission.)

Denonvilliers' fascia is a visceral pelvic fascia formed by a condensation of fused peritoneum; it extends from the anterior peritoneal reflection superiorly to the urogenital diaphragm inferiorly. In its caudal extent, Denonvilliers' fascia envelops the posterior surface of the seminal vesicles and remains affixed to the posterior prostatic capsule (386). We suspect that the disputed existence of grossly identifiable anterior and posterior components of this fascial layer (369) as delineated in Fig. 32.4 is the result of their variably fused anatomic status rather than a misinterpreted rectal fascia propria.

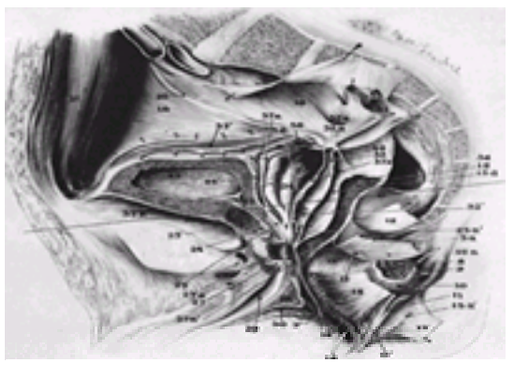

FIGURE 32.4. Detailed anatomic dissection of the retrovesical space. This anatomic approach permits a unique view of the ventral *(37a)* and dorsal *(37b)* leaf of the genital fascia, which envelops the ampulla *(33R)* and seminal vesicle *(34).* In addition, close inspection reveals the discrete separation of the anterior layer of Denonvilliers' fascia from its posterior *(32)* component. The last-named item is synonymous with the rectovesical septum. (From Uhlenhuth E. *Problems in the anatomy of the pelvis: an atlas.* Philadelphia: Lippincott, 1953, with permission.)

The endopelvic fascia corresponds to that condensation of extraperitoneal connective tissue that forms a subserous covering for the pelvic viscera and envelops their contiguous neurovascular pedicles. A sheetlike proliferation of the endopelvic fascia contributes to the formation of the puboprostatic ligaments. These avascular facial condensations, varying from a pillarlike to a fan configuration, lie on either side of the prostatic midline. They anchor the anterior and lateral aspect of the prostate to the posterior aspect of the pubis and superior fascia of the pelvic diaphragm (374).

The lateral pelvic fascia, also described as the parietal layer of the endopelvic or prostatic fascia, serves as the fascial envelope to the levator ani muscle and maintains continuity with the capsule of the prostate along its anterior and anterolateral aspects. The tributaries of the dorsal vein complex traverse this fascial layer

(Fig. 32.5). Anatomic dissections by Walsh and Donker (372) revealed that the major neurovascular bundles to the prostate are contained posterolaterally within the lateral leaves of this fascia.

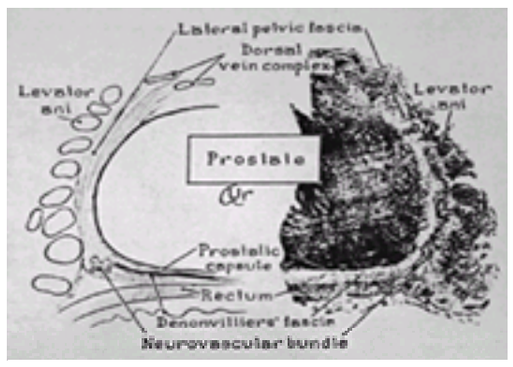

FIGURE 32.5. Cross section through the prostate gland. The levator ani is covered by the lateral pelvic fascia, which contains both the neurovascular bundle and dorsal vein complex. The latter consists of contributions from the dorsal vein of the penis and the plexus of Santorini. (From Walsh PC, Lepor H, Eggleston JC. Radical prostatectomy with preservation of sexual function: anatomical and pathological considerations. *Prostate* 1983;4:473, with permission.)

Blood Supply

The prostatovesicular artery, the major arterial supply to the prostate and seminal vesicles, is a branch of the inferior vesical artery that originates from the anterior division of the hypogastric artery and courses medially on the levator muscle to the bladder base. After providing tiny branches to the bladder base, prostate, and tip of the seminal vesicles, its terminal arborizations supply the prostate with its main arterial supply in the form of urethral and capsular branches (208). The urethral branches course along the posterolateral aspect of the vesicoprostatic junction and usually enter the bladder neck and periurethral aspect of the prostate gland at the 5 and 7 o'clock positions (Fig. 32.6). Capsular arteries supply the peripheral portion of the prostatic parenchyma via four to six branches traversing the posterolateral aspect of the gland. Walsh and Donker (372) determined that the nervi erigentes form an extensive plexus enveloping these capsular branches that serve as a vascular scaffold and a demonstrable anatomic landmark. The anterior division of the hypogastric artery also supplies the inferior aspect of the prostate, as well as the seminal vesicles and vas deferens, with accessory vessels from the middle hemorrhoidal and internal pudendal arteries (208,386).

Wide, thin-walled veins on the lateral and anterior aspect of the prostate gland merge with veins of the vesical plexus and the deep dorsal vein of the penis to form the plexus of Santorini within the puboprostatic space. This confluence of veins empties into the hypogastric vein. Of importance, these prostatic vessels freely communicate with the plexiform venous arborizations (Batson's plexus) that envelop and enter the lumbosacral spine and the wings of the ilia. The lack of competent valves in this nervous system has been postulated by some to provide direct access for embolic spread of prostate carcinoma to the skeletal system (23).

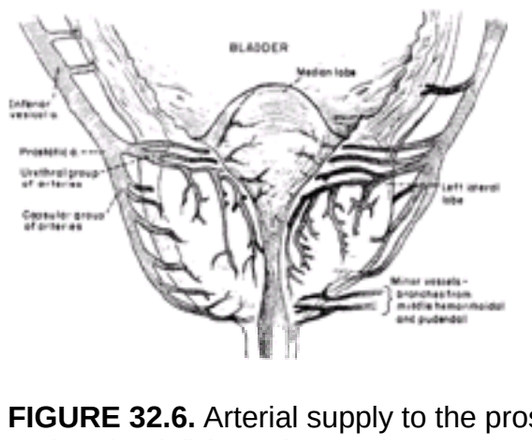

FIGURE 32.6. Arterial supply to the prostate gland. The anterior division of the hypogastric artery supplies the primary (inferior vesical) and secondary (middle rectal and pudendal) branches to the prostate gland. The prostatovesicular artery (prostatic artery) is a terminal tributary of the inferior vesical branch and arborizes into urethral and capsular components. In addition, it supplies the dorsal aspect of the seminal vesicles and bladder base. The urethral branches typically enter the bladder neck at the 5 and 7 o'clock positions, but this relationship is variable and inconstant. Note the presence of four to six branches from the capsular division supplying the outer aspect of the prostatic parenchyma. (From Carson CC III, Malek RS. Transurethral prostatic resection: surgical anatomy of the prostate and prostatic hyperplasia. In: Greene LF, Segura JW, eds. *Transurethral surgery.* Philadelphia: Saunders, 1979, with permission.)

Nerve Supply

In 1982, Walsh and Donker (372) published landmark observations describing the anatomic relationship of the pelvic (autonomic) plexus and the prostate gland. The prostate, other pelvic organs, and corpora cavernosa receive their autonomic innervation from the pelvic plexus, a fenestrated rectangular plate 4 cm long and 2.5 to 3.0 cm high lying retroperitoneally adjacent to the rectum within the sagittal plane (201). Both the parasympathetic and sympathetic divisions of the autonomic nervous system contribute to the plexus. Parasympathetic visceral efferent preganglionic nerve fibers from the second through fourth levels of the sacral cord enter the plexus by way of the pelvic splanchnic nerve (nervi erigentes). This nerve is a composite of five or six branches rather than a discrete entity. The sympathetic component emanates from the thoracolumbar center (T-11 to L-2) and courses via the hypogastric nerve, arborizations of the sacral sympathetic chain (S-4 to S-5), and branches that originate from the autonomic inferior mesenteric plexus and accompany the superior hemorrhoidal artery to join the plexus (201,215).

As stated previously, the prostatovesicular artery provides the macroscopic landmark and extrinsic support for these delicate nerves (Fig. 32.7). They lie outside of the confines of the prostatic capsule and Denonvilliers' fascia but traverse the lateral pelvic fascia (374). The prostate receives its branches from the pelvic plexus through the lateral leaves of this fascial layer (Fig. 32.5). These observations, initially made by dissections performed in fetal and newborn tissue, have been confirmed by studies in the adult male pelvis (201,215).

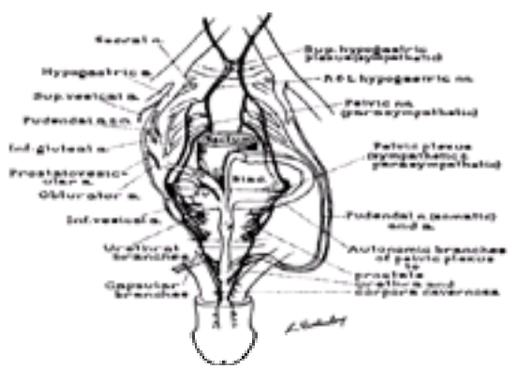

FIGURE 32.7. Innervation of the prostate, urethra, and corpora cavernosa. The branches to the prostate are contained within the lateral pelvic fascia and maintain an intimate relationship with the vascular scaffold created by the prostatovesicular artery. (From Walsh PC, Lepor H, Eggleston JC. Radical prostatectomy with preservation of sexual function: anatomical and pathological considerations. *Prostate* 1983;4:473, with permission.)

Lymphatics

Small lymphatic vessels surround each prostatic acinus, ultimately forming larger channels that contribute to the periprostatic plexus on the surface of the gland. This network communicates with branches from the perivesical lymph node group. The first major portal of lymphatic drainage from the prostate is to the iliopelvic lymph nodes (312). This lymphatic network can be conveniently divided into three nodal groups: the external iliac, the internal iliac, and the common iliac. The composition of these groups has been clearly summarized by Lieber (209).

The external iliac lymph node system consists of three separate groups. The lateral chain, consisting of one to three lymph nodes, lies along the lateral aspect of the external iliac artery. The most inferior node in this group is designated the lateral crural lymph node. The intermediate node group traverses the area between the external iliac artery and vein. The medial group of lymphatic vessels, the most significant of the three, lies superior to the obturator nerve and medial and posterior to the external iliac vein. The middle node of this medial chain is called the obturator lymph node; the most inferior node, designated the internal retrocrural node, communicates with the node of Cloquet within the femoral canal and with other deep inguinal nodes.

The internal iliac group (hypogastric chain) most often constitutes four to eight lymph nodes affixed to the areolar investment of the hypogastric vessels. This chain is rarely delineated on lymphography (55).

The common iliac lymph node group represents a continuation of the external iliac chain and also possesses lateral, intermediate, and medial groups. The last, by far the most important, usually consists of three to six lymph nodes. It gives rise to the nodes of the sacral promontory, opposite the second and third sacral foramen. The medial chain of the common iliac lymph nodes provides access to the perigastric nodes. Extensive cross-communication exists between right and left common iliac chains. Figure 33.45 depicts the anatomy of the pelvic lymph nodes and their relationship to the retroperitoneal abdominal lymphatics (see Chapter 33).

Normal Internal Architecture

Regionally organized tissue configurations have gained increasing acceptance in principle, if not in specific detail, in the prostate. Nevertheless, the proposed organization of the fetal, newborn, and adult prostate into discrete lobes has been regarded with skepticism (12,128,212,213,388). With a focus on the development of BPH, Franks (100,101) conceptualized a prostate with an inner (urethral) and outer glandular configuration (Fig. 32.8). McNeal (235) argues, as did Lowsley, that the urethral (inner) glands be considered separately from the prostate and its intrinsic architecture. However, the major physiologic and biochemical similarities of these glands and those of the prostatic parenchyma weigh against this concept.

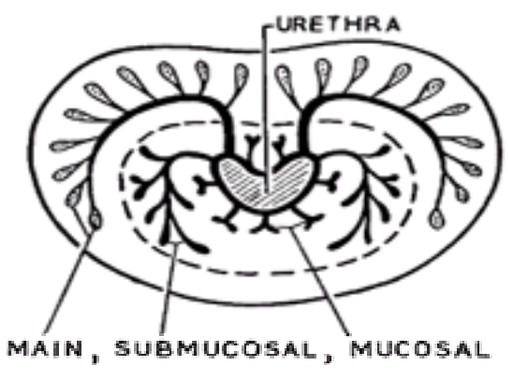

FIGURE 32.8. Cross section of normal prostate gland with the dorsal aspect superiorly placed demonstrating ductular architecture and three relatively concentric glandular arrangements. The mucosal component consists of delicate glands draining into short ducts, which empty circumferentially into the prostatic urethra. The submucosal group contains more extensive arborizations, which empty lateral to the urethral crest. These two groups constitute the periurethral area involved in benign prostatic hyperplasia. The acini constituting the lateral-most group of glands have a distinct cystic configuration. This outer or peripheral aspect constitutes the surgical capsule of hyperplastic glands. (From Grant JCB, Basmajian JV. *Grant's method of anatomy,* ed 7. Baltimore: Williams & Wilkins, 1975, with permission.)

McNeal (235,237) has proposed and promoted acceptance of anatomic subdivisions with probable pathophysiologic significance in the adult prostate. In his studies, McNeal emphasized the use of coronal and oblique coronal sections of prostates obtained between puberty and the third decade of life to study normal anatomy. Tisell and Salander (361), who used meticulous dissection techniques, observed subdivisions of the prostate gland that had several similarities to those reported by McNeal, but they interpreted these as evidence for prostatic lobes.

McNeal observed that the urethra separates the prostate into ventral (fibromuscular) and dorsal (glandular) portions. Approximately midway between the apex and base, the posterior wall of the urethra undergoes an acute 35-degree ventral angulation that serves to segregate the urethra into proximal and distal segments. The verumontanum and ejaculatory duct orifices exist exclusively within the distal segment. McNeal separates the glandular prostate thus delineated into four distinct regions: peripheral zone, central zone, transition zone, and periurethral gland region (Fig. 32.9).

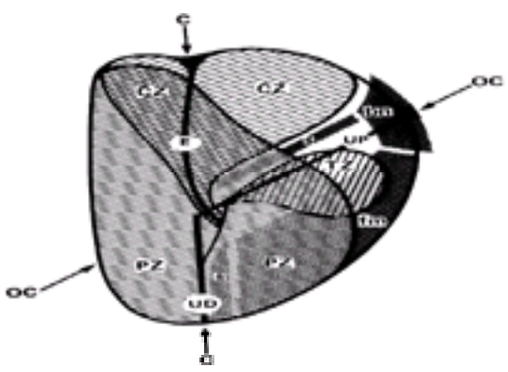

FIGURE 32.9. Sagittal diagram of distal prostatic urethral segment *(UD)*, proximal urethral segment *(UP),* and ejaculatory ducts *(E)* showing their relationships to a sagittal section of the anteromedial nonglandular tissues [bladder neck *(bn),* anterior fibromuscular stroma *(fm),* preprostatic sphincter *(s),* distal striated sphincter *(s)*]. These structures are shown in relation to a three-dimensional representation of the glandular prostate [central zone *(CZ),* peripheral zone *(PZ),* transitional zone *(TZ)*]. Oblique coronal plane *(OC)* of Fig. 32.10 and coronal plane *(C)* of Fig. 32.11 are indicated by *arrows.* (From McNeal JE. Normal histology of the prostate. *Am J Surg Pathol* 1988;12:619, with permission.)

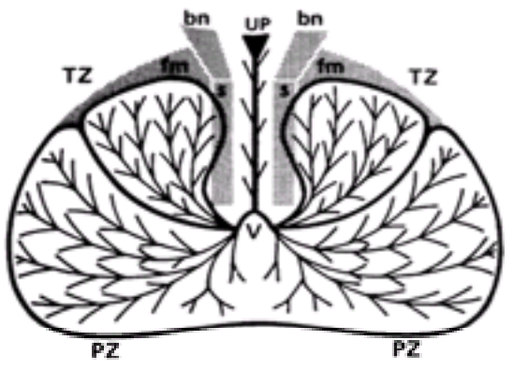

FIGURE 32.10. Oblique coronal section diagram of prostate showing location of peripheral zone *(PZ)* and transition zone *(TZ)* in relation to proximal urethral segment *(UP),* verumontanum *(V),* preprostatic sphincter *(s),* bladder neck *(bn),* and periurethral region with periurethral glands. Branching pattern of prostatic ducts is indicated; medial transition zone ducts penetrate into sphincter. fm, fibromuscular stroma. (From McNeal JE. Normal histology of the prostate. *Am J Surg Pathol* 1988;12:619, with permission.)

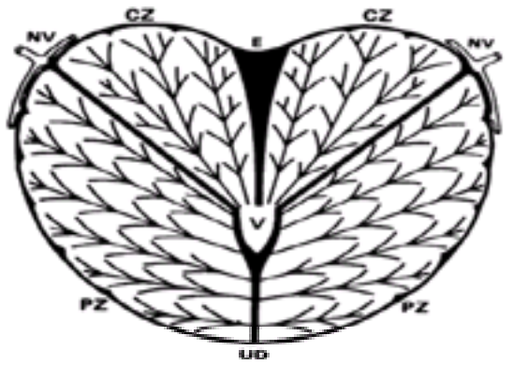

FIGURE 32.11. Coronal section diagram of prostate showing location of central zone *(CZ)* and peripheral zone *(PZ)* in relation to distal urethral segment *(UD),* verumontanum *(V),* and ejaculatory ducts *(E).* Branching pattern of prostatic ducts is indicated; subsidiary ducts provide uniform density of acini along entire main duct course. Neurovascular bundle *(NV)* is located at the junction between the central zone and the peripheral zone. (From McNeal JE. Normal histology of the prostate. *Am J Surg Pathol* 1988;12:619, with permission.)

The peripheral zone constitutes approximately 75% of the glandular prostate. Its ductal system enters the urethra along the posterolateral recesses of the urethra extending from the verumontanum distally to the prostatic apex (Fig. 32.3 and Fig. 32.10).

The wedge-shaped central zone, whose base is positioned superiorly at the bladder neck, occupies approximately 20% of the glandular prostate. Its ductal network closely follows the ejaculatory ducts to the urethra and empties adjacent to orifices of the ejaculatory ducts on the apex of the verumontanum (Fig. 32.11).

The transition zone, accounting for about 4% to 5% of the adult glandular prostate, is not well defined in the prepubertal prostate (234). It consists of two modest lobules of paraurethral tissue anterior to the peripheral zone. Its ducts empty in the posterior lateral recess of the urethra just proximal to peripheral zone ducts. The transition zone is lateral to McNeal's preprostatic sphincter, a smooth muscle cylinder enveloping the proximal urethra from the bladder neck to the base of the verumontanum (Fig. 32.9). The last anatomically discrete area within the glandular prostate is the periurethral gland region, representing less than 1% of the total volume of the glandular prostate. Its ductal network represents a more proximal extension of those of the peripheral and transition zone areas. These various regions have differing acinar, stromal, and cellular configurations. McNeal postulates that the anatomic and histologic similarities of the peripheral and transition zones and periurethral gland region are attributable to a common urogenital sinus embryonic origin. In distinction, he postulates that the close association between the central glandular zone, the ejaculatory ducts, and the seminal vesicles may reflect a common wolffian duct embryonic origin (235).

Last, the anterior or ventral fibromuscular stroma forms an apron that extends distally, covers the entire anterolateral aspect of the glandular prostate, and is responsible for the anterior convexity of the prostate gland. It represents approximately one-third of the tissue within the prostate capsule (237). This unusually distinct area, composed predominantly of smooth muscle fibers, maintains continuity proximally with the detrusor muscle fibers of the bladder neck.

As noted, the so-called capsule of the prostate is a condensation of stromal elements that envelopes the underlying parenchyma in a rather uniform manner (Fig. 32.12) except at the apex. Periodically, distinct septa emanate from the capsular sheath and penetrate the interior of the gland, segregating it into lobules. The peripheral aspect of the capsule consists predominantly of fibroblasts, collagen, and elastic fibers. The septations differ from the bulk of the capsule in that they contain abundant smooth muscle cells (SMCs). The resulting epithelial folds and papillae are buttressed by the union of capsular septa and filamentous stromal branches. A complex network of lymphatics, blood vessels, and nerves courses through these branches. The capsular septa and stroma represent a dynamic scaffolding system for the underlying parenchyma. As a unit, they constitute 25% to 30% of the total volume of the prostate gland (7,246,252).

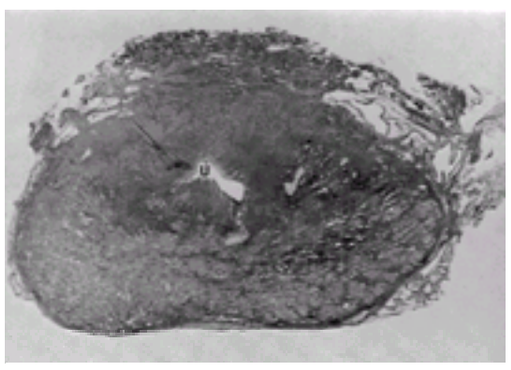

FIGURE 32.12. Transverse section of normal prostate gland. The fibrovascular constitution of the capsule surrounding otherwise normal, peripherally distributed acinar elements is well illustrated. Note the absence of hyperplastic tissue in the periurethral area. (From Kirchheim D. Histochemistry. In: Hinman F Jr, ed. *Benign prostatic hypertrophy.* New York: Springer-Verlag, 1983, with permission.)

Prostatic stroma consists predominantly of SMCs and fibroblasts arranged in close proximity to the distinct basal lamina of the epithelium. However, the fibroblasts tend to be organized parallel to the long axis of these tubulosaccular glands and form a more predictable relationship with the basement membrane (252). The smooth muscle surrounds individual glands and is thought to play a pivotal role in the release of glandular secretions. Furthermore, contraction of the circular smooth muscle of the bladder neck and preprostatic sphincter assists in the elimination of secretions within the prostatic urethra; this smooth muscle probably forms the major working element of the internal urethral sphincter. The anterior and anterolateral aspects of the prostate contain smooth and skeletal muscle, which joins the fibers of the external sphincter, augmenting urinary control in that region (223).

The excretory ducts are lined by simple or pseudostratified columnar epithelium for most of their course, but transitional epithelium is noted distally as they enter the

floor and lateral surfaces of the urethra adjacent or distal to the verumontanum. From a teleologic standpoint, these ducts are inefficiently arranged. As noted previously, rather than a single main excretory duct, there are 16 to 32 separate ducts with distinct urethral orifices. Moreover, the ducts have an irregular branching pattern with numerous cystic outgrowths. This serpiginous pattern seems likely to restrict rather than promote the transit of secretions. The ductal network possesses both columnar and basal cells. However, neither has a secretory capability. Analysis of their ultrastructure reveals a few randomly distributed organelles. The generous investment of the ductal compartment by SMCs admixed with nerve axons is noteworthy. These elements appear to be integrally related to emptying the ducts (see Secretory Mechanisms) (84,339).

Blood capillaries that traverse the stromal labyrinth consist of both continuous and fenestrated subtypes. These vessels and their associated nerves probably play an active role in both the elaboration and propagation of the gland's secretions (84).

The acinar epithelium consists of two well-recognized cell types: (a) a tall, columnar glandular secretory cell that is luminal in orientation, and (b) a nonsecretory basal cell that is flattened, cuboidal, and abuts a distinct eosinophilic basement membrane approximately 0.07 to 0.12 mm thick. Both cell types make direct contact with the latter (Fig. 32.13). The predominating glandular secretory cells possess a variety of distinctive light and electron microscopic features (Fig. 32.14), including the following:

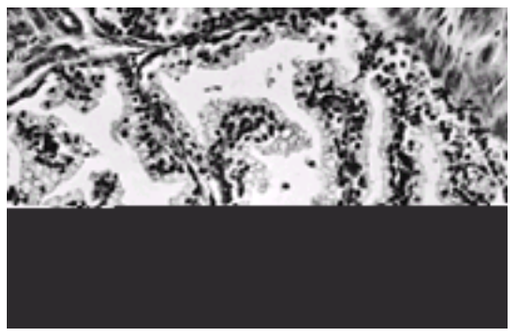

FIGURE 32.13. Photomicrograph of normal prostatic acini demonstrating double cell layers. The latter consists of basal cells and adluminal (secretory) cell components (×200). (From Mostofi FK, Price EB. *Tumors of the male genital system,* series 2, fascicle 8, *Atlas of tumor pathology.* Washington, DC: Armed Forces Institute of Pathology, 1972, with permission.)

FIGURE 32.14. Electron micrograph of normal prostatic epithelial cells. The adluminal cells contain prominent nuclei *(N)* with mitochondria, lipid droplets, and secretory vesicles *(SV)* easily demonstrated. Apocrine secretion (release of secretory products plus a portion of the cell wall) is reflected by the loss of the villous extension apparent in the center of the field. Merocrine secretion (release of secretory product through the intact cell) is also demonstrated in the prostate. The basal cell *(BC)* abuts a distinctive basement membrane (not shown) and contains a prominently serrated nucleus. Lu, lumen acinus. (From Kirchheim D. Histochemistry. In: Hinman F Jr, ed. *Benign prostatic hypertrophy.* New York: Springer-Verlag, 1983, with permission.)

1. Although typically tall and columnar in profile, the cell may appear compact in areas with high cellular density.
2. Nuclei are located in a dependent position with a long axis paralleling that of the cell.
3. Nucleoli are rarely encountered; they are separated from a double nuclear membrane by punctate areas of delicate heterochromatin.
4. The basal cytoplasm harbors free ribosomes, rough endoplasmic reticulum (RER), and some short mitochondria.
5. The supranuclear area is characterized by the presence of a Golgi apparatus consisting of aggregates of small vesicles and elongated lacunae, RER, some lipid droplets, and secretory granules and vacuoles with a solitary limiting membrane.
6. Active lysosomes and different types of dense bodies, the most prominent of which contains lipofuscin, are present within the apical cytoplasm.
7. The apical cytoplasm contains numerous villiform extensions that project from glandular cells into the acinar lumina that vary in prominence depending on the secretory status of the cell.
8. Glandular cells react with monoclonal antibodies to prostate-specific antigen (PSA), prostate-binding protein, and acid phosphatase. Acid phosphatase is noted predominantly within the secretory vacuoles and lysosomes; in contrast, aminopeptidase and PSA are located in the apical cell border and cytoplasm, respectively.
9. A distinct lateral plasma membrane exists; cell-to-cell contact is accomplished through apical junctional complexes and numerous desmosomes (184,252,339). Cytokeratins (CKs) 8 and 18 appear to be specific for the prostate secretory cell (331).

The basal or nonsecretory cell subpopulation also possesses distinctive histologic and ultrastructural characteristics, including the following (Fig. 32.13 and Fig. 32.14):

1. Basal cells are polygonal in orientation and possess a relatively large nucleus with a serrated border. As with glandular cells, the long axis of the nucleus parallels that of the cell itself.
2. Extension of these cells never appears to reach the lumen of the gland.
3. Their cytoplasm, lacking secretory granules, is more electron dense than that of glandular cells.
4. In addition to lacking secretory granules, basal cells reveal an inconspicuous array of mitochondria, endoplasmic reticulum, and free ribosomes and possess a much abbreviated Golgi apparatus.
5. Despite possessing linear attachments, basal and columnar cells are commonly separated by lacunae containing cytoplasmic projections.
6. Basal cells possess a number of intracytoplasmic filaments, some of which may serve a contractility function (or functions); others are CKs. CKs 5 and 15 appear to be basal-cell specific (331).
7. Pinocytotic vesicles that may facilitate transfer of materials between the glandular and stromal compartments are present.
8. The basal cell compartment appears more prominent in the inner than in peripheral prostatic glands.
9. Basal cells do not react with monoclonal antibodies directed against acid phosphatase, PSA, and prostate-binding protein (PBP).
10. The basal cell compartment is thought to function as reserve or stem cells and to be primarily responsible for tissue repair.

Although cytokeratin characterization distinguishes adult basal and adluminal epithelial cells (22,329,331), Xue and associates (390) identified intermediately located cells with mixed basal and adluminal cell cytokeratins in the developing prostate; they postulate that these may facilitate a transition between basal and adluminal cells. Interestingly, no apparent qualitative differences in CK expression were found between central and peripheral zone tissues (329).

The prostate contains two groups of cells: the neuroendocrine (NE) or endocrine-paracrine (EP) cells, native to the prostate, and inflammatory cells that have the potential to secrete recognized growth factors and other potential growth-modifying agents. With regard to the latter, macrophages and mast cells are encountered in

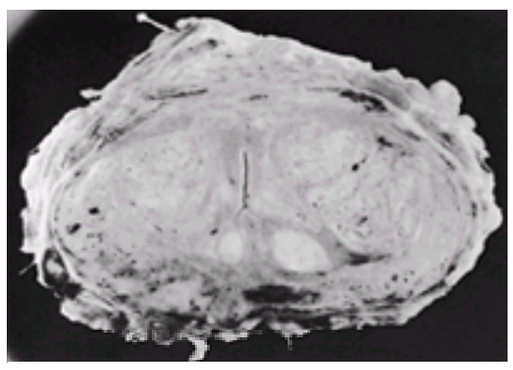

FIGURE 32.21. Transverse section of human prostate gland demonstrating small focal nodules of predominantly stromal hyperplasia. Their modest size and periurethral location are characteristic. Also note concomitant glandular hyperplasia. (From Mostofi FK, Price EB. *Tumors of the male genital system,* series 2, fascicle 8, *Atlas of tumor pathology.* Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.)

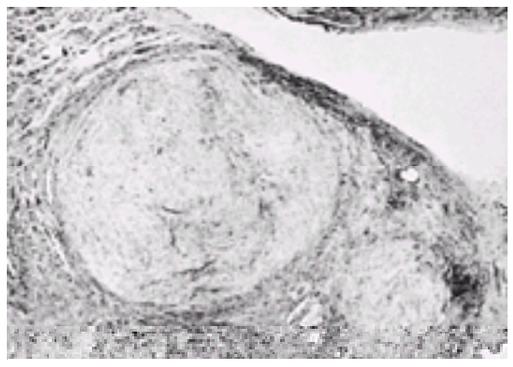

FIGURE 32.22. Stromal hyperplasia. This represents a higher magnification (×10) of the stromal nodules demonstrated in Fig. 32.21. Again, note the close proximity of the urethral lumen. (From Mostofi FK, Price EB. *Tumors of the male genital system,* series 2, fascicle 8, *Atlas of tumor pathology.* Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.)

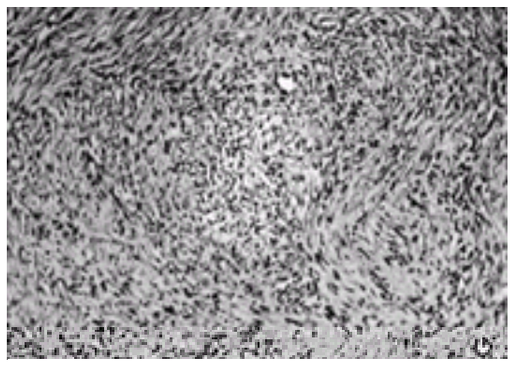

FIGURE 32.23. Stromal hyperplasia (×115). In benign prostatic hyperplasia (BPH), the fibromuscular stroma is often found to loosely envelop adjacent hyperplastic acini or occasionally form discrete compact nodules. In distinction to the hyperplastic process found in breast, the fibromuscular stroma in BPH lacks excessive amounts of elastic tissue. (From Mostofi FK, Price EB. *Tumors of the male genital system,* series 2, fascicle 8, *Atlas of tumor pathology.* Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.)

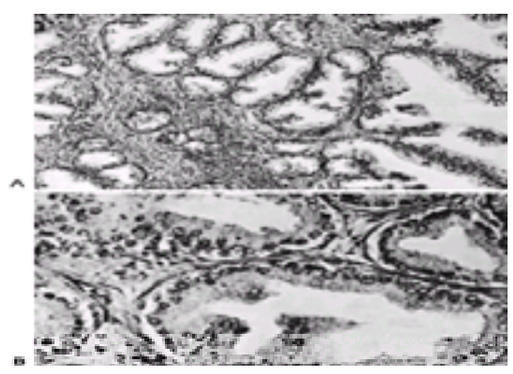

FIGURE 32.24. A: Photomicrograph (×80) of a focus of predominantly glandular hyperplasia. Note occasional papillary infolding, the two-cell layer composition of the acini, and the abundance of surrounding and intervening stromal elements. **B:** Higher-magnification view (×300) better demonstrating the consistent presence of basal and adluminal cell components to the individual acini, as well as the loose intervening stromal component. Adluminal papillary proliferation is well demonstrated. (From Mostofi FK, Price EB. *Tumors of the male genital system,* series 2, fascicle 8, *Atlas of tumor pathology.* Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.)

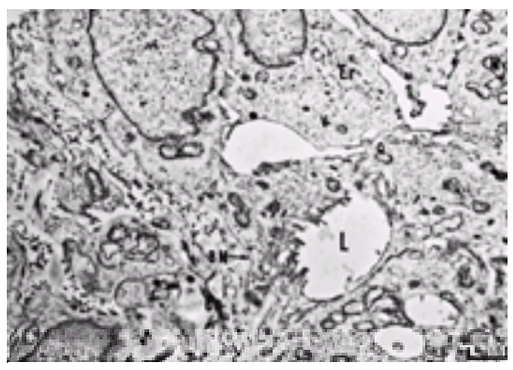

FIGURE 32.25. Electron micrograph of epithelial cells in benign prostatic hyperplasia (×7,000). No distinct ultrastructural differences are noted between normal and hyperplastic prostatic epithelial cells except occasionally prominent intercellular lacunae *(L).* Prominent basement membrane *(BM)* and subadjacent collagen bundles are noted. (From Fisher ER, Jeffrey W. Ultrastructure of human normal and neoplastic prostate with comments relative to prostatic effects of hormonal stimulation in the rabbit. *Am J Clin Pathol* 1965;44:119, with permission.)

Associated Pathology

Infarction of the prostate, thought to occur predominantly in prostates of substantial size exhibiting nodular hyperplasia (1,16,247), is said to be present in approximately 25% of large glands. Acute massive prostatic infarction has been observed in association with septic shock, hemorrhagic shock caused by a ruptured abdominal aortic aneurysm, coronary artery bypass, repair of aortic and iliac artery aneurysms, and pyonephrosis (93). Infarcts vary in size from tiny to 5-cm lesions and are commonly located periurethrally. A speckled, grayish-yellow appearance occasionally associated with hemorrhagic streaks and a sharply delineated, often hemorrhagic periphery are characteristic. Spiro and associates (338) noted prostatic infarction in 85% of the glands in patients with and in 3% of those without acute urinary retention. Others have found no definite or a lesser predominance of identifiable infarction in patients treated for acute retention (8). Prostatic infarcts may be associated with significant elevation of the serum prostate markers (308). Histologically, infarcted areas reveal centrally located coagulation necrosis with hemorrhagic changes in the peripheral margins. Metaplasia of adjacent ductal and acinar epithelium often results in a squamous or transitional epithelial configuration (252). Although acini involved with metaplasia (308) may lack the characteristic basal cell layer, all the cells involved are typically well differentiated and demonstrate no evidence of anaplasia or invasion that would be expected with malignancy.

Prostatic calculi have been recognized with an incidence varying from 7% in prostate pathology specimens to 20% at autopsy, 30% in radiologic studies, and even higher incidence on ultrasound evaluation (128). The calculi have either a lobular or polyfaceted laminar surface (371). Based on their composition, they have been classified as primary, forming inside the acinus, or secondary, forming within the prostatic ducts. Primary calculi characteristically have a nucleus of apatite with concentric layers of apatite and whitlockite. Peripheral layers of whewellite and occasionally weddellite may be present. These calculi may be completely crystalline or have areas with a sizable amount of organic material, or a nucleus suggesting an amylaceous body. Secondary calculi may have a nucleus of whewellite or uric acid (290). Classically, the calculi are deposited within the cleavage line that exists between the nodular hyperplasia and the surgical capsule. On routine radiographs, true prostatic calculi appear as scattered calcifications overlying the pubic symphysis and the superior pubic rami. Multiple clustered calculi may be recognized on rectal examination by characteristic crepitation. Single calculi have a firmness on rectal examination suggestive of carcinoma.

Two lesions that warrant discussion because of their resemblance to or association with BPH are papillary adenoma of the utricle (aberrant prostatic tissue) and blue nevus of the prostate. Aberrant prostate tissue may involve the utricle, the base and perimeter of the verumontanum, or the entire prostatic urethra. These lesions tend to occur in younger men, manifest clinically most often with gross painless hematuria, and are indistinguishable from adenomatous hyperplasia of the prostate (252). Postmortem specimens suggest that these lesions usually represent a hyperplastic proliferation of normal tissue.

Blue nevus of the prostate may be associated with prostatic hyperplasia and cause confusion with malignant melanoma. Histologically, this lesion is characterized by infiltration of the prostatic stroma by clumps of spindle-shaped cells containing a granular brown, iron-negative, bleachable, Fontana-Masson–stained pigment within their cytoplasm (252).

Biochemical Characteristics

The concentration and content of steroids, enzymes, minerals, and a variety of compounds have been determined in the hyperplastic tissue and compared with normal and carcinomatous tissue. Identification of normal tissue and preservation of its biochemical characteristics for analysis is a problem that requires persistent attention. The variable composition of tissue samples of BPH and carcinoma as demonstrated on histologic study undoubtedly increases the challenge to obtain consistent results in their analysis. Nevertheless, a sizable body of information regarding steroid content, metabolism, and specific binding, as well as other biochemical characteristics of normal and pathologic prostate tissue, has been published in the past 30 years. As analytic techniques have improved, a significant portion of these data have been modified or discarded. The following seems a reasonable summary of the current state of our knowledge.

The observations (90) that dihydrotestosterone and androstenediol are the principal metabolites of radioactive testosterone incubated with human BPH tissue *in vitro* have been adequately confirmed. However, reports that BPH tissue has a higher concentration of DHT than normal or peripheral prostate have not been supported in repeated assessments of appropriately preserved surgical tissue. In these specimens, BPH and peripheral prostate had similar tissue levels of DHT (5.0 and 5.1 ng/g) and testosterone (1.8 and 1.2 ng/g) (373). These findings were eventually confirmed by Bartsch and colleagues (21) and Norman and colleagues (266). A weak correlation was observed between DHT concentration and the content of glandular tissue. Bartsch and colleagues (21) reported low levels of progesterone, estrone, estradiol, and estriol (0.02 to 0.06 ng/g tissue) in surgically removed BPH and normal prostate tissue from kidney donors. In contrast, Krieg and associates (191) found markedly increased estradiol (6.2 versus 2.2 fmol/mg protein) and estrone (7.4 versus 0.9 fmol/ng protein) levels in mechanically separated stroma from suprapubic prostatectomy specimens compared with prostate tissue from six brain-dead 21- to 61-year-old kidney donors. DHT and T concentrations in stroma were similar in surgical and kidney donor specimens but were reduced in prostate epithelium from kidney donors. Normal tissue levels of DHT in BPH tissue seem paradoxic in view of the decreased serum testosterone levels in aging men (125,370); the increased 5a-reductase activity of BPH stroma could partially account for this finding (36) but seems unlikely to do so.

Evidence that 5a-reductase activity is increased two to three times in BPH (35,162,166) and is predominantly localized to the stroma is substantial. Prostatic tissue obtained from 50 men subjected to open prostatectomy and 15 brain-dead organ donors 14 to 38 years of age had 6 to 15 times greater 5a-reductase activity in the crudely separated stroma than did the epithelium regardless of the histology of the prostate (36). These observations suggest that the relatively increased amount of stromal tissue in BPH as compared with normal tissue may contribute significantly to its (BPH) reported increased 5a-reductase activity. Availability of an antibody to 5a-reductase type 2, the isoenzyme present in prostatic tissue, has permitted immunohistochemical evaluation of a variety of tissues for this enzyme. Limited observations demonstrate perinuclear staining of basal and stromal cells in normal and BPH tissue. The predominant staining in BPH as contrasted with “normal” prostate was in the stroma rather than basal cells (332,333). No 5a-reductase antigen was detected in luminar epithelial cells.

Attempts to characterize, localize, and quantify steroid receptors in BPH as compared with those in normal or peripheral prostatic tissue have been persistent. The gene for the androgen receptor has been cloned and sequenced, and its protein product has been characterized (48,58), adding sophisticated tools to study this aspect of androgen effect on cells. With immunohistochemical techniques (225,245) the physiologically important androgen receptor is localized in the nucleus. Evidence suggests that nuclear androgen receptor content is increased in BPH compared with peripheral prostate (59). The presence of estrogen receptors in the prostate has now been confirmed by most investigators. In general, estrogen-binding sites are reported to be more numerous in stroma than in epithelial cells and to be decreased in concentration in BPH as compared with normal tissue (59,77,180,321). Interest in the role of estrogen receptors has been increased by the isolation of a second estrogen receptor in the rat prostate and confirmation of its presence in human prostate (49). Progesterone receptors are also present in appreciable concentrations in the cytosol of prostatic epithelial cells; the concentration in BPH is significantly greater than that in normal tissue (21). However, progesterone receptors have not been identified in the nucleus of prostatic cells. Although the receptor–steroid complexes clearly have significant roles in the growth and function of prostatic cells, the exact mechanisms involved and the significance of receptor data with regard to the development and growth of BPH are still unclear.

Enzymes

Evaluation of the concentration of a series of enzymes involved in steroid metabolism in BPH as compared with normal or peripheral prostate in addition to the previously discussed 5a-reductase has not provided insightful information. Observations of significantly decreased 3a- and 3b-hydroxysteroid oxidoreductase reductase and 17b-hydroxysteroid oxidoreductase oxidase activities in surgically removed BPH compared with surgically removed normal prostate (166), changes favoring increased DHT formation in BPH, were not confirmed later by the same group (34). Brendler and colleagues (34) reported a three to six times higher acid phosphatase activity in BPH than in peripheral prostatic tissue. The activity of several other cytoplasmic enzymes, including alkaline phosphatase and lactic dehydrogenase, did not differ in BPH and normal tissue. Histochemical studies have demonstrated marked b-glucuronidase and *N*-acetyl-b-glucosaminidase activity in the prostatic epithelium of BPH (265) and of aminopeptidase in normal prostate and BPH (185). However, aminopeptidase activity was diminished or absent in some BPH nodules (185) and was decreased in concentration in tissue homogenates compared with normal tissue (264). Histochemical staining revealed no difference for a group of oxidative enzymes in BPH and normal prostate tissue (264). Interestingly, staining for glucose-6-phosphate dehydrogenase and b-hydroxybutyrate dehydrogenase activity was almost absent and weak, respectively. Nonspecific esterase and succinic dehydrogenase staining were similar in normal and hyperplastic prostate.

Organic Compounds and Metal Ions

BPH has a high concentration of citric, lactic, and aconitic acids per gram of tissue, but accurate comparisons with the concentrations found in normal tissue are not available. No a-ketoglutaric or succinic acid was detected in BPH (335). Zinc content has variously been reported to be elevated (141) and identical (142) to the high

level noted in normal prostatic tissue. Cadmium has been reported to be present in much higher concentration in BPH than in normal tissue (142). Magnesium has been shown to be increased in concentration in the epithelial cells of BPH by histochemical studies and in the tissue by atomic absorption spectrophotometry (141).

Summary of Biochemical Aspects of Benign Prostatic Hyperplasia

As indicated, despite extensive and continuing efforts, no qualitative differences in steroid content or metabolism, enzyme activity, organic compounds, or metal ions have been documented between BPH tissue and either normal prostatic tissue or the peripheral prostate from a gland with BPH. The few quantitative differences in biochemical characteristics reported require confirmation and have not helped identify a unique aspect of the metabolic activity characterizing BPH.

Natural History of Anatomic Benign Prostatic Hyperplasia

The first pathologic evidence of BPH occurs in less than 10% of the men in the 31- to 40-year-old group (Table 32.2). This observation may indicate that the initiating factor is present in most men of this age, with its effect being recognizable only in a few, or that young men with recognizable BPH have a discrepancy between physiologic and chronologic aging. Evidence of histologic and anatomic BPH increases with age; by the ninth decade the former is identifiable in approximately 90% and the latter in probably over half of men (150). The initial lesion of BPH almost always occurs in the periurethral area proximal to the verumontanum. Although descriptions of the ductal and glandular structure of this area vary, it is generally agreed that BPH arises from an inner set of prostatic ducts and glands that reside within the urethral wall or adjacent to it. McNeal (235) designates the paraurethral portion of this tissue the transition zone; it composes approximately 5% of the normal gland. The histologic characteristics of the earliest BPH lesions are probably variable. Those that develop within the urethral wall are usually composed of a mass of loose embryonic-appearing stroma devoid of glands; however, glandular tissue predominates in early lesions developing in the transition zone (234). McNeal (235) and Franks (101) agree with the latter's statement that stromal and epithelial hyperplasia may occur alone or together. Once the process is initiated, all elements of the normal prostate—stromal and glandular—participate to a variable degree in its progression. The glands in the hyperplastic nodules seem to have the capacity to bud and form new ducts and acini; in contrast to normal tissue, these new glandular elements grow toward each other. Pure stromal nodules rarely reach large size. The variable local response to a postulated inductive agent is evident from the nodular nature of the BPH. Not all the nodules of BPH are in the same phase of development, as is clearly indicated by Moore's observation (247) that small stromal nodules were present in every enlarged prostate. This observation does not preclude the possibility that BPH results from a sequence of initiating and promoting effects that are episodic. Both the average weights of the prostate and the incidence of prostatectomy by decade suggest that once BPH has developed, it is progressive in most men. The rate of growth calculated by Berry and colleagues (27) indicates a prolongation of the doubling time with age. The important question of whether established BPH ever stabilizes or regresses spontaneously cannot be evaluated from the information available. Based solely on clinical criteria, many authors, including ourselves, are of the opinion that both occur (see also Natural History of Benign Prostatic Hyperplasia Voiding Dysfunction).

TABLE 32.2. AGE PREVALENCE OF HUMAN BENIGN PROSTATIC HYPERPLASIA (BPH)

Etiology

Identifying the etiology of BPH has been a continuing challenge. The universal regional development of histologic BPH (167) in aging men with testes that produce an androgen-diminished environment (125) is an as yet unexplained paradox that is independent of race and environment. The subsequent development of mass-producing BPH is selective (166) and seems potentially to be related to a variety of factors, at least some of which are associated with environment and lifestyle. In proposing etiologic factors in this common benign growth in humans, the unusual pathologic features of BPH including nodular growth and stromal predominance require consideration in addition to its characteristic periurethral localization. Over time, neoplastic, inflammatory, metabolic and nutritional, vascular, racial, and a variety of other etiologic factors have been considered as causes of BPH (251). Newly identified systemic or local prostatic growth-promoting agents traditionally receive prompt consideration. Evidence has been presented suggesting a genetic factor in a small group of men developing BPH. Currently, four hypotheses regarding the etiology of BPH are prominent: the DHT or altered hormone environment hypothesis, the embryonic reawakening hypothesis (236), the stem cell hypothesis (167), and the nonandrogenic testis secretory factor hypothesis (129,133). Two of these, the embryonic reawakening and the stem cell hypotheses, focus on intrinsic cellular phenomena. The embryonic reawakening theory proposes that the interaction between glandular tissue of prostatic origin and stroma related to the bladder produces a reawakening of embryonic inductive interactions resulting in tissue with growth characteristics that lead to the development of BPH (236). Subsequent growth of BPH is postulated to be multifactorial (197,277), with altered hormone environment and stromal epithelial interaction having varying degrees of prominence in this phenomenon. The stem cell hypothesis proposes an increase in prostate stem cell number and that of the amplifying and transient cells derived from them as the basic phenomenon leading to the development of BPH. Neither the embryonic reawakening nor the stem cell hypothesis proposes an identifiable inducing mechanism to initiate or sustain the phenomena proposed.

The so-called DHT hypothesis, perhaps more appropriately termed the *altered hormonal environment* hypothesis, and the nonandrogenic testis secretory factor hypothesis center on alterations in testis secretory function or changes in local or systemic hormone metabolism with age that may initiate or sustain phenomena leading to the development of BPH. Several studies demonstrate that with aging the male human develops an androgen-diminished environment. This decrease in systemic androgen is accompanied by stable or possibly slightly altered systemic estrogen and increased steroid hormone binding serum levels (125,137,255). The latter further decreases the biologically available systemic testosterone. Although DHT and androgen receptor (AR) concentrations in BPH tissue are high, they do not differ from peripheral or normal prostate levels. The evidence suggests that androgens are necessary for but not sufficient to induce development of BPH. Estrogens have demonstrated physiologic effects on male accessory sex gland growth, including the prostate in animals (224); this primarily involves the stromal tissue (171). BPH can be induced in the dog by coadministration of androstanediol and estrogen (277,375). The recent discovery of a second estrogen receptor, estrogen receptor-b (ERb), has stimulated additional speculation about potential mechanisms for and role of estrogen in prostate BPH growth. Of interest, genistein and other phytoestrogens have a much higher affinity for ERb than ERa (49). However, despite the appreciable information from animal experimentation, and human tissue and serum hormone analysis with aging in men, the role of estrogen in the development and progression of BPH remains controversial. Attempts to correlate serum hormone levels with benign prostate pathology in radical prostatectomy specimens (278) and with ultrasound-assessed prostate size and anatomic configuration in twins (241) and longitudinal evaluation of serum hormone levels and manifestations of BPH (108) have also failed to provide insights into its etiology. Excluding the possible significant effects of estrogen imprinting on the neonatal prostate (288), these data suggest that estrogen may share a potential role in BPH mass development with a variety of other variously derived agents. Overall, the multiple studies of changes in known steroid hormone secretory products of the testis have not provided a highly probable explanation for the critical role of the testis in the development and growth of BPH in humans.

The nonandrogenic testis factor (NATF) hypothesis proposes that the testes secrete a nonandrogenic prostate growth-stimulating factor, almost certainly a protein, that plays a critical role in the ubiquitous development of histologic BPH and possibly a contributory role in the subsequent development of mass-producing BPH (129,133,165). Biologic evidence supporting the presence of a nonandrogenic male accessory sex gland growth-stimulating substance in the aging male human was derived from assessment of age-related changes in the concentration of selected prostate and seminal vesicle secretory products and seminal vesicle weight (126,130). The testes were targeted as a source of this hypothesized prostate growth-stimulating agent based on the evidence that neither endogenous nor exogenous testosterone or estradiol could replace a normally functioning testis in producing BPH in dogs (131,176) and evidence for a systemic prostate growth-stimulating substance that was not a steroid in the testis-intact but not the castrated rat. Evaluation of possible secretion of a nonandrogenic prostate stromal cell stimulating protein by the testis (NATF) was carried out using stimulation of the proliferative response of human prostate stromal cells to testicular epididymal plasma derived from human spermatoceles (STEP) *in vitro* as evidence for its existence. Exposure to STEP produced both androgen-independent and androgen-synergistic stromal growth stimulation repeatedly in this system (133). Isolation and identification of the protein (NATF) responsible for this stimulation is

progressing. Animal studies indicate that the prostate is exposed to NATF by a systemic delivery route; in addition, the presence of NATF in the testosterone-rich testicular epididymal plasma fosters potential exposure of periurethral prostatic tissue to these independent and synergistic prostate growth-stimulating compounds. We postulate that this exposure induces the almost universal periurethrally localized development of histologic BPH. Subsequent selective stimulation of prostatic mass is postulated to be induced by multiple factors with a significant but less well defined role for exposure to systemic or local NATF.

Pathophysiology

Concepts regarding the etiology of urinary symptoms and sequelae resulting from BPH traditionally focused on the development and progression of mechanical obstruction from the prostatic mass as the cause. The perception that the mass and configuration of the hyperplasia dictated the degree of outflow blockage undoubtedly resulted from the early experiences in treatment of patients with acute and chronic urinary retention. Renal failure, urinary tract infection, and calculi were common indications for various approaches to relieve bladder neck obstruction. The commonly observed reversal of these serious secondary phenomena and restoration of normal or markedly improved voiding patterns reinforced the mass-obstruction concept. Failures in both of these therapeutic goals were overshadowed by the frequent correction of the various significant problems that existed. Absence of a direct correlation between the size of the prostate and presence or degree of obstruction was recognized as indicated by the designation “prostatism sans prostate” or the admonition “small prostate, big residual.” If functional results of mass removal were less than optimal, the concept of probable persistence of mechanical obstruction was pursued by determining postvoid residual urine to evaluate bladder emptying, carrying out endoscopic reassessment of the lower urinary tract primarily to assess the possibility of persistent mass, and at times performing a simple urodynamic evaluation. Proposals implicating intrinsic prostatic tension from contracting prostate stromal smooth muscle (43,198) or extrinsic tension on the BPH prostate mass by a contracting or contracted prostate capsule (164,272) have been proposed as potentially having important roles in primary or persistent bladder outlet obstruction. The proposed role of stromal smooth muscle–mediated increased intrinsic prostate tension has been reinforced substantially by *in vitro* physiologic and to a lesser degree clinical observations with a-adrenergic agonists and receptor blocker agents, respectively (198). The proposed role of peripheral capsular tension on bladder outlet obstruction is supported by the results of transurethral incision (230,239) and impressively by the report of anterior commissurotomy carried out by Shafik (326). Although a-adrenergic agonist mechanisms may potentially affect voiding in a variety of ways that may complement the effects of BPH (198), these secondary phenomena seem unlikely to play a direct role in the primary BPH-mediated effects on voiding.

BPH-mediated bladder outlet obstruction results in a series of changes in bladder tissue mass, composition, and function; it also affects blood supply and nerve status and function. Although not well documented, it seems probable that the functional status of each of these physiologically important components of the bladder moderates its response to outlet obstruction. Nevertheless, the degree and persistence of the obstruction is thought to play a pivotal role in the resulting anatomic and functional bladder effects. The sequence of obstruction-induced pathophysiologic changes is variable, multifocal, and incompletely characterized (206,229). In humans, outlet obstruction can be the primary cause of physiologic changes varying from hyperfunction and hyperirritability to nonfunction or atony. Evaluation of this spectrum of functional states is difficult and confusing. Consequently, evidence of bladder changes associated with well-characterized bladder outflow obstruction is derived largely from observations in animals; the resulting observations probably are but may not be transferable to humans. In general, partial bladder obstruction results initially in a detrusor muscle hypertrophy and increased bladder weight that are reversible (206,229). Typically, increased muscle mass is associated with increased intravesical pressure on voiding (54). Studies in obstructed pigs demonstrate a decrease in functional bladder capacity, increased residual urine, detrusor instability associated with incontinence, and a prolonged period of hypoperfusion and associated tissue hypoxia (206), a sequence of physiologic changes that seem probable in humans. The human and the pig usually develop a thickened trabeculated bladder in response to outflow obstruction. However, the likelihood that a stable, balanced outlet obstruction or detrusor functional status and response state will be maintained if achieved seems problematic. Chronic retention of urine can lead to a thin-walled, flaccid bladder in the bladder outlet obstructed pig just as it does in some humans. In addition to impaired emptying, persistent obstruction is associated with increased collagen deposition and decreased compliance in humans (229). Rabbits with bladder outlet obstruction (229) develop a change in detrusor muscle myosin phenotype suggesting a trend to a dedifferentiated phenotype.

The varying mixes of anatomic and physiologic alterations described in response to obstruction probably play a major role in the specific bladder and renal changes that occur in individual patients. Currently, loss of bladder compliance is probably the major factor in producing upper urinary tract functional and anatomic damage. The etiology of the involuntary obstruction-related bladder contractions (319) remains problematic, but *in vitro* studies with isolated detrusor muscle from the obstructed pig bladder suggest that they have a myogenic, not neurogenic, basis (206). Fortunately, these involuntary contractions are reversible in clinical practice and animal models with relief of obstruction. Cellules, saccules, and diverticula are recognized and related anatomic bladder changes with potential clinical significance that develop and progress unpredictably. Based on their extensive experience with the pathophysiology of bladder obstruction induced bladder changes, Levin and colleagues (206) suggest that bladder outlet obstruction should be relieved as soon as possible after diagnosis to maximize the chance for bladder recovery.

Clinical Evaluation

Clinical evaluation to assess the presence and degree of voiding dysfunction or the role of BPH in its presence has an increasingly broad spectrum of potential goals. These include providing information for a range of epidemiologic studies, selecting patients for drug or interventional studies, and providing information and advice to individual patients. The specific goal often plays a significant role in the character and extent of a patient's evaluation. The discussion of clinical evaluation that follows focuses on the management of the individual patient.

The goals of the clinical evaluation of the individual with voiding dysfunction caused by BPH are to identify the patient's voiding or, more appropriately, urinary tract problems, both symptomatic and physiologic; to establish the etiologic role of BPH in these problems; to evaluate the necessity for and probability of success and risks of various therapeutic approaches to these problems; and to present the results of these assessments to the patient so he can make an informed decision about management recommendations and available alternatives. The clinical evaluation centers on an evaluation of symptoms, physical findings, and results of laboratory and selected imaging and endoscopic studies.

Symptoms

Most patients with medical problems caused by BPH have symptoms of dysfunctional voiding. This symptom complex is nonspecific and is identified by many eponyms, including the currently favored nonspecific term *lower urinary tract symptoms* (LUTS) and the traditional term *prostatism,* implying an established etiologic relationship. We prefer the term *BPH voiding dysfunction* once the etiologic relationship with the prostate warrants serious consideration. As emphasized by Blaivis (31), the clinically recognizable bladder response to various stresses or pathologic changes can be the result of overactive (frequency, nocturia, urgency, urge incontinence) or underactive (hesitancy, intermittency, weak stream, urinary retention) detrusor activity. Blaivis (31) states that BPH symptoms are essentially caused by prostatic obstruction-induced impaired detrusor contractility, detrusor instability, or sensory urgency. They have multiple potential causes varying from those primarily associated with the lower urinary tract to systemic diseases (Table 32.3). The symptoms can be associated with primary diseases of the bladder, neurogenic and metabolic disorders, a variety of diseases of the cardiovascular renal system, use of pharmacologic agents (including antihistamines and antidepressants), markedly increased or abnormal fluid intake, and apparently also normal aging. A small group of patients with “silent prostatism” have severe physiologic sequelae of BPH-induced bladder neck obstruction such as bladder atony or renal failure with minimal or no voiding problems.

Other causes of bladder outlet obstruction
Vesical neck obstruction
Prostatic cancer
Adenocarcinoma
Squamous cell carcinoma
Sarcoma
Other rare tumors
Müllerian duct cysts
Urethral obstruction
Stricture
Valves
Impaired detrusor contractility
Neurogenic origin
Myogenic origin
Psychogenic origin
Detrusor instability/hyperreflexia
Inflammatory and infectious conditions
Cystitis
Bacterial cystitis
Abacterial cystitis
Interstitial/tuberculosis/radiation
Carcinoma in situ bladder
"Prostatitis syndromes"
Acute bacterial prostatitis
Chronic bacterial prostatitis
Chronic abacterial prostatitis
Fungal prostatitis
Miscellaneous prostatitis

TABLE 32.3. DIFFERENTIAL DIAGNOSIS OF BENIGN PROSTATIC HYPERTROPHY

Separation of lower urinary tract symptoms into those related to voiding (delivery) and storage seems reasonable (172). Voiding symptoms include the following: hesitancy, a delay in initiating micturition; intermittency, an involuntary interruption of voiding; weak urinary stream; straining to void; sensation of incomplete emptying; and terminal dribbling. Of these symptoms, the prevalence of a weak urinary stream correlated with increasing age. The storage symptoms include the following: frequency, normal (longer than 3 hours) and abnormal (less than 2 hours); nocturia, awakening to void; urgency, an increasingly strong desire to void; incontinence (urge, stress, overflow, anatomic); and bladder pain (pain in pelvis without voiding) or dysuria (pain and discomfort with voiding). Of these storage symptoms, nocturia, urgency, urgency incontinence, and frequency correlated with increasing age. Jepsen and Bruskewitz's review (172) of prevalence of bother from lower urinary tract symptoms indicated that nocturia was the most bothersome and urgency the second most bothersome urinary symptom, confirming a long-standing urologic dictum. Frequency was judged to have an intermediate bother level. This assessment of symptom bother probably provides a rationale for a difference in symptomatology between patients seeking medical care and those discovered by screening or recruitment. In either circumstance, using knowledge of the patient's perceived or elicited problems to direct thoughtful initial inquiry into the character and circumstances of voiding dysfunction is essential. Selectively supplementing this information with a voiding diary and knowledge of habits regarding food and fluid intake, sleep patterns, medication history, and so on can be invaluable in directing appropriate diagnostic and therapeutic approaches in patients in whom BPH-induced voiding dysfunction is suspected.

Patients with BPH-induced bladder outlet obstruction may have complications of this problem, including acute urinary retention, manifestations of chronic urinary retention such as overflow incontinence or renal failure, or urinary tract infection. Acute urinary retention is signaled by the sudden onset of a persistent ineffectual urge to void and severe unremitting bladder pain. Retention may be precipitated early in the course of BPH voiding dysfunction by ingestion of decongestants containing an a-adrenergic agonist, antihistamines, or a variety of medications with parasympatholytic properties, including disopyramide (Norpace), tricyclic antidepressants, and numerous tranquilizers (380). Its occurrence postoperatively is well recognized. A retention episode may also be precipitated by a forced and prolonged delay in voiding, by a precipitous increase in urinary output caused by ingestion of ethanol or diuretics, and possibly by chilling.

Persistent or chronic urinary retention may manifest its presence by producing overflow incontinence or renal failure. Patients with a decompensated bladder caused by BPH-induced bladder neck obstruction may have problems of constant dribbling (overflow) incontinence accompanied by evidence of a persistently distended urinary bladder. Similarly, laboratory or clinical manifestations of renal failure may be the initial evidence of a significant upper tract effect of lower urinary tract obstruction. Both constant dribbling incontinence and renal failure have several potential etiologies. However, the possibility of lower urinary tract obstruction as the cause is easily evaluated and warrants consideration even in the absence of preceding or concurrent typical symptoms.

BPH bladder outlet obstruction–induced urinary stasis and accompanying bladder stones or diverticula may predispose to development of urinary tract infection. The predominance of symptoms such as dysuria, stranguria, urgency, and other irritative voiding symptoms often delays consideration of the role of BPH-induced abnormalities in development of the infection. Again, awareness of this possibility and of other diseases that produce similar symptom complexes is essential to minimize clinical diagnostic errors (Table 32.3).

BPH is the most common cause of gross hematuria in men older than 60 years of age. Usually, hematuria from BPH is “initial” or “terminal,” but it can manifest as a significant bleeding problem requiring catheter placement or other acute intervention. Carcinoma of the prostate rarely manifests in this manner.

Symptom Indexes

The construction and use of symptom indexes to evaluate patients with bladder outlet obstruction caused by BPH has escalated. An increasingly scientific approach to target and evaluate appropriate symptoms resulted in the American Urological Association (AUA) symptom index in 1992. Development of this index was preceded by the Boyarsky symptom index, the Madsen-Iversen index, and the Maine Medical Assessment index; an International Prostate Score questionnaire and other assessment tools have been developed essentially concomitantly with the AUA symptom index. The indexes target questions that reflect changes in symptoms; they are not meant to be used as diagnostic screening instruments for BPH or bladder outlet obstruction. Several studies failed to document strong correlations between the AUA symptom index and anatomic and physiologic measurement of BPH effects (18,19,274). Despite the shortcomings indicated, the symptom indexes are recommended and used to compare results of research protocols and are recommended for the initial patient evaluation in an office setting (274) by U.S. and international guidelines. They are also used routinely in drug and interventional protocol studies. Many, including ourselves, have found the AUA symptom indexes to have a limited role in daily practice (173). One of us (KTM) uses them to confirm components of the history and quantify changes in response to treatment.

Physical Examination

The physical examination should be systematic and meticulous; it should be appropriately expanded based on history or observed physical abnormalities. The patient's general appearance and specific externally apparent abnormalities should be noted. The abdomen and genitalia should be examined by inspection, palpation, and appropriate percussion to identify any organomegaly, asymmetry, tenderness, or mass. Ordinarily, the bladder must contain at least 150 mL fluid to allow its detection by percussion; a residual urine in excess of 500 mL will usually produce a visibly distended bladder (44). Eliciting a sense of urgency by suprapubic pressure tends to confirm the nature of the identified mass. Ultrasound provides a noninvasive procedure to clarify the nature of a lower abdominal mass. Visual evidence of marked urethral meatal stenosis or recognition of a urethral or paraurethral mass on palpation may guide further appropriate evaluation.

A properly performed rectal examination provides essential information in evaluating patients with voiding dysfunction. In the male, the genitourinary aspects of the examination are usually enhanced by examining the supported, bent-over patient from behind. After inspecting the anal area, the rectal sphincter tone, noted on inserting the examining finger, provides evidence of the functional status of the somatic, sensory, and motor components of the sacral reflex arc and indirect evidence of parasympathetic input to the lower urinary tract (253). A thorough examination of the rectum, including the sacral hollow, may identify unsuspected rectal pathology. During examination of the prostate, its size, consistency, and the integrity of its landmarks (median furrow, lateral sulci) should be noted and recorded.

Enlargement of the prostate may be manifested by increases in its normal width (4.4 cm), length (3.4 cm), or thickness. A universally accepted nomenclature describing prostatic size is not available. Perhaps an estimation of dimensions (width, length, vertical prominence) in centimeters constitutes the most reproducible form of assessment. A conventional paradigm for assessing prostatic size involves a grading scale ranging from normal through 4+. A normal gland (approximately 20 g) is about the size of a chestnut and is minimally perceptible on rectal examination. A 1+ enlarged prostate (about 25 g) is about the size of a plum and occupies a bit less than one-fourth of the rectal lumen. A 2+ enlarged gland (about 50 g) is about the size of a lemon and fills somewhat less than half of the rectal lumen. A 3+ enlarged prostate (about 75 g) attains the size of an orange and fills approximately three-fourths of the rectal diameter. A 4+ gland (100 g) may attain the size of a small grapefruit and fill so much of the rectal lumen that adequate examination is difficult. Digital assessment risks failing to recognize the presence or size of an enlarged prostate. On the other hand, a positive recognition of prostate enlargement is almost always confirmed. The consistency and symmetry of the prostate and presence, character, and location of nodules and induration (slight, moderate, stony), particularly with regard to distorting or compromising the median furrow and lateral sulci, should be noted. Crepitation should be recorded, if present. Palpable identification of the normally nonpalpable seminal vesicles or bladder base requires identification of a cause. After anatomic assessment of the prostate, massage should be performed unless acute prostatitis is suspected. Gentle rolling pressure with the examining finger from a lateral to a medial direction, progressing from the prostate base to the apex on each side, followed by stripping of the urethra distally usually produces fluid at the urethral meatus. The fluid should be retrieved on a slide and examined microscopically. Cultures of the expressed fluid directly or in a small volume of voided urine should be considered.

Laboratory Evaluation

Additional tests may aid in formulating the final clinical impression and treatment plan. These include blood and urine analyses, urodynamic evaluation, selected radiologic and ultrasound imaging studies, and cystourethroscopy. Their complexity, risk, and cost affect their selective employment. The urine should be tested for glucose, protein, occult blood, and pH with a multiparameter dipstick, ideally complemented by gross inspection and microscopic analysis of an initial (10 to 30 mL) and midstream sample of a freshly voided urine specimen. Urine culture, localization studies, and urinary cytology warrant selective considerations.

Blood studies may be desirable at the initial evaluation. A complete blood count (CBC), including differential count and gross assessment of platelet number, and a multiparameter chemical profile, including the guideline-recommended serum creatinine, warrant consideration. A careful history and physical examination will usually identify patients at risk for bleeding tendencies. In fact, the best screening test for disorders of hemostasis in surgical patients is a carefully acquired history soliciting examples of bleeding tendencies in the patient and in close relatives (64). In the absence of clinical evidence of a hemostatic disorder, there is only a 0.008% probability that a given patient will have non–drug-induced intraoperative clotting disorders (82,346). Obviously, all surgical candidates should be questioned regarding their use of aspirin, nonsteroidal antiinflammatory drugs, and other agents capable of altering normal hemostasis. The determination of the absolute platelet count, bleeding time, and partial thromboplastin time (PTT) constitutes a reasonable screening procedure to verify clinical suspicions (45). Although controversial

(302), the serum PSA level is commonly determined in men in the BPH age group, preferably before the rectal examination.

A urodynamic evaluation tailored to provide critical diagnostic information with the least risk, discomfort, and cost deserves consideration. Residual urine and urine flow rates can be determined noninvasively. An ultrasound assessment of postvoid residual urine in a patient who has been instructed to empty his bladder is the most common urodynamic study performed in our group; the patient is then asked to void again and the void volume also recorded. The postvoid residual has traditionally been used to assess bladder function, to guide diagnostic inquiry, and to evaluate efficacy of treatment efforts. Recently, these roles, particularly with regard to the evaluation of treatment efficacy, have been challenged because of numerically variable residual urine determinations, a feature shared with most urodynamic and other complex physiologic indicators. This failure to determine residual urine volume and use this information with judgment is a questionable practice, especially with the availability of ultrasound to measure volume. The Olmsted County study clearly demonstrates that most men in all age groups empty their bladder with less than 12 mL of residual urine. Approximately 20% of men in each decade from 40 to 80 had residuals of greater than 50 mL. Presence of BPH was disproportionally represented in this group. Men with a postvoid residual greater than 50 mL had a threefold increased risk of developing acute retention (188). These considerations, along with the evidence suggesting that residual urine volume measurements are at least as reproducible as other urodynamic determinations (302), deserve increased emphasis in evaluating the potential clinical roles of residual urine determinations. Maximum flow rate, flow pattern, and volume voided provide important information (see Chapter 26B). Voided volumes less than 150 mL or more than 500 mL provide suspect information. Review of the available literature indicated that prevalence of urine volumes greater than 200 mL varied with age (4). Data regarding flow rate determination indicate the following (302):

1. A significant variability (most, 1 standard deviation; half, 2 standard deviations) in repetitiously performed individual flow rates
2. A definite tendency toward substantially increased flow rate with sequential determinations
3. An appreciable decrease in maximum flow rate with age with 69% of 75- to 79-year-old men in the Olmsted County study below 15 mL per second and 35% below 10 mL per second

The evidence supporting the use of a peak flow rate of less than 15 mL per second to select patients for therapeutic trials of presumed BPH voiding dysfunction seems challengeable, as does the presumed advantage of flow rate over residual urine measurements. Simultaneous pressure-flow studies appropriately supplemented by video assessments provide the maximum opportunity to differentiate detrusor and outlet effects and have largely replaced the use of the cytometrogram. Data from initial and particularly repetitious urodynamic studies can provide very useful diagnostic and therapeutic insights.

In the past, evaluation of the upper urinary tract by radiologic or ultrasound imaging was commonplace in patients with bladder neck obstruction. Now these assessments are done selectively in patients with a history, physical findings, or laboratory studies that suggest a significant possibility of an important independent or secondary urinary tract abnormality accompanying the bladder outlet obstruction.

Cystourethroscopy to confirm the presence and effect of bladder neck obstruction from BPH is commonly done with local anesthesia in an outpatient setting. The presence, configuration, and site of obstructive tissue can usually be identified, but not its physiologic effect. The latter can be assessed to some degree by determination of residual urine and recognition of the presence and degree of trabeculation (Fig. 32.26) and bladder pathology such as diverticula and stones. Prostate size can be estimated crudely from the increase in length of the prostatic urethra, the degree and length of the adenomatous occlusion, posterolateral and anterior clefting present, and the thickness of the prostate when palpated rectally with the cystoscope in place.

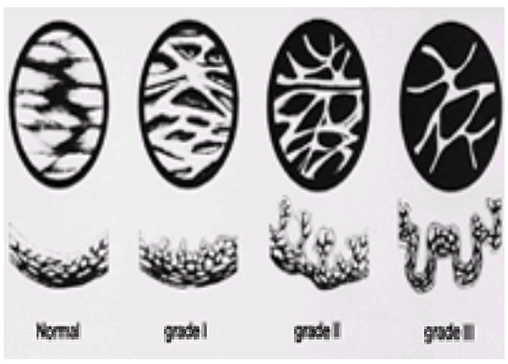

FIGURE 32.26. Grading of bladder wall trabeculation. Tight, compact detrusor muscle bundles ultimately show evidence of hypertrophy and splaying of fibers (grade 1) with the gradual demonstration of multifocal cellules (grade 2) to small diverticula (grade 3). These changes appear to correlate with elevation of opening urethral pressure (degree of obstruction), as well as associated detrusor reflex instability. (From Andersen JT, Nordling J. Relation of prostatic lobes to degree and rate of obstruction. In: Hinman F Jr, ed. *Benign prostatic hypertrophy.* New York: Springer-Verlag, 1983, with permission.)

Rectal or abdominal ultrasound may be used to assess prostatic size and weight with accuracy to within 5%. An assessment of residual urine and possibly the thickness and configuration of the bladder wall may provide some supportive evidence for bladder neck obstruction (5,336). Computed tomography and magnetic resonance imaging studies can provide information with regard to prostatic size, but, again, not its physiologic significance; they are rarely indicated to assess BPH and its associated voiding dysfunction.

Cystography and retrograde and voiding urethrography can at times provide invaluable information with regard to the diagnosis and evaluation of bladder or urethral diverticula. These studies warrant consideration in patients with clinical evidence of bladder neck obstruction who have an unusual course or unexplained findings.

Natural History of Benign Prostatic Hyperplasia Voiding Dysfunction

Data regarding clinically important aspects of the natural history of BPH center on the age-related development and course of anatomic changes in the prostate, BPH-induced dysfunctional voiding symptoms, and pathophysiologic functional changes in the bladder or upper urinary tract. The previously presented information regarding age-associated prevalence of histologic and anatomic BPH has been generated from autopsy observations and rectal or ultrasound evaluation of the prostate in clinical studies. The prevalence of histologic BPH increases progressively from the fourth (8%) through the eighth (82%) decade (27). The prevalence of gross, potentially clinically significant lesions shares this association with increasing age. For example, an autopsy study disclosed a prevalence of histologically confirmed BPH in prostates with gross enlargement of 14%, 37%, and 39%, respectively, in men 50 to 59, 60 to 69, and older than 70 (300); this prevalence paralleled that of a palpably enlarged prostate found on rectal examination of 6,975 men evaluated for life insurance (217). Limited reported data correlating autopsy prostate weight and histology revealed prostate weights exceeding the 18-g mean normal weight by 50% or more in 61% of 69- to 70-year-olds compared with 18% of 51- to 60-year-olds (127).

The cumulative prevalence of a history and physical examination–based diagnosis of “prostatism” or BPH voiding dysfunction increased progressively from 26% to 79% from the fifth to eighth decade of life in the Baltimore longitudinal study of 1,057 men (Fig. 32.27) (140) and was recorded in 78% of the 2,049 healthy volunteers by age 80 in the Veterans Administration (VA) normative aging study (119). Prevalence as contrasted to cumulative prevalence of symptoms of prostatism was recognized in 26%, 33%, 41%, and 46% of 2,110 men ages 40 to 49, 50 to 59, 60 to 69, and over 70, respectively, in Olmsted County, Minnesota (53). Reports based on a Scottish community study yielded lower prevalence rates than the U.S. studies, and reports on a Japanese cancer screening program yielded higher prevalence rates than the U.S. studies. Interestingly, some symptoms, such as nocturia, weak stream, intermittency, urgency, and incomplete emptying, appear to increase with age, whereas others, such as frequent urination, dribbling, hesitancy, straining, and repeat urination within 10 minutes, did not. An unequivocal role for BPH in the symptom data cited should be viewed with some reservation because although symptom scores and some symptoms showed an increasing prevalence with aging, individual subjects showed a disturbing tendency to have variably present and absent symptoms (10), and several studies have documented a comparable prevalence of similar symptoms in aging women (46,127).

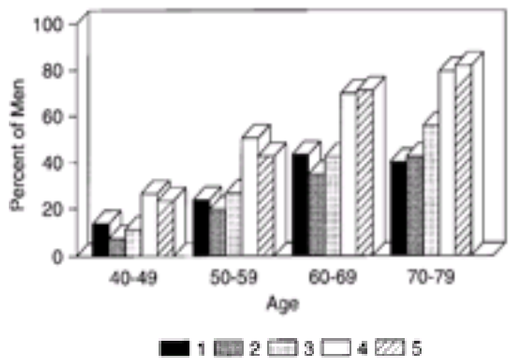

FIGURE 32.27. Age-specified prevalence of benign prostatic hyperplasia. *1,* Community prevalence in Bridge of Allan, Scotland, based on a case definition using symptoms, prostate size, and urinary flow rates (*n* = 699) (108a); *2,* clinical prevalence based on an enlarged prostate on manual rectal examination from a compilation of life insurance examinations (*n* = 6,975) (217); *3, 4,* clinical prevalence in the Baltimore longitudinal study of aging (BLSA) (*n* = 1,057) (140) (*3,* based on presence of an enlarged prostate on manual rectal examination; *4,* based on history and physical examination); *5,* prevalence of pathologically defined BPH from a compilation of five autopsy studies (*n* = 1,075) (27). (From Guess HM. Natural history of benign prostatic hyperplasia. In: Romas NA, Vaughn ED, eds. *Alternate methods in the treatment of benign prostatic hyperplasia.* Berlin: Springer-Verlag, 1993, with permission.)

As indicated, the reported presence of a symptom in a given patient varies appreciably in longitudinal studies without treatment. Of men reporting hesitancy on the initial visit in the Baltimore longitudinal aging study, 27% failed to do so on the second visit and an additional 19% on the third visit (10). Barry (18), Barry and colleagues (19), and Guess (139) summarized consistency of observations from five reports of patients evaluated longitudinally for approximately 3 to 5 years with BPH voiding dysfunction. Symptomatically improved or stable individuals were noted in every study and constituted roughly one-half to two-thirds of the patients who were not operated. The prominence of this improved-stable group is probably inflated by patients with progressive symptoms electing surgery. Nevertheless, the phenomenon of apparently unexplained improved voiding based on symptom and frequently urodynamic assessment is observed repetitiously in the placebo group of short- and longer-term drug studies. Global improvement was reported in 51% and the maximum flow rate increased more than 3 mm per second in 17.7% in the placebo group of the finasteride study (121). The BPH guideline review recorded global symptomatic improvement in 40% of placebo and watchful waiting groups. Multiple factors varying from an inaccurate presumptive diagnosis to behavioral modification may play a role in this phenomenon; they must be identified and evaluated.

Prevalence data on urodynamic assessment of unselected individuals in a community setting is limited but informative. The Olmsted County survey demonstrated a progressive decrease with age of peak median urinary flow from 20 mL per second in 40- to 44-year-olds to 11.5 mL per second in 75- to 79-year-olds and an accompanying decrease of median voided volume from 355 to 222 mL. The prevalence of peak flow rates less than 15 mL per second increased from 24% to 69% in these age groups (118). Although somewhat more supportive of progressive obstruction and possible bladder decompensation, urodynamic data, including peak flow rates, voiding pressure, and residual urine, have variously been observed to become worse, become better, and remain the same (17,29). In addition, despite the age-related association of anatomic BPH and abnormal physiologic voiding parameters, the absence of a correlation in individual men between clinical and urodynamic evaluations (18,19) and limited observations of significant urodynamic evidence of detrusor instability and sensory urgency in older women clouds the interpretation of these findings (47,127).

In considering the natural history of BPH voiding dysfunction, two phenomena—acute urinary retention and development of hydronephrosis or renal failure—deserve special consideration because of the significant clinical impact they have. Although acute urinary retention is the indication for prostatectomy in approximately 25% to 30% of the operated patients, the risk of having acute retention was highly variable in longitudinal studies. Barry (18) and Barry and colleagues (19) projected 10-year rates from 4% to 73% (17,29). These differences probably reflect the status of the study population. In the community-based Olmsted County study (168), 57 of the 2,115 patients (1,412 were 59 years of age or younger) studied developed acute urinary retention; half of these episodes were related to surgical procedures. Only eight patients required a transurethral resection of the prostate (TURP) within 6 months of retention; one other patient had two subsequent episodes of retention. Severity of symptoms and increasing age increased risk of urinary retention, as did the presence of a low flow rate (less than 12 mL per second) or an enlarged (greater than 30 mL) prostate. The risk of acute retention was increased in young men with intermittency or the necessity to repeat void in 10 minutes. In older men, the presence of symptoms enhanced the risk of retention. The data generated suggested a 23% probability that a 60-year-old would experience acute urinary retention if he lived 20 years. In the 4-year finasteride (Pless) trial of men with BPH-recognized voiding dysfunction, untreated men had a 7% and finasteride-treated men a 3% chance of developing urinary retention. Surgery was carried out in 72% of placebo as compared with 33% of treated patients and 24% with spontaneous versus 10% with precipitated acute retention (231). These observations contrast with the infrequent (2 of 29 men) resumption of normal voiding by individuals randomly presenting in acute urinary retention with a greater than 900-mL retained urine volume observed by Taube and Gajraj (352); in their report, 15 of 34 men with less than 900 mL residual urine were able to void after catheterization without surgical intervention. Overall, approximately two-thirds of the patients presenting in acute retention failed to void. Additional data characterizing the patient population at high risk for developing acute urinary retention and their response to various treatment alternatives must be generated to guide development of reasonable management proposals for this group.

The risk of hydronephrosis with renal failure or of permanent or prolonged detrusor failure in monitored individuals is not documented. Guess (139) cites data indicating that at prostatectomy 7% of men had an elevated plasma creatinine and 5% had upper tract dilation at inpatient evaluation for prostatism. He pointed out that 17% of the cases evaluated for acute renal failure in the Boston VA Medical Center were due to urinary obstruction, with 65% of these thought to be caused by BPH. Sarmina and Resnick (317) documented previously unrecognized renal failure in 34 (3.7%) of 909 men treated for BPH from 1980 to 1986. They estimated that greater than 5% of men with unrelieved BPH bladder outlet obstruction would have chronic renal insufficiency. Patients at particular risk were those with symptoms of prostatism for more than 1 year, a history of enuresis, renal insufficiency, urinary tract infection, or urinary retention or a palpable bladder. Although they agreed with George and colleagues (110) regarding the increased risk of renal failure in men with high-pressure chronic retention, occurrence of this phenomenon has limited documentation and is unpredictable. Unquestionably, hydronephrosis and potentially, but not invariably, reversible renal failure do occur as the result of BPH (174); at one time, an appreciable cohort of the patients subjected to surgery had one or both of these complications. The discriminatory risk factors for their development remains uncertain, as does the rate at which they occur in monitored patients or in those with current sporadic medical care. The results of the prompt versus watchful waiting/delayed TURP VA study suggested compromised detrusor recovery in the watchful waiting group eventually subjected to surgery, but the role of delaying TURP in development of azotemia in two patients could not be evaluated from the information presented (95).

In the longitudinal observations summarized by Barry (18), Barry and colleagues (19), and Guess (139), the cumulative prevalence of BPH surgery varied from 0% to 45% of the patients during limited follow-up. Surgical procedures were predominantly carried out during the first year after diagnosis in the series with high surgical rates. The risk of surgery by age 80 years was considerably greater (29%) for a man 40 years old in the VA normative aging study, carried out prospectively from 1961 to 1982 (119), than in the New Haven Hospital record study (10%), a retrospective analysis of 1953 to 1961 data (218). In both, the incidence rates for BPH surgery increased through the eighth decade. In the Baltimore longitudinal study of aging (10), a change in size and force of the urinary stream and a sensation of incomplete emptying of the bladder in a patient with digitally detected prostatic enlargement were predictive of future prostatectomy. In the Kaiser Permante medical care program analysis cited by Guess (139), the symptoms predictive of prostatectomy were hesitancy, a weak stream, painful urination, loss of bladder control, and nocturia.

Two other observations are of interest. Despite the lack of correlation between prostate size and outflow obstruction, a correlation seems to exist between election of surgical intervention and prostate size (27). Second, there is suggestive evidence from postmortem anatomic assessments supporting clinical impressions that the prostate of some aging men may undergo regression in size (350).

Indications for Treatment

The following are accepted criteria for interventional relief of bladder neck obstruction caused by BPH.

Acute urinary retention is often indicative of end-stage bladder decompensation requiring operative relief. The patient whose retention is triggered by ingestion of drugs such as a-adrenergic agonists or anticholinergic agents may void satisfactorily once the medication is stopped and the bladder drained for a time. A supervised attempt at decatheterization for minimally symptomatic patients with an incident-related (e.g., postoperative or acute bacterial prostatitis) or spontaneous episode of retention is often reasonable. Use of a-adrenergic antagonists in conjunction with this voiding trial is worthwhile . For repeated episodes of retention, management by

intermittent catheterization or continued catheter drainage is possible but is usually an unacceptable alternative to an operative approach. The patient with urinary retention is usually treated satisfactorily by insertion of a urethral catheter. For difficult catheterizations, a percutaneous suprapubic cystotomy tube remains an appropriate alternative that is usually well tolerated and associated with few catheter-related complications. If chronic retention is suspected, the bladder should be emptied gradually to avoid diffuse mucosal cracking and bleeding that may follow rapid decompression. Use of a variety of internalized catheters is currently being evaluated in selected patients at high risk.

Bilateral hydronephrosis with renal functional impairment requires relief of the obstruction to preserve the integrity of the upper tracts. On catheter insertion, a postobstructive diuresis may ensue, requiring meticulous fluid and electrolyte management. The patient's general condition should be optimized before operative intervention is undertaken.

The presence of multiple bladder stones, prominent narrow-necked bladder diverticula, overflow incontinence, and other signs of end-stage bladder decompensation are indications for therapeutic intervention. Recurrent or chronic urinary tract infections caused by an elevated residual urine are also an indication for considering intervention. Acute or chronic bacterial prostatitis should be excluded as a possible source of infection. A careful history, physical examination, and lower tract localization cultures should help clarify this issue.

Gross hematuria is an infrequent but legitimate indication for so-called prostatectomy, particularly when the episodes are multiple and associated with clot retention or significant blood loss. The usual limited initial hematuria associated with BPH is commonly best managed conservatively. Antiandrogen measures such as the use of finasteride almost always have a favorable impact on recurrent prostatic bleeding (96).

Obstructive and irritative symptoms that significantly interfere with the quality of life of the patient are common indications to consider prostatic surgery and other therapeutic approaches. The cause of the symptoms should be established with a very high degree of probability. In the past, most patients have had multiple indications to support the decision to initiate therapy (239). Both the urologic surgeon and the patient must be clearly aware of the results that can be expected and the risks involved in achieving them.

THERAPEUTIC OPTIONS

The options available to patients with BPH have expanded rapidly in the last two decades. In addition to monitored observation, various forms of intervention directed at modifying the physiologic effects of BPH with or without directly altering the prostatic mass or its configuration are being used with varying effectiveness and risk. The following is a brief discussion of indications, techniques, and results of observation, catheterization, and selected medical, tissue-destructive, and excisional approaches currently used to treat patients with BPH voiding dysfunction.

Observation

Patients may see their physician for evaluation of the prostate for a variety of reasons, including voiding symptoms of variable severity and physician-observed prostate-related (or presumed prostate-related) abnormalities. Their evaluation usually includes a history, with particular emphasis on voiding status and degree of bothersomeness; physical examination, including abdominal, genital, and rectal examinations; and indicated laboratory studies, such as urinalysis and serum total or fractionated PSA and creatinine. Determination of postvoid residual urine and urinary flow rate, pressure-flow studies, and urodynamic and endoscopic evaluations are done selectively. The resulting patient cohort may include individuals with recognized significant secondary bladder or renal changes from BPH. In some instances, these changes will be present in patients with minimal symptoms, so-called silent prostatism (incidence less than 5%) (367). Most prostate problem patients have definite but limited complaints or objective findings and only marginal indication for therapy. Guidelines to help triage these patients to immediate treatment or periodic observation are not well established. The number of patients with prostate-related renal functional impairment, secondary stone disease, infection, or markedly decompensated bladder requiring effective, prompt intervention is limited. Physician surveillance at regular intervals varying from 3 to 18 months in our practice is an appropriate recommendation. These episodic assessments include a review of genitourinary symptoms but focus on the patient's major complaints. A symptom score is calculated only as an ancillary aid in assessing the patient's symptom, never as a diagnostic aid or as a substitute for a detailed history. The abdominal, genital, and rectal examinations are supplemented by an office urinalysis, a yearly serum PSA, and other selected laboratory studies. Cystoscopy is used selectively and urodynamic evaluation infrequently to confirm the diagnosis of BPH voiding dysfunction and to guide appropriate management. Indications for urodynamic evaluation typically include concurrent assessment for neurologic or medical diseases that can mimic the voiding complaints associated with BPH. The trigger to consider medical or surgical treatment must be individualized for patients, taking into account the entire spectrum of the patient's complaints, degree of bother, and results of the objective findings.

The urologic fate of individuals selected for observation is unpredictable. The patient's genitourinary organ and symptom status, general health, and life expectancy play a significant role in his desire and need for various types of intervention. In addition, spontaneous improvement in flow rates and symptoms is common in studies with short run-in control periods. This has led to the one-third improved, one-third stable, one-third worsened paradigm for patients selected for watchful waiting or control populations in studies of limited duration. The improved group probably reflects behavioral modification rather than organic change in the prostate bladder relationship. The data from the Olmsted County observation study (168) and the control groups in the long-term finasteride (231) and VA observation/TURP studies (95) seem to indicate that patients with moderate to severe symptoms (i.e., AUA symptom score greater than 7), low peak urinary flow rates (less than 12 mL per second), increasing size of an enlarged prostate, and older age (older than 70) have increased risk of acute urinary retention and requirements for surgical or pharmacologic treatment. Consequently, monitoring changes in prostate size and objective measures of voiding such as residual urine and flow rate probably provides very useful objective information to guide treatment recommendation. Prolonged observation of a functionally deteriorating lower urinary tract has traditionally been thought to jeopardize functional recovery; the observations in the control group of the TURP VA study tend to support this concept (95).

Although some effects of BPH voiding dysfunction such as renal failure or acute urinary retention clearly require intervention, the decision to treat patients with BPH voiding dysfunction is usually optional. The treatment selected may target the secondary changes resulting from BPH or attempt to reduce or eliminate the BPH mass or its functional effects. The approaches used include catheterization, pharmacologic approaches, and mass reduction or elimination efforts by excision, tissue destruction, or physiologic alterations (Table 32.4).

Mass Reduction	Physiologic/Physical Manipulation
Hormonal	Transurethral incision
5α-Reductase inhibition	α-Adrenergic blocker
LH-RH antagonists	
Excision	Drainage Maneuvers
TURP	Catheters
Open prostatectomy	Transurethral
Laser prostatectomy	Suprapubic
Tissue destruction—*in situ*	Stents
Transurethral microwave thermotherapy	Clean intermittent catheterization
Interstitial laser coagulation	
Transurethral needle ablation	

LH-RH, luteinizing hormone–releasing hormone; TURP, transurethral resection of the prostate.

TABLE 32.4. CATEGORIES OF BENIGN PROSTATIC HYPERPLASIA TREATMENT

Catheter Drainage

Transurethrally or suprapubically inserted catheters of various materials and configurations have been used acutely, intermittently, or as permanent indwelling conduits to treat the acute and chronic effects of BPH for centuries. Clean intermittent catheterization is discussed in Chapter 26B. Indwelling catheters are subject to displacement and occlusive encrustation; they require periodic planned or incident-provoked replacement. Acute and chronic urinary tract infections complicate their long-term use. In the past two decades, internalized catheters, or urethral stents variously designed from a range of inert materials, have been used in select patients with obstructing BPH and urethral stricture. A prominent middle lobe or median bar is commonly cited as a contraindication to stent placement. Use of titanium (Titan), corrosion-resistant metal alloys (UroLume stent) (138), and more recently, a nickel-titanium thermosensitive alloy, nitinol (Memotherm stent) (113), has improved

physical and biologic characteristics of the available stents. Recognition that stents should appropriately extend from just at or distal to the bladder neck to just proximal to the verumontanum or urethral sphincter has facilitated selection of stent length; direct-vision placement under general, spinal, or local anesthesia using the ventral bladder neck as a guide to location has increased achievement of appropriate positioning. Stent design and anchoring mechanisms vary. The nitinol stent expands at body temperature to a maximum diameter of 42 Fr. Metal stents are essentially incorporated in the superficial urethral tissue, permitting catheterization and endoscopic procedures. Proliferative ingrowth of transitional epithelium is a troublesome complication in patients with BPH; it requires treatment such as transurethral resection or fulguration. Stent migration affects voiding and the development of complications.

The reported experiences indicate that almost all patients are able to void promptly or within a few days of stent placement. The latter usually are managed temporarily with a suprapubic catheter. Patients commonly experience frequency, urgency, dysuria, or perineal pain for a few weeks to months after stent placement. Persistent symptoms may respond to anticholinergic medications or infrequently require stent removal. Most patients demonstrate a significant increase in urine flow rate and decrease in residual urine. However, improper stent placement is often responsible for poor functional results and complications. Urinary tract infections complicating stent placement respond to appropriate antibiotic treatment. Removal of stents is challenging. Milroy and Chapple (244) advocate placing a guidewire through the retrogradely displaced UroLume stent to aid its entrapment in a resectoscope sheet and to facilitate removal. The knitted single-wire construction of the Memotherm stent permits its simple removal by unraveling it by traction on the wire (113). This procedure traumatizes the covering urothelium, however. The majority of reported observations of patients treated with stents are 1 year or less in duration, but there are limited numbers of patients with stents who have been observed for 2 to over 4 years.

Consideration of the use of internalized stents rarely has a high priority in many groups, including ours. The options to achieve mass reduction or physiologic alterations (Table 32.4) that facilitate improved voiding have expanded and can be accomplished with anesthetic and technical risks that are comparable to or less than those related to stent placement, maintenance, and removal.

MEDICAL THERAPY

Use of pharmacologically defined and a variety of so-called alternative medications to attempt to improve BPH voiding dysfunction by reducing BPH mass or producing functional alterations of the voiding mechanism is expanding rapidly. Pharmacologic efforts to reduce prostate mass essentially target known androgen-mediated prostate growth induction or maintenance phenomena. Those aimed to produce physiologic alterations essentially target the a $_1$-adrenergic agonist modifiable smooth muscle contraction of prostate stroma, bladder, and components of the central nervous system (CNS) affecting voiding symptoms.

Endocrine Approaches

Endocrine-based approaches to management of BPH have focused on disrupting hormone-mediated growth mechanisms characterized in the normal prostate and persisting in BPH. Consequently, most center on attempting to eliminate testis hormone production directly or indirectly (e.g., castration, pituitary hormone inhibition), altering intraprostatic androgen metabolism (e.g., 5a-reductase inhibition), interfering with intracellular transcription of androgen-stimulated events (e.g., receptor blockade), or a combination of these mechanisms. Castration and luteinizing hormone–releasing hormone (LH-RH) agonist administration produce marked regression of the epithelial component of BPH in humans (163,320,381). However, these approaches, as well as administration of estrogens (280) or estrogen-androgen combined therapy (181), have yielded equivocal or limited clinical improvement. LH-RH agonist administration produces a 25% to 30% decrease in prostate volume; a 90% and 75% reduction in prostate tissue DHT and T concentration, respectively; and decreased prostate 5a-reductase activity and androgen receptor levels. With cessation of therapy, prostatic size returns to pretreatment levels (228,285). Flutamide, a nonsteroidal androgen receptor competitor, and cyproterone acetate (323), an inhibitor of gonadotropin release and receptor competitor, have been reported to increase flow rate or to decrease prostate size 23% to 30% (228) in patients with BPH. Other progestational agents, including medrogestone, 17a-hydroxy progesterone, chlormadinone acetate, and gestonorone caproate, have been used in clinical trials without consistent effects on voiding patterns in patients with BPH voiding dysfunction (109,293). LH-RH antagonists induce a substantial and rapid (less than 12 hours) decrease in serum testosterone and DHT. Preliminary evidence suggests increased flow rates and reduction in symptom score comparable to a-adrenergic agonist therapy (200). The applicability of these agents to BPH management has not moved beyond the preliminary stages. LH-RH therapy is frequently associated with hot flashes and sexual dysfunction (87). Gynecomastia and diarrhea are recognized complications of single-drug flutamide therapy (344).

Evaluation of purposely altered androgen effect on BPH and BPH voiding dysfunction currently centers on the results of finasteride administration. Finasteride inhibition of 5a-reductase type 2 activity results in decreased DHT (5.4 to 0.5 ng/g) and increased T (0.3 to 2.2 ng/g) prostate tissue concentrations (266). The following observations of clinical effect seem reasonable based primarily on the results of the 4-year multicenter study of prostate patients with moderate to severe BPH voiding symptoms and a moderately enlarged prostate.

1. Maximum effect on the prostate is delayed at least 6 to 12 months (121,231).
2. Quasi AUA symptom score improvement in finasteride-treated (F) versus placebo (P) patients is definite but slight (all patients F 2.5 versus P 1.0; completed study patients F 3.3 versus P 1.3) (231).
3. Reduction in prostate volume in men completing the study is limited (18%) but contrasts with an increase of 14% in the placebo group; decreased prostate volume in the finasteride group stabilized at 1 year, whereas the placebo group showed progressively increased volume over 4 years (231).
4. Statistically significant but clinically minimal increased flow rate was seen in finasteride-treated men who completed the study (F 1.9 mL per second versus P 0.2 mL per second) (231).
5. Using intention to treat patients, a quasi bother score (range of 0 to 34) and an approximated activity interference evaluation (range of 0 to 28) of finasteride-treated men demonstrated a statistically significant but clinically limited greater improvement at 4 years in both; bother decreased 3.0 versus 1.2 and activity interference 2.5 versus 1.24 in finasteride compared with placebo patients (39).
6. The study was discontinued by 524 (34%) of finasteride-treated and 633 (42%) of placebo-treated men; most perceived lack of improvement or worsening of BPH voiding dysfunction or desired other medical or surgical treatment. Adverse events accounted for the other (F 11.5%; P 10.9%) withdrawals (231).
7. Acute urinary retention (4% F versus 7% P) and BPH-related surgery (5% F versus 10% P) were reduced in finasteride as compared with placebo patients in the 4-year observation period using an intention-to-treat analysis. In absolute numbers, approximately 100 of 1,384 treated patients avoided these events (231). In this study of symptomatic men with enlarged prostates, patients with larger prostate volume as indicated by PSA measurement seemed to be at greater risk for these events (303).
8. Finasteride has had almost universal success in controlling spontaneous BPH-related urinary bleeding promptly and persistently (96). The prompt control of hematuria contrasts with other therapeutic achievements with this drug. Men with bothersome symptoms and no or little enlargement of the prostate are less likely to show comparable improvement (204). Various aspects of sexual dysfunction and possibly gynecomastia may occur with greater frequency in a limited number of finasteride-treated patients. The effects on libido, erection, and volume of ejaculate are slightly increased with finasteride. Overall, results of these studies should be made available to patients, but definite recommendation for finasteride treatment would seem to depend on the patient's general health, his risk/benefit assessment, and the rapidity at which he expects improvement.

Endocrine therapy for the treatment of BPH voiding dysfunction, regardless of method, is accomplished by reduction of prostate mass. This change in gland volume is limited to components of the prostate that are androgen sensitive. Available data indicate that prostate volume decreases by no more and usually appreciably less than 30% with more meager impact on symptoms. Based on this information, it appears that endocrine therapy has a limited utility in patients with symptoms and signs of bladder neck obstruction (BNO) from BPH. Chronic therapy to prevent disease progression may have a role in some patients but is usually not readily accepted by patients who otherwise feel well.

Adrenergic Antagonists

The most common medical approach to manage effects of BPH voiding dysfunction centers on neuropharmacologic manipulation of the lower urinary tract. Contraction of the autonomically controlled prostate or bladder neck smooth muscle is postulated to be a significant modifiable functional component of BPH-mediated bladder neck obstruction. The predominance of a $_1$-adrenergic receptors in the bladder neck or prostate (40 times the bladder concentration) helped focus interest on a-adrenergic blocking agents in the treatment of symptomatic BPH. Demonstration that administration of phenoxybenzamine, a nonselective a-adrenergic antagonist, reduced symptoms and improved parameters in patients with BPH voiding dysfunction (43,202) reinforced pursuit of this approach. Efforts to maximize desired physiologic activity and reduce undesirable side effects led to the development and use of selective a $_1$-adrenergic antagonists. Of these, drugs that can be given once daily, including terazosin (Hytrin), doxazosin (Cardura), and tamsulosin (Flomax), an a-adrenergic blocker with more selectivity for the prostate-dominant a $_{1A}$- and a$_{1D}$-adrenergic receptors, are the most commonly used a-adrenergic receptor blocking agents. Despite the subtype selectivity of tamsulosin for the a $_{1A}$- and a$_{1D}$- over that of the a$_{1B}$-adrenergic receptor, there is no evidence that this conveys a clinical advantage for the treatment of symptoms (Table 32.5). The a-adrenergic blocking agents share the characteristic of producing their effects on voiding within hours of administration regardless of prostate size without altering serum PSA or volume.

The reported studies of efficacy focus on change in symptom score and peak flow rate. The absolute improvement in maximum flow rate, the clinically important effect, is greater than placebo, yet still relatively small. This increase in maximum flow rate is similar for the various a-adrenergic blockers (Table 32.6). The maximum flow rate achieved is generally between 11 and 13 mL per second; this may represent an achievable maximum for a-adrenergic blocker pharmacotherapy (50,91,304). In most studies, the decrease in total AUA or comparable symptom score (range of 0 to 35) was approximately 3 ± 1, and the increase in peak flow rate was usually 1 to 2 mL per second. Both are statistically but clinically marginally significant. Assessments of severity, bother, problem, and global scores tended to reinforce this range of activity (115,205,258).

Agent	Change in Symptom Score	% Change in Symptom Score
Terazosin	3.3–7.6	33–38
Doxazosin	2.8–5.7	10–40
Tamsulosin	3.3–9.6	35–48

*Symptom relief is measured in different ways in the literature, making global assessments difficult to quantitate and compare. The range of improvement in symptom scores in the various α-adrenergic blockers varies from 2 to 5 points on their respective scales. Use of percentage rather than numerical change in score avoids the problem of different scoring systems and is probably a better indicator of the relative effectiveness of these agents. In this fashion, it becomes clear that lower urinary tract symptoms improve anywhere from 30% to 50%. Placebo effect generally ranges 15 to 20 percentage points behind that of the active drug (50,51,304).

TABLE 32.5. a-ADRENERGIC THERAPY SYMPTOM SCORE CHANGE

α_1-Adrenergic Agent	Improvement in Flow Rate (mL/sec)	% Flow Rate Change
Terazosin	1.7–3.0	21–34
Doxazosin	1.8–3.2	25
Tamsulosin	1.7	18

TABLE 32.6. a-ADRENERGIC THERAPY FLOW RATE CHANGE

Potential cardiovascular and other systemic effects of these drugs may limit their use alone and in particular with other vasoactive agents. Postural hypotension, dizziness, headache, syncope, anesthesia or fatigue, rhinitis, and abnormal ejaculation may complicate a-adrenergic blocker administration. The development of more selectively targeted a-adrenergic blocking agents, coupled with a better understanding of their effects, has been associated with reduced undesirable reactions. Currently available information suggests that tamsulosin may lessen their occurrence selectively and within dose ranges. Patients with complex medical problems often benefit by a coordinated internist-urologist interaction in guiding a-adrenergic blocker therapy.

Indication for use of a-adrenergic blocking agents in patients with BPH voiding dysfunction centers on symptomatic complaints and failure to void satisfactorily. The diagnosis is often not confirmed as objectively as in surgically directed patients. Cystoscopic evaluation of the prostate or the bladder is often omitted despite its use as an exclusionary criterion, and postvoid residual urine is not used regularly to assess therapy. Paradoxically, changes in urinary symptoms and flow rate do not correlate strongly (198,199), leading to questions regarding the role of prostate smooth muscle relaxation in symptom reduction . Effects of a-adrenergic blocking agents on bladder and CNS function could result in the altered voiding patterns observed (198,340). Despite the predominant pharmacologic role of a-adrenergic blocker therapy in treating BPH voiding dysfunction, more than 30% of patients discontinue therapy. This *de facto* dissatisfaction demonstrates the incompleteness of understanding of a-adrenergic blocker effect, as well as an inability to pinpoint the exact cause of BPH voiding dysfunction.

Drug choice depends on primary and secondary (antihypertensive; complications) effects. These drugs are most commonly administered at bedtime to minimize cardiovascular symptoms or hypotension. Terazosin and doxazosin are commonly titrated to establish effective, complication-free dosage levels; most men in the United States receive these drugs at a 5- and 4-mg daily dose, respectively, although limited evidence indicates that double these levels may be optimal. Tamsulosin, commonly given after breakfast, is used at 0.4 mg per day in most men; 0.8 mg daily is slightly more effective but has increased side effects (199). Although many patients have concurrent LUTS and hypertension, treatment for each disease should be optimized individually rather than attempting to treat both simultaneously with a single agent and potentially compromising treatment of both. Most authorities on hypertension suggest that a-adrenergic blockers are a third- or fourth-line drug after (a) angiotensin-converting enzyme inhibitors and (b) calcium channel blockers and diuretics (6,337).

Alternative Therapies

Increasing attention has been paid to plant extracts (or phytotherapy) use by patients to self-treat medical ailments. Use of these products has grown rapidly to an estimated $6 billion yearly expenditure despite the frequent lack of a scrutinized demonstration of efficacy. Saw palmetto, derived from the berry of the American dwarf palm *(Sabal serrulata),* is the most popular of these medications for LUTS. The proposed mechanisms of action for saw palmetto include 5a-reductase inhibition, intraprostatic androgen receptor blockade, and adrenergic receptor antagonism (111). There is little or no evidence that any of these mechanisms play a role in saw palmetto when used clinically. Clinical evidence suggests that this medication does no harm, is associated with few side effects, and has no effect on PSA (211). Placebo-controlled trials and meta-analyses suggest that saw palmetto leads to only minor subjective and objective improvements in men with LUTS (384). Most studies demonstrating any positive effects of saw palmetto suffer from methodologic flaws, small patient numbers, and short treatment intervals. Clearly, large-scale placebo-controlled trials are needed to assess efficacy of these medications. Their U.S. Food and Drug Administration classification as a food additive allows public promotion of these products without regulated manufacture or demonstrated efficacy. Unfortunately, significant questions persist concerning their use.

Summary

Current evidence indicates that medical therapies have variable limited effectiveness in altering the symptomatology and pathophysiologic effects of BPH. Use of drugs with established physiologic effects on the prostate or bladder, alone or combined, warrants consideration in selected patients with acute or chronic voiding problems caused by BPH. The long-term effects of a-adrenergic antagonists and 5a-reductase inhibitors on BPH and its associated voiding dysfunction are not established. The risk that prolonged exposure to therapies with limited effectiveness may permit conversion of a potentially reversible to a permanent voiding dysfunction should not be overlooked. The most cost-inefficient use of health care expenditure is serial treatment with multiple medications followed by surgical or minimally invasive therapies. Prioritizing of these issues for and with patients remains the urologist's challenge and role.

SURGICAL AND RELATED INTERVENTIONAL TREATMENT

Selection of Operative Approach

The term *operative approach* is used here in the broadest sense to include tissue excisional and destructive as well as incisional and other procedures that modify prostate, bladder neck, or urethral relationships without or with alteration in tissue mass. Success in these endeavors depends on identifying BPH as the cause of dysfunctional voiding correctly; recognizing the changes in BPH configuration or mass that have a high probability of correcting or modifying the dysfunctional voiding; identifying alternative approaches to accomplish this goal; and objectively assessing the achievable degree and duration of improvements in voiding and the risk

involved to achieve them. In addition, the physical, emotional, and monetary costs are important considerations. Risks of failure to pursue and accomplish an effective treatment require delineation. The discussion of individual approaches in this section represents a combination of reported observations and personal judgments regarding treatment alternatives available.

Physical Intervention

Physical intervention procedures to alter BPH voiding dysfunction have traditionally centered on removal of the hyperplastic, usually adenomatous, growth by open or transurethral surgical excision (Fig. 32.28). Recently, alternative approaches including transurethral incision, laser "prostatectomy," needle ablation, interstitial laser treatment, and electrovaporization, as well as transurethral thermotherapy, high-intensity focused ultrasound, and balloon dilation, have been used for this purpose. Most of these latter maneuvers, so-called minimally invasive alternative treatments, are usually restricted to glands of limited size without significant median lobe development. Their current status is discussed briefly.

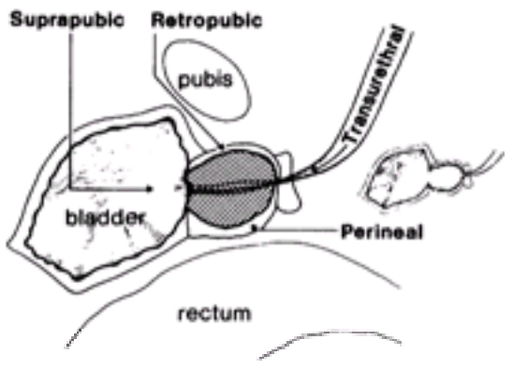

FIGURE 32.28. Traditional surgical approaches for the treatment of benign prostatic hypertrophy. [From Grayhack JT, Sadlowski RW. Results of surgical treatment of benign prostatic hyperplasia. In: Grayhack JT, Wilson JD, Scherbendke MJ, eds. *Benign prostatic hyperplasia, NIMADD workshops proceedings, Feb 20–21, 1975.* US Department of Health, Education and Welfare pub no (NIH) 76-1113, 1976, with permission.]

Surgical Treatment

The goals of surgical treatment of BPH voiding dysfunction are to correct significant pathophysiologic effects of bladder neck obstruction (i.e., renal failure, stone formation, and possibly infection) and to improve the quality of the patient's life by allowing him to void to completion at normal intervals with an excellent urinary stream while retaining good urinary control and unaltered sexual function. The treatment approach that allows these patient-prioritized goals to be reached with the least risk of morbidity and disability should be chosen. The patient's general condition, the size and configuration of obstructing prostatic tissue, the functional status of the bladder, the surgeon's skills, and the patient's preference warrant careful consideration as a so-called prostatectomy is planned.

Preoperative Preparation

Careful assessment of the patient's general and genitourinary status is essential to establish a proper diagnosis and plan appropriate therapy. Prostatectomy is an elective procedure. Even in the patient with the most severe degree of bladder neck obstruction and its anatomic sequelae, the obstruction can be adequately relieved by catheter drainage while the patient's condition is optimized before definitive therapy. Adoption of this concept has played a major role in reducing mortality and morbidity rates of surgical treatment of BPH. Every aspect of the surgical approach to the treatment of BPH has improved, including preoperative assessment, performance of the procedure, and the postoperative management (216). Consequently, the outcomes have been preserved or improved despite the numerically decreased experience of individual urologists (38,153,216,389).

Systemic Considerations

The elderly patient with BPH often has cardiovascular, pulmonary, neurologic, or other abnormalities that affect the choice of and preparation for a therapeutic approach, as well as the anesthetic used. Patients with chronic obstructive pulmonary or valvular or ischemic heart disease may require sophisticated evaluation to provide baseline information, focus preoperative management, and help select the optimal anesthetic approach. Drug allergies and use of drugs that affect coagulation, particularly aspirin or antiinflammatory agents, should be noted. The status of the veins of the patient's lower extremity warrants attention, as does the integrity of the coagulation mechanism. The risk of postoperative deep vein thrombus (DVT) and pulmonary emboli deserves special mention. Urologic patients contribute significantly to the group of postsurgical patients prone to DVT (20% to 40%) and embolic phenomena (25,65,260). In patients not given prophylactic medication, the incidence of DVT with TURP is 10% (26). Prophylactic measures such as adequate hydration, early ambulation, and use of extrinsic soleal compression of the extremities are advised. High-risk patients such as those with lower extremity venous disease, heart disease such as atrial fibrillation or myocardial infarct, history of malignancy, obesity, or immobility deserve consideration of more aggressive approaches. Intermittent pneumatic compression, our preferred prophylactic measure, appears to reduce risk of lower extremity deep vein thrombophlebitis. Use of heparin at a dose of 5,000 units every 8 hours reduces the incidence of fatal pulmonary embolism without seeming to predispose to major perioperative hemorrhage; however, the incidence of nonfatal wound hematomas increases slightly. Although the efficacy and safety of drug-induced anticoagulation in urologic surgical patients has been questioned (56,368) and is rarely used by us, formal anticoagulation deserves consideration in selected patients at high risk. The use of low-molecular-weight heparin (dalteparin) and dextran have been shown to slightly increase blood loss with TURP (155). The use of other low-molecular-weight heparin agents such as enoxaparin (Lovenox) in this setting has not been reported and is not used routinely in our hands.

Genitourinary Considerations

Renal failure resulting from bladder neck obstruction caused by BPH is often reversible, but unpredictably so. Catheter drainage of the bladder usually relieves the obstruction and results in maximum renal functional improvement. Sarmina and Resnick (317) listed characteristics of patients with obstructive uropathy caused by BPH that are more likely to exhibit irreversible renal dysfunction. This "at-risk" patient profile includes bladder neck obstructive symptoms for more than 1 year; a history of marked enuresis or renal insufficiency; antecedent urinary tract infection; palpable bladder or urinary retention; creatinine clearance of less than 20 mL per minute at hospitalization; and decreased cortical thickness or increased echogenicity on renal ultrasonography. The possibility of postobstructive diuresis resulting in significant hypovolemia following catheterization of these elderly patients exists and must be monitored. This phenomenon is primarily induced by osmotic load but can be associated with some degree of renal tubular dysfunction (114). Fluid administration should be regulated by monitoring urine output, supine and erect blood pressure and pulse rate, serum electrolytes, and creatinine and blood urea nitrogen levels. Excessive fluid replacement can lead to a spiraling fluid intake/urine output phenomenon. Catheter drainage should be maintained until renal functional status has improved sufficiently to restore creatinine and electrolyte blood levels to normal or to stabilize abnormal values. Failure of renal function to improve should signal consideration of suboptimal bladder catheter drainage or supravesical obstruction. Persistent significant azotemia predisposes to platelet dysfunction and bleeding that is often at least partially reversible by presurgical dialysis and by administration of antidiuretic hormone analogue L-desamino-8-D-arginine vasopressin (DDAVP). Renal functional status significantly affects appropriate anesthetic and pharmacologic management in these patients.

Sepsis has been a major contributor to infrequent mortality after transurethral resection (240). Bacteremia occurs postoperatively in 10% to 32% of patients without recognized preoperative bacteriuria (158) and much more frequently in patients with infected urine (68,250). Appropriately timed initiation of antibiotic therapy selected on the basis of *in vitro* culture findings is an accepted and effective presurgical practice in the latter patients. However, prophylactic antibiotic administration to reduce immediate and long-term infection-related risks in patients without preoperatively documented urinary infection has a limited effect on perioperative infections or fever (158), although reduction in the incidence of postoperative bacteremia has been noted (187). Because as many as 20% of prostatectomy tissue specimens harbor demonstrable bacteria (120), antibiotics used for prophylaxis should ideally provide bactericidal tissue as well as urine levels. A recent study using ciprofloxacin 500 mg orally or parenteral cefotaxime demonstrated results that were comparable with but not significantly superior to placebo in achieving satisfactory bacterial prophylaxis (187). Currently, empiric 24-hour intravenous (IV) or intramuscular (IM) antibiotic prophylaxis has become common in prostatectomy patients because of the practice of admission on the day of surgery and rapid postoperative discharge. Patients with increased risk factors for infection such as azotemia,

upper tract calculi and other significant abnormalities, significant residual urine, debility and immunocompromised states, and diabetes mellitus are maintained on longer-term oral antibiotic prophylaxis.

Antibiotic prophylaxis is indicated at the time of prostatic surgery or endoscopic urinary tract manipulations such as cystoscopy or urethral dilation in patients who have an increased risk of infection from transient bacteremia because of local organ pathology or prosthesis. The American Heart Association recommends endocarditis prophylaxis for patients with prosthetic cardiac valves (including porcine valves), most congenital cardiac malformations, surgically constructed systemic-pulmonary shunts, rheumatic and other acquired valvular dysfunction, idiopathic hypertrophic cardiomyopathy, a history of bacterial endocarditis, mitral valve prolapse with regurgitation or thickened leaflets, or recent (6 months) cardiac surgery. Enterococci are the most common cause of endocarditis after gastrointestinal and genitourinary procedures. A standard parenteral regimen of antibiotic prophylaxis for genitourinary surgery and instrumentation consists of 2.0 g of ampicillin (50 mg/kg) IM or IV plus 1.5 mg/kg of gentamicin to a maximum of 120 mg administered within 30 minutes of starting the procedure. Ampicillin 1 g IM or IV or 1 g of amoxicillin orally should be administered 6 hours later for high-risk patients. Moderate-risk patients can be treated with 2 g of amoxicillin orally 1 hour before or 2 g of ampicillin IM or IV within 30 minutes of the planned procedure. In penicillin-allergic patients, vancomycin is substituted for ampicillin (1 g IV infused slowly over 1 hour beginning 1 hour before surgery). High-risk patients include individuals with prosthetic heart valves or a history of endocarditis and those taking continuous oral penicillin for rheumatic fever prophylaxis (357).

Other Considerations

Compared with the 12.5% mean requirement for blood transfusion in patients with TURP and the 35% for patients with open prostatectomy cited in the BPH clinical practice guidelines (230), transfusions are currently rarely required in patients subjected to prostatectomy. Transfusion rates below 1% are now commonly quoted in the literature (186). In a survey of 3,885 patients from 13 institutions, almost all undergoing transurethral prostatectomy between 1980 and 1987, 2.5% required blood during the operation and 3.9% required it in the postoperative period (240). The decreased size of adenomatous tissue removed (256) and the improved preoperative preparation, instrumentation, and anesthetic and surgical techniques all probably contribute to lessen blood loss (112,186). Greene (135) estimated a blood loss of approximately 9.5 mL/g of tissue resected. Blood typing, matching, or consideration of use of autologous blood is used only selectively in our hands. Finasteride use preoperatively has further reduced need for transfusion (143).

Operative Approach

The decision of whether the patient will benefit appreciably from surgical treatment of BPH should be made by a critical evaluation of his symptoms and findings. Once made, selection of appropriate therapy to maximize benefit and minimize risk is necessary. Historically, incompletely removed gross BPH tissue has been associated with failure to correct or early recurrence of BPH-related voiding dysfunction. This failure was frequently corrected by removal of additional tissue. Consequently, the goal to remove BPH tissue completely became an accepted dictum. The results with antiandrogenic and limited interventional therapy, especially when followed by procedures that remove the residual gross BPH, provide further support for this idealized goal. The choices to achieve complete excision of BPH have been open prostatectomy by a variety of anatomic approaches or transurethral resection or its surrogates (Fig. 32.28). Alternative mechanical approaches such as interstitial laser and transurethral microwave thermotherapy are being used selectively with variable immediate and long-term successes. In selecting an appropriate approach for a patient, several factors warrant consideration, including the size and configuration of the adenoma, the presence of other bladder or prostatic pathology such as diverticula or stones, the presence of complicating abnormalities such as fusion or ankylosis of the joints of the lower extremities, a large scrotal hernia, a rigid penile prosthesis, multiple urethral strictures, the skill and experience of the surgeon, and the expectations and prejudices of the patient. Selective use of interventional approaches reduces the risk of procedures and increases the likelihood of achieving a good result. Urologic surgeons should be skilled in a variety of operative techniques to relieve bladder neck obstruction caused by BPH and should use them with objectively identified goals.

Transurethral Resection of the Prostate

Anesthetic Considerations

Restall and Faust (296) cited a variety of reasons regional anesthesia in the form of a spinal or subarachnoid block is highly desirable in patients undergoing transurethral prostatic surgery. Excellent skeletal and smooth muscle relaxation allows easy filling of the bladder and reduces bladder spasms. Bladder perforation, water intoxication, and congestive heart failure are best perceived early by maintaining verbal contact with the awake patient. Airway-related complications (unexpected coughing, gagging, or bucking) are largely avoided with regional anesthesia, and a comfortable, quiescent patient aids in providing hemostasis (232,262). The presence of documented central or peripheral neurologic deficits, potential bleeding tendencies, chronic low back pain, osseous metastases, and lack of patient acceptance weigh against the use of regional anesthesia (37).

Urologists should be aware of the risk of hypotension and postspinal headache associated with subarachnoid block (296). Significant hypotension, usually responsive to additional crystalloid or a-adrenergic agonist administration, can result from the chemical sympathectomy extending to four dermatomes higher than the apparent sensory level. Risk of myocardial infarction is not substantially different in these patients with coronary artery disease with either spinal or general anesthesia. A postspinal headache, which is usually occipital and characteristically relieved by recumbency, is produced by the sustained transdural leakage of cerebrospinal fluid. If necessary, this can be controlled by use of an epidural patch of autologous blood (72).

Steps Preliminary to Resection

Before the technique of endoscopic resection is discussed, prophylactic vasectomy, management of the urethra, cystoscopy before resection, and the choice and preparation of the resectoscope deserve brief consideration.

The reported 0.2% incidence of epididymitis by Mebust and colleagues (240) in 3,885 patients, only 10% of whom had had a vasectomy, reflects the currently diminished incidence of this complication. Nevertheless, prophylactic vasectomy effectively diminishes the risk of epididymitis (124) and warrants consideration in high-risk individuals with a chronic urinary tract infection, history of prolonged catheter use, previous epididymitis, or increased systemic or local risk factors for infection.

Urethral stricture, reported in 1.5% to 20% of patients after TURP, can be caused by urethral trauma from the resectoscope, catheter, or bacterial infection (148,149,161,393). Emmett and associates (85) found that the external urethral meatus and fossa navicularis of only 62% of men calibrated to 28 Fr or greater; in addition, the anterior urethra calibrated to 24 or 26 Fr in 9%. These sites of natural narrowing of the male urethra affect the selection of an appropriately sized resectoscope sheath. Calibration of the meatus–fossa navicularis and visual inspection of the urethra on insertion of the cystoscope are used to guide this selection. Gentle, progressive, manual dilation will usually allow introduction of the well-lubricated resectoscope sheath. Consideration of prolonged (2 weeks) administration of antibiotics to reduce the rate and severity of postresection stricture is worthwhile (149). A dense, narrow, external meatal or fossa navicularis stricture is best managed by a ventrally or dorsally placed meatotomy (Fig. 32.29). We prefer the latter to prevent a distorted urinary stream postoperatively.

FIGURE 32.29. The technique of urethral meatotomy. Insertion of a bougie into the fossa navicularis facilitates the incision **(A);** placement of continuous approximating hemostatic sutures **(B).** When performed in the ventral aspect of the meatus, significant spraying on urination will often be reported by the patient. This may be obviated by creation of a frenular skin flap **(C–E)** or by performing the initial incision on the dorsal aspect of the meatus. (From Thompson IM. Transurethral

surgery. In: Glenn JF, ed. *Urologic surgery,* ed 2. New York: Harper & Row, 1975, with permission.)

Impassable or dense strictures of the distal urethra can often easily be incised at the 12 o'clock position with the direct-vision optical urethrotome by the use of a stenting ureteral catheter as a guide. Their presence may prompt reevaluation of the diagnosis. A perineal urethrostomy may be required if the entire urethra is significantly narrow, in the presence of severe ankylosis of the hip, or in patients with an excessively long (whether naturally or prosthesis produced) penis (Fig. 32.30). Stay sutures incorporating skin and urethral edges serve to provide repetitive access to the urethra. At the conclusion of the endoscopic resection, suture reapproximation of the urethra is generally not required if the urethral catheter is passed in the standard fashion. The skin can be approximated loosely with interrupted absorbable suture material.

FIGURE 32.30. Technique of perirenal urethrostomy. A Van Buren sound is used to create an accentuated projection of the bulbous urethra in the midperineum **(A).** A 2- to 3-cm vertical incision is then made down to and through the exposed urethral segment **(B).** Stay sutures facilitate exposure of the urethral lumen and ensure reentry capability should that prove necessary **(C**, **D).** Following completion of the procedure and insertion of the catheter, the urethra may be loosely reapproximated followed by skin closure **(E, F).** (From Thompson IM. Transurethral surgery. In: Glenn JF, ed. *Urologic surgery,* ed 2. New York: Harper & Row, 1975, with permission.)

Cystourethroscopy should precede the resection. Use of a complementary rigid lens system or flexible cystoscope with either direct or video monitoring permits complete evaluation of the urethra and bladder. Passage of the cystoscope under direct vision maximizes the opportunity to recognize urethral pathology and minimizes urethral trauma. Each centimeter increase in the normal 2.5 cm prostate ureteral length from the verumontanum to the vesical neck has been equated with approximately 10 g of additional prostate weight. The visual anteroposterior distance of the prostatic urethra, the depth and angle of the posterior lateral (5 and 7 o'clock) and anterior (12 o'clock) tissue clefts, the thickness of the prostate on digital examination with the endoscope in place, and the configuration of the prostatic hyperplasia including evidence of subtrigonal extension are useful to estimate the size of the prostatic adenoma and to evaluate the appropriateness of therapeutic alternatives. However, the most accurate method to estimate prostate size is a transrectal ultrasound measuring both total and transitional zone volume. Clefting of the bladder neck is important in differentiating a median lobe and median bar. The relationship of the prostatic hyperplasia to the ureteral orifices, verumontanum, and external urethral sphincter should be noted.

The presence of tumors, unexplained patchy inflammatory changes, calculi, trabeculation, and diverticula should be noted (Fig. 32.26). If identification of the ureteral orifices is difficult, IV administration of methylene blue or indigo carmine may assist in their visualization. Bladder diverticula should be assessed as to number, size, location, and probable emptying ability. An unsuspected pathologic finding may require reevaluation of the planned surgical procedure.

Before the rectoscope is inserted, it should be assembled to make certain all elements are appropriately fitted and working. The resectoscope sheath with deflecting (Timberlake) obturator in place is usually easily passed into the bladder. If a problem is encountered, insertion of the resectoscope may be accomplished under direct vision. If false passages or the prostate configuration make insertion particularly difficult, an endourologic guide-wire system or a small-diameter urethral catheter guide may be helpful in passing the resectoscope sheath into the bladder.

Various working elements, including a rack-and-pinion gear and a spring-activated mechanism, are available to control the movement of the cutting loop. We prefer the spring-mechanism instruments because of their “one-handed” operation. This permits insertion of the index finger of the free hand into the rectum to elevate the prostatic floor and facilitate the resection, particularly of the apical tissue. Many urologists prefer the video camera hookup and the lens eyepiece when performing TURP. In doing so, they watch the video screen for visual monitoring. Advantages of this technique are many, including a more comfortable upright position and keeping one's face away from resectoscope efflux. Potential disadvantages include a brief learning curve, reduced visual field, a reluctance to use rectal manipulation via the O'Conor drape to aid resection of the apex and other elusive sites, and the additional bulk of the resectoscope apparatus. Some urologists prefer instruments that permit continuous flow of irrigating fluid or insertion of a suprapubic drainage device for that purpose (159). The use of these types of devices is a matter of personal comfort and choice.

Technique of Endoscopic Resection

The anesthetized patient should be secured comfortably in the dorsolithotomy position. A routine abdominal examination of the anesthetized patient may disclose unexpected pathology and serves as a baseline for any subsequent examination. Shaving the genitalia and perineum is unnecessary unless perineal urethrostomy is anticipated. Any one of a variety of standard bactericidal preparations, including hexachlorophene (pHisoHex), povidone-iodine (Betadine), or chlorhexidine applied to the lower abdomen, genitalia, and perineum is adequate. Use of the O'Conor-type rectal shield provides ready, sterile access to the rectum. The grounding pad should be placed so that it will not be dislodged. The irrigating fluid should be maintained at body temperature and positioned at the lowest level relative to the patient that will allow adequate visualization. With these maneuvers completed, the resection may commence.

No one way to perform endoscopic removal of obstructing adenomatous tissue is applicable to all cases. Each urologist will develop an approach and modify it on a case-by-case basis. Despite the multiplicity of potential modifications, some generalizations are proposed.

Before the resection is initiated, the prostatic fossa should be carefully reexamined. The bladder neck, trigone, and ureteral orifices proximally and the verumontanum and external sphincter mechanisms distally should be noted and their relationship to the prostatic adenoma reaffirmed. A nontoxic isotonic or slightly hypotonic solution with satisfactory visual capabilities such as glycine (1.5%) or sorbitol should be used for irrigation.

Prominent obstructive middle lobe or bladder neck tissue that constitutes an impediment to movement of the resectoscope or the flow of chips into the bladder should be dealt with during the earliest phases of the resection. Currents with various characteristics may be desirable during different phases of these procedures. Mixed currents provide greater hemostasis but cut less freely. Undamped currents cut rapidly with little resistance or hemostasis. The urologist should monitor current settings closely during the procedure. Any organized, systematic approach to the resection of the intraurethral adenoma can be used effectively. Some prefer to resect the floor of the prostatic urethra initially. Others use a modification of the Nesbit (259) “encirclement” approach, whereby the anterior and lateral lobe tissue is allowed to “drop” onto the floor of the prostatic fossa for easy resection (135,359). This usually entails initiating the resection at the level of the bladder neck in two sweeping arcs, the 11 to 9 o'clock and 1 to 3 o'clock positions. Bladder neck fibers are exposed but not resected, carrying the longitudinal sweep of the resection just proximal to the base of the verumontanum.

During the initial stages of the resection, the tissue cuts smoothly with minimal effort. The chips thus produced should be boatlike in shape and equivalent in length to the extended loop. A synchronized rocking movement of the resectoscope sheath allows clean cutting of the chips. One should avoid cutting “mini-chips” because this produces an irregular prosthetic bed, which can hide bleeders and reduce operative efficiency . As the resection progresses, more deliberate movements are necessary to engage tissue by exerting a downward pressure on the sheath to facilitate the fulcrum effect. Digital elevation and manipulation of the prostate via the O'Conor shield can be a significant aid at this time. For added protection, the bladder should be partially filled while resection is performed in the area of the bladder

neck.

Aggressive resection at the bladder neck, the 12 o'clock position anteriorly, and near the prostatic apex is best postponed until the end stage of the resection. The anterior aspect of the prostatic fossa is thin and easily perforated; it contains the most fragile portion of the external sphincter fibers. Risking overresection in any limited area before the major portion of the adenoma is removed may expose large venous sinuses and compromise the resection. The prostatic apex is best removed at the end of the procedure in a bloodless field with a finger in the rectum.

Hemostasis should be maintained throughout the procedure. Observations of the character and amount of blood in the irrigating fluid as it drains from the bladder will provide valuable feedback of the type and severity of bleeding. Arterial bleeding is identified not only by its bright color but also by its persistence during filling and drainage. Venous bleeding is not only dark but also decreases markedly or disappears with irrigation and increases with drainage. Arterial bleeding should be controlled by precise fulguration. This is facilitated by advancing the resectoscope close to the bleeder to attempt to visualize the vessel “in profile.” The possibility of “ricochet” bleeding with the actual site on the opposite wall or of a cryptic bleeding site that requires further resection to expose it should be kept in mind (136). Identifying bleeding at the bladder neck area can be facilitated by inspection with a nearly empty bladder (Fig. 32.31). Prompt recognition of the presence of transected venous sinuses is essential and can be facilitated by watching the drainage from the resectoscope. Partially occluding the inflow tubing intermittently may help locate arterial bleeders and identify venous bleeding. Identifying venous sinuses may be difficult; controlling them by fulguration almost always is difficult. The presence of a large open venous channel is an indication to lower the irrigating fluid as low as possible and to complete the operation with dispatch. Persistent inspection in the face of bleeding that is primarily venous can lead to significant fluid absorption and water intoxication. If the patient has signs of significant fluid absorption or the tissue remaining is appreciable, a catheter should be inserted to control venous bleeding quickly by tamponade and the procedure terminated.

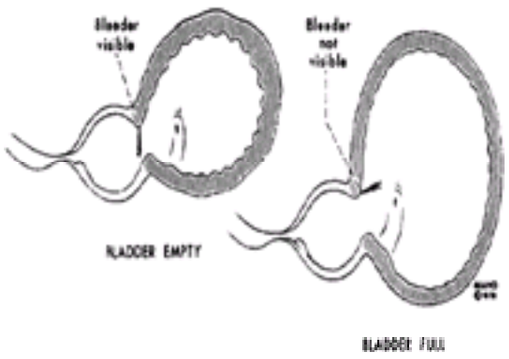

FIGURE 32.31. Arterial bleeding from the bladder neck is best appreciated with a moderately empty bladder, which permits projection of the bleeding site toward the operating surgeon. (From Greene LF. Transurethral prostatic resection: technique. In: Greene LF, Segura JW, eds. *Transurethral surgery.* Philadelphia: Saunders, 1979, with permission.)

The endpoint of the operation should be a cleanly excavated prostatic fossa exposing bladder neck and capsular fibers while leaving intact the trigone and ureteral orifices, the verumontanum, and the external sphincter mechanism. A very limited amount of residual tissue may be left abutting the external sphincter. It is far preferable to repeat the resection than to render the patient incontinent. Residual anterior and anterolateral tissue has been the most common problem we have noted in patients requiring repeat resection within a short time. This technically challenging area should be inspected carefully to make certain it is adequately but not overly resected.

Before the operative procedure is concluded, all tissue must be evacuated from the bladder with a Toomey syringe or similar device. The bladder, particularly diverticula, should be carefully inspected for residual tissue fragments. Reexamination of the prostatic fossa to secure final and adequate hemostasis is then best performed in the normotensive patient. If a venous sinus has been entered, persistent endoscopic searching and fulguration is ineffectual and can aggravate fluid absorption. Placing a Foley catheter with a distended balloon on moderate traction will usually result in prompt cessation of the bleeding. Despite considerable discussion regarding the advisability of using Foley catheter traction, no deleterious effect of this procedure has been documented. Although we share the practice of many in attempting to place and keep the balloon at the bladder neck, the studies carried out by Greene (135) would suggest that a distended balloon at least intrudes significantly into the prostatic fossa. Our practice is to maintain traction at least until the patient is back in his own room and then to release it as indicated by the degree of residual hematuria.

Closed-drainage systems reduce the risk of bacilluria in the postoperative period. The necessity to evacuate clots and maintain free drainage has resulted in the use of a number of different closed irrigating systems. Use of a three-way catheter with continuous inflow and outflow is effective if it is monitored by a skilled nursing group. If obstruction to the outflow tract is not recognized promptly, overdistention of the bladder can increase the problem with bleeding with this system. Intermittent irrigation from a reservoir is also commonly used and is our preference. A Y-tube connector that permits instillation of irrigating fluid into the bladder without breaking the closed system is affixed to the catheter. If it is necessary to break the closed system to irrigate the bladder manually, this should be done with concern for an aseptic technique.

Transurethral Incision of the Prostate

Evidence supporting a dynamic role for the peripheral condensation of stroma that acts as a prostatic capsule in the etiology of BPH-associated dysfunctional voiding has gradually accumulated (164,272). The partial resolution of symptoms noted in the patient with BPH treated with a-adrenergic blocking agents and the results achieved by open excision of the anterior prostatic commissure (326) suggest that capsular contraction or hypertonicity probably is a factor in the pathophysiologic changes resulting in BPH voiding dysfunction in some patients. Clearly, capsular contraction or constriction could augment the degree of luminal obstruction from adenomatous hyperplasia of the prostate.

Transurethral incision of the prostate (TUIP) is an operative approach attempting to disrupt the prostatic capsule to overcome these effects. Most reports of this procedure restrict its use to glands with estimated weights in the range of 30 g or less. A single or bilateral incision is usually made through the bladder neck to verumontanum. A cold or hot knife or resectoscope loop may be used. Incisions located posterolaterally (8 and 4 o'clock) are preferred. Loop excision aids visualization of the prostatic floor (239). Orandi (275) avoids bladder neck and complete capsular incision in young men to reduce risk of retrograde ejaculation. Li and Ng (207) advocate routine exposure of extracapsular fat with a resection from the trigone to the verumontanum. Most often the incision through the bladder neck should cause it to spring open (297). Bleeding and extravasation are associated with capsular division; Li and Ng (207) caution that bleeding should be controlled as soon as it is identified. Biopsies obtained with the resectoscope loop or a biopsy needle are generally desirable (207). Catheter drainage is used routinely in the postoperative period. Although bleeding may be severe and require transfusion, this is uncommon. The BPH panel literature review (230) indicated improved or satisfactory flow rates (7.5 mL per second preoperative to 15.1 mL per second postoperative), reduced residual urine (94%), and satisfactory improvement in subjective symptoms (80%) in patients selected for one of the approaches to TUIP. The reported incidence of retrograde ejaculation varied from 0% to 37%. Stress incontinence was experienced in 1.1% and total incontinence in 0.1% postoperatively. The re-treatment rate was 4% (239). TUIP warrants consideration as an alternative procedure to manage bladder neck obstruction in selected patients, particularly young men with limited prostatic hyperplasia and those wishing to preserve antegrade ejaculation.

Postoperative Management

The postoperative course for most patients undergoing transurethral resection of the prostate is remarkably uneventful (132,239). The estimated fluid absorption of 800 to 1,000 mL in an uncomplicated resection should be kept in mind when ordering postoperative fluids (270). The patient is generally able to tolerate a liquid diet on the day of surgery. The development of bladder spasms should raise a question regarding unobstructed catheter drainage. Bladder spasms occurring without identifiable cause are often difficult to control with the catheter in place despite the use of a variety of anticholinergic agents, including belladonna and opium suppositories, oxybutynin (Ditropan), tolterodine (Detrol), and propantheline (Pro-Banthine). Because straining to eliminate hard, impacted stool may precipitate bleeding, administration of a stool softener is worthwhile. In the absence of documented capsular perforation or significant bleeding, the Foley catheter can generally be removed within 24 to 48 hours. Instillation of sterile saline into the bladder just before catheter removal provides a convenient opportunity to assess the adequacy of the urinary stream and may aid in the passage of small clots and tissue debris. A three-glass voiding cycle should be initiated to assess the volume and color of

subsequent micturition. Experiences indicating that day-of-surgery discharge is feasible in patients at average risk with uncomplicated procedures are being reported (389). We usually advise avoiding aspirin and antiinflammatory agents affecting platelet function and blood coagulation until the risk of significant secondary bleeding is minimal (2 to 3 weeks). The patient should be instructed to avoid straining and vigorous physical and sexual activity for several weeks. Epithelization of the excavated prostatic fossa is accomplished by migration and proliferation of transitional cells from resection margins and usually requires 6 to 12 weeks. Consequently, the patient should be informed of the possibility of mild delayed bleeding, often associated with the passage of sloughed tissue or eschar. Increased fluid consumption and realistic restriction of activity are usually successful in abating such symptoms.

Complications

Aside from the potential medical and surgical complications after anesthesia and surgery in general, several problems unique to endoscopic surgery require review. The intraoperative difficulties that must be recognized and discussed include the following: persistent penile erection; obturator spasm; hemorrhage; undermining of the bladder neck and trigone; perforation of the prostatovesical junction, capsule, or bladder; damage to the external sphincter; fragmentation of a prostatic lobe; and burn injury (136).

Persistent penile erection may develop at any point during general or regional anesthesia and may drastically limit endoscopic accessibility of the prostate and bladder. Detumescence often occurs without specific changes in management. Although detumescence may be associated with use of various nonspecific interventions, intracorporal lavage with pharmacologic agents such as phenylephrine (200 mg per injection) (214) or dilute epinephrine (1:100,000) is currently the procedure of choice. If all of these maneuvers fail, temporary discontinuance of the procedure or use of a perineal urethrostomy should be done (Fig. 32.30).

The obturator reflex is most often triggered during a resection of bladder neoplasms located along the lateral wall but can be initiated during resection of a laterally situated intravesical adenoma. If this reflex is vigorous, exaggerated movement of the ipsilateral leg and pelvis can result in perforation. Use of high-intensity cutting current in a distended bladder predisposes to this event. Although downward adjustment of the current strength and partial evacuation of the bladder may obviate further problems, the risk of recurrent spasm usually requires a more aggressive approach. Use of a muscle relaxant, or alternatively, blocking of the obturator nerve as it traverses Alcock's canal by injection of a local anesthetic agent, usually solves the problem.

The usual techniques for controlling bleeding during transurethral resection are described in the previous section. Persistent significant bleeding as the procedure approaches its termination is usually due to the surgeon's failure to control arterial and venous bleeding during the course of the resection. However, the possibility of a coagulopathy also warrants consideration and selective evaluation, particularly if clotting is absent or poor. As indicated previously, if venous bleeding is suspected, balloon catheter tamponade will usually quickly control the bleeding and demonstrate the validity of this suspicion. If the bleeding is arterial, a systematic inspection of the prostatic fossa with variable, controlled, irrigating fluid inflow should lead to its identification and control. Extra care should be taken to inspect the anterior aspect of the bladder neck with the bladder empty and partially full to identify occult arterial bleeding in that troublesome spot. Balloon tamponade can also be used to control significant arterial bleeding, although direct surgical control is preferable. Every effort should be made to achieve satisfactory hemostasis at the time the patient leaves the operating room. If the bleeding persists despite these efforts and no underlying coagulopathy is identified, an open surgical approach may be necessary to control it either before termination of the resection or in the immediate postoperative period. As indicated, bleeding of sufficient severity to require transfusions occurs infrequently during the resection and in the postoperative period (240). If hypotension and shock develop, hypovolemia usually warrants primary consideration in patients with significant blood loss. However, other potential causes such as sepsis-, cardiac-, and drug-related etiologies should not be dismissed without consideration, especially in patients with limited blood loss. The neodynium:yttrium-aluminum-garnett (Nd:YAG) laser with the right-angle noncontact fiber has been used successfully to control prostatic bleeding (193).

Frank perforation may occur at the level of the prostatovesical junction, the prostatic capsule, or the bladder itself. In addition to actual electroresection, the trauma from the beak of the instrument or overdistention of a thin prostatic capsule or bladder may be a factor in perforation. Overresection of the bladder neck and trigone may not only lead to perforation but also has been postulated to cause postoperative bladder neck contracture (136). Varying degrees of perforation are more common at the posterior aspect of the bladder neck, but anterior or lateral perforation of the prostatovesical junction is usually associated with substantially greater volume of extravasation. Extravasation associated with prostatic resection is almost always extraperitoneal. Visual evidence of perforation may vary from a cavernous opening with identifiable periprostatic or perivesical tissue to a subtle elongation of the prostatic urethra with eventual elevation and lateral impression of the bladder. The prostatovesical junction may become more distant and distorted. Extraperitoneal perforations in the bladder neck area do not generally produce sufficient abnormality in the irrigation pattern to allow their recognition. If unrecognized, signs of diminished bladder capacity and, in patients under regional anesthesia, peritoneal irritation (including abdominal pain, guarding, and tenderness) and nausea and vomiting may develop. Recognition of a perforation requires an assessment of existing and potential extravasation to guide subsequent management. A cystogram with a drainage film provides useful information. Limited extravasation can usually be handled with catheter drainage and observation. More extensive extravasation in a symptomatic patient usually requires perivesical drainage. The morbidity associated with prevesical space drains placed through a limited low-midline incision is not sufficiently great to warrant extensive measures to avoid it.

Intraperitoneal extravasation usually results from advancing or reinserting the resectoscope sheath vigorously and injuring the bladder dome. This can usually be avoided if the bladder is kept moderately filled. The probability of intraperitoneal extravasation is often signaled by a bizarre irrigation pattern where inflow greatly exceeds outflow and by peritoneal irritative symptoms, including unilateral or bilateral subdiaphragmatic pain. Endoscopic visualization of the bladder defect may be difficult and unnecessary. A cystogram should be performed to document the suspected abnormality. Modest degrees of intraperitoneal perforation can probably be handled with catheter drainage. Massive extravasation in a patient with profound symptoms usually requires lower abdominal transperitoneal exploration with appropriate drainage and possibly closure of the perforation (299).

Under normal circumstances, the internal sphincter constitutes the predominant continence mechanism in men. During the course of an adequate transurethral resection of the prostate, this sphincter mechanism is removed or rendered incompetent (305). The integrity of the external sphincter mechanism must be preserved, or total or stress urinary incontinence will ensue. Injury to the external sphincter mechanism can occur by actual cutting of its muscle fibers, aggressive and injudicious fulguration about the verumontanum and prostatic apex, and mechanical trauma induced by the beak of the resectoscope during the course of the resection of apical tissue. Needless to say, the verumontanum is an invaluable landmark that should be preserved. In general, resections that are terminated proximal or adjacent to the verumontanum are unlikely to be associated with significant injury to the external sphincter. As stated previously, the recognizable sphincter is represented by the area of the urethra that assumes a nearly circular shape and a corrugated appearance as the sheath is advanced into the membranous urethra and approaches the verumontanum area. However, the extent of the complex of smooth and striated muscle that makes up the external sphincter is not clearly demarcated, particularly as the fibers interdigitate and splay out proximally. The anterior muscle in this cone-tube configuration is the least substantial. These considerations should lead to caution in selecting not only the extent of the resection but also the depth distally. This is particularly true anteriorly (see Chapter 26A). When one considers the extent of sphincter resection necessary to affect sphincter function in purposeful external sphincterotomy, the fact that the mechanism of post–transurethral resection sphincter dysfunction is poorly understood becomes clear. Nevertheless, experience has indicated the need for caution in avoiding overresection in the distalmost portion of the prostate.

Resection of a portion of the prostate too large to be evacuated through the resectoscope sheath is an unusual complication that has been described during resection of a prominent intravesical middle lobe. This is avoidable if resection of the pedicle of the adenoma is done last. On completion of the resection, the surgeon can grasp the fragment with the loop or grasping forceps and draw it into the resectoscope beak; the entrapped fragment can then be removed as a single unit. Alternatively, it can be morcellated within the bladder or the prostatic fossa. Delayed retrieval of the fragment poses the danger of catheter occlusion in the immediate perioperative period.

The advent of solid-state electrosurgical units possessing isolated circuitry has made burn injury to patients and surgeons a rare event. Nevertheless, the possibility of inadequate grounding should be considered in the event of a less-than-optimal function of the working element during the resection. As more electronic and metallic devices are implanted in patients, the position of the ground and active electrode may require increased consideration to prevent interference with the function of these units (11). One other complication can occur as a result of interaction of the electric current with the irrigating fluid, namely, the possibility of an intravesical explosion caused by liberated gases. This potentially volatile interaction of electrical current, hydrogen, and air should be recognized by the urologist.

A variety of perioperative and postoperative complications have been associated with transurethral resection of the prostate. These include hemorrhage, the transurethral resection syndrome, catheter malfunction, development of urethral stricture and bladder neck contracture, urinary tract infection, shock, development of DVT and pulmonary embolus, and disorders of the cardiovascular, gastrointestinal, and central nervous systems.

Significant bleeding in the perioperative period is most often due to faulty intraoperative hemostasis, which has been discussed at length. Some delayed postoperative bleeding, usually caused by sloughing ischemic tissue or, less frequently, clot lysis is a relatively common event. Its incidence decreases as the postoperative period lengthens. In our experience, significant bleeding is far more common in patients who have had intraoperative venous sinus bleeding. It is rare

after 21 days. Usually, a significant secondary bleed is controlled by insertion of a catheter, evacuation of clots, and tamponade. Reoperation is occasionally required to achieve complete clot evacuation and to fulgurate the arterial bleeders. Limited bleeding may occur for several weeks after the initial resection, is usually transient in nature, and customarily responds promptly to curtailing physical activity and initiating liberal fluid intake. In patients with prolonged or recurrent bleeding, the possibility of a variety of important contributing hematologic disorders such as disseminated intravascular coagulation, primary fibrinolysis, decreased factor VIII, and von Willebrand's factor warrant consideration.

Many of our current conceptions regarding the etiology of the transurethral resection syndrome stem from the observations of Hagstrom (144) and Harrison and associates (151). The pressure within the prostatic venous system is approximately 10 mm Hg. Uncomplicated resections will ultimately expose multiple small venous sinuses as the resection approaches the capsule. Excessive absorption of irrigating solution can occur if the solution is administered under a pressure that exceeds normal venous pressure, particularly during the course of a lengthy resection (greater than 1 hour). Consequently, most urologic surgeons currently use a nonisotonic irrigating solution such as 1.5% glycine with an osmolality of about 200 mOsm/L compared with the serum osmolality of 290 mOsm/L. Excessive systemic absorption of this solution will result in a dilutional hyponatremia, hypoproteinemia, and ultimately a decreased serum osmotic pressure. Such events promote fluid shifts that are ultimately responsible for cerebral or pulmonary edema. As cerebral edema becomes more pronounced, the intracranial pressure rises and produces the characteristic clinical signs of the so-called transurethral resection syndrome: bradycardia, hypertension, tachypnea, confusion, agitation, muscular twitching, nausea, vomiting, and headache. This chain of events may progress to frank convulsions and coma, particularly if the serum sodium level plummets to less than 120 mEq/L (157). This syndrome was diagnosed in 2% of the 3,885 patients subjected to transurethral resection from 13 institutions reviewed retrospectively by Mebust and associates (240). Transurethral resection syndrome was not listed as a cause of any of the nine deaths in this series. As discussed previously, prompt recognition of increased risk of irrigating fluid absorption is the hallmark of prevention and treatment. The irrigating solution container should be lowered to the minimum level necessary to facilitate visualization. The procedure should be terminated after securing hemostasis and evacuating tissue fragments. Peripheral IV lines should be adjusted to a keep-open rate. Serum electrolyte levels should be obtained promptly to confirm the diagnosis. Our current practice is to obtain a prompt postoperative serum sodium in any patient with a recognized risk factor for increased irrigating fluid absorption, making failure to recognize mild forms of this syndrome unlikely. A serum sodium level less than 120 mEq/L indicates a significant dilutional effect. Intravenous furosemide (Lasix) should be administered. Because the diuretic response of the elderly patient is unpredictable, it seems best to start with a relatively small dose, about 5 to 10 mg IV, and adjust the dosage accordingly. Transient visual disturbances or blindness during the initial stages of this syndrome signify significant CNS toxicity. Although rare, these problems can be distressful to both the urologist and family. Full reversibility is generally reported. In the presence of profound CNS symptoms, the administration of hypertonic saline should be done; the amount required to restore serum sodium levels and osmolality can be calculated. In general, the administration of about 200 mL of 3% sodium chloride solution during a 3- to 6-hour period will produce a dramatic improvement in clinical signs and symptoms. Although concern regarding judicious rapid correction of severe hyponatremia with hypertonic saline to achieve a mild hyponatremic state is probably not warranted from the standpoint of development of a demyelinating lesion of the brain (central pontine myelinolysis), rapid conversion of hyponatremia to normonatremia or hypernatremia, an increase of more than 25 nmol/L with initial therapy, or both, may be a factor in the development of these lesions. This risk is accelerated by the presence of a hypoxic-anoxic episode, alcoholism, or hepatic coma (14). The patient's hourly urine output and fluid intake should be recorded. In the presence of severe cerebral and pulmonary symptoms, invasive cardiopulmonary monitoring in an intensive care setting is advised.

The cause of the transurethral resection syndrome may be potentially more complex than previously suspected (157,315). Immediate or delayed encephalopathic symptoms associated with markedly elevated serum ammonia levels have been reported after TURP with glycine as the irrigating fluid. With excessive absorption of glycine, several metabolic pathways that involve deamination and liberate free ammonia are activated in addition to the major one involving interconversion of glycine with serine. James and associates (169) have hypothesized that cerebral astrocytes detoxify ammonia by the production of glutamine from glutamic acid. The accumulation of glutamine and its conversion to serotonin, accompanied by a decrease in dopamine and norepinephrine, may be important etiologic factors in the neurologic symptoms of patients with hyperammonemia (157). Patients at high risk include those with documented hepatic disease, marked skeletal muscle atrophy, urinary tract infection and bladder stones, and obstructive uropathy. Treatment is generally supportive, with the realization that the encephalopathy may be somewhat prolonged, lasting up to 36 hours. If seizure activity develops, anticonvulsant medication may be required.

The indwelling Foley catheter can contribute directly to immediate and delayed complications by failing to deflate and indirectly by facilitating urethritis and probably stricture formation. A variety of maneuvers have been used to deflate the inflated retention balloon. These include simple compression of the filling stem, overdistention with additional fluid, injection of mineral oil, and puncturing the balloon with a wire stylet inserted through the access channel or with a fine spinal needle introduced suprapubically. Success has also been reported with procedures using a ureteroscope passed along the catheter or a cystoscope introduced to puncture the balloon after the divided catheter secured by a dangle suture has been pushed into the bladder (24).

The role of the catheter in urethral stricture formation is supported by the decrease in this complication after suprapubic as compared with urethral catheter drainage (149). The potential etiologic role of urethritis is supported by the decreased stricture incidence associated with prolonged antimicrobial therapy after transurethral resection. The urethral meatus should be cleaned of mucus and crusts regularly; the catheter surface should be kept free of foreign substances. The rare development of a severe generalized urethritis with fever warrants an attempt to identify the organism and to institute antibiotic therapy promptly. The catheter should be removed as soon as possible. If an inflammatory reaction such as a meatitis is recognized, gentle, frequent dilation of the inflamed site will usually prevent development of a stricture. In the case of a severe meatitis, our practice is to provide the patient with a dilator and teach self-dilation. If the constricting urethritis is in the more proximal urethra, frequent, atraumatic dilation by the urologist in the postoperative period will also often prevent development of a significant stricture. Concern for the prevention of strictures does not stop with removal of the catheter.

With regard to the related topic of bladder neck contracture, the estimate that as many as 2% of the patients undergoing transurethral electroresection of the prostate have this complication seems high in our experience (136). As indicated in the section on technique, contracture is thought to result from overresection and injudicious fulguration about the bladder neck. Undermining of the bladder neck and trigone may create a free flap that heals as a membrane. Early recognition of the risk of a contracture is facilitated by careful attention to the patient's description and observation of his urinary stream or by routine flow studies. An unusual degree of pain in the postoperative period should also raise suspicion of an inflammatory reaction in the area of the bladder neck. Prompt outpatient endoscopic evaluation is informative and easily accomplished (Fig. 32.32). If a significant constricting inflammatory reaction is identified in this region, gentle calibration and dilation are worthwhile. Contractures usually become manifest with obstructive symptoms from 3 weeks to 10 years after resection, with an average interval of approximately 6 months (136). If gentle dilation does not suffice, reevaluation with endoscopy is advised. If the bladder neck orifice cannot be located endoscopically, IV administration of methylene blue, induction of a diuresis, and use of suprapubic pressure may produce an identifying jet of blue urine. A ureteral catheter passed into the bladder can guide the incision of the constricting ring with an optical urethrotome, Collins knife, or resectoscope loop until it springs open. Once complete division of the constricting tissue band is achieved, more extensive resection of the scarred tissue is probably best avoided. Again, frequent, gentle postoperative calibration and dilation will help prevent recurrence. In recurrent contractures, a Y-V–plasty of the bladder neck will usually solve the problem and should be considered.

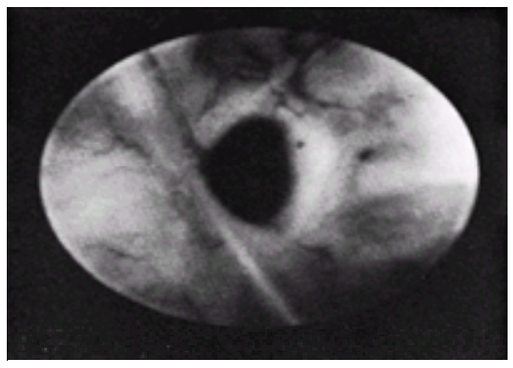

FIGURE 32.32. Typical appearance of bladder neck contracture. The opening to most diaphragmatic contractures can be found in the anterior position near 12 o'clock. (From Greene LF, Holcomb GR. Transurethral resection in special situations. In: Greene LF, Segura JW, eds. *Transurethral surgery.* Philadelphia: Saunders, 1979, with permission.)

Open Prostatectomy

Suprapubic Prostatectomy

As the instrumentation and skills for endoscopic resection of the prostate have improved, the indications for open prostatectomy in the practice of most urologists have diminished. Factors influencing the choice of the suprapubic approach for enucleation of obstructing adenomatous tissue include the presence of a prominent, intravesical component; associated bladder pathology, such as a large, narrow-necked vesical diverticulum or multiple large bladder stones; and the need for an open prostatectomy in an obese patient in whom the retropubic approach is technically more cumbersome (69). Suprapubic prostatectomy is a relatively simple procedure that nevertheless requires meticulous attention to surgical detail (256,267).

After the induction of satisfactory general or regional anesthesia, the operating table should be gently flexed in the modified Trendelenburg position to facilitate exposure of the male pelvis and retraction of the peritoneal reflection. Exposure of the bladder is enhanced if the latter is filled to approximately 150 to 200 mL. Use of a fiberoptic headlight may aid visualization of the prostatic fossa after enucleation.

A transverse (Pfannenstiel) or lower midline incision may be used depending on the procedure planned, the patient's build, and the presence of previous surgical scars. In the preferred Pfannenstiel incision, extending the incision too far laterally should be avoided to decrease the risk of postoperative hernia. Awareness of potential injury to the underlying inferior epigastric vessels is important with either incision. Incision and separation of the thin fascial envelope constituting the umbilicoprevesical fascia and partial separation of the peritoneal reflection from the dome of the bladder facilitate exposure of the partially distended bladder. After stay sutures are placed in the bladder wall, a transverse incision 1.5 to 2.0 cm above the bladder neck provides exposure of the prostatic fossa with minimal risk of disrupting the bladder neck and the prostatic capsule. Incising the detrusor muscle with electrocautery or scalpel exposes the mucosa. After this is incised and the edges of the incision are secured with Alice clamps, it is enlarged by careful lateral digital traction. After evacuating the bladder contents, a single moistened lap pad inserted into the bladder dome provide *s* a buttress for a retractor. Further exposure of the bladder neck can be achieved by placing a Deaver along the lateral vesical wall. Careful examination of the bladder, especially to locate the trigone and the ureteral orifices and identify associated bladder pathology, is important before enucleating the obstructing adenoma. Circumferentially scoring the mucosa bordering the bladder neck with electrocautery prevents excessive tearing during enucleation of the prostate (Fig. 32.33). The enucleation should be initiated by inserting the index finger into the prostatic fossa and cracking the anterior commissure with anterolateral pressure against the larger adenoma. Blunt enucleation should be carried out in the cleavage plane between the surgical capsule and the adenoma with pressure primarily directed against the adenoma (Fig. 32.34).

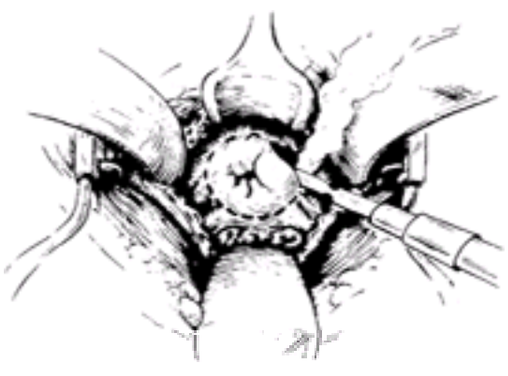

FIGURE 32.33. Circumferential bladder neck incision before transvesical enucleation of prostatic adenoma. The bladder neck is most easily exposed by the placement of small Deaver and malleable retractors laterally and a medium Deaver superiorly. The trigone and ureteral orifices should have been exposed and kept from harm's way. The incision through the mucosa overlying the bladder neck is best established with electrosurgical instruments. (From O'Conor VJ Jr. Suprapubic and retropubic prostatectomy. In: Harrison JH, et al, eds. *Campbell's urology,* vol 3, ed 4. Philadelphia: Saunders, 1979, with permission.)

FIGURE 32.34. Finger enucleation of the prostatic adenoma is best accomplished by “cracking” anterior commissural tissue and then establishing the plane between the adenoma and the surgical capsule on both lateral aspects. Although esthetically pleasing, intact removal of very large glands may be ill-advised. In that case, the use of lobe forceps may facilitate the sequential removal of lateral and middle lobe tissue. (From O'Conor VJ Jr. Suprapubic and retropubic prostatectomy. In: Harrison JH, et al, eds. *Campbell's urology,* vol 3, ed 4. Philadelphia: Saunders, 1979, with permission.)

The apex of the adenoma should be separated from the area adjacent to the external sphincter bilaterally; both lateral lobes should be free. The urethra should be divided sharply or bluntly by “pinching” just proximal to the distal apical adenoma. Traction on the distal urethra should be avoided while the capsule is teased from the apex of the adenoma to minimize sphincter injury. Finally, the adenoma should be separated with care from the bladder neck, especially posteriorly in the area of the ureteral orifices. Enucleation may be facilitated by placing the fingers of the free hand or an assistant's hand in the rectum to push the prostate ventrally in a cephalad direction. The sequence of the enucleation should be varied depending on the configuration of the adenoma and the ease of enucleation. At times, the median or subtrigonal lobe should be attacked initially. In a large gland with multiple adenomas, sequential removal is preferable to traumatic removal of the adenomatous growth in toto.

Unusual adherence of the adenoma to the capsule should increase suspicion of carcinoma. Once the adenoma is removed, rapid control of bleeding becomes the major concern. Often, a portion of the blood supply is identifiable as the adenoma is being removed and can be clamped and ligated. Unless bleeding is massive, rapid inspection of the prostatic fossa with supplemental lighting, a narrow Deaver, and partially open ring forceps to aid in the exposure is usually advisable at this time. Irregular tissue tags or fragments can be sharply removed; sizable bleeders can be controlled by suture ligature or by fulguration. Introduction of a gauze pack into the prostatic fossa with blunt-tipped forceps, a standard hemostatic procedure in the past, is now used selectively. It is an excellent maneuver to achieve rapid control of significant bleeding. Placement of side-on (Halsted) hemostatic mattress sutures of absorbable suture incorporating bladder mucosa, bladder neck, and prostatic capsule at 5 and 7 o'clock (Fig. 32.35) is facilitated by use of the so-called genitourinary (five-eighths) curved needle. The needle-bearing end of the tied suture can be used later to anchor the bladder neck to the prostatic fossa. The fossa should be inspected again by retraction as before, and significant bleeding should be controlled with suture ligatures or fulguration. Persistent bleeding from deep in the posterior aspect of the prostatic fossa can be controlled at times by three transverse plication sutures of 0 chromic catgut placed in the prostatic fossa as described by O'Conor (268) (Fig. 32.36). Before trigonalization of the prostatic fossa, a V-shaped wedge can be removed from the 6 o'clock area of the bladder neck if it is extremely tight (Fig. 32.37). Anchoring the bladder neck to the posterior aspect of the prostatic fossa facilitates hemostasis and prevents the formation of an obstructing membrane (Fig. 32.38). This maneuver also aids any subsequent catheter placement. At this point, a 22- or 24-Fr Foley catheter with a 30-mL balloon is directed into the bladder, the balloon is distended appropriately for the size of the bladder neck, and traction is applied.

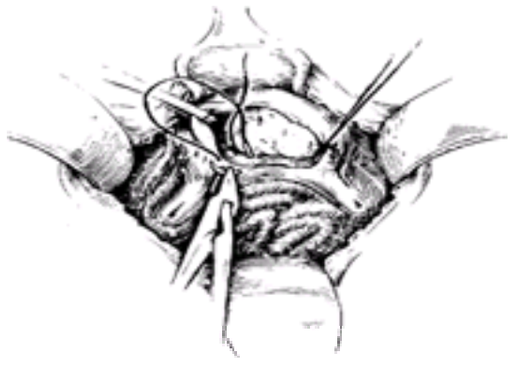

FIGURE 32.35. Placement of hemostatic sutures at the bladder neck. Although the urethral branches of the prostatovesicular artery traditionally enter at the 5 and 7 o'clock positions, this is highly variable. Placement of 0 or 2-0 hemostatic chromic sutures at the bladder neck or within the prostatic fossa is greatly facilitated by the use of $^{5}/_{8}$ curved genitourinary needles and fiberoptic lighting. (From O'Conor VJ Jr. Suprapubic and retropubic prostatectomy. In: Harrison JH, et al, eds. *Campbell's urology,* vol 3, ed 4. Philadelphia: Saunders, 1979, with permission.)

FIGURE 32.36. Placement of hemostatic plication sutures. Uncontrolled bleeding from the depths of the prostatic fossa can often be contained by the placement of several 0 chromic plication sutures into the posterior aspect of the prostatic fossa, creating an accordion-like effect. (From O'Conor VJ Jr. Aid for hemostasis in open prostatectomy: capsular application. *J Urol* 1982;127:448.)

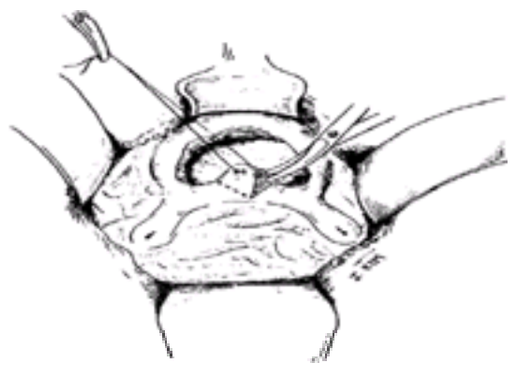

FIGURE 32.37. Wedge resection of bladder neck. Following enucleative prostatectomy, the bladder neck is generally patulous, and routine wedge resection is not necessary. In fact, one can take advantage of the capacious bladder neck by using the previously placed hemostatic sutures to “retrigonalize” the posterior aspect of the prostatic fossa. Should the bladder neck appear unduly snug, a ventrally directed wedge resection can be performed following either suprapubic or retropubic approaches.

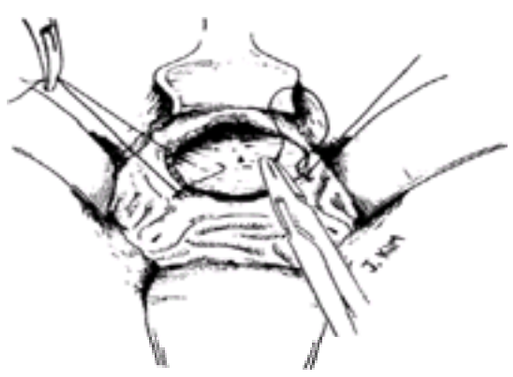

FIGURE 32.38. “Retrigonalization” of prostatic fossa. The previously placed and tied hemostatic mattress sutures at the bladder neck can be anchored to the posterior aspect of the surgical capsule to advance the bladder neck into the prostatic fossa. This maneuver aids hemostasis and facilitates appropriate healing.

Traditionally, problem bleeding has been approached by attempts at direct visualization and suture or cautery control, use of hemostatic agents such as microfibrillar collagen (Avitene) or oxidized cellulose (Surgicel) placed in the prostatic fossa with temporary gauze packing or wrapped around the balloon, or on rare occasions, by an occlusive, preferably removable, pull-out suture of the bladder neck (221). Use of modern endoscopic visualization and hemostatic procedures warrants consideration in these unusual circumstances. A large (28- to 36-Fr) Malecot or de Pezzer catheter placed through a separate stab wound in the bladder dome away from the peritoneal reflexion and the trigone functions as a drainage tube. After removal of all sponges, drains should be placed on each side of the bladder neck and brought through a stab wound just above and away from the symphysis. Bladder closure should be performed in two or three layers. The mucosa can be approximated with a running suture of 3-0 or 4-0 plain catgut, usually incorporating muscle as well. The superficial and deep muscle of the bladder can be reapproximated with interrupted Lembert sutures of 2-0 chromic catgut. The adequacy of closure and hemostasis can be assessed by through-and-through irrigation. The effluent should be pink to clear. The suprapubic tube should exit through a separate, superiorly placed stab wound. The appropriately placed drains and suprapubic tube should be secured at the skin level. Routine wound closure with absorbable sutures should include approximation of the rectus muscle. As the patient awakens from anesthesia, catheter irrigation should be repeated and traction maintained on the Foley catheter with adhesive strapping to the thighs. The urethral and suprapubic catheters are attached to separate drainage systems and intermittent or continuous closed irrigation used as desired. The patient should be observed as his blood pressure normalizes postanesthesia to ensure that adequate hemostasis has been achieved and patency of the catheter is maintained. Ordinarily, the Foley catheter traction can be released within 12 hours and the catheter removed on the second or third postoperative day. The drains may be removed when clinically apparent drainage ceases or after removal of the suprapubic catheter. The latter has generally been discontinued on the sixth or seventh postoperative day. This schedule is commonly advanced currently. If voiding is not resumed and the suprapubic tube site closed by 48 to 72 hours, reinsertion of the urethral catheter may be necessary. Persistent suprapubic drainage usually requires endoscopic and, at times, cystographic assessment to evaluate the possible presence of persistent obstructing tissue or a foreign body. Other, more remote causes may warrant consideration if the fistula becomes chronic.

Retropubic Prostatectomy

Retropubic prostatectomy using a direct ventral capsulotomy is judged by many to permit a more exact adenomectomy and facilitate direct hemostasis (156). Since its refinement and popularization by Millin (243), this approach has been preferred by many, particularly for BPH associated with prominent intraurethral components.

Antibiotic prophylaxis probably has added importance in the retropubic approach because of the increased risk of osteitis pubis (387). The preoperative preparation and operative approach are identical to those described for suprapubic prostatectomy except for advisability of decompressing the bladder before dissection on or about the prostatic capsule. As the result of experience with radical retropubic prostatectomy, exposure and suture ligation of the dorsal vein on the anterior surface of the prostate to permit incision of the capsule has become a common experience. After placing proximal and distal tagged sutures, a transverse capsulotomy is generally made with electrocautery or a scalpel 1 cm distal to the bladder neck. The capsulotomy should be extended to the lateral borders of the anterior capsule without violating or undermining the inferior edge of the capsule. Establishing the plane between the surgical capsule and the underlying adenoma (Fig. 32.39) is facilitated by using gentle traction on the stay sutures and curved Mayo or Metzenbaum scissors for dissection.

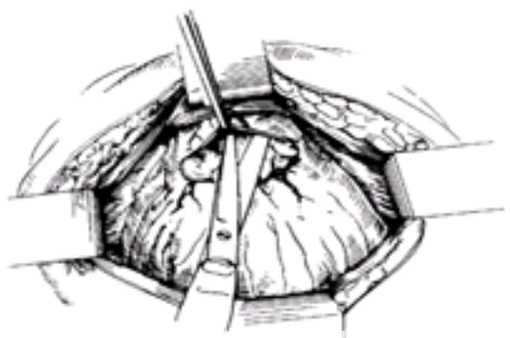

FIGURE 32.39. Retropubic prostatectomy is best performed through a transverse capsulotomy incision. Once the latter is established, the plane between the true capsule and the adenoma is best established with sharp dissection followed by standard digital enucleation. (From Staffon RA. Retropubic prostatectomy. In: Glenn S, ed. *Urologic surgery,* ed 3. Philadelphia: Lippincott, 1983, with permission.)

Once the appropriate surgical plane has been entered, the enucleation of the obstructing adenoma is similar to that described for suprapubic prostatectomy. In general, larger glands are more easily enucleated with blunt-finger or closed scissor-tip dissection. Unexpectedly small glands may be more precisely dissected sharply with curved tissue scissors. The enucleation should usually begin in the apical aspect of the gland. The urethra is easily divided under direct vision at the apex of the adenoma without tension. Bleeding sites are visualized and fulgurated or secured with suture ligatures. The direct access to the prostatic fossa provided by the transcapsular incision facilitates the achievement of hemostasis. After bleeding has been controlled, a wedge resection of the bladder neck may be performed if indicated. Similarly, retrigonalization of the bladder neck to the prostatic fossa should be considered to facilitate hemostasis, accelerate reepithelization, prevent fibrosis, and aid future retrograde catheter manipulations.

A 22- or 24-Fr Foley catheter with a 30-mL balloon should be inserted into the bladder, the balloon inflated appropriately, and gentle traction applied. After the catheter has been inserted, the capsulotomy is closed, usually with interrupted mattress sutures of 2-0 chromic catgut. Closure of the wound proceeds in a fashion identical to that described previously. A suprapubic catheter is customarily avoided but can be inserted if necessary. Again, intermittent or continuous closed irrigation can be used. The urethral catheter is usually left indwelling for 4 to 7 days.

Complications of Open Prostatectomy

Recent reports of short- and long-term experiences with open prostatectomy are conspicuously lacking. Consequently, the improvements in morbidity and mortality rates in surgical procedures in general that have occurred in the last two decades are reflected minimally in the data available regarding these presumably technically mature procedures. The reports of open prostatectomy used for the BPH guideline studies summary (230) were published in 1987 or earlier. The mean perioperative mortality rate was 2.4% (90% CI 1.0% to 4.6%). This compares with the progressively decreasing mortality rate at our institution: from 8.5% in 1942 to 1950, to 2.1% in 1961 to 1965, to 1.4% in 1965 to 1970, to 0% in 1971 to 1982 (257). The mean and median overall (any complication regardless of severity) complication rate cited in the guidelines is 21% (90% CI 7.0% to 42.7%). The 1.5% mean risk of perioperative intervention for bleeding and 35% risk of transfusion compares with 0.3% and 8%, respectively, by Nicoll and colleagues (261). In the latter series, more than half of the patients undergoing transfusion received 1 unit of blood, an unlikely occurrence today. The guidelines review indicated a mean incidence of epididymitis of 2.6% and of urinary tract infection of 13.4%.

Osteitis pubis is an uncommon postprostatectomy complication that can cause nagging to severe pain in the region of the symphysis, pelvis, or lower abdomen. Although most often associated with the retropubic approach, it can follow suprapubic and transurethral prostatectomy and even simple urethral instrumentation (107). Symptoms usually begin within 6 weeks of the operation. A low-grade fever, limited adduction of the thighs, and significant discomfort on bilateral medially directed pelvic pressure raises suspicion of the presence of osteitis pubis. Radiographic changes in the bone, although not always present, are usually recognizable 2 to 4 weeks after the onset of symptoms (385).

Complications usually but not always recognized with more prolonged follow-up include urethral stricture, with a mean incidence of 2.6%, and bladder neck contracture, with a mean incidence of 1.8% reported in the guideline review of open prostatectomy (230). Both are reported to occur more frequently with a suprapubic than a retropubic approach, but this may be more reflective of the period of data accumulation than the procedures. The mean incidence of new onset of postoperative erectile dysfunction (32% perineal, 16% retropubic, 18% suprapubic) is much lower than the risk of retrograde ejaculation (77%). The median risk of stress incontinence (retropubic, 1.5%; suprapubic, 2.6%) and total incontinence (retropubic, 0.5%; suprapubic, 0.3%) noted in the literature review seems likely to be relatively stable. Postoperative erectile dysfunction and incontinence are phenomena with multiple age-related causes that may be related temporally but not necessarily etiologically to the surgical procedure. The BPH guidelines report (230) cites an estimated re-treatment rate of 2% (CI 1% to 4%) within 1 to 5 years of performance of an open prostatectomy. No data are presented regarding the need for immediate intervention in patients who either are unable to void or have unimproved or worsened voiding dysfunction after surgical intervention. Patients who are unable to void, have persistent drainage from the suprapubic site, have unchanged or troublesome symptoms, or have chronic urinary tract infection require prompt evaluation, usually including consideration of endoscopic, voiding cystourethrographic, or urodynamic studies. Although less common than after TURP, failure to remove obstructive BPH tissue may occur with open procedures. Other factors, especially unsuspected neurogenic dysfunction, may be identified. In a Health Care Financing Administration–sponsored retrospective review of 2,617 Medicare patients undergoing a prostatectomy for BPH in 1985 (168 open, 2,449 TURP), the probability of reoperation in a 2-year time frame was 1.84% for patients undergoing open prostatectomy and 2.72% for those undergoing TURP (354). To our knowledge, no deleterious, long-term, systemic effects of open prostatectomy have been recognized or proposed on the basis of evidence.

Operative Results of Transurethral Resection of the Prostate and Open Prostatectomy

As recently as 25 years ago, a summary of mortality from BPH and its sequelae indicated surprisingly high rates in many countries. Admittedly, these data represent use of different criteria for assignment of cause of death and variable accuracies in reporting and accounting (310). Nevertheless, the development of adequate diagnostic and therapeutic approaches to BPH has been accepted by urologists and the medical community in general as an important advance in improving both survival and quality of life. Surprisingly, despite the fact that approximately 106,000 prostatectomies are performed yearly in the United States and that this procedure ranks high with regard to compensation by Medicare, reliable objective assessments of the effect of this procedure on prolongation of life and its quality are relatively sparse (153,160,389). During the past 50 years, the operative mortality rate associated with all of the commonly performed surgical procedures used to relieve bladder neck obstruction caused by BPH has declined (132) and continues to do so despite a continuing contraction of the pool of individuals who are denied consideration for these procedures because of the severity or multiplicity of comorbidities.

Recent reports in the United States indicate that the risk of mortality from open prostatectomy is much less than 1.0%, and the risk of death to patients undergoing

transurethral prostatectomy is less than 0.01% (240,354,378). This low mortality rate seems remarkable, because a selective survey of patients undergoing transurethral resections in the United States in the 1980s showed that a distinct minority (less than 25%) had no significant concurrent medical problems. In this survey, patients older than 66 years of age had a somewhat increased risk of death (0.33% compared with 0.09%); those older than 80 years and those with resected adenomas weighing more than 45 g had an increase in postoperative complications (240). The published results of a multi-institutional retrospective evaluation of 3,885 patients undergoing transurethral resection indicated a postoperative death rate of 0.23% within a 30-day postoperative period or during the postoperative hospital stay, whichever was longer (240). The common causes of death were sepsis and myocardial infarction. More recent studies report an operative mortality rate of 0% (378). This progressive drop was achieved despite the fact that TURP patients are prone to multiple medical problems. Information from the Medicare claims data suggests that the TURP mortality rate is age dependent, ranging from 0.01% at age 65 to 6.2% at age 85 (20). Roos and Ramsey (306) reported that the mortality rate from prostatectomy is more than double that usually reported if the observations include the 90-day period after operation rather than simply the time from operation until hospital discharge. Roos and colleagues (307) reported that review of data from substantial centralized data banks in the United Kingdom, Denmark, and the province of Manitoba in Canada revealed an increased death rate within a 5-year period in patients subjected to transurethral resection as compared with those subjected to open prostatectomy. The excess risk seemed to be related to death caused by myocardial infarction. The role of patient selection in this outcome, a highly probable explanation in the view of most urologists, could not be confirmed with the data available to the authors. Subsequent efforts attempting to compensate for comorbidity have yielded conflicting results. Malenka and colleagues (222) reported no evidence that comorbidity played a role in the 5-year mortality rate of patients subjected to TURP as compared with those subjected to open prostatectomy in a retrospective chart review of individuals operated at the Manitoba Health Center, Winnipeg, Canada, from 1974 to 1980. Open prostatectomy was the chosen procedure in about one-fourth of these patients. An evaluation based on record reviews of 1,617 Medicare patients operated in 1985 in seven geographically separated states failed to confirm an increased risk of death independent of comorbidity within the 2-year follow-up period in the 93% of patients undergoing TURP (354). In a related study of the incidence of acute myocardial infarction and cause - specific mortality after TURP and transurethral microwave thermotherapy (TUMT), investigators identified a higher number of myocardial infarctions than expected in the general population (145). The incidence of myocardial infarction following TUMT was slightly higher than after TURP. This phenomenon was judged to reflect an association of prostate enlargement and BPH voiding dysfunction with cardiovascular disease rather than being linked to either procedure. We agree with the BPH guidelines assessment (230) as well as others (327) and judge that the data supporting an independent role of TURP in delayed postoperative mortality is unconvincing at this time.

Prostatectomy by any route is a significant surgical undertaking that attempts to achieve a satisfactory functional and symptomatic status in a complex multifunctional system. Mebust and colleagues (240) cited an 18% incidence of complications in the immediate postoperative period after transurethral resection, including bleeding requiring transfusion, clot retention, and infection. Although Roos and Ramsey (306) reported that only 65% of the patients had no surgery-related problems within 2 years after prostatectomy, this figure seems likely to represent an overstatement of true complications because it includes, for example, patients who had a single urethral sounding postoperatively. Our estimate of the nonlethal, postsurgical complication rates after prostatectomy of 15% to 20% (132) compares to the mean incidence of surgical complications regardless of severity of 21% for open prostatectomy, 12% for TUIP, and 15% for TURP reported in the BPH guidelines (230). Not surprisingly, undesirable results occur because of inappropriate patient selection, unrecognized preexisting and imminent pathologic changes, and technical errors. Of the undesirable results, the inability to void and the development of incontinence are thought to be the most disturbing.

In the cooperative evaluation of transurethral resection, 6.5% of patients were unable to void when the catheter was removed, and 2.4% were sent home with an indwelling catheter; more than half of the latter had atonic bladders (240). Seaman and colleagues (324) documented impaired detrusor contractility in 25% of 129 symptomatic men undergoing delayed postprostatectomy urodynamic evaluation. This perplexing voiding dysfunction may result from chronic severe obstruction and may be at least partially reversible with long-term catheter drainage. We frequently use suprapubic catheter drainage in this group, often as a planned approach, to permit achievement of satisfactory symptomatic and objective voiding status.

Center studies report a low incidence of incontinence ranging from 0% to 1.4% for both open and endoscopic procedures (161,269). However, a prospective study of patients subjected to prostatectomy by urologists in the state of Maine reported that 4% had a problem with dripping or wet pants persisting for 1 year after operation (99). This study also reported a 15% incidence of one or more episodes of acute retention caused by blood clots within 3 months of surgery. The BPH guideline studies (230) indicate a median incidence of stress incontinence of 1.9% after open prostatectomy, 1.75% after TUIP, and 2.1% after TURP. The median incidence of total incontinence was 0.5%, 0.1%, and 1.0%, respectively.

With regard to sexual function, retrograde ejaculation is an anticipated phenomenon whose incidence has been reported to vary from 30% to 100% (42,242). A mean probability of retrograde ejaculation of 24.9% for TUIP, 73.4% for TURP, and 77.2% for open prostatectomy reported in the BPH clinical practice guidelines (230) supports the importance of surgical approach and technique in the occurrence of this phenomenon. In general, this postoperative sequela does not constitute a disabling problem for the elderly patient adequately prepared for its eventuality. In contrast to incidence of postoperative retrograde ejaculation, most men who are sexually active and have a willing sexual partner preoperatively maintain satisfactory erectile function after prostatic surgery. Finkle and Prian (94) reported potency rates of 95%, 87%, and 71% after transurethral, suprapubic, and perineal prostatectomies, respectively. Fowler and associates (99) reported that 5% of the patients in their survey indicated a persistent inability to achieve erections after transurethral resection. TUIP is associated with a 12% and TURP a 14% incidence of postoperative erectile dysfunction.

Current data indicate that previous estimates of re-treatment rates after surgical therapy of BPH have probably represented an underestimate. Taylor and Krakauer (354) cited a 2.7% probability of repeat prostatectomy within 2 years of TURP and a 1.8% probability within 2 years of an open prostatectomy. Many, if not most, of these repeated procedures resulted from technical errors. Others may represent unrecognized diagnostic errors. Roos and Ramsey (306) assessed the reoperative rate to be 17% for transurethral resection, 5% for suprapubic procedures, and 7% for retropubic procedures in an 8-year data accumulation based on Manitoba claims information. Data from Denmark and the United Kingdom (307) indicated a 12% reoperation rate, and data from Wisconsin showed a 16% reoperation rate (263) after transurethral resection in 8- and 7-year operation periods, respectively. The open prostatectomy reoperation rates at 8 years were 5% for Denmark and 2% for the United Kingdom (307). The estimated reoperation rate at 5 years cited in the BPH guidelines is 2% for open prostatectomy, 9% for TUIP, and 10% for TURP. These re-treatment rates include treatment of complications of the surgical procedure and removal of residual or recurrent BPH.

The previously mentioned mortality and morbidity data should not detract from the fact that most, approximately 90%, of all men subjected to prostatectomy for the treatment of BPH demonstrably benefit from the procedure (286,334). A variety of approaches to assess the results achieved by prostatectomy have been advocated and used, including subjective evaluation by the patient and objective assessments based on symptom scores, urodynamic evaluation, or both. Each has its advantages and disadvantages. The varying indications for surgical intervention complicate the evaluation when rigid criteria are used, as does the knowledge that approximately 45% and 40% of patients treated with placebo or watchful waiting report overall symptomatic improvement (230). The percentage of patients who judge their voiding symptoms to be better or much better after surgery varies from 75% to 93%, in part depending on the severity of the patient's initial symptoms and the duration of the follow-up (41,99,203). The BPH guidelines (230) review indicates an overall symptomatic improvement of 98% (90% CI 94% to 99.8%) for open prostatectomy, 88% (90% CI 75% to 96%) for TURP, and 80% (90% CI 78% to 83%) for TUIP. The guidelines data review indicates that the surgical procedures produced about an 80% improvement in symptom scores, appreciably higher than the 30% to 40% range for placebo and nonsurgical therapies. A multicenter randomized trial conducted at VA hospitals compared transurethral surgery with watchful waiting in a group of men classified as having moderate symptoms (378). Transurethral resection was significantly more effective than watchful waiting in improving genitourinary symptoms and avoiding treatment failure. The men who were substantially bothered by urinary problems had a 91% (134 of 148) chance of improvement as compared with 62% (45 of 73) for those with less bother. Complications and re-treatment rates were low. Nielsen and colleagues (263) provided some evidence that the improved symptomatology is maintained in most patients for more than 7 years. In every series, some patients' symptoms are unaffected by the prostatectomy, and some (3% to 12%) are worse. Although many have cautioned that patients with irritative as opposed to obstructive symptoms are at greater risk for poor results (175,203), an evaluation by Jorgensen and colleagues (175) failed to confirm this finding. Clearly, careful evaluation and selection are indicated in patients with predominantly irritative symptoms and may have accounted for the good results (90%) reported in this latter group of patients.

Postprostatectomy urodynamic evaluation usually demonstrates a marked shift in the various urodynamic parameters, including an increase in maximum urine flow rate and voided volume and a decrease in residual urine and voiding pressure that would be anticipated if a mechanical or functional outlet obstruction were diminished or relieved (3,203,263). The mean improvement in maximum flow rates in the BPH guidelines review was 14.4 mL per second after open prostatectomy and 9.8 mL per second after TURP, far greater than any other treatment analyzed except TUIP (approximately 7.3 mL per second). Current assessments tend to interpret the initial and posttreatment postvoid residual determinations with uncertainty and caution. Voiding is usually almost complete in normal individuals, and failure to approximate this normal state with treatment should be documented. Even with the casual way in which the data analyzed were accumulated, the mean posttreatment postvoid residual was less than 25 mL for TURP and open prostatectomy in the BPH guideline literature review (230). Reversal of some of the preoperative urodynamic abnormalities is much less predictable (Table 32.7). Furthermore, normalization or marked improvement of the preoperative urodynamic abnormalities does not necessarily correlate with a satisfactory clinical outcome. The role of urodynamic evaluation in the routine selection and monitoring of patients subjected to prostatectomy is not clearly established (79). However, use of these procedures as a part of preoperative assessment of patients with a symptom complex of equivocal etiology or with a postsurgical result that is less than expected or optimal is gaining increasing acceptance. The selective inclusion of

synchronous video pressure-flow cystometry promises to enhance the useful information derived from these studies (324).

Preoperative Cystometric Diagnosis	Postoperative Cystometric Diagnosis (% of Patients)		
	Normal (70%)	Hypersensitive (7%)	Unstable (23%)
Normal (28%)	23	1	4
Hypersensitive (16%)	12	4	0
Unstable (56%)	35	2	19

ALTERNATIVE PHYSICAL INTERVENTION APPROACHES

In the past decade, the number of procedures that use new devices and technology, yet are based on old concepts of mechanical disruption or tissue destruction, to modify or eliminate bladder neck obstruction has proliferated. These efforts are not inappropriate. Past experiences indicate that technical improvements and refined understanding have resurrected useful therapeutic alternatives from essentially discarded approaches for a number of medical problems. Enthusiastic reassessment of procedures that may reduce local and overall morbidity and maintain or improve immediate and long-term physiologic results is understandable and laudable. Currently, assessment of these various efforts is hampered by the limited number of patients subjected to evolving selection and technical approaches and the limited period and, at times, the nature of the follow-up information provided. Most of these treatment efforts, including laser and microwave techniques, use heat effects to alter or destroy prostatic tissue.

Heat-induced Tissue Alterations/ Destruction Procedures

Use of local heat to attempt to reduce tissue mass or produce functional change to improve objective and symptomatic effects of obstruction has been attempted repeatedly by numerous approaches since the beginning of the twentieth century. Efforts with hot water administered by irrigation through the rectum or urethra, and a wide range of attempts using electrical current with high-frequency faradic or galvanic stimulation administered via the urethra, rectum, or perineum, have been reported (80). Edwards (80) also cites the rectal thermoprobe heated to 108° to 122°F used by Corbus and O'Conor in the late 1920s and the localized high-frequency current applied directly by transurethral application for short periods of time by Kerwin in the 1930s. Historically, the problems with therapeutic attempts using heat were related to ineffectual, inadequate, or uncontrolled heating of the targeted site and inadvertent heat damage of adjacent tissue.

Three novel basic approaches are currently being used to generate intraprostatic tissue heat and consequent tissue destruction. One uses laser energy, a second, microwave energy, and a third, ultrasound energy. All of these approaches use a source that has the potential to produce quantifiable amounts of transportable energy that can be directed regionally or focused and can be converted with reasonable predictability to regionally confined heat. None yields tissue for analysis. Removal of the heat-damaged tissue usually relies on active participation of biologic phenomena. Transiently increased tissue volume or dysfunctional states frequently require posttreatment catheterization, at times for prolonged intervals.

Microwave Treatment of Prostate Disease

Electromagnetic waves have the potential to penetrate tissue and induce local changes that produce heat. These microwaves are transverse electromagnetic waves with frequency in the range of 30 to 3,000 MHz. The physical properties governing clinical treatment depend on wave propagation that is reflected or scattered in a tissue at interfaces where two substances with different impedence occur. This raises the temperature of the tissues. Those treatments that achieve temperatures of less than 44°C are termed *hyperthermia,* those achieving a temperature of more than 44.5°C are termed *thermotherapy,* and those achieving a temperature above 65°C are termed *thermoablative* (283). To destroy prostate tissue, microwave treatment must deliver a crucial *thermal dose,* defined as a multiplicative product of exposure temperature and duration of exposure. The energy applied by the system is not a predictor of the thermal dose. The critical values are the temperature achieved within the gland and the period for which that temperature is maintained. The amount of energy deposited within a given tissue depends on the size, shape, and electrical properties of the tissue being treated, the frequency and intensity of the microwaves being used, and the size and shape of the microwave antenna. Antenna design can be crucial in the efficient transfer of microwave energy into the prostate as heat. The dipole antenna found on certain microwave devices is designed to exhibit impedence matching with the target tissue. Monopole designs found in other devices (Prostatron) have been found by experimental observation to lack the capability for impedence matching. Differences in impedence matching affect efficacy and translate into higher delivered thermal doses and ultimately greater clinical benefit. Temperature mapping studies have shown that the treatment area within the prostate is not symmetric and that the temperature within the prostate during treatment may be different in different areas of the gland and even at the same distance from the catheter. Current evidence indicates that substantial intraprostatic temperature elevations are required for thermal ablation and necrosis and optimal clinical outcome. The variation in intraprostatic temperature during treatment results in varying amounts of coagulation because BPH tissues require at least 30 minutes at temperatures greater than 45°C.

Transurethral therapy has been used for both hyperthermia and thermotherapy. However, the need for repeated treatments requiring urethral catheterization has resulted in loss of interest in the use of hyperthermia by this route. The objective of TUMT is thermoablation or thermotherapy to induce necrosis of the obstructive prostatic tissue while maintaining normal temperatures in nontargeted tissues. Significant differences exist between microwave treatment systems. Differences pertaining to the antenna design, the heating pattern generated, and the treatment protocol should be carefully considered when choosing microwave treatment for patients. TUMT was pioneered using the Prostatron (Technomed, France) microwave system, and this system has been extensively investigated. A more recent modification of this system, the so-called high-energy TUMT (HE-TUMT) Prostatron treatment protocol (Prostosoft, version 2.5), has been introduced to enhance treatment efficacy. The more recently developed Targis microwave system (Urologix, Minnesota) has also been the subject of investigations. Less investigated clinical trials include the Microthermer (Laser Electro-optics, London, UK), Prostalund (Lund Instruments, Lund, Sweden), Urowave (Dornier, Germany), Prostcare (Wissenborg, France), and Thermex-II (Direx, Israel).

The Prostatron and Targis devices can generate intraprostatic temperatures of 45° to 70°C. In the current nomenclature, HE-TUMT has become synonymous with the application of these higher thermal doses. In this context, the HE-TUMT has been applied both to the updated Prostatron 2.5 software treatment and to the use of the Targis system by either standard or abbreviated protocols. For optimal results, the thermal dose should be confined to the prostate gland with minimal heating of nontarget tissues such as the rectum, bladder neck, and sphincter. Hitting nontarget tissues increases the risk of complications, limits treatment efficacy by inducing automatic power shutdowns, and reduces the patient's ability to tolerate the treatment. Nontarget heating also necessitates the use of significant anesthesia, reducing the appeal of the outpatient procedure. Both devices use cooling channels on the urethral catheter to preserve the urethral mucosa in an attempt to reduce discomfort and promote a faster recovery.

Patient selection is crucial when considering TUMT. Patient factors such as prostate volume, prostate gland configuration, and willingness to undergo a urethral treatment under local anesthesia must be addressed. Prostates with marked middle lobe configurations may distort the urethral catheter positioning, making for irregular prostate heating. In addition, prostate volume and size at the extremes (less than 25 g or greater than 100 g) may preclude effective heating; thus size constraints should be addressed before beginning treatment. Urethral strictures may confuse evaluation of BPH voiding dysfunction and interfere with proper catheter placement. Such obstructions should be ruled out before treatment. Patients with pacemakers, defibrillators, and pelvic and penile prostheses should not be treated with such devices because of significant mechanical or electronic damage to the devices.

The potential advantages of the microwave technique include the relief of lower urinary tract symptoms with an in-office procedure using minimal anesthesia and a potentially rapid recovery. Because the Prostatron device has a longer period of evaluation, many of the long-term studies of microwave treatment and the associated failures involve this device. Many of the more current devices and software programs have not been available for long enough to be critically evaluated with long-term

follow-up. Consequently, this limitation does not necessarily reflect a difference in clinical outcome between devices.

A recent prospective sham-controlled study addressing HE-TUMT in BPH revealed that active treatment resulted in a significant and marked decrease in AUA symptom score from a mean of 20.8 to 10.5 while the sham group also decreased but to a lesser extent (21.3 to 14.3) (195). Peak urinary flow rate in the microwave group increased 51% at 6 months; this postprocedural increase was significantly greater in the microwave than in the sham group. Similarly, quality-of-life score also improved in the active arm. Although follow-up was short (at 6 months), this study demonstrated effective treatment for BPH with an impact on important outcome measures. Of more concern is the durability of improved response in patients undergoing TUMT. Using an HE-TUMT device (Targis), one group of investigators has demonstrated significant improvement in symptom score, quality-of-life score, maximum flow rate, postvoid residual, and decreased mean detrusor opening pressure that was durable at 24 months (356). One provacative study using an older software version (Prostatron 2.0) demonstrated initial significant improvement in patients' level of satisfaction with treatment (146). However, over a 4-year period there was a marked decrease in the number of satisfied patients from 62% at 1 year to 23% at 4 years. The initial decrease in symptoms and increase in flow rates was followed by reversal at the 4-year follow-up. Of concern, two-thirds of patients received supplementary BPH treatment within the 4-year time period. The cumulative risk of subsequent TURP re-treatment of 40.5% at 5 years of follow-up, and a percent cumulative risk of any re-treatment (including a-adrenergic blockers) of 57% (182), added to this concern. In summary, this minimally invasive therapy appears to balance efficacy versus tolerability, and this balance might be tenuous for patients in the long term.

In comparing HE-TUMT versus a-adrenergic blocker treatment in patients with BPH voiding dysfunction, a-adrenergic blockers afford a more rapid improvement in symptoms, voiding function, and quality of life. When compared with HE-TUMT–treated patients, this advantage is present for a relatively brief 6 weeks because HE-TUMT offers a superior clinical outcome after the recovery phase is complete (6 to 12 weeks) (75). Other investigators have identified neoadjuvant and adjuvant a-adrenergic blocker treatment resulting in significantly better early symptom reduction after TUMT, suggesting that post-TUMT complications can be reduced by using a-adrenergic blockers in the immediate post-TUMT period (76).

Currently reliable pretreatment identification of patient characteristics that consistently predict a successful outcome to TUMT is not possible. In one controlled study, the proportion of patients achieving AUA symptom scores less than 9 was similar among patients with initially moderate symptoms versus those with severe symptoms (195). Surprisingly, no significant correlation has emerged between pretreatment prostate volume and TUMT outcomes. However, our experience has been that patients with a prostate volume at the extremes (less than 25 g or greater than 100 g) are less likely to be successfully treated with TUMT therapy.

Complications reported for TUMT cite an overall rate of 38%, including 3% with acute incontinence, 13% with infection, and 11% with urinary retention of a mean duration of 17.5 days (291). One study demonstrated posttreatment convalesce as being relatively rapid, with 55% of patients with less than 3 days at home and a mean of 5 days at home (291). This suggests in some patients relatively early return to full activity. Pain management has been addressed in several prospective studies, with approximately 70% of patients describing discomfort with HE-TUMT and only 30% describing treatment-associated moderate or severe pain. These observations appear to substantiate claims of minimal anesthesia for this technique.

In general, such minimally invasive techniques may strike a precarious balance between patient tolerability and efficacy. The long-term results of this compromise are not yet clear. It should be stressed when considering these types of therapies that the most cost-inefficient treatments of a disease are serial treatments in which patients are run through a gamut of therapies such as a-adrenergic blockers or minimally invasive techniques before more standard prostatic surgery is performed. The old surgical advice of “doing the last operation first” may well apply to many such minimally invasive treatments.

Laser Prostatectomy

The rationale, technical considerations, and results of the use of the laser to reduce prostatic mass are presented in detail in Chapter 6. Tissue destruction by the laser relies on conversion of light energy to heat. Although laser energy can be delivered through narrow-diameter fibers that can be accommodated in small endoscopes, appropriate direction of the energy and controlling and judging the depth of its penetration have presented continuing challenges.

Because of the potential appeal of an ambulatory prostatectomy procedure and the increased availability of lasers in the operating room, many methods for performing a so-called laser prostatectomy using a variety of laser sources, wavelengths, and beam delivery systems to achieve combinations of coagulation necrosis, tissue vaporization, and cutting have been developed. Although variations in technique and delivery are marked, commonalties of all laser prostatectomies depend on prostate tissue heating by absorption of the laser energy and its conversion into thermal energy. The volume of tissue that heats beyond coagulation temperature (60°C) during these laser prostatectomies is dependent on laser variables (irradiation time and power), delivery fiber variables (diameter, beam angle, divergence, power intensity), tissue variables (carbonization, tissue absorption, and light scatter), and surgical variables such as the distance of the fiber to the tissue and the number of lasings. The Nd:YAG laser has been used for coagulation prostatectomy [visual laser ablation prostatectomy (VLAP)] since the 1990s with a goal of creating zones of coagulation to eventually result in a decrease in prostate outflow obstruction. This technique, although popular with patients and physicians, has been largely supplanted by contact lasers using a variety of techniques but sharing in the attempt to duplicate prostate nucleation akin to a TURP. This newer technique requires tissue vaporization using either the Nd:YAG laser at a high power density or a holmium:yttrium-aluminum-garnet (Ho:YAG) laser. Variable techniques employed use tissue vaporization to enlarge the prostatic urethral cavity and remove prostatic tissue. The pulsed Ho:YAG laser offers an additional thermomechanical vaporization and is used as a cutting tool analogous to the TURP. These laser techniques offer the advantage of reducing blood loss because the wavelength and pulsed energy delivered creates enough heat below the cut prostate surface to provide hemostasis. Another approach to laser prostatectomy includes the placement of interstitial light guides [interstitial laser coagulation (ILC)] directly into the prostatic adenoma during cystoscopy. This allows the creation of larger coagulation lesions than the free beam laser penetration because laser penetration is possible circumferentially around the diffusing fiber tip. With ILC, intraprostatic temperatures rise as high as 85°C, and they are automatically adjusted by intrinsic temperature probes and computerized feedback mechanisms.

Several investigators have reported on the comparison of standard TURP with contact laser vaporization. Using laser vaporization, the symptom score, quality of life, peak urinary flow rates, and postvoid residuals improve similarly although to a variable degree to those found in patients undergoing TURP (78,183,227). Distinct advantages of the laser approach include reduced blood loss and less concern with patient coagulation status. These patients may also have higher rates of recatheterization and reoperation. Operating time using the laser increases when compared with TURP (116). Urodynamic results were equivalent at 6 months, and effects on continence, potency, and symptoms are similar between both groups (364). Our experiences with this technique are limited; however, we have found it more cumbersome in the operating room and without distinct advantages to physician, patient, or institution. The effectiveness of the interstitial laser therapy is more controversial. This stems from its hybridization of an intra–operating room procedure combined with a minimally to moderately invasive technique. Whether this combination of characteristics supplants a more standard intraoperative intervention is yet to be determined. In the limited number of publications available concerning this technique, it appears that there are significant improvements in AUA symptom scores, flow rates, and postvoid residuals between baseline and relatively short follow-up periods (9 months) (134). One study demonstrated significant increases in peak flow rates from 8.3 to 12.0 in 9 months and marked decreases in AUA symptom scores from 20.2 to 9.8 during the same interval. Although patient groups tend to be small in these limited reports, intraoperative complications are few. A sizable minority of patients subjected to ILC have prolonged urinary retention requiring intermittent catheterization (9). One study reported significant changes in peak flow rates (having increased by 50% from a preoperative average of 7.4 to 11), postvoid residual urine (decreasing by 57%, 102 to 44), and marked changes in symptom scores. Surprisingly, only 8% of patients required re-treatment for persistent obstructive symptoms during a 12-month follow-up period (9). Side effects include retrograde ejaculation and urinary tract infections with a minimal impact on sexual function. A prolonged postoperative mean catheterization of 13 days is less than ideal. At this point, it is not clear what the exact role of interstitial laser coagulation will be; however, it is likely that improvements in efficiency will continue.

Transurethral Electrovaporization of the Prostate

As stated, laser prostatectomy has perceived advantages over conventional TURP, including a nearly bloodless tissue ablation (even in anticoagulated patients) and, possibly, a more abbreviated hospitalization. It has achieved improvements in parity with TURP, as reported in short-term follow-up studies. However, laser-assisted TURP possesses a number of observed and potential disadvantages that have tempered enthusiasm for this approach. Based on previous experiences, failure to achieve removal of most or all BPH tissue constitutes a significant concern as to the durability of the reported results. In addition, laser machines and fibers are expensive, and their use requires an easily acquired, but nevertheless special, expertise. Transurethral electrovaporization of the prostate (TUVP) was developed by making simple modifications to existing TURP equipment in the hope of maintaining the advantages and minimizing the disadvantages of laser prostatectomy at the tissue level.

The strategic component of TUVP is any one of several modifications of a multigrooved electrode that replaces the traditional loop to achieve tissue vaporization for a 3- to 4-mm zone and coagulation of an underlying 1- to 3-mm zone (Fig 32.40). The electric current is concentrated on the outer edges of the resulting ridges, producing a thermal reaction that raises tissue temperatures to greater than 100°C. Because the procedure is performed under glycine irrigation, the desiccated tissue rehydrates, rendering it susceptible to vaporization on a subsequent pass. If bleeding occurs, a coagulation current of about 60 W is used for local control. In

theory, the end result eliminates the targeted obstructing prostatic tissues while minimizing both bleeding and water absorption.

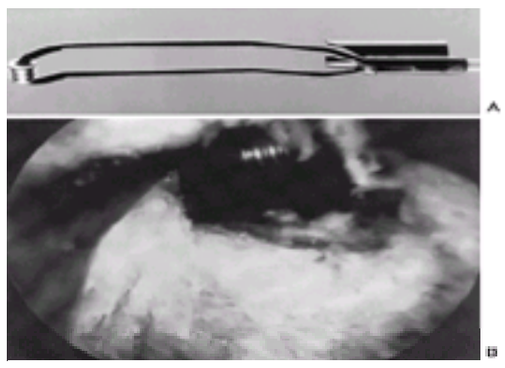

FIGURE 32.40. A: Terminal configuration of Vaportrode electrode. **B:** Tissue effect of TUVP. Too rapid progression of the electrode results in less vaporization and more coagulation. Too slow progression results in vaporization with a greater zone of coagulation, hampering subsequent vaporization. (From Kaplan SA, Te AE. Transurethral electrovaporization of the prostate: a novel method for treating men with benign prostatic hyperplasia. *Urology* 1995;45:566, with permission.)

As described by Kaplan and Te (179), the operative technique is similar to a standard TURP. In general, the middle lobe is vaporized first from the bladder neck to the verumontanum. Overlapping sweeps of the electrode from 1 to 5 o'clock and 11 to 7 o'clock are used to remove the lateral lobes. The surgical goal remains the visualization of the white fibers of the surgical capsule. Desired tissue sampling can be achieved with a standard resectoscope with subsequent resumption of the TUVP. The indwelling catheters are removed within 24 hours. Patients are frequently discharged on the first postoperative day or, increasingly, on the day of the procedure. The reported experiences and personal clinical experiences with TUVP attest to the safety and short-term effectiveness of this technique (106,147,178). As a composite, these studies demonstrate that patients observed for approximately 1 year after undergoing TUVP exhibited a significant improvement in their AUA symptom scores and peak urinary flow rates. None of the patients demonstrated significant changes in hematocrit or serum sodium levels. The procedure has been used successfully in patients on anticoagulation therapy (179). When compared with TURP, TUVP is as effective with regard to changes in symptom scores, postvoid residual urine volumes, and peak urinary flow rates (86). Some investigations report a slight advantage to the standard TURP in the aforementioned outcome parameters, but with significantly longer operative times (178). The incidence of retrograde ejaculation appears to be significantly higher in the TURP group (192). The reported results will require confirmation with additional long-term studies. The reported opportunity to combine visually controlled tissue ablation with increased hemostasis while using familiar, generally available basic equipment to treat BPH voiding dysfunction has significant appeal and apparent promise.

Transurethral Needle Ablation

The transurethral needle ablation (TUNA) procedure uses low-level radiofrequency (RF) energy to coagulate hyperplastic prostate tissue and create zones of heat-induced coagulation necrosis. The RF electrical energy is applied to the tissue by having two electrodes in contact with the patient. The electrode responsible for delivering RF energy and heating the tissue is the “active” electrode with a characteristically small surface area. The second electrode is referred to as the “indifferent,” or return, electrode and is characteristically large in surface area and is applied externally. The indifferent electrode serves to collect the RF current being delivered by the active electrode. Because the indifferent electrode is large in size, RF current is diffuse and therefore no tissue heating occurs. Because the active electrode has a small surface area, RF current is concentrated in the area immediately surrounding the electrode. In the present design, the active role of the electrode is played by two needles, which are deployed at acute angles from the tip of a specifically designed TUNA cystoscope, which is directed strategically into the adenoma. The needle lengths of this active electrode are adjustable to accommodate varying sizes of prostates. During the procedure, the needle temperatures are periodically raised to obtain a temperature of 53°C at the tip of the needle shield, which just barely penetrates the urethral mucosa. Adjacent to the needle tips, temperatures are as high as 100°C. Two centimeters beyond the needle tips, the temperatures approximate normal body temperatures. The high temperatures induce tissue desiccation and coagulative necrosis, which is reabsorbed over several months, causing cavitation that ultimately is filled in by expansion of the surrounding tissue. It is said that patients have a mild sensation of dysuria while the procedure is ongoing, but a significant number supposedly tolerate the procedure under local if not vocal anesthesia. Short-term results of the TUNA procedure to treat symptomatic BPH have been moderately encouraging. In a prospective randomized 1-year clinical trial comparing TUNA versus TURP, both TUNA and TURP resulted in statistically significant improvement in AUA symptom scores, bother, and quality of life (40). Peak flow rates and postvoid residuals were also improved. TUNA had less effect on sexual function, with TURP being associated with a greater incidence of retrograde ejaculation. However, TURP had a statistically significant, greater improvement in AUA symptom scores and peak urinary flow rates than TUNA. This suggests that both procedures are efficacious, but TURP may be more so. Side effects of TUNA include inability to tolerate the procedure, irritative voiding symptoms that can last up to 3 weeks, urinary retention greater than 1 week, hematuria, retrograde ejaculation, and urinary tract infection. Our group has chosen not to use this device as a minimally invasive alternative. Its long-term acceptability will depend on the durability of the results and its comparison with other minimally invasive techniques (318).

High-intensity Focused Ultrasound

Exploration of the use of high-intensity focused ultrasound (HIFU) to achieve selective tissue ablation is in its infancy in clinical medicine. As ultrasound waves propagate through a tissue, they are progressively absorbed and the energy is converted to heat. Therapeutic systems generating clinically significant heat with ultrasound are being developed. With use of these systems, a beam of high-intensity ultrasound is brought to a tight focus at a specific location within the prostate to produce a dense area of thermal energy that can selectively destroy tissue without damage to the surrounding structures. Ultrasonic energy can be focused in a small volume of tissue with the local production of temperatures of 80° to 90°C. The resulting coagulation necrosis achieves a reasonably predictable reduction in tissue volume in targeted tissues (28). Development of a transducer combining the potential for visualization and high-power ablation in the same element was made possible by the use of piezoelectric ceramics. The delivery probe covered with a condom is inserted transrectally. When the ultrasound energy is focused on the prostate, the temperature rises to exceedingly high levels, inducing protein denaturation, cell death, and cavitation effect. Because high temperatures are reached rapidly within the prostate, each location is treated for a short period of time; multiple sequential targeting is necessary to treat a larger prostate volume. To achieve positional and target accuracy, the prostate must remain completely immobile throughout the treatment. General or regional anesthesia is usually necessary to ensure this and permit extensive thermometry monitoring. Consequently, designation of HIFU as a minimally invasive technique may be questioned. Initial clinical experiences in patients with BPH have been reported. A marked increase (4.8 to 18.2 ng/mL) in serum PSA at 48 hours has been noted. In one study, cystoscopic evaluation at 6 weeks varied from no discernible change to an evident necrotic channel transurethral defect (28). In this group of patients, the AUA symptom score at 3 months decreased by 10 or more in 13 of 15 patients; the average flow rate improved in 13 patients but increased 3 mL per second or more in only 8; and mean residual urine decreased from 154 to 123 mL, with 6 patients showing stable or increased residual urine. In another study consisting of 36 patients, comparable changes were noted (219). At 6 months, the average AUA symptom score of 25 decreased to 13 in these patients. The maximum flow rate increased from 9.0 to 13.4 mL per second, and mean postvoid residual urine decreased from 128 to 57 mL. More recently, Uchida and colleagues (365) reported a preliminary study of patients with BPH; they demonstrated significant changes in AUA symptom scores (20.6 to 11.7), increases in flow rate (8.9 to 15 mL per second), and reduction in total prostate volume (32.2 to 22.8 g). There was a significant urinary retention rate (64%) that required an average of 5 days of catheterization. More disappointing, TURP was performed within 3 years in 31% of these patients, suggesting the early state of development of this technique. Focused ultrasound has a potential advantage of producing very exact and localized tissue-destructive lesions without direct invasion of the lower urinary tract and is an approach that seems to deserve further effort and consideration.

Balloon Dilation

Mechanical dilation of the bladder neck and prostatic urethra has been used in the past to attempt to treat bladder neck obstruction from BPH. It has been undergoing a reassessment with pressured balloon dilation to arbitrarily selected diameters. The recent success of balloon dilation of diseased blood vessels and strictures of the biliary and urinary systems led to a reassessment of the possibility that balloon dilation of the prostatic urethra may result in relief of bladder neck obstruction. Because of the lack of significant clinical effect and high re-treatment rates at relatively short intervals, enthusiasm for this technique has deflated.

At this time, the local anatomic and physiologic goals of balloon dilation are not clearly identified. Disruption of the integrity of the anterior commissure, reduced functional tissue mass, and possible local nerve damage have all been observed or postulated. However, a predominant procedural requirement for successful relief of BPH voiding dysfunction has not been defined. As a consequence of this, procedure-related predictors of successful accomplishment of this goal are lacking.

Clearly, some patients void with decreased symptoms and improved objective urodynamic parameters after balloon dilation of the prostate or bladder neck. The mechanism and durability of the improvement have not been clearly identified.

Recently, a procedure combining balloon distention with transurethral water-induced thermotherapy was reported (253a). In this technique, an 18-Fr catheter with a positioning balloon is placed such that the in-series 50-Fr treatment balloon occupies the entire prostatic urethra. Heated water maintained at 60°C is circulated for 45 minutes. Although there was no control group for comparison, the majority of the 125 patients treated had significant changes in their symptom scores and peak urinary flow rates that were durable for 1 year. How this technique compares to other minimally invasive techniques is not known, but it appears to require lengthy periods of catheterization after treatment and a slower symptom improvement time frame. Further investigations using a control group are warranted.

PERSPECTIVES

In this chapter, we attempted to summarize the current status of our understanding of various aspects of growth, development, and pathophysiologic effects of BPH and what can be done about them. We are impressed by the effort reflected in the number of studies of these phenomena, but our enthusiasm for the new information being put on our table is limited. We still do not know why BPH develops universally or why it grows selectively in the androgen-diminished environment of the aging male. Investigative efforts to add insights into these questions are disappointingly limited. Attempts to improve clinical evaluation to identify, understand, and characterize the changes in the urinary tract associated with and resulting from BPH seem at times targeted at the easy to do, measure, or calculate. We continue to think that evaluation of the ability of the bladder to empty and visualization of the configuration of BPH and the changes it may cause in the bladder are important both to help confirm the impression that a patient's voiding dysfunction is probably caused by BPH and to guide treatment efforts. However, we often seem to relegate this information to a secondary role and then fail to document the effect of the various treatment efforts on the diagnostically discriminatory abnormalities we identify. For example, if an enlarged BPH mass that is postulated to be the cause of voiding dysfunction is treated by drugs or physical means such as surgical excision or direct or indirect heat ablation, how often is a decrease in prostatic mass documented? At least with excision, the amount of tissue removed can be determined and reported. Residual prostatic mass can be assessed after treatment using imaging studies, but this seems to be done, or at least reported, infrequently. Similarly, if a postvoid residual urine is determined to provide evidence of BPH effect on voiding, its posttreatment status should be evaluated and determined. Reports of the effects of various treatment approaches including drugs should contain an appropriate spectrum of physical and physiologic observations, as well as symptomatic status. The concept of an intrinsic functional component to BPH bladder outlet obstruction, whether by internal prostatic or bladder neck constriction or by external prostatic capsular constriction, seems reasonable, but convincing direct evidence of its role is not. The possibility that a behaviorally induced and modifiable functional abnormality can produce significant symptoms and pathophysiologic effects in the lower urinary tract is adequately confirmed in children and, based on data from the control groups participating in drug treatment trials, seems likely to occur in adults. Objective evidence must be presented to correlate symptomatic, physiologic, and anatomic changes after, as well as before, therapeutic efforts.

At this point, we have an escalating number of alternative procedures that attempt to reduce BPH mass in patients with presumed BPH voiding dysfunction. In general, these constitute new approaches to achieve historical aims, namely, appropriate tissue removal and destruction. The procedures have varying advantages and disadvantages that center on the necessity to use anesthesia, risks of adjacent tissue damage or bleeding, use or duration of urethral catheter drainage, rapidity of systemic and local recovery, availability of tissue for histologic study, and durability of effects achieved. To evaluate the effect of these on BPH voiding dysfunction and BPH, we need to accumulate objective evidence of what we have done to the BPH tissue, the effect of this on objective and subjective voiding parameters during and after healing, and longer-term effects on prostatic mass and voiding. This information is necessary if we are going to identify appropriate management alternatives for patients with BPH and voiding dysfunction. Our challenge is to maintain our commitment to identify and do what is best for our patients while being open to new, better ways to do it and especially to new concepts of disease or treatment.

Adenocarcinoma of the prostate (CaP) is a major factor in the health of the male population in the United States and many other countries in the Western hemisphere. It is the most commonly diagnosed cancer among American males and constitutes the second most common cause of male cancer death (386). Projected estimates for the year 2000 from the American Cancer Society (ACS) suggest that CaP will account for approximately 29% (180,400 cases) of newly diagnosed cancers in males. Similarly, CaP will be responsible for 11% (31,900) of all male cancer deaths (386).

CaP remains the most common malignancy in males. Incidental or latent CaP has been detected in approximately 10% to 20% of prostate tissue specimens analyzed following prostatectomy performed because of benign prostatic hyperplasia (BPH) voiding dysfunction (448,604,1110). Unsuspected CaP has been identified in approximately 30% of autopsy specimens in males older than 50 years of age. Its prevalence increases progressively with age, tripling by the ninth decade.

Prostate-specific antigen (PSA), first characterized in 1979 (1071), has been widely used since the late 1980s to identify individuals with increased risk of CaP. As a consequence, the incidence of CaP in the United States increased significantly in a manner consistent with the pattern anticipated following introduction of a sensitive screening test. Concomitantly, the mean age at diagnosis of CaP was lowered from 70.7 to 68.8 years (650). Furthermore, many cancer registries have reported a distinctive “stage shift” with a trend toward diagnosis at an earlier stage of disease than would be predicted by early cohort studies. Accruing evidence suggests PSA and related testing may be responsible for a reduction in the mortality rate from CaP. Between 1900 and 1995, the CaP death rate in the United States for white men younger than 75 years decreased more than 14% (829). Aside from the pervasive use of PSA testing, no other obvious changes in treatment or diagnosis can logically account for the perceived decline in death rates.

African American men have the highest incidence of and mortality from CaP in the world (21). The differences in the incidence of CaP between white and African Americans are most dramatic in men younger than 65 years; in this age group, whites had a rate of 45.5 per 100,000 compared with 81.5 per 100,000 for African American men (96). Despite the trend toward decreased mortality rates from CaP that have been observed recently, the mortality rate remains greater in African American men than in their White counterparts (668). Specifically, the mortality rate of 55.1 per 100,000 observed in African American men is more than two times that observed in their white counterparts (24.7 per 100,000) (527). This striking difference in incidence and mortality may be due to various factors. For example, African American men have a rate of high-grade prostatic intraepithelial neoplasia (PIN) 50% higher (854), exhibit a greater percentage of high Gleason histotype tumors (769), and present with an advanced pathologic stage more often (646) than white men. However, once adjustments are made for stage and grade at diagnosis, age, number of primary cancers, and initial treatment, there appears to be no difference in the likelihood of CaP mortality between the two races (646). These observations are concordant with those of Eastham and Kattan (491) whose analysis of radical prostatectomy specimens failed to demonstrate significant differences in pathologic stage or grade in white and African American men diagnosed with clinically localized CaP. Furthermore, there was no obvious difference in the rate of biochemical recurrence between the groups, despite the fact that African American men presented with higher pretreatment serum PSA levels (8.0 versus 6.1 ng/mL) and higher PSA densities. The latter two studies suggest that black men presenting with clinically localized CaP in an equal access setting have similar cure rates following radical prostatectomy. Cultural issues that may contribute to a delay in diagnosis in African American men include inadequate access to health care, a decreased knowledge of the disease, economic issues, concern regarding treatment-related complications, and an inherent distrust of a predominantly white medical establishment (48). The postulated genetic and epigenetic factors that influence the biology of CaP in African American men are discussed in the next section.

Although efforts to identify causal mechanisms in the development and progression of CaP are being pursued vigorously, the etiology of this malignancy remains elusive. The use of molecular methodology to study CaP biologically has resulted in the identification of numerous adverse tumor cell properties that typify biologically aggressive tumors and distinguish them from more indolent neoplasms. To date, none of these exciting observations have become mainstream components of established diagnostic and therapeutic (598) clinical pathways. Techniques to identify the presence of the cancer remain relatively gross and inexact. Although radical prostatectomy offers a patient with locally contained disease an excellent opportunity for cure, the procedure is a major surgical undertaking. Furthermore, many patients with advanced disease may not be amenable to such an approach. No major therapy advances have been forthcoming for the latter group since the observation of Huggins and Hodges regarding the efficacy of androgen ablation (446,447). This assessment must be tempered by the realization that intense clinical effort has added to our diagnostic and surgical skills and that sophisticated scientific approaches are beginning to yield significant insights into the genetic and biochemical nuances of CaP. This chapter presents an overview of this challenging disease.

ETIOLOGY

Advancing age is the strongest risk factor for the development of CaP. By the ninth decade, CaP is observed in 67% of male cadavers that undergo autopsy and can be identified in tissue from approximately 37% of patients who undergo transurethral prostatectomy (TURP) (968). These findings are consistent with more generic observations regarding the increased frequency of cancer and cancer-related deaths (827) in the geriatric population. Indeed, the median age for all cancer patients in the United States is approximately 70 years. Potential reasons to explain these associations in CaP patients are numerous. First, malignant tumors that occur after menopause (or andropause) tend to develop over many decades. Second CaP is a chronic disease with increasing survival times. Third, a decline in DNA repair mechanisms and a diminution in constitutive regulators of cellular proliferation occur with aging (279). Finally, older men are most likely to manifest evidence of high-grade PIN. Qian and associates (805) demonstrated the volume of high-grade PIN in 195 radical prostatectomy specimens was positively correlated with Gleason score, pathologic stage, and increasing age.

The postpubertal presence of an intact hypothalamic/pituitary/testicular axis is required for the development and progression of CaP. Men castrated before the onset of puberty have little risk of developing CaP (220). The prostate will not develop without androgens and the normal gland will undergo atrophy if androgen support is withdrawn. Furthermore, the majority of CaPs depend on androgens early in their progression and demonstrate regression following androgen ablation (798). Consequently, implicating excessive androgen stimulation as a primary causal factor in prostatic carcinogenesis seems logical. Despite the logic in this supposition, data correlating the development of CaP in men with increased circulating androgen levels are surprisingly contradictory. Some recent studies support this association (331), while others refute it (134,408). An alternative hypothesis suggests that declining androgen levels may play a causative role in prostatic carcinogenesis. This is based on the observation that as individuals age and the risk of CaP rises, the serum androgen levels fall (533). Prehn (798) has proposed that continued selection pressure in an environment of declining androgen levels may induce hyperplastic foci more resistant to atrophy, less dependent on androgens to support their growth, and more susceptible to oncogenic change.

Epidemiologic observations highlight African American and white males with a strong family history of CaP as constituting two cohorts at increased risk of developing CaP and more prone to disease progression. With respect to African American men, genetic factors have been proposed to account for the observed racial differences in CaP incidence, progression, and mortality, including (a) higher circulating sex steroid levels; (b) shorter androgen receptor CAG (glutamine) repeat length, which enhances androgen-mediated inactivation; (c) genetic variability of the SRD5A1 gene encoding the type 1 enzyme of steroid 5a-reductase; and (d) polymorphic variation in the VDBP gene encoding a vitamin D–binding protein (21,668). Various adverse environmental factors also have been proposed, including (a) higher fetal exposure to circulating androgens; (b) a diet higher in animal fat content; (c) diet deficient in the non–provitamin A carotenoid, lycopene; (d) increased calcium intake, suppressing circulating 1,25 $(OH)_2D$, which in turn increases the risk of developing CaP; (e) reduced consumption of fresh fruits and soy products, which provide high concentrations of protective isoflavones (genistein); and (6) decreased consumption of cruciferous vegetables of genus *Brassica* (broccoli), which contain high concentrations of the isothiocyanate, known as *sulforaphane,* which is an inducer of phase II detoxification enzymes, such as quinone reductase and

glutathione S-transferase (74,668).

The first report documenting the presence of a dominantly inherited form of CaP emanated from research conducted at Johns Hopkins Hospital (124,125). The actual proportion of CaP caused by mutations in autosomally dominant susceptibility genes is approximately 5% to 10% (87,125). Hereditary susceptibility is much more common in men with early-onset CaP and may account for up to one-third of cases diagnosed before the age of 60 years (87) and almost half of those in men younger than 55 years (125). The excess risk varies with the closeness and the number of afflicted relatives. Men with a first-degree relative (brother or father) have a twofold risk, and those with a second-degree relative (grandfather or uncle) have a lesser but still increased risk of developing CaP. The presence of the disease in two or three first-degree relatives or a first- and second-degree relative increases the risk of its development almost fivefold, elevenfold, and ninefold, respectively (125). The increased risk is maximized in relatives of men with the onset of clinically recognizable CaP at an early (less than 53 years) age and is minimized in those with a later (older than 65 years) age of onset. Identification of the hereditary prostate cancer gene 1 (HPC1) on chromosome 1q24-25 was the result of a genomewide search with linkage analysis in which this genetic locus was “linked” to approximately one-third of 79 North American and 12 Swedish families studied (927). Linkage to HPC1 is more prevalent in families of early-onset CaP and is more readily demonstrated in kindred families with many affected members (387). More recently, a CaP susceptibility gene, designated HPCX, has been located to the long arm of the X chromosome (Xq27-28). Expression of this gene appears to account for 15% to 16% of the North American and up to 41% of the Finnish hereditary CaP cases analyzed (1111). Two additional CaP susceptibility genes have been putatively identified and located to chromosome 1q42.2-43 (58) and to chromosome 1p36 (356). Apart from families with multiple cases of breast cancer, germ-line mutations in BRCA1 and BRCA2 appear to have a limited role in familial CaP (88,921).

The genetic basis for sporadic CaP remains elusive. The recent observation of hypermethylation of the regulating sequences of the glutathione S-transferase gene (GSTP1) in human CaP, but not in BPH or normal tissues, may constitute an initial significant step to fill this void (563). More recently, a new prostate-specific gene, designated *DD3,* has been shown to be highly overexpressed in CaP tissue in comparison to adjacent nonmalignant prostatic tissue. The DD3 gene has been mapped to chromosome 9q21-22, and its expression appears to be restricted to the prostate (111). The fact that no extensive open reading frame could be identified suggests that DD3 may be another new member of a growing unique class of noncoding RNAs.

NATURAL HISTORY AND EPIDEMIOLOGY

The following characteristics of the natural history of CaP have potential or established clinical importance and warrant emphasis: (a) Histologic carcinoma is identifiable at autopsy in some individuals before the age of 40; its prevalence increases progressively with each subsequent decade. (b) The identical prevalence of histologic CaP at autopsy in various populations is not reflected in the prevalence of clinical CaP. (c) CaP develops predominantly in the peripheral or outer prostate; some evidence suggests that the potential for biologically aggressive behavior may vary between neoplasms originating peripherally, as compared with centrally. (d) Histologic and biochemical evidence suggests the presence of a field change in prostates developing carcinoma. (e) The histologic grade correlates with local development of mass, invasion, and dissemination. (f) Intragland and extragland local spread of carcinoma tends to follow natural anatomic planes and conduits. (g) The pelvic lymph nodes and the bones of the axial skeleton are the identifiable sites of the initial dissemination; the mechanism involved in the predilection for these metastatic sites has not been fully elucidated. (h) Evidence of continued dependence upon androgen for maintenance and/or stimulation of some of the cells in the majority of CaPs is substantial. Observations that support and expand some of these statements are discussed briefly in the following paragraphs.

The development of histologic CaP is an age-related phenomenon. It is infrequently recognized before the age of 50 years. Its prevalence is substantial in autopsy studies in the 50- to 60-year-old age groups (29%) and increases progressively with each succeeding decade, approaching a straight-line relationship on a double logarithmic scale (312,313). Of autopsied males, 40% dying in their seventies and 67% dying in their eighties have histologic evidence of this malignancy. Race and geographic areas have little, if any, documented influence on the autopsy prevalence (139). In contrast to histologic carcinoma, the prevalence of clinical CaP varies significantly in different geographic regions and racial groups in a given region. Black males in Nigeria and the United States have a similar age-adjusted prevalence of incidental CaP, but the former have a lower prevalence of invasive CaP (465). The incidence of clinically apparent carcinoma is sixfold greater in American than Nigerian blacks. Similarly, despite the comparable age-adjusted prevalence of CaP in male inhabitants of Japan and the United States, clinical carcinoma shows as much as a twentyfold greater prevalence in males living in the United States, as compared with those living in Japan. In addition, although the incidence of histologic carcinoma of the prostate in an Oriental male living in Japan and a male of Japanese descent living in Hawaii is essentially comparable, the age-adjusted prevalence of clinical carcinoma for the latter is approximately tenfold greater. However, Japanese Hawaiians have a prevalence rate for CaP of only approximately 50% of that of the local white population (895). Compared with white U.S. males, African American men present at a younger age and with a higher stage and grade of disease (574,828). The probability of an American black man being diagnosed with CaP and of dying from CaP is 85% and 114% greater, respectively, than his white fellow countrymen (675). Furthermore, when white males are compared with American Indians, Hispanics, and Orientals, the latter groups are at relatively low risk of dying from prostate cancer (196,315,643). Unquestionably, variable rates of clinical cancer detection, data accumulation, and reporting may skew these results substantially.

Various epigenetic factors have been linked causally with CaP. These include nutritional and endocrine factors, environmental carcinogens, and exposure to infectious agents (532,533). Dietary differences, in particular the Western-type diet rich in saturated fatty acids, have been thought by some investigators to play a potentially important role in the incidence of carcinoma noted in some of the migration studies and high- or low-risk geographic areas cited (68), but others disagree (675). Vitamin D deficiency (endemic to geographic areas with low ultraviolet radiation) also has been implicated (74). Studies of men of Japanese ancestry in Hawaii have suggested that increased consumption of rice and tofu was associated with a decreased risk of CaP and that consumption of seaweed was associated with an increased risk (905). Recently, Blumenfeld and associates (74) provided a thorough and well-balanced review of the nutritional aspects of prostate cancer. Table 33.1 provides a summary of their observations.

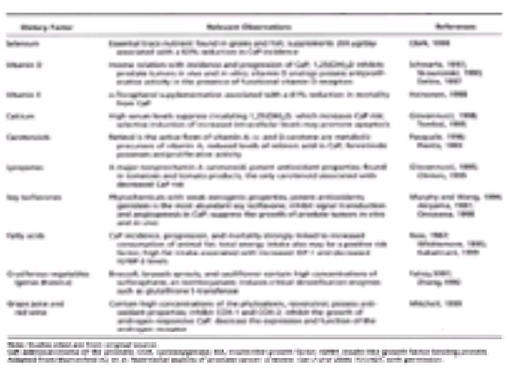

TABLE 33.1. NUTRITIONAL ASPECTS OF PROSTATE CANCER

Reports of high levels of cadmium and decreased levels of zinc in patients with CaP (507) raise the possibility that exposure to cadmium, other heavy metals, and toxins may affect trace elements found in the prostate and contribute to proliferative abnormalities. Some occupations such as rubber and textile workers, printers, painters, mechanics, loggers, ship fitters, porters, janitors, farmers, and ship receiving clerks have been reported to be associated with a higher risk for CaP (1097,1098).

A very tenuous association exists between the acquisition of sexually transmitted infections and CaP. Sexual hyperactivity or promiscuity as well as antecedent bouts of gonococcal urethritis or other venereally transmitted diseases have been targeted as significant risk factors (886,972). Consistent statistically significant data to support these contentions have not been presented, however. Current evidence would suggest that human papillomaviruses (HPVs), at least HPV types 16 and 18, are not associated with the prostate carcinogenesis (252). Recent data suggest that vasectomy is associated with increased risk of prostate cancer (359). The assessment of the evidence supporting this association led to a statement by the World Health Organization indicating that any causal relationship between vasectomy and the risk of CaP is unlikely. The caveat that further investigation of this possibility is warranted seems appropriate (432).

In summary, current evidence indicates that development of histologic CaP is an age-related phenomenon in males that is not clearly influenced by race; heredity; geographic location; or identifiable environmental, social, physiologic, or disease-related phenomena. However, a number of these factors are associated with an increased incidence of biologically aggressive or clinically important carcinoma. Recognition of the probability that potentially identifiable mechanisms exist for the

conversion of histologic to biologic cancer has not yet been accompanied by their identification but almost certainly will be.

The concept that atrophic glandular cells are the typical precursors for development of carcinoma (311,671) has been challenged by evidence suggesting that prostates that develop carcinoma have increased glandular activity compared with BPH (632,633 and 634). The association of high-grade PIN and development of carcinoma has added support for this concept. The probability that both histologically atrophic and metabolically stimulated cells may facilitate development of malignancy would seem to warrant continued serious consideration.

Two anatomic considerations relevant to the development of CaP—its regional distribution and multicentric origin—provide important clinical, and very possibly biologic, information. Most (70% to 75%) of presumably early carcinomas are found in the peripheral portion of the prostate, indicating this as the common site of origin (312,633,671,824). The role that the metabolic characteristics of the cells or simple cell density has in the predilection for this site remains controversial. A comparative analysis of ploidy and volume of malignancies in the peripheral and transition zone of radical prostatectomy specimens (383) tends to support a biologic difference in carcinoma arising in these two areas, as contrasted to the view that the differences in a tendency to invade and perforate were due to anatomic opportunities (631). Greene and co-workers (383) observed nondiploid tumors occurred with a much greater frequency both in tumors less than 1 mL volume (29% versus 0%) and tumors larger than 1 mL volume (94% versus 36%) in peripheral as compared with transition zone tumors. In addition, the median (2.34 mL versus 7.30 mL) and mean (3.6 mL versus 6.0 mL) volume associated with the appearance of nondiploid tumors were much smaller in peripheral as compared with transition zone sites. Recently, Noguchi and associates (715) documented the clinical and histologic characteristics of 148 consecutive transition zone cancers. Their findings are summarized in Table 33.2.

Histologic Characteristics	Involvement (%)
Organ-confined disease	80
Stage T_{1a} disease	70
Initial positive prostatic biopsy	63
Unilateral TZ cancer	62
Secondary tumor in PZ only	52
Serum PSA ≥10 ng/mL	61
Cancer volume ≥6 mL	36
≥50% Gleason grade 4/5	24
Location within proximal third segment	20
Capsular penetration	15
Anterior positive surgical margin	29
Seminal vesical invasion	2.7
Lymph node metastasis	3.4
Biochemical PSA cure rate	72

PSA, prostate-specific antigen; PZ, peripheral zone; TZ, transition zone (radical prostatectomy specimens).

TABLE 33.2. HISTOLOGIC CHARACTERISTICS OF TRANSITION ZONE CANCERS (*N* = 148)

With regard to its multicentric origin, an appreciable incidence of multiple separate tumor sites differing in both size and cellular characteristics (112,659,671) has been noted in both autopsy and radical prostatectomy specimens. These findings suggest a high frequency of multicentric origin and support the possibility of a field change (382). The probability of a diffuse or field change in the prostate that develops malignancy derives further support from two observations: (a) the high incidence of histologically discernible atypical changes (PIN) in the benign glands in the prostate with recognizable adenocarcinoma (740) and (b) evidence of a diffuse biochemical change in the histologically benign tissue and the expressed prostatic fluid of patients with carcinoma (379,380). Whether the changes are premalignant or induced is unclear. Further evaluation of the “field change” concept is derived from the molecular studies conducted by Cheng and associates (164). That study involved an analysis of microsatellite alterations in the DNA from separate tumors in the same prostate specimen. Their study targeted the putative tumor suppressor gene on chromosome 8p and for the BRCA1 gene on chromosome 17q. The pattern of allelic loss documented in that evaluation was compatible with independent tumor origin in 15 of 18 informative cases.

Organized and disorganized groups of cells that share histologic features that lead to the diagnosis of CaP may have other histologic characteristics that make local spread or dissemination probable or improbable. This attempt to characterize biologic activity on the basis of histologic characteristics is commonly translated into a numeric grade. Clinical evidence indicates the development of local tumor mass and invasion, and dissemination correlates with tumor grade (275,376,659,965). For example, Stamey and associates (965) observed that 76% of the carcinomas in 34 radical prostatectomy specimens with a tumor volume of less than 3 mL had 5% or more identifiable Gleason grade 4 or 5 malignancy. On the other hand, 96% of 34 tumors exceeding 3 mL in volume had 5% or more and 46% had 50% or more Gleason grade 4 or 5 malignancy. In another analysis of radical prostatectomy specimens, Miller and Cygan (660) demonstrated a correlation between tumor volume and grade, but small-volume high-grade (Gleason score 7 to 10) and high-volume low-grade tumors clearly were present. Organ-confined disease predominated in glands containing Gleason score 2 (35 of 38; 92%), Gleason score 3 to 4 (81 of 114; 71%) and Gleason score 5 to 6 (49 of 84; 50%); only 6% (3 of 50) of Gleason 7 to 8 and 14% (1 of 7) of Gleason 9 to 10 tumors were organ confined. Even small-volume (less than 1 mL) tumors had identifiable extraorgan disease in all grade groups. Even though Gleason 7 score was packaged with Gleason 5 and 6, a recent analysis of postradical prostatectomy evidence of persistent disease based on clinical and PSA assessments revealed a much higher progression rate in patients with tumors of Gleason score 7 or greater (59%) than in those with tumors of Gleason score 6 or less (13%) (275). Our data (720), based on 251 patients who were subjected to radical prostatectomy for clinically localized CaP, who underwent biopsy before PSA was used as the sole indication for biopsy, and who underwent follow-up for a mean of 6.1 years, are similar. The incidence of extraorgan disease in pathologic assessment increased, and the PSA progression–free survival decreased with each grade grouping (2 to 4, 5 to 6, 7, and 8 to 10) of Gleason score.

Multivariate analysis in both these retrospective studies indicated that Gleason score was the best predictor of progression; in both, the status of the surgical margins enhanced prediction of progression, but less so. Although histologic grade clearly does not approach absolute predictability with regard to intraorgan, periprostatic, or disseminated growth of carcinoma of the prostate, demonstration of high-grade (Gleason 4 or 5) tumor signals a significant risk of biologically aggressive tumor. More recently, Stamey and associates (966) evaluated radical prostatectomy specimens from 379 men with the primary intention of identifying biologic determinants of cancer progression in men treated only by surgical excision. The relative importance of eight morphologic variables was assessed using a Cox proportional hazards model. The variables involved included percentage Gleason grade 4/5, cancer volume, vascular invasion, lymph node involvement, seminal vesicle invasion, capsular penetration, positive surgical margins, prostate weight, and preoperative PSA level. In their analysis, cancer grade expressed as percent Gleason grade 4/5 and cancer volume was highly predictive of disease progression. Positive lymph node findings and intraprostatic vascular invasion were the only other variables that achieved statistical significance. Importantly, biochemical failure increased almost linearly with each 10% increase in Gleason grade 4/5 cancer within the prostate. Of potential significance, the traditional Gleason score, capsular penetration, and positive surgical margins were not independently predictive of failure after radical prostatectomy. These findings must be tempered with the realization that estimating cancer volume can be problematic and associated with significant potential for both intraobserver and interobserver variability. Evidence that other assessments, including ploidy analysis, equal or add to this information has not been convincingly presented at this time.

The routes of growth and spread of carcinoma are important considerations in diagnosis and treatment. Observations of autopsy and radical prostatectomy specimens support the probability that the early growth of CaP is usually intraglandular. The concept that a carcinoma almost always needs a critical mass to progress to an extraorgan or disseminated status probably has general but not absolute validity (660). Prostatic malignancies tend to grow initially along normal tissue planes in the gland. McNeal (631) observed that most cancers less than 3.7 mL in volume tend to follow rather than cross the plane between the transition and peripheral zones. High-grade (Gleason 4 and 5) tumors have a much greater tendency to invade rather than conform to fibromuscular structures. The continuity of intraprostatic and periprostatic tissue planes or conduits such as perineural spaces, ejaculatory duct fibromuscular sheath planes, and spaces between the muscle bundles of Denonvilliers' fascia and the periurethral sphincter afford natural potential organ exit sites for the carcinoma cells (1048). The lack of these planes and the presence of anatomic barriers are proposed explanations for the relative infrequency of periprostatic spread of transition zone tumors (1048).

Perineural space invasion was identified as a unique feature in 50% and the predominant feature in capsular perforation in 85% of a group of radical prostatectomy specimens from patients with stage B (T_2) prostate carcinoma. Anatomically unfacilitated perforation occurred as a unique feature in only 5% and a predominant feature in 15%. The regional localization of extraorgan spread to the area of the superior and inferior neurovascular bundles reflects the importance of these perineural space pathways (Table 33.3) (1048). The concept that CaP cells traverse along the perineural spaces because they constitute a plane of lowest resistance may be an oversimplification. More recently, it has been suggested that the perineural space may have a microenvironment with growth advantage that may facilitate tumor cell proliferation and dissemination (1134). In this regard, recent studies performed on human pancreatic cancer may have relevance. Perineural invasion extending to the extrapancreatic nerve plexus is the most common route of spread for pancreatic cancer cells and is a histopathologic characteristic of this disease (1134). Molecular analysis of pancreatic cancers has demonstrated an important neurotrophin [nerve growth factor (NGF)] in the cytoplasm of pancreatic cancer cells. The biologic effects of NGF are mediated through tyrosine-kinase receptor proteins, designated Trk (A,B,C), which are coded by the Trk protooncogenes (391). Of

great interest, TrkA is avidly expressed in the perineurium of pancreatic nerves but not in pancreatic cancer cells. It therefore has been postulated that enhanced expression of the NGF TrkA system may influence perineural invasion and may contribute to the pain syndrome typical of human pancreatic cancer. NGF is present within the prostate. In addition, the abnormal growth of prostatic epithelium is accompanied by increased TrkA expression and the induction of TrkC expression in epithelial cells (391). It is reasonable to assume that a constitutive affinity exists between CaP cells and the perineural microenvironment. Attraction to the perineural space may be a dynamic process that subsequently results in amplified tumor growth and expression of invasive phenotypes.

Sites of Extraprostatic Spread	Frequency		Pathways of Extraprostatic Spread	
	Non-TZ	TZ		
Lateral pelvic fascia at the posterolateral surface	50%	20%	Along perineural spaces Direct	50%-95% 5%-40%
Denonvilliers' fascia at the rectal surface	19%	0%	Along muscular bundles	100%
Seminal vesicles at the base	23%	0%	Along ejaculatory ducts-thumb Direct	91% 9%
Bladder neck at the base	7%	–	Along urethral preprostatic sphincter	100%
Membranous urethra at apex	1%	0%	Along urethral distal striated sphincter	100%

TZ, transition zone cancers.

TABLE 33.3. SITES, FREQUENCY, AND PATHWAYS OF CANCER PERIPROSTATIC SPREAD IN A SERIES OF 243 RADICAL PROSTATECTOMIES

Involvement of Denonvilliers' fascia is related to extension of adjacent tumor along the planes resulting from fusion of stroma and fascia; it occurs most frequently in the basal area in association with seminal vesicle spread. In one series (1046), seminal vesicle spread was recognized independent of midbase involvement of the prostate in only 13 of 56 incidences; only five of the midbase tumors associated with vesicle spread did not show perforation. The reported predominance of an apical location for positive surgical margins is probably multifactorial but may be related to an anatomically incomplete Denonvilliers' fascia in this region. Although microscopically documented malignant cell bladder neck invasion is relatively uncommon on histologic evaluation of radical prostatectomy specimens (7%) (275,1048), bladder neck and trigonal invasion have been features of advanced carcinoma of the prostate. In these cases, extension into the bladder neck has been observed in approximately 35%, with resulting ureteral obstruction in 8% to 35% (653,853). True rectal invasion is uncommon in most series but was reported in 126 of 1,367 autopsy cases by Saitoh and colleagues (853), a frequency of approximately 9.4%. Invasion of the membranous urethra also is documented infrequently (1%) (1048) in radical prostatectomy specimens and is a finding associated with advanced disease (143).

Sites of commonly recognized extraorgan spread in carcinoma of the prostate are the following: (a) periprostatic and perivesicle, (b) pelvic lymph nodes, and (c) bones of the axial skeleton. In patients subjected to radical prostatectomy, capsular perforation is documented more frequently than perivesicle invasion; as noted, perivesicle capsular perforation accompanies perivesicle invasion 75% of the time (1046) (Table 33.3). Although extraprostatic spread is a clear indication of a biologically active malignancy, the former occurs without concurrent histologic or ultimate clinical evidence of dissemination to pelvic lymph nodes or bone. Seminal vesicle invasion is associated with immediate or delayed dissemination in most patients (1046). Clinical evidence supports the probability that pelvic lymph node and bone dissemination occur independently in some patients, although pelvic node involvement almost always is an identifiable manifestation of systemic disease (275). Patients who have no identifiable extraprostatic disease on histologic evaluation of radical prostatectomy specimens may eventually manifest disseminated disease without a clinically identifiable residual local tumor. This observation and the reverse transcriptase–polymerase chain reaction (RT-PCR) identification of PSA- and prostate-specific membrane antigen (PSM) producing cells in the peripheral blood of a surprising number of patients with organ-confined tumors on pathologic examination suggest that the risk of vascular dissemination as an early independent event in the natural history of prostatic carcinoma may be much greater than previously appreciated (457,492).

Clinical findings with regard to lymph node spread indicate that the medial group of the external iliac chain situated around the obturator nerves and vessels, the so-called obturator nodes, are the most frequent initial site of identifiable metastatic involvement (630). In order of frequency, the other lymph nodes involved include hypogastric, external iliac, presacral, presciatic, common iliac, inguinal, periaortic, mediastinal, and supraclavicular lymph nodes (143,630,853). The clinical stage, reflecting local tumor mass, and tumor grade correlate with the prevalence of histologically identified lymph node metastasis (687,749). High-grade and increased local tumor mass are associated with increased risk of pelvic lymph node tumor dissemination. The side of lymph node and prostate involvement usually but not always corresponds in a unilateral tumor. Metastatic involvement of the external or common iliac nodes may occur independent of the deep pelvic nodes but does so infrequently. Recognition that periaortic and supraclavicular node involvement occurs in advanced CaP (20,268) is occasionally useful clinical information. Involvement of the axial skeleton is a common event that often correlates with significant lymph node and distant organ involvement (122). In the Veterans Administration Cooperative Urologic Research Group (VACURG) study of patients with stage D carcinoma, the bones most frequently affected by metastasis were the ileum (83%), followed by the ischium (78%), lumbosacral spine (71%), thoracic spine (60%), ribs (53%), femur (48%), and shoulder (39%) (114). The findings in a bone scan evaluation of 176 patients with metastatic CaP in a more recent EORTC study were similar. The location of skeletal metastasis was as follows: pelvis, 73%; dorsal spine, 63%; lumbar spine, 62%, ribs, 61%; cervical spine, 51%; femur, 40%; skull, 28%; sacrum, 25%; and humerus, 24% (935). Metastatic bone sites do not reflect the relative blood flow to the individual structures but may be related to red marrow content. The latter observation probably accounts for the infrequent identification of “hot spots” on radionuclide imaging below the elbows and knees. The radius/ulna and tibia/fibula are relatively deficient in red marrow and would constitute “infertile” sites of metastatic colonization based on the precepts of the “seed and soil” hypothesis of Paget (741). Earlier autopsy studies by Elkin and Mueller (268) revealed bone metastases of the pure osteoblastic variety in more than 50% of cases. A mixture of osteoblastic and osteolytic lesions were observed in approximately one-third of cases and pure osteolytic metastases in less than 10% of patients dying of CaP. Blastic foci often revealed a disorganized array of new bone formation. The mechanism for this stimulated osteoblastic activity has been postulated to be directly or indirectly related to the effect of prostatic tumor cell secretions (467) on hydrolysis of receptor-bound insulin-like growth factors (IGFs) (879). CaP cells produce various well-characterized growth factors of the fibroblast growth factor (FGF) and transforming growth factor-b (TGF-b) families (534). Bone morphogenetic protein (BMP)-6, a member of the TGF-b superfamily of polypeptide signaling molecules, can produce bone formation from mesenchymal cells at extraskeletal ectopic sites. Recently, Maillette and associates (615) used an immunohistochemical technique to demonstrate BMP-6–positive cells in 50% to 65% of radical prostatectomy but not in normal prostate specimens. Although BMP-6 expression did not correlate with Gleason score, over 80% of patients with node-positive disease and all patients who developed skeletal metastases demonstrated BMP-6–positive cells in the primary tumor. These observations suggest a significant correlation between BMP-6 expression and the likelihood of developing bone metastases. Brown and associates (104) used immunohistochemistry, *in situ* hybridization, and RT-PCR to demonstrate CaP cells express many osteoblast-related factors. In their evaluation, osteonectin and osteopontin facilitate tumor cell migration, invasion, and attachment to bone. Osteoprotegerin and its ligand (OPGL) are directly linked to the proliferation of mesenchymal elements within the bone marrow microenvironment and mediate the effects of bone morphogenic proteins and parathyroid hormone–related protein on bone turnover. These investigators suggest that expression of these osteoblast-associated factors by prostate cancer cells, combined with cathepsin K expression by those cells, is ultimately responsible for the initiation and progression of osteoblastic metastases.

The mechanisms of metastatic spread of CaP have been controversial. However, questions concerning lymphatic spread have diminished as evidence supporting the presence of lymphatics in the prostate has been presented (324). Past speculation regarding the mechanism of bone marrow metastasis centered on the role of the perivertebral veins (Batson's plexus). These veins lack valves and presumably provide ready access to the vertebral system. Consequently, this system has been thought to play a major role in the pattern of bone involvement seen in carcinoma of the prostate (42). However, bone scan studies suggest a random distribution of CaP bone metastasis similar to that noted in breast carcinoma. PCR studies cited previously demonstrated an unexpected incidence of presumed malignant cells in the systemic circulation. Consequently, the importance of the venous system with regard to the frequency and site of bone involvement by CaP is open to question (236). Local or regional anatomic relationships seem unlikely to account for this “bone-seeking” affinity of CaP cells. Indeed, skeletal metastases in these patients may reflect a fertile microenvironment more consistent with the “seed and soil” hypothesis of Paget than serendipitous deposition of tumor cells by a unique venous access system (741).

The sequence and interrelationships of dissemination to lymph nodes and bone are not clearly established. Clinical data from the select group of patients subjected to radical prostatectomy indicate that perforation of the capsule and perivesical tumor invasion occur without recognizable spread to lymph nodes or bone; identifiable lymph node involvement and bone dissemination occur independently of each other. Although recognition of CaP outside the gland in any site is often ultimately associated with evidence of this neoplasm in other sites, this sequence of events is far from inevitable. The common assumption that lymph node involvement always indicates associated bone marrow dissemination, or vice versa, ignores the evidence supporting the site selectivity for metastatic cells.

Metastatic involvement of other visceral organs tends to be a late manifestation of CaP and is usually associated with an overwhelming, multifocal tumor burden.

Visceral metastases are often clinically cryptic; their identity and extent become apparent only at the time of postmortem examination. Autopsy studies have cited tumor involvement in a multitude of organs, but those noted most frequently include lungs (49.1%), liver (35.6%), adrenals (17.3%), and kidneys (10.6%) (853). With regard to pulmonary involvement, a correlative autopsy and roentgenologic study (268) revealed over half of the cases of pulmonary metastases were apparent only on microscopic analysis. Their observations coincide with reports of lymphangitic rather than nodular metastases in more than three-fourths of patients with clinically demonstrable lung involvement (567). Recently, Smith and associates (928) reported the development of a putatively solitary, nodular pulmonary metastasis in a patient who had undergone radical prostatectomy for a stage $pT_2N_0M_0$ Gleason 4+5 adenocarcinoma with negative surgical margins 18 months earlier. Following excision of the chest nodule, the patient's PSA reverted to the previously undetectable level with limited follow-up. This rare scenario suggests optimal control of the primary may influence the type and extent of tumor relapse.

The time frame for the development and progression of CaP is highly variable. The regional (racial) differences observed in clinical (versus histologic) malignancies support the presumption of different biologic characteristics and growth rates that correlate with the histologic grade and stage in groups of patients with CaP. Clinically, these correlations are not invariably evident in individuals within the group. Both anatomic and image-documented evidence of tumor growth have been used to provide gross estimates of rates of progression. Less than 10% of patients with a clinically well-differentiated focal CaP (stage T_{1a}, A_1) exhibit progressive disease in follow-up intervals approaching 10 years (117,143,604). Retrospective studies of patients with a palpably organ-confined (T_2), predominantly low-grade, or intermediate cytologic grade carcinoma demonstrated that progression to palpable extraorgan disease occurred in approximately 50% of the observed patients at 5 years. The progression rate was almost linear at 10% per year. These data are surprisingly similar to the 10% to 12% yearly and 60% 5-year progression rate noted in untreated patients with stage C (T_3) carcinoma in the Veterans Administration (VA) studies of carcinoma of the prostate. In the reports separating groups of men with clinically localized CaP by grade, increasing rates of progression were observed with increasing grade. In a pooled analysis of six studies, Chodak and associates (169) found a metastasis-free survival at 10 years of 81% for grade 1, 58% for grade 2, and 26% for grade 3 disease; poorly differentiated CaP also affected mortality from the disease. The median survival of 36 months from detection of metastasis in this report (169) was similar to the 30-month median survival for men with metastatic disease noted in the VA study (65). The effect of age at diagnosis on cancer-specific survival has been controversial. On pooled analysis of untreated patients (169), those who were younger than 61 years at diagnosis had an improved chance of cancer-specific survival at 10 years. Benson (50) concluded that the prognosis for younger and older men was comparable for a given grade and stage of disease. Data regarding individuals with presumed hereditary CaP, characterized in part by early onset of disease, suggest grade and pathologic stage are similar in sporadic and familial prostate cancer groups (125). This observation tends to support the probability they are biologically similar diseases. Increases in serum PSA have been used to calculate tumor doubling times of greater than 4 years in 70% of untreated men with organ-confined cancer and of more than 2 years in 79% of the entire small group of patients studied by the Stanford group. These rates are very similar to the 2.4- and 1.8-year doubling rates for an untreated local/regional and advanced/metastatic prostate cancer, respectively, noted by Carter and associates (124).

Stamey (968) and others expressed the concept that time leads to progressive change in the biologic characteristics of CaP. Epidemiologic evidence of prolonged latency as compared with increased biologic aggressiveness of carcinoma in groups of patients, pathologic evidence of the coexistence of multiple tumors with varying grades and evidence of biologic activity in a radical prostatectomy or autopsy specimen, and the relationship of diagnostic tumor grade to ultimate clinical course seem to argue for identifiable episodic metabolic alterations that may require time to manifest themselves but may occur at any period in the development of individual malignancies.

Associations between CaP and other neoplasms are being recognized in various ways with increasing frequency. Clinically unrecognized and usually, but not always, organ confined, CaP has been identified in 27% to 38% of the specimens from patients undergoing cystoprostatectomy for carcinoma of the bladder (478). In contrast to an expected 5% frequency of second primaries in the general populations, Liskow and associates (589) noted the development of at least one additional primary cancer in 24 of 146 patients with nonmetastatic carcinoma of the prostate. In patients with multiple primaries, CaP was the initial neoplasm in 75%; approximately 25% had a third primary. Additional primary sites include the gastrointestinal (GI) tract, lymphomas, lung, genitourinary (GU) tract, and skin. The second primary was diagnosed more than 5 years after the first in approximately half the patients. Black men and individuals with high Gleason scores have an increased risk of multiple primaries. Of interest, 5-year actuarial survival rates were virtually identical for the multiple primary and single cancer groups.

PATHOLOGY

Malignant prostate tumors can be conveniently segregated into four categories by adapting from the International Histological Classification of prostate tumors as proposed by Mostofi and associates in 1980 (678). These categories include epithelial carcinomas, nonepithelial cancers, miscellaneous (exotic) malignant primary tumors, and tumors metastatic to the prostate (secondary neoplasms).

Cancers originating from the epithelial cells of the prostate constitute well over 95% of all prostatic malignancies (112). They usually originate in the outer portion of the prostate, designated the “posterior subcapsular stratum” by Young (1121), the “outer margin” by Rich (824), the “posterior lobe” by Moore (671), the “outer zone” by Franks (312), and the “peripheral zone” by McNeal (633).

Gross Features

CaP tends to present with a relatively characteristic firm, homogeneous, and often distinctive yellow-orange gross appearance. At times the tumor is gray to white rather than yellow (Fig. 33.1). To be apparent in an enucleated or total prostatectomy specimen, the tumor focus must attain a size approximating 5 mm (677). Early lesions may be uninodular or multinodular, possess an irregular outline, and frequently abut the so-called capsule. They often interface indistinctly with the adjacent normal parenchyma. Involvement of the capsule is common; capsular perforation is reported in more than half of radical prostatectomy specimens obtained from patients with clinically localized prostate cancer (839,1048). Perforation is not confined to large-volume tumors; it has been documented in 71 of 237 tumors (30%) with volumes of less than 3 mL and in 30 (16%) of 185 with volumes of less than 1 mL in one series (660). A scirrhous and granular texture is typical, but soft or “medullary” tumors thought to be associated with an exaggerated epithelial component do occur. Denonvilliers' fascia constitutes a formidable barrier to tumor spread, as noted by Young (1121) and verified by the Stanford group (1048). This accounts for the fact that rectal invasion by CaP has been documented in 1.5% to 9.4% of all reported cases (322,853). Multiple foci of tumors with variable volume and grade are common (see Natural History), a finding that has been interpreted as supporting the concept of a field change in this neoplasm (382). This multifocal distribution also has been interpreted as possibly representing intraprostatic metastasis (633) by intragland extension through a network of intraprostatic ducts, blood vessels, and lymphatics. As stated previously, recent molecular studies strongly validate the “field change” concept (164).

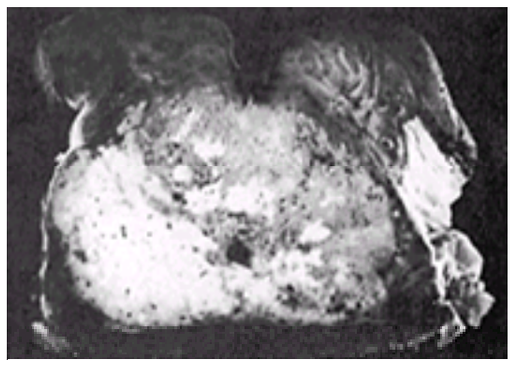

FIGURE 33.1. Advanced, multifocal carcinoma of the prostate. This transverse section of a whole-gland specimen reveals extensive tumor involvement of the left prostatic lobe, with penetration and invasion of the capsule in its posterolateral aspect. Distinct foci of grayish-white–appearing tumor can be seen scattered throughout the remainder of the gland without distinct demarcation from the surrounding normal parenchyma. [From Mostofi FK, Price EB Jr. Tumors of the male genital system. In: Universities Associated for Research and Education in Pathology, National Research Council (U.S.). Committee on Pathology, eds. *Atlas of tumor pathology,* Second series, fascicle 8. Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.]

The loss of intervening or enveloping stroma produces the back-to-back arrangements of the acini, a histologic hallmark of CaP (Fig. 33.2 and Fig. 33.3). Mostofi has noted that evidence of invasion of the surrounding stroma is an important aid in the histopathologic diagnosis of carcinoma (677). Ordinarily, smooth muscle bundles

are arranged in a rather organized and concentric fashion around the distinct acinar basement membrane. Focal loss of this basement membrane with islands of neoplastic cells entering the stromal compartment may provide early evidence of tumor invasion. With progression, the normal, whorled, concentric pattern of the smooth muscle bundles is lost, and pockets of isolated smooth muscle fibers separated from one another by malignant glandular elements are seen (Fig. 33.4).

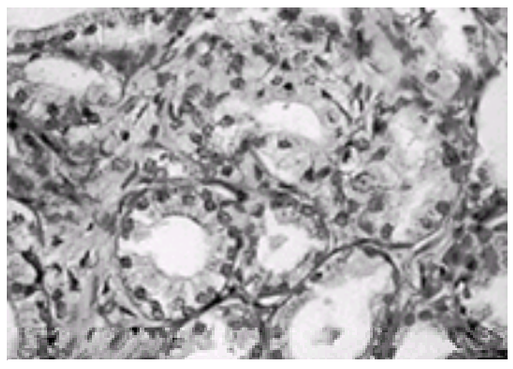

FIGURE 33.2. Well-differentiated carcinoma of the prostate. This tissue section reveals a back-to-back arrangement of glandular elements, a relative deficiency of intervening stroma, and the loss of the double layer of cells characteristic of benign glands. Cellular features include nuclei exhibiting little pleomorphism, the presence of discernible nucleoli, and clear to acidophilic cytoplasm. These characteristics are consistent with a type 1 Gleason's pattern (hematoxylin-eosin, 435× magnification). (Photomicrograph courtesy of R. Oyasu, M.D.)

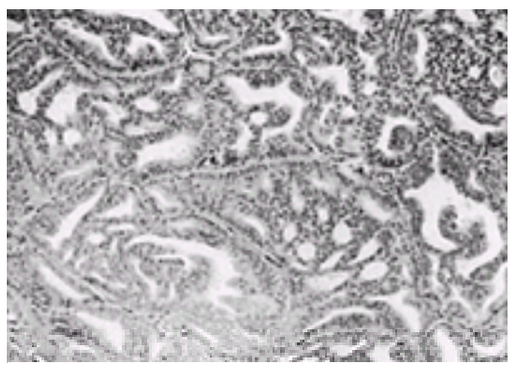

FIGURE 33.3. Cribriform pattern of prostate cancer. This photomicrograph is illustrative of a Gleason's pattern 3 tumor and demonstrates the presence of rounded, expansile masses of medium to large glands that exhibit papillary infoldings (115× magnification). (Photomicrograph courtesy of R. Oyasu, M.D.)

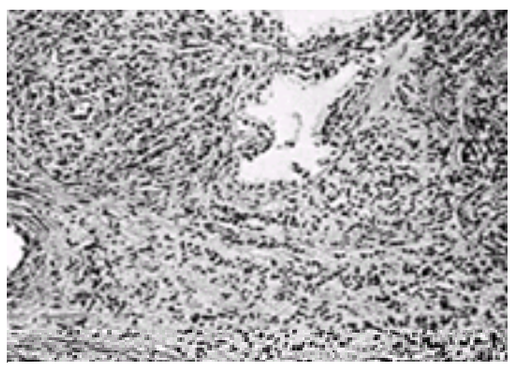

FIGURE 33.4. Poorly differentiated adenocarcinoma of prostate. Photomicrograph demonstrates an “Indian-file” pattern of highly anaplastic prostate cancer cells exhibiting diffuse stromal invasion. Clusters of tumor cells can be seen surrounding normal acini. Note virtual absence of gland formation in this tumor pattern, which would be characteristic of a type 5 Gleason's pattern (hematoxylin-eosin, 189× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

The stroma, a supportive base for the epithelial layer, exhibits a significant degree of cellular heterogeneity, being composed of fibroblastic, smooth muscle, inflammatory, endothelial, and nerve cells (734). Observations suggesting that stromal elements are more than “innocent bystanders” and that these cells may play a strategic role in BPH and CaP are accumulating (203). Embryonic epithelial-stromal interaction involves an elaborate reciprocal molecular dialog that ensures normal organ development and function (202). Evidence suggests that stromal cells located in the vicinity of malignant lesions receive and transmit altered molecular signals when contrasted to similar stromal elements associated with normal nontransformed epithelial elements (734). Alterations in these stromal cells have been postulated to enhance various tumorigenic phenotypes expressed by transformed epithelial cells (506,831). Indeed, the phenotypic changes associated with these cancer-associated fibroblasts (CAFs) include abnormal migratory behavior *in vitro,* altered expression of growth factors (IGF-I, IGF-II, TGF-1), and facilitating the growth of initiated (SV-40 transfected) or frankly neoplastic prostatic epithelial cells *in vitro* and *in vivo* (317,734). These and many other similar observations suggest that therapeutic alteration of the stromal microenvironment in CaP might effectively abrogate subsequent tumor growth and progression.

Invasion of the intraprostatic perineural spaces has been used as evidence of an invasive process and a histologic criterion for the diagnosis of CaP (Fig. 33.5). Such invasion has been seen in 85% of incidental and early carcinomas. The microdissection studies of Rodin and associates revealed that these areas are true perineural tissue spaces rather than lymphatic channels. It has been speculated that nerve growth factor–like proteins may be important mitogens for CaP cells (372,391,1134).

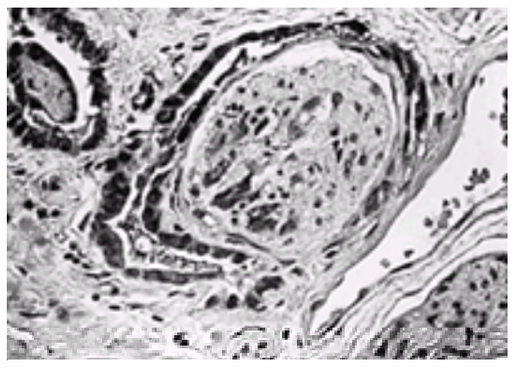

FIGURE 33.5. Invasion of perineural space. Encroachment and invasion of perineural tissues by malignant acinar elements are demonstrated. The perineural spaces are not contiguous with the lymphatic system, but they do provide a pathway of “least resistance” through the prostatic capsule. (hematoxylin-eosin, 459× magnification) (Photomicrograph courtesy of R. Oyasu, M.D.)

Until recently, the anatomic and biologic significance of perineural space invasion was poorly understood. Villers and associates (1047) analyzed 176 radical prostatectomy specimens and noted that in 50% of the cases, capsular penetration occurred exclusively within the perineural spaces. Furthermore, in 85% of the specimens, perineural extension accounted for more than half of the total area of capsular invasion. In most cases, perineural involvement followed the oblique vertical course of the nerve branches superiorly to the region of the prostatic base abutting the superior vascular pedicle. In such cases, transport of tumor cells along extracapsular nerves was measured for distances up to 9 mm, and in 11% of specimens, positive superior pedicle margins were the direct result of perineural space invasion outside the capsular perimeter. For tumors involving the prostatic apex, perineural invasion was associated with positive surgical margins in 89% of cases owing to the short length of the inferior pedicle. Prostate epithelial cell penetration of these perineural spaces has been noted in the absence of malignancy (629).

Skeletal muscle is a normal stromal component within the prostate gland itself (529). Consequently, intermingling of prostate acini with skeletal muscle cells or fibers has no diagnostic significance unless other criteria for carcinoma are established (Fig. 33.6). On the other hand, tumor emboli in unequivocal vascular or lymphatic channels within the prostate does constitute a diagnostic and ominous prognostic sign (677).

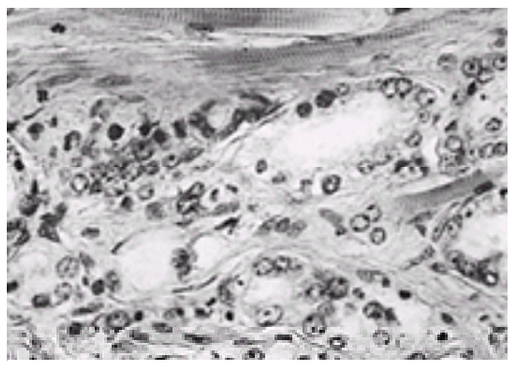

FIGURE 33.6. Prostate cancer adjacent to skeletal muscle fibers. The presence of malignant acinar elements in proximity to skeletal muscle fibers is neither correlated with a poor prognosis nor the presence of capsular penetration. These fibers are normal stromal components. Note prominent cross-striations present in the skeletal fibers as demonstrated in this photomicrograph (459× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

Findings on light microscopy with regard to cellular detail can vary depending on the degree of anaplasia or differentiation of the tumor. Well-differentiated lesions characteristically have a single row of nuclei constituting the acinus; the loss of the double layer of cells present in normal glands is obvious (Fig. 33.2). The nuclei may be diminutive and demonstrate minimal pleomorphism. A thin nuclear membrane with scattered delicate strands of chromatin is commonly appreciated. The cytoplasm is generally clear or acidophilic; the nuclear-cytoplasmic ratio may appear higher than normal. Mitotic figures are encountered infrequently, possibly as a function of a rapid metaphase (677). Antibody staining for specific cytokeratins (CKs) to differentiate basal and luminal glandular cells has become important in assessing the malignant potential of small foci of suspected or equivocal carcinoma (92,1040). Various CK antibodies with differing degrees of specificity for basal and luminal cells are available. As stated in the preceding chapter, the adluminal and basal populations of the prostatic acinus can be distinguished based on their expression of specific CKs. Adluminal cells preferentially express the CKs tandem 8/18 while basal cells are highlighted by monoclonal antibodies targeting CKs 5/15 (909,910). Established CaP cell lines PC-3, DU-145, and LNCaP demonstrate expression of CKs 8/18 but not CKs 5, 7, and 15 (909). The failure of CaP specimens to express CK5 has led several investigators to postulate that these tumors arise from malignant transformation of adluminal epithelial cells (92,696). Verhagen and associates (1040) demonstrated that K14 and K basal reacted with nonmalignant basal cells and that K18 did not. None of the malignant cells tested was positive for K14, all were positive for K18, and some were positive for CK. Consequently, CK antibody information should not be transcribed without documentation.

More anaplastic carcinomas demonstrate considerable variation in cellular and nuclear pleomorphism (Fig. 33.7). The cells may be cuboidal or columnar in shape. Nuclei vary substantially in size, with the nuclear membrane appearing irregularly thickened and the chromatin distribution being quite coarse and random. One or two large nucleoli frequently are encountered, as is a prominent internuclear vacuole. The cytoplasm assumes a granular or vacuolated appearance. The acinar arrangement may be completely lost and replaced with solid cords and clumps of cells (Fig. 33.4).

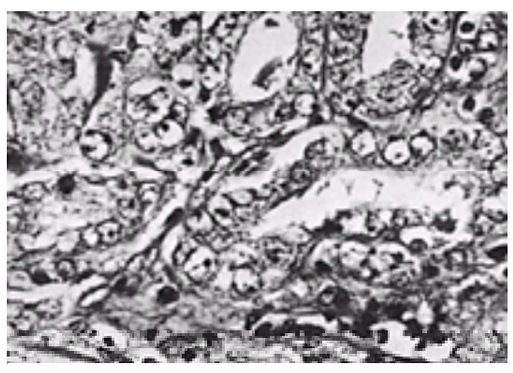

FIGURE 33.7. Anaplastic carcinoma. Photomicrograph represents a grade 3 carcinoma of the prostate. Note the presence of severe nuclear anaplasia with marked vacuolization, pleomorphic nucleoli, an irregularly thickened nuclear membrane, and the presence of a course chromatin pattern (hematoxylin-eosin, 450× magnification). [From Mostofi FK, Price EB Jr. Tumors of the male genital system. In: Universities Associated for Research and Education in Pathology, National Research Council (U.S.). Committee on Pathology, eds. *Atlas of tumor pathology,* Second series, fascicle 8. Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.]

Electron Microscopy

Transmission electron microscopy has revealed ultrastructural abnormalities paralleling the light microscopic features cited. These include enlarged and structurally pleomorphic nuclei and nucleoli, increased numbers of abnormal mitochondria, scanty endoplasmic reticulum with an increase in free ribosomes, prominent intracytoplasmic lipid droplets, and the occasional demonstration of rod-shaped intranuclear inclusions (Fig. 33.8).

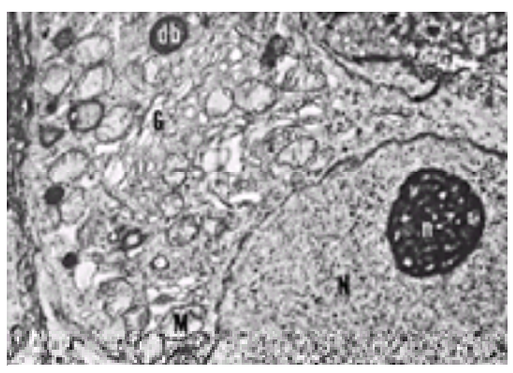

FIGURE 33.8. Ultrastructural features of anaplastic prostate cancer. This electron micrograph reveals a large nucleus *(N),* prominent nucleolus *(n),* abundance of hypertrophied Golgi *(G)* structures, mitochondria *(M)* possessing needlelike cristae, and dense bodies *(db)* (9,300× magnification). (From Fisher ER, Jeffrey W. *Am J Clin Pathol* 1965;44:119, with permission.)

Differential Diagnosis

Various histopathologic entities must be considered in the differential diagnosis of prostate cancer. These include typical hyperplasia (BPH), atypical hyperplasia, basal cell hyperplasia, senile atrophy and associated secondary hyperplasia, metaplasia, granulomatous prostatitis, and involutional changes within the seminal vesicle (677). The features associated with typical BPH, including prominent acini consisting of a basal cell and adluminal cell component surrounded by a prominent collar of avascular connective tissue, usually make the distinction between this lesion and prostate cancer relatively easy. Such is not the case when one or more foci of atypical hyperplasia exist. Because of their potentially premalignant nature, entities previously described as atypical hyperplasia, duct-acinar dysplasia, and intraglandular dysplasia are now designated prostate intraepithelial neoplasia (PIN). Three grades or subsets of PIN were initially described. PIN grade I is characterized by (a) acinar crowding, stratification, or both, with preservation of the basal layer; (b) nuclei of variable size with normal appearing chromatin; and (c) rare nucleoli. In contrast, PIN grade II is associated with (a) increased acinar crowding with some evidence of disruption of the basal layer, (b) nuclei of variable size with increased chromatin, and (c) the occasional presence of large nucleoli. Finally, grade III PIN demonstrates (a) a cribriform-like acinar architecture, (b) disruption of the basal cell layer in 56% of cases, (c) significantly enlarged nuclei displaying an increased chromatin pattern, and (d) the frequent presence of large pleomorphic nucleoli (93). These features are illustrated in Fig. 33.9. In 1989, an international consensus group proposed that PIN be divided into low-grade (PIN 1) and high-grade (PIN 2 and 3) lesions (80,83,242).

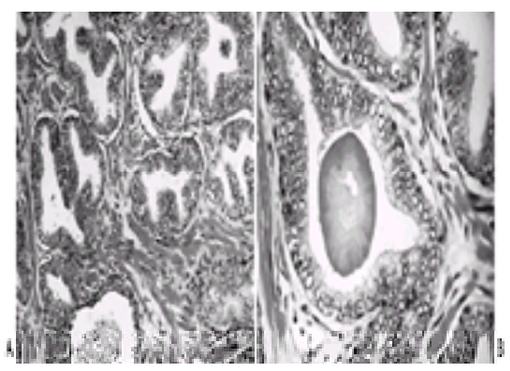

FIGURE 33.9. High-grade prostatic intraepithelial neoplasia (PIN). A pseudocribriform pattern is seen in these photomicrographs **(A, B).** Such acini frequently demonstrate abnormal proliferative activity, large nuclei, pleomorphic nucleoli, and disruption of the basal cell layer. Note the maintenance of intervening stroma (hematoxylin-eosin, **A:** 90× magnification, **B:** 200× magnification). (Photomicrographs courtesy of R. Oyasu, M.D.)

Four architectural patterns of high-grade PIN—tufting, micropapillary, cribriform, and flat—have been recognized (Fig. 33.10). Although most cases exhibit multiple patterns, the tufting pattern predominates and can be identified in 97% of declarative cases (80). No apparent correlation exists between the Gleason grade of the tumor and the associated pattern(s) of high-grade PIN. Thus recognition of the various histotypes of high-grade PIN appears to have only a descriptive or a diagnostic value. High-grade PIN can traverse prostatic ducts by one of three mechanisms. First, the tumor cells can replace normal luminal secretory epithelial, with preservation of the basal cell layer and basement membrane. In the second pattern, tumor cells directly invade through the ductal or acinar wall, disrupting the basal cell layer. The final, and most unusual, pattern of invasion involves invagination of tumor cells between the basal cell and columnar secretory cell layers. The latter phenomenon has been described as “pagetoid spread” (80,83,85). Most foci of high-grade PIN are located exclusively in the peripheral zone (63%) or simultaneously in the transition and peripheral zones (36%). Only 1% of high-grade PIN lesions can be identified exclusively in the transition zone (80,83,85). High-grade PIN exhibits multicentricity in greater than 70% of cases, which further validates the “field change” hypothesis (382).

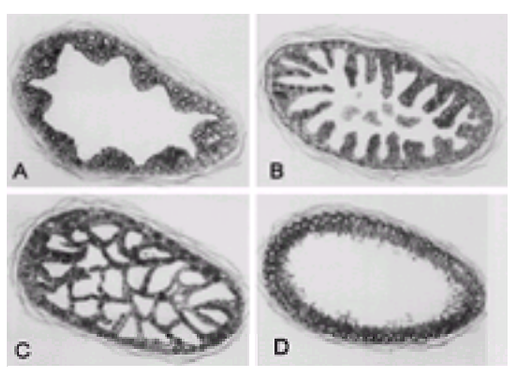

FIGURE 33.10. Illustration of architectural patterns of high-grade prostatic intraepithelial neoplasia (PIN). **A:** Tufting pattern is exemplified by undulating mounds of cells protruding into the lumen. **B:** Fingerlike projections, with or without fibrovascular cores, are seen in the micropapillary pattern. **C:** The cribriform pattern demonstrates a sieve-like pattern. **D:** The flat pattern demonstrates one or two layers of cells. [From Bostwick DG, Amin MB, Dundore P, et al. Architectural patterns of high-grade prostatic intraepithelial neoplasia. *Hum Path* 1993;24(3):298, with permission.]

Most studies suggest that the incidence, extent, and severity of PIN increase with patient age. An interesting study by Sakr and associates (855) demonstrated the presence of PIN in men in their twenties (9%) and thirties (22%). This finding antedated the onset of carcinoma by more than 10 years. The clinical significance of recognizing high-grade PIN is its strong association with CaP. Approximately 82% of step-section autopsy prostates with cancer and 86% of radical prostatectomy specimens with cancer contain high-grade PIN often within 2 mm of invasive cancer (80,85). Moreover, up to 16% of transrectal biopsies performed because of an abnormality of the PSA profile or the digital rectal examination (DRE) contain high-grade PIN (497). Additional studies have shown that patients with high-grade PIN but no cancer in core biopsies have a 50% risk of CaP on subsequent biopsies (812). Several recent studies have demonstrated conclusively that high-grade PIN alone does not contribute significantly to serum total and percentage of free PSA levels (673,812).

From a phenotypic standpoint, high-grade PIN is much more closely related to carcinoma than to benign epithelium. The karyotypic abnormalities of high-grade PIN and invasive CaP are highlighted in Table 33.4. Tumor cell properties linking high-grade PIN and CaP are summarized in Table 33.5. The general perception is that high-grade PIN is associated with progressive abnormalities of phenotype and genotype, which lie intermediate between normal prostatic epithelium and invasive CaP (81). Figure 33.11 highlights the strategic role proposed for high-grade PIN in this morphologic continuum.

TABLE 33.5. HIGH-GRADE PROSTATIC INTRAEPITHELIAL NEOPLASIA AND INVASIVE ADENOCARCINOMA OF THE PROSTATE: PHENOTYPIC SIMILARITIES

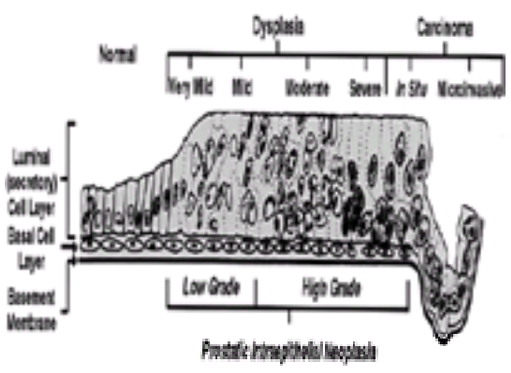

FIGURE 33.11. Proposed model of prostate carcinogenesis. Spectrum of presumed morphologic changes that occur following malignant transformation of normal luminal (secretory) prostate epithelial cells. High-grade prostatic intraepithelial neoplasia (PIN) is thought to be the precursor lesion to invasive acinar prostate cancer. (From Bostwick DG. What is the clinical significance of high-grade PIN? *Contemp Urol* 1998;March:43, with permission.)

Basal cell hyperplasia is a unique, characteristically multicentric variant present in approximately 5% of BPH specimens (677). The closely packed, hypercellular clusters of pure basal cells are difficult to distinguish from CaP (Fig. 33.12). Although generally considered a benign lesion, Mostofi (677) has reported several histopathologic subsets of basal cell hyperplasia, some of which may have ominous significance.

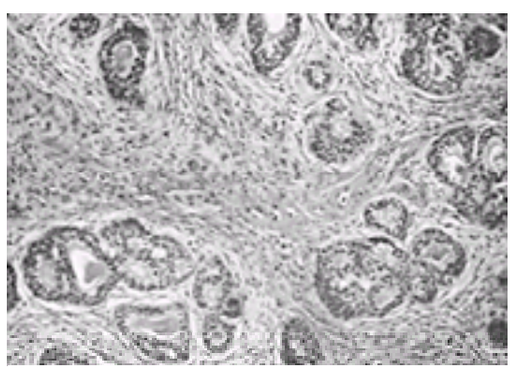

FIGURE 33.12. Basal cell hyperplasia. Basal cells may constitute a reserve population of prostatic cells capable of differentiating into typical secretory columnar elements. In basal cell hyperplasia, multifocal nests of such cells are often seen admixed with glandular and stromal hyperplasia. Carcinoma can coexist as well, especially in the presence of atypical variants. Typical features include rarity of mitotic figures, absence of infiltrative or perineural growth, peripheral palisading of cells within each nest, absence of cytologic atypia, and high affinity of these cells for toluidine blue. Most of these features are demonstrated in this photomicrograph (100× magnification). (Courtesy of R. Oyasu, M.D.)

In senile atrophy, the characteristically small, collapsed acini, which may contain cuboidal epithelium with prominent nuclei, may simulate carcinoma. However, such acini are always surrounded by a distinctive collar of collagenous connective tissue, and the atrophic changes involve the entire lobule diffusely (Fig. 33.13). These involutional or atrophic changes generally commence at approximately the fifth decade and appear primarily in the peripheral or outer zone of the prostate.

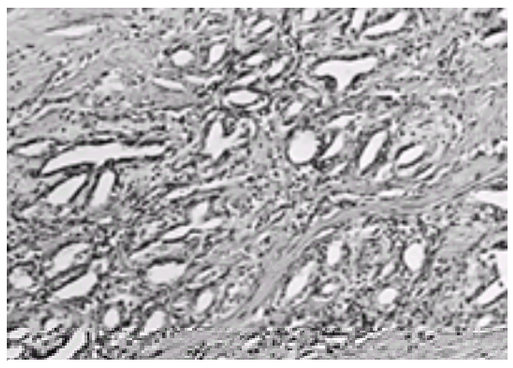

FIGURE 33.13. Senile atrophy of the prostate. The atrophic changes most often involve glandular and stromal elements. The former become collapsed, possess cuboidal cells with prominent hyperchromatic nuclei, and are closely packed. The stroma often undergoes sclerotic atrophy with hyalinization of the collagen component being a noteworthy feature. This photomicrograph (130× magnification) typifies these features. [From Mostofi FK, Price EB Jr. Tumors of the male genital system. In: Universities Associated for Research and Education in Pathology, National Research Council (U.S.). Committee on Pathology, eds. *Atlas of tumor pathology,* Second series, fascicle 8. Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.]

Interpretation of other histologic changes also may be a diagnostic challenge. Granulomatous prostatitis (Fig. 33.14) may present as a sheet of cells with small nuclei and a large clear cytoplasm. At times the cells show marked pleomorphism mixed with inflammatory cells. Multinucleated giant cells also may be present. Histologic changes associated with a healing infarct may include prominent squamous and transitional metaplasia, but these lack any evidence of anaplasia or invasion. Last, cells with bizarre hyperchromatic nuclei are often encountered in an involuting seminal vesicle. Although these cells may suggest CaP, they possess a normal nuclear cytoplasmic ratio and lack prominent nucleoli and the internuclear halo characteristic of CaP (677).

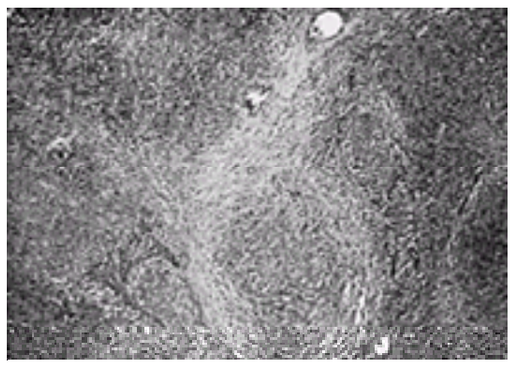

FIGURE 33.14. Granulomatous prostatitis. This process is thought to arise as a consequence of ductal obstruction with subsequent destruction of ductal epithelium and release of irritating protease-rich products into interstitial tissue. Grossly, prominent, firm yellowish nodules may be appreciated. As demonstrated in this photomicrograph (130× magnification), the normal prostatic architecture may be destroyed and replaced with a monotonous array of mononuclear phagocytes, plasma cells, and lymphocytes. Giant cells may be seen and their periductal location is characteristic. (Photomicrograph courtesy of R. Oyasu, M.D.)

Histochemistry

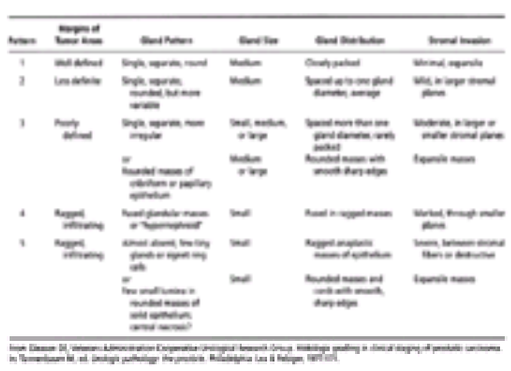
Histochemical techniques utilizing specific antibodies to enzymes and various other proteins are being used with increased frequency to evaluate tissue specimens with recognized or suspected CaP. These procedures are used to identify the tissue of origin of a recognized carcinoma, to accumulate evidence of characteristics that help differentiate benign and malignant tissue, or to provide evidence regarding the biologic potential of CaP. Histochemical confirmation of the presence of PSA and/or prostate acid phosphatase (PAP) provides strong evidence that the prostate is the parent organ of a typical malignancy. Both PSA and PAP usually show a decreasing histochemical content as the degree of differentiation of the malignancy decreases. Recently immunohistochemical techniques to evaluate the presence and possibly crudely quantify human kallikrein 2(hK2), a trypsin-like protease that shares a 78% amino acid homology with PSA, have become available. hK2 converts pro-PSA into enzymatically active PSA capable of complexing with a_1-antichymotrypsin. It is present in benign and malignant prostatic tissue.

The role of CK staining of basal and luminal cells in facilitating recognition of malignancy has been discussed. Established LNCaP, DU-145, and PC3 cell lines demonstrated expression of CK8 and 18 but not 5, 7, and 15 in our experience (909); the latter were observed in BPH. CK5 was selectively expressed in the basal cell population of human prostate (696), a characteristic shared with K14 (1040). Staining techniques using antibodies for proteins expressed by prostate cancer cell lines and clinical tumor specimens are becoming increasingly available, including probes for (a) nuclear androgen receptor (AR) (697), (b) bcl-2 (626), (c) p53 (79), and (d) parathyroid hormone–related peptide (463) and OA-519 (fatty acid synthase) (274). Useful markers of neuroendocrine differentiation include chromogranin A and neuron-specific enolase (455). No cancer-specific antigen has been isolated.

Grading

Grading is an effort to use histologic characteristics of a tumor to predict its biologic activity. Various microscopic observations have been used in this effort. These include the configuration and arrangement of acini; cellular characteristics, including the distinctiveness of cell borders, the degree of nuclear distortion, and pleomorphism; the number and size of the nucleoli; and significant biologic evidence of behavioral patterns such as invasion of lymphatic or vascular channels or tumor cell volume.

All the systems proposed to grade CaP use the acinar pattern. The Gleason and M.D. Anderson systems use this characteristic exclusively. Others, including the Mostofi, Gaeta, and Mayo Clinic systems, also use the cellular characteristics in this effort. None of the systems described has an established advantage with regard to prediction of biologic behavior of the tumors assessed. The Gleason classification scheme, currently the most popular, uses low-power magnification (40× to 100×) to assess the glandular pattern of the tumor and its relationship to the stromal compartment (Table 33.6 and Fig. 33.15). Five tumor grades progressing from the most (1) to the least (5) differentiated are recognized. Tumor grade(s) 1 through 5 noted in a specimen are recorded; a Gleason score consisting of the sum of the most and next to most prevalent (mass) grade is calculated.



Pattern	Margins of Tumor Areas	Gland Pattern	Gland Size	Gland Distribution	Stromal Invasion
1	Well defined	Single, separate, round	Medium	Closely packed	Minimal, expansile
2	Less definite	Single, separate, rounded, but more variable	Medium	Spaced up to one gland diameter, average	Mild, in larger stromal planes
3	Poorly defined	Single, separate, more irregular	Small, medium, or large	Spaced more than one gland diameter, rarely packed	Moderate, in larger or smaller stromal planes
		or	Medium or large	Rounded masses with smooth sharp edges	Expansile masses
		Rounded masses of cribriform or papillary epithelium			
4	Ragged, infiltrating	Fused glandular masses or "hypernephroid"	Small	Fused in ragged masses	Marked, through smaller planes
5	Ragged, infiltrating	Almost absent, few tiny glands or signet ring cells	Small	Ragged anaplastic masses of epithelium	Severe, between stromal fibers or destructive
		or	Small	Rounded masses and cords with smooth, sharp edges	Expansile masses
		Few small lumina in rounded masses of solid epithelium; central necrosis?

TABLE 33.6. HISTOLOGIC PATTERNS OF ADENOCARCINOMA OF THE PROSTATE

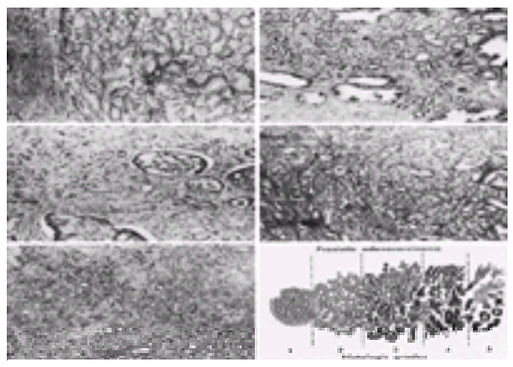

FIGURE 33.15. The Gleason grading system. This assessment is made under low-power magnification (40× magnification; 100× magnification) and involves a determination of glandular differentiation coupled with the growth pattern of the tumor in relation to the surrounding stroma. Representative examples of the five histologic grades are depicted as follows: Pattern 1 **(upper left),** pattern 2 **(upper right),** pattern 3 **(middle left),** pattern 4 **(middle right),** and pattern 5 **(lower left.)** (From Gleason DF, Veterans Administration Cooperative Urological Research Group. Histologic grading in clinical staging of prostatic carcinoma. In: Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:171, with permission.)

Grade (pattern) 1 contains a rather homogeneous array of single, round-to-oval, separate but closely packed glands. Stromal invasion is uncommon and, when present, is expansile in nature. Tumor margins are very well defined (Fig. 33.16). Intraluminal crystalloids (Fig. 33.17), identified in approximately 10% of differentiated prostate cancer specimens and thought to be associated exclusively with malignancy, also have been noted in approximately 3.6% of BPH tissues. Of interest, the biochemical nature of the interacinar crystalloids remains elusive (766).

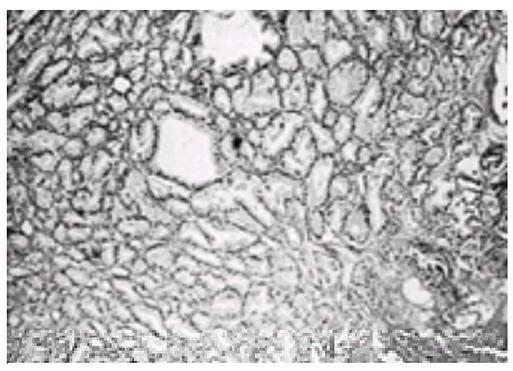

FIGURE 33.16. Gleason pattern 1. Note the rather monotonous array of closely packed acinar elements (hematoxylin-eosin; 130× magnification). Additional features include loss of the basal cell layer and absence of intervening stroma (Fig. 33.2). (Photomicrograph courtesy of R. Oyasu, M.D.)

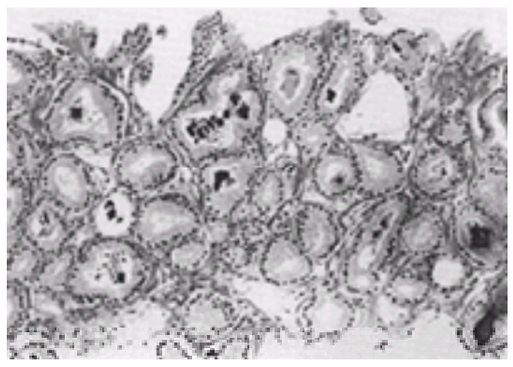

FIGURE 33.17. Prostate adenocarcinoma with intraacinar crystalloids. Dark, well-defined crystals (none uniform in size and shape) are present within the lumens of multiple neoplastic glands. Ordinarily, these crystals are intensively eosinophilic.

Grade (pattern) 2 has an acinar pattern quite similar to that of pattern 1 except that there is less uniformity in glandular shape and often up to one-gland diameter distance between acinar units. A mild amount of stromal invasion is encountered; consequently, the tumor margins are less well circumscribed (Fig. 33.18).

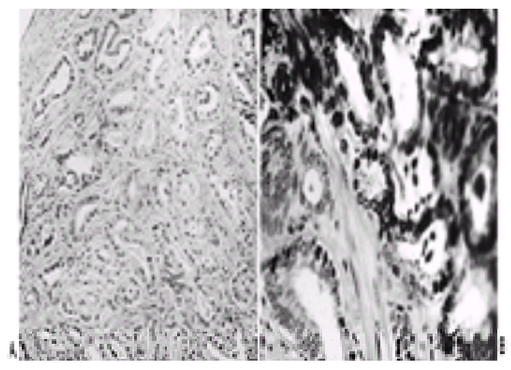

FIGURE 33.18. Gleason pattern 2. These acini demonstrate less uniformity in shape and less cohesiveness than pattern 1 acini (**A:** 130× magnification). Areas of stromal invasion can be appreciated and account for a less well-circumscribed tumor margin (**B:** 400× magnification). (Photomicrographs courtesy of R. Oyasu, M.D.)

Grade (pattern) 3 contains three distinctive subpatterns. The first is characterized by single but very irregular glands separated from one another by more than one gland diameter. Stromal invasion is exhibited to a moderate degree, and the tumor margins are generally poorly defined. The second consists of microglandular nests of cells that form small groups or cords. The last subpattern manifests sharply circumscribed rounded masses of papillary or cribriform epithelium possessing smooth, sharp edges. They present as expansile masses within the stroma, are found in medium to large glands, and also are associated with poorly defined tumor margins (Fig. 33.3).

Grade (pattern) 4 contains two subpatterns. The first consists of coalescence or fusion of ragged glandular masses that exhibit prominent branching. Stromal invasion

is marked and the tumor appears quite ill defined. The second subpattern consists of the same morphologic type of tumor except for the presence of large cells with very pale, clear cytoplasm reminiscent of clear-cell carcinomas of the kidney and designated “hypernephroid” cells.

Grade (pattern) 5 is characterized by irregular infiltrating masses of malignant cells, usually without any gland formation. A second rare variant consists of an irregular cribriform arrangement with central necrosis mimicking comedocarcinoma of the breast. This pattern is typified by extensive stromal invasion, a virtually imperceptible interface between tumor and adjacent normal parenchyma, and its frequent occurrence in small glands (Fig. 33.19).

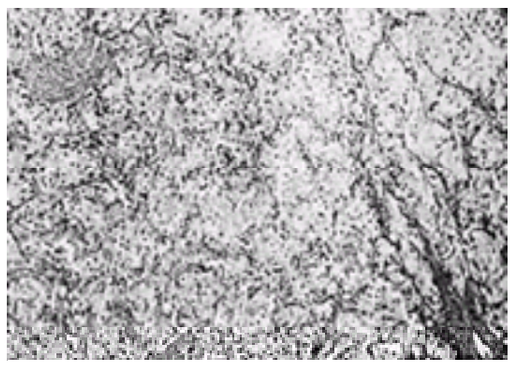

FIGURE 33.19. Gleason pattern 4 to 5. The presence of large cells with pale cytoplasm is characteristic of the “hypernephroid” variant of pattern 4 tumors. The absence of true gland formation and diffuse stromal invasion is more typical of pattern 5 neoplasms (hematoxylin-eosin; 200× magnification). (Courtesy of R. Oyasu, M.D.)

Recognition that approximately 50% of tumors will manifest more than one of Gleason's histologic patterns and that the presence of a histologically heterogeneous tumor had biologic significance led to the use of the sum of the primary and secondary patterns as the Gleason (pattern) score (363). Possible pattern scores range from 2 to 10, with the former being indicative of very well-differentiated tumors and the latter of the highly undifferentiated variety. The Gleason tumor score correlates with various parameters indicative of tumor systems possessing invasive and metastatic capacity. These include the presence of lymphatic and skeletal metastasis, ureteral obstruction, the rate of clinical progression, and cancer death rate (143,363,535). An attempt to augment the biopredictive accuracy of this classification by adding staging to the histologic observations to establish tumor category has largely been abandoned.

The Mostofi, Gaeta, and Mayo Clinic grading systems assume that independent assessment of acinar and cellular detail provides additional prognostic information.

The Mostofi system differentiates tumor-forming glands composed of epithelial cells with slight nuclear anaplasia (grade 1), moderate nuclear anaplasia (grade 2), or marked nuclear anaplasia or completely undifferentiated without gland formation (grade 3). Proponents of this system believe it to be equivalent to the Gleason classification scheme, although this remains to be proved (679).

The Gaeta system used by the National Prostate Cancer Project (328), uses the worst combination of gland morphology and/or cellular anaplasia noted in at least one-third of the tumor specimen to establish grade. Grade 1 tumors consist of well-defined, medium to large glands with uniform normal sized cells with an inconspicuous nucleolus separated by scant intervening stroma. Grade 2 tumors consist of medium to small acini associated with a moderate amount of intervening stroma. Slight pleomorphism and prominent nucleoli characterize the cells. Grade 3 prostate cancers have small glandular elements lacking acinar organization, often with cribriform and scirrhous patterns and cells with pronounced pleomorphism, containing vesicular nuclei, and acidophilic nucleoli. Finally, grade 4 tumors show round, expansile tumor cell masses without evidence of true gland formation and contain cells that may be quite uniform or very pleomorphic that are not infrequently associated with significant mitotic activity. The proponents of this system cite a definite correlation between the Gaeta histologic grade and the likelihood of lymphatic metastasis, overall tumor stage, and the associated mortality of CaP.

The Mayo Clinic grading system also relies on assessment of glandular structure, cytoplasmic-nuclear-nucleolar morphology, mitotic activity, and tumor invasiveness (532,533). Grade 1 neoplasms consist of glandular elements that are uniform in shape with little intervening stroma, and cuboidal cells with prominent hyperchromatic nuclei and nucleoli and infrequent mitotic activity. Nuclear pleomorphism, diminution in acinar size, and an increase in the surrounding stromal element characterize grades 2 and 3. Grade 4 neoplasms lack distinct acinar structure; the cells have highly pleomorphic, markedly hyperchromatic nuclei, scanty cytoplasm, and frequent mitotic figures. Prominent tonguelike cords of cells are seen invading the surrounding stroma.

Several reports (275,376,720) indicate that histologic tumor grade is the most important predictor of tumor progression. Nevertheless, the recognition that most CaPs are classified as intermediate grade, indicating a variable biologic potential, increases the importance of efforts to identify other indicators of risk of invasion and dissemination. The demonstration that even the lowest grade or most differentiated prostate cancers may possess these characteristics (660) reinforces this need.

Cytology

Currently, the systematic use of transrectal ultrasound (TRUS)-guided prostatic needle biopsies constitutes the most common method of tissue procurement in patients considered at risk for CaP. Nonetheless, patients who exhibit a focal area of induration or nodularity may benefit from the adjunctive use of digitally directed needle core biopsies or transrectal needle aspiration cytology. The latter approach is minimally traumatic and may have appeal in those patients for whom concern regarding the potential for bleeding and infection is heightened. Accurate cytologic assessment of the material obtained by needle aspiration of the prostate is critical to this procedure. This brief discussion should serve to familiarize the reader with the cytologic findings associated with BPH, PIN, the various grades of prostate carcinoma, and various common cellular contaminants. A thorough review of these areas has been provided by Koss and associates (528).

Aspirates of BPH typically contain clusters of flat, cohesive, epithelial cells possessing finely granular cytoplasm, round-to-oval nuclei of uniform size, the distinct absence of mitotic figures, and only the most diminutive nucleoli. The closely approximated polygonal cells that compose these cohesive sheets have well-defined cytoplasmic borders that result in a characteristic honeycomb configuration (Fig. 33.20). Very few detached cells are encountered. Many of the latter are myoepithelial cells containing small, spindly, hyperchromatic nuclei. In the presence of coexisting chronic prostatitis, occasional lymphocytes and plasma cells are noted. Aspirated stromal fibroblasts are generally elongated cells with sharp pointed nuclei, whereas smooth muscle elements possess nuclei with rounded ends.

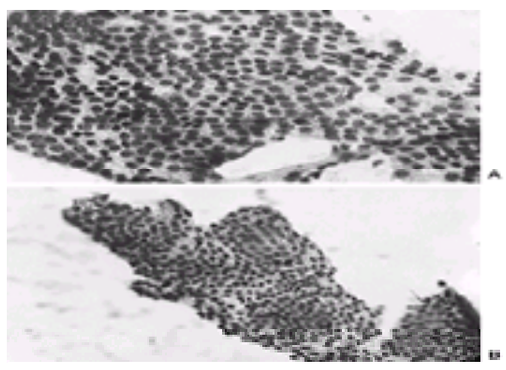

FIGURE 33.20. Benign prostatic hyperplasia (BPH): prostate needle aspirate. Transrectal needle aspiration of benign hyperplastic elements reveals flat sheets of monotonously uniform epithelial cells, which demonstrate a high degree of affinity for one another. The cells constituting such honeycomb clusters have typically normal features and lack the presence of mitoses and prominent nucleoli. Stromal elements (myoepithelial cells) are frequently encountered. The similarity between aspirates of normal prostate (**A:** 200× magnification) and BPH (**B:** 100× magnification) can be appreciated. (Photomicrographs courtesy of D. Hidvegi, M.D.)

PIN is easily confused with invasive CaP when the diagnosis relies solely on cytologic interpretation of fine-needle aspirates. PIN (grade I) may resemble BPH except for the presence of slight nuclear enlargement and hyperchromasia. On the other hand, PIN (grades II and III) may be indistinguishable from CaP and manifest (a) absence of flat, cohesive clusters, (b) occasional evidence of detached single epithelial cells, (c) enlarged hyperchromatic nuclei, and (d) prominent nucleoli. In most instances, needle biopsy of the prostate is required to establish the diagnosis and exclude the presence of coexistent carcinoma (340,740).

Moderately differentiated CaP (Fig. 33.21) consists of an admixture of rosettelike clusters together with numerous dispersed cells. Honeycombing is never encountered. The detached epithelial cells have characteristic large hyperchromatic nuclei with conspicuously enlarged or duplicated nucleoli. Mitotic figures are seen occasionally. Myoepithelial cell nuclei are not present.

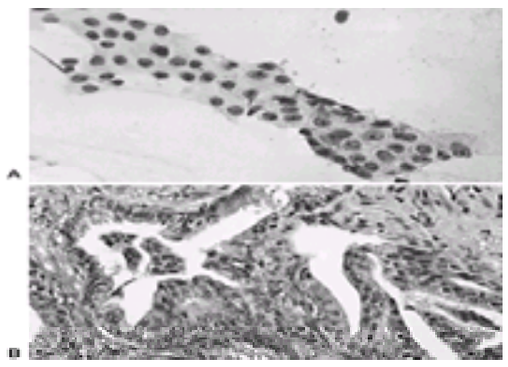

FIGURE 33.21. Prostate needle aspirate of well-differentiated carcinoma. These tumors can be differentiated from benign prostatic hyperplasia by the presence of thick cell clusters, which have lost the typical honeycomb configuration. Detached cells are encountered occasionally, and all cellular elements display hyperchromatic nuclei and prominent nucleoli **(A)** (200× magnification). Note the correspondence of the aspirate to its representative tissue section **(B)** (150× magnification). (Photomicrographs courtesy of D. Hidvegi, M.D.)

Aspirates containing poorly differentiated CaP are very distinctive (Fig. 33.22) and consist primarily of dispersed cells containing significantly enlarged and irregularly shaped nuclei and nucleoli. Abnormal mitotic figures are encountered frequently. The smear pattern is so bizarre that a clear-cut diagnosis of prostate cancer may require histochemical staining to differentiate it from a high-grade urothelial cancer invading the prostate.

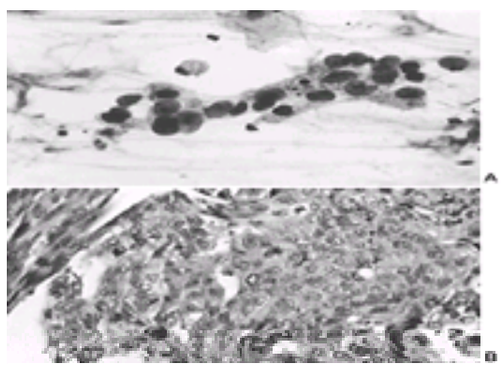

FIGURE 33.22. Needle aspirate of poorly differentiated prostate cancer. Loosely adherent and detached cells predominate and possess pleomorphic nuclei and significantly enlarged nucleoli, and often exhibit mitotic figures. Again, note the similarity between the aspirate **(A)** (200× magnification) and its tissue counterpart **(B)** (150× magnification). (Photomicrographs courtesy of D. Hidvegi, M.D.)

Contamination of the aspirate by cells from the rectum, seminal vesicle, or bladder can result in confusing findings. Transrectal prostatic aspirates may contain some rectal mucosal cells. These cells are generally larger than prostatic cells. They tend to form prominent cohesive sheets, with the typical honeycomb appearance characteristic of BPH. Peripheral palisading of cells with a central rosettelike pattern is fairly typical, as is the presence of small peripherally located nuclei (528). Seminal vesicle cells characteristically containing prominent hyperchromatic nuclei four to eight times larger than normal prostatic nuclei must be distinguished from anaplastic carcinoma. Unlike the latter, however, the cytoplasm is very generous, often vacuolated, and classically contains granular yellow-brown pigment (528). Aspiration of nodules along the midline or close to the bladder neck may result in the inadvertent aspiration of urothelial cells. The latter may consist of prominent, flat, multinucleated umbrella cells or the more diminutive and elongated subadjacent transitional cells. The presence of either acute or chronic prostatitis may make a definitive diagnosis of CaP difficult (528). In the former, necrotic or degenerating epithelial cells may reveal bizarre aberrations of size and shape. Polymorphonuclear leukocytes are abundant; macrophages are present occasionally. In contrast, chronic prostatitis is often associated with abundant fibroblasts and smooth muscle cells together with a prominent mononuclear cell infiltrate. Foamy macrophages and multinucleated giant cells are also characteristic.

Unusual Prostate Tumors

The preceding discussion appropriately emphasized prostatic adenocarcinomas of acinar origin because they constitute well more than 95% of prostatic neoplasms (112). In this section, we highlight some of the features of infrequently encountered malignant prostatic tumors. For purposes of discussion, these neoplasms can be segregated as follows: (a) atypical adenocarcinomas, (b) sarcomas, (c) exotic primary tumors, and (d) secondary tumors (1075).

Ductal cancers, the largest subset of atypical prostate adenocarcinomas, include carcinomas originating from either the primary or secondary ductal networks, endometrioid (papillary) carcinomas, and transitional or squamous cell cancers. Less frequently encountered neoplasms include mucinous and adenoid cystic carcinomas, along with carcinosarcomas.

The low columnar epithelium lining the primary and secondary ductal system of the prostate contrasts with the transitional cell lining of the periurethral component. Primary and secondary ductal tumors arising from these columnar cells constitute approximately 3% of prostate cancers (142). Primary ductal cancers, thought to originate from the prominent, centrally located, periurethral ductal network, may progress via intraluminal extension or local invasion.

These tumors often present with gross hematuria; cystourethroscopy often reveals the characteristic papillary morphology. The present consensus is that so-called endometrioid carcinomas of the prostate (Fig. 33.23) (639) are variants of primary ductal adenocarcinoma with endometrioid (i.e., papillary) features (277,532,533). Among carcinomas with ductal differentiation, the cribriform pattern is more common than the papillary (or endometrioid pattern). Ductal adenocarcinoma components are generally not assigned a Gleason grade, because doing so has not been shown to be of prognostic significance. At the time of diagnosis, the majority of these tumors are large and of advanced stage. They tend to have a more adverse prognosis than carcinomas without distinctive ductular differentiation (171).

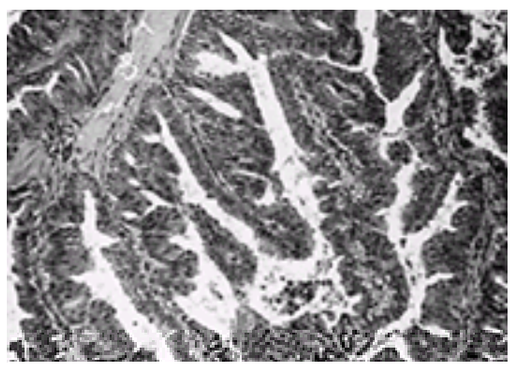

FIGURE 33.23. Endometrioid carcinoma of the prostate. This variant of ductal carcinoma may present as a papillary or infiltrating tumor. The former variety is illustrated here. Note the typical exophytic character. Cells may vary from tall columnar epithelium possessing a vacuolated cytoplasm to aggregates of cuboidal cells in which the cytoplasm is distinctly granular. Such tumors may coexist with foci of atypical hyperplasia and more common variants of primary ductal cancer (76× magnification). (Photomicrograph courtesy of R. Oyasu, M.D.)

Secondary ductal carcinomas, thought to originate in a multicentric fashion from the secondary and tertiary ducts, are associated with desquamation of necrotic debris within the ductal lumen. They often assume a comedo-like appearance. These variants are thought to be more aggressive with a proclivity for early stromal invasion (244,384). Secondary ductal carcinoma may be perceived on rectal examination. Although conflicting information exists regarding androgen dependence of intraductal neoplasms, several studies using special histochemical techniques have documented the presence of PAP and PSA in the majority of them (542,1070). The bony metastases associated with both the primary and secondary ductal cancers tend to be osteoblastic, with associated elevations of blood markers (244,639).

Many patients with metastatic ductal carcinoma respond to androgen deprivation therapy. However, as a group, these patients tend to have a slightly worse prognosis compared with those with tumors arising from acinar elements (142,143). Undoubtedly, some CaP are composed of a mixture of ductal and microacinar elements. With regard to this last subset, recent observations demonstrate that the ductal spread of prostatic (acinar) carcinoma is a frequent event and occurs in approximately half of cases studied (531). Carcinoma cells have been observed to penetrate the wall of benign ducts and gradually replace the normal epithelial component. Such a phenomenon might be easily misconstrued for a primary ductal cancer.

Transitional and squamous cell carcinoma of the prostate are appropriately considered together, because the latter tumor represents a metaplastic variant of the former (680). They typically arise in the central or periurethral ductal transitional epithelium of the prostate gland and constitute 2% to 3% of prostate cancers (Fig. 33.24) (1075). Although they probably share some etiologic factors (see Chapter 30), these tumors must be differentiated from panurothelial transitional cell carcinomas associated with transitional cell carcinoma of the bladder. At times, differentiation of this malignancy and poorly differentiated prostate carcinoma is challenging. Use of histochemical stains for PSA, PAP, and other selected cellular proteins assists in identifying the cell of origin. Transitional cell carcinoma of the prostate is characterized by local extension in the prostatic stroma and to the bladder neck, regional spread to the pelvic lymph nodes, and distant dissemination to bone and lung. The presence of a palpable rectal lesion usually indicates widespread disease. Bone lesions are commonly osteolytic; lung lesions usually are subpleural nodular deposits rather than the lymphangitic metastasis typically associated with CaP (385).

FIGURE 33.24. Transitional cell carcinoma of the prostate. Photomicrograph reveals a large, centrally located prostatic duct totally occluded by transitional cell elements. Approximately one-third of patients with such biopsy findings will have primary transitional cell neoplasms of the prostate without a history of synchronous or metachronous transitional cell tumors of the urethra and bladder (189× magnification). (Photomicrograph courtesy of R. Oyasu, M.D.)

Adenoid cystic and pure mucinous (colloid) carcinomas of the prostate are rare. Adenoid cystic carcinoma (0.01% of prostatic malignancies) has both glandular and cystic elements and often mimics the cribriform pattern of acinar carcinoma (1075). However, the small deeply staining cells resembling basal cells and the hyaline or mucoid material seen in the honeycomb, or Swiss cheese glandular pattern, are distinctive (Fig. 33.25). This tumor pattern also has been reported to originate in Cowper's glands. Mucinous (colloid) carcinoma (694) must be distinguished from both primary acinar adenocarcinoma with mucinous elements and secondary mucin-producing tumors. The latter generally originate from colon, bladder, and Cowper's gland. This designation is reserved for tumors in whom the mucinous component constitutes more than 25% of the tumor. Mucinous carcinoma of the prostate replaces the bulk of the prostate with a diffuse nonpapillary (colloid) pattern of “lakes” containing acidic mucins (Fig. 33.26) that does not disturb the ductal pattern. The lesion usually remains confined to the prostate, indicating a relatively favorable course; local extension and metastasis to the lung, liver, lymph node, and brain have been reported (264). These tumors tend to react positively with PSA and PAP, which distinguishes them from bladder tumors of similar histology. As was true with tumors exhibiting ductal differentiation, a Gleason grading is performed only on the nonmucinous components of the tumor (690). Pure mucinous prostate carcinomas tend to be hormone insensitive (694).

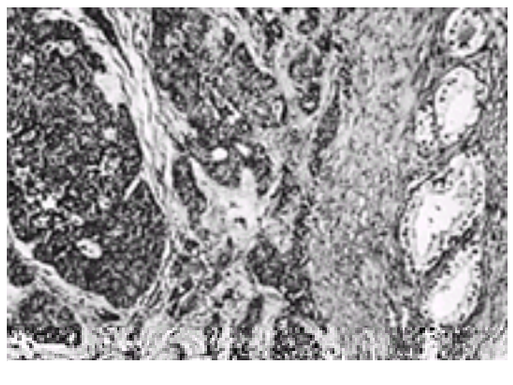

FIGURE 33.25. Adenoid cystic carcinoma. Although several cell types are clearly represented in this photomicrograph, the majority possess deeply staining cytoplasm reminiscent of basal cells (Fig. 33.10). Numerous cystic spaces (“Swiss cheese” pattern) are found in between glandular elements. The latter are surrounded by a prominent mucoid matrix (189× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

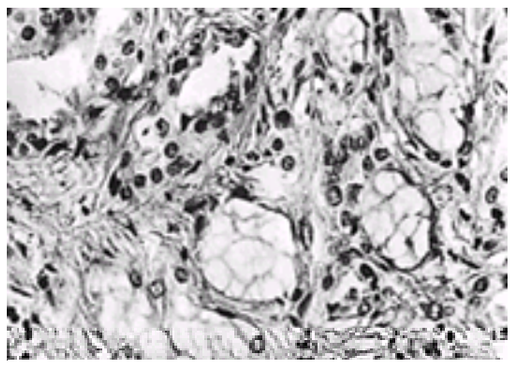

FIGURE 33.26. Colloid carcinoma of the prostate. Mucinous adenocarcinomas as depicted in this photomicrograph often have a soft consistency, as judged by rectal examination. Although nonsulfated acid mucin production can be documented in approximately 75% of prostate cancers, pure colloid carcinomas are rare, with only about 20 cases having been reported. Mucin production can be focally aggregated, as depicted here, or may present as a “mucinous lake,” which may replace large amounts of normal parenchyma (459× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

As the name implies, carcinosarcomas contain elements of both adenocarcinoma and sarcoma (Fig. 33.27) (705,1000). Carcinosarcomas usually are manifested by the presence of highly neoplastic cartilage, bone, and smooth or skeletal muscle. A pelvic mass is often appreciated at the time of initial diagnosis, reflecting the aggressive nature of the disease. Metastases to the spine, liver, lung, and lymph nodes occur early in the onset of the disease. Because the sarcomatous element of these lesions is hormone-resistant, androgen deprivation therapy is only temporarily palliative. These tumors are uniformly fatal with a mean survival of 21 months (705).

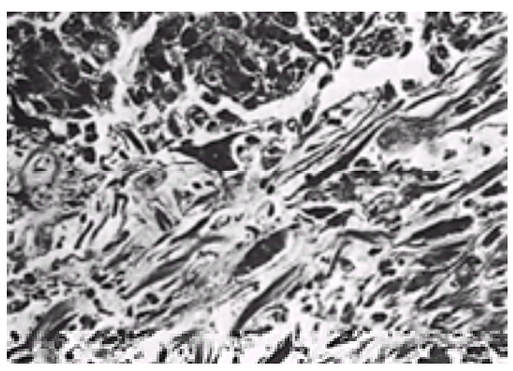

FIGURE 33.27. Carcinosarcoma of prostate. Both carcinomatous *(top left)* and sarcomatous *(bottom right)* elements are depicted in this photomicrograph. In this case, malignant stroma is characterized by the presence of pleomorphic straplike cells not unlike those found in rhabdomyosarcoma (328× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

Pure sarcomas of the prostate are exceedingly rare lesions and constitute less than 0.1% of all malignant prostatic neoplasms (1075). Approximately one-third of these lesions occur within the first decade of life. The most common of these childhood sarcomas is the rhabdomyosarcoma. The latter consists of three histologic subtypes: embryonal (sarcoma botryoides), alveolar, and pleomorphic. This tumor grows posteriorly to involve the rectum and anteriorly to produce a pelvic or abdominal wall mass with impressive rapidity. Lymphatic and hematogenous dissemination occurs early, accounting for frequent involvement of regional lymph nodes, liver, and lungs. When bony metastases occur, they tend to be painful osteolytic lesions. The diagnosis is established by formal biopsy techniques that characteristically reveal large ballooned giant cells often admixed with elongated straplike cells with a typical cross-striation pattern. A discussion regarding the clinical features of these childhood sarcomas is presented elsewhere in this text.

Although 75% of prostatic sarcomas involve males younger than the age of 40 years, these neoplasms do occur in the older age groups. With regard to the latter, the most frequently encountered variants include the leiomyosarcoma, fibrosarcoma, and lymphoma. Less commonly noted lesions include neuroblastoma, neurogenic sarcoma, osteogenic sarcoma, chondrosarcoma, malignant fibrous histiocytoma, fibrosarcoma, and angiosarcomas (1075). The natural history of the more common variants is similar to that of those cited previously. Anterior and posterior extension of the tumor with projection toward the abdominal wall, rectum, and perineum occurs in approximately 75% of these cases. Again, formal tissue biopsy is imperative to establish the diagnosis unequivocally. For example, the very cellular pattern of leiomyosarcoma with characteristic interlacing cell bundles that form a whorled or herringbone pattern (Fig. 33.28) may be difficult to distinguish from stromal hyperplasia (296). Lymphomas and lymphosarcomas may present histologically as a uniform array of large lymphocytes that infiltrate the stroma and acinar elements. These cells often infiltrate between muscle bundles, causing compressive atrophy. A definitive histopathologic diagnosis in these cases may require electron microscopy and an assessment of cytoskeletal features.

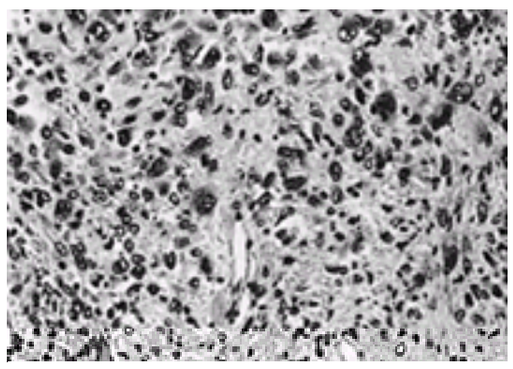

FIGURE 33.28. Leiomyosarcoma of the prostate. These tumors are hypercellular and often present as interlacing bundles of cells suggesting a whorled appearance. Although low-grade leiomyosarcomas may be difficult to differentiate from stromal hyperplasia, the more anaplastic variant depicted in this photomicrograph reveals a highly pleomorphic picture characterized by the presence of occasional multinucleated cells (260× magnification). (From Tannenbaum M, ed. *Urologic pathology: the prostate.* Philadelphia: Lea & Febiger, 1977:303, with permission.)

The literature contains isolated, anecdotal case reports of various unusual or exotic primary neoplasms involving the prostate. Tumors of the amine precursor uptake and decarboxylation (APUD) system, including extrapulmonary small-cell carcinoma, carcinoid tumors, and paragangliomas, have been noted. Ectopic adrenocorticotropic hormone (ACTH) secretion has been reported with some of these lesions. Such observations are not surprising, considering that argentaffin and argyrophil cells have been demonstrated within the normal prostate, glands involved with BPH, and prostatic carcinomas. These cells are of neuroepidermal (neuroendocrine) origin and may be demonstrated by specific staining techniques utilizing various potential probes, including chromogranin A, bombesin, CEA, neuron-specific enolase, serotonin, adrenocorticotropic hormone, somatostatin, synaptophysin, parathormone, calcitonin, S100 protein, human heart factor 35, gastrin, and glucagon. Some of these tumors also may arise from differentiation occurring within acinar epithelial cells. Other reported primary neoplasms include

malignant melanomas, osteochondrosarcomas, and signet ring adenocarcinomas (1075).

Small-cell carcinoma of the prostate is being recognized with increasing frequency (Fig. 33.29) and possesses the following features in common: prominent size, dissemination at the time of diagnosis, poor prognosis, and a large component of small cells with anaplastic nuclei and scant cytoplasm (690). Its development may be associated with adenocarcinoma, or it may be the sole identifiable tumor component. Limited observations suggest a rapid progression of metastatic androgen-independent disease with involvement of multiple organs. These tumors usually retain evidence of neuroendocrine origin based on immunohistochemical and ultrastructural features. Their development from totipotential high-grade prostate adenocarcinoma also warrants consideration. Prostate cancers exhibit three forms of neuroendocrine (NE) differentiation: (a) small-cell (NE) carcinoma, (b) carcinoid-like tumors, and (c) conventional prostate cancer with focal NE features. The latter is extensive in 10% of cases and constitutes a poor prognostic indicator.

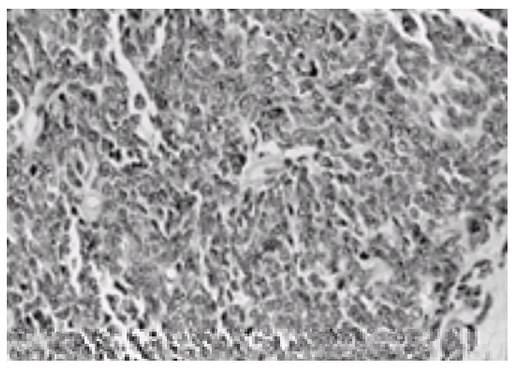

FIGURE 33.29. Small-cell carcinoma of the prostate. These cells exhibit nuclei with condensed chromatin and very scanty cytoplasm (300× magnification). (Photomicrograph courtesy of R. Oyasu, M.D.)

Zein and associates reported one of the most exhaustive studies of secondary tumors of the prostate. On reviewing reports of more than 6,000 autopsies of males with a median age of 66 performed at Roswell Park Memorial Institute during a 25-year period, they noted secondary involvement of the prostate in 328 (5.6%) cases. Prostatic involvement resulted from contiguous or extensive local regional disease in 143. The primary tumors involved the bladder, urethra, colon, rectum, anus, malignant lymphomas, and an assortment of alimentary tract carcinomas and bone or soft-tissue sarcomas. Of 185 (3.1%) true metastatic lesions, leukemia was the most common. In fact, prostatic involvement was demonstrated in 10.3% of all male leukemia autopsies and in 20% of those dying from chronic lymphocytic leukemia. Similarly, 8% of patients dying of non-Hodgkin's lymphoma have prostatic involvement. Of interest, metastasis to the prostate was encountered infrequently in patients dying of Hodgkin's disease. If only nonleukemic, nonlymphoma cases were considered, Zein and co-workers (23) noted prostate involvement in approximately 1% of the autopsied patients. This contrasts to a frequency of 0.5% cited by Johnson and colleagues (471). The most common primary sources encountered in both series were malignant melanoma and lung carcinomas. Other primary sites included pancreas, germ cell tumors, thyroid, stomach, kidney, esophagus, and trachea. Metastases to the prostate gland invariably reflect the presence of a large tumor burden and multiorgan system involvement. In fact, approximately 98% of these patients had extensive disease noted in five or more organs. Although most instances of prostatic metastasis are attributed to the arterial dissemination of tumor emboli, documented cases of venous involvement also exist.

CLINICAL EVALUATION

The proper treatment of patients with CaP depends on proper histologic diagnosis, an assessment of those tumor-related properties possessing prognostic significance, and accurate staging. The following sections present an evaluation of our current diagnostic and staging procedures. At present, the diagnosis of CaP depends on at least three steps: (a) recognition of an indication for tissue sampling, (b) selection and utilization of appropriate tissue procurement techniques, and (c) the unequivocal confirmation of the diagnosis. The status of the criteria used to guide each of these steps is discussed briefly in the following sections.

Identification of Risk

Some studies have documented that a substantial proportion of patients diagnosed with clinically localized CaP may anticipate favorable clinical outcomes and normal life expectancies in the absence of early aggressive treatment. In general, this cohort consists of an older population of men with low-grade tumors. Conversely, the risk of death secondary to CaP is substantial in younger patients exhibiting moderate- or high-grade tumors. Indeed, long-term survival is significantly diminished in patients with CaP spread beyond the capsular perimeter with subsequent involvement of the regional lymph nodes and bone (1014). With respect to this issue, several points are clear. First, the acknowledged disparity between the high prevalence rates for histologic CaP and the relatively low lifetime risk of CaP death (approximately 3%) merely highlights the need to reliably distinguish those tumors destined to adversely affect the quality and/or duration of life from those that will not. Second, avoiding a problem has never solved it.

General Indicators

Increased concern for the presence of CaP is appropriate based on selective hereditary and racial information, symptoms, abnormal findings on the DRE, and the serum PSA profile. The latter two assessments as well as observations made during transrectal ultrasonography (TRUS) are also used to guide appropriate tissue sampling.

Hereditary and Racial Considerations

The importance of hereditary and racial factors with regard to the development of CaP has been covered in detail in the sections on epidemiology and natural history. The American Urological Association (AUA) recently convened a multidisciplinary task force to address the issue of PSA-based screening. It was their consensus recommendation that candidates for early detection testing include (a) men age 40 to 50 with a family history of prostate cancer or African American ethnicity and (b) men age 50 or more with an anticipated life span of 10 years or more (1014).

Symptoms

Until the advent of PSA-based screening in the late 1980s, symptomatic-driven physician encounters were responsible for identifying the vast majority of patients in whom a clinical diagnosis of CaP was made. The traditional teaching that CaP usually does not cause symptoms until it is advanced has most often been confirmed. Problems relating to lower urinary tract voiding dysfunction are most common and those relating to metastatic disease are a distant second in prevalence in these patients. The association with advanced disease reflects the appreciable mass that prostate carcinoma usually must achieve to alter voiding patterns. All of the symptoms characterizing BPH voiding dysfunction occur in these patients. Slow stream, increased urinary frequency, dysuria, and complete retention have historically been identified most commonly in patients with prostatic carcinoma (503), but nocturia, hesitancy, intermittency, sense of incomplete voiding, and urgency also occur. None of these alone or in combination is unique for CaP. In many patients with carcinoma, BPH is the actual cause of the dysfunctional voiding. The physical examination and laboratory evaluation often lead to recognition of increased risk and histologic confirmation of asymptomatic CaP. In addition, unsuspected carcinoma is identified in the excised tissue judged clinically to be BPH. Historically a diagnosis of unsuspected CaP designated stage T_{1a}, T_{1b}, or A_1, A_2 based on the grade and mass of the tumor, has occurred in approximately 10% of men subjected to prostatectomy in the United States. (604). Hematuria occurs in less than 15% of patients with CaP. The suggestion that up to 25% of men with acute urinary retention will have unrecognized CaP as the underlying cause (147) lacks current support. Reports of back, leg, and perineal pain have been present in 20% to 40% of the patients presenting with CaP in the past but constitute a much smaller percentage currently. Constitutional symptoms such as weight loss and general weakness are less common, each occurring in less than 15% of the patients.

Physical Examination

The DRE, preferentially performed with the patient in the supported, bent-over erect or knee-chest position, has traditionally been used to evaluate the size, consistency, and configuration of the prostate to identify changes suggesting a diagnosis of CaP. The presence, configuration, location, intraglandular and

extraglandular extent, and the distinctness of the margins of any indurated or irregular area should be noted and recorded. The status of the median furrow and lateral sulci should be assessed and stipulated. The areas at the base of the seminal vesicle and bladder also should be examined for extension of induration. A two-dimensional diagram helps clarify and record the digital findings (Fig. 33.30).

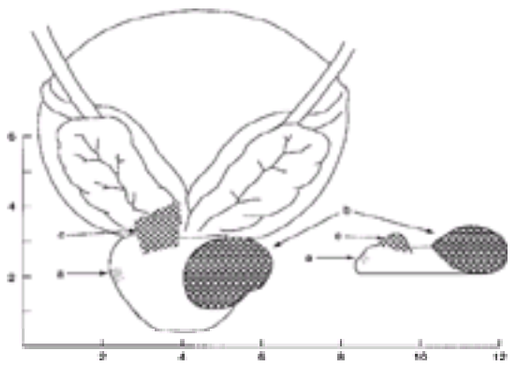

FIGURE 33.30. Diagrammatic representation of findings on digital rectal examination of the prostate gland and seminal vesicles. Nodule configuration is conveyed on the transverse diagram. We conventionally record indurations in a systematic fashion. Minimal degrees of induration are represented by a single series, moderate by a double series, and marked by a triple series of oblique lines. Scale is in centimeters. a-B1 (T_{2a}), tumor involving half of a lobe or less; b-B2 (T_{2b}), tumor involving more than half of a lobe, but not both lobes; c-C (T_{3c}), tumor invades seminal vesicles. (From Kim E, Grayhack JT. Clinical signs and symptoms of prostate cancer. In: Vogelzang NJ, Shipley WU, Sardino PT, eds. *Comprehensive textbook of genitourinary oncology.* Baltimore: Williams & Wilkins, 1996, with permission.)

The classical physical features of CaP include an irregular; stony hard; or notably indurated, flat, or nodular area with indistinct margins. Extension of abnormal findings across normal landmarks increases suspicion of, but is not exclusive for, malignancy. Aside from the median furrow, which is rarely an isolated location for carcinoma, a CaP risk-signaling palpable abnormality may be located anywhere in the gland. Gradually evidence has accumulated indicating that any change in consistency and possibly configuration should lead to consideration of carcinoma as a cause. Alternative causes of a nodule or induration include a calculus, prostatitis, tuberculosis, focal infarction, a postbiopsy tissue reaction, and even a spheroid of benign hyperplasia. X-ray or ultrasound examination usually identifies calculi; microscopic examination of prostatic fluid obtained by massage provides information regarding inflammatory processes. The presence of an alternative cause for the palpable abnormality does not exclude carcinoma. In most circumstances, reexamination after a limited period of observation with or without an active treatment regimen is desirable to confirm the persistence and importance of the palpable abnormality.

Clearly a definite diagnosis of CaP cannot be made on the basis of the physical findings. In a series of 211 patients subjected to open perineal biopsy because of findings on DRE indicating probable localized carcinoma, only 50% had documented malignancy. A literature review of needle biopsy results in 4,939 patients disclosed that only 39% of patients selected for tissue sampling on the basis of the abnormal DRE were found to have carcinoma (89). Brawer (89) cites evidence from his own experiences, as well as the literature, that indicates that carcinoma is found much more frequently on biopsy of the prostate that is a site of a markedly indurated or nodular area highly suspicious for carcinoma (54%), as contrasted to the simple presence of induration (25%) or asymmetry (12%). The rate of positive biopsies in the latter group was approximately the same as in a group of men with normal glands on palpation who underwent biopsy because of an elevated serum PSA or a planned alternative therapy for BPH (15%).

The limitations of DRE as an indicator of the presence and extent of carcinoma of the prostate are well documented. Hudson and associates (441) found approximately one-fourth of the carcinomas, identified on multiple biopsies of the prostate in a group of men with no or minimal symptoms, were associated with areas of no or minimal induration. In a multicenter study of 6,630 men, the intra-gland location of carcinoma as judged from the findings on a routine four-quadrant sampling in addition to lesion-directed biopsies was found only in quadrant(s) lacking induration in 16 of 42 patients with cancer with serum PSA values of 4 ng/mL or less and in 121 of 183 patients with serum PSA levels of greater than 4 ng/mL. In all 624 patients who had an abnormal DRE as an indication for biopsy, regardless of serum PSA levels, cancer was found in 220 of the quadrants biopsied; 110 of these were from quadrants lacking palpable abnormalities (297). Nevertheless, in this study, which included PSA serum levels and DRE as an indicator for biopsy, 146 (55%) of 264 of the patients with biopsy-identified carcinoma had a suspicious DRE; this was the only indication for biopsy in 48 (18%) patients.

The relative lack of sensitivity and specificity associated with the DRE has prompted some physicians to recommend that it be omitted as a routine part of the physical examination. This nihilistic approach is unwarranted and dangerous for several reasons. First, approximately 20% of prostate cancers with aggressive features are detected in men with PSA levels less than 4 ng/mL (825). Fortunately, many of these tumors will present with an abnormal DRE. In addition, evidence has accumulated from three uncontrolled studies that allow a direct comparison of PSA and DRE as screening tools (100,825). Volunteers in these studies were assessed uniformly with both PSA and DRE. Approximately 18% to 26% had either an abnormal PSA or abnormal DRE. CaP was detected in 3.5% to 4.0% of these populations. Although PSA testing detected more tumors than DRE, PSA and DRE each detected cancers not identified by the other modality. For these and other reasons, the AUA multidisciplinary task force recommended that both tests be used in any early prostate cancer detection program (1014). The DRE should be performed by a knowledgeable, skilled individual who recognizes alternative causes and the possible effects of treatment and/or observation on a palpable abnormality. Coordinating a touch diagram and clinical information is particularly helpful in longitudinal patient assessments.

Physical Imaging

The currently available imaging modalities add little to the combination of PSA and DRE for early detection of prostate cancer. The anatomic information provided by transrectal ultrasound of the prostate (TRUSP) usually has been superior to that obtained by either computed tomography (CT) scanning or conventional magnetic resonance imaging (MRI). Recently, reported observations suggest endorectal MRI imaging and spectroscopy may be useful to target suspicious areas/sextants and improve the diagnostic yield of subsequently performed TRUSP-biopsies (1083). In this study, tumors were identified based on low-signal intensity on endorectal MRI T_2-weighted images and magnetic resonance spectroscopy identified areas of abnormal metabolism. Knowledge of this combination of findings enhanced the ultimate yield of ultrasound-guided biopsies in patients who were biopsy-naïve and in those individuals who had undergone previous tissue sampling. The proper use of TRUSP in the diagnosis and staging of CaP is contingent upon the urologist's working familiarity with a reliable 7- to 7.5-MHz multiplane instrument and biopsy system (Fig. 33.31); an appreciation of the recognized ultrasonic features of normal prostate, BPH, and prostate cancer; and an understanding of the limitations of this approach.

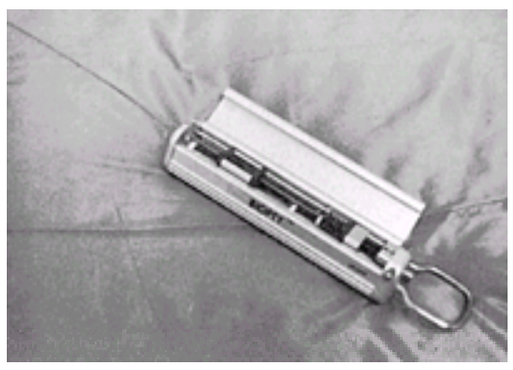

FIGURE 33.31. Example of the Bard automatic biopsy system (i.e., the Biopty gun). (Photomicrograph courtesy of D. Grapey, M.D.)

Ultrasonic imaging of the normal prostate usually identifies distinct peripheral (corresponding to the anatomic peripheral zone) and central (corresponding to the

anatomic central and transition zones) regions. The peripheral region constitutes 75% of the normal glandular volume and occupies the posterior, lateral, and apical regions (Fig. 33.32). Its ultrasonographic appearance is typically described as isoechoic. BPH, developing within the anatomic transition zone, expands the central region of the ultrasound image. This often produces a more rounded configuration of the entire gland, with the most noticeable increase seen in the anteroposterior (AP) diameter (Fig. 33.33). The intact capsule is well defined, but areas of thickening may be apparent. The isoechoic pattern may be disrupted by both hypoechoic and hyperechoic foci, which reflect the presence of viscous secretions within prostatic ducts and the presence of calculi and prostatitis.

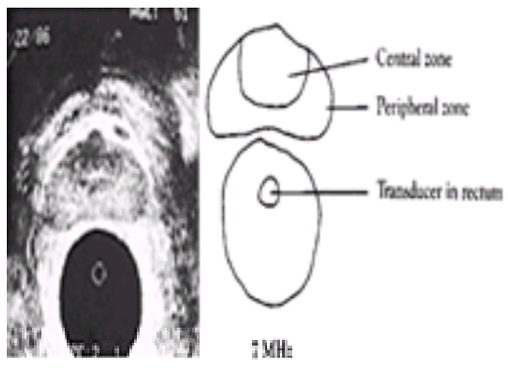

FIGURE 33.32. Transrectal ultrasound of normal prostate. A high-resolution (7-MHz) transducer was used to obtain this transverse scan of the midprostate. Echogenic homogenicity of the parenchyma is apparent along with an echo-rich prostatic capsule. A prominent component of the venous complex is nicely demonstrated in the 1 o'clock position of the capsular parameter. (From Ragde H. *Prostate imaging with transrectal ultrasound.* Seattle, 1986:1, with permission.)

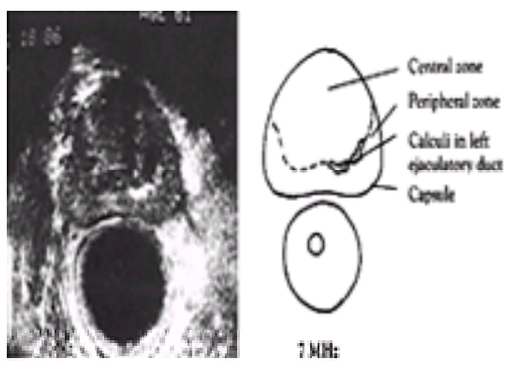

FIGURE 33.33. Transrectal ultrasound of benign prostatic hyperplasia (BPH). Transverse echogram was taken at the level of the verumontanum as demonstrated by the proximity of the *left ejaculatory duct.* The surgical capsule is well defined as an interphase between the prominent adenomatous hyperplasia and the peripheral zone of the prostate. The latter demonstrates homogeneity of its echo pattern and the anatomic capsule is well defined. (From Ragde H. *Prostate imaging with transrectal ultrasound.* Seattle, 1986:1, with permission.)

Attempts to use prostatic ultrasound observations to identify the presence and site of carcinoma of the prostate have been significantly hampered by the failure to identify an echogenic pattern with a high degree of sensitivity and/or specificity for the risk of its presence. The initial experiences with ultrasound resulted in the suggestion that a peripherally located hypoechoic area identified with the available high-resolution equipment indicated a significant risk of CaP (Fig. 33.34). However, an expanding experience demonstrated the limited sensitivity and specificity of this observation. Carcinomas may be associated with hypergenicity, isogenicity, or mixed echogenicity; the hyperechoic patterns with CaP lack the brightness and acoustic shadowing seen with calculi. Hypoechoic foci may result from acute inflammation, infarcts, small nodules of hyperplasia, blood vessels, cystic atrophy, or muscle tissue. In addition, the 20% to 30% of prostate cancers originating in the central or transition zone (631) are difficult to detect on TRUSP. The demonstration of asymmetry, capsular deformity, distorted or obliterated seminal vesicles (Fig. 33.35), and/or a periprostatic mass are observations that raise questions about local extent more often than presence of CaP.

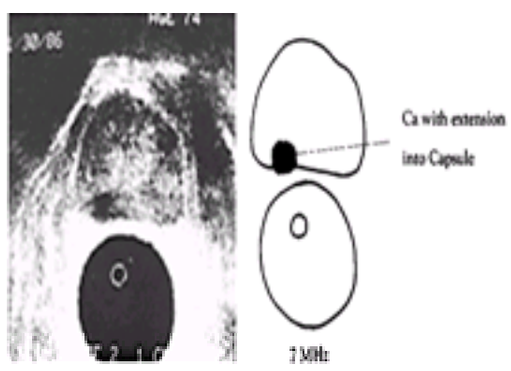

FIGURE 33.34. Transrectal ultrasound of prostate cancer. A conspicuous echo-poor region is seen in the peripheral zone of the prostate on this transverse echogram. The lesion contrasts sharply with the normal aspects of the peripheral zone, which are typically echo rich. (From Ragde H. *Prostate imaging with transrectal ultrasound.* Seattle, 1986:1, with permission.)

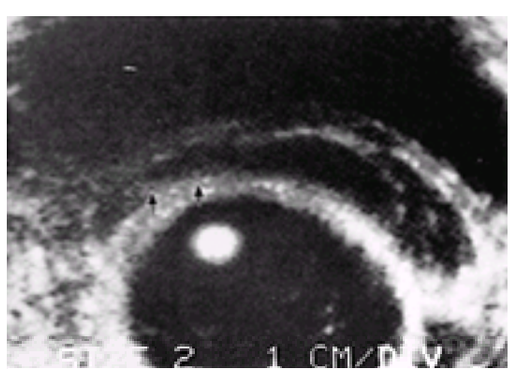

FIGURE 33.35. Obliteration of seminal vesicle *(arrows)* by invasive prostate cancer demonstrated by transrectal ultrasonography (TRUS). Such an observation should prompt a consideration of ultrasound-guided needle biopsy to confirm the presence of stage T_3 disease. (From Waterhouse RL, Resnick MI. The use of transrectal ultrasonography in the evaluation of patients with prostatic carcinoma. *J Urol* 1989;141:233, with permission.)

The limitations of ultrasound evaluation to diagnose risk of CaP have been emphasized by several reported experiences. For example, Devonec and associates (227)

reported only 11 (6.7%) of 162 men with demonstrated hypoechoic areas with TRUSP had cancer, and 6 had high-grade PIN on biopsy. Using six ultrasound-guided biopsies, Vallancien (1035) found carcinoma of the prostate in 14 of 100 men without palpable evidence of malignancy; 18 patients had hypoechoic areas on TRUS, but CaP was diagnosed in only 2 of these. In the previously described multicenter diagnostic efforts (145,297), use of characteristic ultrasound abnormality to justify biopsy of patients with a suspicious rectal finding, a serum PSA greater than 4 ng/mL, or both would have resulted in a failure to diagnose 39% of the cancers ultimately detected. In patients with a PSA greater than 4 ng/mL, with or without an abnormality on DRE, exclusive biopsy of TRUS-identified hypoechoic sites would have missed 106 of 203 patients and 243 of 368 prostate quadrants with carcinoma. Even accepting possible equipment or operator deficiencies, the results seem to reflect current practice expectations. The lack of pathognomonic appearance of CaP on TRUS is probably a very significant factor in these disappointing results. The inability to image anatomic transition and central zone tumors well probably has a limited impact. Available evidence suggests that the use of color Doppler ultrasonography (with or without contrast enhancement) does not increase the sensitivity and specificity of this modality to a statistically significant degree (167,702). Currently, the lack of specificity and sensitivity of information currently derived from TRUSP has reduced its role to a selective ancillary one in diagnosis and treatment of this disease.

SERUM PROSTATE-SPECIFIC ANTIGEN

PSA was first identified in human prostatic tissue extracts in 1970 (2), purified and characterized by Wang and associates in 1979 (1071), and detected in human serum by Papsidero and associates in 1980. PSA is a single chain, 240–amino acid glycoprotein with a molecular weight of 33 kDa. The human PSA gene is located on chromosome 19 (544). The mRNA of PSA, like other cytoplasmic serine proteases, is translated as an inactive pre-PSA/pro-PSA precursor. Following passage through the intracellular secretory pathway, the signal peptide is cleaved, yielding the proform of the protein. Evidence suggests the conversion of pro-PSA to the mature enzymatically active PSA requires the action of human kallikrein 2 (hK2) (544). Recent evidence suggests that truncated forms of pro-PSA are differentially elevated in the peripheral zone of the prostate, the site where most cancers are localized. Little or no pro-PSA has been identified in the transition zone (656). This observation suggests that pro-PSA is more highly correlated with prostate cancer than with BPH. Cleavage of the propeptide from pro-PSA by hK2 converts PSA to the enzymatically active mature form, which is then capable of complexing with a_1-antichymotrypsin (95). PSA shares sequence homology with the human kallikreins and in fact, a 78% homology with hK2. PSA possesses chymotrypsin-like activity and has a weak interaction with the plasma inhibitor, aprotinin. PSA also has modest overlapping homology with urokinase-like plasminogen activator and is capable of facilitating the degradation of the extracellular matrix.

PSA is primarily produced by adluminal or secretory cells of the prostate and the epithelial lining of the periurethral glands (785). The basal cells of the prostate do not express this protein. It is androgen regulated and one of the most abundant serine proteases in the seminal plasma (1,000,000 ng/mL). Its major physiologic role is to promote the liquefaction of seminal clot. Seminal clotting is due to the presence of semenogelin 1 and semenogelin 2 and fibronectin. PSA targets the semenogelin component, thus liquefying the seminal clot, which in turn facilitates sperm motility. The half-life of PSA is 2.2 to 3.2 days (967).

Molecular Forms of Prostate-specific Antigen

Each PSA molecule contains five immunoreactive, antibody-binding sites or epitopes (1072). The currently available commercial PSA assays detect total PSA, PSA a_1-antichymotrypsin, and free PSA (1072). PSA a_1-antichymotrypsin generally represents between 70% and 85% of the total measured PSA in the serum of men (1041). Free PSA, which typically accounts for less than 30% of total measured PSA, is detected by assays that measure the enzymatically inactive, uncomplexed form (625). a_2-Macroglobulin and other proteins bind a smaller proportion of PSA. a_2-Macroglobulin completely encapsulates the PSA molecule, blocks the epitope sites, and cannot be reliably assayed because of this lack of immunoreactivity (1041). Recently, Ornstein and associates (737) used laser capture microdissection to characterize the intracellular PSA from benign and malignant prostatic epithelium. PSA derived from normal and malignant epithelial cells did not differ in molecular weight or the ability of the respective PSA moieties to bind to a_1-antichymotrypsin. Furthermore, no differences were identified in isoforms of benign- and malignant-derived PSA. These findings indicate that PSA produced by malignant prostate epithelium is not mutated or differentially processed. Last, they documented that the intracellular PSA exists in the “free” form and that binding to a_1-antichymotrypsin occurs exclusively outside of the cell.

Nonprostatic Sources of Prostate-specific Antigen

Low levels of PSA and/or PSA-gene expression have been detected in various tissues, particularly those that have constitutive expression of the steroid receptor superfamily, including the uterine endometrium and amniotic fluid, normal/lactating breast tissue and the milk of lactating women, breast cancer; perianal/periurethral glands, salivary glands, adrenal/renal neoplasms, and various other malignant tumors (785).

Biologic Functions of Prostate-specific Antigen in Health and Disease

As stated previously, the major constitutive role of PSA is to degrade and dissolve the seminal clot by breaking the semenogelin bonds. PSA is a weak matrix-degrading protease. In this capacity, it may facilitate the microinvasion of malignant acinar elements into the extracellular matrix (ECM). PSA is both a direct and indirect mitogen for prostatic epithelial cells. With respect to the latter, PSA is an important regulator of the IGF system. The latter is composed of two ligands (IGF-I, IGF-II), two receptors (IGFR-I, IGFR-II), and six unique binding proteins (IGFBP-1 to IGFBP-6). This IGF system plays a strategic role in the autocrine growth regulation of prostate cancer (15). PSA can function as an IGFBP-3 protease. Through this mechanism of action, PSA cleaves sequestered IGFs from this binding protein, which serves as a negative regulator of cell proliferation. Once released, the two ligands are free to interact with their receptors and stimulate prostatic cell growth. Finally, PSA is a mitogen for osteoblasts and may be one of many factors responsible for the typical osteoblastic reaction following the colonization of red marrow sinusoids by metastatic prostatic cells.

Mechanism of Elevated Prostate-specific Antigen

As stated previously, the prostatic acinous contains the highest concentration of PSA in the body (95). In the normal prostate, the majority of PSA is secreted into the acinar/ductal lumen. Under normal circumstances, only a modest amount of PSA enters the systemic circulation. The latter may be due to the release of PSA from cells undergoing programmed cell death. Formidable barriers are interposed between the prostatic acinous and capillary blood, including the prostate basement membrane, the intervening stroma, the capillary basement membrane, and the capillary endothelial cell (95). Prostate cancer is associated with serum PSA levels at least tenfold higher per gram of tissue than BPH (967). In cancer, there may be loss of polarity and increased fragility of the basement membrane, which would facilitate PSA entry into the systemic circulation (Fig. 33.36).

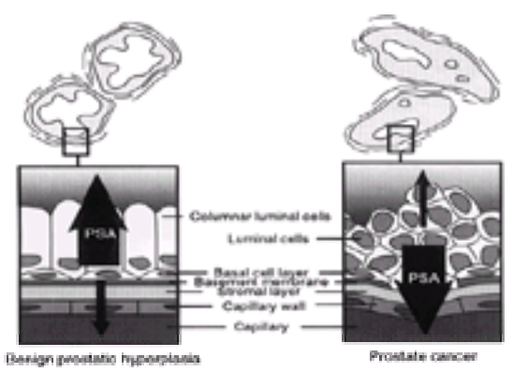

FIGURE 33.36. Normally, significant tissue barriers are between the lumen of the prostate gland and the capillary bed. In prostate cancer these barriers are compromised. PSA, prostate-specific antigen. (From Brawer MK. Prostate-specific antigen: current status. *CA Cancer J Clin* 1999;49:264, with permission.)

Serum PSA levels require critical evaluation to maximize their usefulness with regard to CaP risk. We have always routinely examined prostatic fluid microscopically after rectal examination and used the number of white blood cells (WBCs) present (greater than or equal to 10 WBCs/HPF) (873) to consider the possibility that an elevated PSA serum level might reflect modifiable prostatic inflammation. This practice has recently been supported in principle by the observations of Potts (795). Transient serum PSA elevations have been observed in the following situations: postejaculation, acute prostatitis, subclinical prostatitis, urinary retention; following

vigorous prostatic massage, as a consequence of ischemia associated with cardiopulmonary bypass, and following prostate needle biopsy. The literature is equivocal with respect to the impact of cystoscopy and urethral catheterization on serum PSA levels. Most studies do not demonstrate a statistically significant increase in the serum PSA following a routine DRE or TRUS alone. a-Adrenergic antagonists do not affect circulating PSA levels. On the other hand, finasteride decreases total serum PSA values by approximately 50% after a 6-month course. PSA density is lowered by long-term finasteride therapy, but the percent serum free PSA is unaffected by this treatment. Following the resolution of a significant provocative event, it is prudent to permit 4 to 6 weeks to elapse before using serum PSA levels to serve as the catalyst for clinical decision making (785).

Role of Prostate-specific Antigen in Prostate Cancer Detection

The use of serum PSA levels to identify patients with increased risk of CaP has been the subject of intense evaluation and controversy. The initial stimulus to use serum PSA for this purpose was the unexpected result of several astute clinical observations. Although histochemical observations demonstrated the PSA content of BPH epithelial cells is usually greater than that of CaP cells, Stamey and colleagues (961) presented evidence that the contribution to serum PSA levels by a gram of cancer (3.5 ng/mL) exceeds that associated with a gram of BPH (0.3 ng/mL) by approximately tenfold. More than 50% of patients with organ-confined CaP, as compared with approximately 25% of patients with histologically confirmed BPH, exhibit serum PSA levels greater than 4 ng/mL (727). Similarly, Cooner and associates (184) demonstrated the increased recognition of CaP using a serum PSA level greater than 4 ng/mL to prompt selective ultrasound-guided needle biopsies. Studies by Catalona and associates (149) and Brawer (90) demonstrated that a total serum PSA greater than 4.0 ng/mL in a man 50 years of age or older is associated with an approximately 33% chance of detecting CaP on initial systematic ultrasound-guided needle biopsies. These observations have been confirmed by many other investigators (Table 33.7).

TABLE 33.7. CORRELATION OF PROSTATE-SPECIFIC ANTIGEN LEVEL GREATER THAN 4.0 NG/ML AND CANCER: CONFIRMATORY STUDIES

As a composite, these and other studies permit several observations: (a) the presence of an abnormal DRE and/or ultrasound observation in a patient with an abnormal serum PSA increases the CaP detection rate, (b) a normal serum PSA does not exclude the presence of identifiable CaP, and (c) an abnormal serum PSA is the single most predictive risk indicator for the presence of CaP. Longitudinal observations in the physician health study using stored sera reinforced these perceptions (332). A serum PSA value greater than 4 ng/mL at the initiation of the study identified 73% of the men who had a diagnosis of CaP in the next 4 years and 87% of those classified as having aggressive cancer. Although maximum validity was obtained with a 3.3 ng/mL serum cutoff value, the gain as compared with 4 ng/mL was considered minimal. Furthermore, the risk of an eventual diagnosis of CaP increases in relation to the initial PSA level observed in these studies of selectively and nonselectively recruited males (148,332). Gann and others (332) noted a fivefold increased risk of CaP and a sevenfold increased risk of aggressive CaP on a longitudinal follow-up for 10 years in men whose single initial serum PSA level was 2.01 to 3.0 ng/mL compared with those with a PSA level of 1.0 ng/mL or less. PSA testing clearly has had a profound impact on CaP screening. Clinical stage T_{1c} prostate cancer (nonpalpable, PSA detected) presently constitutes the most prevalent clinical CaP stage (797). Less than 20% of these PSA-driven diagnoses reflect the detection of clinically insignificant tumors. Indeed, only 60% of stage T_{1c} prostate cancers are pathologically organ confined (747). Nonetheless, the majority of these tumors are amenable to curative treatment with currently available therapies; they probably account for the recently reported decline in CaP death rate. Current evidence supports the perception that the PSA with DRE improves detection of CaP (145,184) and increases the lead time for diagnosis (332).

Recommended Frequency of Prostate-specific Antigen Measurements for Prostate Cancer Detection

Both the ACS and the AUA recommend annual PSA screening for all men 50 years of age or older. An exception is the recommendation to initiate PSA testing at age 40 for men with a family history of prostate cancer or for men of African American descent (785). Studies conducted by both Carter and associates (129) and Smith and associates (927) suggest annual PSA screening for men with a normal DRE and a stable PSA level of less than 4 and greater than 2.5 ng/mL and biannual PSA screening for men with a normal DRE and a serum PSA of less than 2.5 ng/mL appear safe. Recent data from the Baltimore Longitudinal Study (131) suggesting that using a PSA level of 1.0 mg/mL or less in men aged 65 to discontinue routine evaluation would still result in recognition of 94% of patients developing CaP by age 75 are unlikely to modify these suggestions without additional observations.

Strategies for Enhancing Prostate-specific Antigen Specificity

Attempts to improve the specificity of serum PSA determinations as a risk indicator for prostate cancer have focused on the following approaches: (a) age-specific PSA, (b) PSA density, (c) PSA velocity, (d) PSA transition zone density, (e) free-to-total PSA ratio, and (f) ACT a $_1$-antichymotrypsin) complex PSA.

Age-specific Prostate-specific Antigen

The mean and median PSA serum levels increase with each decade, and the mean increases at 5-year intervals in men 50 years of age and older (94,208). Clearly, both PSA and CaP increase with age. Oesterling and associates (725) proposed age-related PSA reference ranges to improve prostate cancer detection sensitivity in younger men and specificity in older men. These and other investigators also have recommended further stratification of these age-adjusted reference ranges based on ethnicity (681). These recommendations, summarized in Table 33.8 remain controversial. A lower PSA cutoff in younger men would obviously result in additional unnecessary negative biopsies and generate greater health care costs. In contrast, raising the PSA cutoff level in older men will result in the detection of fewer cancers. The studies by Catalona and associates (145) and Littrup and associates (590) both appear to validate the standard reference range of 0.0 to 4.0 ng/mL as being the most effective and least costly method for screening compared with age-adjusted PSA reference ranges. In addition, Etzioni and associates (283) confirmed previous analyses based on the United States Life Table Actuarial Figures and noted a significant increase in population longevity if 4.0 ng/mL is used as the PSA cutoff for all men compared with the use of age-adjusted cutoffs.

	White Patients		Black Patients		Asian Patients

TABLE 33.8. RECOMMENDED AGE-SPECIFIC PROSTATE-SPECIFIC ANTIGEN REFERENCE RANGES

Prostate-specific Antigen Velocity

PSA velocity assesses the change in PSA over time. It is calculated by the following equation:

$$[(PSA2 - PSA1/Time_1 \text{ in years}) + (PSA3 - PSA2/Time_2 \text{ in years})]$$

In this equation, PSA1 is the first, PSA2 the second, and PSA3 the third serum PSA measurement. Three PSA measurements should be obtained during a 2-year period or at least 12 to 18 months apart. Using this approach, Carter and associates (124) determined that a PSA velocity of 0.75 ng/mL per year is strongly suggestive of CaP (72% sensitivity, 95% specificity). Unfortunately, the determination of PSA velocity possesses several inherent limitations, including (a) PSA is not cancer specific, (b) PSA velocity is difficult to calculate, (c) biologic variation of PSA on a daily basis is well recognized, and (d) the use of different assays can lead to confounding results (95,785). Other investigators have confirmed that a 0.75-ng or greater annual rate of PSA increase constitutes a risk indicator for men whose initial PSA was 4 ng/mL or less (94,930). However, Smith and Catalona (930) found that 0.4 ng/mL or greater annual increase was an optimal risk indicator for men whose initial PSA was greater than 4 ng/mL. At present, a PSA velocity of greater than 0.75 ng/mL per year may add useful monitoring information to (a) men with PSA values in a normal range, (b) men being considered for repeat biopsy with an increasing PSA in any range, and (c) possibly any individual with at least two serial PSA measurements in a 2-year period (785).

Prostate-specific Antigen Density

PSA density is the total serum PSA level (ng/mL) divided by TRUS determined prostate volume (mL). Benson and associates (51) introduced this concept in the hope that such an evaluation would help differentiate between prostate cancer and BPH in men with intermediate (4 to 10 mg/mL) PSA levels and a normal DRE. To that end, they recommended a PSA density cutoff of 0.15 (892). Recent large studies conducted by Brawer and associates (89) and Catalona and associates (145) have not confirmed the utility of PSA density. Indeed, Catalona and associates (145) documented that approximately 50% of CaP would have been missed using a cutoff of 0.15. These conflicting results may be related to the difficulty in obtaining accurate/reproducible measurements of prostatic volume by TRUS and the fact that the estimated BPH volume may not correlate with serum PSA levels because of variability of epithelium (PSA-producing) and stroma (PSA-deficient) compartments.

The calculation of transition zone PSA density has emerged in an attempt to improve the specificity of cancer detection by accounting for the proportion of PSA generated by the transition zone. It is calculated by dividing the serum PSA level (ng/mL) by the transition zone volume (mL). Djavan and associates (235) proposed a calculated cutoff for transition zone PSA at 0.35 ng/mL. This cutoff provided a positive predictive value for prostate cancer detection of 74% in 939 men with PSA serum values less than 10 ng/mL. Other studies have failed to confirm the utility of transition zone PSA density (95,586). A major problem is the difficulty in obtaining an accurate and reproducible assessment of transition zone volume.

Free/Total Prostate-specific Antigen

In the ejaculate, PSA exists in the free (noncomplex) form. However, in the serum, PSA is complexed with several protease inhibitors, most notably a_1-antichymotrypsin and a_2-macroglobulin (95). As stated previously, two epitopes remain unmasked in the PSA/a_1-antichymotrypsin complex and are responsible for its detection with immunoassays (total PSA). The complexing of PSA/a_1-antichymotrypsin increases in prostate cancer, but the mechanisms underlying this phenomenon remain elusive. Assays usually using a dual antibody format have been developed to quantitate the PSA complexed to a $_1$-antichymotrypsin (ACT-1) or contrariwise, uncomplexed to ACT-1 (free PSA). Determination of these PSA fractions are assuming increasing clinical significance (Table 33.9). Catalona and associates (144) conducted the definitive study on the performance of the free-to-total PSA diagnosis of CaP. This prospective, multicenter trial, using the Hybritech assay and a free-PSA no biopsy cutoff of 25% or more for decreased risk of CaP, found this information could reduce biopsies by 20%, while maintaining a 95% cancer detection rate in men with 4 to 10 ng/mL total PSA levels. Assessment of the free-to-total PSA ratio using a 27% cutoff in 914 men 50 years of age and older with serum PSA levels of 2.6 to 4 ng/mL and a normal DRE yielded a 90% cancer detection rate and indicated 18% of unnecessary biopsies could be avoided (144). The detected disease was organ confined in 81% and judged to be clinically significant in 83% of patients undergoing radical prostatectomy. Finally, measurement of the free and total PSA also may permit an assessment of tumor aggressiveness. Carter and associates (129) confirmed a relationship between abnormally low percent free PSA (less than 14%) and aggressive neoplasms characterized by clinical stage T $_3$, nodal or bone metastases, pathologic positive margins, or a Gleason score of 7 or greater. Indeed, the data suggested tumor aggressiveness might be predicted several years earlier by percent free than total PSA. The currently recommended use for the percent free PSA is to determine whether a patient with a normal DRE and a total serum PSA between 4 and 10 ng/mL would benefit from an initial or repeat biopsy (785). The fact that free PSA is less stable in serum than total PSA needs emphasis. All specimens should be processed within 3 hours of collection and frozen at –70°C if not assayed within 24 hours (1106).

PSA	Probability of Cancer (%)	% fPSA	Probability of Cancer (%)
2 ng/mL	1	0–10	56
2–4 ng/mL	15	10–45	28
4–10 ng/mL	25	15–20	20
>10 ng/mL	>50	20–25	16

TABLE 33.9. PROBABILITY OF CANCER, BASED ON PSA AND PERCENT FREE PSA (FPSA) RESULTS (MEN WITH NONSUSPICIOUS DRE RESULTS, REGARDLESS OF AGE)

The PSA/a_1-antichymotrypsin complex is being investigated as an independent tumor marker to improve CaP. Stenman and associates (981) initially suggested that complexed PSA levels are increased in men with prostate cancer. Using refined assay methodology, Sokoll and associates (944) reported that the specificity of prostate cancer detection was enhanced with the use of complexed versus total PSA in men with total PSA levels between 4 and 10 ng/mL. Meyer and associates (651) reported their analysis of 300 frozen serum samples using assays for complexed, free, and total PSA. At 95% sensitivity, the specificity was 26.5%, 21.8%, and 15.4%, respectively. The ultimate utility of complexed PSA measurements awaits the outcome of ongoing clinical trials.

Controversial Aspects of Prostate-specific Antigen Screening

Despite the increased detection of organ-confined (and potentially curable) prostate cancer with the use of serial PSA monitoring, many have opposed its use as a screening test for various reasons, including limited sensitivity and specificity; increased monetary, physical and psychologic costs; and the lack of prospective, randomized trials demonstrating unequivocal reductions in prostate cancer mortality with PSA testing (135).

Despite the legitimacy of these counterarguments, PSA monitoring appears to fulfill the prerequisites for a successful cancer screening program, which include (a) an increase in detection lead time, (b) a transient increase in the incidence of the disease since the introduction of a screening test—most previously undetected cases are identified in the cohort at risk, (c) the number of cases exhibiting advanced disease should be reduced at some finite point following introduction of the screening test, and (d) a reduction in mortality should be documented and proportional to the intensity of screening (135). The estimated increase in detection lead time resulting with PSA testing is approximately 5 years, a period intermediate between the 1.7 years noted with mammography and the 10 to 20 years noted with cervical cytology (136,332). The initial rise (and subsequent diminution) in CaP detection rates after the introduction of widespread PSA testing and the subsequent decreased incidence of advanced CaP provide further supporting evidence for its significant effect on the status of clinically recognized carcinoma of the prostate. Although an

inverse relationship between disease-specific mortality and the intensity of PSA screening has not yet been demonstrated, CaP mortality in the United States has decreased, particularly among the younger white men most likely to be involved in early detection and treatment efforts (407).

There is little doubt that PSA testing has had a profound impact on the “vital statistics” for CaP (402). Particularly promising are the statistics documenting a decline in the incidence of and mortality from distant stage disease. Nonetheless, it is appropriate to emphasize that population data are complex, with attribution bias (incorrect labeling of death from other causes as death from prostate cancer) being more common than previously acknowledged, and attributing relatively small changes in mortality to any one cause with confidence is inherently difficult (291,402).

Current Status of New Markers for the Detection of Localized Prostate Cancer

As stated previously, human glandular kallikrein-2 shares many similarities with PSA, including a 78% amino-acid sequence identity. Both are androgen-regulated proteases expressed in the prostatic epithelium; they can be detected in serum and seminal fluid, and they form complexes with androgenous protease inhibitors. In addition, hK2 demonstrates a significant positive relationship to prostate volume and PSA level (746). Recently, a research prototype assay for total hK2 (thK2) has been developed. Partin and associates (746) proposed a model for cancer detection using percent fPSA and the thK2-to-fPSA ratio when the PSA is 2 to 4 ng/mL in patients with a normal DRE. Their model identified approximately 40% of the cancers and would require TRUSP biopsies in only 16.5% of men in this particular PSA range. In this evaluation, they used a thK2/fPSA cutoff of 0.25 to identify patients at higher risk for prostate cancer. In a similar analysis, a thK2/fPSA cutoff of 0.18 was a useful discriminator for men with total PSA serum levels between 4 and 10 ng/mL and a normal DRE. Nam and associates (698) evaluated the potential utility of assessing hK2 levels to predict the presence of prostate cancer among patients prescreened by PSA testing. They observed that the mean hK2 levels and hK2/fPSA ratios were significantly higher in patients with prostate cancer than in controls (1.18 versus 0.53 ng/mL, respectively for hK2; 1.17 versus 0.62 for hK2-to-fPSA ratio). In addition, patients with high hK2 measurements have a fivefold to eightfold increase in risk for prostate cancer, adjusting for PSA level and other established risk factors. Two studies by Becker and associates (45,46) also reinforce the utility of hK2 measurements in the discrimination of men with BPH from those with prostate cancer. Obviously, all of these studies are preliminary and the ultimate role of hK2 assays in our diagnostic armamentarium must await the results of additional clinical trials.

IGF-I possesses mitogenic and antiapoptotic effects on both normal and transformed prostate epithelial cells *in vitro* (200,463). Six IGF-binding proteins (IGFBPs) have been identified of which IGFBP-3 is the most prevalent in the serum (493). IGFBP-3 exerts an antiproliferative effect on prostatic epithelium by inducing prostate cell apoptosis and blocking IGF interaction with its receptor (181). Of interest, the studies conducted by Tricoli and associates (1025) demonstrated lower IGFBP-3 plasma levels in African American men than in white men, suggesting that this phenotype could explain in part the increased risk of prostate cancer in that cohort.

Chan and associates (156) observed in a nested case-controlled study within the Physician's Health Study that the risk of CaP was associated with increased IGF-I levels. In addition, IGFBP-3, after adjustment for IGF-I was inversely related to the risk of prostate cancer in that same study. More recently, Djavan and associates (234) evaluated 245 consecutive white men with PSA levels between 2.5 and 15 ng/mL. These patients underwent octant biopsies and a second biopsy was performed 6 weeks later if the first biopsy was negative. In that study, IGF-I serum levels did not enhance the performance of PSA. However, at a sensitivity of 95%, the specificity of the IGF-I-to-PSA ratio was significantly greater than that of all other parameters. Indeed, a cutoff value of 25 afforded a 95% sensitivity for detecting CaP and would have avoided unnecessary biopsies in approximately 24% of these patients. The study by Kurek and associates (546) also failed to identify an association between IGF-I serum levels and CaP. However, that study did not address the issue of IGF-I-to-PSA ratios.

Prostate-specific membrane antigen (PSMA) is a 100-kDa type II membrane protein, which is expressed in benign prostatic epithelium, high-grade PIN, and prostate cancer (158). The PSMA gene is located on the short arm of chromosome 11 and encodes for a protein with a three-part structure. The latter includes a 19–amino acid internal domain, a 24–amino acid transmembrane domain; and a 707–amino acid external portion (458,718). Two variations of the PSMA protein have been recognized and are designated PSMA and PSM^1 (spliced variant). PSMA is the predominant form in cancer and possesses a transmembrane domain. PSM^1 lacks 266 nucleotides near the 5^1 aminoterminus and does not have this transmembrane domain. PSM^1 predominates in nontransformed prostatic epithelial cells (375,989).

Anti-PSMA antibodies currently are available to both the intracellular and extracellular PSMA domains (159). Murphy and associates (685,686) suggested that serum PSMA measurements could be used to distinguish late-stage from early-stage CaP or to monitor regressors more effectively than PSA. In a more recent study, Beckett and associates (47) measured PSMA in the sera of 236 normal individuals and cancer patients by Western blot analysis. They observed that PSMA levels increased with age and were significantly elevated in subjects greater than 50 years of age when compared with younger men. Their study did not confirm the previous observations by Murphy and associates (685,686). It is possible that the expanded library of new antibodies may permit the development of a useful sandwich radioimmunoassay to detect PSMA more reliably. Until then, the use of this methodology must be considered investigational. The potential utility of probing for PSMA expression as a staging tool is discussed later in this chapter.

Prostatic Fluid and Urine

Cytochemical and biochemical evaluation of digitally expressed prostatic fluid has been carried out in attempts to identify those individuals at increased risk for the development of CaP. Exfoliated cytology has, at most, a very limited role in diagnosing CaP today. Although some observers have reported a high yield of diagnostic cells in the prostatic fluid and postmassage urine, these results have been difficult to duplicate (532). Attempts to identify individuals with increased risk of carcinoma by biochemical characterization of expressed prostatic fluid have been carried out with the presumption that the metabolic changes associated with cancer are diffuse and involve anatomically normal as well as histologically abnormal cells (field change). The enzyme, protein, polyamine, cholesterol, citric acid, and zinc concentrations, as well as the physical characteristics such as pH and specific gravity, have been determined in the expressed prostatic fluid of patients with normal prostates, BPH, and CaP (380). Compared with normal men and men with BPH, prostatic fluid from men with carcinoma has been found to have decreased concentrations of acid phosphatase and zinc and increased concentrations of the specific complement proteins (C3 and C4) and transferrin. The lactate dehydrogenase (LDH) isoenzyme concentrations are reversed, with LDH5 exceeding LDH1 in patients with carcinoma and BPH. The magnitude of this ratio and the frequency of a ratio exceeding two are greater in patients with cancer than in patients with BPH. The PSA concentration surprisingly has been found to be comparable in men with clinical BPH and cancer, but reduced in individuals with histologically confirmed BPH (503). Basically, these observations tend to confirm a diffuse metabolic change in the prostate with cancer and are compatible with the presumed concept of a field change. Recently, the observations of a prostate-specific membrane antigen with a significant homology with transferrin receptor coupled with the prior identification of transferrin receptor in prostatic cancer cell lines (458,496) has served to reinforce the potential use of prostatic fluid to identify and characterize metabolic alterations associated with and possibly important to the development and growth of CaP. The changes observed in the biochemical composition of prostatic fluid and prostatic cancer have not yet proven clinically useful because of the lack of specificity; however, they have not been explored in conjunction with serum PSA studies.

At this time, the most commonly used and efficient indicators of increased risk of asymptomatic prostatic cancer are the serum PSA levels and the rectal examination. An initial PSA level greater than 4 ng/mL that is persistent with time or following treatment for an inflammatory process usually identified by routine microscopic evaluation of prostatic fluid (greater than 10 WBCs/HPF) is a reasonable level to trigger the consideration of CaP. A significant interval increase in the PSA of approximately 0.75 ng/mL in a patient with an initial PSA of 4 or less or 0.4 ng/mL in an individual with an initial serum PSA greater than 4 increases our concern for the presence of malignancy. Generally, with the first such increase, we elect to confirm the finding and then decrease the interval to 3 to 6 months between PSA determinations and patient evaluations. If the trend (probably more so than an absolute quantitative rate) continues, our suspicion of malignancy increases and a recommendation to biopsy is seriously considered. The DRE is part of our regular interval evaluation. New nodularity or induration that persists on reexamination with or without interval treatment at 2 or 4 months or that is accompanied by an increase in PSA is used to determine the need for biopsy.

Tissue Sampling

TRUSP Biopsies

The goals of tissue sampling are to (a) confirm the presence of CaP if it exists; (b) provide reliable information regarding histologic grade and other indicators of biologic potential; (c) document (if possible) extraorgan spread and intraorgan location and information to assist in estimation of probable tumor mass; and (d) accomplish the sampling procedure with minimal risk, anxiety, inconvenience, and expense. Depending on the patient and clinical circumstances, these goals have variable priorities. Traditionally, tissue-sampling attempts to maximize the probability of identifying a suspected malignancy were almost always site directed. The selection of the site was usually guided by abnormalities recognized on digital examination. In the past several years, ultrasound-detected abnormalities, primarily hypoechoic areas with or without accompanying digital rectal changes, also have been targeted. However, evidence previously cited has led to a consensus that systematic sampling of the entire prostate, in addition to targeted biopsies, increases the yield of diagnostic needle biopsies appreciably. This approach now is used

preferentially by many physicians, including us, in patients thought to be at increased risk for CaP (90,145,425).

Hodge and associates (424) introduced the technique of systematic sextant biopsy of the prostate under TRUS guidance. This involved the acquisition of six directed biopsies of the base, middle, and apical portions from each side of the prostate gland in the parasagittal plane. CaP can be identified in approximately 25% of men with a normal DRE and serum PSA values between 4 and 20 ng/mL. Of importance, a positive biopsy rate for a second set of sextant biopsies approaches 20% in those men with initially negative biopsies. Their observations, and those of many subsequent investigators, highlighted concern that the traditional sextant technique may undersample the prostate and that alternative biopsy techniques, particularly those involving the acquisition of more tissue cores, would improve diagnostic yield (511).

Stamey (969) recommended shifting biopsies to a more lateral position to better sample the anterior horn of the peripheral zone. Eskew and associates (280) introduced the five-region prostate biopsy technique, which incorporates the traditional sextant biopsy cores and adds two biopsies from the far right lateral and far left lateral aspects of the prostate gland and three biopsies from the midline. They were able to demonstrate a 35% increase in the prostate cancer detection rate using this approach as compared with the standard sextant technique. These findings have been validated by Presti and associates (799) who confirmed the utility of an 8 to 10 biopsy scheme, which combined the traditional sextant biopsy approach and lateral peripheral zone biopsies (Fig. 33.37). In their study, the indications for biopsy were an abnormal DRE and/or PSA levels greater than 4.0 ng/mL. Using the extended biopsy approach, cancer was detected in 42% of patients. In contrast, traditional sextant biopsies missed 20% of cancers, while a sextant regimen incorporating lateral peripheral zone biopsies of the midgland and base along with the apex missed 11% of the cancers. The increased yield of CaP associated with the acquisition of additional laterally targeted biopsies is consistent with the results generated using biopsy simulation of three-dimensional (3D), reconstructed, whole mount radical prostatectomy specimens (43). Specifically, the 3D models demonstrate that the highest cancer probability areas involve the far lateral crescent-shaped regions of the peripheral zone from the apex to midgland. The acquisition of laterally directed biopsies is particularly important in patients who have a PSA of less than 10 ng/mL (with smaller cancers) and for those patients with a prostate volume greater than 50-mL larger prostates. In both instances, the likelihood of a sampling error is increased and the use of an extended biopsy scheme has both theoretic and practical advantages (799).

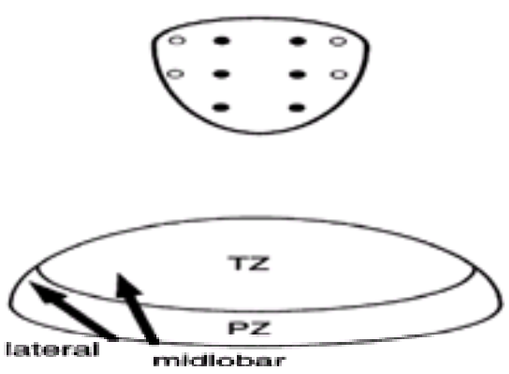

FIGURE 33.37. A ten-biopsy scheme of the peripheral zone *(PZ)* has been proposed by Presti and associates (799). The *dark circles* delineate the sites of standard sextant biopsies. Additional biopsies are obtained from the lateral aspect of the PZ at the base and midgland. An eight-biopsy scheme would eliminate the base biopsy from the standard sextant regimen. TZ, transition zone. (From Presti Jr JC, Chang JJ, Bhargava V, et al. The optimal systematic prostate biopsy scheme should include eight rather than six biopsies: results of a prospective clinical trial. *J Urol* 2000;163:163, with permission.)

Various disposable and reusable instruments are available to obtain digitally directed needle core biopsies. These include the hand-powered Franklin modification of the Vim Silverman and Tru-Cut needles and the spring-driven Bard biopsy and Microvasive ASAP 18-gauge needle biopsy devices. Currently, the spring-driven devices commonly are used to obtain multiple transrectal biopsies of palpable abnormalities. They can be introduced repeatedly and fired through a larger finger-anchored conduit that serves for multiple reentry. Alternatively, the conduit can be placed through the locally anesthetized perineum with rectal finger guidance into the apex of the prostate. In our hands, this transperineal approach facilitates the sampling of transition zone tumors and the acquisition of tissue from patients with large-volume prostates. It also obviates the need for the repetitious insertion/withdrawal of the entire needle, which has several theoretic disadvantages, including increased risk of bleeding, infection, and needle-track implantation.

The development of multiplane 7- to 7.5-MHz transducers that permit transrectal imaging of the prostate in transverse and longitudinal planes and provide coordinated visual and mechanical guides for biopsy has facilitated targeted site and area biopsies. This approach requires an easily acquired working familiarity with the instrumentation and the ultrasonic features of the normal prostate (Fig. 33.31), BPH (Fig. 33.32), and prostate cancer (Fig. 33.33). Patients are advised to stop aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and other agents capable of inhibiting platelet function for 7 to 10 days before biopsy. Additional preparation includes the use of a Fleet enema and a single tablet of quinolone antibiotic 1 to 3 hours before the biopsy. Systemic antibiotics are administered selectively to patients at high risk such as diabetics and those at risk for bacterial endocarditis.

In general, both the traditional sextant and extended biopsy approaches can be performed without the benefit of anesthesia and with the anticipation of minimal patient discomfort (703). To optimize patient comfort, Nash and associates (701) performed a TRUS–guided prostatic nerve block before systematic needle biopsy and noted significantly enhanced patient satisfaction. Soloway and Öbek (948) modified this approach by using an ultrasound-guided 7-inch 22-gauge spinal needle to inject 5 mL of 1% lidocaine (without epinephrine) bilaterally at the following three prostate locations: (a) at the base near its junction with the seminal vesicle, (b) in lateral aspect of the midportion, and (c) at the apex. These investigators also reported enhanced patient satisfaction. The theoretic disadvantages of this approach include the potential for direct intravascular injection of lidocaine (seizures) and the possibility of injection-induced fibrosis in the vicinity of the neurovascular bundles, which might render a nerve-sparing procedure more problematic (511). More recently, Chun and associates (172) described the benefits of interrectal installation of 10 mL of 2% viscous lidocaine gel approximately 10 minutes before systematic biopsies. They observed a statistically significant increase in patient satisfaction and no apparent complications with this noninvasive anesthetic approach. DRE should be performed before TRUS to ensure the urologist has an accurate perception of the location of suspicious nodules and areas of induration. The multiplane ultrasound probe (with or without balloon) is covered with a sterile condom, properly lubricated, and inserted into the rectal ampulla. It is our preference to initiate scanning at the level of the bladder and proceed in a methodic, stepwise fashion to evaluate (a) bladder base and neck; (b) seminal vesicles; and (c) the base, midzones, and apex of the prostate. Hypoechoic foci, areas of capsular irregularity and distortion of the seminal vesicles usually warrant consideration of biopsy. Routine seminal vesicle biopsies are not indicated but may be of value in patients with: (a) PSA greater than 15 to 20 ng/mL, (b) in the presence of obvious distortion or obliteration, and (c) in the context of asymmetric enlargement (12,1009). Using the ultrasonic needle pathway guide, the biopsy needle tip is located at the proximal aspect of the tissue core to be sampled, and the gun is fired while the lesion is observed and recorded in the sagittal plane. Our current practice is to biopsy ultrasonically or palpably suspicious areas and 8 to 10 additional sites as necessary to accomplish representative regional sampling at the base, middle, and apical areas of each lobe. We concentrate on the peripheral zone and vary the medial and lateral relationship of the biopsy to the midsagittal plane. The larger the gland volume, the more inclined we are to add a random biopsy to an area that has had a targeted biopsy. Objective evidence to identify the optimal biopsy procedure is lacking. The tissue is placed immediately in Bouin's solution. We place all the biopsies from one side in a single container. The additional cost to send each biopsy separately does not seem justified by the information obtained.

After removal of the instrument, the patient is placed in the knee-chest position and gentle digital pressure is applied to the right and left lobes of the prostate to minimize rectal and urinary tract bleeding. The patient is instructed regarding transient hematuria or rectal bleeding. Oral antibiotics are usually continued for 48 hours after biopsy. The patient is advised to notify us promptly in the event of an elevated temperature (100°F), chills, or difficulty voiding.

Hodge and associates (424) demonstrate excellent yields (e.g., cancer in 53% of the patients with a previous negative digitally directed biopsy, biopsy confirmation of cancer in 70% of ultrasonically abnormal seminal vesicles, and 20% of ultrasonically normal seminal vesicles) of TRUS-guided transrectal biopsies with a 2.4% incidence of postbiopsy bleeding, fever, or retention. Histologic evidence of cancer was found in the palpably normal contralateral prostatic lobe in 42% of B1 and 60% of B2 nodules. In an extensive experience, using four-quadrant biopsies routinely in PSA-identified patients, Flannigan and associates (297) found that CaP would have been missed in 137 of 225 patients if only the area identified on rectal examination had been biopsied. Similarly, the CaP would have been missed in 131 of 251 patients if only the hypoechoic lesion identified on ultrasound had been biopsied. These observations coupled with the recognized false-negative rate of targeted needle biopsy procedures provide a strong argument for routine and extended systematic regional sampling of the prostate of the patient identified as having increased risk of carcinoma. Recent reports suggesting that endorectal MRI and spectroscopy—time-consuming, expensive procedures—facilitate localization of

prostate tumor foci and enhance the accuracy of subsequent TRUS-targeted prostate biopsies (761,1083) require confirmation by larger scale clinical trials.

Transrectal Needle Aspiration and Other Techniques

Transrectal aspiration to obtain cell samples for histologic evaluation, widely used in Scandinavia and Europe since its reintroduction by Franzen and associates (314), enjoyed a burst of increased popularity in the United States in the past decade. This experience confirmed the legitimate role of this procedure in establishing the diagnosis of CaP. Transrectal needle aspiration can be carried out as a directed or area tissue sampling procedure in the unanesthetized patient with minimal discomfort.

After a preliminary rectal examination, a Fransen or other needle guide placed on the index finger between the gloves of a double-gloved hand (Fig. 33.38) is introduced into the rectum. The tip of the index finger should be free for palpation. Once the index finger is placed on the suspicious area, a 22-gauge aspiration needle is guided transrectally into the lesion. Special needles with variously configured distal ends to facilitate tissue sampling are available. A syringe connected to the butt of the needle permits the use of negative pressure. The needle is advanced and retracted repetitiously within the prostate to probe the targeted area with variable negative suction before it is withdrawn. An air-filled syringe is used to expel all the aspirated material onto slides. After spreading, the aspirate is air dried or fixed in alcohol, depending on the staining process. The cells remaining can be suspended in a few milliliters of saline solution in the syringe and processed in the Cytospin for cytologic evaluation (Table 33.10). Our usual practice is to carry out a minimum of two aspirations using different needles each time. A preaspiration or postaspiration antibiotic usually is used.

FIGURE 33.38. Instrumentation for transrectal needle aspiration of the prostate. The correct positioning of the Franzen needle guide, 22-gauge aspiration needle, and syringe is illustrated. Before rectal insertion, the double-glove technique should be used. (Courtesy of Dr. George Daniels.)

	Benign Hyperplasia	Well-differentiated Carcinoma	Moderately Differentiated Carcinoma	Poorly Differentiated Carcinoma
Cell clusters	Flat, cohesive	Rarely flat and cohesive, often thick	Usually thick, loose	Rare, thick
Honeycombing	Conspicuous	Rare	Absent	Absent
Myoepithelial cell nuclei	Present	Exceptional	None	None
Detached single epithelial cells	Few with normal nuclei	Few with abnormal nuclei	About equally represented as clusters, abnormal nuclei	Dominant, highly abnormal nuclei

TABLE 33.10. DIFFERENTIAL DIAGNOSIS OF PROSTATIC ASPIRATES

Until recently, digitally guided transrectal and transperineal approaches for core biopsy were the most commonly used. Transrectal biopsy has the presumed advantages of better digital localization of the needle course and tolerable discomfort without anesthesia. The incidence of postbiopsy infection is increased, and the opportunity to carry out multiple or random contralateral biopsies is restricted. Use of a prebiopsy antibiotic is common. Although the transperineal route can be carried out under local anesthesia, the procedure is conducted optimally with the patient under general or spinal anesthesia. It provides less direct access to the suspicious area and probably less certain sampling of it. Multiple and random biopsies are performed more readily, and the risk of infection is diminished. Ultrasound guidance has been used in an attempt to improve the accuracy of tissue sampling with this biopsy approach (581).

Purposeful diagnosis of CaP by TURP is limited by many, ourselves included, to patients with a large local tumor mass. Others identify the indurated area by rectal examination and then carry out an extended local excision to attempt to sample this area. The effectiveness of this latter diagnostic approach has not been verified. TURP is used very selectively by some, including members of our group, to obtain transition zone tissue from patients with suspected stage T_1 tumors. Open perineal biopsy requires a spinal or general anesthesia, with the patient placed in the exaggerated lithotomy position and limited exposure of the posterior aspect of the prostate with a perineal incision as in the perineal prostatectomy. Passage of an unopened Lowsley curved retractor or a sound into the prostatic urethra to act as a posterior inferior lever for the gland is an important aid in this procedure. After exposing Denonvilliers' fascia in the suspicious area, a wedge biopsy is carried out. If the patient is a suitable candidate, radical prostatectomy can be carried out on the basis of a positive frozen section report. If the frozen sections are negative or equivocal, the biopsy site is fulgurated and irrigated and the wound is closed. The literature contains numerous reports on the specificity and sensitivity of various procedures. However, aside from Hudson's (441,442 and 443) reports from the mid-1950s documenting a significant advantage of open perineal over punch and transurethral biopsy procedures, prospective studies evaluating the multiple available tissue sampling procedures in the same patient have been avoided. Several studies (297,1035) have demonstrated the advantage of multiple systematic TRUS-guided prostate tissue sampling over targeted procedures in identifying existing carcinoma. Although false-negative observations clearly occur with this approach, their incidence is not clearly established.

Digitally (Table 33.11) and ultrasonically guided targeted biopsies have failed to identify the carcinoma present in an appreciable group of patients. Our review (377) found that false-negative results ranged from 6% to 23% for digitally guided transrectal biopsy and 7% to 27% for digitally guided perineal biopsy. Catalona and associates (148) carried out ultrasonic-guided biopsies on a group of men selected from 10,251 individuals 50 years of age or older on the basis of a serum PSA level greater than 4 ng/mL and a suspicious finding on rectal or ultrasound evaluation. Initial biopsies revealed carcinoma in 296 of 902 patients who underwent biopsy; with serial follow-up, cancer was detected on the second biopsy in 84, on the third in 17, and on the fourth in 4. The yield of positive diagnoses clearly increases with repeated biopsies. The larger the local tumor mass is, the more likely tissue sampling procedures are to be successful. Although conflicting evidence has been presented (823), the report of Liddel and associates (581) indicating an advantage of ultrasound-guided over digitally guided biopsy has been confirmed, especially with the use of the biopsy gun (424,564). A distinct advantage of the ultrasound-monitored procedure is the ability to assess the course of the needle to some degree.

TABLE 33.11. POSITIVE BIOPSY RATES (%),[a] BY DIGITAL EXAMINATION AND PSA RESULTS, PROSTATE CANCER AWARENESS WEEK, 1989–1991

Sufficient information (Table 33.12) has accumulated to indicate that needle aspiration, particularly when used transrectally, is a useful tissue sampling procedure to confirm the presence of CaP. Our review of the reported experiences (532) led to the following conclusions: (a) The diagnostic accuracy of fine-needle aspiration (FNA) is equivalent or superior to that of digitally directed core biopsies. (b) Test sensitivity and specificity initially exceeds 90%, but the false-negative rate increases somewhat during the course of long-term follow-up. (c) The degree of cytologic pleomorphism correctly predicts the Gleason sum range in approximately 80% of the cases, being most accurate with respect to poorly differentiated cancers. (d) FNA can detect most stage T_{1b} tumors but is not useful in the identification of patients with stage T_{1a} disease. (e) FNA cannot accurately distinguish PIN from invasive prostate cancer (3,5,168,373,561,699).

TABLE 33.12. INCIDENCE OF PROSTATIC CARCINOMA DIAGNOSED BY PERINEAL PUNCH BIOPSY AND TRANSRECTAL ASPIRATION BIOPSY WITH AGREEMENT IN BOTH TECHNIQUES AS REVIEWED IN THE LITERATURE

Tissue Sampling: Complications

No tissue sampling approach is free of complications (532). The incidence of the more common complications of infection, bleeding, and urinary retention reported in the past with digitally guided transrectal and perineal needle biopsy procedures has been significantly reduced in recent experiences using ultrasonic guidance and the spring-controlled biopsy devices. A reported infection rate of 16% to 48% after digitally guided transrectal biopsy (143) seems certainly to have been decreased by use of prebiopsy antibiotics. The reported incidence of infection after transperineal biopsy varied from 0% to 3%. Significant bleeding occurred in 1% to 2% of patients after either procedure. Urinary retention was reported in as high as 11% of patients after transrectal biopsy. Less than 1% of patients subjected to transrectal aspiration procedures had a febrile reaction; overall reported complications with this procedure are few. In contrast to these reports Cooner (184) reported an incidence of septicemia of 1% (2 per 206) in patients biopsied with the biopsy gun or Menghini needle transrectally under ultrasound guidance without prophylactic antimicrobials and of 0.5% (3 of 629) in those with prophylaxis. A pelvic hematoma requiring 4 units of packed cells was the only significant bleeding encountered. No patient had acute urinary retention. Hodge (424) reported an overall 2.4% (6 of 251) complication rate after TRUS-guided, spring-driven, transrectal prostate biopsy procedures carried out with preceding enemas and norfloxacin. The complications included rectal bleeding, 1.2%, all in patients on aspirin or NSAIDs; fever, 0.8%; and acute urinary retention, 0.4%. Several factors, particularly prebiopsy rectal preparation and antibiotics, ultrasound control of the direction and extent of the biopsy, and decreased trauma with spring-loaded devices with automated tissue sampling needles probably contribute to the reduced complication rate. Eliminating the need for anesthesia also reduces potential complications and cost.

A confirmed diagnosis with an indication of tumor grade aids us in rational management approaches. Currently, we use TRUS-guided, transrectal, spring-activated needle biopsy in the vast majority of patients. Occasionally, in patients in whom we wish to perform more adequate transition zone sampling, we use a perineally placed access needle through which multiple, variously directed tissue samples are obtained bilaterally with the biopsy or similar device, or, rarely, we carry out TUR tissue sampling. In elderly patients or patients at high risk in whom we desire confirmation of the diagnosis of carcinoma, we often use digitally directed needle aspiration.

Prostate Tissue Sampling Following Proctectomy

The evaluation of men who have undergone previous abdominoperineal resection (APR) for the diagnosis of prostate cancer represents a diagnostic challenge (912). Previously, several relatively ineffective tissue sampling techniques have been proposed, including blind transperineal biopsies, transabdominal ultrasound-targeted biopsies, and TURP. Shinghal and Terris (912) evaluated transperineal ultrasound-guided biopsies in 20 patients with prostate cancer previously diagnosed by TRUS-guided biopsies immediately before radical prostatectomy. Six biopsies were obtained with the patients in lithotomy position. Cancer was detected in only 2 of 20 patients (10%). Simultaneously performed TRUS-guided biopsies were positive in 13 of 20 patients (65%). These observations suggest possibly screening such patients for prostate cancer before the APR. Evaluation of these patients may be enhanced by the use of transurethral ultrasound to guide transperineal biopsies (893). Similarly, recent reports suggest the potential utility for computed tomography-guided and MRI-guided biopsies in this cohort (539,622,744).

Histologic Recognition of Malignancy

The criteria for histologic diagnosis of CaP are detailed in the preceding section on pathology. Histochemical studies for cellular proteins and enzymes are playing an increasingly important role in assessing equivocal light microscopic findings. If the core or wedge biopsy specimen is negative for malignancy, it should be reviewed to make certain that an adequate specimen of prostatic tissue was obtained. The presence of atypia should be noted, recorded, and considered in assessing the need for and timing of rebiopsy.

Staging

Staging is a clinical effort to identify the phase of the natural history of CaP that exists in a patient by documenting the site and the mass of tumor involvement. These observations have importance with regard to selection of the various treatment options currently available. With regard to site, the critical clinical information currently is to separate patients with carcinoma localized to the prostate from those with local or distant spread of the disease. If the disease is recognized to be extraprostatic, knowledge of the sites and organs involved by tumor plays an important role in rational management. Because the mass of the tumor is an important predictor of tumor progression and response to therapy, information derived from attempts to assess the tumor mass usually are used to subdivide tumors at a given site into substages that share a common natural history and treatment response. In some instances a histologic observation, tumor grade, also has been used for this purpose. Although clinical and pathologic stages should not be interchanged in the assessment of results of therapy, the use of selected histologic information has become accepted in most clinical staging studies. Table 33.13 presents representative staging designations in current use.

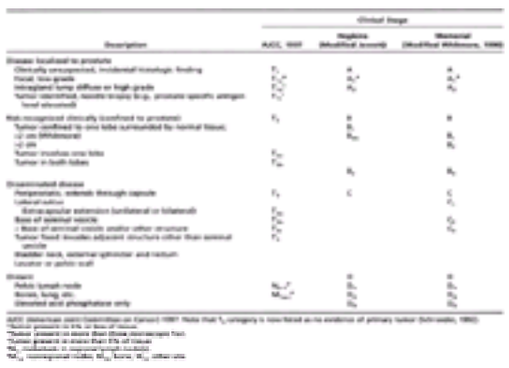

TABLE 33.13. STAGING DESIGNATIONS FOR CARCINOMA OF THE PROSTATE

Staging information designated as clinical routinely uses histologic information to identify stage T_1(A) disease and for reclassification of patients with clinical stage T_{1a}, T_{2b}, and T_{3c} on the basis of histologic (pathologic) evidence of metastases to the pelvic lymph nodes (N). Because the information provided by lymph node assessment is a factor commonly affecting clinical management, confusing the differentiation between clinical and pathologic staging in this instance is probably appropriate. The current criteria for the various stages used in management considerations are discussed in the following section.

General Staging Classifications

In the TNM staging system, tumors are staged according to three basic components: primary tumor (T), regional nodes (N), and metastasis (M) (Table 33.6). Stage T_1 or A is a designation used for CaP that is clinically unsuspected and is discovered on tissue removed to relieve bladder neck obstruction (stage T_{1a}, T_{1b}; A_1, A_2) or because of an elevated serum PSA (stage T_{1c}). The grade and amount of carcinoma is evaluated histologically in the removed tissue and is utilized to substage the clinically unsuspected tumors into two groups: one with high (T_{1b}; A_2) and one with low (T_{1a}; A_1) probability of biologically aggressive growth. An evaluation of the probability of dissemination using pretreatment serum PSA levels, DRE and TRUSP findings, Gleason score, and other staging procedures (if indicated) is usually carried out. Rarely, an unsuspected intermediate or high-grade CaP involving much of the removed tissue is found associated with secondarily acquired (e.g., histologic evidence of seminal vesicle invasion), evidence of extraorgan spread. These patients are usually classified as having advanced stage disease and, perhaps inappropriately, are removed from the T_1 (A) clinical staging category.

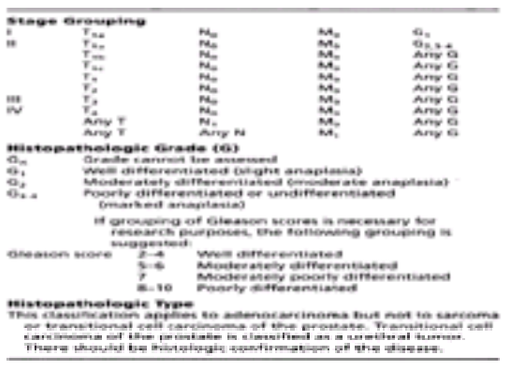
Serial PSAs obtained after transurethral or open prostatectomy often help identify T_1 or (A) patients with low and high risk of progressive or significant residual disease. Observations by Carter (132) and Voges (1053) indicate a serum PSA level of 1 ng/mL or less usually is associated (16 of 17 T_1 patients) with a residual tumor volume less than 0.5 mL in radical prostatectomy specimens whereas higher PSA levels are less discriminatory. Lowe and Listrom (605) have provided several additional insights with respect to this issue, including (a) the identification of increasing age, Gleason score, and percentage of tumor involvement as variables signaling the likelihood of disease progression; (b) the establishment of probability tables for disease progression at 5 and 10 years based on a consideration of these variables; and (c) a recommendation of definitive local therapy in “high-risk” patients. With respect to the last-named, the authors noted a statistically significant advantage of radical prostatectomy over observation alone in producing disease-free survival and a smaller but probable advantage over radiation therapy. The PSA level and/or its rate of change is useful in identifying patients with stage A tumors requiring serious consideration of repeat tissue sampling or therapy.

Patients with histologically confirmed tumor associated with palpable nodularity or induration involving one prostatic lobe are assigned to stage T_{2a}. Clinically apparent involvement of both lobes (without evidence of dissemination) requires assignment to stage T_{2b}. It is important to note that tumors identified in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, are still classified as T_{1c}.

Stage T_3, T_4 (C) tumors that have demonstrated periprostatic extension on clinical examination but have no evidence of distant metastases are classified as stage $T_{3,}$ T_4 (C). Patients with tumor classified in this stage have an incidence of pelvic node metastases as high as 50% or more (240). Substaging on the basis of the site of extraprostatic tumor extension differs. The 1997 American Joint Committee on Cancer (AJCC) classification separates extracapsular extension (unilateral or bilateral) (stage T_{3a}) from seminal vesicle(s) invasion (stage T_{3b}). The biologic significance of these substages is uncertain. Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is not classified as T_3, but as T_2. The 1997 AJCC classification modifies the category T_4 for tumors that are fixed or invade adjacent structures (other than seminal vesicles) bladder neck, external sphincter, rectum, levator ani muscles, and/or the pelvic sidewall.

Tumors that have metastasized distantly are classified as stage $T_{1-4,}$ $N_{0-1,}$ $M_{0-1,}$ (D). According to the 1997 AJCC classification, the regional lymph nodes are the nodes of the true pelvis, which are located below the bifurcation of the common iliac arteries and include pelvic, hypogastric, obturator, external/internal iliac, and sacral nodes. N_0 indicates the absence of regional lymph node metastasis. N_1 disease implies metastasis in a regional lymph node or nodes. Laterality does not affect the N classification. The designations N_1 (one regional lymph node 2 cm), N_2 (one regional lymph node greater than 2 cm but less than 5 cm or multiple regional nodes), and N_3 (regional lymph node greater than 5 cm) as proposed in the 1992 AJCC have now been abandoned. Assignment to a M_0 status implies the absence of distant metastasis. The presence of distant metastasis mandates assignment to the M_1 category. The latter has been divided into three subsets by the 1997 AJCC. M_{1a} implies involvement of a nonregional lymph node(s). The latter can include aortic, common iliac, superficial/deep inguinal, supraclavicular, cervical, scalene, or retroperitoneal lymph nodes. Involvement of one or more sites in the skeletal system is designated as M_{1b}. Involvement of other soft tissue sites is designated M_{1c}. Note, when more than one site of metastasis is identified, the most advanced category—pM_{1c}—is used. Individuals with an isolated finding of a persistently elevated serum enzymatic acid phosphatase are designated stage D_0. The current TNM system allows a more accurate quantitation, and to some extent, site identification in the patient with disseminated disease. Table 33.14 and Table 33.15 provide useful versions of the 1997 AJCC staging definitions, stage group assignments, and a tumor-grading nomenclature.

TABLE 33.14. 1997 AJCC STAGING DEFINITIONS



Stage Grouping				
I	T_{1a}	N_0	M_0	G_1
II	T_{1a}	N_0	M_0	$G_{2,3,4}$
	T_{1b}	N_0	M_0	Any G
	T_{1c}	N_0	M_0	Any G
	T_1	N_0	M_0	Any G
	T_2	N_0	M_0	Any G
III	T_3	N_0	M_0	Any G
IV	T_4	N_0	M_0	Any G
	Any T	N_1	M_0	Any G
	Any T	Any N	M_1	Any G

Histopathologic Grade (G)

G_x	Grade cannot be assessed
G_1	Well differentiated (slight anaplasia)
G_2	Moderately differentiated (moderate anaplasia)
$G_{3,4}$	Poorly differentiated or undifferentiated (marked anaplasia)

If grouping of Gleason scores is necessary for research purposes, the following grouping is suggested:

Gleason score	2–4	Well differentiated
	5–6	Moderately differentiated
	7	Moderately poorly differentiated
	8–10	Poorly differentiated

Histopathologic Type

This classification applies to adenocarcinoma but not to sarcoma or transitional cell carcinoma of the prostate. Transitional cell carcinoma of the prostate is classified as a urothelial tumor. There should be histologic confirmation of the disease.

TABLE 33.15. 1997 AJCC STAGE GROUP ASSIGNMENTS AND TUMOR GRADING NOMENCLATURE

Evaluation of Local Mass—Periprostatic Extension

Rectal Examination

Efforts to assess tumor mass and the presence and site of extraorgan disease rely on findings on physical examination, primarily the DRE, and various imaging studies including TRUS, MRI, and CT scans. These approaches, especially, the rectal examination, provide useful information, particularly in some patients with extensive disease. However, they all lack sensitivity and specificity for identification of extraorgan disease and quantifying tumor mass.

The prominent role of a carefully performed DRE in staging and substaging CaP has diminished somewhat as the number of malignancies identified without induration or nodularity of the gland has increased. Nevertheless, DRE is the major tool currently available for recognizing locally extensive disease. The extent and configuration of the induration that prompts recognition of probable CaP should be observed and recorded before attempts are made to obtain histologic confirmation of carcinoma by tissue-sampling procedures. Recognition of the violation or obliteration of landmarks such as the median furrow or lateral sulci is particularly important to the staging effort. The incidence of false-positive evaluation such as induration at the base of the seminal vesicle or across the lateral sulci indicating periprostatic spread has not been evaluated systematically. Histologic observations in small groups of patients suspected of having seminal vesicle or capsular perforation on physical examination but nevertheless selected for radical prostatectomy failed to confirm the clinical impression of dissemination in more than 25% (112,1027). In clinical practice the induration noted on DRE is usually interpreted as confined to the prostate, clearly extraprostatic, or questionable with regard to extent. The presence of previous prostatic disease or surgery, including biopsies, diminishes the critical role of DRE in staging. Histologic examination of specimens removed at radical prostatectomy for presumed local disease indicates a significant incidence of understaging or false-negative assessments by rectal examination (147,968,1048).

The size and location of the induration noted on rectal examination has established validity to provide clinical information for substaging (e.g., $T_{2a,2b}$; B_1B_2). The traditional observation that the extent of induration almost always underestimates the extent of gland replacement by tumor is verified regularly by detailed mapping of radical prostatectomy specimens. Interestingly, these efforts document that the site of induration and histologic carcinoma do not always coincide; this observation has been reaffirmed clinically by the discordant results on DRE and histologic findings following TRUS biopsies (771).

Physical Imaging

Physical imaging procedures, including TRUS, CT, and MRI, have been used to provide information to facilitate local staging of CaP. Personal and reported experiences with TRUS, the most widely used of these procedures, indicate that it is of little assistance in assessing intragland mass or site (126,635,1008). CT and MRI (683,790) also have not been able to differentiate intraorgan benign and malignant tissues reliably. The CT scan has proved as disappointing in identifying periprostate tumor and tumor mass as it has in diagnostic studies (Fig. 33.39) (683,857). In a comparative evaluation of the recognition of organ-confined and extraorgan disease in 62 patients subjected to radical prostatectomy, DRE (62), TRUS (47), CT (41), and MRI (38) correctly predicted the stage in 21%, 65%, 24%, and 56% of the studied patients, respectively. Overstaging occurred in 1.2% (DRE) to 9.5%, and understaging occurred in 77% (DRE) to 33% (TRUS). In several instances the actual and imaging site of capsular perforation did not coincide (250). Although the image obtained using endorectal surface coil MRI appears to provide superior tissue detail to body coil MRI, extraprostatic disease was recognized with approximately the same accuracy by both (68% versus 69%) (161,830). The more recently reported correlation of endorectal MRI and pathologic evidence of extracapsular extension or seminal vesicle invasion in 70% and 90% of cases, respectively by D'Amico (206) conflicts with less than 50% identification of stage T_3 disease with endorectal MRI by Lee (566). Stratifying patients by Gleason grade or number of positive biopsies did not improve the ability to assess pathologic stage. Even more recently, D'Amico (204) suggested a combination of preoperative PSA level, biopsy Gleason score, percentage of positive biopsies, and endorectal MRI T-stage can predict early PSA failure in patients with clinically localized CaP. Finally, the use of magnetic resonance spectroscopy did not appear to provide additional staging information with respect to the presence or absence of extracapsular extension.

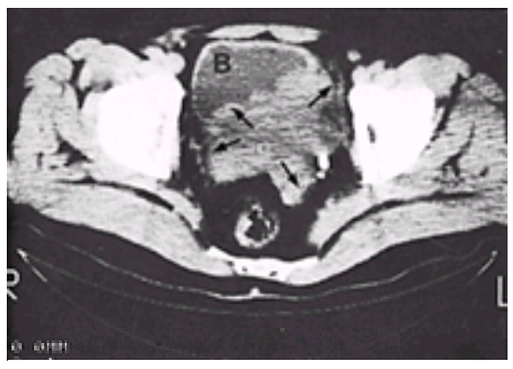


FIGURE 33.39. Pelvic computed tomography scan demonstrating local extension of prostate cancer with involvement of the bladder *(upper arrows)* and seminal vesicles *(lower arrows).* The left ureter (contrast enhanced) appears to be dilated as it approaches the tumor mass. (From Spirnak J, Resnick MI. Clinical staging of prostatic cancer: new modalities. *Urol Clin North Am* 1984;11:221, with permission.)

These and other similar observations (635,683,830) have led us to use TRUS selectively and other standard imaging studies very infrequently to evaluate possible periprostatic spread of prostate carcinoma. If TRUS examination suggests periprostatic spread, we prefer to obtain corroborative ultrasound-guided biopsy evidence before finalizing acceptance of this finding.

In 1997, Partin and associates (747) developed a nomogram that combines PSA, biopsy Gleason sum, and clinical stage to predict final pathologic stage. This approach was based on a logistic regression analysis of the 4,133 untreated patients with clinically localized prostate cancer who underwent radical prostatectomy at one of three institutions: Johns Hopkins University, Baylor College of Medicine, and the University of Michigan. Using the previously stipulated parameters, this nomogram can estimate the 95% confidence intervals for the probability of organ-confined disease, established capsular penetration, seminal vesicle involvement, and lymph node involvement. It is important to emphasize that this nomogram and other similar multivariant algorithms are far from perfect. For example, subsequent validation of the Partin nomogram has demonstrated that it correctly predicts the probability of pathologic stage to within 10% approximately 72% of the time (785). The updated version of this nomogram is depicted in Table 33.16.

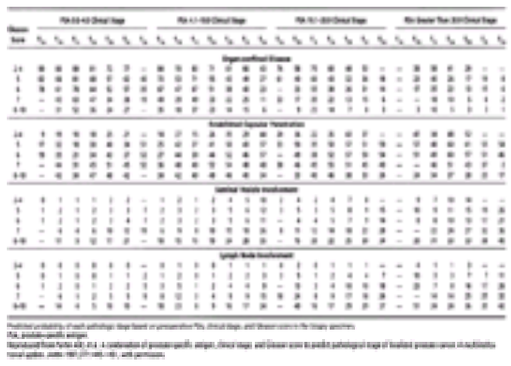

TABLE 33.16. THE PARTIN NOMOGRAM

Evaluation of Disseminated Disease

The evaluation of disseminated disease in patients with CaP centers on two related but independent efforts. One is to quantify the probability of disseminated disease and the other is to identify sites involved. An array of approaches is available to aid these efforts. The distinction between the probable and the established is often blurred in clinical practice. Biologic markers, including PSA, acid and alkaline phosphatase, and more recently, PSMA and human glandular kallikrein-2 (hK2), have a range of potential uses. Attempts to identify metastatic sites concentrate on imaging studies with a variable degree of specificity, tissue or cell sampling for histologic and immunohistologic studies, and combinations of those efforts. A brief discussion of the markers, the imaging studies, and to some degree, the combined approaches to evaluate disseminated disease is presented.

Biologic Markers

Although a host of biologic markers have been used to evaluate the probability of disseminated disease in patients with histologically or cytologically documented CaP, only three have contributed sufficient useful information to have been or to be used regularly: serum PSA, acid phosphatase, and alkaline phosphatase. Currently, PSA is used regularly and acid and alkaline phosphatase are used selectively in this effort. Efforts to use PSMA and hK2 markers are being pursued actively with promise.

Prostate-specific Antigen

An impressive amount of data has been accumulated during the past several years regarding the proper role of PSA in the staging and monitoring of patients with CaP (8,278,556,788,962,964,967). Some current perceptions regarding the utility of this marker include the following: (a) In CaP, PSA generally increases with advancing clinical stage and is roughly proportional to the estimated tumor volume. (b) Serum PSA is crudely proportional to the Gleason score of the primary tumor. (c) PSA rises proportionally to the amount of cancer tissue present (3.5 ng/mL per gram in one study) (961,962 and 963). (d) Patients with serum PSA levels of less than 10 ng/mL are most likely to respond to local therapy (1014). (e) Lymph node metastases are unusual in patients with a pretreatment PSA level of less than 10 ng/mL and in patients with a Gleason score of 6 with pretreatment serum PSA levels less than 20 ng/mL (1014). (f) If the PSA is greater than 50 ng/mL, two-thirds of patients have microscopic lymph node metastases, and 90% demonstrate seminal vesicle invasion (963). (g) In the absence of history or clinical examination suggesting skeletal involvement, bone scans are generally not required in patients with pretreatment PSA levels less than 20 ng/mL (1014). (h) It is reasonable to consider a bone scan (even if the pretreatment PSA is less than 10 ng/mL) in patients with a high Gleason histotype tumor (8 to 10) or stage $T_{3,4}$ disease (95). (i) CT and MRI scanning are rarely positive when the PSA is less than 25 ng/mL (10).

PSA is a more sensitive tumor marker than PAP. In the study conducted by Ercole and associates (278), PSA was elevated in 98% of patients with stage D_2 disease compared with an increased PAP noted in 78%. PAP was the only marker elevated in 1% of patients and neither marker was elevated in 2%. Other studies have suggested that PSA is a more sensitive and potentially more useful marker than PAP in this context (8). Despite the recognized advantages of PSA over PAP, we continue to monitor PAP in addition to PSA selectively in multiply treated patients at high risk for relapse.

Acid Phosphatase

PAP, an orthophosphoric monoester phosphohydrolase with an isoelectric point between 4.5 and 5.5, is produced and secreted in large quantities by normal postpubertal and BPH prostatic epithelial cells. Malignant prostatic cells usually continue to produce this enzyme in appreciable, although decreased, quantities. Demonstration of elevated serum levels of acid phosphatase in patients with CaP by Gutman and Gutman (396) and the effect of endocrine manipulation on them by Huggins and Hodges (446) initiated an appreciation of the potential roles of biologic markers in this and other malignancies. Because isoenzymes of acid phosphatase are present in almost all body tissues, acid phosphatase lacks organ and disease specificity. Multiple diverse attempts to improve clinical specificity beyond that provided by selected enzymatic assays have not succeeded (532). Elevations of acid phosphatase serum levels have been noted sporadically in a wide variety of diseases and following surgical and digital manipulation of the prostate (Table 33.17).

TABLE 33.17. DISORDERS ASSOCIATED WITH AN ELEVATION OF SERUM ACID PHOSPHATASE

At present, the following statements seem a reasonable summary of the results of both total and prostatic acid phosphatase determination using the various enzymatic immunologic techniques currently available: (a) Persistent elevation of serum PAP levels as determined by enzymatic procedures in patients with CaP indicates a very high probability of dissemination of the disease outside the prostate to bony or soft tissue, including periprostatic extension. An isolated limited elevation of serum PAP is usually not accepted as an absolute indication of disseminated disease, although, as the DO classification indicates, concern for probable metastatic disease is appreciable. (b) Local and/or distant dissemination of CaP may be present without an elevation of total or prostatic acid phosphatase. (c) Total and prostatic acid phosphatase levels may provide a useful marker to follow the course of patients with CaP after treatment. Although serum PAP may fail to signal tumor progression after therapy, confirmed recurrent posttherapy elevation of serum PAP is an excellent indication of recurrent tumor activity and progression (143,413,789,872).

Alkaline Phosphatase

Alkaline phosphatases, a series of enzymes that hydrolyze phosphate esters at a pH of 7 or greater, are present in various tissues including bone, intestinal mucosa, and liver. Each of these tissues has characteristic isoenzymes that can be assayed in a clinical setting. In addition, a placental form of alkaline phosphatase,

designated Regan or tumor isoenzyme, has been recognized.

Serum levels of total alkaline phosphatase are frequently elevated in patients with CaP. These elevations are neither disease nor site specific and are known to occur in a wide variety of clinical disorders (143,413,872). This nonspecificity of total alkaline phosphatase (TAP) diminishes its value for staging CaP. Furthermore, an elevation of bone alkaline phosphatase was detected more frequently than an elevated total alkaline phosphatase (91% versus 87%) in patients with bone metastases evaluated in the National Prostate Cancer Project (1056), suggesting an advantage for it in identifying risk of bone metastases. High pretreatment levels of total or bone alkaline phosphatase may reflect an increased tumor burden and a poor prognosis. Serial determinations of serum alkaline phosphatase have potential value in identifying bone involvement and following the course of the patient's disease (872). For example, the initial rise, or flare, followed by a fall in serum levels frequently seen in patients with bony metastases responding to initiation of hormone therapy provides supporting evidence both for the presence and response of bone lesions (446).

Reverse Transcriptase–Polymerase Chain Reaction Prostate-specific Antigen and Prostate-specific Membrane Antigen

To enhance the recognized usefulness of serum PSA monitoring, several investigators have pursued methods to detect PSA-positive cells within the systemic circulation, lymph nodes, and bone marrow. A major incentive for this effort is the fact that up to 40% of surgically treated patients with CaP subsequently are found to be clinically understaged (492).

One of the earliest studies of the systemic circulation detected PSA-positive tumor cells with analytic flow cytometry in all 25 of the untreated CaP patients with a positive bone scan evaluated (401). Of note, 7 of 15 patients with a negative bone scan also had circulating PSA-positive cells. Indeed, demonstration of more than 2% PSA-positive circulating cells had a greater sensitivity (96%) and specificity (60%) for detection of skeletal metastases than did a serum PSA level of 20 ng/mL (sensitivity 76%, specificity 53.5%). On light microscopy, the PSA-positive cells exhibited characteristic cytologic features, including the presence of multiple nucleoli and slightly clumped chromatin, but were not easily differentiated morphologically from cells of the monocyte/macrophage lineage.

Subsequently, RT-PCR amplification was used to assay for PSA. This technique is capable of recognizing one PSA-expressing cell from a population of 10^5 to 10^7 background cells (492,1105). However, poor differentiation and decreased PSA message of some circulating cancer cells makes their detection in some patients difficult. Attempts to use RT-PCR assay to detect PSA-producing circulating cells in individuals with clinically localized prostate cancer have produced variable results; for example, Katz (492) reported 38.5% (25 of 65) and Seiden (897) only 7.7% positive findings. The results in patients with metastatic disease were similarly discrepant.

RT-PCR also has been used to document unrecognized lymph nodes and bone marrow dissemination. In a retrospective study using paraffin-embedded lymph nodes, Edelstein and associates (251) reported that 88% of 16 patients with a positive RT-PCR assay and no histologic evidence of lymph node metastasis eventually developed metastatic disease; however, recurrent disease also was detected in 30% of 20 patients with pathologic and RT-PCR negative lymph nodes. Recently, Okegawa and associates (731) noted nested RT-PCR was positive in lymph nodes of 2 of 18 patients (11%) with stage pT_{2a} and 5 of 20 (25%) with stage pT_{2b} disease. Ultimately, these patients all exhibited biochemical recurrence. These investigators acknowledge the potential for false-negative results because half of each lymph node was used for pathologic and the other half for molecular analysis.

With regard to detection of bone marrow micrometastases, Wood and Banerjee (1104) reported that with a mean follow-up of 15.4 months (range of 1 to 43) only 2 of 47 patients (4%) with a negative bone marrow RT-PCR PSA exhibited recurrence compared with 10 of 39 (26%) with positive RT-PCR PSA results. Gao and associates (335) reported a 2-year disease-free survival rate of 96.6% versus 77.5% in radical prostatectomy patients with negative versus positive RT-PCR PSA bone marrow results. Multivariant analysis of their study, as contrasted to Wood and Banerjee (1104), demonstrated bone marrow RT-PCR for PSA was an independent prognostic factor.

At present, RT-PCR analysis of PSA expressing cells in the systemic circulation (and elsewhere) does not have a firm place in our diagnostic armamentarium. Despite the observations by Olsson and associates (733) that demonstrating PSA by RT-PCR in peripheral blood cells was a statistically significant predictor of early biochemical recurrence following radical prostatectomy, neither Ellis and associates (272) nor Gao and associates (335) documented a predictive value for this finding in regard to biochemical recurrence or, in the Gao study, of pathologic stage. In addition to the nonspecificity of the targeted information, these dichotomous results reflect, in part, inherent limitations in RT-PCR technology, which include (a) a lack of standardization of sample collection/processing, storage, and shipping conditions; (b) a lack of uniform methodologic protocols and oligonucleotide primers; (c) varying results among institutions using slightly different methodology; and (d) a predisposition to false-negative and false-positive results (785).

Recently, Israeli and associates (458) reported the molecular cloning of a novel M_r 100,000 prostate-specific membrane glycoprotein, designated PSM. Analysis of its complimentary DNA sequence revealed a 54% homology to the human transferrin receptor mRNA. Unlike PSA and PAP, which are secreted proteins, PSM appears to be an integral membrane protein with a transmembrane domain that helps delineate its intracellular and extracellular portions. Primers derived from both PSA and PSM cDNA sequences used in conjunction with a nested RT-PCR assay facilitate detection of occult hematogenous micrometastatic prostate cells (457). In 77 patients with prostate cancer, PSM and PSA primers detected the presence of circulating prostate cells in 48 of 77 (62.3%) and 7 of 77 (9.1%) patients, respectively. More recently, PSM primers detected presumed micrometastatic disease in 21 of 31 (67.7%) postradical prostatectomy patients with negative serum PSA values. PSA primers detected circulating tumor cells in only 1 of 33 (3%) of these patients. In treated stage D disease patients, PSM primers detected presumed micrometastatic disease in 16 of 24 (66.7%) of the patients as contrasted to only 6 of 24 (25%) using PSA primers. Finally, presumptive evidence of micrometastases was noted in 4 of 40 controls, 2 of whom had evidence of BPH and subsequently developed biopsy-confirmed prostate cancer. A follow-up analysis by Israeli and associates (456) further confirmed enhanced detection of circulating micrometastases using nested RT-PCR in conjunction with PSM primers. Recently, Okegawa and associates (732) reported that nested RT-PCR for PSM in peripheral blood cells was useful for predicting biochemical recurrence with a mean follow-up of 16.7 months and that these results were the most effective parameter evaluated.

As a composite, these studies suggest the development of lymphatic and hematogenous metastasis may be a relatively early event in the natural history of human CaP. Furthermore, molecular approaches seem likely to enhance our ability to detect micrometastatic disease, particularly in patients who are apparently disease free by clinical and biochemical criteria after radical prostatectomy. However, long-term follow-up is necessary to determine the implications of a positive RT-PCR assay for either PSM or PSA in these patients.

Other Biochemical Markers

Several other biochemical compounds have been explored and, in some instances, advocated in patients with carcinoma of the prostate. These include determination of serum levels of creatinine kinase bone band (CK-BB), LDH isoenzymes, isocitric dehydrogenase, phosphohexose isomerase, carcinoembryonic antigen, ribonuclease activity, prostacyclin, and erythrocyte polyamines as well as urinary levels of hydroxyproline, nonesterified and total cholesterol, spermidine, fibronectin, and human glandular kallikrein (789,872).

Several laboratories have confirmed the association of elevated tissue and serum levels of urokinase-type plasminogen activator (u-PA) with CaP possessing the aggressive or metastatic phenotype (343,419,508). A trypsinlike serine protease with a shared structural homology with PSA, u-PA may play an important role in tumor invasion of the extracellular matrix and metastasis. These potential markers are all nonspecific—a factor that undoubtedly has led to limited enthusiasm for their use. Nevertheless, the failure to continue exploration of their possible role (in particular as indicators of tumor response to therapy) may deprive us of useful information.

Bone Metastasis

As noted under Natural History, the bones of the axial skeleton are a common site of metastatic spread of CaP, with identifiable involvement in up to 84% of patients at autopsy (467). Pain, presumably secondary to metastatic spread to the pelvis and lumbar spine, has been and is prominent in the CaP patient with symptoms. The majority of the long-term (21%) and short-term (25%) American College of Surgeons survey patients presenting with stage D disease had dissemination recognized because of bone involvement. Bone metastases can be present and progress without abnormal findings on serum marker or pelvic lymph node studies. Because the red marrow sinusoids are the first site of bone involvement in metastatic disease, detection of dissemination to bone is often difficult and delayed.

Various efforts to identify metastatic tumor cells in marrow using specific markers were discussed in the previous setting. However, a unique attempt to use a mixture of antisera to PSA, PAP, epithelial membrane antigen, and CK to probe bone marrow aspirates from patients with presumably localized and metastatic prostate

cancer deserves mention (616). This antisera cocktail detected large numbers of tumor cells in 11 of 15 patients (73%) with known metastatic disease, and small numbers of tumor cells in 2 of 15 patients (13%) with “localized” disease. In contrast, conventional staining procedures detected tumor cells in only 2 of 15 patients (13%) with established skeletal metastases. Analysis of bone marrow aspirates using innovative immunocytochemical and molecular biology techniques for accurate staging deserves additional consideration. The remainder of the discussion in this section focuses on the imaging studies available to assess bone and/or soft tissue CaP metastasis.

Bone Scan

The radionuclide bone scan is the most sensitive imaging technique to detect skeletal metastases. Bone scans are positive in 10% to 50% of patients with metastatic CaP who have nondiagnostic conventional x-ray studies (874). They have the disadvantage of providing nonspecific information. Several benign and malignant bone lesions, including osteomyelitis, benign and malignant neoplasms, Paget's disease, metabolic bone disease, and degenerative joint disease, as well as trauma, may result in radionuclide “hot spots.” Most metastatic lesions from carcinoma of the prostate appear as asymmetric areas of intense uptake of radionuclide (484,957). The distribution and configuration of areas of increased radionuclide uptake aid in assessing the probability they are due to metastatic disease (Fig. 33.40). However, this diagnosis remains doubtful without confirmation on routine or tomographic radiographs, CT or MRI studies, or bone biopsy. On the other hand, presumptive evidence of metastatic carcinoma on bone radiographs, with a bone scan interpreted as negative (false negative) is low, ranging from 0% to 8% (957). The false-negative scans have been associated with lesions producing little or no reactive bone or with the so-called super-scan associated with extensive symmetric metastatic disease that sequesters the majority of the isotope, producing a faint or negligible renal image (Fig. 33.41).

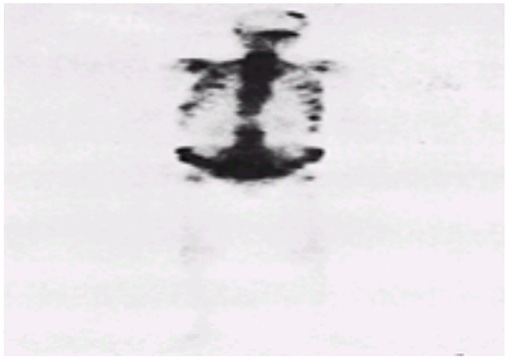

FIGURE 33.40. ^{99m}Tc bone scan demonstrating multifocal areas of increased uptake in the calvarium, maxilla, humerus, ribs, sternum, lumbosacral spine, pelvis, and femur. These findings are certainly consistent with metastatic cancer in a patient with a known prostate primary. (From Spirnak J, Resnick MI. Clinical staging of prostatic cancer: new modalities. *Urol Clin North Am* 1984;11:221, with permission.)

FIGURE 33.41. ^{99m}Tc “superscan” in a patient with metastatic prostate cancer demonstrating faint renal visualization and an intense symmetric uptake of the isotope by the ribs and axial skeleton. (From Spirnak J, Resnick MI. Clinical staging of prostatic cancer: new modalities. *Urol Clin North Am* 1984;11:221, with permission.)

Bone Radiographs

Most CaP patients with bone x-ray films demonstrating metastatic involvement have pure osteoblastic (75%) or mixed osteoblastic-osteolytic lesions (15%). Pure osteolytic lesions (10%) occur much less commonly (1094). The osteoblastic lesions are characteristically multiple and nodular, but many have a mottled appearance or even produce lesions suggesting an ivory vertebra (Fig. 33.42). In attempting to evaluate a particular site identified as abnormal by bone scan, magnification and tomographic techniques may provide useful information. Although other metastatic tumors, including those of breast, stomach, and lung, produce osteoblastic bone responses, these tumors are either uncommon in aging men, or the osteoblastic bone response is an unusual one for them. In an older man, osteoblastic bone lesions suggesting metastatic disease should be considered to be due to CaP until that possibility is excluded. Past roentgenographic and autopsy studies indicated the sacrum, pelvis, and lumbar spine were the bones most involved by recognizable metastatic deposits. Bone scan results suggest the frequency of rib metastasis equals or exceeds that of the pelvis and that metastasis from CaP has a more random distribution than we had appreciated (236). Dodds and co-workers (236) also reported the pelvis, lumbar spine, and sacrum were free of demonstrable disease in 25% of the patients with skeletal metastasis from CaP.

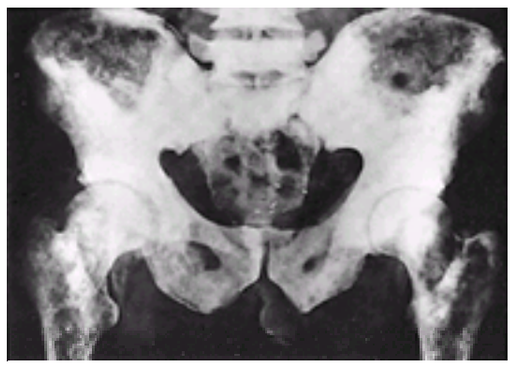

FIGURE 33.42. Osteoblastic skeletal metastases characteristic of prostate cancer. Metastatic bone lesions are discrete dense areas, commonly adjacent to joint surfaces, but do not affect the joint space. [From Mostofi FK, Price EB Jr. Tumors of the male genital system. In: Universities Associated for Research and Education in Pathology, National Research Council (U.S.). Committee on Pathology, eds. *Atlas of tumor pathology,* Second series, fascicle 8. Washington, DC: Armed Forces Institute of Pathology, 1973, with permission.]

Differentiation of metastatic CaP from Paget's disease on the basis of roentgenographic findings can be very difficult (1094). Paget's disease is usually multifocal but not generalized throughout the skeleton; some normal bone remains. The disease is characterized by cortical widening or thickening; accentuation of the bony striae, producing a ropy striated pattern; irregularly associated rarefied or “cystic” and uniformly dense osteosclerotic areas; and an intact periosteum (Fig. 33.43). Males are affected by Paget's disease approximately twice as often as females. The facts that the pelvis is the most frequently affected bone and that Paget's disease and CaP may coexist create a problem in evaluating patients. Roentgenographic observations alone may not allow a satisfactory assessment of the probability of bone

metastasis in a patient with Paget's disease. Tumor marker information such as that provided by serum PSA and acid phosphatase is often invaluable in these circumstances. Bone biopsy or marrow aspiration also may be warranted (236).

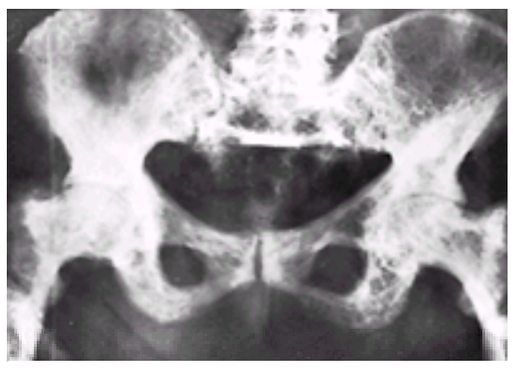

FIGURE 33.43. Paget's disease of the bone. Roentgenographic hallmarks that distinguish such a picture from metastatic prostate cancer include the characteristic cortical thickening, the prominent striated pattern admixed with cystic areas, and an intact periosteum. Unlike blastic lesions, which typically have well-demarcated edges, degenerative sclerosis produces more diffuse changes. Note the distortion of both hip joints. (From Dickson DD, Camp JD, Ghormley RK. *Radiology* 1945;44:449, with permission.)

Computed Tomography and Magnetic Resonance Imaging

At present, CT is not thought to provide significant additional information in the routine diagnosis of metastatic bone disease. Occasionally, however, metastatic lesions in the pelvis, sternum, and vertebral column that are questionable or not evident on routine radiography may be detected by CT studies (816). MRI is a more sensitive and specific study for bone metastases than a bone scan. Metastatic lesions commonly are associated with a decreased marrow signal on T_1-weighted images. Although the T_2-weighted image signal is increased in most bone metastases, it commonly, but not always, is decreased in association with osteoblastic metastases. Unfortunately, the MRI pattern does not always distinguish metastatic lesions, leukemia, lymphoma, multiple myeloma, and other benign marrow changes; however, thoughtful use of imaging sequences and occasional use of enhancing agents can assist in increasing the discriminatory information provided. We use MRI selectively with patients in whom our suspicion of possible metastatic disease is unconfirmed or requires further supportive evidence.

Albertsen and associates (10) performed a perspective, population-based survey targeting 3,690 men with prostate cancer. Using information captured in primary medical record reviews, they estimated the overall positive yield of bone scans, CT, and MRI in this cohort. They noted that the positive yield of bone scan and CT was less than 5% and 12%, respectively, for men with PSA levels of 4 to 20 ng/mL. These figures dropped to 2% and 9%, respectively, for men who also had a Gleason score of 6 or less. Only men with PSA levels greater than 50 ng/mL and those with Gleason scores of 8 to 10 and PSA levels greater than 20 ng/mL had positive yields greater than 10% and 20% for bone scan and CT, respectively.

Lymph Node and Soft Tissue Metastases

Observations documenting the presence and supporting the importance of an intraprostatic lymphatic system have increased (1088). The iliopelvic lymph nodes, constituting the first echelon of lymph drainage from the prostate gland, can be divided into three main groups: external iliac, internal iliac, and common iliac (845) (Fig. 33.44). The external iliac group consists of lateral, intermediate, and medial chains. Of these, the lateral and medial chains are the most important. The lateral retrocrural lymph node is prominent, relatively constant, and represents the most inferior node of the lateral chain. With respect to the metastatic spread of CaP, the medial chain is the most strategic. The so-called obturator node actually represents the middle node of the medial external iliac lymph node chain. It is located cephalad to the medial retrocrural node, which is the most inferior node in the medial chain and represents a continuation of the deep inguinal lymph nodes.

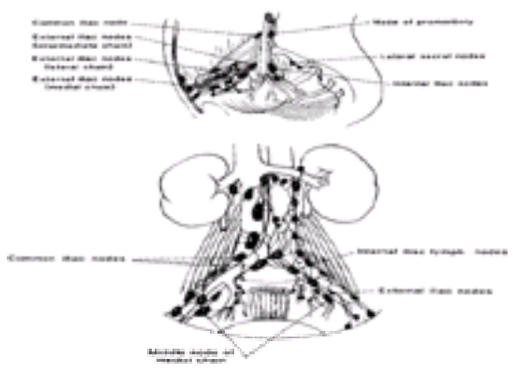

FIGURE 33.44. Sagittal **(A)** and coronal **(B)** views of the iliopelvic lymph nodes. The medial chain of the external iliac lymph nodes (“obturator” nodes) usually constitute the first echelon of lymphatic involvement in prostate cancer. (From Rouviere H. *Anatomy of the human lymphatic system.* Ann Arbor, MI: Edwards Brothers, 1938, with permission.)

Four to eight nodes lie along the internal iliac artery and its tributaries (hypogastric/internal iliac group). These lymphatics are a common site of CaP metastases and are infrequently visualized on standard pedal lymphangiograms.

The common iliac lymph node group, also subdivided into lateral, intermediate, and medial chains, represents an extension of the external iliac lymph nodes. Again, the medial chain is the most important because it constitutes a major pathway by which the pelvic viscera communicate with the periaortic nodes. The nodes of the sacral promontory (i.e., subaortic nodes) are part of this medial chain. It should be emphasized that the right and left common iliac chains are frequently cross-communicative.

Evidence supporting the frequency (18,301) and documenting the importance to clinical stage of pelvic lymph node metastasis from CaP has accumulated rapidly in the last 40 years. As expected from anatomic studies, the obturator, presacral, presciatic, hypogastric, and external iliac nodes are most commonly involved in metastasis (143). The so-called obturator nodes are involved more frequently and usually but not always earlier than other pelvic nodes (367,630). Apparently isolated metastases to other pelvic node sites do occur (307). The incidence of lymph node metastasis is related to the grade, and local mass and anatomic extent of the carcinoma.

With the advent of the use of serum PSA levels as an indication for prostatic biopsy, the prevalence of positive nodes removed at pelvic lymphadenectomy is much lower than it has been in the past (532,533). It approximates 5% or less in stage A_1, A_2, B_1, and T_c patients (355). Danella and associates (210) reported a node positive finding in 1 of 105 (less than or equal to 1%), 6 of 90 (6.7%) and in 5 of 19 (26.3%) stage B_1, B_2, and C patients. Use of stage, grade, and PSA data seems likely to identify a group of patients in whom omission of lymph node assessment before radical prostatectomy or radiation therapy is an alternative that deserves consideration.

The imaging studies such as MRI and CT scanning with and without needle aspiration are currently used very selectively and lymphangiography rarely to evaluate pelvic lymph nodes for the presence of metastatic carcinoma of the prostate. Radioimmunologic and positron emission tomography (PET) scan procedures are being used and evaluated in attempts to achieve more diffuse specific site recognition. The following is a brief discussion of the accuracy, advantages, and disadvantages

of these procedures.

Computed Tomography Scan and Magnetic Resonance Imaging

The hope that CT scanning can identify enlarged masses (greater than 1.0 cm short axis) in a large percentage of the patients with pelvic lymph node metastasis has not been realized. The difference in results achieved with lymphoma as compared with metastatic deposits has been attributed to the difficulty in detecting microscopic deposits and in differentiating malignant and nonmalignant nodal enlargement. Experience with CT evaluation in a limited number of patients with various malignancies (565) and stage A_2 to C prostate cancer (49) indicated a false-negative rate of 40% and greater than 80%, respectively. Even nodal enlargement identified on CT scan was not always confirmed (false-positive result in one of two patients). Others have reported both confirmatory and contrary experiences in groups of patients subjected to CT scanning of the pelvis in whom pelvic lymphadenectomy was used selectively (868). An initial reported minimal experience with MRI evaluation of the pelvic structures in patients with clinically localized CaP (683) also indicated a high incidence of false-negative observations with regard to nodal metastases. The accuracy of CT or MRI in identifying enlarged pelvic nodes in patients with clinically advanced periprostatic disease (stage C, $T_{3,4}$) with or without attempted percutaneous aspiration or biopsy has not been evaluated systematically. Despite a strong positive correlation between PSA levels above 25 ng/mL and development of pelvic lymph node metastases, the sensitivity of CT (and probably MRI) scanning for detecting positive lymph nodes in this context approaches a disappointing 30% to 35%.

Lymphangiography

Visualization of the internal architecture of the pelvic lymph nodes by injecting ethiodol or a similar agent into the lymphatics of the dorsum of the foot is an established procedure to attempt to identify primary or metastatic malignancies in these structures. The medial chain of the external iliac nodes, the “obturator nodes,” is usually visualized by foot lymphangiography (647), but the hypogastric chain is demonstrated in only 50% of cases (143). The reported sensitivity and specificity of lymphangiography have varied considerably. Studies reporting an accuracy as high as 85% (138) or a false-positive rate of only 5% (755) conflict (29,105,390) with those reporting a high incidence of false-positive and false-negative observations, with the latter ranging from 40% to 50%. Patient selection is likely to be the major factor influencing the accuracy of the reported studies, although technical aspects of the study, as well as the skill of the radiologist interpreting it (757), may play a role. Currently, we rarely consider using lymphangiography to evaluate the pelvic lymph nodes for metastatic disease in CaP patients.

Radioimmunologic Imaging

Attempts to use tagged antibodies to PAP or PSA to identify and image tumor in metastatic sites are emerging. g-Scintillation camera imaging 24 to 48 hours after the injection of an IgG ^{131}I-labeled antibody to PAP identified true primary and metastatic tumor sites in seven of the nine patients with metastatic carcinoma of the prostate but failed to identify bone metastasis (366). Babaian and associates (23) reported use of an antiprostatic acid phosphatase monoclonal antibody, PAY 276, labeled with indium-111 (^{111}In) to attempt to image metastatic foci from carcinoma of the prostate. This antibody did identify bone metastases but failed to image lymph nodes containing tumor. Increasing the quantity of unlabeled antibody used decreased PAY 276 concentration in the liver and was associated with increased specificity and sensitivity of the imaging procedure. The ProstaScint scan using the ^{111}In tagged antibody CYT-356, which reacts with cytoplasmic epitope of PSM recently has been shown to enhance visualization of soft-tissue nodal metastases (24) and occult prostate cancer recurrence after radical prostatectomy (480). With respect to lymph node metastases, a negative predictive value of 83% and a positive predictive value of 50% have been observed. At present, the ProstaScint scan appears to have limited value for pretreatment staging (1014). Sodee and associates (938) analyzed a multiinstitutional retrospective study of 2,292 ProstaScint imaging scans of 2,154 CaP patients. Of interest, those patients with newly diagnosed CaP had a significant correlation between PSA and ProstaScint positivity in the prostate bed and pelvic metastases, but not for extrapelvic metastatic disease. ProstaScint imaging has been used primarily to identify metastatic disease in patients who exhibit a rising PSA after radical prostatectomy. The potential utility of this imaging modality in that particular clinical context is summarized in a subsequent section of this chapter.

Positron Emission Tomography

Malignant tumors generally grow at a more accelerated rate than normal tissues, and thus possess increased rates of DNA synthesis, amino acid transport, protein synthesis, and increased rate of glucose metabolism (865). With respect to the latter feature, tumors generally exhibit increased rates of aerobic glycolysis versus most normal tissues. The Fluorine-18 (^{18}F) labeled analog of 2-deoxy-D-glucose (FDG) is transported into cancer cells like glucose by facilitative glucose transporters, and is phosphorylated to FDG-6-phosphate by hexokinase. ^{18}F has a 109-minute half-life and is generally cyclotron or accelerator produced. Normal FDG *in vivo* distribution in man includes the brain, heart, kidneys, and urinary tract, at 1 hour after tracer injection. FDG-PET has been identified as a useful imaging modality for staging lung, colorectal, and head and neck cancers and melanoma. It appears PET has limited utility with respect to detection and characterization of the primary tumor site in CaP. The latter observation probably reflects the similarity of metabolic activity in most primary prostate tumors and BPH tissue. In addition, anticipated activity in the bladder renders analysis of subtle activity in the prostate difficult. Seltzer and associates (900) compared helical CT imaging and PET and CTY-356 monoclonal antibody scans for evaluation of lymph node metastases in patients with prostate cancer exhibiting relapse after treatment for localized disease. PET and CT were both positive for distant disease in 50% of 22 patients with PSAs greater than 4 ng/mL and in 4% (PET) and 17% (CT), respectively, of 23 patients with PSA levels less than 4 ng/mL. PET and CT had similar detection rates for metastatic disease, which were higher overall than for monoclonal antibody scanning. CT-guided FNA documented metastases (true positive) in only 1 of 6 antibodies as contrasted to 6 of 9 PET-identified patients. These investigators suggest new PET tracers, such as C-11 methionine and C-11 choline, and emergence of informative PET-iterative image reconstruction algorithms may expand the utility of this imaging modality for prostate cancer. In contrast, Sanz and associates (865) observed that PET, using deoxyglucose labeled with ^{18}F, could not reliably identify tumor in the iliac and obturator lymph nodes before surgery. However, in radical prostatectomy patients with biochemical relapse, PET appeared to have better sensitivity than CT in identifying diseases in soft tissues but was inferior to bone scintigraphy in detecting skeletal metastases.

Excision and Histologic Evaluation of Pelvic Nodes

Identification of CaP cells in a pelvic node provides information regarding the biologic activity and the site of the tumor that is important to management decisions. Procedures attempting to identify node metastases that do not allow histologic or cytologic confirmation have limited sensitivity and suspect specificity. Consequently, evaluation of minimally invasive efforts to remove or successfully obtain tissue samples from lymph nodes and other sites potentially or probably involved by metastatic CaP are appropriately ongoing. The probability of recognizable lymph node involvement is related to the histologic grade and mass (clinical stage) of the primary tumor (see Natural History). This information combined with serum PSA levels has been used to attempt to assess the likelihood of node metastases (73,749) and may be useful in guiding decisions regarding the desirability and extent of pelvic node dissection before proceeding with definitive therapy (Table 33.16).

Several groups have documented the ominous prognostic significance of even one microscopically positive node (932,1139). Gervasi and associates (348) presented long-term follow-up information on 511 patients with CaP that had undergone bilateral pelvic lymph dissection and radiation. Although the results of treatment are confused by the high frequency of persistent local tumor, the difference in observed progressive disease at 10 years in N_0 (31%) and all N^+ (87%) regardless of extent of node involvement supports the biologic significance of node involvement. Consequently, an accurate assessment of the status of the nodes with regard to tumor dissemination is highly desirable. The limited sensitivity and suspect specificity of studies that do not provide an opportunity for histologic or cytologic evaluation of the nodes that are common sites of metastasis have been major factors in establishing pelvic lymphadenectomy as a common staging procedure in patients with CaP confined to the prostate and at times in patients with periprostatic disease. The optimal extent of lymphadenectomy, the accuracy of the evaluation for nodal metastasis on frozen and permanent section, and the immediate and delayed risks of the procedure warrant a brief discussion.

A risk-benefit assessment is important to determine the optimal extent of the pelvic lymphadenectomy. The purpose of the procedure is to provide staging information, although a therapeutic effect cannot be excluded. Accurate knowledge of the incidence and interrelationships of metastatic involvement of nodes in the obturator fossa and the external, internal, and common iliac, as well as the periaortic region in patients with prostatic carcinoma judged to be localized to the prostate or periprostatic area is essential to guide this assessment. In patients with nodal metastases staged by lymphangiography and pelvic lymph node dissection (PLND), Pistenma and associates (780) noted involvement of obturator, hypogastric, external iliac, common iliac, and paraaortic groups in 31%, 24%, 22%, 17%, and 18% of cases, respectively. The fact that only 61% (21 of 35) of the 35 solitary node metastases reported by Fowler and Whitmore (307) were located in the hypogastric-obturator area and that 39% (14 of 35) were in the external iliac group of nodes is of particular interest. This group observed a 16% (13 of 82) incidence of contralateral lymph node metastasis only in patients with primary tumors clinically confined to one lobe of the prostate. These observations indicate that a lymph node dissection confined to the obturator-hypogastric region may possibly miss nodal metastases in 15% to 40% of the patients evaluated. Although an extensive systematic study of the relationship of pelvic and abdominal node metastasis is not available, Ray and colleagues (815) noted all 11 patients with extrapelvic node metastasis in their series had concurrent pelvic lymph node involvement.

Recently, Bader and associates (26) performed an extensive PLND in 333 patients with prostate cancer before undertaking radical prostatectomy. Their “extensive” dissection was performed along the external iliac vein, the obturator nerve, and internal iliac artery. Of this cohort, 77 of 333 (23%) had evidence of lymph node positive disease. Of interest, the median number of nodes removed was 20 (range of 6 of 41) and the median number of positive nodes was 2 (range of 1 of 19). Not surprisingly, the percentage of patients with positive lymph nodes increased with the extent of local disease: organ-confined (10%), capsular infiltration (21%), seminal vesicle infiltration (42%), and gross extraprostatic disease (43%). Of potential importance, internal iliac lymph nodes were positive in 45 of 77 (59%) patients. Of 77 patients, 30 demonstrated additional positive lymph nodes along the external iliac vein and/or obturator nerve. Internal iliac lymph node involvement alone was noted in 15 of 77 (19%). The authors emphasized the potential importance of internal iliac lymph node dissection in that 1 of 5 patients would have been understaged if the dissection template had not included this region. Burkhard and associates (110) analyzed this same cohort to determine which clinical subset of patients actually requires lymph node dissection. They observed that 15 of 75 (20%) patients with lymph node metastases had a PSA less than 10 ng/mL and 36 of 75 (48%) had a preoperative PSA level of less than 20 ng/mL. They observed that 7% of the “low-risk” group harbored micrometastatic disease to the regional lymph nodes. These investigators speculate that the extensive lymph node dissection performed in this study accounts for the higher percentage of patients with positive lymph nodes than would be anticipated based on other recent reports. Whether or not extensive lymph node dissection has a favorable impact on regional tumor control and patient survival must await long-term follow-up.

Intraoperative assessment of the status of the pelvic lymph nodes is particularly important when pelvic lymphadenectomy and radical prostatectomy are carried out as a single operative procedure. Evaluation of node status on the basis of size, configuration, and consistency has not been studied systematically. In one series (151), 88% of tumor-bearing nodes recognized on frozen section were abnormal to inspection. However, the incidence of false-positive gross assessment was not cited. When node metastases are present in patients with clinically localized CaP, the gross assessment of these nodes often does not identify them (false negative). Epstein and co-workers (276) reported that 40 of 310 node dissections for clinical stage A and B carcinoma of the prostate disclosed metastatic disease; the nodes were grossly “unremarkable” in 33 of these cases.

The accuracy and extent of regional lymph node dissection in malignant melanoma and breast cancer has been dramatically influenced by sentinel lymph node mapping. Recent reports emphasized intratumoral or peritumoral injection of a radiolabeled colloid and subsequent identification of sentinel lymph nodes with a handheld g-probe. In many instances, a similarly injected vital blue dye facilitates visual identification of the pertinent lymph node–bearing areas. Wawroschek and associates (1080) modified this approach before PLND in 80 prostate cancer patients. Ultrasound-guided intraprostatic injection of technetium-99m colloid before pelvic staging lymph node dissection was followed by dynamic lymphoscintigraphy with both early and late uptake imaging. Positive lymph nodes were identified in 23 of 80 patients (29%). Sentinel lymph nodes could be identified intraoperatively with a g-probe in 20 of 22 patients with micrometastatic disease. Nineteen of twenty-two of these patients exhibited evidence of micrometastatic disease following tissue processing. Of interest, only the sentinel lymph node was involved in 14 of 22 patients. On average, one sentinel lymph node was identified per patient. The authors speculate that further modifications of this approach may enhance the sensitivity of lymph node dissection, shorten operative time, and reduce dissection-associated morbidity.

The accuracy of frozen section analysis for nodal metastases depends on node selection and sectioning procedures as well as on the accuracy of the histologic interpretation. A positive finding on frozen section is almost always confirmed on permanent section (151,276). On the other hand, false-negative evaluations of approximately 3.5% to 16% can be expected (151,276,537,630). Although the surgeon's attitude about the possible therapeutic role of lymphadenectomy may modify his or her determination to pursue intraoperative recognition of nodal metastases, the fact that an appreciable percentage of micrometastases present in grossly normal nodes (67%) (276) can be identified by frozen section studies indicates that these efforts are informative and reasonable.

Lymphadenectomy carried out as a staging or therapeutic procedure in patients with carcinoma of the prostate is associated with definite morbidity but very low risk of death. Early experience (25) reported wound complications were a cause of this morbidity in more than 20% of patients. Risk of wound infection seemed to be decreased by wound irrigation but not by drainage. Postoperative anticoagulation therapy probably reduces the risk of pulmonary embolism (583), but increases the risk of lymphocele formation (141). The incidence of wound (22% versus 30%) and other complications (12% versus 52%) increased when pelvic lymphadenectomy was combined with another procedure, such as radical prostatectomy. Currently, isolated staging pelvic lymphadenectomy is performed infrequently, and often by an endoscopic approach, making comparative assessment difficult.

The extent of the lymph node dissection, the presence of metastatic disease, and the postlymphadenectomy treatment regimen seem to influence the incidence and severity of postoperative complications. The reported incidence of chronic lymphedema of the legs and genital region varies from 0% to 18%. Low rates are apparently associated with a lymph node dissection limited to the hypogastric-obturator nodes (98) and with avoiding postoperative radiation therapy. An extended node dissection followed by radiation therapy or combined with additional surgical procedures increases the risk of postoperative complications (320,583). Combining a transperitoneal, pelvic, and periaortic node dissection with definitive radiation therapy was followed by development of radiation enteritis in 12 of 13 patients and subsequent small-bowel obstruction in 8 (320).

These observations have been used to guide the surgical procedures used to assess the presence of nodal metastases. The routine evaluation of the abdominal nodes is not advocated at this time. The extent of the pelvic node dissection varies depending on the perceived risk–reward relationship and the surgeon's and patient's priorities. One group, to which we belong, advocates removal of nodes from the level of the common iliac vessels to the circumflex vein using the genitofemoral nerve as the lateral margin, encompassing the nodes surrounding the obturator nerve and vessels, and overlying the hypogastric artery. A few urologists also add a dissection of the presacral nodes. A second group limits the dissection to the medial aspect of the external iliac vein and to the bifurcation of the external iliac artery. With the advent of frequent PSA testing, a distinct “stage shift” has been observed (145), such that fewer patients present with clinically obvious stage D disease. This may well account for the significantly decreased frequency of positive pelvic nodes encountered at node dissection. At this time, most would agree that using tumor grade, clinical and histologic evidence of tumor mass, and serum PSA levels, a group of patients with presumed organ-confined prostate cancer can be identified in whom the limited risk of lymph node metastases makes consideration of omission of histologic assessment reasonable (355).

Surgical Therapy

Surgical procedures play an important role in the staging and treatment of CaP. Pelvic lymphadenectomy generally provides important information with regard to the stage of the tumor and may occasionally have a therapeutic role. Radical prostatectomies (retropubic, perineal, laparoscopic) are performed in an attempt to cure previously untreated localized CaP and select patients with T_3 disease, and along with cystoprostatectomy, they may play a salvage role in a small subset of patients harboring tumor following definitive radiotherapy. Finally, regimens designed to palliate the disease process and improve the quality of life for the patient with CaP often include scrotal orchiectomy as a form of androgen ablation and channel TURP to relieve bladder neck obstruction. The surgeon's role in all phases of CaP management is likely to increase in the future as our surgical armamentarium improves and our attitudes toward aging change. The surgical approaches to CaP with the exception of those used in conjunction with interstitial radiotherapy are discussed briefly in this section.

Preoperative Considerations

The patient with a diagnosis of CaP should be informed about the variable natural history, the advantages and disadvantages of the multiple treatment options, and the differing opinions regarding patient management so that he realizes that an absolute recommendation with regard to treatment is difficult to make. Potential complications to the proposed surgical procedure require discussion. An assessment of cardiac risk seems prudent in patients being considered for radical pelvic surgery, particularly those with a history of coronary artery disease, peripheral vascular disease, diabetes mellitus, and long-standing essential hypertension and in patients with strong family histories of these and other relevant comorbidities. For such patients, the performance of a stress echocardiogram should be considered. Alternatively, dipyramidale-thallium cardiac imaging or a dobutamine echocardiogram is appropriate for exercise-intolerant patients. Often, a consultation with a radiation/medical oncologist will help the patient understand the choices better.

Although the likelihood of rectal laceration during routine radical retropubic prostatectomy is low (approximately 1% to 2%), the potential morbidity following this injury can be reduced by a clear liquid diet and mechanical cleansing of the colon/rectum the day before surgery. With respect to the latter, reasonable options include the use of a Fleet enema, oral Fleet Phospho-Soda, or the use of tap water enemas. In addition, consideration should be given to using a 1% neomycin retention enema (200 to 300 mL, total volume) several hours before surgery. Unless preoperative urine cultures or the need for SBE prophylaxis mandate the use of a specific drug regimen, we generally use cefazolin (Ancef) in our perioperative antimicrobial prophylaxis regimen. If a salvage procedure is anticipated, a formal mechanical and antibiotic bowel preparation before surgery is prudent. We use the Go-Lytely (or Nu-Lytely) mechanical bowel preparation (4 L at 5 PM) with increasing frequency for this purpose. Neomycin (500 mg) and metronidazole (Flagyl, 500 mg) are administered at 1, 2, and 10 PM on the day before surgery (712). When this regimen is followed, the neomycin retention enema is probably unnecessary.

At this point, it is appropriate to revisit the concept of blood use strategy. It is generally recognized that volume replacement is best accomplished by the infusion of crystalloids (and other suitable plasma expanders). The goal of red blood cell (RBC) transfusion is to increase tissue oxygen delivery (13,357). In the absence of an acute critical illness or a history of significant cardiac disease, an appropriate threshold for transfusion should be a hemoglobin level of 7.0 to 8.0 g/dL. On the other hand, transfusion may be considered in patients with these mitigating conditions if hemoglobin levels fall below 9 to 10 g/dL (13,357). The theoretic advisability of autologous blood transfusion before prostatic surgery was previously alluded to. The impetus for this approach is directly linked to the estimated risks of disease transmission following the transfusion of allogenic blood units (Table 33.18). Autologous blood can theoretically be donated up to 72 hours preoperatively (5 to 7 days is preferred) and may be stored for approximately 35 days. The freezing of autologous units significantly increases their shelf life, but mandates prompt transfusion after thawing. As important technical modifications have been made in the technique of radical prostatectomy, the outcome has become increasingly safe and successful (155,201). One of many important outcome improvements has been a significant diminution in mean interoperative blood loss (1,200 to 1,500 mL). As a consequence, the utility/necessity of autologous blood donation has been questioned. For example, O'Hara and associates (717) estimated that 64% of autologous units were discarded or inappropriately transfused during radical retropubic prostatectomy. Furthermore, studies conducted by Renner and associates (819) documented that up to half of the autologous blood that is collected is subsequently discarded. Current policies do not allow unused autologous blood to be used in patients other than the donor (357). Other potential disadvantages of autologous blood donation are summarized in Table 33.19. We continue to discuss the relative advantages and disadvantages of autologous blood donation with our patients. Those electing to proceed with such donations are encouraged to bank 1 to 2 units. These patients are maintained on supplemental iron (FeSo4, 325 mg two to three times daily) during the process of donation and for an additional 6 to 8 weeks.

Risk Factor	Estimated Frequency		Deaths per Million Units (n)
	Per Million Units	Per Actual Unit	
Infection			
Viral			
Hepatitis A	1	1/1,000,000	0
Hepatitis B	7-32	1/30,000-1/250,000	0-0.14
Hepatitis C	4-36	1/30,000-1/32,000	0.5-17
HIV	0.4-1	1/200,000-1/1,000,000	0.5-5
Bacterial			
Red blood cells	2	1/500,000	0.1-0.25
Platelets	83	1/12,000	21
Acute hemolytic reactions	1-4	1/250,000-1/1,000,000	0.67
Delayed hemolytic reactions	1,000	1/1,000	0.4
Transfusion-related acute lung injury	200	1/5,000	0.2

TABLE 33.18. RISKS OF BLOOD TRANSFUSION

Advantages	Disadvantages
Prevents transfusion-transmitted disease	Does not eliminate the risk of bacterial contamination or volume overload
Avoids red blood cell alloimmunization	Does not eliminate the risk of administrative error, resulting in ABO incompatibility
Supplements the blood supply	Costs more than the allogenic blood donation
Provides compatible blood for patients with alloantibodies	Results in discarding untransfused blood
Prevents some adverse transfusion reactions	Causes perioperative anemia and increases the likelihood of transfusion

TABLE 33.19. ADVANTAGES AND DISADVANTAGES OF AUTOLOGOUS BLOOD DONATION

Transfusion-avoidance approaches that may have utility in properly selected patients include (a) intraoperative autotransfusion using cell saver suction and cell-washing devices, (b) acute normovolemic hemodilution, and (c) the use of recombinant human erythropoietin. The relative strengths and weaknesses of these respective approaches are nicely summarized in the review by Gilbert and Smith (357). Of these alternatives, the use of epoetin alfa (recombinant human erythropoietin) is perhaps the most appealing.

The rationale for administering erythropoietin preoperatively is to increase the rate of RBC production in the bone marrow with a resultant increase in red cell volume. Studies conducted by Chen and associates (163) and Rosenblum and associates (841) validated the safety and efficacy of this approach in men before radical prostatectomy. For individuals with a baseline hematocrit of less than 45%, two doses of 600 IU/kg epoetin alfa, administered 14 days and 7 days preoperatively significantly increased RBC mass and decreased the need for allogeneic blood transfusion. When used in this manner, erythropoietin-induced complications—arterial hypertension, cerebral convulsions, influenza-like syndrome, and an increase in thromboembolic events—documented in patients with chronic renal failure who require long-term administration were not encountered. It appears epoetin has a legitimate role for use in patients with hemoglobin levels less than 13 g/dL, who are about to undergo surgical procedures that entail moderate to significant blood loss, and who are anxious and/or religiously opposed to allogeneic blood use.

The predisposition to deep vein thrombosis (DVT) associated with prostatic surgery was discussed in detail in the preceeding chapter. Indeed, a predisposition for venous thrombosis, migratory thrombophlebitis, arterial emboli, and nonbacterial endocarditis all have been reported in association with CaP (851). Adamson and associates (4) demonstrated that the prevalence of coagulopathy in patients with untreated prostate cancer was correlated with elevations in serum fibrinopeptide A and D-dimer in 40% and 24% of such patients, respectively. Fibrinopeptide A is formed by thrombin-mediated cleavage of fibrinogen. Because its half-life is only a few minutes, fibrinopeptide A is a very sensitive marker of coagulation activity and ongoing fibrin formation. D-dimer is produced as a result of cleavage of cross-linked fibrin by the fibrinolytic enzyme plasmin, and abnormal levels of D-dimer are associated with reactive fibrinolysis. Noncontroversial measures such as adequate hydration, avoidance of techniques or circumstances that increase venous stasis, and use of procedures that increase venous return (i.e., early ambulation and pneumatic compression boots) certainly warrant serious attention. Although mini-dose heparin (5,000 units administered subcutaneously every 12 hours) may also be beneficial when used prophylactically, the incidence of hematomas and wound infections seems to be increased. Catalona and colleagues (141) noted an increased incidence of lymphocele formation following mini-dose heparin therapy. Other investigators have confirmed these observations (942). Of interest, the administration of low-molecular-weight heparin (Lovenox 30 mg administered subcutaneously every 12 hours) into upper extremity sites may diminish the risk of pelvic lymphocele formation. Patients at high risk may require the initiation of an anticoagulation regimen perioperatively, but the urologic surgeon must be aware of the increased risks attendant to such an approach.

Pelvic Lymph Node Dissection

As stated previously, pelvic lymphadenectomy often constitutes the final staging procedure performed before attempting curative therapy for localized CaP. Before radical retropubic prostatectomy, it is most convenient to perform either a standard or modified lymph node dissection using a traditional umbilicus to pubis or a mini-laparotomy incision, popularized by Steiner and Marshall (976). Alternatively, a laparoscopic PLND can be performed as a first-stage procedure with the patient under a separate anesthetic. The latter approach is infrequently used at our institution given its logistic inconvenience and additional expense. A radical perineal prostatectomy may be performed without the benefit of the previous nodal staging or may follow either a laparoscopic or mini-laparotomy approach to the nodes under the same anesthetic. Occasionally, patients with clinical stage C disease based on DRE and/or TRUSP will undergo pelvic lymphadenectomy to determine the status of the regional nodes before finalizing a treatment plan.

The frequency of positive lymph nodes in patients undergoing radical prostatectomy has decreased from 25% to 30% to less than 5% within the past 15 years (9,17,263). Undoubtedly, this development is related to the PSA-induced stage-shift. Epstein and associates (275) documented that men with Gleason scores of less than 7 and PSA values of less than 10 mg/mL have a markedly low frequency of pelvic lymph node metastases; consequently, they may not require pelvic lymphadenectomy. More recently, Alagiri and associates (9) have expanded these limits to include PSA values from 10 to 20 mg/mL and tumors with a Gleason score

of 7. PLND is recommended for patients with cT_{2b} tumors, PSA values greater than 10 mg/mL, and primary or secondary Gleason grade 4 pattern on biopsy. Despite these observations, we continue to perform a limited PLND (i.e., removal of the medial group of the extrailiac lymph node chain) in all patients scheduled to undergo radical prostatectomy. The approach generally adds approximately 15 to 30 minutes to the operative time. In our experience, it has been associated with a very low complication rate. Finally, we believe that the results of lymph node dissection provide useful prognostic information that may facilitate the identification of patients most likely to benefit from various forms of postoperative adjuvant therapy.

Surgical Technique

Most patients undergoing pelvic lymphadenectomy alone or in conjunction with radical prostatectomy receive general anesthesia. Peters and Walsh (763) documented that these procedures can be performed using spinal or continuous epidural anesthesia. Patients undergoing the latter techniques required less intraoperative and postoperative blood replacement when compared with patients under general anesthesia. However, the differences between the two groups did not approach statistical significance.

Following the induction of satisfactory anesthesia, it is appropriate to ascertain that TED hose, sequential compression stockings, and heel protectors are properly applied and that the pneumatic compression boots are functioning properly. Exposure within the male pelvis is enhanced by gently flexing the table 10 to 15 degrees (Fig. 33.45). We do not routinely place the legs in spreader bars, but this has been suggested as a useful maneuver (143). The entire abdomen and genitalia are then prepared and draped in the standard fashion. If a cystoscopic examination had not been done previously, it is our practice to perform flexible cystourethroscopy at this point. This is done with the intention of excluding unsuspected mucosal pathology involving the lower urinary tract and to better ascertain the length of the prostatic urethra and determine the relationship of the prostatic base to the trigonal complex. A 20-Fr Foley catheter (with 30-mL balloon) is inserted and attached to gravity drainage after the sterile operative field has been established.

FIGURE 33.45. Surgical positioning suitable for pelvic lymphadenectomy and radical retropubic prostatectomy. Partial elevation of the kidney rest and the lumbar spine area together with 10 to 15 degrees of table flexion optimize exposure to the pelvic depths. The Foley catheter is generally inserted in sterile fashion after draping has been completed. A midline incision from the pubic symphysis arching laterally around the umbilicus is illustrated. (From Crawford ED, Kiker JD. Radical retropubic prostatectomy. *J Urol* 1983;129:1145, with permission.)

Optimal exposure is obtained through a midline incision that extends from the pubic symphysis to the lateral edge of the umbilicus (Fig. 33.45). The posterior sheath should be incised for a distance of 3 to 4 cm above the level of the semilunar line, and the lower aspect of the incision extended over the symphysis to facilitate retraction of the wound and dissection of the peritoneum off the undersurface of the rectus muscles. The latter maneuver exposes the inferior epigastric vessels, which should be preserved. In the obese patient it may be helpful to partially incise the insertion of the rectus muscle bellies. The prevesical fascia is incised and then bluntly separated from the transversalis fascia with a gentle sweeping motion with the fingers. Attention is then directed laterally to the attachment of the peritoneal envelope overlying the femoral canal and the spermatic cord. Blunt and sharp dissection usually permits mobilization of the peritoneum to the level of the bifurcation of the common iliac vessels. Should additional exposure be required, further mobility almost always can be obtained by dividing the transversalis fascia laterally and high on the pelvic wall, with or without concomitant ligation and division of the obliterated umbilical artery and vas deferens. At this point, the structures of the pelvic sidewall should be in clear view. Wound towels are secured to the fascia with 3-0 silk. Moist lap pads buttress the wound edges.

Adequate exposure is essential for this procedure. The spermatic cord is retracted laterally. We prefer the use of a Balfour wound retractor; Deaver or malleable retractor superiorly; a Richardson retractor laterally, and a Harrington, Glass, or malleable retractor medially. During the past few years, we have commonly used the table-mounted, self-retaining retractor unit (Omni retraction).

With the pelvic sidewall thus exposed, the ureter can be identified as it crosses the common iliac artery. When performing a standard pelvic lymphadenectomy, the surgical margins include the genitofemoral nerve laterally, the bifurcation of the common iliac artery superiorly, the circumflex iliac vein distally, and the obturator nerve inferiorly and posteriorly (Fig. 33.46). The fibroareolar investment of the structures contained within these anatomic boundaries can be removed en bloc or segmentally. As stated previously, our current preference is to perform a modified PLND, which entails the removal of the nodal tissue constituting the medial group of the external iliac lymph node chain. The superior border is the bifurcation of the common iliac artery. The medial border is the interface between the external iliac artery and vein. The distal boundary is the circumflex iliac vein/femoral canal. The obturator nerve and associated vessels constitute the posterior limit of the dissection. The template parameters associated with limited, standard, and extended lymph node dissections are highlighted in Fig. 33.46. We perform a standard lymph node dissection in those patients whose first echelon of lymph nodes demonstrate metastatic involvement and in those patients thought to be at high “up-front” risk for metastatic disease. We are intrigued by recent reports (26) that suggest that even in the modern era, conventional lymph node dissection may underestimate the frequency of metastatic disease, particularly that which involves the internal iliac nodal issues. The optimal extent and role of lymphadenectomy may well require reexamination based on accumulating evidence.

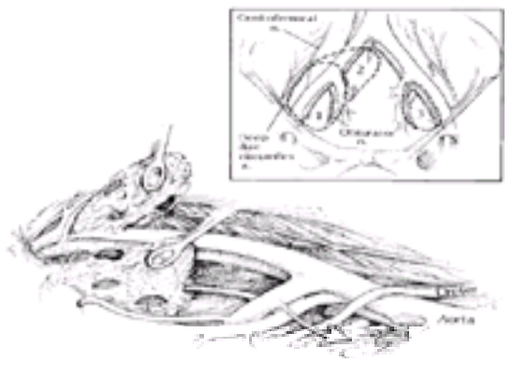

FIGURE 33.46. Pelvic lymph node dissection. The anatomic boundaries of standard *(1),* extended *(2),* and limited *(3)* lymphadenectomy are delineated in the inset panel. In the central illustration, note the removal of the external iliac lymph node packet **(top portion).** The genitofemoral nerve coursing along the surface of the iliopsoas muscle is clearly seen and represents the lateral boundary of the standard pelvic lymph node dissection. Dissection of this lymph node packet terminates at the level of the circumflex iliac vessels, which are seen arching laterally. The hypogastric-obturator lymph node packet **(lower portion)** often can be mobilized off the pelvic sidewall and obturator nerve with careful blunt dissection. Care must be taken to avoid inadvertent injury to the subadjacent accessory obturator vessels.

Mini-lap Lymphadenectomy

The mini-laparotomy staging pelvic lymphadenectomy (mini-lap) was popularized by Steiner and Marshall (976). In this technique, the patient is placed in the supine

position and the operating room table is hyperextended to increase the space between the umbilicus and pubic symphysis. A 22-Fr Foley catheter (30-mL balloon) is passed into the bladder and attached to a gravity drainage after inflating the balloon to 50 mL. A 6-cm midline skin incision is made with the distal extent approximately 2 cm from the superior aspect of the pubic symphysis. The anterior rectus fascia between the rectus muscles and the transversalis fascia is incised to permit access to the retropubic space of Retzius. The peritoneum is mobilized superiorly, and the space of Retzius is entered and developed. A Richardson retractor is used to engage the vas deferens and the peritoneum superior-laterally to enhance exposure. The incision itself can be moved from one side to the other to enhance exposure. Bladder retraction also is facilitated by the use of an Omni retractor. At this point, the node dissection is performed in standard fashion. Of note, the originators of the procedure did not place pelvic drains.

In their report of the first 16 patients on whom the mini-lap procedure was performed, the average intraoperative time was 32 minutes and the blood loss 15 to 20 mL. The mean number of pelvic lymph nodes removed was similar to that described for standard lymphadenectomy. No perioperative complications were reported. In particular, no patient had clinical evidence of a pelvic lymphocele despite the absence of drains. Most patients were discharged on postoperative day 2 or 3. Finally, the authors cite several advantages of the mini-lap over laparoscopic pelvic lymphadenectomy, with an emphasis placed on the shorter operating time of the mini-lap procedure (32 minutes), compared with an average of 2.5 hours for the laparoscopic PLND. They note that the 6-cm incision compares favorably with the four punctures/incisions made for laparoscopic procedures, some of which are as long as 11 mm. Moreover, the mini-lap procedure avoids peritoneotomy and the possible adverse sequela attendant to such a maneuver.

At our institution, the mini-lap is used in concert with radical perineal prostatectomy and as a “stand alone” procedure. Although there are proponents for simultaneous laparoscopic PLND and radical perineal prostatectomy (575), we have been quite pleased with the mini-lap procedure in this context.

Laparoscopic Pelvic Lymphadenectomy

Laparoscopic PLND was originally described by Schuessler and associates (884). Since then, several reports have emerged validating the utility and safety of the procedure (499,555,849). In most instances, the technique used is relatively similar from series to series and is summarized in the following paragraph.

The same preoperative preparation described for patients anticipating radical prostatectomy are initiated for those undergoing laparoscopic PLND. The patient is placed in the supine position. Following the induction of general endotracheal anesthesia, a nasogastric tube is placed and a Foley catheter inserted. The pelvis is gently hyperextended. Carefully positioned adherent 2-inch-wide straps are placed across the thighs and upper chest to support the patient on the operating table. The arms are adducted to the sides. A pneumoperitoneum is established using CO_2 insufflation following the careful insertion of the Veress needle (Fig. 33.47) or a Hasson cannula through the superior crease of the umbilicus. During this phase of the procedure, the patient is placed in a 15-degree head-down position, which is maintained during the passage of the primary and secondary trocars. With respect to the latter, both a “diamond” and a “fan” configuration can be used. The former involves a creation of four ports: (a) umbilicus—11-mm trocar, (b) the midline of the abdomen midway between the umbilicus and pubic symphysis—11-mm trocar, and (c) two 5-mm trocars, one on either side of the abdomen midway between the umbilicus and the anterior superior iliac spine. The fan array (Fig. 33.48) may be useful in obese patients and consists of five ports: (a) umbilicus-11 mm, (b) one 5-mm port on each side at the level of the anterior superior iliac spine, lateral to the inferior epigastric vessels, and (c) one port on each side midway between the anterior superior iliac spine and the umbilicus. For the latter ports, an 11-mm trocar is used for the left port and a 5-mm (or 11 mm) trocar for the right. As was the case with establishment of the pneumoperitoneum, trocar placement must be done with great caution and under direct vision. The surgeon stands on the side of the table opposite the site of the PLND node dissection.

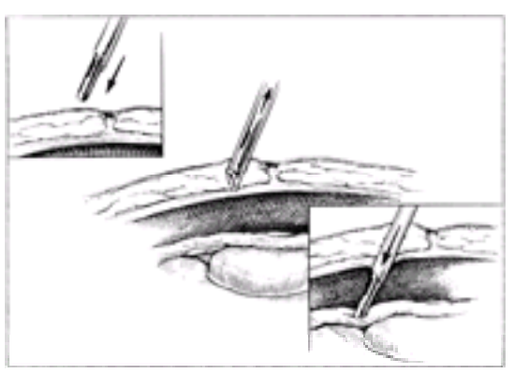

FIGURE 33.47. Insertion of the Veress needle. The needle consists of an inner, blunt, spring-loaded core that retracts on resistance, which exposes the sharp outer sheath. The insertion at the base of the umbilicus is facilitated by tenting the abdominal wall upward. Proper positioning should be ascertained by performing the standard aspiration, saline injection, and saline “drop” tests. (From Loughlin KR, Kavoussi LR. Laparoscopic lymphadenectomy in the staging of prostate cancer. *Contemp Urol* 1992;May:69, with permission.)

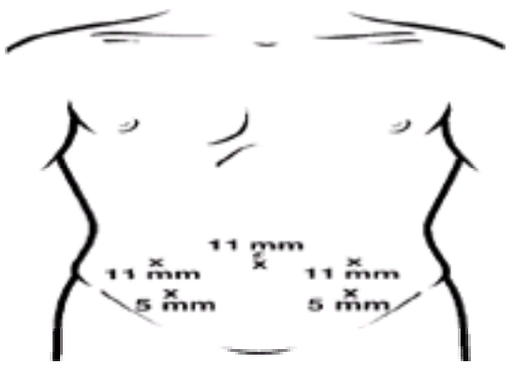

FIGURE 33.48. “Fan” trocar configuration for laparoscopic pelvic lymph node dissection. (From Parra RO, Andrus C, Boullier J, et al. Staging laparoscopic pelvic lymph node dissection: comparison of results with open pelvic lymphadenectomy. *J Urol* 1992;147[3 Pt 2]:875, with permission.)

Winfield and Schuessler (1096) have nicely summarized the steps involved in the limited pelvic lymphadenectomy. In brief, the peritoneum should be incised lateral to the medial umbilical ligament (Fig. 33.49). An inverted V incision may enhance exposure (Fig. 33.50). Next, the vas deferens is identified and incised. The external iliac vein should be identified and dissected from the bifurcation of the common iliac to the pubic bone, developing the lateral border of the nodal packet. The medial border of the packet is developed by dissecting tissue lateral to the medial umbilical ligament until the pubic bone is identified. The caudal border of the nodal packet is developed by joining the medial and lateral inferior corners of dissection by connecting them over the pubic bone. To develop a posterior surface of the nodal packet, the obturator nerve must be identified and dissected from the level of the pubic bone at the point where it disappears beneath the internal iliac vein (Fig. 33.51). The cephalic extent of the nodal packet is defined and freed from the V-shaped area lying between the external and common iliac vein and the obliterated umbilical artery. At this point, the nodal packet can be delivered through the largest cannula and submitted for frozen section analysis. During the course of the node dissection, liberal use is made of carefully activated cautery and Endoclips. After completion of the contralateral side, the trocars are removed in sequence under vision to ensure no significant bleeding occurs at the insertion sites. Following evacuation of the pneumoperitoneum (including the scrotal component), the 11-mm (or larger) trocar sites are closed with fascial and subcuticular sutures and the 5-mm port sites usually are closed with adhesive skin strips.

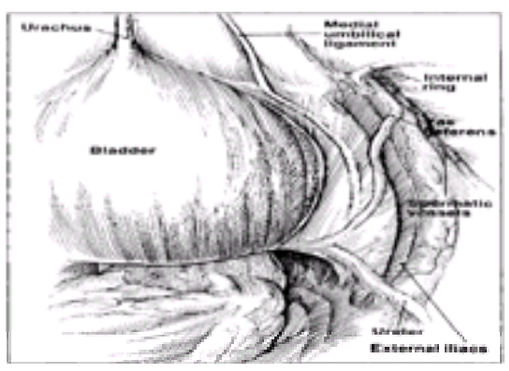

FIGURE 33.49. Standard anatomic landmarks for laparoscopic pelvic node dissection. The peritoneal incision will be placed lateral to the medial umbilical ligament. (Loughlin KR, Kavoussi LR. Laparoscopic lymphadenectomy in the staging of prostate cancer. *Contemp Urol* 1992;May:69, with permission.)

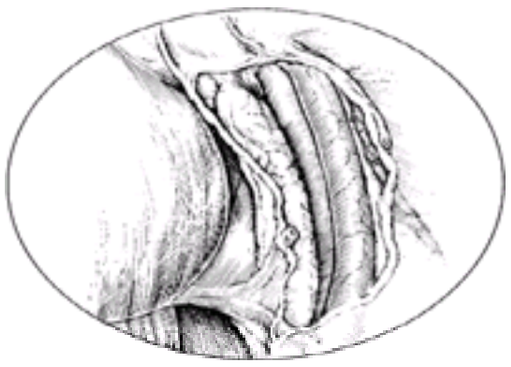

FIGURE 33.50. The laparoscopic dissection has now defined the lymph node packet (medial group of the external iliac lymph node chain), which remains attached distally to the pubic bone. (From Loughlin KR, Kavoussi LR. Laparoscopic lymphadenectomy in the staging of prostate cancer. *Contemp Urol* 1992;May:69, with permission.)

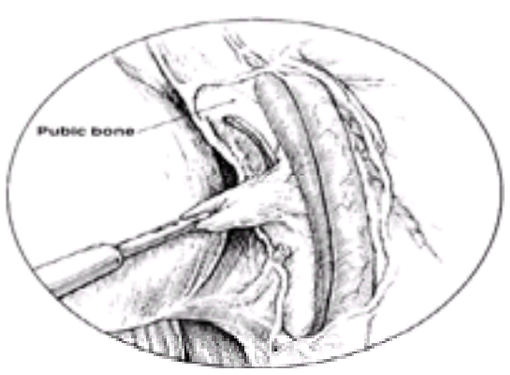

FIGURE 33.51. Following detachment of the lymph node packet from the pubic bone, the obturator nerve and vessels become readily apparent. (From Loughlin KR, Kavoussi LR. Laparoscopic lymphadenectomy in the staging of prostate cancer. *Contemp Urol* 1992;May:69, with permission.)

Das and Tashima (212) described an extraperitoneal laparoscopic staging PLND. In this technique a 2-cm incision is made in the midline approximately 2 cm below the umbilicus. Following incision of the subcutaneous tissue and linea alba, the underlying extraperitoneal space is developed by digital dissection inferiorly/laterally behind the rectus abdominous and the subsequent use of a distention balloon. A 10-mm trocar is then passed through the incision with high-flow CO_2 insufflation. Under laparoscopic vision, another 10-mm trocar is passed 3 cm above the symphysis pubis. Finally two 5-mm working ports are introduced lateral to the rectus abdominous muscle at a level midway between the umbilicus and the pubic symphysis. At this point, the dissection proceeds in a manner quite analogous to that of a standard extraperitoneal, open lymph node dissection. This approach avoids the potential complications associated with transperitoneal access and intraperitoneal dissection. Assessment of the ultimate utility of this modification requires clinical trials comparing it with transperitoneal laparoscopic PLND.

Complications of Pelvic Lymphadenectomy

The complications of pelvic lymphadenectomy are discussed briefly in the section on lymph node metastasis under Staging. If a lymphocele is suspected postoperatively (pain, mass, unilateral leg swelling), a pelvic ultrasound or a CT scan should be performed. A cystogram excludes urinary extravasation; a venous Doppler study can rule out lower extremity DVT. A sizable lymphocele causing symptoms (0.5% to 10% of cases) requires therapeutic intervention. CT or ultrasound-guided percutaneous drainage of the cavity with a pigtail catheter is a reasonable initial approach to this problem. When recognized promptly, prolonged decompression may allow the walls of the lymphocele to collapse and facilitate the sealing of the lymphatic vessels. If drainage persists, instillation of a sclerosing agent (e.g., tetracycline, Betadine) warrants consideration. A recurrent lymphocele is probably best treated with open or laparoscopic marsupialization into the peritoneal cavity (176,437,889). The potential complications of laparoscopy are listed in Table 33.20 and Table 33.21. Other complications attendant to pelvic lymphadenectomy are uncommon. Transsection of the obturator nerve appears in less than 1% of patients. Complete transection results in an inability to abduct the ipsilateral thigh. Complete transsection should prompt an attempt at intraoperative repair. Generally, two to three 4-0 nylon sutures placed with the aid of 4× loop magnification are sufficient. Fortunately, the lower extremity dysfunction resulting from an unsuccessful repair does not have a significant impact on the quality of life of most patients. Bleeding from the obturator and iliac vessels is most always avoidable and, if encountered, is easily managed with a combination of patience and optimal exposure. Fortunately, ureteral injuries are highly unusual if standard surgical precepts are followed. Ligation, crush injury, and total transsection are probably best managed by ureteral reimplantation. A clean partial transsection may be managed with stenting, primary repair, and adequate drainage.

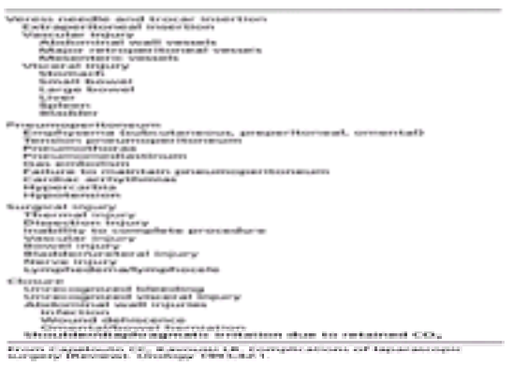

TABLE 33.20. POTENTIAL COMPLICATIONS OF LAPAROSCOPIC SURGERY

TABLE 33.21. COMPLICATIONS OF LAPAROSCOPIC PELVIC LYMPH NODE DISSECTION (327 PATIENTS)

Radical Prostatectomy

Selection of patients for radical prostatectomy on the basis of current clinical evaluation presents a problem because of understaging in a significant percentage of patients. For example, early in the Johns Hopkins series, approximately 60% of the patients subjected to radical retropubic prostatectomy had extraprostatic disease on pathologic examination of the specimen removed (254). The survival data on patients with a small localized tumor mass confined to one lobe on clinical examination (stage T_1) (426,1060) support the observation that patients with tumor in this stage are unlikely to have extraprostatic extension. Restriction of the radical prostatectomy to those patients would deprive many others of the possible benefits of radical prostatectomy. As our ability to recognize the presence of extraprostatic extension improves, the possibility for a more selective use of radical prostatectomy without unnecessarily limiting consideration of the procedure probably will be realized. Some groups have used and are using radical prostatectomy in patients with known stage C and D_1 disease. The Mayo Clinic is gaining a considerable experience in these patients and has used orchiectomy as an adjunctive therapeutic measure in this group (1138,1139 and 1140). The therapeutic yield of these attempts to extend radical excision in patients with CaP has been unexpectedly encouraging in the past (1137).

These perceptions notwithstanding, several features define the ideal candidate for radical prostatectomy: (a) clinically localized CaP and select patients with stage cT_{3a} disease; (b) patients whose tumor volumes exceed 0.2 mL; (c) tumor Gleason score greater than or equal to 5; (d) serum PSA less than or equal to 10 ng/mL; (e) a life expectancy of greater than 10 years; (f) and the absence of other, serious comorbid medical conditions (155).

Technique of Radical Retropubic Prostatectomy

In addition to popularizing the retropubic approach to the prostate gland for the treatment of benign disease, Millin was one of the first to describe the technique of radical retropubic prostatectomy (663,664). His approach using division of the urethra as an initial step in the removal of the prostate was adopted by other groups (578,642). Campbell (115) described antegrade removal of the prostate and thought this approach facilitated the vesicourethral anastomosis and minimized blood loss by early ligation of the vascular pedicle. Other investigators (584) adopted and modified this technique.

Reiner and Walsh (818) emphasis of important surgical aspects of the anatomy of Santorini's plexus as it relates to the anterior surface of the prostate facilitated the routine safe ligation of the dorsal vein complex (Fig. 33.52). Despite the innovations noted above, a major source of morbidity of radical prostatectomy was the high incidence of sexual impotence following the procedure. In 1982, Walsh and Donker (1058) presented anatomic observations regarding the location of the branches of the pelvic plexus that innervate the corpora cavernosa and their relationship with the prostatovesicular artery and lateral pelvic fascia. Using these observations, Walsh and associates (1061) modified the technique of radical retropubic prostatectomy to preserve the critical branches of the pelvic plexus and preserve potency in more than 80% of their patients (Fig. 33.53 and Fig. 33.54). Subsequent observations confirmed the efficacy of the nerve-sparing approach in preserving potency while maintaining adequate margins of resection (140,254). The approach to the nerve-sparing radical retropubic prostatectomy is briefly summarized in the following paragraphs.

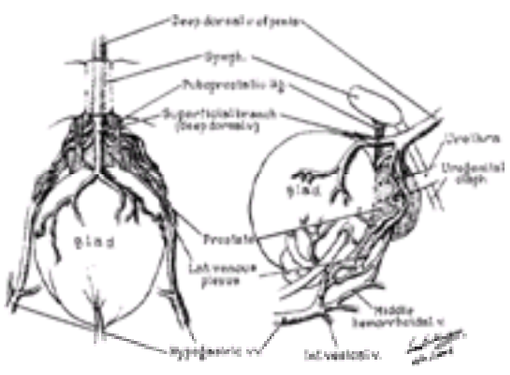

FIGURE 33.52. The anatomy of Santorini's plexus. The structures depicted are devoid of their normal investment of lateral pelvic fascia and fibroareolar tissue. **A:** The anterior view demonstrates the three major branches of the deep dorsal vein of the penis, namely, the superficial branch and the right and left lateral venous plexuses. **B:** The lateral view demonstrates that cutting of the puboprostatic ligaments flush with the undersurface of the pubic symphysis can be performed with impunity because the major venous tributaries are inferior to this avascular plane. (From Reiner WG, Walsh PC. An anatomical approach to the surgical management of the dorsal vein and Santorini's plexus during radical retropubic surgery. *J Urol* 1979;121:198, with permission.)

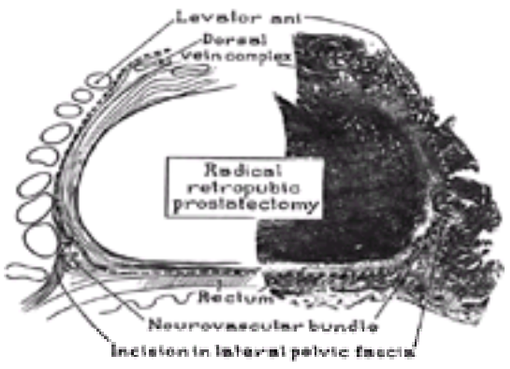

FIGURE 33.53. Cross section of the prostate gland illustrating the surgical approach to the lateral pelvic fascia required to preserve the integrity of the adjacent neurovascular bundle. (From Walsh PC, Lepor H, Eggleston JC. Radical prostatectomy with preservation of sexual function: anatomical and pathological considerations. *Prostate* 1983;4:473, with permission.)

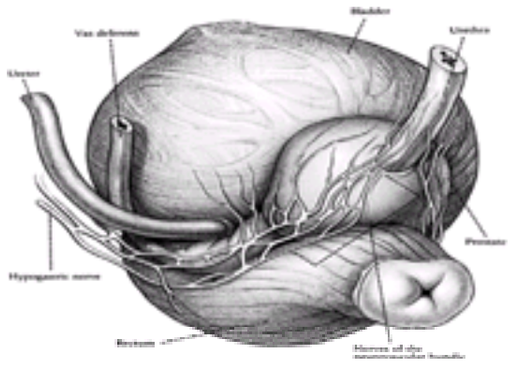

FIGURE 33.54. Oblique perineal view demonstrating the posterolateral distribution of the pelvic splanchnic nerves. (From Resnick MI. Radical perineal prostatectomy. In: *Urologic surgery.* Bristol-Myers, Learning Technology, 1988, with permission.)

The preparatory steps were discussed previously as a preface to the description of pelvic lymphadenectomy. As stated, we flex the table 10 to 15 degrees to enhance pelvic exposure. We have not routinely used straddle bars for the legs or a small sacral sandbag. These techniques are, however, used by other surgeons with good results. It is helpful for the operating surgeon and/or the first assistant to wear a fiberoptic headlight to facilitate visualization of the pelvic depths. We proceed with the nonirreversible steps of prostate mobilization while awaiting the frozen section results. We generally, but not invariably, terminate the operation in the presence of gross lymph node involvement. In the absence of flagrant seminal vesicle extension or capsular penetration, the presence of one or two microscopically involved lymph nodes would not deter us from proceeding with a radical prostatectomy in a younger man.

Before proceeding with radical prostatectomy, it has been recommended that the temporary placement of occlusive vascular clamps on the hypogastric artery laterally significantly decreases intraoperative blood loss (763). We do not use this maneuver, although its selective use may have value. We use a malleable retractor on the inflated Foley balloon (1067), our Omni retractor blade, or the left hand to facilitate bladder retraction and maximize exposure of the anterior surface of the prostate. In each case, care must be taken to avoid tearing superficial veins. In fact, elective ligation of the superficial branch of the deep dorsal vein with 3-0 Vicryl can be advantageous at this point.

Endopelvic Fascia

Once adequate visualization of the prostate has been accomplished, the endopelvic fascia lateral to the prostate should be completely exposed and incised with the point of the scissors (or the no. 15 scalpel) near the point of its reflection along the sidewall of the pelvis. This lateral superficial approach avoids inadvertent injury to the components of the inferior vesical pedicle and adjacent nerves that course under this fascial layer. Once fasciotomy has been established in a focal area, the fibers of the fascia are easily elevated and slit in a lateral curving arc that extends from the bladder neck to the base of the puboprostatic ligaments. Dense adherence of the fascia to the levators is unusual. Remnant levator fibers that loosely adhere to the lateral perimeter of the prostate generally can be swept back into a normal anatomic configuration by gentle sharp and blunt dissection. The latter can be facilitated by the proper use of a sponge stick or Kittner dissector. Once accomplished, this exposes the fused parietal (levator) fascia with prominent periprostatic veins, which reside beneath this layer and the underlying visceral (prostate) fascia (Fig. 33.55) (201). If bleeding is encountered from communicating pudendal arterial/venous branches (which traverse through the levator musculature), control can be obtained through the application of figure-of-eight suture ligatures of 3-0 Vicryl. Rarely, additional compression is required; this can be facilitated by using small pledgets of Vicryl mesh.

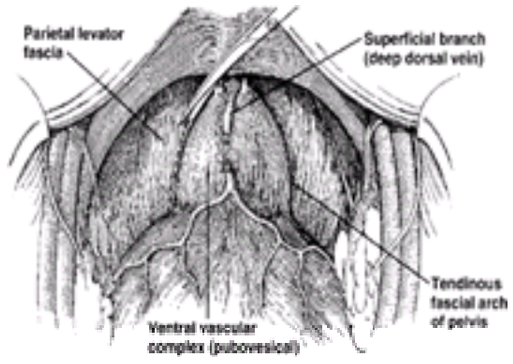

FIGURE 33.55. The superficial branch of the deep dorsal vein has been identified and ligated. The parietal layer of the levator fascia (endopelvic fascia) is incised to expose the lateral prostate. A combination of sharp and blunt dissection permits opening this important anatomic window from the base of puboprostatic ligaments to the bladder neck. Remnant levator fibers can be swept off the lateral perimeter of the prostate with careful blunt dissection. Ultimately, the fused parietal (levator) fascia, the associated periprostatic venous plexus, and the underlying visceral (prostate) fascia will be identified. (From Cummings KB. Refining the anatomic approach to nerve-sparing radical retropubic prostatectomy. *Contemp Urol* 2000;July:46, with permission.)

Puboprostatic Ligaments

On the basis of anatomic dissections performed on hemipelves of normal fresh male cadavers, Steiner (980) determined that the puboprostatic ligaments are not a discrete “band” of fascia that simply affixes the prostate gland to the synchondrosis of the pubic symphysis, but in fact constitute a pyramid-shaped structure that serves as a component of the urethral suspensory mechanism (Fig. 33.56). The latter attaches the membranous urethra to the pubic bone. This urethral suspensory mechanism is composed of three structures: (a) the suspensory ligament of the penis and fascial reflection of the perineal membrane, which are designated the anterior pubourethral ligament; (b) the arcuate and transverse ligaments, which as a group are designated the intermediate pubourethral ligament; and (c) the puboprostatic ligament or the posterior pubourethral ligament. Steiner has described the important structural and functional components of the external striated urethral sphincteric complex, which includes (a) the entire circumferential musculature of the rhabdosphincter, (b) the anterolateral (pubourethral) ligaments and posterior (median fibrous raphe) fascial investments, (c) innervation of the rhabdosphincter by the intrapelvic branch of the pudendal nerve (somatic), and (d) the innervation of the mucosal and smooth muscle components by way of the urethral branch of the inferior hypogastric plexus (autonomic) (978). Preservation of this sphincteric complex has promoted “no touch” or “avoidance” surgical principles, which subsequently are discussed (430).

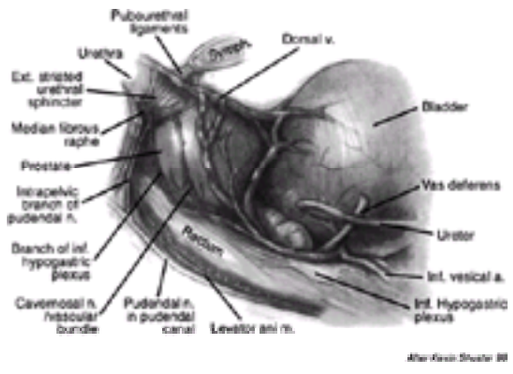

FIGURE 33.56. The paired pubourethral ligaments consist of anterior, intermediate, and posterior divisions. These elements form a median suspensory structure for the proximal pendulous urethra and corpora spongiosum (distally) and the external striated urethral complex proximally under the pubic arch. (From Steiner MS.

Anatomic basis for the continence-preserving radical retropubic prostatectomy. *Semin Urol Oncol* 2000;18:9, with permission.)

While maintaining optimal exposure to the anterior prostatic surface, blunt dissection can be used to gently tease the tissue off the periosteum of the pubic arch and to expose the puboprostatic ligaments. Care must be taken to avoid inadvertent blunt injury to the superficial branch of the deep dorsal vein that lies in the midline between the two puboprostatic ligaments and the other components of Santorini's plexus, which diverge laterally and beneath the ligaments. At times, a prominent posterior protuberance of the pubic symphysis can interfere both visually and physically with this and other aspects of the apical dissection. Visualization can be optimized by various techniques, including wedge pubectomy (547); partial resection of the symphysis using an osteotome/bone rongeur (620); and the use of electrocautery if the protuberance is primarily cartilaginous (505). Once they are clearly visualized, the puboprostatic ligaments should be incised flush to their attachment to the pubic symphysis. The curve of the Richter scissors should be pointed ventrally toward the periosteum. The surgeon will notice a very definite “give” when the ligamentous attachments have been finally severed. As long as the tips of the scissors hug the bony arch, very little bleeding is encountered with this maneuver. In keeping with the acknowledged contribution of the puboprostatic ligaments to obtaining normal anterior support of the urethra, it is now our practice to preserve as much of this ligamentous support as possible. Indeed, techniques that permit the routine preservation of this ligament support have been described (469). The total release of this ligamentous support is unnecessary and injudicious as long as adequate exposure of the apical prostate/urethral interface can be obtained.

Dorsal Vein Complex

The previously placed 20-Fr Foley catheter now serves as a guide to the prostatourethral junction. The surgeon should identify the urethra using the catheter as a guide. This is done in anticipation of ligating the dorsal vein complex. The latter is enveloped within a surprisingly thick (2 cm) layer of fibroareolar tissue and lateral pelvic fascia. In our experience it is helpful to maintain cephalad traction on the bladder neck using the left hand with a split-finger approach. The index finger of the right hand is used to identify the depression that localizes the avascular plane that separates the anterior surface of the urethra from the dense wad of tissue through which the dorsal vein complex courses (Fig. 33.57). The tip of a long right-angle clamp (preferably the specifically curved McDougal clamp) is placed at this point and worked through to the opposite side. When the clamp is optimally placed, a subtle “pop” is perceived as it penetrates the first layer of lateral prostatic fascia (518). It should be emphasized that the resistance encountered should be very modest. Exaggerated resistance to the passage of the clamp will be noted if an improper plane has been traversed and the clamp is in fact passing through prostatic or urethral tissue. Too distal an approach places the rhabdosphincter in jeopardy, given the fact that it measures only 1.5 to 2 cm in total length (518). Then a gentle spreading motion is used to expand the rather narrow and rigid tunnel thus established. Number 1 Vicryl is our preference to ligate the dorsal vein complex and its investing fascia. A simple knot is generally adequate, but a double looping technique or a surgeon's knot may provide some additional security. In general, two ties are placed on the distal aspect. At this point, it is helpful to use a Babcock or Allis clamp to engage the midline tissues overlying the prostate–bladder neck interface. This defines the major area of anticipated back-bleeding, which will occur following transection of the complex. Once grasped, these veins can be controlled with figure-of-eight suture ligatures using 2-0 chromic catgut or Vicryl, either before or after passage of the distal ties. It is important to emphasize that this maneuver can induce the anterior displacement and possible subsequent injury of the neurovascular bundles. To obviate this and other potential technical problems that might endanger the neurovascular bundles, other technical modifications have been proposed. The latter consist of incision of the lateral pelvic fascia, release of the neurovascular bundles, and development of the plane between the prostate/rectum from the lateral aspect of the prostate before proceeding with other aspects of the apical dissection (511) (Fig. 33.58).

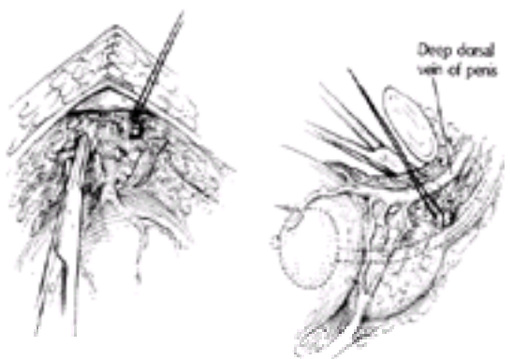

FIGURE 33.57. Control of the dorsal vein complex requires ligation (1 Vicryl) of the vascular component together with a 2- to 2.5-cm mass of investing fibroareolar tissue. The latter is accomplished by establishing the proper avascular plane immediately anterior to the urethral surface. A McDougal or a long right-angle clamp are best suited for this purpose. **Left:** Vertical midline view. **Right:** Lateral view.

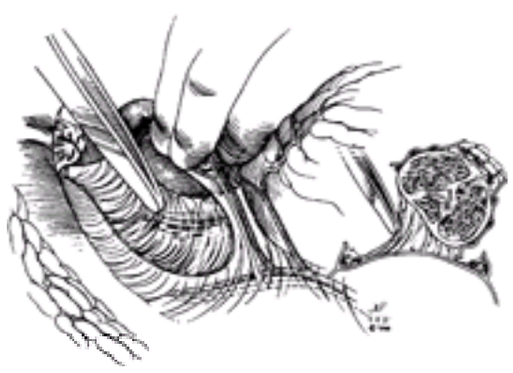

FIGURE 33.58. In this diagram, the lateral pelvic fascia has already been incised (longitudinally) medial to the neurovascular bundles, exposing the groove between the rectum and prostate. Following the release of both bundles with sharp and blunt dissection, the prostate can be rotated gently and the plane between the prostate and rectum further developed. (From Klein EA. Initial release of the lateral pelvic fascia. *Semin Urol Oncol* 2000;18:38, with permission.)

A suture ligature placed proximally anterior to the prostate reduces back-bleeding. Several technical modifications have been described to control the dorsal vein complex. A large needle can be used to undermine this structure and facilitate en masse ligation. In addition, Yu and associates (1122) described their approach, which involves ligation of the puboprostatic ligaments and the dorsal vein complex together as a single unit and then dividing the puboprostatic ligaments and the venous complex cephalad (proximal) to the ligatures. This technical modification was prompted by their concern that adjacent superficial dorsal veins were more likely to rupture as the prostate and bladder dropped posteriorly following transection of the admittedly avascular puboprostatic ligaments. In our experience, this phase of the procedure is infrequently problematic, and for that reason we have not felt the need to adopt such modifications. Admittedly, alternative approaches might be useful in select patients.

Once satisfactory ligation has been achieved, the right-angle clamp is replaced to guide the superior transection of the tissue cephalad to the ligatures (Fig. 33.59 and Fig. 33.60). A no. 15 scalpel or Richter scissors can be used for this purpose. Significant back-bleeding is unusual but can be controlled by temporary tamponade or the use of a few running suture ligatures of 2-0 Vicryl. If the ligatures on the dorsal vein complex are inadequate, significant bleeding may occur. Definite hemostasis usually can be achieved with figure-of-eight sutures. Until the latter can be accomplished, gentle, direct compression with a stick sponge usually suffices. We avoid metal clips in this site. Fiberoptic lighting and a curved GU needle prove useful in this endeavor.

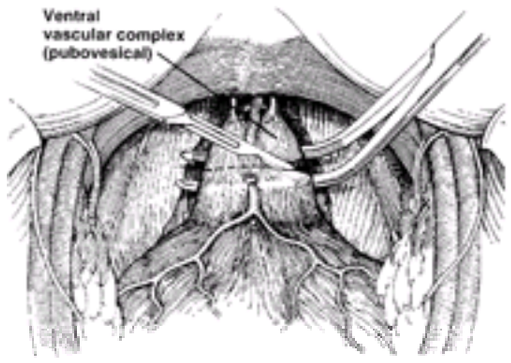

FIGURE 33.59. The dorsal vein (ventral vascular) complex can be undermined carefully with a right-angled clamp and transcected using a no. 15 scalpel. With this maneuver, care must be taken to avoid injury to the underlying striated urethral sphincter and its components. (From Cummings KB. Refining the anatomic approach to nerve-sparing radical retropubic prostatectomy. *Contemp Urol* 2000;July:46, with permission.)

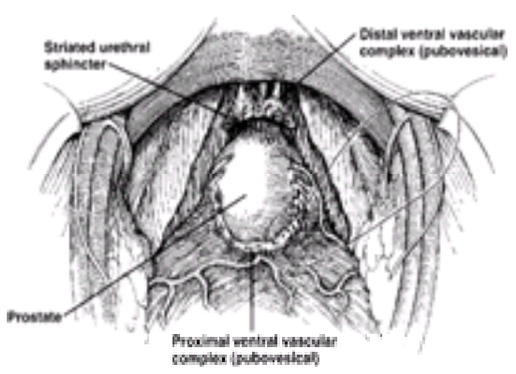

FIGURE 33.60. The ligated stump of distal ventral vascular complex can also be controlled with a running 2-0 Vicryl suture. Alternatively, several carefully placed figure-of-eight sutures of the same material can be used. Back-bleeding vessels from the proximal ventral vascular complex that were not adequately controlled with the initially placed midline suture ligature can be easily controlled with several running 2-0 chromic catgut (or Vicryl) sutures. (From Cummings KB. Refining the anatomic approach to nerve-sparing radical retropubic prostatectomy. *Contemp Urol* 2000;July:46, with permission.)

Urethral Transection

The surgeon should maintain cephalad traction on the apical portion of the prostate using the second and third fingers of the left hand. The membranous urethra is usually exposed once the dorsal vein complex has been divided. The scissors should then be insinuated alongside the urethra and a gentle spreading motion initiated to separate the urethral wall from the “pillars of the prostate.” The latter represent the ischioprostatic ligaments, which are located lateral to the striated urethral sphincter at the 2 o-clock and 10 o-clock positions. Once accomplished, a right-angle clamp can be placed medial to the tissue along and behind the urethra, freeing it. The clamp can be left in place to facilitate transection or preferably can be substituted with a small Silastic sling. If blunt isolation is difficult, the urethra can simply be carefully divided under direct vision.

The anterior wall of the urethra is incised at its junction with the apex of the prostate. The curve of the scissors (or the no. 15 scalpel) should be directed in an arc toward the prostate, hugging but not resecting the apical tissue (Fig. 33.61). Once the anterior aspect of the urethra has been transected, a sufficient length of the Foley catheter is delivered with a right-angle clamp to permit its use as a holder throughout the remainder of the procedure. After clamping the catheter to maintain the distention of the balloon, the catheter is divided and the distal aspect removed. At this point, we may insert a lubricated 18-Fr red rubber catheter in the distal urethra to help define the urethral lumen and the nontransected (intact) posterior wall with precision. The posterior wall of the urethra is then transected under direct vision. We may place stay sutures in the urethra before or after dividing the urethra, but we do so selectively and with caution depending on the anatomic situation. We regard the internal smooth muscle urethral cylinder as a fragile important component of the urinary control mechanism and consequently attempt to minimize trauma to other distal urethral segments. The latter selectively involves incorporation of the lateral and anterior components of the striated urethral sphincter with running or interrupted sutures before urethral transection. Lateral tag sutures are then placed to facilitate subsequent transection of the posterior elements of the striated urethral sphincter and to ensure their incorporation with the anastomotic sutures.

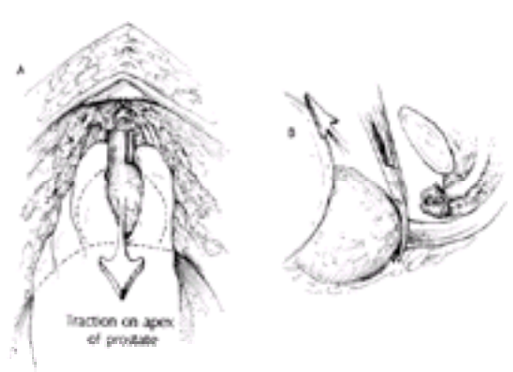

FIGURE 33.61. Exposure of the membranous urethra is facilitated by cephalad traction applied to the prostatic apex **(A).** The endopelvic fascia and puboprostatic ligaments have been incised and the dorsal vein complex with its investment of fibroareolar and fatty tissue has been severed. The neurovascular bundles are represented by the laterally positioned bands of tissue coursing parallel to the exposed urethra. **B:** The proper orientation of the curves of the Richter scissors before urethral transection is shown. Obviously, the junction of the prostatic apex and membranous urethra should first be established by incising the anterior urethral wall. Once this is accomplished, the catheter is mobilized and secured and the posterior urethral segment incised in sequential fashion.

An alternative approach avoiding the placement of a right-angle clamp or tape posterior to the urethra has recently been suggested to replace the risk of stretching or damaging the external striated sphincter as well as its somatic (pudendal) and autonomic (inferior hypogastric) nerve supply and its anterior/posterior attachments. The proposed technical modification involves incision of the anterior rhabdosphincter just distal to the prostatic apex, using scissors or a no. 15 scalpel blade. The anterior 180-degree arc of the urethral wall is then transected, exposing the underlying Foley catheter. Following this, the distal component of the 2 and 10 o-clock anterior anastomotic sutures should be placed using 2-0 Monocryl on UR6 needles. At this point, the right-angle clamp can be used to retract the intraluminal Foley catheter and expose the posterolateral urethra. Once identified, the posterior 180-degree arc of the membranous urethra is incised. The 5 o-clock and 7 o-clock anastomotic sutures are then placed. This approach eliminates manipulation/stretching of the posterior components of the sphincteric complex.

Rectourethralis

The next goal in the dissection is to expose, identify, and incise the rectourethralis without injury to the rectum or the cavernous nerves. A gentle cephalad tug should be maintained on the Foley catheter to facilitate the visualization and severance of this muscle, which is located directly in the midline (Fig. 33.62). Undermining this muscle with a right-angle clamp facilitates its transection and the identification of the intact Denonvilliers' fascia (Fig. 33.63). Once the white Denonvilliers' fascia is

exposed, the rectum can usually be freed from the prostate and the seminal vesicles with gentle digital pressure applied to the undersurface of the prostate. If the rectum does not disengage easily, sharp layer-by-layer tissue dissection with the knife or scissors pointed at Denonvilliers' fascia is prudent. Tenting of the rectum is a problem that requires constant concern and attention. If exposure of Denonvilliers' fascia is difficult and uncertain by one approach, we try another. Lateral access to the plane separating the rectum and the fascia is at times much easier from a midlateral or basal lateral approach than a standard apical one. Once Denonvilliers' fascia is clearly identified, the risk of incising or disrupting the rectum or prostate is significantly reduced. The priorities with regard to nerve sparing and periprostatic excision of tissue need to be kept in mind as alternative dissection procedures are explored.

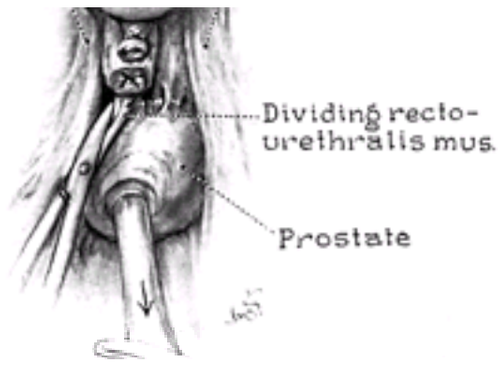

FIGURE 33.62. Division of the rectourethralis muscle. The proper transection of these fibers provides access to the desired midline plane between the anterior and posterior leaves of Denonvilliers' fascia. This can be facilitated by undermining the muscle fibers with a right-angle clamp before incision. (From Walsh PC. Radical retropubic prostatectomy. In: Walsh PC, Gittes RF, Perlmutter AD, et al, eds. *Campbell's urology,* 5th ed. Philadelphia: WB Saunders, 1986:2754, with permission.)

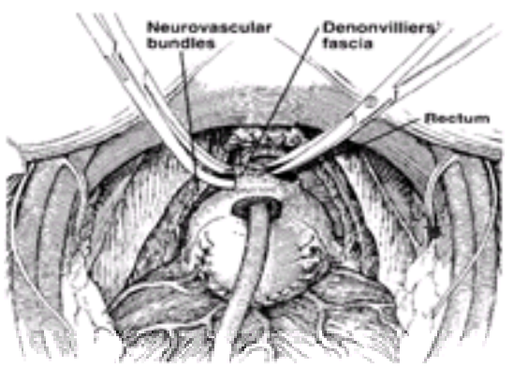

FIGURE 33.63. In this diagram, the lateral pelvic fascia has already been incised and the neurovascular bundles have been freed from the prostate-rectal interphase. The rectourethralis has been undermined with a right-angle clamp and prepared for transection. This generally permits identification of the ideal midline plane between the prostate and anterior rectal surface. If properly performed, Denonvilliers' fascia should be attached to the prostate, which can then be mobilized in cephalad fashion with care taken to avoid tethering the rectal wall. (From Cummings KB. Refining the anatomic approach to nerve-sparing radical retropubic prostatectomy. *Contemp Urol* 2000;July:46, with permission.)

Neurovascular Bundles

The decision to spare the corporal nerves is not inviolate and should be abandoned in favor of a wide excision on one or both sides if the intraoperative findings strongly suggest extension. Contraindications include (a) cT_3 disease, (b) palpable disease at the apex and a flagrant extraprostatic extension elsewhere, (c) tumors exhibiting a significant Gleason grade 5 component, (d) pretreatment PSA levels greater than 20 mg/mL, and (e) preoperative erectile dysfunction. Relative contraindications for nerve sparing include (a) cT_{2b} disease; (b) tumors exhibiting greater than 50% Gleason grade 4 on biopsy; (c) pretreatment PSA levels between 10 and 20 mg/mL; (d) extensive perineural invasion or periprostatic involvement on biopsy; (e) documentation of cancer in three or more needle cores from the same prostatic lobe; and (f) finding of soft tissue reaction involving the neurovascular bundles, which makes interoperative mobilization difficult.

As stated previously, nerve sparing can be initiated before or after urethral transsection. In either case, the exposed edge of the lateral prostatic (pelvic) fascia is used to establish a plane of separation between the prostatic capsule and the overlying prostatic fascia. In general, a right-angle clamp can be insinuated beneath this transparent fascial membrane (Fig. 33.64). Using a no. 15 scalpel blade an “inverted V” incision (Fig. 33.65) can be established from apex to bladder neck (349). During this maneuver, care must be taken to stay well anterior to and parallel with the easily identified neurovascular bundles. The combination of sharp and blunt dissection facilitates the posterior displacement of the neurovascular bundles (Fig. 33.66). Bleeding from small venous and arterial tributaries that may be transected or avulsed during the process of displacing the neurovascular bundles posteriorly often stops spontaneously with gentle compression. Persistent bleeding can be controlled with the careful application of small clips or 4-0 absorbable sutures. The Cavermap is a device that uses intraoperative nerve stimulation with real-time tumescence monitoring to permit identification of the course of the cavernous nerve fibers during radical prostatectomy. Although it has been suggested (516) that the use of this device may improve the results of nerve-sparing prostatectomy, it is rarely utilized by us.

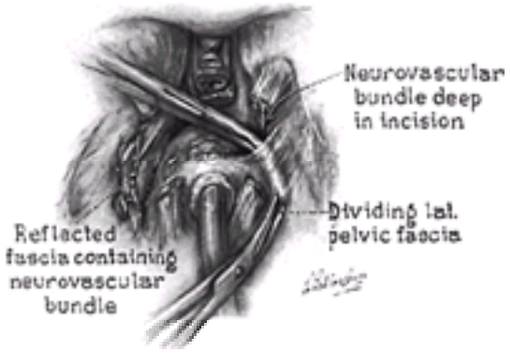

FIGURE 33.64. Division of the lateral pelvic fascia along the anterolateral aspect of the prostate. Dissection within this plane should preserve the integrity of the posterolaterally oriented neurovascular bundle. (From Walsh PC. Radical retropubic prostatectomy. In: Walsh PC, Gittes RF, Perlmutter AD, et al, eds. *Campbell's urology,* 5th ed. Philadelphia: WB Saunders, 1986:2754, with permission.)

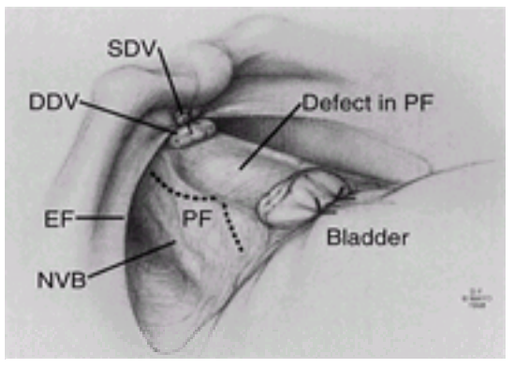

FIGURE 33.65. In this diagram, the dorsal vein complex has been ligated and transected. The *dotted line* demarcates the "inverted V" incision into the lateral pelvic (prostatic fascia). In this incidence, the left neurovascular bundle *(NVB)* is identified deep to the prostatic fascia *(PF)* and the anticipated line of incision. EF, endopelvic fascia; DDV, deep dorsal vein; SDV, superficial dorsal vein. (From Ghavamian R, Zinke H. Technique for nerve dissection. *Semin Urol Oncol* 2000;18:43, with permission.)

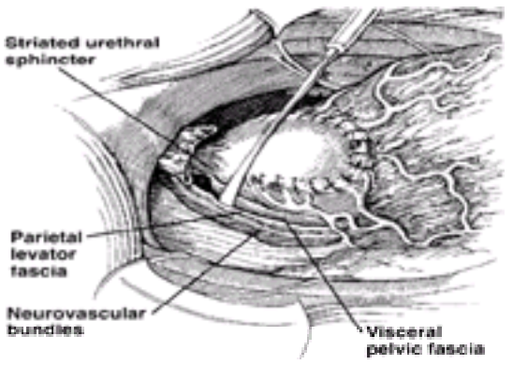

FIGURE 33.66. Additional sharp and blunt dissection permits separation of the neurovascular bundles and the parietal levator fascia from the lateral parameter of the prostate and the visceral pelvic fascia. (From Cummings KB. Refining the anatomic approach to nerve-sparing radical retropubic prostatectomy. *Contemp Urol* 2000;July:46, with permission.)

Cephalad traction on the Foley catheter in concert with judicious blunt dissection (with pressure directed on the prostate/seminal vesicles), facilitates mobilization of these structures and identification of a covering layer of fascia thought to represent, in part, a superior leaf of Denonvilliers' fascia. At this point, the seminal vesicles and their covering fascia are clearly separated from the rectum. The prostate remains attached to its blood supply, the bladder at its outlet, and the vasa, seminal vesicles and the posterior superior extension of Denonvilliers' fascia. The goal to complete the removal of the prostate, and the seminal vesicles, distal vasa/ampulla, and adjacent tissue including Denonvilliers' fascia without or with the nevi erigentes and its adjacent tissue, can be initiated and pursued by an anterior (ventral) or posterior approach. If a posterior approach is chosen, the fascial barrier is usually breeched near the base of the prostate rather than near the vesicle tip and the targeted tissue excision package may become less discrete. On the other hand, identification of the vesicle neck/prostatic urethral junction, the posterior bladder wall, and possibly, the ureters may be facilitated. Identifying, isolating, and clamping, dividing, and ligating the *in situ,* and clipping the specimen, side of the prostate vesicular branches of the inferior vesicle artery (lateral vascular pedicle, Fig. 33.67), as well as preserving or sacrificing the neurovascular bundle, is accomplished with equal ease by either approach.

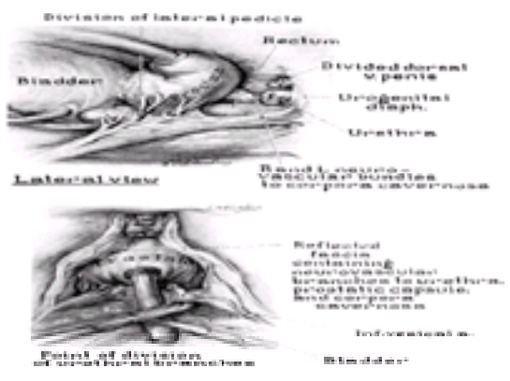

FIGURE 33.67. Transection of the lateral vascular pedicle. To preserve the nervi erigentes, the branches of the prostatovesicular artery should be divided anteriorly, as close to the prostate and seminal vesicles as is consistent with a good cancer operation. (From Walsh PC. Radical retropubic prostatectomy. In: Walsh PC, Gittes RF, Perlmutter AD, et al, eds. *Campbell's urology,* 5th ed. Philadelphia: WB Saunders, 1986:2754, with permission.)

If the posterior approach is chosen, the posterior perivesicle fascial envelope is incised horizontally and the ampulla of the vas deferens is identified, grasped with an Allis clamp, isolated with sharp and blunt dissection, clamped, and divided, and the proximal vas deferens is tied with 2-0 Vicryl sutures. Sharp and blunt dissection is utilized to dissect the seminal vesicles and adjacent tissue. Once completed the vascular pedicle can be divided and secured as described. If the anterior approach is chosen, the surgeon may secure and divide the vascular pedicle without or with the neurovascular bundle. The seminal vesicle fascial barrier remains intact.

Bladder Neck

At this point, the plane between the rectum and prostate/adnexa has been clearly established. The separation of the prostate/adnexa from the bladder neck constitutes the next step in the dissection in the posterior approach utilized by many and is the initial procedure in the traditional anterior approach. The first step in this technique is to identify the interface of the prostate and bladder neck to guide appropriate localization of a ventral transverse cystotomy. If the appropriate site is in doubt, we prefer a cystotomy to a prostatotomy. Following intravenous (IV) administration of Indigo carmine, sharp dissection is used to separate the bladder from the prostate anteriorly and laterally. Most often, a small cuff of bladder neck tissue will accompany the prostate specimen. Placing a small malleable retractor in the bladder after it is entered and a transurethral catheter sling facilitates exposure of the posterior elements. After the trigone and ureteral orifices are identified, the posterior bladder neck is transected using sharp dissection. Care must be taken to remove all middle lobe (subtrigonal) prostatic tissues. The trigonal complex must be kept from harm's way during this maneuver. Following transection of the posterior bladder neck, judicious dissection in the midline aspect identifies the plane that separates the bladder neck and base from the residual elements of the adnexal structure, as well as nonligated components of the lateral pedicle. Usually this plane is easily identified and dissected from the bladder base; if it is not, insertion of catheters to help identify the ureters warrants consideration. If an initial posterior approach to the vasa/seminal vesicle complex has been utilized, this plane has probably been identified and, at least partially freed from the bladder. With the anterior approach, identification and division of the vasa, a procedure already accomplished with the posterior approach, is usually the next step. Then, with a lap pad or tagged sponges protecting the rectum, the seminal vesicle/vasa, and their adjacent tissues are freed by blunt and sharp dissection. Bleeding is controlled by ligating, clipping, or fulgurating bleeding sites. The tissue cephalad to the tip of the vesicle is secured by clipping or by ligation, divided on the specimen side, and the specimen removed intact. The removed prostate/seminal vesicle: adjacent tissue specimen should be inspected for any capsular or other evidence of incomplete removal. After irrigating the wound gently, the bladder, rectum, and tissue bed are also inspected for bleeding or unrecognized injury. Visualization of effluxing urine in the bladder is a reassuring observation. At this time, the patient's status should be reassessed, reports of results of tissue biopsies obtained, and preparations made

as discussed subsequently to proceed with reconstruction of the lower urinary tract.

Inherent advantages of this technique, in addition to its speed and simplicity, are the ability to achieve bladder neck margins unlikely to contain residual prostatic tissues and perhaps the opportunity to resect perivesicle tissue more adequately. Elective bladder biopsy is easily accomplished. Relative disadvantages include the need for a formal reconstruction of the bladder neck using a typical tennis-racket configuration with establishment of an anteriorly located neobladder neck. Another theoretic disadvantage is the loss of additional smooth muscle fibers from the bladder neck, which constitute the remnant of the internal urethral sphincter.

An alternative dissection strategy that is receiving increasing consideration by some involves formal bladder neck preservation. This is easily accomplished once the seminal vesicles and vas deferens have been mobilized using the previously described posterior retrograde approach. Cephalad retraction of these structures facilitates sharp dissection to separate the prostatic base from the bladder neck (Fig. 33.68). During this process, most of the circular fibers of the bladder neck can be preserved circumferentially. An indwelling catheter facilitates identification and separation of the prostatic urethra from the bladder neck proper. The anterior aspect of the urethra is then incised, exposing the indwelling catheter. Following balloon deflation, the catheter is reconfigured as a sling. The posterior urethra is then transected.

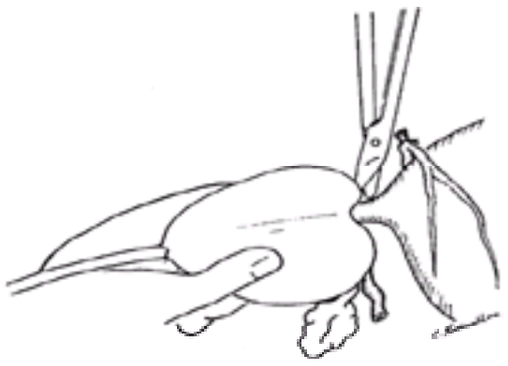

FIGURE 33.68. The mobilized prostate/adnexal structures permit their separation from the bladder neck using sharp and blunt dissection. When done carefully, the majority of the circular fibers of the bladder neck can be preserved. (From Soloway MS, Neulander E. Bladder-neck preservation during radical retropubic prostatectomy. *Semin Urol Oncol* 2000;18:51, with permission.)

One proposed advantage of this approach is the preservation of the circular smooth muscle fibers of the bladder neck (internal sphincter), which may result in a more rapid return of urinary control (510,579,606,951). Although somewhat more time consuming than traditional bladder neck transsection, preservation of the bladder neck minimizes the time necessary for posttranssection reconstruction. It also has been suggested that this approach minimizes the likelihood of anastomotic stricture (330,951). A potential disadvantage is the intuitive likelihood of leaving residual prostatic tissue (cancer) attached to the bladder neck. Studies conducted by Wieder and Soloway (1090), Catalona and Bigg (139), and Lepor and associates (573) suggest that the bladder neck is a rare site of involvement of CaP. Indeed, it is the only positive site in approximately 1% to 2% of patients. Although controversial, it is our practice to carefully obtain representative biopsies, and submit them for frozen section interpretation. It should be emphasized that, despite a trend toward the more rapid achievement of urinary control, there is no statistical difference in ultimate continence, regardless of which bladder neck approach is chosen (606). Finally, we believe it is preferable to perform bladder neck preservation or transsection using sharp dissection, as opposed to electrocautery, to minimize tissue damage.

Before proceeding with the reconstructive aspects of the procedure, several “housekeeping” chores should be performed at this point. The operative site must be carefully inspected to obtain adequate hemostasis. Additional carefully placed suture ligatures of 2-0 or 3-0 absorbable suture may be required in the area of the dorsal vein complex, lateral perimeter tissues, bladder base, and bladder neck. The anterior rectal surface should be carefully reinspected to exclude inadvertent injury, which can occur during the early phase of the apical section or during the process of mobilizing the seminal vesicles. The dissection zone should be inspected for the presence of suspicious tissue that might represent prostatic remnants. If encountered, these tissues should be removed carefully with sharp dissection and submitted for pathologic evaluation. Obviously, the integrity of the rhabdosphincter should not be compromised merely to remove every vestige of abnormal-appearing apical tissue. In the event that nerve sparing has been performed, it has been recommended that the posterolateral margins of the prostatic specimen be marked with sutures in a line adjacent to the location of the bundles. Those areas can be subjected to frozen section analysis. If tumor is present at the inked margin, it has been recommended that the entire ipsilateral neurovascular bundle be resected en bloc from the urogenital diaphragm to the bladder neck, along with a margin of soft tissue. Once all of these issues have been addressed, the pelvis is then irrigated with several liters of warm sterile water (or a gentamicin-containing solution) as a prelude to reconstruction.

Bladder Neck Reconstruction

Bladder neck closure (if required) should be accomplished with care taken to avoid injury to the ureteral orifices. It has been our preference to use an anterior opening sufficient to admit a “snug” index finger. If this requires partial closure of the bladder neck, we prefer to carry this out posteriorly using full-thickness interrupted sutures of 2-0 chromic catgut. If the orifices are near the edge of the bladder neck incision, posterior closure with carefully placed Lembert sutures will roll them in. To facilitate mucosa-to-mucosa coaptation during the vesicourethral anastomosis, exteriorizing the mucosa of the new bladder neck aperture with interrupted 4-0 biodegradable sutures may be helpful (Fig. 33.69). Tubulization of the anterior bladder neck is rarely necessary and may predispose to anastomotic stricture.

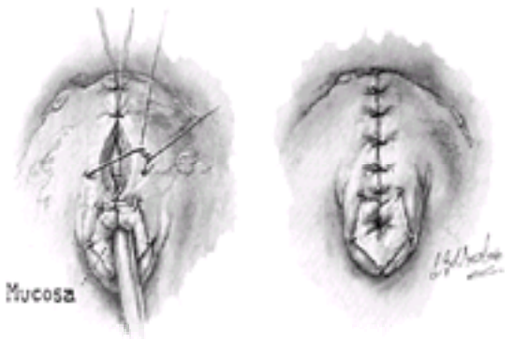

FIGURE 33.69. When bladder neck closure is required, a traditional “tennis-racket” reconstruction is generally sufficient. The “handle” is created using full-thickness 2-0 chromic catgut sutures. If the trigonal complex is in close proximity to the posterior lip of the native bladder neck, inverting Lembert-type sutures can be used to invert the posterior elements and avoid injury/obstruction to the ureteral orifices. The “racket” component of the closure should ultimately admit a “snug” index finger. The mucosal of this new aperture is then inverted with interrupted 4-0 chromic catgut sutures to facilitate a mucosa-to-mucosa reapproximation with the membranous urethra. Although tubulization of the anterior bladder neck is depicted in this diagram, this reconstruction is needed infrequently and can predispose to stricture. Its use can be considered following the removal of large prostates and in situations in which the native anterior tissues are unusually thin. (From Steiner MS, Burnett AL, Brooks JD, et al. Tubularized neourethra following radical retropubic prostatectomy. *J Urol* 1993;150[2 Pt 1]:407, with permission.)

Vesicourethral Anastomosis

Once this anteriorly situated bladder neck aperture has been created, a new pretested 20- or 22-Fr Foley catheter with a 5-mL balloon is inserted and its tip advanced into the open pelvis. Downward displacement of the rectum with a padded hand and/or stick sponge is helpful to present the membranous urethra in its full circumference. To facilitate suture placement, some advocate use of a grooved-urethral sound or perineal compression (if the patient has been positioned with

spreader bars).

Various anastomotic techniques, varying from two laterally placed mattress sutures exiting the perineum (Vest sutures) to a multiple suture mucosa-to-mucosa anastomosis, have been advocated. We usually place 2-0 or 3-0 Monocryl urethral sutures with the UR 6 needle at the 5, 7, 3, 9, and 12 o'clock positions. We also use an approximating Halsted mattress suture that incorporates puboprostatic retropubic tissue and proximal and distal urethral tissue at 12 o'clock if necessary. Care must be taken in the placement of the laterally situated sutures to avoid incorporating the neurovascular bundle, which lies in close proximity. When visibility is poor, a catheter guide helps ensure proper placement of these sutures and incorporation of adequate tissue on the urethral side. We avoid metal suture guides and try to minimize trauma from suture placement or other manipulation.

Lange and Reddy (558) have suggested that construction of the vesicourethral anastomosis can be facilitated by (a) use of the modified dorsal lithotomy position with the legs extended and gently abducted, (b) the application of perineal pressure with a stick sponge to accentuate the presentation of the membranous urethra, and (c) excision of a V-shaped wedge of the pubic symphysis (wedge pubectomy). Although we have not used these techniques, they may be helpful in selected cases. As indicated, we often incorporate a portion of the puboprostatic retropubic and periurethral tissue with these sutures and apply modest traction to them after they are placed to be certain each is well anchored. Before placing the final 12 o'clock suture, the pretested Foley catheter is negotiated between the right- and left-sided sutures; and inserted into the bladder. The balloon is inflated with 10 mL of sterile saline, and protected during placement of the final suture. At this point, it is appropriate to straighten the table if gentle flexion had been used during initial positioning. In addition, the tension should be taken off of the sidewall by gently loosening the retractor unit. Finally, all of the placed sutures should be “snugged” and the bladder brought down toward the urogenital diaphragm. The catheter should be straightened, and the balloon negotiated into a dependent position. It is our practice to tie the sutures in the same sequence they are placed, assisted by gentle downward pressure on the bladder to eliminate tension. Some have advocated construction of a vascularized “sling” of rectus abdominus muscle to support and envelop the anastomotic site. We lack experience with this approach, but believe that, as a routine, sling augmentation of the vesical urethral anastomosis is not required.

Closure

Once the sutures have been tied, the Foley catheter is irrigated to assess the integrity of the anastomosis and to ensure patency. One or two 10-mm flat-type closed-system sump drains are placed through separate, inferiorly directed stab wounds (avoiding the inferior epigastric vessels) and positioned along the pelvic sidewall bilaterally near, but not in direct contact with, the anastomotic site. Securing the Foley catheter with a 3-0 nylon suture through the glans (foreskin) or a heavy nylon suture placed through the eye and brought out the abdominal wound are examples of techniques designed to prevent its inadvertent displacement (Fig. 33.70). Aggressive taping is another alternative. At this point, the wound is irrigated with saline solution and a standard closure is performed. With respect to the latter, we reapproximate the rectus muscle/posterior sheath with loosely tied figure-of-eight sutures of 2-0 or 3-0 PDS. This is done to obliterate the rectus diastasis. The anterior fascia is reapproximated with interrupted (buried) 0-prolene sutures tied in figure-of-eight fashion. The subcutaneous tissues are loosely reapproximated with running 3-0 PDS. The skin is closed with a 4-0 Maxon subcuticular closure, which is reinforced with 0.5-inch Steri-Strips. A medium Tegaderm dressing is placed over the drain site, and the wound is covered with an occlusive gauze dressing.

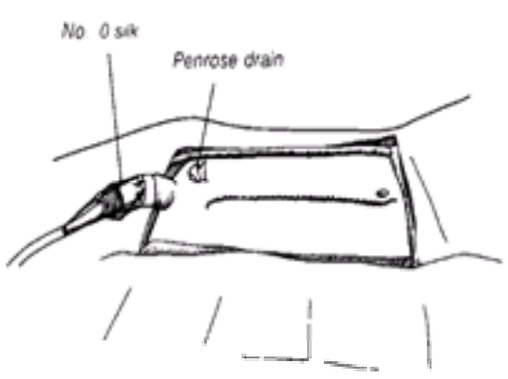

FIGURE 33.70. After completion of the radical retropubic prostatectomy, a Penrose or sump drain should be placed through a separate inferiorly oriented stab wound. It is important to avoid injury to the inferior epigastric vessels. Furthermore, the distal extent of the drain should be carefully positioned so as to avoid direct contact with the anastomotic site. The Foley catheter should be secured as described in the text or as illustrated by using a Velcro strip or adhesive tape to anchor several 0-silk sutures secured to the catheter. (From Crawford ED, Kiker JD. Radical retropubic prostatectomy. *J Uro*l 1983;129:1145, with permission.)

Routine Postoperative Course

In general, the postoperative recovery is relatively “routine,” considering the technical complexity of the procedure. Most of our patients are transferred to the floor from the recovery room. IV fluids are maintained until postoperative ileus resolves, generally within 1 to 2 days of the operative procedure. With respect to postoperative pain control, we have been pleased with the results obtained with the use of ketorolac tromethamine (Toradol) after intramuscular injection. This member of the pyrrolo-pyrrole group of NSAIDs should be avoided in patients with a history of peptic ulcer or other conditions predisposing to an increased risk of bleeding. In general, the recommended initial dose is 30 to 60 mg intramuscularly, as a loading dose, followed by 15 to 30 mg administered every 6 hours. Toradol is restricted to short-term therapy (not more than 5 days). Given its demonstrated efficacy and cost-effectiveness, we currently use this approach preferentially for postoperative analgesia.

Early ambulation is a high priority and until the patient is fully mobile, TED hose and an intermittent compression device are used on the lower extremities. These prophylactic measures appear to be particularly warranted in patients with prostate cancer. A recent study conducted by Oefelein and associates (719) suggests that the patients with prostate cancer do indeed have an intrinsic predisposition to thromboembolism. In their study, more than 5% (12 of 209) of the men diagnosed with prostate cancer had an antecedent thromboembolic event without documentation of any classical risk factors or venous thrombosis. Once the patient is tolerating a general diet, stool softeners [docusate sodium (Colace)] and iron supplements are initiated. It is our current practice to remove the pelvic drains when their respective outputs are quantitated to be less than 10 to 15 mL per 8 hours. In most cases, patients are discharged on the fourth postoperative day, free of drains and with proper instructions provided regarding the management of their indwelling Foley catheter. A urine culture is obtained at the time of discharge.

The patients are advised to take a fluoroquinolone antimicrobial agent every 12 hours starting 3 days before anticipated decatheterization. That event is usually performed 2 weeks postoperatively following the completion of a cystogram demonstrating integrity of the vesicourethral anastomosis. Although we had previously attempted to render our patients catheter free before discharge (209), this prolonged the hospitalization and added to the attendant expense. Moreover, only 62% of those patients were rendered catheter free by day 11. The remainder underwent repetitive cystograms, which may have contributed to the high incidence of anastomotic stricture that was encountered. It should be noted that the latter did respond to single outpatient dilation in most instances, but its incidence seems significantly decreased since we postponed performing an initial cystogram until 2 weeks postoperatively. At that time, almost all anastomotic sites are leak free.

Recent refinements in surgical technique and lingering concerns regarding the discomfort associated with prolonged catheterization have prompted a revisitation of this concept of early catheter removal. DeMarco and associates (222) reported that gravity cystograms were performed on the third or fourth postoperative day in their series of 82 patients. In 70 of 82 patients (85%), the gravity cystogram (with postdrain radiographic views) demonstrated only minimal or no contrast extravasation. In these patients, the catheters were successfully removed before discharge. It appeared that early catheter removal in this group was not associated with the development of symptoms suggesting stricture formation at a minimum follow-up of 6 months. This approach did not adversely affect the return of good urinary control. It is assumed that more precise surgical technique with construction of a near-watertight mucosa-to-mucosa anastomosis accounts for outcome differences when one compares more recent studies such as this with earlier clinical trials.

Many patients experience some hesitancy and a weak stream with accompanying urgency and stress incontinence for several weeks following decatheterization. They should be encouraged and instructed in the management of these symptoms without resorting to a device or aggressive pharmacotherapy. The aggressive use of sphincter exercises and drug regimens for incontinence should be postponed for several weeks following decatheterization. In the great majority, voiding and

control improve rapidly.

Complications

Despite the fact that the majority of patients have a relatively uneventful hospital course and a satisfactory surgical result, radical retropubic prostatectomy has been associated with various complications of varying degrees of severity (Table 33.22). A mortality rate of 1% or less would seem to be a reasonable representation of available series addressing this issue (194,450,558,584,654). A recent update of the mortality statistics following radical prostatectomy was compiled by Mark (619), who observed a 0.5% 30-day mortality and a 1.8% 1-year mortality rate. These figures were derived from a 100% sample of Medicare claims in records of patients undergoing radical prostatectomy in 1990. Of note, in the recent American College of Surgeons survey, the operative mortality rate for radical prostatectomy was 0.4% (649). Moreover, it would appear that chronologic age, per se, should not exclude patients from consideration for radical prostatectomy. Middleton (655) compared the mortality and morbidity of the procedure performed on 65 patients 70 years of age or older versus those for 128 men younger than 70 years of age and noted no significant difference in the complications incurred. He concluded that radical prostatectomy is a desirable and safe therapeutic option for all men with clinically localized CaP whose general health suggests a 10-year or greater probable life expectancy. However, it must be emphasized that nonlethal complications occur more frequently in older patients. Catalona and associates (155) documented a 4% complication rate in men in their forties; 9% in those in their fifties; 11% in men in their sixties; and 14% in those men in their seventies.

TABLE 33.22. PERCENTAGE OF COMPLICATIONS FOLLOWING RADICAL RETROPUBIC PROSTATECTOMY

Of the potential intraoperative complications, hemorrhage was addressed during the description of operative techniques. Significant bleeding that is difficult to manage usually is associated with inadequate occlusive control of the dorsal vein complex and/or from vessels traversing the levator muscles. With respect to the latter, the use of pledgets of Vicryl mesh provides additional compression and support of mattress sutures targeting bleeders within the lateral muscular element. As stated, use of mattress sutures after temporary tamponade to permit visualization of the bleeding site usually effects satisfactory hemostasis. Should this approach fail, balloon tamponade or exposure of the veins from the penile side of the symphysis warrants consideration; use of a mass ligation with a mattress suture placed from the space of Retzius through the subsymphyseal skin also has been described.

Failure to establish the proper plane when dissecting the posterior aspect of the bladder neck can endanger the ureters. Should a transection injury occur, ureteral reimplantation should be performed. Under these circumstances ureteral stenting is advisable. Ureteral injury was reported to occur in 1.4% of cases in the series by Kopecky and associates (525), but more recent series have not cited this as a complication, and in our experience this is an exceedingly unusual event.

Rectal injury can occur if the proper plane is not established between the Denonvilliers' fascia and the rectum. The risk of this injury is increased by disease process (cancer; prostatitis) or prior procedures (TRUSP biopsies) that obliterate this plane. The incidence of this complication varies from 0% to 3% in the available literature (194,584,654). The injury is usually readily apparent, but the operating surgeon should make a practice of carefully inspecting the anterior rectal surface following the full mobilization of the prostate. If an injury is identified, any ischemic component to the wound edges should be excised. A double-layered interrupted closure with mucosa-inverting sutures of 3-0 or 4-0 silk for the inner row and Lembert-type sutures of 3-0 silk (or 3-0 Vicryl) for the muscular component of the rectal wall is satisfactory. Because the injury occurs below the peritoneal reflection, the rectum will lack serosal covering that would ordinarily provide additional support for the sutures. Additional reinforcements of the closure can be obtained by patching the area of repair with a generous portion of mobilized omentum, endopelvic fascia, and/or preperitoneal fat. In the absence of previous irradiation therapy and in the presence of an adequate bowel preparation, these maneuvers plus manual dilation of the rectal sphincter are probably adequate to protect against leakage from the suture line with subsequent development of an adjacent abscess, rectourethral fistula, or both. When this closure is precarious, a diverting colostomy is certainly indicated. Although it is most convenient to exteriorize a segment of sigmoid colon, a transverse loop colostomy or loop ileostomy is certainly acceptable.

Generic postoperative complications occur in approximately 10% of patients (155) and include (a) thromboembolic phenomena in 2%; (b) vesicourethral anastomotic stricture in 4%; (c) delayed inguinal hernia in 2%; and (d) 1% or less incidence of lymphatic, infectious, neurologic, or other miscellaneous complications. Although the urethrovesical anastomosis usually is watertight within 1 or 2 weeks, persistent extravasation or leakage may occur, particularly if the initial anastomosis is faulty. These leaks will stop as long as the anastomotic site is free of foreign bodies (e.g., a drain), and the Foley catheter is well positioned and functional.

A sizable pelvic hematoma occasionally can develop from persistent oozing at the operative site. This can displace the bladder and lead to a partial disruption of the vesicourethral anastomosis. Modest hematomas usually require no intervention. With natural resolution, the bladder will revert to its normal midline position and any attendant anastomotic leak will subside. A large hematoma that subsequently becomes infected requires evacuation. At times, this can be accomplished by ultrasound- or CT-guided cutaneous puncture with the insertion of a pigtail catheter and irrigation with urokinase (1052). Reexploration of the pelvis for bleeding and infection also warrants consideration. To that end, Hedican and Walsh (409) state that significant postoperative hemorrhage occurred in 0.5% (7 of 1,350) of radical prostatectomies. They defined the hemorrhage as significant if it required acute transfusion of blood to support blood pressure. Four of these seven patients underwent exploration for bleeding, and three were treated conservatively. Only one of the four patients who underwent exploration experienced prolonged mild incontinence. In the patients treated nonoperatively, the pelvic hematoma drained through the anastomosis, with symptomatic bladder neck contraction developing in all three patients and long-term incontinence in two. It is their recommendation that for patients requiring acute transfusions for hypotension following radical prostatectomy, serious consideration be given to surgical evacuation of the pelvic hematoma.

Despite adequate precautions, the Foley catheter may dislodge. If this happens, a limited and judicious attempt to reinsert a 16- or 18-Fr Foley catheter is reasonable. Should such an effort fail, flexible endoscopy should be performed to identify the anatomic relationships with certainty. This knowledge and the insertion of a guidewire under direct vision usually permit reintroduction of a Foley catheter. If the anastomotic site is well drained and the surgeon is confident of its integrity, a suitable option is to defer the replacement of the catheter and accept temporary urinary extravasation. This is particularly reasonable if the catheter dislodges late in the hospital course.

Even in experienced hands, bladder neck contracture may develop in approximately 4% of cases (155). Potential etiologic factors include (a) the use of electrosurgical instruments to transect the bladder neck with attendant focal devascularization at the anastomotic site, (b) the failure of the surgeon to achieve satisfactory approximation during the placement of the anastomotic sutures, and (c) overzealous attempts to fashion a snug bladder neck aperture (including anterior tubulization). Techniques proposed to reduce the incidence of bladder neck contracture to a reported 1.3% to 5.4% include the following: (a) optimal exposure of the membranous urethra using the modified lithotomy position, exerting perineal pressure with a sponge stick, and wedge pubectomy (558); (b) performing an eight-suture vesicourethral anastomosis (655) or a modified Vest procedure of vesicourethral reconstruction (450); and (c) deliberate eversion of the bladder neck mucosa before anastomosis to obtain a more secure mucosa-to-mucosa realignment (1064).

Development of a bladder neck contracture may be heralded by a spectrum of symptoms ranging from a diminished, thin stream or dribbling, to urinary retention. If an attempt to pass a catheter into the bladder is unsuccessful, urethroscopy should be performed to ascertain the degree of contracture and the location of the aperture. Dilation under direct vision or with filiform and followers or van Buren sounds is usually possible. The former can be accomplished under local anesthesia even with a minute visual opening by steady directed pressure with a 17-Fr cystoscope in a patient with a fully distended bladder. One or two such dilations usually prove sufficient. If not, other options include internal urethrotomy (143) or dilation with the patient under anesthesia followed by the injection of steroids into the area of stricture. Walsh (1067) recommends the injection of triamcinolone acetonide (200 mg) and has noted permanent resolution of the problem with this maneuver. In the

event that an obliterative stricture occurs at the urethrovesical anastomosis, continuity may be reestablished using an endourologic technique such as that described by Appel and Lebenson (16). This procedure uses a percutaneously placed suprapubic tube for drainage and to permit antegrade (as well as retrograde) evaluation and manipulation of the strictured area. Potter and Marshall (793) have proposed a more recent variation of this approach. The use of electrocautery is associated with a high incidence of subsequent incontinence and should be avoided.

Mild stress and urgency incontinence are commonly experienced for several weeks following initial decatheterization. In our experience, this is resolved in approximately 80% of patients by 2 months postoperatively. Most patients achieve optimal urinary control within 6 months. Although some patients exhibit additional incremental improvement up to 18 months postoperatively, this constitutes the exception rather than the rule. In most modern series, incontinence is defined as urinary leakage requiring any type of protection (e.g. pads, tissue) to keep clothing dry. Catalona and associates (155) documented some degree of postoperative urinary incontinence in 8% of patients. Approximately 1% to 2% of patients exhibit incontinence severe enough to require surgical treatment. In this same study, 96% of men younger than 70 years of age, and 87% of men 70 years of age, recovered urinary control within 18 months of radical prostatectomy. Of interest, Strasser and associates (987) have documented an age-dependent increase of apoptosis of the striated muscle fibers of the rhabdosphincter. This phenomenon may account for the higher incidence of stress incontinence in elderly patients following radical prostatectomy. Walsh and associates (1062) reported complete urinary control in 92% of patients; stress incontinence in 8%; 6% of patients required one or fewer pads per day; and 0.3% required placement of an artificial sphincter for severe incontinence. In addition to patient age, intrinsic sphincter function is the prime determinant of postprostatectomy control. With respect to the latter, preservation of maximum urethral length and maintaining the structural/functional support of the striated rhabdosphincter appear to be critical for achieving postoperative continence (469). Preservation of the neurovascular bundles does not appear to affect postoperative urinary control (155). In the prostate cancer outcomes study, a population-based longitudinal cohort study with up to 24 months of follow-up, 8.4% of men were incontinent 18 months or more following radical prostatectomy. For such patients, it is our practice to perform video urodynamic testing and flexible endoscopy. Detrusor instability and bladder outlet obstruction should be managed in a traditional fashion. Lingering incontinence is usually of the stress-type. Patients with a Valsalva leak-point pressure of greater than 60 cm of water may achieve some improvement with collagen injections (368). Patients with leak-point pressure of less than 60 cm of water are most expeditiously treated with an artifical urinary sphincter (368) or consideration of a bulbourethral sling (177,178).

Walsh (1066) and Walsh and associates (1059) have shown that potency can be preserved in 72% of patients when both nerves are left intact. In this group, 58% recovered potency within 6 months, 95% by 1 year, 99% by 18 months, and 100% by 2 years. Potency was recovered in 69% of patients in whom only one neurovascular bundle was preserved. Of note, more than 50% of the patients in this study were less than 60 years old, and only 3% were greater than 70 years of age. It would appear that younger patients with normal or active preoperative sexual function are most likely to recover potency following this procedure. When capsular penetration is suspected by the presence of fibrosis and induration, Walsh (1064) advocates sacrificing one or both nerves as the situation demands. He reports deliberate sacrifice of one neurovascular bundle in 16% of patients with stage B_1N, 35% with stage B_1, and 80% with stage B_2 tumors. In these same groups, both nerves were sacrificed in 5%, 4%, and 12% of cases, respectively. More recently, Walsh (1065), reported the outcomes in 64 men who underwent radical prostatectomy for the treatment of localized prostate cancer. Each of these men were potent preoperatively and had sexual partners. The median age of this cohort was 57 years (range of 36 to 67). All men underwent anatomic radical prostatectomy performed by one surgeon, and the neurovascular bundles were preserved bilaterally in 89% of the patients. Potency, defined as the ability to have unassisted intercourse with or without the use of sildenafil, improved gradually, and by 18 months, 86% of patients were potent (84% of the patients considered sexual bother as none or small). At 18 months, approximately one-third of these patients were using sildenafil intermittently, but only two patients were not able to have intercourse without its use.

Catalona and Bigg (139) reported preservation of sexual potency in 63% (71 of 112) of patients in whom both neurovascular bundles were preserved. In contrast, only 39% (13 of 33) of patients regained potency following a unilateral nerve-sparing procedure. In this series there was a strong correlation between patient age, pathologic stage, and the preservation of potency following a bilateral nerve-sparing technique. Potency was preserved in 81% of patients 40 to 59 years old, 57% of those 60 to 69 years old, and 33% of those 70 to 79 years old. Similarly, preservation of potency was noted in 63%, 75%, 52%, 50%, and 50% of patients with stage A, B, C_1, C_2, and D_1 disease, respectively. The correlation between the quality of preoperative erections and the likelihood of their recovery postoperatively appears to be strong. Approximately 20% of patients with marginal preoperative erections recovered erections as compared with nearly 80% whose preoperative erections were judged to be completely normal. In most patients, postoperative erections were perceived to be less rigid when compared with preoperative erections, but some patients did report erections that returned to their preoperative baseline (155).

In general, the recovery of erections takes longer than the return of urinary control. In most patients, erectile activity resumes within 3 to 6 months following prostatectomy, and further improvement can be anticipated for 18 to 24 months or longer (155). This time frame may be required for surgery-induced neuropraxia to resolve. Montorsi and associates (669) have suggested that the early use of artificial means of inducing erections may hasten the return of natural erections. To that end, suitable patients have been encouraged to initiate therapy with sildenafil (Viagra), intraurethral alprostadil (MUSE), intracavernosal injections of alprostadil, or a vacuum erection device. In most instances, we have encouraged the prompt initiation of such treatment following the removal of the indwelling catheter.

Concern has arisen regarding the possibility that the nerve-sparing modification might compromise already tenuous surgical margins. In the study conducted by Eggleston and Walsh (254), extracapsular tumor extension was infrequently noted exclusively in the vicinity of the neurovascular bundles. Conversely, Stamey and associates (965) have reported the frequent association of positive capsular margins along the course of penetrating nerve fibers. In fact, they advise that the modified nerve-sparing procedure be limited to the contralateral side in stage B disease. Catalona and Bigg (139) noted that the improper application of the nerve-sparing technique may contribute to some instances of positive surgical margins, particularly at the points of urethral transection and establishment of the posterior extracapsular plane. To avoid these problems, they recommend (a) delineation of 1 to 2 cm of membranous urethra distal to the insertion of the paraurethral bands to the prostatic apex to avoid retention of apical tissue in the urethral remnant with the development of a posterior subcapsular plane, (b) isolation of the rectourethralis muscle with a right-angle clamp and its division distal to the posterior lip of the prostatic apex, and (c) conversion to antegrade dissection at the level of the bladder neck to reestablish the proper posterior plane of dissection if the prostatic apex has been undermined. We generally adhere to the absolute and relative contraindications to nerve sparing previously articulated.

Radical Perineal Prostatectomy

The perineal approach to the bladder and prostate has been used since the earliest surgical attempts to treat diseases of these organs. The approach was attractive because it was direct and avoided risk of injury to most intraabdominal organs; it did not require muscular relaxation; it was a relatively avascular approach to the lower urinary tract; and it provided dependent drainage, a particularly important advantage in the preantiseptic and preantibiotic eras. As these considerations have become less critical, and other concerns, such as more accurate staging and possibly improved preservation of a range of functions have superseded them, the perineal approach for radical and enucleative procedures has become less popular and less frequently used. The exacting knowledge of anatomy and the limited exposure provided by this approach have certainly been factors in its reduced use. Nevertheless the perineal approach to the radical prostatectomy retains many of these inherent advantages.

Recently, interest in radical perineal prostatectomy has been renewed. In part, this is attributable to the advent of laparoscopic PLND and, to a lesser extent, the mini-lap procedure for pelvic lymph node sampling. Another incentive for reconsidering the procedure is the current perception that metastasis to the pelvic lymph nodes are encountered infrequently in most modern series (Table 33.23). For example, Petros and Catalona (768) reported on the frequency of pelvic lymph node metastasis in 521 consecutive patients undergoing radical retropubic prostatectomy between 1983 and 1991. Of 32 patients with clinical stage A_1 disease, none had positive nodes compared with 2 (3.3%) of 61 with stage A_2, 10 (5.3%) of 189 with stage B_1, and 23 (9.7%) of 236 with stage B2 disease. In properly selected patients (low volume, Gleason score of 6 or below, PSA less than 10), it may be reasonable to forego pelvic node staging and proceed directly to a radical perineal prostatectomy.

TABLE 33.23. PERCENTAGE OF POSITIVE PELVIC LYMPH NODES BY CLINICAL STAGE

The perineal approach has some potential advantages over the retropubic with regard to avoiding rectal injury, controlling blood loss, and accomplishing the urethrovesical anastomosis. Urologists should strive to maintain their knowledge of the anatomy and technique that allows them to carry out this procedure. Patients selected for perineal prostatectomy must be able to tolerate significant flexion of their hips to permit placing them in the extreme lithotomy position. Patients with a wide separation of their ischial tuberosities and low-lying prostates are ideal candidates for this approach.

Proper positioning is critical to the perineal exposure. The desirable flat perineum lying parallel to the floor can be achieved by elevating the buttocks and by marked flexion of the thighs (Fig. 33.71). In achieving this position, pressure on the legs and on the shoulders must be avoided by proper padding and careful placement of supports. The arms should be kept as close to the body as possible; this is often achieved by simply taping the hands to the knees.

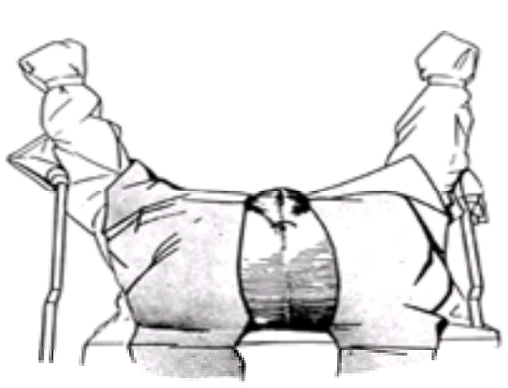

FIGURE 33.71. Exaggerated lithotomy position required for radical perineal prostatectomy. The extremities must be carefully padded and protected to prevent a neurovascular or compartment injury. Also shown is the semicircular skin incision, which should extend between the ischial tuberosities. (From Brendler H. Prostatic hypertrophy and perineal surgery. In: Boyce WH, Glenn JF, eds. *Urologic surgery,* 2nd ed. Hagerstown, MD: Harper & Row, 1975:424, with permission.)

Once the patient is positioned, shaved, prepared, and draped, a curved Lowsley tractor is introduced into the bladder and then withdrawn into the prostatic fossa. A semicircular skin incision extending between the ischial tuberosities is placed appropriately in relation to the mucocutaneous junction for the planned suprasphincteric or infrasphincteric approach to the prostate. The incised skin and subcutaneous tissue are anchored to an inferiorly placed drape or towel. In the suprasphincteric approach, Colles' fascia is incised sharply on each side of the central tendon. Posteroinferior pressure on the Lowsley tractor is applied to push the prostate toward the perineum. Each ischiorectal fossa is developed superiorly and posteriorly, with the handle of the knife working on the superior aspect of the inferiorly placed index finger until the posterior aspect of the prostate is felt. The index fingers of each hand then are used in a gentle seesaw motion ventral to the rectum and behind the central tendon to isolate this structure. The central tendon is then divided over a clamp (Fig. 33.72). Appropriately designed right-angle (often designated lateral) retractors are placed posterior to the deep transverse perineal muscle on each side, exposing the fibers of the levator ani muscle covering Denonvilliers' fascia. A properly placed pediatric or perineal Omni retractor aids in achieving or maintaining exposure. Often, these fibers fuse in the midline, forming the so-called rectourethralis muscle (Fig. 33.73). At this point Denonvilliers' fascia is hidden by the converging levator ani fibers and the tented-up rectum. With manual retraction, the sponge-covered rectum is reflected posteriorly. The levator fibers can often be separated with the handle of the knife to expose Denonvilliers' fascia (Fig. 33.74). This is usually attempted in the midline at the apex of the prostate just proximal to the urogenital diaphragm. If this is not possible bluntly, careful sharp dissection with the knife as far distal on the prostate as possible, accompanied by blunt lateral and superior freeing of the tissue with the knife handle, will expose this fascia. Use of the lateral retractors to maintain every advantage in exposure that is achieved is critical to this procedure.

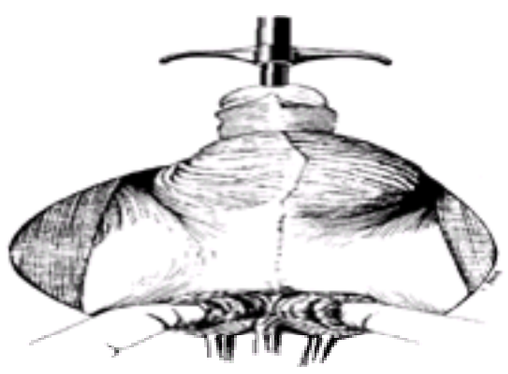

FIGURE 33.72. Delineation of the central tendon following blunt dissection with the intended line of transection marked by the *dashed line.* Note the presence of the Lowsley tractor. (From Brendler H. Prostatic hypertrophy and perineal surgery. In: Boyce WH, Glenn JF, eds. *Urologic surgery,* 2nd ed. Hagerstown, MD: Harper & Row, 1975:424, with permission.)

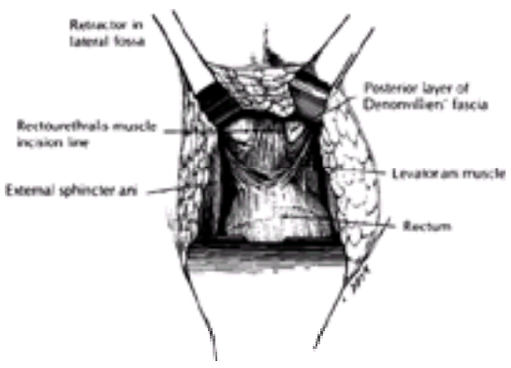

FIGURE 33.73. Midline fusion of fibers of the levator ani muscle (rectourethralis) covering the posterior layer of Denonvilliers' fascia. At this point in the dissection, the rectum would be reflected posteriorly and protected by a surgical sponge. (From Brendler H. Prostatic hypertrophy and perineal surgery. In: Boyce WH, Glenn JF, eds. *Urologic surgery,* 2nd ed. Hagerstown, MD: Harper & Row, 1975:424, with permission.)

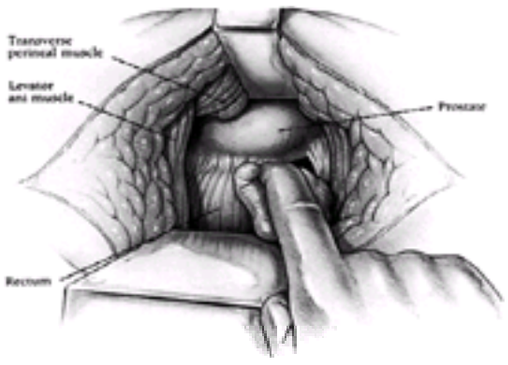

FIGURE 33.74. Establishment of the cleavage plane between anterior and posterior layers of Denonvilliers' fascia. Following transection of the central tendon, separation of the levator ani muscles, and division of the rectourethralis fibers, the desired midline plane between prostate and rectum is delineated with blunt dissection. (From Resnick MI. Radical perineal prostatectomy. In: *Urologic surgery.* Bristol-Myers, Learning Technology, 1988, with permission.)

Following exposure of the shining white posterior layer of Denonvilliers' fascia, the curved tractor is readvanced into the bladder, the blades opened, and the prostate again levered into the wound. Often, the levator fibers will strip easily from the remainder of the intact Denonvilliers' fascia, making the classic transverse incision to separate the currently disputed posterior and anterior leaves unnecessary. Posterior mobilization should then be carried to the tip of the seminal vesicle. Often, a sponge stick placed on a padded posterior tractor is very useful in dissecting to the level of the pouch of Douglas. The lateral aspect of the prostate is then mobilized by blunt finger dissection between the gland and the lateral prostatic fascia. The dissection to this point should result in very limited blood loss. Persistent bleeding during the exposure of the prostate may indicate that the dissection has entered the wrong plane, for example, the bulbourethral muscle.

After the lateral aspect of the prostate has been mobilized, the membranous urethra can be elongated by gentle posterior traction on the prostate and a right-angle clamp guided around its ventral aspect. The urethra is then divided sharply, hugging but avoiding the apex of the prostate. The posterior lip of the divided prostatic apex is grasped with an Allis clamp and the curved Lowsley tractor removed. A straight Lowsley tractor is used to replace it, and the blades are opened. Gentle traction on this instrument allows better visualization of the prostate in the perineum. The anterior surface of the prostate is then exposed to the level of the bladder neck with blunt dissection. The tractor blades are placed in an AP direction so that the bladder neck can be identified by palpation. The neck is incised sharply anteriorly with the scissors, and the incision is carried around each side posteriorly. At this point, the tractor can be replaced with a red rubber catheter to act as a sling and the bladder inspected to identify the ureteral orifices. If this is difficult, injection of chromogen such as indigo carmine will help. Ureteral catheterization is rarely necessary.

Once the orifices are identified, the bladder neck is incised in its posterior aspect as close to the prostate as the neoplastic involvement will allow. The entire bladder muscle must be divided, exposing the fascia overlying the seminal vesicles and vas deferens. Once this plane has been entered, blunt dissection can be used to separate the bladder from these structures. The vas deferens is identified, isolated, grasped with an Allis clamp, elevated from its bed, clamped, divided, and ligated on each side. Then with the finger of the left hand separating the prostate from the rectum, the vascular pedicle that enters the gland at its superolateral margin is isolated, clipped or clamped, divided, and ligated first on one side and then on the other. Heaney or gooseneck clamps are ideal for this maneuver. Then the tissue along with the blood supply at the tip of the vesicle is clamped, divided, ligated, and the specimen removed. The rectum is inspected to make certain there has been no injury. Minimal oozing from the rectum can be controlled by light fulguration but will usually stop when the patient is taken out of the perineal position. The bladder is inspected to make certain that the orifices are intact. A 22- or 24-Fr Foley catheter with a 5-mL bag is passed through the urethra and brought out the perineum. This serves to identify the distal urethra at the site of the urogenital diaphragm during the subsequent anastomosis.

The bladder neck is then narrowed using a Y-V type of reconstruction similar to that used in the retropubic prostatectomy. A small piece of tissue is then taken from the anterior and posterior bladder neck margins for frozen section evaluation to document the absence of retained prostatic tissue and/or a recognizable tumor. If the ureteral orifices are near the cut edge of the bladder neck, they can be infolded using interrupted Lembert sutures for the tail of a Y-type closure. The bladder neck urethral anastomosis is carried out as described previously. The enhanced apical exposure provided by this approach facilitates the placement of anastomotic sutures. The catheter is positioned just cephalad to the anastomotic site.

Drains are placed in the perineum and brought out through one corner of the perineal wound. The levator fibers are approximated with interrupted chromic catgut sutures, whereas the subcutaneous tissue is approximated with interrupted 3-0 plain catgut and the skin with subcuticular or vertical mattress sutures. The bladder is irrigated. It is our practice to anchor the catheter to the penis with a nylon suture placed through the glans. The patient is removed from the exaggerated lithotomy position with both legs being rotated inferiorly and simultaneously. Because irrigation is rarely necessary after this procedure, the catheter is simply connected to straight drainage. The perineal wound is covered with a perineal pad held in place by a T-binder.

On the following day, the drain is removed and the wound is then exposed to the air. Perineal care includes the use of a local heat lamp and an antiseptic agent such as povidone-iodine (Betadine) or merbromin (Mercurochrome). In our experience, most of these patients are discharged drain free with an indwelling Foley catheter on the third or fourth postoperative day. The decatheterization scenario is then identical to that previously described for radical retropubic prostatectomy. The use of an approach that stays close to the prostate and out of the lateral prostatic fascia and its adjacent areolar tissue on mobilizing the lateral aspect of the prostate and close to the prostate on clamping the vascular pedicle would seem likely to facilitate preservation of the autonomic nerves important to erection and continued sexual function (approaching 80% in some series). Many perineal surgeons prefer the infrasphincteric approach described by Belt to expose the prostate for radical and simple perineal prostatectomies, because the rectum is certainly in view during this procedure.

As enumerated by Hudson and Hakky (444), radical perineal prostatectomy preserves the following structures: (a) endopelvic fascia; (b) the puboprostatic ligaments; (c) the lateral pelvic fascia; (d) the anterior sheath (postsymphysial muscle and fascia); (e) the lateral lower bladder muscular attachments; (f) the circular bladder neck components, with intact nerve and blood supply; (g) the external striated urethral sphincter, including looping strands that can be “teased” off the apex of the prostate along with intact blood and nerve supply to the rhabdosphincter; and (h) the deep dorsal vein and its branches (444).

Radical perineal prostatectomy can be carried out with a limited blood loss (1% transfusion rate in large series) and complication rate. For example, Paulson and associates (756) performed radical perineal prostatectomy on 76 patients with stage A prostate cancer and reported no instances of perioperative death, rectal injury, or incontinence. Of note, the authors report positive surgical margins in 32% of the cohort, which they attributed, in part, to prior TUR. Walsh (1069) has suggested that the perineal approach provides inordinately thin anterior margins that can be particularly problematic in patients with stage A tumors in whom the disease tends to be preferentially localized to the anterior aspect of the gland.

Frazier and associates (316) compared the outcome of 122 patients who underwent radical perineal prostatectomy with 51 patients who underwent radical retropubic prostatectomy, both for the treatment of organ-confined prostate cancer (stage T_1 or T_2). Although the total operative time was somewhat shorter for the perineal group, the anesthesia time was similar for both groups. There was no difference in the incidence of positive surgical margins, nor was there any difference in the short-term/long-term complication rates between the two groups. Of note, the median estimated blood loss for the perineal group was 565 mL compared with 2,000 mL for the patients undergoing radical retropubic prostatectomy. These favorable results coupled with technical modifications of the radical perineal prostatectomy that permit preservation of the neurovascular bundles and a watertight vesicourethral anastomosis (755) make it an attractive surgical option for these patients.

These perceptions are validated by a more recent comparison regarding the relative merits of radical perineal versus radical retropubic prostatectomy, conducted by Sullivan and associates (993). In general, the results of radical perineal and radical retropubic prostatectomy are comparable. There was no significant difference in operative duration, or the incidence of positive margins or global complications. The advantages of the perineal approach included minimal blood loss, low-intensity postoperative nursing care, low analgesic use, and earlier discharge from the hospital.

Recently, Bishoff and associates (62) conducted a survey that revealed that the incidence of fecal incontinence following radical retropubic and perineal prostatectomy occurs more frequently than previously recognized. The fecal incontinence among radical perineal (18%) and retropubic (5%) prostatectomy patients surpassed the expected incidence of 4% for this age group (60 to 70 years). The incidence was significantly higher for radical perineal prostatectomy patients. The exact mechanism of injury leading to fecal incontinence has not yet been defined. The rectal sphincter consists of subcutaneous, superficial, and deep components.

Any or all of these muscles are certainly subject to trauma during the perineal approach to prostatectomy. Prolonged retraction also may lead to neuropraxia. Finally, reconstruction of the levator ani muscles may contribute to damage and possibly prevent proper functioning of the continence mechanism. These authors suggest that a combination of new electromyography techniques with anal rectal manometry may help define preoperatively patients who may be at increased risk for this complication. It would appear that these observations should constitute part of the pretreatment discussion when the risk/benefits of available treatment options are reviewed with patients.

Laparoscopic Radical Prostatectomy

Guillonneau and Vallancien (393) recently reported their experience with laparoscopic radical prostatectomy performed on 120 consecutive patients from February 1998 to May 1999. The procedure is performed with the patient in the dorsal supine position. The lower limbs are abducted to provide access to the perineum. A slightly exaggerated Trendelenburg position also is used. For a right-handed surgeon, five trocars are used. A 10-mm trocar is placed in the umbilicus for the telescope. Three 5-mm trocars are placed in the left iliac fossa, midway between the umbilicus and pubis, and in the right pararectal fossa. Finally, a 10-mm trocar is positioned in the right iliac fossa at McBurney's point. In their series, the surgeon stands to the left of the patient with an assistant opposite him or her. A voice-controlled robotic arm is used to manipulate the scope to ensure stability of image and to free a hand, which can then be used to manipulate other instrumentation.

The procedure commences with a laparoscopic PLND, which follows the precepts already discussed. To approach the adnexal complex, an incision is made in the lower peritoneal arch, which represents the peritoneal fold along the vesicorectal apposition. This gives access to the vas deferens and seminal vesicles. Through this transperitoneal approach, the vasa deferentia are dissected, coagulated with bipolar current, and transected. A seminal vesicle dissection is the next phase of the procedure. In each case, the tip of the respective seminal vesicle is completely mobilized, and ultimately, only the base of the seminal vesicle remains attached. At this point, the sagittal striations of Denonvilliers' fascia become apparent, and these are incised in a transverse fashion. This approach permits access to the proper plane, which permits identification of prerectal fat that leads to the posterior surface of the prostate. At this point, the bladder is filled to clearly visualize its contours. Dissection is initiated along the lateral aspects of the bladder, medial to the obliterated medial umbilical ligament. This ultimately permits access to the retropubic space and lateral incision of the pelvic fascia. The puboprostatic ligaments are then sectioned and the prostatic apex is released laterally. Santorini's venous plexus is ligated with 2-0 absorbable suture material, but is not transected at this point in order to decrease the risk of bleeding, which would render subsequent phases of the operation difficult. Transsection of this venous complex is delayed until control of the prostatic pedicles has been achieved. An intervesicoprostatic dissection is performed with the intent of bladder neck preservation. Posterior dissection of the bladder neck reveals the previously transected vasa deferentia and the mobilized seminal vesicles. At this point, dissection of the posterosuperior pedicles of the prostate is performed, using coagulation with bipolar forceps. The neurovascular bundles are preserved when prudent to do so. Following this, Santorini's venous plexus is transected and the urethra is identified and incised with a cold knife. Finally, the distal insertion of Denonvilliers' fascia with rectourethralis attachments is sectioned. This releases the operative specimen. A watertight urethral vesicle anastomosis is performed using 6 to 8 polyglactin 3-0 interrupted sutures tied over an 18-Fr Foley catheter. The operative specimen is extracted using a laparoscopy bag after enlarging the trocar site at McBurney's point.

The mean operating time for the first 120 consecutive patients was 239 minutes. Mean interoperative blood loss was estimated to be 402 ± 293 mL. The transfusion rate was 10% overall. Conversion to open surgery was necessary in seven cases, and reoperation was performed in 1.7% of cases. The mean postoperative bladder catheterization time was 6.6 ± 2.4 days. The positive/questionable surgical margin rate was approximately 15%. Serum PSA reverted to undetectable in 94.7% of patients. At 6 months postoperatively, 72% of patients were continent. In patients who underwent bilateral nerve sparing, approximately 45% demonstrated spontaneous postoperative erections.

This same group provided an update on their experience after having performed 20 consecutive cases between January 1998 and December 1999 (393). In that series, the operating time was approximately 3 hours. The estimated blood loss was 250 mL, and the transfusion rate was less than 1%. The open surgical conversion rate was 0%. Postoperative pain was described as minimal, and analgesics were generally not required by postoperative day 2. These patients were discharged home without urethral catheterizations starting on postoperative day 3.

These investigators and others (1) have validated the feasibility of laparoscopic radical prostatectomy. Clearly, in experienced hands, the operation is technically feasible and associated with patient outcomes that appear to be in parity with standard radical retropubic prostatectomy. The potential advantages include a low risk for bleeding and subsequent transfusion, minimal postoperative pain, and rapid urethral decatheterization. The ultimate utility and safety of this approach awaits multiinstitutional confirmation.

Surgical Salvage Following Failure of Definitive Radiation Therapy

Available evidence indicates that a positive prostate biopsy performed more than 18 months after radiation therapy indicates failure of tumor control (870). For patients with stage A and B cancers, recognized local tumor recurrence or persistence 10 years after treatment may approach 36% in patients treated with interstitial and external beam therapy (871), and 26% after iodine-125 (^{125}I) seed implantation (284). It should be emphasized that these studies were not performed with the benefit of either serial PSA measurement or the use of systematic TRUS-guided biopsies. With use of these endpoint parameters, residual disease has been observed in more than 80% of patients having undergone radiation therapy with curative intent (960).

Both radical prostatectomy and cystoprostatectomy have been performed as “salvage” procedures in relatively small numbers of such patients (123,358,614,954).

Neerhut and associates (706) described their experience with salvage radical prostatectomy in 16 patients who failed an attempt at definitive radiation therapy for the treatment of stages A_2, B, and small C prostate cancers. Selection criteria included (a) excellent performance status; (b) a projected life expectancy of at least 10 years; (c) no previous systemic treatment that might mask occult metastases; and (d) the absence of demonstrable nodal, skeletal, or soft-tissue visceral involvement following a thorough staging evaluation. Although no operative deaths were reported, several major complications were noted, including (a) rectal injury (19%), (b) anastomotic stricture (25%), (c) ureteral transection (6%), (d) stricture at the ureterovesical junction (6%), and (e) total urinary incontinence (25%). In addition, positive surgical margins were observed in 37.5% of patients, with the apical margin most frequently involved. Because the bladder neck margins were rarely problematic, the authors did not believe that radical cystectomy would have improved the overall results. The follow-up period was too short to permit a meaningful analysis of recurrence or survival figures.

Rainwater and Zincke (809) reported similar results in their series of 30 salvage procedures (radical prostatectomy, 27; radical cystectomy, 3). Again, no perioperative deaths were reported, but complications include bladder neck contracture (17%), lymphedema (10%), and total incontinence (10%). Eight patients were upstaged to a D_1 disease. Tumor progression and survival were most dependent on the DNA ploidy status of the tumor.

Rogers and associates (836) provided an update of the Baylor experience with salvage radical prostatectomy for locally recurrent prostate cancer. Forty patients were involved in that series. Most of these tumors were detected by DRE or by increasing serum PSA levels. They reported six (15%) rectal injuries, two of which required temporary colostomy. Of note, urinary incontinence persisted in 18 (58%) of 31 patients. Other serious technical complications occurred more frequently in those patients who had undergone PLND before radiation therapy as compared with the group treated with external radiation alone (31% versus 9%). Of interest, the preoperative PSA levels (but not clinical stage or biopsy grade) correlated most closely with pathologic stage. For those patients in whom the preoperative PSA was less than 10 ng/mL, only 15% had advanced pathologic stage, compared with 86% if the PSA was 10 or more. The best results were obtained in those patients in whom the prostate cancer was confined to the gland or the immediate periprostatic tissue. In that cohort, 82% exhibited no evidence of progression at 5 years.

With respect to operative preparation and technique, several points deserve special emphasis. A thorough mechanical and antibiotic bowel preparation is important to minimize the impact of pelvic contamination in the event of rectal injury. The frequency of rectal injury might be decreased by (a) initial separation of the prostate from the rectum via a perineal approach with completion of the procedure retropubically, (b) the use of a sterile O'Connor shield to permit free and repetitive access to the rectum if the retropubic approach is used exclusively, or (c) adoption of the Campbell (antegrade) approach to facilitate the mobilization of the prostate from the rectum. In the event of rectal injury, devitalized tissue should be excised, a precise two-layer closure performed, and the repaired laceration covered with omentum followed by dilation of the anal sphincter. If the repair is considered tenuous, a diverting sigmoid loop colostomy should be constructed.

More recently, Bochner and associates (76) described the feasibility of performing salvaged radical cystoprostatectomy and constructing an orthotopic urinary diversion in 18 patients in whom definitive radiation therapy for bladder (12) or prostate (6) cancer had failed. The terminal ileum, which demonstrated no evidence of radiation enteritis, was used for neobladder construction in 17 patients and sigmoid colon was used for pouch reconstruction in 1 patient. These investigators did not identify any difference between irradiated and nonirradiated patients with respect to operative characteristics, postoperative outcomes, and postoperative

complications. Good day and night continence after surgery was reported by 67% and 56% of irradiated patients, respectively. Patients who exhibited poor postoperative urinary control were successfully treated by the placement of an artificial sphincter.

Pisters and associates (782) describe a technique of salvage prostatectomy with the construction of a continent catheterizable urinary reconstruction. The development of this technique was prompted by the high rate of total urinary incontinence that follows salvage radical prostatectomy (and salvage cryotherapy). In their approach, a wide dissection of the apical tissues is performed, including removal of surrounding skeletal muscle. Similarly, a wide proximal margin is obtained, with liberal transsection of the bladder neck just inferior to the trigonal complex. After completion of the salvage prostatectomy, the bladder neck is closed in two layers with interrupted 2-0 and 3-0 polydioxanone sutures. Reconstruction with an appendicovesicostomy to the native bladder was performed in nine patients. The appendix was mobilized based on its mesentery with the distal cecal tip. The appendix and an angulated component of adjacent cecal wall are transected using the GIA stapler. The appendix is dilated with Hegar dilators, to accommodate a 12- to 14-Fr catheter. Most often, the cecal end is anastomosed to the bladder, and the distal appendiceal tip is brought to the skin for the creation of a stoma; however, the reverse orientation also is feasible. In either event, a V-incision is made in the skin with the apex of the V sutured to a corresponding counterincision on the appendiceal tip. In four patients, an ileovesicostomy was performed in concert with the principles of a modified Monti procedure. In all cases, an omental pedicle flap was placed over the bladder neck closure area.

The authors cite no intraoperative complications. Four patients did experience serious complications requiring reoperation, including colovesicourethral fistula requiring delayed cystectomy; wound dehiscence with disruption of the appendicovesical anastomosis; leakage from the small bowel anastomosis that resulted in a septic death; and stomal stenosis requiring delayed revision. Of the 12 patients, 10 were dry at night and during the day with a catheterization interval of 2 to 6 hours. Two patients (17%) used pads for incontinence. It would appear that this technique can be used successfully in properly selected patients. Indeed, this approach has several theoretic advantages. Bladder neck preservation permits normal ureterovesical function, prevents reflux, and minimizes upper tract infection/deterioration. In addition, bladder preservation avoids the risk of ureteral anastomotic strictures, which often complicate reconstructive surgery involving radiated ureters. Finally, this approach requires less extensive dissection than a standard cystoprostatectomy with urinary diversion, which may be advantageous in patients with significant medical comorbidities.

The limited number of patients reported does not provide an opportunity to assess the results of these attempts; it does indicate that the radical surgical procedures should not be excluded from the therapeutic options considered in this group of patients. Conversely, given the substantial morbidity attendant to these “salvage” attempts, the majority of these patients may be better served by the prompt initiation of endocrine therapy (152).

Neoadjuvant Hormonal Therapy Before Radical Prostatectomy

Approximately 50% of clinical stage T_2 prostate cancers are noted to be understaged at the time of step-section analysis. This critical and most challenging problem has prompted interest in neoadjuvant hormonal deprivation before radical prostatectomy. In most instances, this constitutes total androgen ablation using a luteinizing hormone–releasing hormone (LHRH) agonist (leuprolide) and an antiandrogen (flutamide) administered 3 months before anticipated radical prostatectomy. The goals of anticipatory treatment are essentially twofold. The first is to achieve downsizing of the prostate gland, which could conceivably facilitate its subsequent removal. Second, it is hoped that this therapy would “sterilize” microscopically compromised surgical margins (Fig. 33.75).

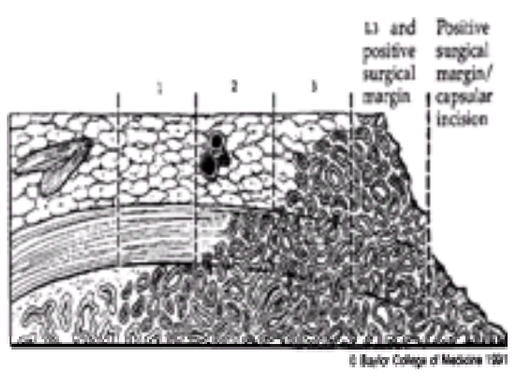

FIGURE 33.75. The various levels of capsular involvement are depicted. Cancer confined within the prostatic glandular tissue is designated level 0. Level 1 represents extension of cancer into the prostatic stroma beyond the level of normal glands. Extension of cancer into but not through the fibrous capsule is defined as level 2 involvement. Finally, extension of tumor into the periprostatic connective tissue, adjacent bladder, or skeletal muscle represents level 3 involvement. (Rosen MA, Goldstone L, Lapin S, et al. Frequency and location of extracapsular extension and positive surgical margins in radical prostatectomy specimens. *J Urol* 1992;148:331, with permission.)

Several investigators reported encouraging results with this approach. Monfette and associates (667) used total androgen ablation before radical prostatectomy in 34 patients and observed (a) a 55% decrease in prostate volume, (b) no pathologically detectable cancer in the surgical specimen in 10 of 34 patients, (c) a 30% to 40% decrease in operative time, and (d) a 50% decrease in operative blood loss. Soloway (947) also reported favorable preliminary results with this approach.

Despite its theoretic appeal, several studies question the ultimate utility of neoadjuvant hormonal deprivation in this setting. In a retrospective analysis, Oesterling and co-workers (725) compared 22 patients with clinical stage T_2 or T_3 CaP who underwent androgen deprivation therapy before radical retropubic prostatectomy to an appropriately matched patient who had not received preoperative endocrine therapy. In this study, the radical prostatectomy specimens from the two groups did not reveal any statistically significant differences with respect to maximal tumor dimension, pathologic stage, or DNA ploidy status. Moreover, it was felt that the serum PSA became an unreliable indicator of disease status after the initiation of preoperative androgen deprivation therapy.

More compelling is the prospective study conducted by MacFarlane and associates (612). In this study eight patients had clinical stage T_2 and 14 had clinical stage T_3 disease. All patients received 3 months of total androgen-ablative therapy. As determined by TRUS, an average 33% downsizing of the prostate gland was achieved. Similarly, the prehormonal therapy PSA values decreased significantly (30 ng/L versus 0.53 ng/L). Of the eight patients with clinical stage T_2 cancer, four had pathologic stage T_2 disease following the protocol. Of the 12 patients with clinical stage T_3 cancer, three had pathologic stage T_2 disease, four had positive pelvic lymph nodes, and the remainder had pathologic T_3 cancer. Only three (15%) of 20 patients in this study demonstrated pathologic downstaging from the clinical stage. Furthermore, preoperative hormone therapy did not appear to simplify the radical prostatectomy. When compared with a group of 20 consecutive patients with stage T_2 prostate cancer who underwent radical prostatectomy without the preoperative hormonal deprivation, no significant differences were noted with respect to the average operating time or average blood loss.

Recently, Scolieri and associates (890) assessed the outcome of seven randomized prospective clinical trials designed to assess the impact of neoadjuvant hormonal ablative therapy before radical prostatectomy (Table 33.24). They noted a decreased rate of positive surgical margins in 6 of 7 of the randomized prospective studies. Of interest, in none of four randomized prospective series was the rate of seminal vesicle invasion improved. Three of four studies showed no improvement in the incidence of lymph node metastasis following neoadjuvant hormonal therapy compared with controls. Furthermore, no improvement in PSA-free survival was noted. Finally, the complication rates, operative time, operative blood loss, transfusion rates, and hospital stay were comparable in these two groups. This analysis failed to identify any significant improvement in outcome following the use of neoadjuvant androgen ablation, and its routine use before radical prostatectomy cannot be supported based on available data.

TABLE 33.24. IMPACT OF NEOADJUVANT HORMONAL ABLATIVE THERAPY BEFORE RADICAL PROSTATECTOMY

Results of Radical Prostatectomy

For properly selected patients (stage T_1, T_2), radical prostatectomy provides excellent results with regard to local disease control and the prospect for long-term, disease-free survival (Table 33.25). The majority of stage T_{1a} prostate tumors are detected in an elderly population for whom these cancers pose little risk of progression from a biologically indolent to aggressive tumor system. The same assurance cannot be provided to the young patient with localized CaP of the prostate incidentally detected. In these patients, the risk of neoplastic progression toward an aggressive and potentially life-threatening tumor (stage T_{1a-b}) is a legitimate concern (968), and radical prostatectomy should not be dismissed as a treatment option. Available evidence suggests that properly staged patients with T_{1b} prostate cancer are excellent candidates for radical prostatectomy. In the absence of regional lymph node involvement and capsular perforation, one can anticipate local recurrence rates of approximately 8% (40) and an overall clinical (non-PSA) cancer progression rate of approximately 10% (143). Elder and associates (266) reported equally favorable results in their analysis of 25 patients with stage T_{1b} prostate cancer. In this series, tumor was entirely confined to the prostate in 88% of the patients, thus suggesting a chance of long-term cure equivalent to that of patients with pathologic stage T_2 disease. Previous TURP does not seem to have an impact on the morbidity of subsequent radical surgery, regardless of the time frame between one procedure and the other (40). Radical prostatectomy is much more difficult to perform within the context of a patient having undergone an open prostatectomy, unless the two procedures are performed within a week's time (154). In our experience, the procedure in these patients can be facilitated by using combined perineal and retropubic approaches.

TABLE 33.25. SURVIVAL RATES FOLLOWING RADICAL PROSTATECTOMY FOR PROSTATIC CARCINOMA CONFINED WITHIN THE CAPSULE

The superiority of radical prostatectomy as a curative modality receives its greatest support from long-term follow-up studies conducted in patients with stage T_2 tumors who have undergone such treatment. In 1980, Walsh and Jewett (1060) reported on the Johns Hopkins experience assessing the efficacy of radical perineal prostatectomy in patients with clinical stage T_{2a} prostate cancer. Although PLND was not performed in these patients, the 15-year disease-free survival rate reported in this study is 51%. In fact, only 10 (17%) of the 57 patients with T_{2a} tumor subjected to radical prostatectomy by the Johns Hopkins group had documented residual tumor activity in a 15-year follow-up.

In 1979, Hodges and associates (426) reported similar 15-year disease-free survival rates. The efficacy of radical prostatectomy in this subset of patients also is supported by an analysis of the data generated by the Mason Clinic experience. Fourteen of 26 patients were alive 15 years following radical perineal prostatectomy. Of these, 13 were disease free. In the latter series, local recurrence was documented in 5% of 195 patients involved in the study (352,354). Catalona (154) cites an incidence of local recurrence of 7.4% to 9.0% in patients with stage T_1 or T_2 disease subjected to radical prostatectomy. Obviously, such a development is more likely in those patients in whom a portion of apical prostate is inadvertently or deliberately retained. This supposition is based on a study of Byar and Mostofi (112), who documented tumor involvement in the prostatic apex in 75% of cases. Again, properly selected patients with true pathologic stage T_2 tumors fare well after radical prostatectomy. In 1982, Elder and associates (267) reported a 50%, 15-year disease-free survival rate in such patients. These results are contingent on proper patient selection, excluding those with recognized extracapsular disease and regional lymph node involvement.

Walsh and associates (1062) reviewed their experience with 955 men with clinical stages T_1 and T_2 prostate cancer who underwent radical retropubic prostatectomy between April 1982 and March 1991. Using actuarial analysis, the likelihood of maintaining undetectable serum PSA levels at 10 years was 70%. During this same time, biochemical (PSA) relapse was observed in 23%, distant metastases in 7%, and local recurrence in 4% of this cohort. With respect to local recurrence, Pound and associates (796) reviewed the clinical course of 1,916 consecutive men followed during a 14-year period after radical prostatectomy performed at the Johns Hopkins Hospital. Fifty-six men (2.9%) had evidence of local recurrence an average of 6.1 ± 2.7 years following surgery. The mean serum PSA at the time of local recurrence was 5 ng/mL. Of importance, no man had local recurrence with an undetectable serum PSA level. Of interest, 25% of patients exhibiting local disease recurrence maintained undetectable serum PSA levels at 5 years of follow-up, but subsequently exhibited biochemical and clinical relapse. Based on these observations, it was recommended that neither the DRE nor imaging studies be performed in men with undetectable PSA levels following radical prostatectomy provided the patient has had the annual rectal examination recommended for colorectal cancer screening. This caveat is important because, in our experience, most internists appropriately rely on us to examine the rectum. When a subset analysis was performed, the 10-year likelihood of freedom from PSA relapse was 85% for men with organ-confined disease, 82% with focal capsular penetration (perforation), 54% with established capsular penetration (perforation) and a Gleason score of 2 to 6, 42% with established capsular penetration and a Gleason score of 7 to 10, and 43% with seminal vesicle involvement. The generic validity of this relapse risk data was reinforced by the study conducted by Catalona and Smith (150) that involved a series of 925 consecutive men with clinical stage T_1 and T_2 prostate cancer. Of note, the 5-year nonprogression rate was higher in patients whose tumors were not palpable (90% for impalpable tumors detected following TURP, 97% for clinical T_{1c} tumors, and 74% for palpable lesions). They also noted that the nonprogression was closely correlated with pathologic stage.

The role of radical prostatectomy in the treatment of patients with stage T_3 and N^+ disease remains controversial at this time. In the Mayo Clinic experience a combination of radical prostatectomy and androgen ablation (orchiectomy) in patients with stage T_3 and N^+ disease permitted projected 5- and 10-year survival rates in parity with expected survival figures for patients with DNA diploid tumors (894,1143). Such a multimodal approach to locally aggressive or regionally metastatic prostate cancers is indeed intriguing and warrants further consideration. It is currently our impression (and that of others) that achieving optimal control of the primary tumor is an important consideration in those patients with locally advanced and regionally metastatic tumors. This concept, coupled with increasing proficiency in the management of technically challenging cases, has served as the impetus for recommending radical prostatectomy to selected patients with stage T_{3a-b} CaP with or without N^+ disease. In this setting, it is viewed as the first component of a multimodality treatment plan, which may include androgen ablation and adjuvant radiotherapy. Obviously, prospective, randomized clinical trials will be required to rigorously assess the role of radical prostatectomy in such patients. At present, we use this approach in a highly selective fashion.

The nerve-sparing approach has been criticized in some quarters because of the possibility of compromising surgical margins. Obviously, preservation of the neurovascular bundles should not take precedence over the dictates of pristine cancer surgery. The routine use of intraoperative frozen section taken from the posterolateral aspects of the resected specimen and the bladder neck should mitigate against retention of diseased tissue. As discussed in the section on radiation therapy, microscopically compromised margins and local recurrence can often be managed effectively using external beam radiation therapy, particularly if such intervention is initiated promptly (33,557,813).

The routine availability of serum PSA testing has altered our perceptions regarding disease control. All surgeons are aware that within 4 to 6 weeks of a putatively curative radical prostatectomy, the serum PSA levels should revert to undetectable by conventional assay methods. Several studies have emphasized the serious implications of detectable serum PSA levels following radical prostatectomy. Lightner and associates (585) evaluated 63 patients with abnormal PSA levels 6 to 240 months after radical prostatectomy who by all other criteria were considered to have no evidence of disease. Six patients were ultimately noted to have metastatic disease to bone and/or lymph nodes. Of interest, local CaP also was discovered in five of these patients. The remaining 57 patients were deemed free of obvious disease by all criteria except elevated PSA levels. Ultrasound-guided biopsies of the perianastomotic region were obtained and revealed local disease in 42%. Of note, no local disease was documented in 30 patients who had undergone radical prostatectomy and had normal PSA levels. In an analogous study, 43 patients with persistently elevated PSA levels and negative bone scans underwent both DRE and TRUS. Of 43 patients, 22 (51%) had evidence of persistent disease on ultrasound-guided biopsies. Surprisingly, 21 (95%) of these 22 exhibited an abnormal hypoechoic region adjacent to the bladder, retrotrigone, or perianastomotic site. The DRE was suspicious in only 10 (45%) of 22 patients. Finally, among ultrasound-detected recurrences, 15 (68%) were detected at the first biopsy and 7 (32%) at a subsequent biopsy.

The study conducted by Trapasso and associates (1024) suggests that determination of the postprostatectomy PSA doubling times may provide useful information. For example, the median postprostatectomy PSA doubling times for patients who ultimately progressed to distant metastasis was 4.3 months. This compared with a median value of 11.7 months for those patients who either exhibited clinical local recurrence or who maintained a PSA elevation as a sole indicator of recurrence. With respect to the latter issue, a study conducted by Kassabian and associates (490) is of interest. These investigators collected fresh prostatic secretions from radical prostatectomy specimens immediately after removal. All patients had clinical stage T_1 and T_2 prostate cancers. Eleven (14%) of 76 samples contained malignant cells. Six (55%) of eleven cancers with a Gleason score of 8 to 10 in the prostatectomy specimen had a positive cytology result. In contrast, only 4 of 62 tumors with a Gleason score of 5 to 7 exhibited positive cytologies. It is implied that malignant cells shed during prostatectomy may seed the surgical bed and be responsible for some instances of local tumor recurrence. In the majority of instances, however, it is likely that specimens with grossly or microscopically comprised surgical margins are responsible.

Recently, Pound and associates (796) assessed the time course of disease progression in men with biochemical recurrence following radical prostatectomy. This cohort consisted of 1,997 men who underwent radical prostatectomy, by a single surgeon (Patrick Walsh, M.D.), for clinically localized CaP. None of these men received neoadjuvant therapy and none received adjuvant hormonal therapy before the documentation of distant relapse. The actuarial metastasis-free survival for all 1,997 men was 82% at 15 years following surgery; 315 of 1,997 (15%) developed PSA relapse. Eleven patients were excluded from the study because they underwent early hormonal therapy after documentation of biochemical relapse. Of 304 remaining patients, 103 (34%) developed metastatic disease. The median actuarial time to metastasis was 8 years from the time of PSA elevation. Time to biochemical progression (less than or equal to 2 versus greater than 2 years), Gleason score (greater than or equal to 8 versus less than 8), and PSA doubling time (less than 10 versus greater than or equal to 10 months) were predictive of the probability and time to development of metastatic disease. Following the onset of metastatic disease, the median actuarial time to death was 5 years.

The somewhat analogous study of Jhaveri and associates (470) analyzed the outcome of 1,132 consecutive patients who underwent radical prostatectomy for localized disease: 213 of 1,132 (19%) exhibited biochemical failure. Of this group, 99 patients received androgen ablation and/or radiation therapy at the time of biochemical failure. In this study, the 10-year overall survival rates for patients with biochemical failure (88%) versus no biochemical failure (93%) were statistically similar. These authors concluded that at 10 years, patients with PSA recurrence after radical prostatectomy for localized disease exhibit an excellent overall survival that may be equivalent to those without a detectable postoperative PSA.

D'Amico and associates (204) identified several independent predictors of time to PSA failure following radical prostatectomy, including percentage of positive prostate biopsies at diagnosis of greater than 34%, preoperative PSA level greater than 10 ng/mL, seminal vesicle invasion, prostatectomy Gleason score of 8 to 10, and a positive surgical margin. De la Taille and associates (219) documented that the presence of perineural invasion is statistically correlated with PSA recurrence. In their study, Kaplan-Meier analysis revealed disease-free survival rates of 24% versus 64% when perineural invasion was and was not present in presurgical biopsy specimens. However, when perineural invasion was compared with postoperative parameters, including disease stage, surgical margins, and seminal vesicle invasion, it was not an independent predictor because of its close correlation with tumor stage. Southwick and associates (953), using a multivariate logistic regression analysis, demonstrated that percent free PSA was the strongest predictor of postoperative pathologic outcome, followed by biopsy Gleason sum and patient age. In this study, organ-confined cancer, Gleason sum less than 7, and small tumors (involving less than or equal to 10% of the prostate volume) were noted in 75% of patients with percent free PSA levels greater than 15%. These favorable parameters were noted in only 34% of patients with percent free values of 15% or less.

Oefelein and associates (722) reported evidence of hematogenous dissemination of prostate cells during radical prostatectomy by using RT-PCR. In a follow-up analysis, Oefelein and associates (721) demonstrated that a positive RT-PCR result from a peripheral venous blood sample 12 months after radical prostatectomy was not associated with prostate cancer progression at a median follow-up of 22 months. Indeed, no significant correlation was observed between a persistently positive RT-PCR result and biochemical failure. They conclude that although a significant proportion of men have biochemical evidence of hematogenous prostate cell dissemination intraoperatively, the longitudinal molecular and clinical follow-up demonstrated reconversion to a negative status as the predominant trend following radical prostatectomy. It seems likely that further insight (and perhaps confusion) will be generated with the advent of assays for urinary PSA levels (226) and RT-PCR methods for the detection of PSA and PSMA mRNA in circulating tumor cells (457,492).

Cryotherapy

Gonder and associates (369a) pioneered the use of transurethral cryosurgery in 1966. Their approach was a blind procedure unsuitable for the treatment of CaP that occupied the peripheral zone of the gland. In 1969, Flocks used a standard perineal exposure of the prostate for the controlled application of cryotherapy under direct vision. This technique possessed intuitive appeal, in that the bulk of the primary tumor and its periprostatic component might be destroyed while preserving the structural and functional integrity of adjacent structures. The temperature at the tip of the cryosurgical probe approaches –180° to –190°C and produces tissue death by various mechanisms, including intracellular dehydration, electrolyte imbalance, crystallization with membrane rupture, protein denaturation, thermal shock, and vascular stasis (596).

Although proponents suggest that this mode of therapy provides a survival advantage equivalent to that of radical prostatectomy at the 5-year level (78), they currently assess its greatest utility to be in the palliative management of large bulky tumors or for local disease control in patients too debilitated to undergo conventional treatment. Loening and Lubaroff (596) reported a total surgical mortality of 1.9% in a series involving 215 patients. However, major complications do arise and consist predominantly of urethrorectal and urethrocutaneous fistulae, which occur in approximately 10.7% of patients. Most of the latter have been successfully treated by prolonged catheter drainage and curettage of the fistula tract.

In addition to the local cytodestructive effects, some investigators have proposed that cryodestruction of the prostate may result in the release of tumor-associated antigens and provide a form of active specific immunotherapy (395). The latter implies an induction of a host immune response as a result of direct exposure to these tumor-associated antigens. The majority of studies, however, have failed to confirm an immunologic response that can be causally linked to cryotherapy (657). Furthermore, most studies have failed to document a systemic antitumor effect attendant to prostatic cryotherapy, despite sporadic reports to the contrary (937).

Open perineal cryosurgery of the prostate has now been supplanted by ultrasound-guided percutaneous cryoablation of that organ. The latter technique relies upon TRUS to facilitate the transperineal placement of 5 to 6 cryoprobes using a stepwise-modified Seldinger technique (563,735). Both liquid nitrogen and gas (argon-based) systems are available to induce freezing, which is dynamically monitored on TRUS and is perceived as an expanding hyperechoic rim that ultimately approaches the rectal mucosa. Damage to the latter is thought to be minimized by proper ultrasound monitoring and facile manipulation of the transducer so as to increase the space between the rectal mucosa and the prostatic capsule. A urethral warming catheter is used in an attempt to diminish injury to that structure. Optimal positioning of the cryoprobes is contingent upon knowledge of tumor location, sites of obvious extracapsular extension, the size of the tumor, and gland geometry (563). Thermosensors also are used to monitor the cryosurgical “iceball” and to determine the number of freeze-thaw cycles required. It has been advocated that large

prostates be treated with combined androgen ablation to downsize the gland, which facilitates the cryoablative process.

The data generated to date by these efforts have been limited. Miller and associates (659) performed a retrospective chart review of 62 cryosurgically treated patients with presumed clinical stage C prostate cancer. Of note, only 12 of these patients had histologically confirmed negative lymph nodes. Because of the locally advanced nature of the diseases, cryoprobes were frequently placed outside of the prostate laterally or extended into the seminal vesicles to treat presumed areas of tumor involvement. The authors report an average hospital stay of 2 days and minimal morbidity. With respect to the latter, they note sloughed urethral tissue (1.3%), urinary incontinence (2.7%), prolonged urinary retention (1.3%), and urethral stricture (1.3%). Posttreatment biopsies revealed no residual detectable prostatic tumor in 94.8% of patients 3 months after one or two such treatments. The median pretreatment serum PSA was 8.90 ng/mL. In comparison, the median postoperative PSA was reported to be 0.10 ng/mL. In addition, 14 of 23 patients with 1 year or more of follow-up who have maintained negative biopsy status also maintained undetectable serum PSA levels (less than 0.4 ng/mL).

Onik and associates (736) used a similar approach in the treatment of 55 patients with presumed localized prostate cancer. The patients were randomized to two groups. In the first group, freezing was performed using two cryoprobes placed multiple times. In the second group, the tumor was frozen using five cryoprobes (3 mm in diameter) placed simultaneously. The study confirmed the superiority of the latter technique. Of the 55 patients, 23 had 3 months of follow-up with posttreatment biopsies. In the group treated with the 5-probe technique (15 patients), only one (6.7%) demonstrated evidence of residual disease on biopsy. Reported complications included rectal freezing, urethrorectal fistula, sloughing of urethral tissue, perineal ecchymosis, penile edema, ileus, and impotence. With respect to the latter, two-thirds of the patients who were potent before the procedure became impotent after treatment.

De la Taille and associates (218) reported on the impact of cryoablation for clinically localized CaP using an argon-based system. In this study, 35 patients underwent cryoablation of the prostate. Nineteen had received and failed radiation therapy. Cryoablation was used as primary treatment for localized CaP in the remaining 16 patients. All patients received 3 months of combined hormonal therapy before cryosurgery. Twenty-two patients (63%) had an undetectable serum PSA nadir after cryotherapy and 30 (84%) patients had a PSA value of less than 1.0 ng/mL. The mean follow up was 8.3 months. The biochemical recurrence-free survival was 70% at 9 months. Achieving an undetectable PSA nadir was important in this regard. Similarly, patients with a preoperative serum PSA level of less than 10 ng/mL had a statistically higher biochemical recurrence-free survival than patients who had PSA levels of greater than 10 ng/mL (86% versus 42% at 9 months). Complications included rectal pain (26%), urinary infection (3%), scrotal edema (12%), hematuria (6%), and incontinence (6%).

Shinohara and associates (913) reported on the outcomes of 134 patients who underwent 147 cryosurgical ablation procedures for the management of prostate cancer. In their analysis, a PSA nadir of less than 0.4 ng/mL should be achieved following cryotherapy. Higher values were associated with a significant risk of continued PSA elevation and a high likelihood of residual disease detected on prostatic biopsy. Local failure was most often noted at the apex and in the region of the seminal vesicles. Neoadjuvant androgen blockade appeared to reduce the risk of biochemical failure in patients with T_1 and T_2 cancers.

Long and associates (599) reported on the preliminary outcomes of 145 consecutive patients undergoing cryosurgical ablation of the prostate. The minimum follow-up was 12 months and the mean follow-up was 36 months in this cohort. Patients with clinical stages T_{1a} $2T_{3c}$ prostate cancer were included. The overall actuarial rates at 42 months for maintaining PSA less than 0.3 and less than 1.0 were 59% and 66%, respectively. The overall actuarial progression-free rate at 60 months was 56%. Not surprisingly, significantly higher morbidities were seen in previously radiated patients undergoing cryosurgical prostate ablation compared with those who had not undergone previous radiation therapy.

The limited follow-up of these and other patients treated with percutaneous freezing makes any meaningful assessment of the ultimate utility of this technique difficult. At this time, cryoablation and its evolving modifications should be viewed cautiously. In addition, the treatment of patients with progressive disease following prostate cryoablation is a significant concern. In our experience the performance of “salvaged” prostatectomy following failed cryoablation is a technically demanding procedure. In most instances, the patient is already impotent. The major postoperative complication in this context is urinary incontinence, which occurs with distressing frequency. The soft tissue changes induced by cryoablation are in parity with those induced by high-dose radiation therapy. This may very well contribute to problems with postoperative urinary control and healing. The use of external beam radiation (with or without neoadjuvant hormonal therapy) has more intuitive appeal as a salvage option but the ultimate efficacy of radiotherapy has not been rigorously addressed.

Electrohydraulic shock waves, high-frequency ultrasound, and hyperthermia also are being explored with respect to their cytodestructive potential (613). Obviously, any claims regarding antitumor efficacy should be subjected to rigorous scientific scrutiny.

Palliative Surgery

Scrotal Orchiectomy

The advantages and disadvantages of the various androgen-ablative techniques are discussed in detail under Endocrine Therapy. In our opinion, scrotal orchiectomy remains the standard against which all androgen-ablative techniques must be compared. None of the alternative approaches to orchiectomy has demonstrated superiority over this procedure. It has the following various advantages: (a) It can be performed quickly and comfortably with the patient under local anesthesia without mortality. (b) The morbidity, which includes superficial wound infection, scrotal hematoma, wound disruption, and painful cord remnants, is low. (c) Other than its impact on libido, potency, and development of hot flashes and osteoporosis, the systemic effects of the procedure are modest. (d) Upon completion, concerns regarding patient compliance are obviated.

Orchiectomy can be performed by various approaches. We prefer a transscrotal approach through a transverse or midline scrotal incision with the patient under local anesthesia. Routine monitoring of vital signs and IV administration of a mild sedative (e.g., midazolam) can be initiated before the procedure. Following standard surgical preparation and draping, a local anesthetic such as 1% lidocaine or equal volumes of 1% lidocaine and 0.5% bupivacaine (Marcaine) should be injected superficially and into the cord at the base of the scrotum and as a field block at the site of the incision. The skin, dartos, and intervening tunics are incised until the parietal layer of the tunica vaginalis is identified. An extravaginal or intravaginal dissection can be carried out to deliver the testes gently and expose the spermatic cord. The local anesthetic is sprayed or injected appropriately as the cord is freed, isolated into segments by blunt and sharp dissection, clamped securely, and divided. The testis with the adjacent epididymis and distal cord is then removed. It is our practice to doubly tie the cord remnants with a free tie and a suture ligature of chromic catgut. Occasionally, a patient will request insertion of a testicular prosthesis, and this can be done at this time. Additional hemostasis and comfort can be provided by the application of a bulky compressive dressing that can be maintained by the use of elastic-type compression applied in a crossing fashion from the posterior aspect of the buttock to the lower abdomen. Although subepididymal and subcapsular orchiectomy have had their advocates in the past, simple complete orchiectomy as described earlier is our preference.

Channel Transurethral Prostatic Resection

Not infrequently, the elderly patient with locally aggressive or metastatic CaP will be seen with symptoms of significant bladder neck obstruction or acute urinary retention. As discussed in the section on endocrine therapy, the initiation of androgen withdrawal therapy will permit the resolution of obstructive symptoms in most of these patients within 3 to 6 months. If symptoms are severe, patients can be maintained on urethral or suprapubic catheter drainage during this period. Such an approach is reasonable in patients deemed too high a risk for the anesthetic and surgical stress associated with a channel TURP. However, most patients who have significant obstructive sequelae are anxious to achieve a catheter-free status quickly. The majority of patients who are deemed good surgical risks are candidates for channel TURP and scrotal orchiectomy as a combined procedure. The technique of endoscopic resection has been thoroughly discussed in the previous chapter. The urethra may be fixed, rigid, and strictured. When such difficulty is encountered, it may be best to use a smaller (24 Fr) sheath rather than traumatize the friable tissue lining the elongated and irregular prostatic urethra. At times, the resectoscope may best be introduced under direct vision or may need to be introduced over a catheter guide with the bladder full. Once access to the bladder is provided, careful endoscopic inspection of the regional anatomy is imperative. The trigone and ureteral orifices should be identified, if possible, although tumor extension in this area may obliterate normal landmarks. Administration of IV indigo carmine may help identify the ureteral orifices. The verumontanum is usually distinct, but occasionally, the resectionist needs to use rectal palpation to confirm the zone of the external urethral sphincter. The procedure should establish a circumferential channel through the obstructing tissue; in some cases it will be possible to perform a relatively clean endoscopic resection down to the capsule. In other cases, normal landmarks will be obliterated. The goal of the procedure is to achieve satisfactory voiding with control. In previously untreated patients, endocrine control measures usually produce a further reduction in the obstructive symptoms and sequelae.

Radiation Therapy

The first reported application of ionizing radiation for the treatment of CaP was that of Paschkis and Tittinger (750). These investigators used a radium capsule that

was attached to a cystoscope, with the latter being positioned in the prostatic urethra for the duration of treatment. Soon thereafter Hugh Young devised radium carriers that were adaptable for intrarectal and intraurethral use. He used interstitial radium needles for the treatment of CaP and reported his technique and results in 1922. Since then, radiation therapy has assumed an important role in the treatment of locally contained and metastatic CaP.

External beam radiation therapy using high-energy photons (x-rays) or heavy-particle beams (neutrons and protons) may provide potentially curative therapy. Routine use of CT scans and computer-based image analysis to construct dosimetry portals has enhanced the safety and efficacy of these approaches. The development of 3D, conformal treatment planning holds additional promise in this regard (580). Similarly, TRUS-guided interstitial radiation therapy (^{125}I and ^{103}Pd) (103,801,1057) has replaced earlier open-implantation approaches (120,1089). These “guided brachytherapy” techniques are associated with more precise seed distribution and an apparent improvement in local disease control. External beam therapy also appears to enhance local disease control as an adjunct to radical prostatectomy when the surgical margins are shown to be compromised on step-section analysis of the postoperative specimen. From a purely palliative standpoint, radiation therapy has demonstrated utility in the management of pain secondary to skeletal metastases, the relief of ureteral and bladder neck obstruction, and the prevention of painful gynecomastia attendant to the use of estrogen. This section presents a brief analysis of these areas.

General Principles of Radiation Biology

According to conventional nomenclature, 1 gray (Gy) is equivalent to the deposition of 1 joule of energy per kilogram of tissue and equals 100 rad. The latter had constituted the unit of absorbed dose formally used (580). It is now well established that double-strand breaks in the DNA molecule account for most radiation-induced cytotoxicity (269). The M phase and the boundary between G_1 and S phases are the most sensitive to radiation (730,921). Conventional radiation therapy involves the production of high-energy photons that induce these double-strand DNA breaks indirectly through the generation of free radicals, with only a small component of impact attributable to direct DNA damage (398). Thus for optimal effects, the tumor target should be of low volume, well vascularized, and well oxygenated.

Protons are particles of approximately 1,835 times the mass of the electron and carry a single positive charge (991). As was the case with photons and electrons, protons interact primarily by ionization. Indeed, only approximately 2% of their energy is deposited through direct nuclear interactions (924). The point of distinction is that photons and electrons exponentially deposit energy as they travel through tissue, which accounts for significant secondary lateral scatter that mandates use of multifield arrangements. The therapeutic advantage of protons resides in the superior controllability of the beam, which permits deposition of maximum energy within the designated volume from a single port (924).

In distinction, neutrons appear to directly damage DNA and therefore are less dependent on the presence of oxygen to accomplish cell killing. For these reasons neutrons are potentially more advantageous in the treatment of bulky necrotic tumors. In addition, neutron injury to DNA appears to be less reparable than photon-induced injury, and neutron-irradiated cells tend to exhibit less variation in radiation sensitivity across the cell cycle.

In addition to the direct/indirect impact of high-energy photons and heavy particle beams (protons, neutrons) in the breakage of DNA strands, evidence has accumulated that radiation induces programmed cell death (apoptosis) as an additional mechanism, culminating in cellular death (580). The latter is now perceived to be a dynamic process characterized by (a) volume reduction accompanied by an increase in cell density, convolution, and blebbing of the cell surface; (b) chromatin condensation and nucleosomal fragmentation associated with the activation of an endogenous calcium, magnesium-dependent endonuclease; (c) recognition by phagocytic cells; and (d) a dependence upon active protein synthesis (1109).

Figure 33.76 illustrates the classic pathway for apoptosis induction and cell death. It is now evident that tumor-suppressor mutations, oncogene activation, and growth factor signaling all modulate the induction of apoptosis by ionizing radiation (838). It is not fully appreciated how cells actually “sense” the single-and double-stranded DNA breaks associated with exposure to ionizing radiation. In most instances p53 protein activation is a critical early event in this process. DNA damage induced by ionizing radiation results in the binding and activation of several phosphatidylinositol-3–like nucleoproteins. The latter include ataxia-telangiectasia mutated protein (ATM), ATM-related protein (ATR), and DNA-dependent protein kinase (DNA-PK). These products result in the modification and activation of p53 and its downstream target genes (838). A unique 393-amino acid phosphoprotein, p53 contains distinct domains that mediate transcription activa- tion sequence-specific DNA binding, recognize DNA dam- age, and activate the p53 molecule itself, as well as protein–protein interactions. The intracellular accumulation of p53 is in large part attributable to an increase in its nuclear half-life. Transcription activation mediated by p53 involves the binding of this molecule to a consensus sequence in target genes. The latter encode proteins that are strategic for completion of the cell death pathway and include (a) Bax, the inhibitory binding partner of bcl-2, which pushes cells into apoptosis; (b) IGF-binding protein 3, which binds IGF-I and prevents it from activating an antiapoptotic signaling pathway; (c) p21 $^{WAF1/CIP1}$ induces G_1 arrest; (d) Gadd45, which promotes cell cycle arrest and DNA repair; and (e) murine double minute-2 (Mdm-2), which promotes late inactivation of p53 transcriptional activity. These events are summarized in Fig. 33.77. The apoptosis-activating factors (APAFS1-3) mediate deoxyadenosine triphosphate-cytochrome c-dependent cleavage of procaspases into active enzymes. Ultimately, activation of an enzyme (flipase) induces the translocation of phosphatidylserine from the inner to the outer cell membrane. The latter is then recognized by annexins on the surface of macrophages, which results in the elimination of apoptotic cells by phagocytosis so that they do not provoke an inflammatory response (838).

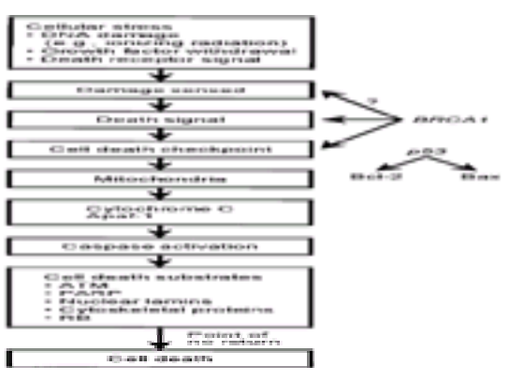

FIGURE 33.76. Classic pathway for apoptosis and cell death. FIGURE 33.77. Small p53-dependent DNA damage response pathways activated by ionizing radiation. DNA damage induced by ionizing radiation causes binding and activation of several phosphatidylinositol-3–like nuclear proteins (ATM, ATR, DNA-PK), resulting in modification and activation of small p53 and its downstream target genes. See text for discussion. (From Rosen EM, Fan S, Goldberg ID, et al. Biological basis of radiation sensitivity. Part 2: cellular and molecular determinants of radiosensitivity. *Oncology* 2000;14:741, with permission.)

Radiation-resistant Phenotype

Irradiated cells arrest for several hours in the G_2 phase of the cell cycle before entering the M phase, which appears to be related to a transient, radiation-induced diminution in the protein cyclin B, which is required for this traverse through the cell cycle (580). It appears that differences in cellular sensitivity to radiation-induced injury may be related to the successful evocation of repair mechanisms during this break in the cell cycle.

Radiation therapy appears to activate signal-transduction pathways mediated by protein kinase CN and tyrosine kinase, which in turn are responsible for the induction of a number of genes (c-fos, c-jun, EGR-1, BRCA1, NF-kB) and proteins (bFGF, TGF-b, TNF, and TPA) (580). It is assumed that some of these molecular events are strategic to the cell survival following radiation injury.

The p53 gene is linked to the transition from the G_1 to the S phase of the cell cycle (61). It appears that wild-type (i.e., normal) p53 function is required for the sensitivity of many tumor cells to ionizing radiation. Moreover, loss of p53 function, which may occur through mutation, may be associated with resistance to radiation-induced cell killing (628). Most p53 mutations appear to be point mutations in the DNA-binding domain, which results in a mutant protein defective in sequence-specific DNA binding. These mutant p53 proteins fail to activate the Bax promoter. Loss of the ability to transactivate the Bax gene would translate into low levels of Bax protein, which is an important inducer of apoptosis (838). Of note, p53 mutations have been reported in both BPH and CaP specimens (79,166,412,704). With respect to the latter, p53 mutations appear to predominate in high Gleason histotype, androgen-independent, human prostate cancers of advanced stage (79,412,704).

As stated previously, radiation therapy can activate programmed cell death pathways that contribute to cell lethality. The bcl-2 protooncogene is unique in that its expression results in extending the viability of cells, independent of promoting cell division, by abrogating programmed cell death mechanisms (626). Bcl-2 prevents apoptotic death ordinarily induced by the c-myc protooncogene. A noteworthy feature of bcl-2 activity is its ability to block irradiation-induced cell death (902,986). This relationship is particularly intriguing given the fact that high-energy photons and protons produce hydroxyl radicals (the most reactive oxygen free radical species), which in turn induce oxidative damage to macromolecules such as DNA. Evidence has accumulated that bcl-2 regulates an antioxidant pathway at sites of free radical generation and prevents the latter from inducing apoptosis (422). Bcl-2 is a pore-forming protein of the outer mitochondrial membrane. It is thought to block apoptosis by binding to Apif-1 and/or preventing the release of cytochrome C from mitochondria (838). It has been demonstrated that the bcl-2 protooncogene is constitutively expressed in the basal cells of the prostatic glandular epithelium (423), which, unlike the secretory epithelial cells, are unaffected by androgen withdrawal (549). McDonnell and associates (626) observed that bcl-2 was undetectable in 13 of 19 cases of androgen-dependent CaP. In contrast, androgen-independent cancers displayed diffuse, high levels of bcl-2 staining. The potential association between the latter finding and the emergence of radiation-resistant phenotype is most compelling.

Scherr and associates (881) performed immunohistochemical staining for bcl-2 and p53 on pretreatment needle biopsies in 54 patients who underwent radiotherapy for localized prostate cancer. In this study, a PSA nadir of less than 1 ng/mL after therapy was considered a successful treatment response. Of the bcl-2 and p53 positive cases, treatment failure was noted in 85% and 88% of patients, respectively. Indeed, a combination of both adverse phenotypes was associated with universal treatment failure. If these results are confirmed, it would suggest that probing of biopsy tissues for bcl-2 and p53 expression might facilitate treatment planning and help identify those patients whose tumors are constitutively radiation resistant.

These and other perceptions suggest that relative or absolute radiation-resistance may be a feature of human CaP systems endowed with the following features: (a) high tumor volume/stage (399); (b) high Gleason score (399,952); (c) aneuploid DNA content (952); (d) pretreatment PSA greater than 15 ng/mL (562); (e) androgen-independent tumor clones (1015); (f) mutated p53; (g) increased bcl-2 expression; and (h) increased tumor angiogenesis-microvessel density (399); and (i) specific growth factors such as vascular endothelial cell growth factor (VEGF), basic fibroblast growth factor (bFGF), hepatocyte growth factor/scatter factor (HGF/SF), and IGF-I (838).

Conventional External Beam Radiation Therapy

Various sources have been used to generate high-energy photons ranging from cobalt 60 sources to the present-day linear accelerators. The advantages of the latter include the production of ionizing radiation with higher energy thresholds (4 to 35 MeV), which are capable of being focused onto the tumor target with greater precision and less attendant “scatter” distributed to the normal surrounding tissues.

Benefit-to-risk ratio of external beam radiotherapy is in large part contingent on the proper construction of the fields (portals) of radiation coupled with the timing and amount of ionizing radiation (dosimetry) delivered to the chosen tissues. Before the advent of CT scanning in the late 1980s, radiation oncologists were required to construct the treatment fields by hand. Obviously, the introduction of whole-body CT scanning made accurate, cross-sectional, anatomic imaging readily available (Fig. 33.78). The next major advance in the construction of dosimetry portals occurred in the 1980s with the application of computer-graphics technology to CT scanning, thus permitting the 3D display of regional anatomy, instead of the more traditional two-dimensional imaging (Fig. 33.79) (580). Although 3D conformal radiotherapy using heavy charge particle beams has been available for many years, this method has only recently been extended to external high-energy x-ray therapy (582). Consequently, most of the early data regarding the risks/benefits of external beam therapy have been generated using a four-field box technique popularized by Bagshaw (30,31) (Fig. 33.80). The technique is described briefly in the following paragraph.

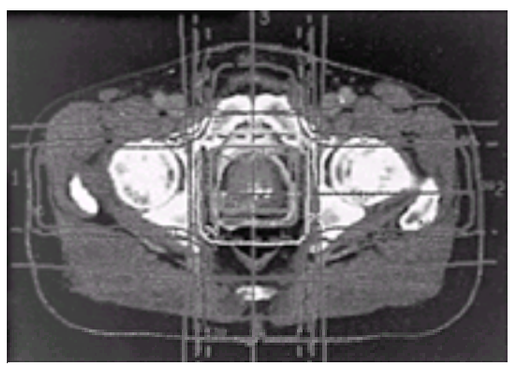

FIGURE 33.78. Example of a computed tomograph–based treatment plan in a patient with prostate cancer. This technique in concert with computer-assisted image analysis greatly enhances the accuracy of external beam radiotherapy. (From Lichter AS, Lawrence TS. Recent advances in radiation oncology [Review]. *N Engl J Med* 1995;332:371, with permission.)

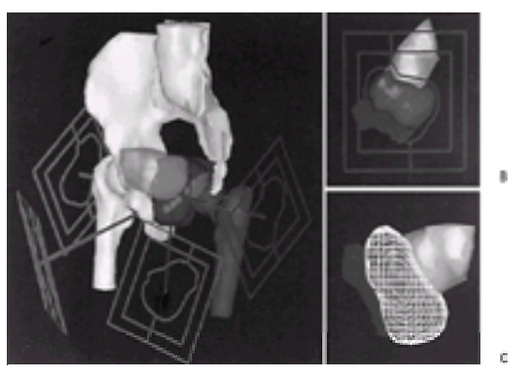

FIGURE 33.79. Three-dimensional treatment planning for radiotherapy of the prostate. **A** demonstrates a three-dimensional view of the pelvis and the orientation of four radiation beams contoured to treat the prostate precisely. **B** is a “beam's-eye-view display,” which demonstrates the “view” of the prostate from the perspective of the radiation beam. **C:** Three-dimensional dose display. (Lichter AS, Lawrence TS. Recent advances in radiation oncology [Review]. *N Engl J Med* 1995;332:371, with

permission.)

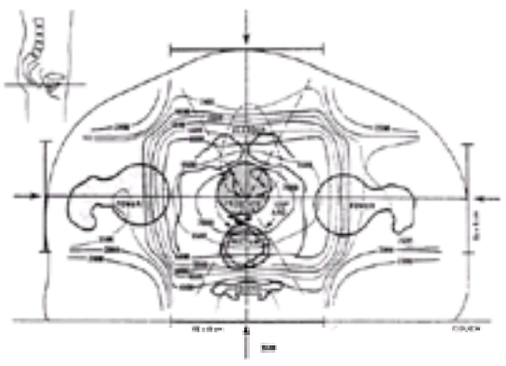

FIGURE 33.80. Anteroposterior and lateral portals of the four-field box technique used by the Stanford Radiation Oncology Group. Also illustrated are the left and right 120-degree lateral arcs for the prostatic boost. (From Bagshaw MA. External radiation therapy of carcinoma of the prostate. *Cancer* 1980;45:1912, with permission.)

Before highlighting the actual radiation portals with indelible ink, the bladder and rectum were identified by the instillation of contrast, a radiopaque marker was placed, and AP and lateral views of the pelvis were obtained. CT imaging was used for further clarification of the pelvic anatomy. Ultimately, the volume of tissue destined for irradiation was quantified. Bagshaw and associates (28) adopted a four-field box technique that was used to treat the pelvis and prostate, with a boost to the prostate delivered via either bilateral 120-degree arches or a four-field technique. The AP portals extended from L-5 to the ischial tuberosities and encompass the entire area of the true pelvis, including the lateral aspect of the iliac nodes bilaterally. The lateral portals projected in the anterior half of the rectal lumen to the ventral portion of the iliac nodes while maintaining the same superior and inferior limits as described for the AP portals. Whole pelvic radiation was not required for patients who have undergone an antecedent PLND, and appropriate adjustments were made in the dosimetry portals. In general, the radiation therapy was delivered through an isocentric technique that entails a circumferential movement of the radiation source about the patient, who is maintained in a supine position. Pelvic dose has been estimated to range from 48 to 54 Gy and the prostatic dose from 68 to 75 Gy (487).

The Stanford group has reported that for organ-confined CaP (stages A and B), survival rates approach 81% at 5 years, 59% at 10 years, and 36% at 15 years. In the case of extracapsular (stage C) disease, the 5-, 10-, and 15-year projected overall survival falls to 62%, 36%, and 18%, respectively (31).

In 1988, Bagshaw and associates (27) updated their experience with radiation therapy in the treatment of more than 900 patients with prostate cancer. They reported an overall 15-year survival of 45%, 35%, 33%, 20%, and 10% for Stanford stages T_0, T_1, T_2, T_3, and T_4. Disease-specific survival at 15 years for the same patients was 85%, 64%, 45%, 33%, and 15%, respectively. For patients with stage B_1 cancer, the 15-year overall survival was 50%. Of those patients potent before therapy, 86% maintained potency at least 15 months after treatment and 50% for 7 years after therapy.

Hanks (404) has reported a more recent update on the effectiveness of external beam radiation therapy for organ-confined and locally advanced CaP. In this review, he reported on 104 patients with clinical T_{1b}, T_2 prostate cancer with pathologically negative lymph nodes who were treated with external beam radiation. In that study, observed actuarial survival of 87% and 63% were noted at 5 and 10 years, respectively. This contrasts with expected survival figures of 81% and 59% at those same time points. The study also demonstrated a cause-specific mortality of 14% at 10 years. Finally, 87% of patients were reported to be free of clinical recurrence at 10 years.

Hanks (404) also provides an analysis of the impact of external beam radiation on locally advanced T_{2b} CaP in his analysis of the 10-year results from Washington University and the 15-year results from Stanford. He reports a 10-year survival of 61% and 15-year relapse-free survival of 33% in this cohort. As anticipated, the results of external beam radiation therapy in the management of stage T_3/T_4 prostate cancers are less impressive. He demonstrated overall survivals of 35% to 45% at 10 years and 18% to 27% at 15 years. His latter observations were derived from an analysis of stage C CaP reported from multiple single institutions, the Radiation Therapy Oncology Group (RTOG) trials, and the Patterns of Care USA National Averages. It should be emphasized at this point that not all studies enthusiastically endorse the role of radiation therapy in the management of locally advanced CaP. For example, Paulson and associates (753) reported their series of 73 patients with stage C CaP who were randomized to either full-field pelvic irradiation or delayed hormonal therapy. When evidence of treatment failure was first used as an endpoint parameter, no difference could be discerned in disease response between the two treatment groups.

Similar controversy involves the role, if any, of radiation therapy in the treatment of patients with stage D_1 disease. Bagshaw (32) reported an actuarial survival of 58% at 5 years following external beam radiation therapy. On the other hand, Smith and colleagues (931) reported that only 17% of patients with stage D_1 disease who received external beam radiation therapy were free of disease at 5 years. Moreover, when compared with a similarly staged group of patients who did not receive radiation therapy, there was no discernible difference in disease-free survival or control of symptomatic manifestations of local disease. It would seem that nodal irradiation alone offers marginal benefit to these patients.

An element of controversy surrounds the advisability of TURP before definitive radiation therapy in patients with CaP presenting with symptoms of bladder outlet obstruction. Fowler and associates (308) stated that TURP may disrupt intraglandular lymphatic and vascular channels and increase the likelihood of tumor dissemination. McGowan's study (627) was perhaps the most condemning of TURP before the initiation of external beam radiation. In those patients with stage B or C disease, 5-year disease-free survival was reported to be 72% in the radiation-only group as compared with 51% in those patients having undergone prior endoscopic resection. In retrospect, these ominous statistics probably reflect the presence of a relatively greater local tumor mass in those patients with severe obstruction and the common perception that patients with obstructive symptoms from carcinoma have a higher incidence of disseminated disease. Furthermore, despite these theoretic concerns regarding the potentially deleterious impact of TURP before radiation therapy, no detrimental impact was documented in the studies conducted by Hoffmann and associates (428), Kuban and associates (540), Paulson and Cox (752), and Meacham and associates (636).

In patients in whom relief of bladder neck obstruction is deferred, only 10% of patients with stage C cancer required TURP after completion of definite radiation therapy (353). In general, we prefer to perform transurethral incision of the prostate (TUIP) or TURP before radiation therapy in patients whose severe obstructive/irritative voiding symptoms have not responded to androgen ablation and appropriate doses of a long-acting a_1-blocking agent. It is our belief that preemptive treatment is preferable to placement of an indwelling catheter during the course of radiation therapy or in the immediate posttreatment period.

Conformal External Beam Radiation Therapy

The failure of high-energy photons to eradicate organ-confined CaP can occur for several reasons. First, it has been demonstrated that conventional, two-dimensional treatment planning often underestimates the true volume of the prostatic target, which results in inadequate treatment. Second, it is a common perception that radiation-resistant prostatic tumor clones develop with a relatively high frequency. It has been demonstrated that higher doses are required to improve local tumor control. However, standard treatment planning techniques are associated with significant complication rates if doses exceed 7,000 cGy because of their inability to adequately shield the bladder and rectum (570).

Advances in computer technology have enabled the implementation of 3D conformal radiation therapy (CRT) as an approach to overcome some of the obstacles encountered by conventional radiotherapy. Three-dimensional treatment planning is based on the ability to anatomically define each critical subvolume within the entire 3D space of irradiated tissues and to accurately calculate the dose delivered at each point (569). 3D CRT uses advanced imaging technology for tumor and normal organ segmentation and computer-aided optimization to generate treatment plans that conform the prescribed dose to the anatomic boundaries of the prostate target volume in its entire 3D configuration, while maximally excluding the adjacent normal organs (569). Indeed, the ability to reduce the volume of normal tissues

that receive high radiation doses is a critical feature of 3D CRT.

The availability of 3D, computer-aided, “conformal” treatment planning permits precise targeting of the treatment field conformed to the shape of the prostate target (Fig. 33.81). In this approach, radiation beams are contoured to treat the prostate precisely, and the nontarget component of the rectangular radiation beam is blocked by a lead alloy to protect the adjacent normal structures. In addition, short-term observations indicate the dose delivered to target tissue can be increased by at least 10% to 20% without increasing the complication rate (570,580). Improved patient immobilization within individually fabricated thermoplastic casts (Fig. 33.82) and the use of real-time portal imaging devices are integral parts of this new technology (404).

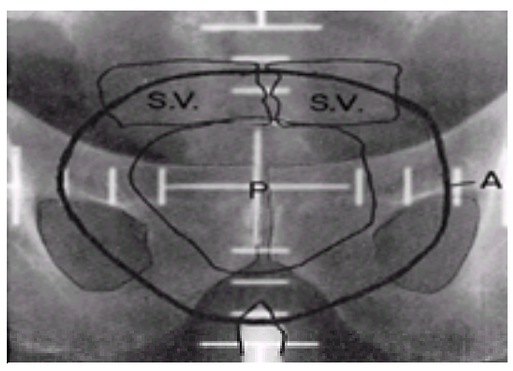

FIGURE 33.81. A-P simulator radiograph highlighting the prostate *(P),* seminal vesicles *(SV),* and portal aperture *(A).* Note that the urethrogram is outlined. (From Hanks GE. Treatment of early stage prostate cancer: radiotherapy. In: DeVita VT, Hellman S, Rosenberg SA, et al, eds. *Important advances in oncology.* Philadelphia: JB Lippincott, 1994, with permission.)

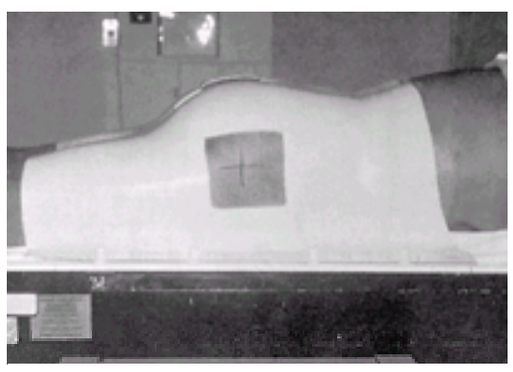

FIGURE 33.82. The development of conformal radiotherapy has been facilitated by the design of thermoplastic immobilization devices, as illustrated in this figure. [From Liebel SA, Heimann R, Kutcher GJ, et al. Three-dimensional conformal radiation therapy in locally advanced carcinoma of the prostate: preliminary results of a phase-I dose-escalation study. *Int J Radiat Oncol Biol Phys* 1994;28(1):55, with permission.]

Leibel and associates (570) reported their preliminary experience in 324 patients with CaP treated with 3D conformal radiation therapy in a phase I dose-escalation study. The treatment planning did not involve pelvic lymph node irradiation because of the absence of a proven benefit for that treatment extension (570). This study included patients with clinical stage T_1 to T_3 disease. Minimum tumor dose was 64.8 to 66.5 Gy in 87 patients, 70.2 Gy in 138, 75.6 Gy in 69, and 81.0 Gy in 30. Fifteen percent of patients required medication for relief of rectal symptoms and 34% for urinary symptoms. Only two (0.6%) patients experienced grade 3 to 4 late complications. The 3-year actuarial probability of survival with a normal serum PSA level was 97% for patients with stages T_{1c} and T_{2a}, 86% with stage T_{2b}, 60% with stage T_{2c}, and 43% with stage T_3 disease. A multivariate analysis demonstrated that biochemical relapse was likely in patients with an initial PSA greater than 20 ng/mL, stage T_3 or greater, and a Gleason histotype of 7 or more.

Three-dimensional Conformal Radiation Therapy and Intensity-modulated Radiation Therapy

Intensity-modulated radiation therapy (IMRT) combines two advanced concepts to deliver 3D conformal radiation therapy: (a) inverse treatment planning with optimization by computer and (b) computer-controlled intensity modulation of the irradiation beam during treatment (1005,1128). Multiple IMRT beams with different profiles are used to achieve a composite with a homogenous dose distribution within the planning target volume. The addition of IMRT to 3D CRT requires both hardware and software modifications that permit a coplanar, five-field technique designed to treat patients to prescription-dose levels of greater than or equal to 81 Gy, while at the same time minimizing the risk of significant rectal and bladder toxicity. Figure 33.83 depicts the impact of dose on local control as assessed by prostate biopsies performed at 2.5 years or longer following 3D CRT/IMRT. Studies by Zelefsky and associates (1128) demonstrate that use of IMRT is associated with an impressive reduction in both acute/late urinary and rectal toxicity in patients with prostate cancer treated to 81 Gy. Leibel and associates (569) also have confirmed the favorable impact of intensity modulation on the conduct of high-dose 3D CRT. Table 33.26 depicts the incidence of late complications by RTOG morbidity grade in 1,100 staged T_{1c} to T_3 prostate cancer patients treated with a combination of 3D CRT/IMRT to dose levels of 64.8 to 86.4 Gy.

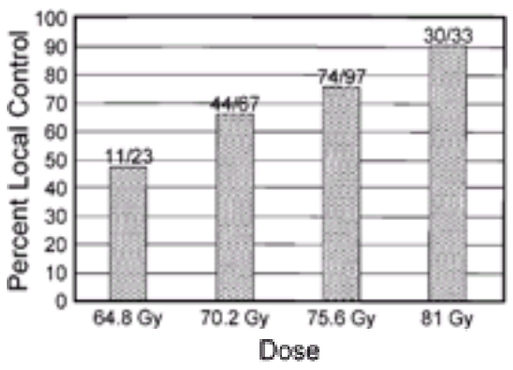

FIGURE 33.83. Impact of dose on local control, as determined by prostate biopsies performed greater than or equal to 2.5 years following 3D-CRT/IMRT. The number of patients with negative biopsy specimens per total number biopsied is depicted above each bar. TABLE 33.26. INCIDENCE OF LATE COMPLICATIONS BY GRADE IN 1,100 STAGE T_{1C} to T_3 PROSTATE CANCER PATIENTS TREATED WITH 3D CRT/IMRT TO DOSE LEVELS OF 64.8-86.4 GY

Heavy Particle Therapy

Russell and associates (850) compared the efficacy of fast neutron radiotherapy used in a mixed-beam (neutron/photon) treatment schedule with conventional photon irradiation alone in 91 patients with stage C or D_1 CaP. Actuarial survival at 8 years was 63% for the mixed beam group and 13% for patients receiving only conventional treatment. Furthermore, "apparent" freedom from locally recurrent CaP was 77% and 31% for the mixed beam and photon-only groups, respectively. In this particular study posttreatment biopsies were performed randomly, and no conclusions can be drawn regarding the impact of fast neutron radiotherapy in respect to the complete histologic eradication of CaP in this cohort. Laramore and associates (559) published a final report of that same RTOG-sponsored phase III clinical trial. The 10-year results for clinically assessed local control were 70% for the mixed-beam group compared with 58% for the photon group. Overall survival was 48% for those patients receiving fast neutron radiotherapy versus 29% for the photon-only group.

As of 1992, 14 centers worldwide were performing proton beam treatments, including three in the United States. Virtually all proton beam therapy has been based on machines designed and installed for basic high-energy particle physics research. In the update provided by Suit and associates (991), a phase III trial of proton beam therapy as the "boost" dose in the treatment of stage T_3 CaP had generated interesting results. In this study all patients received 50.4 Gy × four-field "box" technique using 10 to 25 MV x-ray beams. These patients were then randomly assigned to receive the "boost" dose by either conventional x-rays or protons. The final dose levels of the prostate were 68.4 Gy or 75.6 CGE (60 CoGy equivalent) for the x-ray and proton treatments, respectively. The local control results in the two arms were 81% and 89%, respectively, at 5 years. Whether the theoretic advantages of proton beam therapy will translate into durable clinical results awaits confirmation.

Complications of External Beam Radiotherapy

Catalona (154) has nicely summarized the complications attendant to external beam radiation therapy. GI tract symptoms are quite common and occur in 30% to 40% of patients while undergoing such treatment. These symptoms most often manifest themselves approximately the fourth week of therapy and commonly include diarrhea, rectal pain, and tenesmus. Although common, these symptoms are rarely disabling, and 95% of patients can continue the treatment protocol uninterrupted. Approximately 12% of patients will have longer-lasting GI symptoms, which include chronic diarrhea and anorectal disease (ulcers, fistulae, strictures). The incidence of severe chronic radiation proctitis induced by pelvic irradiation is reported to be 2% to 5% (509). These symptoms include diarrhea, tenesmus, abdominal pain, and rectal bleeding. Less common but more ominous complications include perforation, stenosis, and ulceration. Conservative management includes the use of a low-residue diet, steroidal enemas, and laser therapy or electrocoagulation to halt bleeding. Hyperbaric oxygen therapy improves the microvascular environment and may have a beneficial impact on treatment-refractory radiation proctitis (509). Despite these symptoms, diverting colostomies are rare (less than 1%). GU symptoms are noted with an equivalent degree of frequency, with the most common being urinary frequency and dysuria. Hematuria is uncommon as an acute complication (5%). The incidence of urethral stricture has been cited as between 4% and 8% and seems more likely if bladder neck surgery has immediately preceded radiation therapy (353,814,914). It seems advisable to defer the initiation of external beam therapy 6 to 8 weeks following such procedures.

In the absence of previous pelvic surgery, it is unusual to develop disabling lymphedema of the genitalia and lower extremities. The incidence of this complication rises, however, to approximately 40% in patients having undergone previous lymphadenectomy using standard surgical margins. This complication has been minimized by the use of a limited lymphadenectomy or by using a radiation portal restrictive to the prostate. Severe cutaneous erythema is unusual with the use of modern-day linear accelerators, but occasionally a patient will have a localized problem in the intergluteal fold. Finally, the number of patients experiencing erectile dysfunction following radiation treatments seems highly variable even in reports from the same institution. Recent reports by Zelefsky and associates (1128) suggest the frequency of impotence following external beam radiation ranges from 25% to 60% and from 15% to 25% after permanent radioactive seed implantation (1128). These same investigators documented that sildenafil improved erectile function in greater than two-thirds of patients with postradiotherapy impotence. Patients with less severe dysfunction were most likely to benefit from this pharmacologic intervention. Potosky and associates (792) assessed health outcomes after radical prostatectomy (n = 1,156) versus external beam radiotherapy (n = 435). Almost 2 years after treatment, men who had undergone radical prostatectomy were more likely than men receiving radiotherapy to be incontinent (9.6% versus 3.5%; p <.001) and to have higher rates of impotence (79.6% versus 61.5%; p <.001). Large and statistically significant declines in sexual function were observed in both treatment groups. In contrast, men undergoing radiotherapy reported greater declines in bowel function then did men receiving radical prostatectomy. Many of the chronic complications listed earlier may be due to small-vessel occlusive disease secondary to radiation-induced endarteritis obliterans. A compilation of the complications associated with radiation therapy is depicted in Table 33.27.

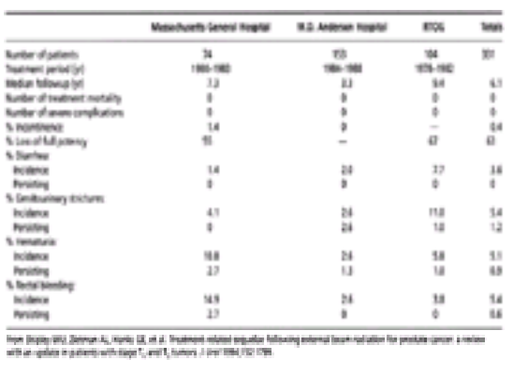

TABLE 33.27. COMPLICATIONS (GRADES 2 AND 3) FOLLOWING EXTERNAL BEAM RADIATION FOR STAGES T_1 OR T_2 PROSTATE CANCER

Interstitial Radiation Therapy

Interstitial radiotherapy has intuitive appeal because of the theoretic ability to deliver supralethal doses of ionizing radiation directly to the area of the primary tumor while sparing the surrounding uninvolved tissues. The appeal of such an approach also lies in the fact that it is technically less demanding than radical prostatectomy and can provide the patient with some reasonable assurance that urinary control and sexual potency will be preserved.

Historic Perspective

Although Barringer reported the transperineal implantation of radium needles in 1917, only isolated reports of this therapy appeared until Whitmore and associates (1089) popularized ^{125}I implantation. Some attractive properties of the ^{125}I isotope include (a) the emission of pure irradiation that simplifies dosimetry calculation; (b) a half-life of approximately 60 days, ensuring potentially cytotoxic levels of irradiation to the involved tissues for approximately 1 year; (c) a half-value of tissue penetration of approximately 1.7 cm, providing relative protection of the surrounding tissues and to persons in contact with the patients; (d) the theoretic ability to

deliver 25,000 cGy to the center of the prostate and 18,000 cGy to its periphery during the year of therapeutic efficacy (103,154). Conversely, disadvantages of ^{125}I therapy include (a) its long half-life somewhat complicates the administration of adjunctive external beam radiation therapy, (b) the construction of the radioactive seeds with welded ends interferes with a homogeneous circumferential radiation field, and (c) the short depth of penetration requires extremely accurate placement of the seeds to obtain a homogeneous distribution of radiation (417). This latter feature was particularly problematic when the retropubic implantation technique was used.

The implantation technique popularized at Memorial Sloan-Kettering Cancer Center was preceded by a limited extraperitoneal PLND performed through a lower midline incision. After completion of the lymphadenectomy, the endopelvic fascia was incised bilaterally, permitting partial mobilization of the gland. When adequate retropubic exposure of the patients had been obtained, a specifically designed instrument (Mick or Henschke) was used to deposit between 40 and 70 radioactive seeds at approximate intervals (5 mm). Manual examination of the rectum was required to ensure proper positioning of the needles (17 gauge and 15 cm long) through which two to four seeds are deposited. Needles were removed after insertion of the radioactive seeds. Periprostatic veins were commonly lacerated during the insertion of the needles, requiring sustained tamponade after their removal to obtain adequate hemostasis. Because accurate seed placement was impossible in the presence of a very thin peripheral rim of tissue, patients who had undergone a previous TURP or open prostatectomy generally were excluded from this procedure. Similarly, patients with clinical stage B_2 or C disease were poor candidates for retropubic ^{125}I implantation because the large tumor burden generally exceeded the penetration capability of the isotope. Finally, antecedent or subsequent external beam radiation therapy was fraught with significant risks due to unpredictable tissue damage.

In 1982, Grossmann and associates (389) provided a reanalysis of the initial 100 patients treated with this technique and originally reported by Whitmore in 1980 (1088). The overall 5-year survival rate was 95% for stage B_1, 64% for B_2, and 59% for stage C lesions. Tumor-free survival, however, was noted to be 66% for B_1, 30% for B_2, and 21% for stage C neoplasms (154). In 1983, Whitmore (1089a) presented 5-year disease-free survival data for T_1, T_2, T_3, and T_4 tumors, citing results of 79%, 53%, 45%, and 19%, respectively. In that study, he noted a local recurrence rate of approximately 7% without any apparent relationship to tumor grade. However, distant treatment failure was directly correlated with tumor grade, being noted in 14% of low-grade tumors and 67% of poorly differentiated prostate cancers. Patients with one positive lymph node and any T category were found to have an actuarial survival of 71.5% compared with 52.4% if two nodes were involved.

Herr (417) summarized the complications attendant to retropubic ^{125}I implantation, which included (a) an operative mortality of 0.5% for 800 patients treated; (b) thromboembolic disease in 7% of patients, (c) complications of pelvic surgery in approximately 10% of patients, including lymphocele formation, abscess, hematoma, and pelvic cellulitis; (d) self-limited irritative voiding symptoms; (e) lower extremity and genital edema in 2% of cases; (f) proctitis, which usually resolved within 1 year; (g) impotence in 10% of patients; and (h) rectourethral fistulae. The development of the latter was most likely in those patients with large glands treated with high doses of radiation, those individuals requiring TURP following ^{125}I implantation, and patients exposed to external beam therapy either before or after seed implantation.

In 1972, Carlton and associates (120) popularized^{198} Au implantation combined with external beam therapy. The unique features of ^{198}Au include (a) the emission of both b and g radiation, (b) a half-life of 2.7 days rendering the seeds virtually depleted of radiation 3 weeks after implantation, (c) a half-value layer (penetration) in tissue of 4.5 cm so that exquisitely accurate seed placement was not necessary, and (d) an intrinsic energy higher than ^{125}I (420 keV versus 28 keV).

These inherent properties of ^{198}Au simplified patient selection. Because of its higher energy threshold and greater depth of tissue penetration, precise seed placement was not a critical factor. Therefore patients who had undergone TURP or open prostatectomy were not excluded from treatment. Similarly the procedure potentially was available to patients with large primary tumors (up to 6 cm) with or without involvement of the prostatic urethra, bladder neck, or seminal vesicles. Furthermore, in the presence of severe obstructive voiding symptoms, a TURP could be performed with a 6-week hiatus before the implantation of gold seeds (870). Patients with stage A_2, B, and C_1 lesions were considered reasonable candidates for this treatment. Patients were excluded if they had a history of pelvic irradiation, significant anorectal disease, or a primary tumor in excess of 6 cm in diameter.

The technique involved a limited PLND performed through a lower abdominal transverse incision. The endopelvic fascia was divided lateral to the prostate, which permitted partial mobilization of the gland. Following adequate retropubic exposure of the prostate, a special needle implanter was used to deposit six to eight high-activity grains throughout the prostate, concentrating in the area of palpable abnormality. This technique provided a dosage of approximately 3,500 cGy to the tumor. In the presence of seminal vesicle involvement seeds were implanted in that area as well. Two to 3 weeks following implantation, adjunctive external beam radiation therapy was initiated using a linear accelerator. For patients with node-negative disease, 4,500 cGy was delivered to the prostate during a 12-week period. More than 1,000 patients were treated with this protocol. For patients with clinical stage A_2 disease, the disease-free survival rate at 5 years was 38%. Moreover, none of these patients remained disease free at 10 years. For stages B_1, B_2, and C_1, disease-free survival at 5 years was reported as 71%, 59%, and 46%, respectively. For the same stages, 10-year survival figures approached 54%, 26%, and 40%, respectively (870).

A more recent analysis conducted by Gervasi and associates (348) compared the incidence of local recurrence based on clinical recognition of progressive disease in patients with node-positive and node-negative status. This study revealed a local recurrence incidence of approximately 85% in node-positive patients and, in contrast, of 34% in node-negative patients at 10% and 41% at 15 years, respectively.

The reported complications of ^{198}Au implantation combined with external beam radiation include (a) lymphocele formation in 2% of patients; (b) wound infection in 4%; (c) a 10% incidence of thrombophlebitis; (d) mild lower extremity or genital edema in 10%; (e) mild symptoms secondary to irritation of the bladder, rectum, and urethra; and (f) erectile dysfunction ranging from 2% to 40%. No incontinence was reported. Several episodes of rectal injury occurred early in the Baylor series (870).

TRUSP-guided Prostate Brachytherapy

The advent of the anatomic radical prostatectomy and conformal radiation therapy diminished enthusiasm for open prostatic implantation substantially. However, the development of TRUSP (and CT-guided) implantation via a transperineal approach has been responsible for a renaissance of interest in brachytherapy for the management of early stage CaP (1057). Blasko and associates (71) pioneered ultrasound-guided, transperineal, prostate brachytherapy. A conceptually similar approach using CT scans (instead of ultrasonography) was developed at Memorial-Sloan-Kettering Cancer Center at approximately the same time (1057). The ultrasound-guided approach popularized by the Seattle group has been easily explanted to other institutions and constitutes the current mainstream approach of prostate brachytherapy.

The prototypic ideal candidate for prostate brachytherapy should meet several relatively well-defined criteria, including a high probability of localized disease (stage T_1T_{2a}), a pretreatment serum PSA level of less than 20 ng/mL, low to intermediate Gleason score, a projected life expectancy of at least 10 years, and a reasonable surgical risk for a formal anesthetic of 1 to 2 hours duration. The prostatic volume should be less than 60 cm^3 and pubic arch interference must be excluded by pretreatment CT imaging. In the latter circumstance, needle placement in the anterolateral portion of the prostate gland is problematic. In most incidences, 3 to 6 months of androgen ablation can effectively downsize the prostate and eliminate pubic arch interference. The efficacy of this treatment must be validated by repeat CT imaging. In general, previous transurethral or open prostatectomy constitutes contraindications to the procedure because stable seed implantation within the periurethral tissues is quite difficult. In addition, such patients have been prone to urethral necrosis/sloughing and subsequent incontinence. Some have proposed that this represents a relative and not absolute contraindication and that the presence of at least 10 mm of normal prostatic tissue around the prostatectomy defect can ensure accurate and safe completion of the procedure (742). In our practice, this contingency remains an absolute contraindication. Rarely, the presence of abundant corpora amylacea (with acoustic shadowing) mitigates against accurate seed placement. Finally, patients with moderate to severe obstructive/irritative voiding symptoms that fail to respond to optimal pharmacologic management may be poor candidates for seed implantation given the high probability that the procedure and its aftermath may exacerbate these symptoms.

Following candidate selection, an accurate ultrasound volume study of the prostate must be performed. Transverse “cuts” through the prostate are obtained and captured in increments of 5 mL from base to apex. These images are evaluated to specify the target volume that will receive the prescribed radiation dose. Computer planning programs use this volume data to determine the number of seeds required to achieve this dose and the optimal placement of seeds. We prefer a loading pattern that adheres to the principles of uniform rather than peripheral distribution (995). This conceptual paradigm and its inherent advantages are highlighted in Fig. 33.84.

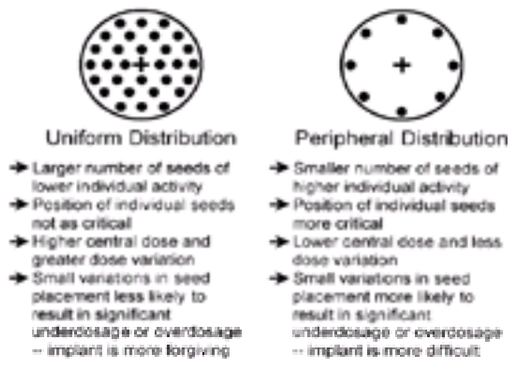

FIGURE 33.84. The relative advantages of uniform versus peripheral seed distribution. (From Sylvester J, Blasko JC, Grimm P, et al. Interstitial implantation techniques in prostate cancer [Review]. *J Surg Oncol* 1997;66:65, with permission.)

In some incidences, patients with more advanced disease (stage T_{2b}, Gleason score 7 or greater, PSA greater than 15) may be considered suitable candidates for brachytherapy approach. In this circumstance, we tend to use a multimodality approach. Most patients are pretreated with total androgen ablation for 3 to 6 months. This treatment is followed by conformal external beam radiation (4,500 cGy) to the prostate and pelvis. An interstitial brachytherapy boost completes this treatment plan (995).

Preparation for the actual procedure is relatively simple. In our practice, most patients are placed on an a-blocker several weeks before the date of surgery. A clear liquid diet is instituted 1 day before implantation. Patients undergo a modified bowel prep and receive appropriate perioperative antimicrobial coverage.

The procedure itself is performed under general or regional anesthesia. The patient is placed in the lithotomy position with both knees at the same height and the buttocks flat on the table surface. An attempt is made to duplicate as much as possible the position established for the ultrasound volume study. The scrotum is anchored to the abdominal wall with sterile adhesive drapes. In our practice, we have not found it necessary to contrast enhance the bladder before the procedure. We previously used an abbreviated urethral catheter through which water-soluble jelly could be instilled to enhance the real-time identification of the urethra so as to avoid injudiciously close seed implantation. We no longer find this approach necessary and instead use liberal transverse/longitudinal imaging, combined with C-arm fluoroscopy. The transrectal probe is inserted and attached to a stabilization unit, which is locked into position on the operating table. The perineal template is secured in position. Real time ultrasound imaging of the prostate is meticulously performed from base to apex at 5-mm intervals. These images are then compared with the hard copy generated during the ultrasound volume study. An electronic grid is superimposed on the image of the prostate and corresponds to the needle-guiding template attached to the stabilization unit (Fig. 33.85).

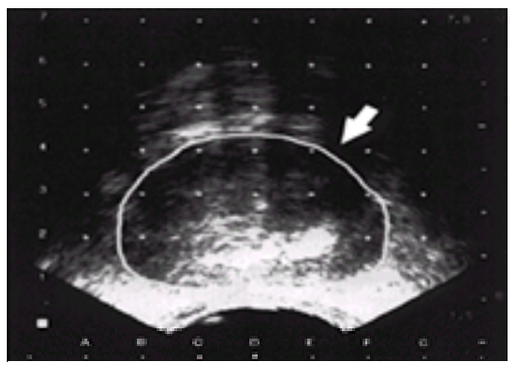

FIGURE 33.85. Transfers ultrasound image of prostate (*arrow* points to outline) in which the electronic grid is superimposed. This image corresponds to that of the needle-guiding template. (From Pais VM, Focht T, Canaday DJ, et al. Brachytherapy for prostate cancer. *Infect Urol* 2000;May/June:59, with permission.)

In the past, we have used two stabilization needles to prevent movement of the gland during the procedure. We and others have noted that this step may in fact produce tissue distortion. Placement of such stabilizing needles is not required in the majority of cases. The urologist and radiation oncologist must both agree that the real-time image accurately duplicates the volume study, particularly with respect to symmetry and the positioning of row one. Ideally, the latter should be a few millimeters within the posterior projection of the prostate. Care must be taken to avoid implantation too close to the rectal wall. The urologist and radiation oncologist work in concert with respect to the placement of the preplanned needles/seeds. Given our desire for homogeneous seed distribution, placement begins from the top row down and from lateral to medial. Once the needle is optimally situated, the radiation oncologist, who holds the stylet in stable position, dislodges the spacer. The urologist (with a gentle and consistent motion) withdraws the 17-gauge needle, and real-time imaging permits identification of the seeds as they are homogenously distributed. Snap fluoroscopic films also validate these observations. Additional seeds beyond the number dictated by the treatment plan are generally ordered to treat any unplanned areas of underdosing. Once completed, cystoscopy is performed and any displaced seeds are removed using grasping forceps. A 20-Fr Foley catheter is then inserted and the patient is taken from the operating room after a thorough radiation safety check has been performed. Although this procedure can be performed in the outpatient setting, it is our practice to admit the patients overnight with the intent of removing the Foley catheter the following morning. To minimize postimplantation edema, patients are given a single dose of IV Decadron (4 mg) and promptly started on a daily dose of a cyclooxygenase-2 (COX-2) inhibitor (Vioxx 25 mg). Prevacid is usually administered for GI protection.

Postimplant analysis is an important process that should be performed in all patients undergoing prostate brachytherapy. CT-based studies appear to be the best approach for postimplant dosimetry. Because the reported half-life of postimplantation edema is approximately 10 to 14 days, the best time to obtain this study may be 30 days after implantation (794). The D90 dose, the minimum dose to 90% of the prostate volume, appears to be a critical variable for assessing the accuracy of prostate brachytherapy. Patients with a D90 dose greater than 140 Gy have been shown to have a 4-year PSA relapse-free survival rate of 92%, whereas those with a D90 dose less than 140 Gy have a 4-year PSA relapse-free survival rate of only 68% (794).

Iodine-125 is the most common permanent radioactive isotope used for prostate brachytherapy. As stated previously, ^{125}I emits a low energy (27 keV photon) and possesses a half-life of 60 days, which results in a relatively low initial dose rate of 7 to 10 cGy per hour at the prescription isodose contour (72). Palladium-103 (^{103}Pd) was introduced in 1987. The characteristics of ^{103}Pd are similar to ^{125}I in that it emits a low-energy photon with an average energy of 21 keV. It differs in that its half-life is 17 days with a resultant initial dose rate of 20 to 24 cGy per hour for a typical prescription dose (72). Consequently, it was thought ^{103}Pd might be more suitable for prostate cancers with a Gleason score of greater than or equal to 7 because these tumors were thought to have faster intrinsic doubling time than low to moderate grade tumors. However, clinical data have been reported for both ^{125}I and ^{103}Pd and do not indicate any difference in biochemical control regardless of tumor grade (794). In our practice, ^{125}I is the predominant isotope used for seed implantation.

In general, prostate brachytherapy is a well-tolerated procedure. Nonetheless, various complications have been identified. Acute complications, which occur during or soon after the procedure, generally involve perineal pain/ecchymosis/swelling or temporary urinary retention. These complications have been identified in up to 5% of patients. Subacute complications occur within 2 to 4 months following implantation and generally involve obstructive/irritative voiding symptoms. Late complications, which develop as a result of chronic normal tissue damage from radiation, have been identified and include proctitis, hemorrhagic cystitis, impotence, and urinary incontinence (especially in patients who have had the antecedent transurethral or open prostate surgery). The most common complications and their relative frequencies are summarized in Table 33.28.

Series	Therapy	Incontinence	Impotency	Radiation Proctitis	Urinary Retention	Urethritis
Priestly and Beyer	^{125}I	1%	–	1%	–	4%
Blasko, et al.	^{125}I	TURP 17% Non-TURP 2%	Age >70, 50% Age <70, 15%	2%	7%	7%

TABLE 33.28. COMPLICATIONS OF CLOSED TRANSPERINEAL BRACHYTHERAPY IN EARLY-STAGE PROSTATE CANCER

Before leaving the subject of complications, the concept of seed migration should be briefly addressed. The radioactive seeds used in brachytherapy are cylindrical, 4.5 mm long, and have a diameter of 800 micron (213). The rate of seed embolization (into the pulmonary vasculature) is approximately 10% to 22% of all cases, whereas the number of seeds that may embolize are between 2 and 8 per 1,000 of those implanted (645). Embolization to the right ventricle has been reported (213). To date, no detrimental effects from seed migration have been reported. The use of linked seeds embedded in an absorbable suture material (Vicryl) has been associated with a reduction in the embolization rate to less than 1% (1002). These constructs are expensive and certainly less “forgiving” with respect to the implantation procedure.

Most of the published data on the results of transperineal permanent isotope prostate brachytherapy are evaluations of patients chosen for low risk of extracapsular disease. Table 33.29 depicts the results of recent series. According to these studies, 4- to 10-year biochemical control rates range from 63% to 92%. Blasko and associates (72) reported 9-year outcomes in 230 patients treated with ^{103}Pd monotherapy. These investigators used a modification of the ASTRO definition of PSA relapse free using survival (two instead of three consecutive increases). Favorable-risk patients had a 94% 5-year PSA relapse-free survival rate (84% at 9 years). Intermediate- and unfavorable-risk patients had PSA relapse-free survival rates of 82% and 65%, respectively. Prestidge and associates (800) have reported that biochemical control rates correlate with postbrachytherapy biopsy rates. Their data indicate a close correlation between PSA control and biopsy results, with 80% of biopsy patients having a negative result.

Study	No. of Patients	Median Follow-up (mo)	Actuarial Results	Definition of Success or Failure
Blasko, et al. (1) 2000	230	42	84% 9-yr PSA-RFS	Modified ASTRO definition (2 PSA rises)
Potters, et al. (22) 1998	717	41	82% 5-yr PSA-RFS	ASTRO definition*
Stock, et al. (23) 1998	134	32	92% 4-yr PSA-RFS	PSA >1.0 ng/mL or 2 PSA rises (for radiation dose >140 Gy)
Grado, et al. (78) 1998	490	27	79% 5-yr DFS	2 PSA rises
Ragde, et al. (2) 1998	208	119	65% 10-yr DFS	Failure defined as PSA >0.5 ng/mL
Zelefsky, et al. (24) 1999	145	24	82% 5-yr PSA-RFS	ASTRO definition*
Storey, et al. (25) 1998	160	35	63% 5-yr PSA-RFS	ASTRO definition*
Critz, et al. (21) 1996	1,000	36	79% 5-yr DFS	Failure defined as PSA >0.5 ng/mL
Beyer and Priestle (58) 1997	489	35	83% 5-yr DFS	Defined as PSA <4.0 ng/mL
Dattoli, et al. (28) 1996	124	42	76% 4-yr DFS	Defined as PSA <1.0 ng/mL

TABLE 33.29. RESULTS OF RECENT SERIES REPORTING ON PERMANENT PROSTATE BRACHYTHERAPY

The combination of external beam radiation (with or without neoadjuvant androgen ablation) followed by an interstitial brachytherapy boost can be considered in selected patients with a significant risk of microscopic extracapsular disease. In these patients, monotherapy would be expected to have a high local recurrence rate given that seed implantation delivers tumoricidal doses of radiation energy only 5 mm from the capsular parameter. Ragde and associates (806) reported on 54 patients treated with conventional external beam radiotherapy to 45 Gy followed by permanent ^{125}I implant delivering 120 Gy. With a median follow-up of 119 months, the 10-year likelihood of maintaining a PSA level less than 0.4 ng/mL was 75%. Only 24% of these patients had Gleason scores of greater than 7 and only 41% exhibited PSA levels greater than 10 ng/mL. Table 33.30 summarizes some of these results.

Series	No. of Patients	Initial Median PSA*	Stage	Therapy	No. of Months Follow-up (Median)	Crude Local Control	Actuarial PSA* Follow-up Results
Blasko, et al.	57	13.5	T_1–T_3	XRT + ^{103}Pd	28	97%	64% <1.0 at 5 yr

TABLE 33.30. CLINICAL RESULTS OF MODERATE-DOSE EXTERNAL BEAM IRRADIATION PLUS TRANSPERINEAL INTERSTITIAL BRACHYTHERAPY BOOST IN EARLY-STAGE PROSTATE CANCER

Despite the accumulation of a vast amount of data over the past 10 years, several uncertainties remain regarding prostate brachytherapy. First, the disease-free survival rate at 15 years and beyond has not been established. Second, the potential utility of routine neoadjuvant androgen ablation needs to be defined. Finally, the role of permanent brachytherapy as a salvage treatment for failed external beam radiation remains controversial. Beyer (59) described a retrospective review of 17 consecutive men seen and treated with permanent brachytherapy for recurrent CaP following an attempt at definitive external beam radiation. The 5-year actuarial freedom from second relapse was 53% in this cohort. Patients with a PSA of 10 ng/mL or less and low-grade tumors were most likely to respond to therapy. Acute and transient toxicity was easily managed. However, there was a 24% risk of incontinence at 5 years in these patients. A final area of controversy involves the routine use of high-dose combination radiotherapy for the treatment of localized (197,1125) and locally advanced (500) prostate cancers. Encouraging short-term results and acceptable toxicity profiles reported in these series await multiinstitutional validation.

Neoadjuvant Hormonal Therapy

Early attempts to use androgen ablation as a therapeutic adjunct to radiotherapy were disappointing. In the Stanford experience, the 10-year survival rate for patients with stage A and B disease that were so treated was 30% compared with 60% of patients receiving radiotherapy alone (814). Even for patients with stage C disease, the 10-year survival rate was better in the group treated exclusively with radiotherapy (30% versus 20%). Catalona (154) suggested that the initiation of androgen ablation might significantly diminish the proliferative index of the androgen-dependent subpopulations, rendering them less susceptible to the lethal impact of ionizing radiation.

The preceding studies were conducted before the advent of current pharmacologic approaches. For that reason, interest has been renewed in the potential value of

neoadjuvant hormonal therapy used before and during the conduct of 3D conformal radiation therapy. Despite the perceived advantages of 3D treatment planning, it is recognized that this approach may not fully encompass the target volume in certain geometrically unfavorable lesions without including a substantial volume of normal tissue within the high-dose dosimetry region. Conceivably, diminution in prostatic volume, which accompanies hormonal therapy, might improve the geometry of the target volume and optimize the efficacy of treatment (1127). In a recent phase I/II clinical trial, neoadjuvant leuprolide acetate (Lupron) and flutamide (Eulexin) were administered 3 months before and concomitant with 3D conformal radiotherapy. The target population included those patients with bulky, geometrically unfavorable prostate cancers. The study demonstrated that the median percentage of target volume reduction after neoadjuvant hormonal therapy was approximately 25%. This treatment also translated into a significant diminution in the amount of radiation exposure to the rectum, bladder, and small bowel.

A similar approach was used in a phase III trial of androgen suppression before and during radiation therapy for patients with palpable T_{2c}, T_3, and T_4 prostate cancers and unknown nodal status. This was conducted under the auspices of the RTOG 8610. In this study, patients were randomized to receive either 2 months of goserelin (Zoladex) and flutamide (Eulexin) before and concomitant with radiation therapy or radiation therapy alone. The latter consisted of irradiation of the pelvic lymphatics to 45 ± 1 Gy and a boost to the prostate of 20 to 25 Gy to a minimum total tumor dose of 65 Gy. After 3 years of follow-up, the actuarial local control rate was 84% with neoadjuvant therapy and 71% with radiation alone, and disease-free survival was 46% versus 26%, respectively. With respect to the latter, the criteria consisted of (a) no evidence of clinical progression, (b) no positive rebiopsy, and (c) a PSA less than 4 ng/mL and not rising. Although the overall survival benefit remains unclear, the results were deemed so encouraging that in future RTOG trials, combined therapy of goserelin plus flutamide with radiation is to become the standard treatment arm with which other modalities will be compared (Table 33.31).

Analysis	% 3-Yr Endpoint: Total Androgen Deprivation with Goserelin Acetate and Flutamide Plus Radiation Therapy	Radiation Therapy Alone	p Value

TABLE 33.31. RTOG STUDY (86-10) OF ANDROGEN DEPRIVATION AND RADIATION

Following the initiation of a total androgen ablation, serial PSA levels should be monitored to determine the point at which the PSA nadir is achieved. In general, this requires a minimum of 2 to 3 months. Once this point is identified, 3D conformal radiation therapy is initiated with the intent of maintaining androgen ablation until the radiation arm of treatment is completed. This approach, which has been commonplace in the United States, has been questioned by European investigators who recently conducted and completed a multiinstitutional clinical trial that suggests the potential utility of prolonged androgen ablation following the completion of external beam radiation. Indeed, this suppression was maintained for an average of 3 years and a survival advantage was documented in this cohort. Additional studies will be required to determine whether androgen ablation should be maintained following completion of radiation therapy. Other logical questions that arise involve the potential utility of either androgen ablation or the use of intermittent hormonal therapy in this clinical context.

The study by Granfors and associates (374) is intriguing. These investigators assessed combined orchiectomy and external beam radiation therapy versus radiation therapy alone for patients with nonmetastatic CaP (with/without pelvic lymph involvement). After a median follow-up of 9.3 years, clinical progression was seen in 61% of the radiotherapy-alone patients and in 31% of the combined treatment patients. Mortality was 61% and 38%, respectively, and the cause-specific mortality was 44% and 27%, respectively in groups 1 and 2. The outcome differences favoring combined treatment were mainly linked to lymph node–positive tumors. Patients with node-negative tumors had no significant difference in survival. Combined modality therapy was associated with better progression-free, disease-specific, and overall survival rates. This study also suggests that early androgen deprivation is superior to deferred treatment in such patients.

Of interest is the recent observation that estramustine phosphate may act as a radiosensitizing agent. This drug binds to microtubule assembly proteins (MAPs), producing an arrest of cancer cells at metaphase. *In vitro* studies using the human prostatic carcinoma cell line DU-145 demonstrated that the presence of estramustine phosphate is associated with a 23% increased sensitization to radiation therapy (262). It is conceivable that estramustine phosphate used alone or in concert with neoadjuvant androgen ablation may enhance the impact of 3D conformal radiotherapy.

Adjuvant Radiotherapy

Several studies validate the contention that external beam radiation administered in the adjuvant setting enhances local disease control in those cases following radical prostatectomy in which the surgical margins are compromised and capsular/seminal vesicle involvement is appreciated on step-section analysis of the surgical specimen. Ray and associates (813) noted a 5- and 10-year disease-free survival of 57% in those patients treated promptly following prostatectomy in whom incomplete excision was documented. This compares with 5- and 10-year survival rates of 40% and 20%, respectively, for those individuals treated after the onset of a palpable local recurrence. These authors suggest the initiation of such treatment within 4 months of prostatectomy when incomplete excision has been documented.

In 1986, Gibbons and associates (351) reported their series of 45 patients following radical prostatectomy who were noted to have microscopic extension of the disease beyond the gland. Of those patients treated with external beam therapy, local recurrences were noted in only 5% as compared with 30% of the untreated cohort. In their experience, delayed radiotherapy of a local recurrence was usually ineffective with regard to retarding disease progression. Other investigators have reported similar results (33,126,557,911).

Kaplan and Bagshaw (486) reported their experience with external beam radiotherapy administered to 39 patients following radical prostatectomy. In this study, the only evidence of persistent disease in 37 of 39 patients was detectable levels of serum PSA. Two patients had palpable recurrences. Pathologic analysis of surgical specimens revealed positive margins (24 of 34), positive seminal vesicles (17 of 32), positive lymph nodes (8 of 37), and a Gleason score of 7 or greater (29 of 38). With a mean follow-up of 26.8 months, local control has been achieved in all but one patient. Of note, the PSA was rendered undetectable 12 months following radiotherapy in 17 (44%) patients who were designated in the low-risk group. Conversely, the serum PSA remained detectable or continued to rise in 18 (46%) patients, who were then designated the high-risk group. Of the latter, 9 of 18 had bone metastases while under observation.

Freeman and associates (318) described 114 patients with pathologic stage C CaP who had undergone bilateral PLND and radical retropubic prostatectomy. Postoperative adjuvant radiation (median of 45 Gy) therapy (without hormonal treatment) was given to 95 of these patients with a median follow-up of 4.4 years. They noted 5- and 10-year actuarial survival rates of 94% and 70%, respectively, for the adjuvant radiotherapy group and the controls, and of clinical plus PSA recurrence at 34% and 46%, respectively. Similarly, disease-specific 5- and 10-year actuarial survival rates were 99% and 78%, respectively. At 5 and 10 years, the chance of clinical recurrence was estimated at 6% and 13%, respectively. Patients with high Gleason scores (8 or greater) and seminal vesicle involvement (stage C3) had the worst outcomes. In their analysis, disease-specific survival and survival without clinical recurrence of patients treated with adjuvant radiotherapy as compared with radical prostatectomy alone were improved over historical controls. Our experience (720) using a retrospective pairwise comparison of patients subjected to adjuvant radiation as compared to nonradical patients indicated a therapeutic advantage for the former.

Most of the these studies involved regimens using a 50- to 60-Gy total dose delivered to the prostatic bed. Proctitis-diarrhea, local skin reactions, lower extremity edema, and urethral stricture were commonly reported complications that were treatable or self-limited in the majority of cases. Most advocates for this approach recommend a 3-month hiatus following radical prostatectomy to ensure adequate healing of the vesicourethral anastomosis and other aspects of the wound. In those incidences when the potential need for adjuvant radiotherapy is deemed likely, performance of a modified PLND with preservation of lymphatic tissue lateral to the external iliac vessels is advisable to minimize the likelihood of lower extremity edema. In addition, radiation therapy should be delivered to the prostatic bed (rather than the whole pelvis) to further minimize the risks of disabling lymph edema and other related toxicities.

The utility of adjuvant radiotherapy following radical prostatectomy is not universally acclaimed. Paulson and associates (754) failed to demonstrate any advantage for

patients with pathologic stage C disease treated with adjuvant radiation therapy following radical perineal prostatectomy when compared with those patients receiving only surgical treatment. In a more recent analysis of this problem, Ellis and Lange (271) emphasized that most of the adjuvant radiotherapy series had short follow-up and did not include serum PSA or ultrasound-guided biopsies of the prostatic bed as endpoint parameters. In their series of 14 patients with elevated PSA levels and unremarkable DREs who received adjuvant radiotherapy, positive needle biopsies were documented in four (28%) patients, which was not deemed to be statistically different from the frequency of positive needle biopsies in similar groups of patients not subjected to adjuvant radiotherapy. They also emphasized that serum PSA levels decreased to undetectable in 8 (53%) of 15 patients subjected to adjuvant radiation therapy. However, this admittedly beneficial impact was not durable in the majority of patients.

Despite attempts at optimal patient selection before radical prostatectomy, between 14% and 41% of patients currently exhibit tumor extension to the surgical margin on final step-section analysis. In this latter group, biochemical (PSA) relapse is identified in 33% to 62% of these patients (716). A slow PSA velocity after radical prostatectomy and a long interval between radical prostatectomy and PSA relapse probably indicates the presence of localized disease. Conversely, a rapidly detectable (PSA) with a high PSA velocity following surgery most often indicates metastatic disease. The standard clinical evaluation of these patients is generally unrewarding. The DRE is usually normal. Targeted biopsies of the vesicourethral anastomosis are positive in only 40% to 50% of cases. CT and bone scan imaging are generally nondeclarative in patients with PSA values less than 20 ng/mL. Indium-111 capromab pendetide (ProstaScint) is a radiolabeled monoclonal antibody to PSMA, which may have clinical utility in the evaluation of PSA recurrence following radical prostatectomy. A multicenter study evaluating ProstaScint imaging in this context, found a sensitivity of 75%, a specificity of 86%, and an accuracy of 81% for this imaging modality (420), which compared favorably to an accuracy of only 48% for CT/MRI. Similarly, Elgamil and associates reported a sensitivity of 89%, specificity of 67%, and an accuracy of 89%, in a series of 100 similar patients. ProstaScint imaging is most useful for detecting recurrence in the prostatic bed and within lymph nodes. Petronis and associates (767) correlated the percent of positive ProstaScint scans with PSA values at the time of recurrence. Even for PSA values between 0.1 and 1.0 ng/mL, ProstaScint imaging was positive in 60% of cases. Between PSA levels of 1.1 and 10 ng/mL, scan positivity ranged from 60% to 83.3%, but for PSA values at recurrence above 10.1 ng/mL, all patients had a positive scan; however, in the latter only approximately 22% exhibited positive scans in the prostatic bed only. These results suggest that even at very low PSA levels, a substantial tumor burden exists. Kahn and associates (479) noted that 70% of men with a normal ProstaScint scan outside the prostatic fossa achieved a complete response after salvage radiotherapy versus only 22% who had a positive scan outside the prostatic fossa and pelvis.

Several recent series have validated the utility of adjuvant radiation therapy in the treatment of patients exhibiting an isolated PSA elevation following radical prostatectomy (572,716,779,1004,1043). Although PSA cutoff values of 1.0, 1.6, 2.0, and 2.5 have been advocated (306), no clear-cut consensus regarding this issue exists. It appears that when radiation therapy is given for postoperative biochemical relapse, it should be instituted at the earliest possible time (contingent with adequate healing) rather than assuming that a similar outcome will result in patients with a PSA below a certain level (779).

In our practice, patients are selected for adjuvant radiotherapy on the basis of tumor cells histologically present in the periprostatic tissue. The identification of cells on the capsular margin is a relative but less definite indication. The grade of the tumor is an important consideration, as are the age of the patient and his priorities. We usually wait a minimum of 3 months after surgery and prefer to have the patient's urinary control optimized and his urinary symptoms minimized before embarking upon treatment. We generally treat the prostatic bed and immediately adjacent site with 5,800 to 6,500 cGy.

Evaluation of Treatment Results

Until recently, the evaluation of treatment results following external beam radiation therapy for CaP was rendered difficult for various reasons, including (a) the variability of treatment regimens used; (b) the often unrecorded use of adjunctive endocrine therapy; (c) lack of accurate pathologic staging in the absence of PLND; (d) the use of different staging systems and the frequent lack of stage breakdown into clinically recognized subset categories; (e) lack of uniformity with regard to the criteria used to assess the continued presence of disease, particularly the frequent lack of histologic confirmation of treatment efficacy as discerned by TRUSP-guided biopsies and serum PSA levels; and (f) the inconstant rates of local tumor regression following the completion of radiation therapy, rendering an assessment of local disease control more difficult. With respect to the latter, it had been thought that approximately 75% of all overt treatment failures occurred within 24 months of completing the respective course of therapy, but this remains a highly variable phenomenon (814) and does not reflect the sensitivity of serum PSA measurements to detect evidence of biochemical relapse.

Despite these acknowledged deficiencies, several interesting and historically relevant statements can be made regarding the conceived efficacy of external beam radiation therapy in the treatment of prostate cancer. As summarized by Catalona (143), when stages A_2 to C were aggregated, clinically demonstrable treatment failure was apparent in one-fourth to one-third of cases. Of the latter, 50% to 65% reflected the presence of metastatic disease, 25% to 30% manifested both local and distant failures, and approximately 10% reflected local failure by predominantly DRE criteria. Not unexpectedly, local failure was deemed most likely in the presence of high-grade tumors (607) and in the presence of advanced-stage disease (707). Again, the validity of the statistics reflecting local disease containment must be tempered with the realization that these perceptions were made without TRUSP biopsies and sequential serum PSA monitoring. Both of these “outcome variables” are discussed briefly in the following paragraphs.

Egawa and associates (253) made some interesting observations regarding the role of sonographic monitoring of prostate cancer after definitive radiation therapy. In their study, 30 patients underwent TRUSP before and after definitive radiotherapy. Before treatment, one or more discrete hypoechoic areas characteristic of cancer were noted in 29 (97%) of the patients. Six months after completion of radiation therapy, a hypoechoic lesion was still observable in the original pretreatment area in 19 (79%) patients. Sonography demonstrated persistent lesions in 65% of 17 patients at 12 months, 79% of 14 patients at 24 months, and 75% of 8 patients at 36 months. Of interest, the maximum diameter of the hypoechoic lesion decreased by a mean of 41% when evaluated 12 months after radiotherapy. This study suggests that hypoechoic lesions noted pretreatment can be monitored by TRUSP after definitive radiation therapy.

Before the advent of TRUSP, postradiotherapy prostatic needle biopsies were performed with digital guidance. Despite the perceived inaccuracies of such an approach, the information generated from such studies is of great importance. For example, in the Baylor series of 510 patients with stage A_2, B, or C_1 prostate cancer treated with radioactive gold seed implantation and external beam radiotherapy, one or more needle biopsies were obtained in 140 patients who had no evidence of local or distant recurrent disease 6 to 36 months after completing treatment. A local recurrence developed in 60% of the 45 patients with a positive biopsy and in 19% of those with a negative biopsy. The probability of local recurrence for patients with a positive biopsy was 52% at 5 years and 72% at 10 years; it was 12% and 30%, respectively, for those with a negative biopsy (871). The relatively poor prognosis with a positive biopsy was present in every stage or grade subset. The prognostic significance of positive and negative biopsy findings seems to extend to the likelihood of disease-free survival (Table 33.32). These observations are all the more compelling when one considers the results of recent studies using systematic TRUSP-guided needle biopsies in patients having received definitive radiotherapy. Kabalin and associates (477) reported positive ultrasound-guided biopsies in 20 of 22 patients with normal postradiotherapy DREs. These findings call into question the reliance on DRE to indicate absence of tumor following radiotherapy. Indeed, a study by Crook and associates (199) demonstrates that TRUSP alone is not better than DRE in predicting a positive postradiotherapy biopsy. Their study and a multitude of others strongly support serum PSA measurements as the best indicator of biologically active tumor following radiotherapy. This latter issue is addressed in greater detail later in this section.

Study	Biopsy Status	% Local Failure 5 Year	10 Year

TABLE 33.32. LONG-TERM FOLLOW-UP OF PATIENTS WITH PROSTATE CANCER TREATED WITH RADIATION THERAPY

The majority of studies tend to support the concept that a positive biopsy occurring more than 18 to 24 months after the completion of radiation therapy is an ominous

prognostic indicator and suggests the presence of residual, viable tumor fully capable of expressing its intrinsic phenotypic characteristics, including those of invasion and metastasis. For example, the studies of Kiesling and associates (502) revealed no significant decrement in positive biopsies when analysis was performed at 12, 18, and 36 months. In that study, positive biopsies were noted in 64%, 57%, and 67% of cases, respectively. More important, of those patients with negative biopsies, 14% had metastatic disease as compared with 28% in the positive biopsy group. These findings contrast the recent observations of Crook and associates (199) correlating the results of routine TRUSP biopsies with DRE, TRUSP, and serum PSA measurements in 100 patients with prostate cancer (stages T_{1b}-T_4) treated with radical radiotherapy. They noted negative biopsies in only 52% of patients at 12 months. Of 31 patients with a positive first biopsy who had a second or third examination, 21 converted to negative at 16 to 29 months. Of note, all of these patients maintained normal or decreasing PSA levels. A compilation of postradiotherapy biopsy results summarized in 1991 is presented in Table 33.33.

TABLE 33.33. THE RESULTS OF NEEDLE BIOPSY OF THE PROSTATE AFTER RADIATION THERAPY

A brief analysis of several recent series serves to highlight the importance of the pretreatment and posttreatment serum PSA levels as prognostic indicators of treatment outcome following radiotherapy for CaP. Studies by Zietman and associates (1136) and Lee and associates (562) concluded that a pretreatment serum PSA level of more than 15 ng/mL constitutes the most powerful predictor of probable failure with conventional radiation therapy. In the former study, if the initial PSA levels for stages T_1 and T_2 tumors were greater than 15 ng/mL, the projected 4-year rate of freedom from biochemical failure was only 7%. Similarly, the study of Lee and associates demonstrated that the freedom from biochemical failure for patients with stage D_1 tumors and a pretreatment level of greater 15 ng/mL was only 38% at 3 years.

The biologic implications of an abnormal posttreatment PSA level are equally compelling. Ritter and associates (832) concluded that the failure of PSA to reach levels equivalent to those reported in disease-free males was a multivariate predictor of subsequent failure. They also observed that delayed versus early PSA increase was associated with clinically localized versus metastatic first recurrence. In 1993, Stamey and associates provided an update on 124 unselected consecutive patients who underwent serial PSA determinations after radiotherapy to the prostate, with a mean overall follow-up of 6 years. During year 1 of irradiation the PSA level was decreasing in 82% of patients, stable in 5%, and increasing in 14%. Of those patients observed longer than 1 year (*n* = 80), 51% had increasing values, whereas 41% were stable. Of note, the latter group had a mean PSA level of 2.9 ng/mL with a variation less than 1 ng/mL on serial determinations. In their extended follow-up of 113 of these patients, 78% exhibited precipitously increasing PSA levels at a mean follow-up of 5 years postradiotherapy. By their criteria, a total of 23 patients (20%) appeared cured with a PSA level of less than 1.7 ng/mL at a mean follow-up of 9 years. The remaining 80% of the patients in whom radiotherapy failed were thought to exhibit accelerated growth of tumor clones, which were repopulated during and following radiotherapy. The studies of Willett and associates (1092) and Zelefsky and associates (1126) suggest that an even more stringent endpoint should be chosen for the serum PSA following radiotherapy. Each of those studies concluded that patients whose PSA values did not reach less than 1 ng/mL after radiation therapy for prostate cancer were unlikely to be long-term clinical disease-free survivors. Indeed, several studies have identified a close correlation between the posttreatment serum PSA and the likelihood of positive TRUS-guided prostatic needle biopsies (Fig. 33.86).

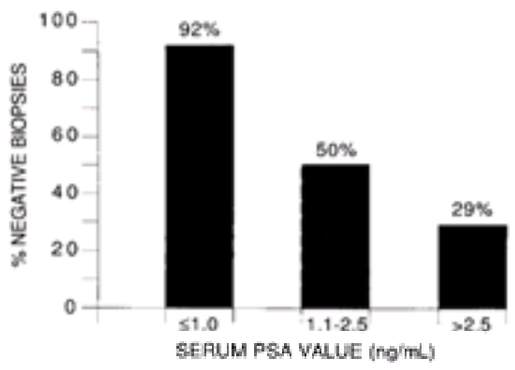

FIGURE 33.86. Rate of negative postradiation prostate biopsies is closely correlated with concomitant PSA values. (From Dugan TC, Shipley WU, Young RH, et al. Biopsy after external beam radiation therapy for adenocarcinoma of the prostate: correlation with original histological grade and current prostate specific antigen levels. *J Urol* 1991;146:1313, with permission.)

In 1997, the American Society for Therapeutic Radiology and Oncology (ASTRO) held a consensus panel to identify guidelines for PSA recurrence after radiation therapy. The panel agreed on four guidelines. First, biochemical failure is not justification, per se, to initiate additional treatment. It is not thought to be equivalent to clinical failure. However, it is an early appropriate endpoint for clinical trials. Second, three consecutive increases in PSA values reasonably define biochemical failure after radiation therapy. The use of three, rather than two, consecutive values reduces the risks of falsely declaring biochemical failure due to “bouncing” PSA. Critz and associates (197) described the latter phenomenon in patients who had undergone radioactive seed implantation followed by external beam radiation. The PSA bounce was observed in 35% of men. The median time to PSA bounce was 18 months from the time of implant, and 92% of bounces were observed within 36 months. Third, no definition of PSA failure has, as yet, been shown to be a surrogate for clinical progression or survival. Fourth, nadir PSA is a strong prognostic factor, but no absolute level is a valid cut point for separating successful and unsuccessful treatments. The nadir PSA is viewed to be similar in prognostic value to pretreatment prognostic variables.

Hanlon and Hanks (406) observed that patients who survived 48 to 60 months without a rise in serum PSA levels have a high probability of cure. Within this context, they observed no treatment failures after 6 years.

Several recent studies validate the importance of high radiation doses delivered by external beam radiation (608,1034) as well as high-intensity radiation delivered through the use of combined brachytherapy/external beam radiation (198). With respect to external beam radiation, it would appear that total delivered radiation doses in excess of 72 Gy are required to have a favorable impact on high Gleason histotype tumors. The study by Critz and associates (198) revealed that posttreatment PSA levels less than or equal to 0.2 ng/mL defined freedom from disease after radiotherapy.

The ultimate importance of the Gleason score on the outcome following radiotherapy is emphasized in the study of Roach and associates (833). These investigators evaluated patients entered on four prospective phase III randomized trials conducted by the RTOG between 1975 and 1992. For purposes of this study, death was disease-related if death was certified as due to prostate cancer, complications of treatment, or unknown causes with clinically active malignancy. The 10-year disease-specific survival for patients with Gleason scores of 2 to 5, 6 to 7, and 8 to 10 was 87%, 75%, and 44%, respectively, following radiotherapy. Of all the parameters evaluated, the Gleason score was the single most important predictor of death in the first 10 years. More recently, Kattan and associates (491) constructed a pretreatment nomogram for predicting the outcome of 3D conformal radiotherapy in prostate cancer patients (Fig. 33.87). This study was a retrospective, nonrandomized analysis of patients treated at Memorial Sloan-Kettering Cancer Center between 1988 and 1998. Clinical parameters of the 1,042

patients included stage, biopsy, Gleason score, pretreatment serum PSA level, whether neoadjuvant androgen deprivation therapy was administered, and the radiation dose delivered. Biochemical PSA treatment failure was scored when three consecutive rises of serum PSA occurred. A validated nomogram was established that predicts the probability of remaining free from biochemical recurrence for 5 years. This approach, if validated by other institutions, might be useful for treatment selection by both physicians and patients.

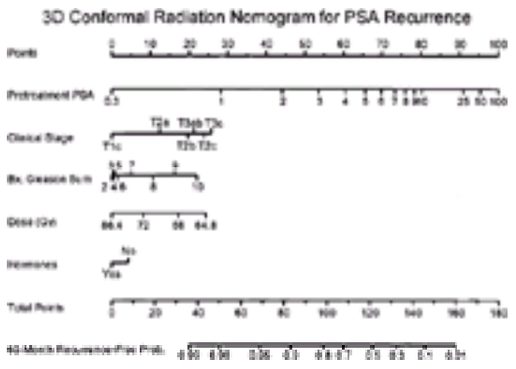

FIGURE 33.87. For each of the evaluation parameters [pretreatment prostate-specific antigen *(PSA),* clinical stage, biopsy Gleason sum, dose, and hormones], draw a straight line upward to the Points axis to determine how many points toward recurrence the patient receives for the given observation. The sum of the points achieved for each predictor should be determined and located on the Total Points axis. A straight line should be drawn down to find the patients probability of remaining recurrence free for 60 months. This nomogram is thought not to be applicable to a man who is not otherwise a candidate for radiation therapy. (From Kattan MW, Zelefsky MJ, Kupelian PA, et al. Pretreatment nomogram for predicting the outcome of three-dimensional conformal radiotherapy in prostate cancer. *J Clin Oncol* 2000;18:3352, with permission.)

Palliative Radiotherapy

External beam radiation therapy has a definite role in the management of pain attendant to skeletal metastases from CaP. Androgen-ablative techniques, particularly orchiectomy, can produce a rapid and profound improvement in such painful sites. Consideration of radiation therapy is warranted in those patients who fail to show an adequate response to androgen withdrawal, particularly those with precarious lesions in the spine or weight-bearing areas. In the study by Benson and associates (54), 42% of patients had complete relief of pain following the completion of 3,000 to 3,500 cGy delivered to the painful site. Another 35% exhibited partial relief of symptoms. Higher doses of irradiation (5,000 to 6,000 cGy) may be required for the relief of ureteral obstruction refractory to androgen withdrawal therapy. Although some authors have reported good results (120), others have been less enthusiastic about its efficacy (653). Many weeks may be required for satisfactory resolution of the obstruction, suggesting the wisdom of using indwelling double-J stents, if feasible. A role for radiation therapy in treating bladder neck obstruction due to locally aggressive CaP is not established. As noted in the section on endocrine therapy, androgen ablation with or without a temporary percutaneous suprapubic cystotomy tube can successfully relieve bladder neck obstruction in the majority of patients within 3 to 6 months and may obviate the need for a channel TURP in high-risk patients. Recently, hyperthermia has proven to be a useful adjunct to 3D conformal radiation therapy and androgen ablation in the management of locally advanced prostate cancers associated with urethral obstruction/hematuria; rectal obstruction/bleeding; genital edema; and ureteral obstruction/hydronephrosis (483). In some incidences, this approach was effective even within the context of antecedent radiation failure.

Finally, patients with painful multifocal skeletal metastases may be benefited by the technique of half-body or whole-body irradiation (494,847). This technique involves the administration of a 600-cGy dose to the upper body followed by a 4- to 6-week hiatus, after which time approximately 800 cGy is delivered to the lower body half. The side effects of treatment are not inconsequential and include severe nausea and vomiting and the expected consequences of bone marrow suppression. As noted by Keen (494), pain relief can be rapid and complete in 28% of patients, with another 70% demonstrating some improvement. As with the application of external beam therapy for focally painful lesions, the lumbosacral spine seems to be a difficult area in which to provide effective palliation (143).

Robinson and associates (835) administered the calcium analog strontium-89 (^{89}Sr) to patients with prostate cancer with painful multifocal skeletal metastases. Response rates in excess of 80% were noted following the IV infusion of 50 to 60 Ci/kg. Strontium-89 is a b-emitting isotope, possesses a half-life of 50.5 days, and follows the biologic pathways of calcium, which in theory provides access to all sites of osteoblastic metastases. Strontium-89 is available as a sterile isotonic solution for IV administration as a single outpatient injection. Each vial contains a single dose of ^{89}Sr chloride (4.0 mCi) in 4 mL solution. More recent studies have demonstrated pain relief in more than 70% of patients (195,791). In general, pain relief is not immediate but begins between 10 and 20 days postinjection, with relief maintained for a mean of 6 months (range of 4 to 15 months). The treatment may be repeated at 3-month intervals contingent on the patient's peripheral blood count. The therapy is well tolerated except for the development of hematologic toxicity (especially thrombocytopenia), which may become manifest at higher doses and following repeat dosing. At present, its primary utilization is for the treatment of symptomatic, multifocal skeletal metastases in patients with hormone-refractory prostate cancer who would otherwise be considered for hemibody radiation. These observations have been validated by more recent studies (321). The section involving treatment of metastatic hormone-refractory prostate cancer addresses the potential utility of other radioisotopes (samarium-153; rhenium-186).

Endocrine Therapy

In 1941, Huggins and Hodges (446) published their landmark observations establishing the efficacy of androgen-ablative/suppressive therapy in the treatment of patients with disseminated CaP. Because normal prostatic epithelial cells were known to undergo atrophy following androgen ablation, and cancer cells shared biochemical and histologic characteristics with normal cells, an equivalent response to androgen withdrawal was predicted and found to occur in the neoplastic subset. Unfortunately, the presence of relatively or absolutely androgen-independent cells became apparent early in the endocrine treatment of CaP and has been the main focus of additional treatment efforts since the introduction of this therapy. With regard to the latter, experimental observations in the Dunning R3327-H rat prostate carcinoma model tend to support the presumption that CaP consists of androgen-dependent, androgen-sensitive, and androgen-independent cellular subpopulations (Fig. 33.88) (452). The necessity for a critical level of systemic androgen for the proliferative activity of most prostate cancer cells is supported by experimental observations in this rat tumor model and by the clinical observation that approximately 70% of patients with advanced CaP exhibit beneficial responses to androgen-ablative/suppressive therapy (821,1022).

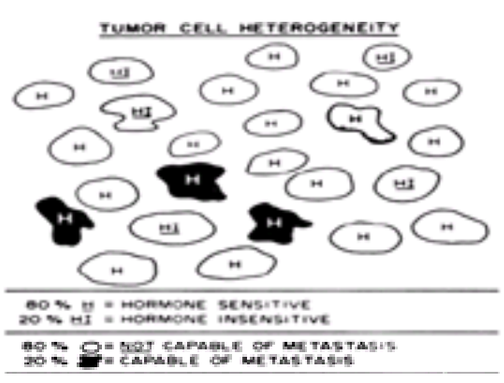

FIGURE 33.88. Human prostate cancers probably consist of hormone-sensitive and hormone-insensitive subpopulations. Each subset is composed of cells possessing varying potential for invasiveness and metastatic capacity. Adding to the complexity, primary tumors may differ substantially from their synchronous and metachronous metastases. In turn, these metastatic foci may differ from one another in a wide variety of phenotypic characteristics. (From Coffey DS, Isaacs JT. Control of prostate growth. *Urology* 1981;17[Suppl]:40, with permission.)

Available Therapeutic Modalities

The interstitial cells of Leydig are responsible for the production of 95% of all circulating androgen in the form of testosterone (1063). Cells constituting the zonae fasciculata and reticularis of the adrenal gland are responsible for the remaining 5% of circulating androgen through the production of dehydroepiandrosterone (DHEA) and androstenedione. Our present perception suggests that the gonadal source of androgen is the predominant and most biologically effective circulating moiety. The ultimate importance of adrenal androgen in stimulating normal or malignant prostatic epithelium has not been clearly established. Various therapeutic approaches are available to eliminate or suppress circulating androgen; these include regimens involving (a) primary gonadal mechanisms, (b) indirect gonadal suppression, (c) the administration of end-organ antagonists, and (d) methods involving panandrogen suppression (Table 33.34 and Fig. 33.89).

Ablation of Androgen Sources	Inhibition of Luteinizing Hormone-Releasing Hormone or Pituitary Luteinizing Hormone	Inhibition of Androgen Synthesis	Antiandrogens
Orchiectomy	Diethylstilbestrol	Medroxyprogesterone	Medroxyprogesterone
Adrenalectomy	Chlorotrianisene (TACE)	Aminoglutethimide	Cyproterone acetate
Hypophysectomy	Conjugated estrogens (Premarin)	Spironolactone	Flutamide
	Medroxyprogesterone (Provera)	Medrogestone	Nilutamide
	Diethylstilbestrol diphosphate (Stilphostrol)	Cyproterone acetate	Bicalutamide
	Polyestradiol (Estradurin)		Nilutamide
	Cyproterone acetate		
	Leuprolide

TABLE 33.34. FORMS OF ENDOCRINE THERAPY IN METASTATIC PROSTATIC CANCER[a]

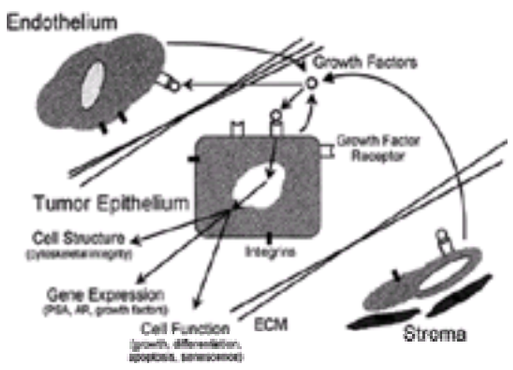

FIGURE 33.89. A dynamic reciprocity appears to exist between the tumor cell and the nontransformed constituents of the host microenvironment. The latter includes stromal elements, surrounding extracellular matrix *(ECM),* organ-specific microcapillary endothelium, and a wide array of growth factors and their receptors. AR, androgen receptor. (From Sokoloff MH, Gerber GS. Emerging therapies for the treatment of advanced prostate cancer. *New Develop Prostate Cancer Treat* 1999;4:36, with permission.)

Ablation of Primary Gonadal Function

Of the potential approaches to eliminate gonadal secretion, *scrotal orchiectomy* remains the standard of therapy for various reasons. (a) It results in a prompt, 95% reduction of serum testosterone, often achieving castrate levels within 3 hours following surgery (609). (b) It is exceedingly unlikely that castrate levels of serum testosterone will be exceeded at any point in the postoperative course (517). (c) The procedure can be performed in the outpatient setting with the patient under local anesthesia without demonstrable mortality and with minimal morbidity. (d) Most men accept the procedure without long-term psychologic sequelae. (e) Although scrotal orchiectomy obviates some of the long-term side effects associated with pharmacologic androgen ablation (breast enlargement/tenderness, chemical hepatitis, diarrhea), it is associated with that constellation of problems designated the “androgen deprivation syndrome.” The latter includes diminished or absent libido in most patients and impotence, which develops in one-half to three-fourths of patients (270); loss of muscle mass; a propensity toward weight gain; changes in cholesterol and fat metabolism; diminished stamina; emotional distress (416); demineralization of bone (osteoporosis); and the induction of hot flashes (249,416,672,770). A brief discussion of the latter two issues is warranted at this point.

Osteoporosis is a significant health problem in the white population in the United States. It has been estimated that more than 16% of white women and 5% of white men will suffer at least one vertebral bone fracture because of osteoporosis in their lifetime (641). Thus preexisting osteopenia and osteoporosis appear to be common in men with prostate cancer before the initiation of androgen deprivation therapy (1085).

In a study of men with non–stage A CaP, 13% of castrated men but only 1% of noncastrated men experienced fractures. The overall incidence of osteoporotic fractures in men with nonstage A cancer has been estimated to be approximately 4.3%, and nearly one-fourth of these fractures have been attributed to androgen deprivation therapy (1084). In a more recent study by Wei and associates (1085), it was determined that 88% of men undergoing androgen deprivation therapy for more than 1 year fulfilled the bone mineral density (BMD) criteria for osteopenia or osteoporosis at one or more sites. Indeed, men who received androgen ablation for more than 1 year had significantly lower BMD in the lumbar spine than men who had not started treatment. Using regression analysis, an estimated 48 months of androgen deprivation therapy was thought to be necessary to develop BMD criteria for osteopenia in the lumbar spine for a man without such evidence before the initiation of therapy.

In the study conducted by Daniell and associates (210a), the average BMD decreased 2.4% and 7.6%, respectively, during years 1 and 2 following castration. Similar losses were documented in men undergoing chemical castration. Average BMD decreased 1.4% to 2.6% per year 3 to 8 years after uninterrupted androgen deprivation. Postcastration bone loss was greater in men who were obese, younger than 75 years, and who failed to exercise regularly.

For men likely to require long-term androgen ablation, consideration should be given to obtaining a pretreatment BMD evaluation and to repeat this assessment every 1 to 2 years thereafter. In addition, daily supplements of calcium (500 mg) and vitamin D (700 units) have been shown to significantly reduce vertebral fractures in men and women over the age of 65 years (770). Alendronate (Fosamax) is a potent biphosphonate that inhibits osteoclast-mediated bone resorption. In postmenopausal women with osteoporosis and in patients with steroid-induced osteoporosis, Alendronate significantly increases BMD and reduces the incidence of major osteoporotic fractures in postmenopausal women (489). A recent study confirmed the utility of Alendronate (10 mg per day) for the prevention of osteoporosis in men (738). Its use within the context of patients undergoing androgen deprivation therapy remains to be defined. Nonetheless, the use of this agent, in concert with calcium and vitamin D supplements, should be considered in men undergoing androgen ablation who develop significant osteopenia/osteoporosis. All of these therapeutic approaches should be administered with caution and monitored appropriately. Finally, a modification of this regimen may prove beneficial to patients with CaP bone metastases. Van Veldhuizen and associates (1037) demonstrated that the oral daily administration of 2,000 units of vitamin D improved pain control, muscle strength, and quality of life in this patient population. It should be emphasized that elderly men are prone to vitamin D deficiency because of decreased exposure to ultraviolet light and decreased ability of aging skin to synthesize vitamin D (888).

Karling and associates, (488) evaluated the frequency and duration of hot flashes in 77 men with CaP treated with either orchiectomy- or gonadotropin-releasing hormonal analogies. Of the 63 evaluable patients, 43 (68%) reported hot flashes during treatment of CaP for a prolonged period. Furthermore, the commonly held notion that there is a gradual diminution in frequency and duration of hot flashes posttreatment may be incorrect. Indeed, approximately three-fourths of men report distressing hot flashes that begin 1 to 12 months after the initiation of therapy and continue a mean of 30 months or more until death (160).

Fortunately, effective treatment exists for this problem. Loprinzi and co-workers (600) evaluated the effect of megestrol acetate (Megace) for the treatment of vasomotor hot flashes in women during menopause and in men who had undergone androgen-deprivation therapy for CaP. This double-blind, placebo-controlled study demonstrated that 74% of the megestrol acetate group (20 mg twice daily) exhibited a decrease of 50% or more in the frequency of hot flashes during the first 4 weeks of therapy. Moreover, the degree of efficacy was noted to be identical in both men and women. The efficacy of low-dose megestrol acetate (20 mg twice daily) also was confirmed in a study conducted by Smith (930). He noted that 70% of treated patients exhibited a complete response, while another 20% had a greater than 50% decrease in the severity of vasomotor hot flashes. This study also confirmed the equivalent efficacy of diethylstilbestrol (DES) (0.5 mg daily) in this regard. Because DES was associated with a higher incidence of side effects, Megace was the preferred agent in the management of this problem. Clonidine has been evaluated in this context but it does not appear to decrease hot flash frequency or intensity significantly (600). Venlafaxine hydrochloride, a structurally novel antidepressant that inhibits neuronal serotonin and norepinephrine uptake recently was shown to be associated with a significant reduction in the frequency and intensity of hot flashes with low-dose (12.5 mg orally twice daily) therapy in men undergoing androgen ablation therapy. Patients suffering from mastodynia (painful breasts) may benefit from the use of tamoxifen (10 mg orally three times daily).

Three currently available pharmacologic agents—aminoglutethimide, spironolactone, and ketoconazole—possess the ability to suppress androgen production in both the testes and the adrenal glands. *Aminoglutethimide* inhibits the enzymatic (desmolase) conversion of cholesterol to pregnenolone and has a negative impact on the function of the cytochrome P-450 microsomal enzyme system. These metabolic events effectively inhibit adrenal steroidogenesis with a less profound impact on the gonads (69,137,864). Its side effects include anorexia, nausea, skin rash, lethargy, vertigo, nystagmus, and hypothyroidism. Because it interferes with an early step in adrenal steroidogenesis, the administration of aminoglutethimide (750 to 2,000 mg per day) requires concomitant supplementation with cortisone (20 to 25 mg per day) and fludrocortisone (Florinef, 0.1 mg per day).

Spironolactone and ketoconazole inhibit both adrenal and gonadal steroidogenesis. *Spironolactone* (100 to 400 mg per day) blocks the action of the 17a-hydroxylase enzyme and interferes with the secretion of testosterone, dehydroepiandrosterone, and androstenedione (1063). Its side effects include gynecomastia, erectile dysfunction, diarrhea, lethargy, mental confusion, urticaria, drug fever, and sporadic cases of agranulocytosis.

Ketoconazole (400 mg every 8 hours) interferes with cytochrome P-450–dependent 14-demethylation and blocks the conversion of lanosterol to cholesterol. It also partially inhibits another P-450–dependent enzyme, 17,20-desmolase, thus affecting the conversion of C21 to C19 steroids (1020). Ketoconazole has been reported to decrease serum testosterone to castrate levels within 4 hours of administration (1020). Although glucocorticoid supplementation is rarely necessary, administration of ketoconazole is associated with weakness, lethargy, hepatic dysfunction, impotence, GI tract upset, and gynecomastia (445,1020).

In patients with previously untreated stage D_2 CaP, ketoconazole may be equivalent to orchiectomy in its ability to rapidly reduce pain; it is safer than DES for patients with vascular disease and, unlike gonadotropin-releasing hormone analogs, is not associated with a “flare” response (787). Unfortunately, dosages approaching 1,800 mg per day may be necessary to maintain serum testosterone levels less than 100 ng/dL. Despite such doses, testosterone levels begin to rise after 1 month, and low normal levels are reached after 5 months (1038). Therefore ketoconazole is not effective as long-term, unimodal therapy. The strict 8-hour dosing intervals required to maintain testosterone suppression, coupled with severe toxicity mandating cessation of therapy in 30% to 40% of patients, further detract from the drug's utility. Long-term objective responses are rare when the drug is administered to patients who have failed previous androgen-ablative therapy.

Indirect Gonadal Suppression

Indirect inhibition of testicular androgen synthesis by affecting the pituitary secretion of gonadotropins can be accomplished by the administration of estrogens, progestational agents, and LHRH agonists. Among the estrogen moieties, *DES* (1 to 3 mg per day), *conjugated estrogens* (Premarin, 1 to 10 mg), and ethinyl estradiol (0.5 to 1.0 mg) have documented efficacy and appear in parity with one another in terms of effectiveness (67). Parenteral preparations of DES diphosphate (1 g intravenously for 7 days) and polyestradiol phosphate are effective and have been shown to rapidly diminish serum testosterone levels (35,302,609,837).

Oral estrogens induce the formation of specific liver-synthesized protein—the result of “the first pass effect.” Of these proteins, coagulation factor VII is one of the most strategic because it has been linked to the progression of atherosclerotic disease, and an increase in factor VII has been correlated with the deterioration of coronary status after the initiation of oral estrogen therapy in patients with prostate cancer (207,414). The parenteral administration of estrogen avoids this “first pass effect” and previous studies have demonstrated that polyestradiol phosphate (PEP) at doses of 240 mg per month IM can suppress testosterone production to castrate levels without any adverse impact on the liver. Recently, Hedlund and associates (410) randomized 915 patients to receive intramuscular injections of 240 mg PEP every second week for the first 8 weeks, followed by a maintenance dose of 240 mg every month, bilateral orchiectomy, or administration of LHRH agonist triptorelin plus flutamide. At a median follow-up of 18.5 months, no evidence of a difference in overall survival or in cardiovascular mortality was identified. PEP was associated with the lowest drug cost and the lowest accumulative direct costs and was thought to be the most cost-effective of the regimens tested. It was proposed that this intramuscular administration of PEP should be included as a serious therapeutic option in the endocrine management of CaP. Obviously, confirmatory clinical studies are required before accepting this proposal.

In addition to these agents, two other estrogen-containing compounds have documented clinical efficacy in the treatment of advanced prostate cancer. *Chlorotrianisene* (TACE) is a synthetic estrogen whose administration (12 to 25 mg) has been associated with positive clinical response despite the incomplete suppression of luteinizing hormone (LH) or testosterone levels.

Estramustine phosphate (EMP) (600 mg/m^2 per day) is a conjugate of estradiol and nitrogen mustard whose mechanism of action was thought to depend on the estrogen moiety for tumor target affinity and the nitrogen mustard component for cytotoxicity. Recent studies revealed that the mechanism of action of estramustine phosphate (EMP) is not related to either its estradiol or alkalylating activity. Indeed, the ultimate *in vitro* and *in vivo* cytotoxic effects of this agent are attributable to inhibition of microtubule assembly by the intact steroid-nitrogen mustard molecule, which is the direct consequence of the binding by estramustine phosphate to critical proteins MAPs (880). In one study, uncastrated patients treated with EMP had a significantly longer duration without progression when compared with a similarly matched cohort treated with DES (53). EMP monotherapy may produce transient, objective response rates of 26% to 63% in patients with CaP who have failed previous hormone therapy (55,665,950).

Although these agents have several possible mechanisms of action, including inhibition of the 3 a-hydroxysteroid dehydrogenase enzyme (1115), and a possible direct toxic impact on the prostatic epithelial cell, their effectiveness in controlling CaP of the prostate is thought to be due to inhibition of pituitary LH release with subsequent diminution of serum testosterone to castrate levels (44,834). Gynecomastia and fluid retention are common potential side effects of estrogens. The incidence of cardiovascular complications such as myocardial infarction, stroke, and venous thrombosis is clearly increased in patients given 5 mg per day of DES and would seem likely to be a risk factor with administration of any estrogen (67,113,114,228). Although high dosages of estrogen often elicit GI tract upset, this symptom is particularly troublesome with the administration of EMP (52). Impotence occurs in 30% to 80% of patients (56).

Megestrol acetate (120 mg per day), medroxyprogesterone acetate (20 to 200 mg per day), and *progesterone* are progestational agents that have been used in the treatment of stage D CaP. These agents suppress pituitary LH release, inhibit steroidogenesis, block 5a-reductase, and bind to ARs in the prostate gland (344,346,347). Compared with DES, progestational agents are associated with a reduced risk of cardiovascular morbidity and gynecomastia. However, they are associated with a loss of libido and with erectile dysfunction. What is more important, prolonged administration (within 2 to 6 months) of these agents has been associated with a secondary rise in testosterone levels, significantly blunting their clinical utility (345). The latter “escape phenomenon” can be prevented by the concomitant administration of 0.5 to 1.5 mg estradiol (346,347).

Some of the side effects of estrogen therapy can be controlled. For example, the gynecomastia associated with DES administration can be prevented by full-breast irradiation before the initiation of treatment. This may be delivered as a cumulative dose per breast of 1,200 cGy in three fractions or as a single dose of 800 cGy per breast (329,760). Such treatment must be completed before estrogen administration because once initiated, the glandular hyperplasia is not reversible. However, the discomfort associated with gynecomastia can be relieved with delayed radiation therapy. Furthermore, the thrombogenic side effects of estrogen can be diminished by using low-dose therapy. Good clinical response has been noted with doses of DES as low as 1 mg per day. When such therapy is initiated, serum testosterone levels should be monitored periodically because castrate levels may not be maintained (113,303). In addition, prophylactic administration of drugs such as aspirin or dipyridamole (Persantine) may prove efficacious in minimizing thromboembolic events associated with estrogen administration (257).

More recently, the *LHRH agonists* have been used to produce indirect gonadal suppression (287,288,1018,1076,1077). Their major mechanism of action stems from a super-stimulation of the pituitary that ultimately results in down regulation of the LHRH receptors leading to a refractory condition of anterior pituitary cells to LHRH secretion (863). This process occurs during a 1- to 3-week period, during which time there may be supersecretion of both LH and testosterone with a twofold to

threefold increase above normal levels of the latter. The transition to castrate levels of serum testosterone occurs gradually during a 2- to 4-week period (931,1095). In addition, animal studies have suggested that LHRH agonists also may cause a quantitative decrease in the number of LH receptors expressed on the Leydig cells (863). Administration of these agents to patients with metastatic CaP has been associated with an apparent transient tumor stimulation manifested by increases in acid phosphatase levels and skeletal pain in some patients. This phenomenon, also designated the “flare response,” is of particular concern in patients with impending cord compression and may be avoided by administering low doses of DES or flutamide 3 to 4 weeks before and 1 month during the administration of therapy. Impotence and hot flashes are reported in the vast majority of patients (530).

Goserelin and *buserelin* are available as depot preparations. These constructs may blunt the transient increase in serum LH levels, which may occur with daily subcutaneous (50 ng per day) or intranasal (two to three times per day to achieve a dose 100 to 500 ng) therapy and also may result in lower serum testosterone levels (1081). Several studies have demonstrated that LHRH agonists induce an endocrinologic effect equivalent to that of orchiectomy, produce clinical effects in parity with those seen following orchiectomy and DES, and are associated with side effects that are significantly less severe than those following DES administration and are equivalent to castration (170,192,759,933). Once relapse is noted (androgen-resistant phase), hormonal suppression should be maintained by continuing the LHRH agonist or by performing an orchiectomy because certain tumor subpopulations may be relatively androgen-responsive. Finally, these agents are expensive, and long-term administration may constitute a financial burden to some patients.

Oefelein (724) recently reported that the median duration of castrate level testosterone was 6 months after a single 3-month (LHRH) agonist injection. In a follow-up study, 32 men *on androgen-ablative therapy for prostate cancer* were treated with 3-month (22.5-mg) leuprolide acetate injection (721). Serum testosterone and PSA levels were obtained every 28 days beginning on the ninetieth day after the last 22.5-mg leuprolide injection. The median duration of castrate level testosterone was 6.0 months. *The median serum PSA at enrollment and when the castrate testosterone threshold of 0.2 ng/mL was exceeded remained stable with no significant change observed during this interval.* A significant association was observed between an increasing duration of physiologic castration after LHRH agonist injection and advancing patient age and increasing duration of hormonal therapy. The latter observations may reflect diminished testosterone recovery after gonadotropin suppression in the aged population. These studies suggest that strict adherence to the advised every 3- or 4-month redosing schedule (depending on the depot preparation used) may be unnecessary. By monitoring serum testosterone levels, redosing could be held in abeyance until serum testosterone concentration rises above castrate levels. Obviously, implementation of this approach might permit a doubling of the dosing interval and the corresponding 50% reduction in medication costs.

Recently, a 1-year leuprolide delivery system (Viadur) was developed. The latter consists of a 4 × 45-mm cylindrical, titanium implant which uses osmotic pressure to deliver the drug continuously at a controlled rate for 1 year. To insert the implant, subcutaneous tissue 5 to 10 cm above the antecubital crease of the inner arm is anesthetized and a 5-mm incision is established. The implant is positioned with a disposable implanter in the fossa between the biceps and triceps muscles. Fowler and associates (309) reported the outcomes of 80 patients who underwent implantation with the Viadur system. They concluded that this leuprolide implant effectively suppressed testosterone concentrations to less than the castrate threshold and maintained that suppression throughout the study. Side effects associated were essentially the same as those reported with standard LHRH agonists depot preparations.

The development of GnRH receptor antagonists would be expected to be devoid of the initial androgen-stimulation characteristics GnRH agonists (183). Abarelix is the first GnRH receptor antagonist in a sustained-duration formulation to progress through clinical trials. This agent blocks GnRH and inhibits LH production, which in turn suppresses the production of testosterone and DHT. Abarelix does not cause an initial stimulation of LH production, testosterone, or DHT (341). Garnick and associates (341) demonstrated that prostate gland volume significantly decreased (median of 35%) in the course of treatment with Abarelix (1 mg). Serum testosterone concentrations decreased to chemically castrate levels (less than 50 ng/dL) by day 15 for most patients. During this same interval, the PSA decreased to less than 4.0 ng/mL in the majority of patients. Garnick and associates (342) and Campion and associates (116) have reported the results of a recent phase II study. In this study, the abarelix depot formulation was compared with depot formulations of leuprorelin and goserelin, with or without concomitant antiandrogen use. Two hundred and nine patients were treated with abarelix depot, 100 mg on days 1 and 15 and then 50 to 100 mg every 4 weeks. A concurrent control group of 33 patients was treated with the alternative regimens. Abarelix induced rapid chemical castration (day 8) in 76% of patients compared with 0% in the other groups. Testosterone surge occurred in all of the other groups but in none of the abarelix-treated patients.

End-organ Antagonists

Cyproterone acetate and megestrol acetate are the two primary steroidal antiandrogens. Cyproterone acetate (250 to 300 mg per day) is a derivative of 17-hydroxyprogesterone and may suppress testosterone production by inhibiting pituitary LH release through a poor gestational effect (843) coupled with its ability to block the C21-19 desmolase enzyme (143). Both steroidal antiandrogens block the interaction between androgens and the receptors in the target tissues. In addition, they possess some progestational activity and consequently lower LH production. Megestrol acetate is used less often than cyproterone acetate as a primary treatment for metastatic CaP. When used as monotherapy, neither agent can effectively suppress androgen production; consequently, plasma testosterone levels ultimately rise toward normal range. Cyproterone acetate appears to be devoid of most side effects except impotence and gynecomastia (933).

Three generations of nonsteroidal antiandrogens have been developed. Flutamide (Eulexin) is a first-generation nonsteroidal antiandrogen. Flutamide has an affinity for ARs in the hypothalamic pituitary system and they paradoxically increase testicular testosterone production by supranormal stimulation of LH release (803). Flutamide possesses a relatively short half-life of approximately 5.2 hours. Its active metabolite is hydroxyflutamide. The standard dosage is 250 mg three times daily. The efficacy of high-dose (1.5 g per day) and low-dose (750 mg per day) monotherapy has been assessed in several studies (803,943). In general, the two dosage levels of flutamide have equivalent antitumor impact; however, few patients can tolerate the side effects of prolonged high-dose therapy. In previously untreated patients with stage D_2 CaP, the clinical impact of low-dose flutamide monotherapy was equivalent to that of DES (1 to 3 mg per day) and estramustine phosphate. For patients with CaP refractory to conventional hormonal therapy, infrequent and transient responses have been reported to flutamide (750 mg per day), and most studies have shown little evidence to support a major role for flutamide monotherapy in this setting (611,940). The side effects associated with flutamide administration include gynecomastia, rash, depression, nausea, vomiting, and liver function abnormalities. With respect to the latter, Gomez and others (369) evaluated 1,091 patients with stage C or D CaP treated with flutamide in concert with LHRH agonist. They noted fourfold or more increases in serum aspartate aminotransferase and alanine aminotransferase in only 4 (0.36%) of 1,091 patients. All clinical and biologic manifestations of liver toxicity disappeared following the discontinuation of flutamide. It was recommended that serial serum aminotransferase measurements be obtained 2 and 4 weeks after the initiation of flutamide therapy to detect early signs of hepatic injury. Potency seems to be preserved in most patients treated with flutamide (611,941).

Nilutamide (Nilandron) is a second-generation antiandrogen. It possesses a long half-life of approximately 45 hours and is thus amenable to once-daily dosing (300 mg per day). This feature may ensure a more permanent saturation of AR binding sites. As with flutamide, nilutamide is effective in preventing LHRH agonist–induced tumor flares (468). Common side effects include nausea, alcohol intolerance, and decreased adaptation to darkness. These side effects abate following discontinuation of the drug. Approximately 50% of patients maintain libido and potency.

Bicalutamide (Casodex) is a third-generation antiandrogen with a prolonged half-life of 5 to 6 days. Dosages ranging from 50 to 150 mg per day can be conveniently administered. Like the other nonsteroidal antiandrogens, Casodex effectively blocks the tumor flare associated with LHRH agonists. In patients with existing metastatic disease, pretreatment with Casodex (or flutamide, nilutamide) should be initiated 2 to 4 weeks before the administration of the LHRH agonists. The standard maintenance dose of bicalutamide is 50 mg per day when used in concert with an LHRH agonist for the purpose of total androgen ablation. Boccardo and associates (75) recently evaluated the impact of high-dose (150 mg per day) bicalutamide monotherapy. In their study, patients were randomly allocated to receive either high-dose bicalutamide monotherapy or maximum androgen blockade (flutamide plus goserelin). Bicalutamide monotherapy yielded comparable results relative to standard treatment with total androgen blockade. However, it was associated with fewer side effects and produced a better quality of life. More recently, Iversen and associates (461) compared bicalutamide monotherapy (150 mg per day) with castration in patients with nonmetastatic locally advanced CaP. In that study, there were statistically significant benefits in the bicalutamide monotherapy group in the two quality-of-life parameters of sexual interest and physical capacity. The highest incidences of adverse events were the pharmacologic side effects of hot flashes in the castration group, and breast pain and gynecomastia in the bicalutamide group. The frequency of other types of adverse events was low. Bicalutamide was well tolerated, with few drug-related withdrawals from study. However, a common problem with bicalutamide monotherapy is cost, which proves to be prohibitive for many elderly patients.

Attempts at Complete Androgen Suppression

The concept of successfully suppressing both testicular and adrenal androgen production in patients with metastatic CaP has a certain theoretic appeal. Various such approaches have been attempted and include (a) combined orchiectomy and adrenalectomy, (b) hypophysectomy (919), (c) orchiectomy and the subsequent administration of an antiandrogen (258,362,468,762), and (d) the use of LHRH agonists together with antiandrogens to effect complete androgen suppression (193,223,460,550). Adrenalectomy and hypophysectomy have been used for the treatment of advanced prostate cancer refractory to castration or estrogen administration, although a few reports are available regarding the use of such approaches in untreated patients (60). Neither approach has been associated with

profound or long-standing subjective or objective improvement in such patients (381). Obviously, the use of either adrenalectomy or hypophysectomy commits the patient to a lifetime of glucocorticoid replacement therapy.

A new wave of enthusiasm has been engendered by the availability of pharmacologic approaches to panandrogen suppression. Labrie and associates (550,551) treated more than 200 patients with stage C and D CaP with leuprolide (to suppress the production of testosterone) and flutamide (to block the impact of adrenal androgens). They report positive responses in over 97% of patients and an 89.2% probability of survival at 2 years compared with a 40% to 60% probability with leuprolide, estrogen, or orchiectomy monotherapy. This drug regimen is predicated on the hypothesis that CaP is unusually sensitive to androgens and that androgens of adrenal origin play a significant role in accelerating disease progression in patients previously exposed to conventional monotherapy. It also is assumed that androgen-insensitive clones arise only when androgen blockade has been incomplete (255). The latter view contrasts with the alternative hypothesis, which assumes that androgen-sensitive and androgen-insensitive clones emerge soon after malignant transformation occurs. Progression of the disease after hormonal therapy is thought to result from the uncontrolled proliferation of the androgen-insensitive subpopulation that is due to aberrations in autocrine or paracrine growth control, possibly involving the exaggerated production of growth factors and their receptors.

Crawford and associates (192) conducted a randomized, double-blind trial involving 603 men with previously untreated stage D_2 CaP. Three hundred patients were randomized to receive leuprolide plus placebo, while the remaining 303 men received leuprolide plus flutamide. The latter group exhibited a longer progression-free survival (16.5 versus 13.9 months; $p = .039$) and an increase in the median length of survival (35.6 versus 28.3 months; $p = .035$). Improvement was most noteworthy in patients with minimal disease and a good performance status and was particularly apparent during the first 12 weeks of treatment. Finally, the flare reaction associated with 8% to 32% of cases involving leuprolide monotherapy was significantly abolished by the addition of flutamide. In the analysis of progression-free survival, the authors chose to discount changes in the bone scan noted at the first 3-month assessment. An analogous study conducted by Denis and associates (223) compared the impact of goserelin acetate and flutamide with bilateral orchiectomy in 327 patients with metastatic CaP. They observed that the time to first subjective disease progression was statistically longer in favor of the combination therapy (87 weeks versus 52 weeks for the orchiectomy arm). Janknegt and others (468) evaluated the impact of orchiectomy and nilutamide (versus placebo) in a similar cohort. They noted that progression-free survival was significantly longer in the nilutamide group (20.8 months versus 14.9 months). Median time to death from CaP was 30 months in the placebo group and 37 months in the nilutamide group. Finally, objective evidence of disease regression was noted more frequently in the nilutamide group (41%) than the placebo arm (24%). It should be emphasized that neither the rate of progression-free survival nor the increase in the rate of overall survival reported in these studies approaches the claims of Labrie and associates (550,551).

Recently, Eisenberger and associates (258) reported on their randomized clinical trial which involved 1,387 patients with metastatic CaP. All underwent bilateral orchiectomy and were randomized either to receive placebo (687) or flutamide (250 mg every 8 hours). The overall incidence of toxic effects was minimal, but diarrhea and anemia were more prominent in the flutamide-treated patients. The difference in overall survival between the two groups was not significant. Flutamide was not associated with enhanced benefit in patients with minimal metastatic tumor burden. These findings conflicted with those of an earlier trial conducted by the same authors, which suggested a small but statistically significant advantage to patients undergoing total androgen ablation (192). Recent enthusiasm for the use of finasteride in combination with antiandrogens and LHRH agonists as a form of “triple” hormonal therapy should be tempered, pending the results of adequately controlled clinical trials. To date, such data are not available.

Other studies have not demonstrated superiority for total androgen blockage. Schulze and associates (885) did not observe a survival advantage for patients with stage C or D CaP treated with bilateral orchiectomy and cyproterone acetate versus orchiectomy alone. Similarly, Schroeder and associates (883) assessed the impact of buserelin versus buserelin plus cyproterone acetate in patients with stage D_1 or D_2 CaP. Again, the superiority of total androgen withdrawal over testicular androgen suppression alone could not be demonstrated. Keuppens and co-workers (501) reported the results of a clinical trial in which 327 patients with metastatic prostate cancer were randomized to either bilateral orchiectomy or treatment with Zoladex and flutamide. Although a statistically significant increase in time to subjective and objective progression was recorded in favor of the combination group, there were no statistically significant differences in time to death by cancer or overall death. Iversen (462) reported the results of an analogous study. Again, a small but statistically significant difference in time to objective progression or death from CaP was found in favor of the combination group. However, there was no difference between the treatment groups in overall survival. Of importance, treatment-related adverse events are more common in pharmacologically treated patients (460). At this time, the conflicting data would suggest that attempts to achieve total androgen ablation likely will have a minor impact on the results of treatment of patients with CaP.

Antiandrogen Withdrawal Syndrome

Scher and Kelly (877) evaluated the impact of the discontinuation of flutamide in patients treated with combined androgen blockade who exhibited evidence of disease progression during the conduct of this therapy. In their study, of the 35 patients with increasing PSA values, 10 (29%) demonstrated a significant diminution in serum PSA following cessation of flutamide. The PSA decline was greater than 80% in 7 patients and greater than 50% in 3. The median duration of this decline was approximately 5 months (range of 2 to 10+). This biochemical response also was associated with improvement in clinical symptoms. Dupont and associates (246) made the same observation. They evaluated a similar cohort of 40 patients with stage D CaP who were exhibiting evidence of disease progression despite flutamide/LHRH or flutamide/surgical castration treatment. Following the cessation of flutamide, the serum PSA decreased by 90% or more in 19 (63%) of the 30 responding patients and normalized in 17 (57%). The average duration of response following cessation of flutamide was 440 days. Sartor (867) also validated the existence of the flutamide withdrawal syndrome in 48% (14 of 29) of their patients with evidence of disease progression despite multipharmacologic therapy. More recently, evidence of a similar withdrawal phenomenon has been associated with the antiandrogen Casodex (713).

The etiology of this withdrawal phenomenon has not been definitively ascertained. Preclinical studies involving the LNCaP cell line have demonstrated that a specific point mutation in the steroid-binding domain of the nuclear AR results in paradoxic growth stimulation following exposure of the cells to estrogen, progesterone, androgens, and various antiandrogens, including hydroxyflutamide, nilutamide, medroxyprogesterone acetate, and cyproterone acetate (887,1120). Gaddipati and associates (327) evaluated advanced-stage CaP specimens and determined that the frequency of mutations involving the identical region in the nuclear AR was present in approximately 30% of evaluated specimens. The obvious implication is that flutamide and all other antiandrogens may promote growth stimulation in CaP systems that have undergone mutational events involving the nuclear AR gene. Several alternative hypotheses have been proposed. For example, flutamide may induce distinct conformational changes after binding to a normal AR, and the resulting conformational changes result in the activation of mutant androgen response elements (867). It also has been proposed that clones of prostate tumor cells that are hypersensitive to very low levels of androgens evolve with time (552).

Regardless of the etiologies, the observation of the flutamide withdrawal syndrome is important. Many patients will exhibit an excellent biochemical and clinical response to androgen-ablative therapy for periods ranging from several months to several years. Once the serum PSA consistently rises from the posttreatment nadir value, concern must exist regarding the emergence of the androgen-independent phenotype. If such patients are being maintained on total androgen ablation, serious consideration must be given to the cessation of the antiandrogen for fear that continuation of this drug will have adverse consequences.

Use of 5a-reductase Inhibitors

Testosterone is converted to dihydrotestosterone by 5a-reductase isoenzymes, type 1 and type 2, with the latter predominating in human urogenital tissues (1011). Expression of the 5a-reductase type 2 isoenzyme has been detected in the basal epithelial and stromal cells of the normal prostate but not in the secretory (adluminal) cells (918). In addition, the type 2 isoenzyme is detectable in prostate cancer stromal cells but is absent in the tumor epithelium (918). The latter observation further validates the concept that the basal cells or cells with a unique basal cell phenotype are lost in prostate cancer.

At present, there is enthusiasm to assess the potential role of 5a-reductase inhibitors in the prevention and treatment of CaP. With respect to the former, the National Cancer Institute initiated the multiinstitutional finasteride CaP prevention trial. Obviously, it will take many years before the outcome of that effort is mature. However, the observations by Silver and associates (918) would suggest that the tumor-associated stroma is the likely target for any putative chemoprotective influence exerted by finasteride.

Fleshner and Trachtenberg (300) conducted a pilot study in which 10 patients with treatment-naive, clinical stage C and D_1 CaP were treated with a combination of finasteride (5 mg twice daily) and flutamide (125 to 250 mg three times per day). All patients were potent before the initiation of therapy, and eight remained potent during the conduct of the study. The mean serum PSA level in these patients was 34.3 ng/mL. At 3 months, the mean PSA level of all patients was 3.8 ng/mL. As anticipated, the serum testosterone level increased in all patients and gynecomastia was noted in three. This study does not permit an assessment of the durability of a response to this unique form of “sequential androgen blockade.” It does, however, suggest that this treatment regimen may offer a benefit similar to total androgen blockade with fewer side effects. Obviously, multiinstitutional clinical trials are required to further address this issue and to ultimately determine the role of finasteride

in our oncologic armamentarium.

Use of Prolactin Inhibitors

In addition to attempts to block androgen production and end-organ effects directly, therapeutic regimens have been devised based on evidence from studies of normal prostate indicating a synergism between androgen and other protein hormones. Concern regarding the potential role of prolactin has been based on its ability to augment testosterone effect on prostatic growth, to stimulate release of dehydroepiandrosterone and androstenedione (466), demonstration of its presence along with follicle-stimulating hormone (FSH) in immunohistochemical studies of the prostate, and on the observation that elevated serum levels of this hormone negatively affected prognosis in patients with advanced CaP (637). Levodopa (0.5 to 5.0 g per day) and bromocriptine (7.5 mg per day) have been used clinically in attempts to eliminate prolactin-related androgen synergism (189). The use of either agent can be associated with GI tract symptoms (anorexia, nausea, vomiting). In addition, levodopa has been noted to produce hypotension; cardiac arrhythmias; and central nervous system aberrations, including confusion, agitation, hyperactivity, blood dyscrasias, and hepatic dysfunction. Aside from transient improvement in pain (286,783,852), no clear clinical effects of these efforts have been evident.

The potential side effects of the various androgen-ablative approaches are summarized in Table 33.35 and their impact on serum testosterone levels is delineated in Table 33.36.

Response to Treatment: Prognostic Indicators

Approximately 20% of patients with advanced CaP fail to demonstrate an objective response to androgen-ablative therapy. From both a practical and theoretic standpoint, it would be useful to segregate those patients likely to respond to androgen suppression from those who will be refractory to such approaches. Several potential prognostic indicators, including assessment of histologic, flow-cytometric, biochemical, and molecular parameters, have been discussed in this chapter. Obtaining representative tissue for these studies represents a problem in all these efforts. Our experience with using grade as a criterion suggests that needle biopsy of the prostate provides tissue representative of the tumor as a whole approximately 75% of the time (339). Multiple biopsies may not eliminate this problem (70). The potential of tissue alteration as a result of the sampling procedure further complicates the evaluation of parameters of biologic potential by these approaches.

Recently, four interesting sets of observations have provided further insights into the various biologic characteristics of CaP and other correlations with biologic behavior. First, Prins and associates (802) used immunocytochemistry and stains of the AR to study paraffin-embedded tumor sections of AR-positive tissue. The receptorgram resulting from image analysis of the AR revealed a unimodal or multimodal peak within a narrow concentration range in 17 of 18 hormone therapy responders. In contrast, the receptorgram of those failing endocrine therapy was highly skewed or clearly bimodal. The authors suggest these observations may have a useful clinical role.

Second, Stege and associates (973) reported on the cytosolic PSA tissue content of prostate (T-PSA) cancer needle biopsies as related to DNA in a series of patients without bone metastasis at diagnosis who were followed at least 71 months or until death after orchiectomy or medical castration. None of the patients with high T-PSA showed progression, irrespective of cytologic grade ploidy, or stage of the neoplasm.

Third, Wise and associates observed a high level of antiinflammatory cytokines [interleukin (IL)-4, IL-6, IL-10] in the serum of patients with hormone refractory CaP. In contrast, these patients—men with hormone sensitive CaP and BPH—as well as controls had comparable levels of serum proinflammatory cytokines (IL-1, IL-2, INF-g, and THF-a). These three studies provide insights into differing characteristics of hormone refractory CaP that may provide opportunities to expand our clinical understanding of and approaches to the problem.

Finally, a study of the CWR22 human prostate cancer xenograft, by Agus and associates (6), identified a sequence of biologic phenomena associated with androgen withdrawal in this model. Early events following androgen ablation included a decrease in AR expression, a short-term increase in expression of p53 and p21/WAF1 proteins, and a marked decrease in the Ki67 proliferative index. Mid-to-late events included progressive and sustained increases in p27 and p16 protein expression, a decrease in retinoblastoma protein expression, and an increase in the transcription factor E2F1. Changes in apoptosis were not observed in this model system, suggesting that androgen withdrawal results in a cell stress response with increased p53 protein producing a cell cycle arrest without activation of p53-mediated apoptosis. The proliferative index is decreased through the action of the cyclin-dependent kinase inhibitors p27 and p16. Emergence of androgen-independent sublines was associated with murine double minute (mdm) to protein overexpression and increased expression of cyclin D1. Both the latter phenotypes prompt the release of these cells from cell cycle arrest.

Several clinical observations also have been evaluated in an effort to predict the long-term effect of endocrine manipulation in patients with disseminated CaP (Table 33.37). Carpenter and colleagues (121) found a correlation between the postorchiectomy decrease in size of the prostate as assessed on ultrasound and subsequent disease stabilization. Several nonendocrine parameters are available that may provide predictive information regarding the adequacy of hormonal response. Of these, the serum PSA and PAP appear to be the most useful. Gutman and Gutman (396) demonstrated that patients who had elevated levels of serum acid phosphatase at the time of initial diagnosis fared poorly when compared with those patients with similar-stage disease but normal serum acid phosphatase levels. Following the initiation of androgen ablation, a failure of PAP to normalize or to approach 50% of the pretreatment values correlates with a poor prognosis (610). Moreover, Vihko and associates (1045) noted a distinct relationship between the rapidity with which PAP falls and the length of response to endocrine therapy. They noted that patients whose PAP levels returned to normal within 7 days of treatment showed no evidence of disease progression during the first year of follow-up. Similar observations relating to the degree and rapidity of postandrogen withdrawal fall in serum PSA levels have been made, and they appear to be very useful predictors of

the length of response to these procedures. For example, Zagars and co-workers (1123) evaluated the outcome for patients with pathologic stage D_1 CaP who underwent immediate androgen-ablative therapy following PLND. In this group, posttreatment PSA levels were a very sensitive index of treatment response and ultimate outcome. For example, those patients who achieved undetectable serum PSA levels experienced only a 5% incidence of disease progression at 8 years. In contrast, all patients who failed to achieve undetectable serum PSA levels exhibited relapse within that time frame. Of interest, the pretreatment PSA levels were not predictive of outcome.

D_0	Disease confined to prostate gland with elevated acid phosphatase
D_1	Positive pelvic lymph node involvement
$D_{1.5}$	Rising PSA after failed local therapy (radiation or resection)
D_2	Bony and/or soft-tissue metastases
$D_{2.5}$	Androgen-independent prostate cancer (may be called *HRPC*)
	Rising PSA after androgen ablation/castrate serum androgen levels
D_3	Hormone-insensitive prostate cancer (true HRPC)

HRPC, hormone-refractory prostate cancer; PSA, prostate-specific antigen.

TABLE 33.37. STAGES OF ADVANCED PROSTATE CANCER (STAGE D)

Serum alkaline phosphatase determinations are of less specific utility when compared with measurements of PSA or PAP because the former enzyme is frequently elevated in the presence of skeletal or hepatic metastasis from any variety of neoplasm. With regard to CaP, a transient elevation of serum alkaline phosphatase is frequently noted following the initiation of hormone therapy. Although the etiology of this flare phenomenon is poorly appreciated, it seems to be associated with a favorable response to therapy (872).

These relatively crude clinical observations have the advantage of reflecting an effect on either the entire local or systemic tumor burden so that they minimize the problem related to sampling. None of the available indicators of disease progression and androgen responsiveness is sufficiently reliable to permit exclusion of any patient group from the potential benefits of androgen-ablative therapy (378).

Timing of Hormonal Therapy

Advanced-stage CaP has a high rate of natural progression. For example, the VACURG has shown that the median survival time of men with roentgenographic evidence of bony metastasis is somewhat less than 12 months (114). Involvement of pelvic lymph nodes by metastatic CaP is associated with clinically identifiable metastatic disease in 50% of patients at 36 months and 80% of patients at 52 months following diagnosis (39). These patients with no D-positive disease have a reported 5-year survival of approximately 50% (1054). These findings are not restricted to patients with definable metastatic tumor burdens, because the VACURG has shown regular progression of patients with stage C carcinoma to recognizable stage D in 30% of patients in 24 months and in half of patients at 52 months following diagnosis (113). There is little doubt that androgen-ablative therapy remains the accepted first-line treatment modality for patients with metastatic CaP. There is considerable controversy, however, with regard to the appropriate timing of such therapy. This apparent dilemma exists because of the lack of definitive evidence that hormonal manipulation prolongs survival and from the conclusions of the VACURG study that suggested that delayed hormone therapy has no adverse effects on survival (65).

It is relatively easy to construct a list of absolute or relative indications for the initiation of hormonal therapy. The onset of frank paraplegia due to spinal cord compression or clinical evidence of impending neurologic involvement mandates the urgent initiation of such treatment, preferably orchiectomy. Obviously, the patient should be observed with vigilance to ascertain the need for emergency decompressive laminectomy and other adjunctive therapeutic measures (steroid and radiation therapy). Similarly, few urologic surgeons would contest the validity of initiating androgen-ablative therapy in patients presenting with intravesical or extravesical ureteral obstruction secondary to progressive CaP. Retrograde or antegrade passage of double-J ureteral stents may be a necessary adjunctive treatment. Approximately three-fourths of the patients with hydronephrosis demonstrate significant improvement following the initiation of castration or multimodal endocrine therapy (653). Extension through the posterior layer of Denonvilliers' fascia with subsequent rectal obstruction is decidedly rare but certainly constitutes an indication for prompt hormonal therapy and diverting colostomy (322). The obvious presence of bone pain due to metastasis, anemia, weight loss, and other systemic symptoms of disseminated disease constitutes legitimate, although perhaps not urgent, indications for treatment. Bladder neck obstruction due to locally aggressive disease can be significantly improved in approximately 65% of men within 6 months of androgen deprivation, with most patients responding within 2 to 3 months (299). This last clinical situation lacks universal acceptance as an indication for the initiation of hormone therapy.

The proponents of delayed initiation of hormone therapy cite several presumably supportive arguments in favor of that approach. Approximately 50% of untreated patients with clinical stage C or pathologic stage D_1 disease will manifest 5-year survival patterns without apparent disease progression (753,882). Another source of reluctance on the part of urologists to initiate hormone therapy is the undesirable side effects of treatment (previously discussed) on the patient without symptoms. Finally, the advocates of delayed hormonal therapy can cite theoretic objections rooted in the biology of tumor systems. Theoretically, a reduction in the mass of androgen-dependent cells in the absence of effective inhibition of the growth of androgen-independent subpopulations could release the latter from a state of decreased proliferation and ultimately augment their growth and dissemination (14,866). More recently, it has been proposed that androgen-independent cells that survive androgen-deprivation therapy may originate because of the ability of a small number of initially androgen-dependent stem cells to adapt to the altered hormonal environment through the induction of androgen-repressed protective mechanisms (820).

Various arguments also can be offered to support the contention of those urologists favoring the prompt initiation of hormonal therapy (532,538,1036,1123,1141). Although the causal mechanism is uncertain, the survival advantage of patients with advanced prostate cancer in the postendocrine as compared with the preendocrine era is prolonged (711,1042). In the VACURG study, treatment of patients with stage C disease with either 1 or 5 mg of DES daily reduced the recognized progression in 52 months following diagnosis from 50% to 10% (113). Furthermore, limited data suggest that the combination of radical prostatectomy coupled with immediate endocrine therapy may possess an advantage over sequential therapy in patients with diploid tumors with regard to disease progression and perhaps survival (1137,1139). Certainly, the early initiation of hormone therapy permits the recognition of nonresponders to such treatment at a point in their disease process before profound weight loss, anemia, and generalized inanition develop.

Theoretically, these hormonal nonresponders would be better candidates for additional multimodal therapy because of the presence of smaller tumor burdens and their enhanced physical status. In his analysis of the Dunning R-3327H rat prostatic adenocarcinoma model, Isaacs (454) determined that prompt initiation of endocrine therapy prolonged survival and that the concomitant use of chemotherapy (cyclophosphamide) was most efficacious when both therapies were begun promptly and simultaneously.

A reanalysis of the VACURG data (66) tended to support the efficacy of early rather than delayed hormonal therapy. Finally, Byar and Corle (112a) presented the most recent reanalysis of the VACURG data and concluded that younger patients with high-grade tumors (Gleason score 7 to 10) and advanced stage disease derive a survival benefit from the initiation of hormone therapy (DES 1 mg) begun at diagnosis. Patients with low-stage disease and low-grade tumors (Gleason score 2 to 6) probably do not need hormone therapy.

More recently, Messing and associates (648) reported on 98 men who underwent radical prostatectomy and pelvic lymphadenectomy and who were found to have nodal metastases. These men were randomly assigned to receive immediate antiandrogen therapy (either goserelin or bilateral orchiectomy) or were followed until disease progression. After a median of 7.1 years of follow-up, 7 of 47 men who received immediate hormonal therapy died, as compared with 18 of 51 men in the observation group. The cause of death was CaP in 3 men in the immediate treatment group and in 16 men in the observation group. They concluded that immediate antiandrogen therapy after radical prostatectomy and pelvic lymphadenectomy improved survival and reduces the risk of recurrence in patients with node-positive CaP. Several explanations were offered to explain the conclusions generated in this study as compared with that of the original VACURG. First it was proposed that patients with less residual cancer are more likely to benefit from prompt and effective androgen ablation as compared with those confronted by substantial tumor burden. This theory underscores the potential importance of controlling the primary tumor and initiating treatment when the metastatic tumor burden is minimal. These

results confirm those of investigators at the Mayo Clinic (691,894). In the latter series, only patients with tumors that consisted of DNA diploid cells had a survival advantage with immediate therapy and that advantage was evident only after 10 years of therapy. The study by Messing and associates (648) was a prospective and randomized clinical trial unlike the retrospective study conducted by the Mayo group. Further validation of the potential value of early hormonal therapy emanated from the study conducted by Bolla and associates (77). In that study patients with clinical stage T_2 or T_3 prostate cancer who received goserelin during external beam radiotherapy and for 3 years thereafter had significantly higher survival rates than similar patients who received radiotherapy alone.

Observations such as these raise legitimate questions about concepts that have guided common practices in treating patients with CaP. We can no longer dismiss the possibilities that early rather than delayed hormone therapy, surgical tumor mass reduction, and radiation/hormone therapy synergism, for example, as well as other novel approaches may have a place in treating patients with this disease. A healthy degree of management uncertainty will probably persist for some time as we appropriately scurry to obtain new data and understanding. In the meantime, we judge it appropriate to use the various tools we have to characterize the patient and his disease to select appropriate choices from alternatives such as early versus delayed initiation of hormone therapy for consideration in management of CaP patients.

Intermittent Endocrine Therapy

It appears that both genetic (453) and epigenetic (106) influences contribute to the emergence of the androgen-independent phenotype. With respect to the latter concept, various compelling preclinical studies have been conducted using the androgen-dependent Shionogi mouse mammary carcinoma. These studies suggest (a) that the parenteral tumor consists of stem cells that are initially androgen-dependent; (b) that following androgen-withdrawal, tumor cell killing is limited to two to three logarithms before compensatory adaptive mechanisms emerge, including disappearance of ARs from the nucleus and expression of androgen-repressed genes such as c-fos and c-myc; (c) that part of this adaptive response also involves the induction of genes that may protect the tumor cells from programmed cell death, such as TRPM-2 (clusterin); and (d) that the alterations in the hormonal environment attendant to androgen withdrawal play a significant role in the induction of the androgen-independent state (106,820). LNCaP tumor cells can adapt to reduced androgen availability by increasing the AR mRNA levels (2.5-fold) and the AR protein levels (15-fold), thus increasing their sensitivity to androgen, which suggests that prostate tumor cells may adapt to the altered hormonal environment induced by antiandrogen and/or androgen ablation therapy by increasing the transcriptional activity or steroid affinity of the AR as a potential survival mechanism. LNCaP cells that have adapted to an androgen-free environment are hypersensitive to very low concentrations of androgen and their growth is, in fact, repressed by moderate androgen concentrations.

These and other *in vitro* observations prompted animal studies using the Shionogi mouse tumor to determine whether the ultimate emergence of the androgen-independent phenotype could be delayed by intermittent androgen suppression. In this study, the tumor was transplanted into a series of male mice, each of which was castrated when the estimated tumor weight became approximately 3 g. Once the tumor regressed to 30% of its original weight, it was again transplanted to the next noncastrated male animal. This “cycle” of transplantation and castration-induced regression was repeated through four generations before the androgen-independent phenotype emerged. The implication of this study is that a similar “cycling” of androgen-ablative therapy might prolong the time to emergence of the androgen-independent phenotype threefold to fourfold.

A modest amount of clinical information exists that tends to support this concept. Klotz and co-workers (515) reported on their experience with 20 patients with advanced CaP. The median duration of endocrine therapy before the withdrawal of treatment was approximately 10 months. Disease progression occurred at a median of 8 months following interruption of therapy. All of these patients who relapsed had a rapid clinical response following the resumption of androgen-ablative treatment. It has been suggested that the most attractive patients for this approach are those individuals who achieve undetectable serum PSA levels following the initiation of total androgen blockade.

Several recent clinical studies attest to the potential utility of intermittent androgen deprivation (IAD). Grossfeld and associates (388) conducted a study involving 47 patients with clinically localized CaP. No patient was found to have systemic disease before the initiation of therapy. In this study, androgen deprivation was continued 1 to 2 months after serum PSA became undetectable or a nadir level was reached. Therapy then was reinstituted after serum PSA reached a predetermined level. The serum PSA level at which therapy was reinstituted was individualized for each patient and was determined by one of the following parameters: (a) serum PSA level greater than 50% of the pretreatment level, (b) serum PSA level greater than 10 ng/mL, or (c) patient request. In this study, only 1 patient failed to respond to reinstitution of treatment and that patient was found to have metastatic disease during his second cycle of treatment. These investigators believe that IAD is a viable treatment option in selected patients with clinically localized prostate cancer.

Strum and associates (988) reported on 52 patients with CaP treated with IAD. Prior treatment in this group included (a) none in 29 of 52, (b) radical prostatectomy with PSA relapse in 13 of 52, (c) failed external beam radiation therapy in 4 of 52, and (d) treatment failure following radical prostatectomy and external beam radiation in 6 of 52. Most exhibited localized disease (46%) or PSA relapse following an attempt at definitive therapy (37%). Four percent and ten percent of patients were assigned clinical stage D_0, D_1, or D_2, respectively. Therapy was stopped upon achieving an undetectable serum PSA level (median of 1 year). Patients were followed off therapy and advised to restart androgen ablation if the PSA level reached greater than or equal to 5.0 ng/mL. In 28 patients who maintained an undetectable serum PSA level for greater than or equal to 1 year, their median off-phase duration was 29 months with 9 (32%) still off IAD after median follow-up of 62 months. Multivariant analysis revealed several significant independent factors associated with prolonged off-phase duration, including undetectable PSA on androgen deprivation therapy greater than or equal to 1 year, PSA-only recurrence after local therapy, and reaching a testosterone level greater than or equal to 150 ng/dL in greater than or equal to 4 months off androgen ablation.

According to Gleave (365), the definition of PSA nadir should be the lowest serum PSA level attained following institution of androgen ablation and, by definition, plateaus out and falls no further. Studies conducted by Goldenberg and associates (366) and Gleave and associates (364) suggest that patients initially should be treated for a minimum of 9 months because PSA nadir and maximal soft tissue regression (when definable) are not reached until 8 or 9 months in many cases. Ideally, androgen ablation should be continued until maximal tumor regression has been induced, but stopped before constitutive development of the androgen-independent phenotype (365). The length of the “off cycle” remains somewhat empirical but should be long enough to permit normalization of libido and reversal of the other symptoms associated with the androgen deprivation syndrome. In addition, the off cycle should be of sufficient duration to permit testosterone-induced tumor cell differentiation (365). Factors that can influence the decision to reinitiate therapy include pretreatment PSA levels, stage, PSA velocity, presence of symptoms, and tolerance of androgen ablation therapy (365). A reasonable PSA “trigger point” for the resumption of androgen ablation in patients being treated for postradiotherapy or postprostatectomy recurrences is a value greater than or equal to 4 mg/mL (365). Similarly, the PSA “trigger point” for the resumption of androgen ablation in patients with metastatic disease would be values ranging from 10 to 20 mg/mL. It would appear that biochemical failures following radiotherapy or surgery are the groups most likely to benefit from intermittent hormonal therapy (77).

A recent concept related to IAD is the potential value of initiating finasteride when patients are taken off cycle. With this strategy, a shift would be induced toward elevated tissue testosterone levels while maintaining suppression of DHT production. Preclinical studies have suggested that testosterone induces more differentiated tumor phenotype. The latter is at least theoretically more likely to maintain a low proliferative potential while the patient is off cycle.

It must be emphasized that the concept of intermittent androgen suppression remains a novel hypothesis, the validity of which must be ascertained through multiinstitutional clinical trials that are currently ongoing. Finally, it is important to state that this concept is not incompatible with the early initiation of androgen-ablative treatment. It merely suggests that once initiated, carefully orchestrated “cycling” may also be beneficial with respect to maintaining a small tumor volume expressing a predominantly androgen-dependent phenotype.

PC-SPES

PC-SPES is an herbal combination used by patients with prostate cancer that consists of the following eight herbs: chrysanthemum, isatis, licorice, *Ganoderma lucidum,* Panax, pseudoginseng, *Rabdosia rubescens,* saw palmetto, and scutellaria (skull cap) (285,397,433). Mass spectrometry has shown that PC-SPES contains estrogenic organic compounds that are distinct from DES, estrone, and estradiol (232). In the latter study, the clinical activity of PC-SPES was evaluated in eight patients with hormone-sensitive prostate cancer, and it decreased serum PSA concentrations in all eight. It also decreased the serum testosterone concentration in the six men tested. All patients had breast tenderness and loss of libido, and one had venous thrombosis. Thus this unregulated herbal dietary supplement had a clinical impact and side effects similar to those of pharmacologic doses of estrogen.

De la Taille and associates (218) performed a preclinical and clinical study assessing the impact of PC-SPES. The *in vitro* evaluation was designed to assess the impact of PC-SPES on the induction of apoptosis using prostate cancer cell lines LNCaP, PC3, and DU145 as the tumor targets. All the cell lines exhibited a significant dose-dependent induction of apoptosis following exposure to PC-SPES. Furthermore, immune-deficient mice xenografted with the PC-3 cell line exhibited

reduced tumor volume compared with sham-treated controls when they were treated with the PC-SPES extract from the time of tumor implantation but not when the treatment was begun 1 week after tumor implantation. Of interest, the testis, prostate, bladder, and seminal vesicles of the treated mice were significantly reduced in weight when compared with the sham-treated animals. In the clinical arm of their study, 69 patients with prostate cancer were treated with three capsules of 320 mg PC-SPES daily. Eighty-two percent had decreased serum PSA levels at 2 months, 78% at 6 months, and 88% at 12 months after treatment with PC-SPES. Side effects included nipple tenderness in 42% and phlebitis requiring heparinization in 2%.

Small and associates (926a) evaluated the impact of PC-SPES on 35 patients with androgen-independent prostate cancer and noted that 19 of 35 (54%) had a PSA decline of greater than 50%, including 8 (50%) of 16 patients who had received prior ketoconazole therapy. Median time to PSA progression was 16 weeks. Of 25 patients with positive bone scans, 2 had improvement, 7 had stable disease, 11 had progressive disease, and 5 did not have a repeat bone scan because of PSA progression. As a composite, these and other studies suggest that PC-SPES may have some activity in the treatment of both androgen-dependent and androgen-independent prostate cancer. This activity may be related to an induction of program cell death and/or a decrease in the expression of AR (397,433,434).

Objective Assessment of Therapeutic Efficacy

The patterns of metastasis exhibited by CaP make the objective assessment of treatment response following the initiation of androgen-ablative therapy somewhat difficult. Until the advent of TRUSP, accurate assessment of changes within the prostate gland with regard to consistency, tumor extension, and overall tumor volume have been dependent on the evaluation afforded by digital examination. Changes in the status of the two common sites of metastases, the pelvic lymph nodes and osteoblastic bone lesions, are likewise difficult to identify or quantify. Even the validity of sequential analysis of serum PSA and PAP has been questioned with the recognition that these levels may fluctuate in patients without treatment or result from faulty handling of the specimen or methods (714,872). These difficulties have required the segregation of large numbers of patients into nonevaluable or stable categories. Clinical and scientific intuition suggests that this subset of patients is undergoing dynamic changes that merely elude our current evaluation procedures.

Even with currently available methods, legitimate assessments can be made with regard to treatment efficacy in a substantial number of patients. Huggins and Hodges (446) were able to convincingly document a significant diminution in serum acid phosphatase following castration in patients. Since then, various studies have reinforced these observations, documenting a greater than 50% decrease in levels of serum PAP in the vast majority of patients treated with the spectrum of available endocrine therapy. Serum PSA now plays a preeminent role in monitoring untreated patients or those subjected to radical prostatectomy or radiation therapy and in patients with endocrine-treated metastatic disease.

Bone scans provide an estimate of cellular activity but give little information regarding bone density (786). Despite this limitation, several studies have documented discernible improvement in bone scans of patients treated with various androgen-ablative therapies. The observed incidence of improvement varied from 48% in a study comparing the efficacy of EMP with DES (63) to 27% by Shearer and associates (907), and 16% as documented by Fitzpatrick and associates (295). The results were even more disparate in the LHRH studies in which Labrie and associates (550) reported 100% of patients with improved bone scan as compared with 1 (8%) of 12 reported by Faure and associates (288). Carefully using our current evaluation procedures, such as TRUSP and serum and urine markers, and developing new techniques to assess the effect of therapeutic procedures on tumor growth are critical to permit identification of effective treatment regimens in patients with CaP without relying on cumbersome, incomplete, and inaccurate survival information.

Hormone-refractory State: The Role of Additional Hormonal Therapy

Patients with stage D_3 (androgen-refractory) disease have a dismal prognosis, with a mean survival of less than 1 year (147). That the vast majority of patients with stage D disease ultimately demonstrate disease progression despite hormonal therapy is an ominous clinical reality whether AID cells preexist or develop in the primary tumor and its metastasis. Despite numerous attempts, no significant palliative or survival advantage has ever been conferred with regularity by further efforts to eliminate androgens or their effects in these patients. Only a selective sampling of such attempts is discussed in the next few paragraphs.

Several studies have assessed secondary DES administration in patients who failed to benefit from orchiectomy. Most of these studies revealed transient objective improvement in 20% to 30% of patients, but no demonstrable survival benefit was discernible (711). Clinical improvement was noted in 20% of patients treated with high-dose DES (Stilphostrol) after failing previous endocrine therapy; three of these patients had a decrease in acid phosphatase levels (174). Conversely, several studies evaluated the effect of orchiectomy following the failure of estrogen therapy. For example, Stone and associates (984) noted one partial objective response and four stable responses in 21 patients after secondary orchiectomy and Klijn and associates (514) reported enhanced survival compared with those treated with estrogens following orchiectomy.

Antiandrogens and inhibitors of steroid synthesis have shown modest efficacy when used as secondary modes of endocrine therapy. Flutamide (and other nonsteroidal antiandrogens) has been associated with favorable objective responses in between 20% and 30% of patients who have failed prior endocrine therapy. However, these responses were of very short duration and produced no apparent survival benefit (700,940,983). Data concerning cyproterone acetate produced discrepant results; several studies report favorable responses ranging between 50% and 70% in patients with advanced-stage prostate cancer (936,1087). Conversely, Tvetor and associates (1028) observed little demonstrable evidence of tumor regression in a similar group of patients.

TREATMENT OF METASTATIC HORMONE-REFRACTORY PROSTATE CANCER

The objective and subjective response of 75% of the patients with metastatic CaP to androgen-ablative therapy has a major positive impact on their management. Unfortunately, after a quiescent period of a few months to several years, most patients develop the uncontrolled growth of so-called hormone-refractory prostate cancer (HRPC). PSA monitoring has permitted earlier recognition of increasing tumor load, magnified the apparent response rates to initial hormone therapy, and extended the recognizable period of survival after development of hormone refractory tumor growth. The ominous probability that half of the patients with HRPC cancer would die within the first year following relapse and the majority of the remainder in the next (143,923) has been modified by the lead time lengthening associated with PSA monitoring of CaP patients. Nevertheless, although problems from progressive disease seem delayed, they are expected. These observations provide an incentive to better understand the biology of HRPC and to develop novel durably effective and well-tolerated therapies.

Mechanisms Underlying the Emergence of Androgen-independent Tumor Clones

Although the actual mechanisms underlying the emergence of HRPC remain unclear, both genetic (453) and epigenetic (106) events appear to play a role in this phenomenon, which is typified by cellular de-differentiation. At present, there is no uniform consensus regarding when HRPC first emerges.

The studies conducted by Isaacs and Coffey (453) using the Dunning rat model of prostate cancer support the concept that *the development of HRPC is a relatively early event at the clonal level*. This perception is supported by more recent studies involving PIN, which have identified phenotypes within PIN foci that are frequently noted in high-grade HRPC. Examples of the latter include frequent identification of aneuploidy (83,57); gains of chromosome 7 (85,804); and the frequent occurrence of allelic loss at chromosomes 7q31-q35, 8pl2-21, 8p22, 8q22, 8q22.2, and 8ql2.2 in both PIN and invasive prostate cancer (83,85,273,1051) (Table 33.4). Also intriguing is the identification of telomerase activity (which prevents apoptosis), present in 92% of CaP (1130), and in PIN (73%), BPH (50%), atrophy (16%), and normal-appearing tissue (36%) located adjacent to prostate cancer foci. This shared enzymatic characteristic could be due to the presence of occult cancer cells or shared molecular alterations that are histologically not apparent. In distinction, the studies conducted by Koeneman and associates (519) could identify telomerase activity in only 4 of 25 samples (16%) of high-grade PIN. Furthermore, all telomerase-positive PIN foci exhibited a diploid DNA content. As stated previously, telomerase is the ribonucleoprotein that adds telomeric repeats to the ends of chromosomes. Excessive telomere shortening can lead to genomic instability. The subsequent gains/loss of genomic DNA is a characteristic feature exhibited by metastatic CaP. In the study conducted by Donaldson and associates (237) there appeared to be a direct correlation between reduced telomere DNA content in CaP specimens and subsequent disease recurrence and death.

We previously addressed the role of bcl-2 oncoprotein with respect to inhibition of program cell death or apoptosis in CaP systems. Indeed, it has been suggested that bcl-2 may play an important role in the emergence of hormone resistance, and several studies have demonstrated enhanced expression of bcl-2 in HRPC (182,626). In the study conducted by Baltaci and associates (34), bcl-2 staining was detected consistently in the basal cell layer of the ducts and acini in BPH samples. No staining was ever apparent in luminal cells. Bcl-2 immunoreactivity was present in 10 of 15 high-grade PIN lesions. Bostwick (85) provides a detailed summary of the phenotypes that link high-grade PIN with invasive (and hormone refractory) CaP.

Recently, Craft and associates (190) performed studies using a novel human prostate cancer xenograft (LAPC-9), which was propagated by serial passage in male severe combined immunodeficiency disease (SCID) mice. This xenograph expresses PSA and wild-type AR. Following castration, LAPC-9 cells undergo growth arrest

and persist in a dormant androgen-responsive state for approximately 6 months. Ultimately, spontaneous androgen-independent outgrowths develop. In this model, progression to androgen independence occurs through two distinct states, initially escaping dependence on androgen for survival and, ultimately, for growth. They demonstrated that the latter stage of androgen independence results from clonal expansion of androgen-independent cells present at a frequency of approximately 1 per 10^5 to 10^6 androgen-dependent cells. They postulated that prostate cancers contain heterogeneous mixtures of cells that vary in their dependence on androgen for growth and survival. Treatment with antiandrogen therapy provides selective pressure and alters the relative frequency of these cells, leading to androgen-independent cancers.

The studies conducted by Bruchovsky and associates (106) using the androgen-dependent Shionogi mammary carcinoma model support the hypothesis that immediately following tumor transformation, most, if not all, of the cells constituting the primary tumor are predominantly androgen dependent. HRPC clones emerge during the course of tumor progression. This event may be influenced by both genetic instability, which is inherent in proliferating tumor systems, and environmental (epigenetic) factors (i.e., sustained androgen ablation).

The molecular mechanisms underlying the emergence of HRPC are almost certainly multifactorial. One popular concept is that methylation of CpG islands results in gene inactivation and that methylated sequences are heritably silenced. CpG islands, cytosine-rich areas located in the 5' regulatory region of a given gene, are unmethylated in most normal adult tissues (739). The methylation of this critical region of the genome can block transcription of downstream sequences that may be critical to normal cellular homeostasis. Examples of aberrant CpG island methylation possibly relevant to the emergence of HRPC include the inactivation of the CDKN2/pl6/MTSI gene (a cell cycle regulator) (415) and loss of E-cadherin expression (which decreases cell-cell cohesiveness) (371).

Alterations in the structure and/or expression of the AR gene also may play a role in emergence and progression of HRPC. The AR gene, located on the long arm of the large X chromosome, codes for a transcription factor within the super family of steroid receptors. Exon 1 encodes the transactivation domain that mediates target gene transcriptional activation. Exon 1 also encodes two polymorphic polyamino acid tracts—poly-Q $(CAG)_n$ and poly-G $(GGC)_n$ (842). Taplin and associates (1003) demonstrated that 5 of 10 HRPC metastases contained mutations in the ligand-binding domain of the AR gene. More recently, single-strand conformational polymorphism analysis and DNA sequencing of the entire AR gene coding region revealed base changes leading to amino acid substitutions in the AR in 44% of 25 advanced primary prostate cancers before endocrine treatment (1016). Marcelli and associates (617) performed a more recent evaluation. These investigators analyzed the frequency and relevance of mutations in the coding region of the AR in genomic DNA extracted from 137 specimens of CaP. The overall number of mutations detected was 11 (8%). Of interest, no mutations were detected in any of the 99 patients with organ-confined disease. Eleven mutations were detected in exons 2 to 8 in 8 of the 38 patients with stage D_1 disease. In contrast to previous reports, these data suggest that AR mutations may be rare and may not play a strategic role in the initial phase of prostatic carcinogenesis. The presence of a significant number of AR mutations in metastatic disease does suggest that these mutations may play an important role in the most advanced stages of this disease process. Finally, Koivisto and associates (521) reported an interesting series of observations. These investigators studied six prostate cancers diagnosed during finasteride treatment for BPH. Comparative genomic hybridization detected genetic alteration in four tumors. Xq and 6q were the most common alterations. The recurrent Xq gains prompted these investigators to study the involvement of the AR gene. One tumor Xq gain had a threefold amplification of the AR gene. This suggested that tumor development in finasteride-treated patients may require increased AR copy number and expression as has previously been shown for prostate cancers recurring during hormonal therapy. In another tumor, an Arg 726Leu mutation of the AR gene was identified. This mutation previously has been reported to affect the transactivational properties of the AR gene.

Description of the Cellular and Molecular Characteristics Associated with the Androgen-independent Phenotype

Numerous adverse tumor cell features have been associated with poorly differentiated HRPC, including the following:

1. Gleason grade 4 or 5 (532)
2. Tumor volume greater than l mL (968)
3. Tetraploid/aneuploid DNA content (906)
4. Abnormal cell shape, motility, and negative surface charge (127,666)
5. Decreased nuclear AR expression (102), despite intact/amplified AR genes
6. AR gene mutations (327) and certain polymorphisms (shorter CAG repeat length) in the AR (361)
7. Gains of chromosomes 7 and 8 (998)
8. Deletion of a putative metastasis suppressor gene (KAI 1) on chromosome 11 P11.2 (449)
9. Increased tumor neovascularity (91,289)
10. Enhanced expression of urokinase-type plasminogen activator, which promotes matrix degradation and its receptors (343,495)
11. Aberrant expression of growth factors, their receptors, and binding proteins (304,427,977)
12. HER-2/neu overexpression (EGFR activity) (230,692,917)
13. p53 gene mutations (controls G1-S breakpoint) (79,412,626,704)
14. Upregulation of the bcl-2 gene with inhibition of programmed cell death (626)
15. Decreased tumor cell cohesiveness and increased invasiveness associated with reduced expression of E-cadherin gene and/or deletion of the a-catenin gene (674,826,1031,1032)
16. Upregulation of thymosin B-15, which enhances tumor cell motility
17. Increased endothelin-1 and endothelin receptor expression (708,709)
18. Elevated serum levels of TGF-b1 (459)
19. Loss of expression of TGF-b1 type I and/or type II receptors (394,504)
20. Increased IL-6 expression (activates AR) (421,728,1029)
21. Decreased expression of neutral endopeptidase 24.11 (inactivates neuropeptides) (743)
22. Loss of cyclin-dependent kinase inhibitor p27 Kipl (394,1119)
23. Differential expression of the nuclear matrix protein, designated YL-I (553)
24. Increased expression of the RET protooncogene tyrosine kinase growth factor receptor on chromosome 10qll.2 (214)
25. Preferential adhesion to human bone marrow endothelial cells (568)
26. Overexpression of caveolin-1 (inhibits apoptosis, mediates molecular transport, augments signal transduction activities) (1118)
27. Overexpression of COX-2 (decreases E-cadherin expression, overexpression of matrix-degrading enzymes, increased production of angiogenic factors) (593)
28. Overexpression of matrix metalloproteinases (476)
29. Inactivation PTEN (tumors suppressor) gene located at 10q 23.3 (1050)
30. Overexpression of parathyroid hormone-related protein (autocrine/paracrine growth factor; binds to receptors on osteoblasts and stimulates bone formation/resorption) (241)
31. Enhanced expression of the GBX2 homeobox gene (upregulates transcription of the IL-6 gene) (334)
32. Increased expression of osteonectin/SPARC (antiadhesive protein involved in cell–matrix interactions, migration, and androgenesis) (1013)
33. Defective generation of ceramides (a key sphingolipid mediator of apoptosis) (1073)
34. Overexpression of neuropeptides (calcitonin, serotonin, somatostatin, bombesin/gastrin—a releasing peptide, thyroid-stimulating hormone, neurotensin) with subsequent induction of type 4 collagenase (896)
35. Increased expression of the proliferation marker KI-67, a nuclear antigen and molecular marker associated with disease progression (682)
36. Increased intracellular levels of SGP-2 (clusterin), apoptosis inhibitor (975)

Several recent and important observations have enhanced our understanding of the genomic changes associated with CaP. These studies involve sophisticated molecular approaches that expand the data generated using basic cytogenetic analysis and include fluorescence in situ hybridization (FISH); comparative genomic hybridization (CGH); and tissue microdissection, DNA extraction, and polymerase chain reaction (PCR) amplification to determine microsatellite alterations.

Step-section analysis performed on whole-gland specimens containing CaP most often reveals the presence of multiple tumor foci (533). It has been debated whether these observations reflect a “field change” phenomenon (382) or merely represent intraglandular spread following unifocal tumor development. Studies conducted by Cheng and associates (164) involved a molecular analysis of microsatellite alterations in the DNA from separate tumors in the same prostate. Their study focused on factors for the putative tumor suppressor gene on chromosome 8p and for the BRCAI gene on chromosome 17q. The pattern of allelic loss documented in that study was compatible with independent tumor origin in 15 of 18 informative cases. This finding tends to validate the “field change” hypothesis.

Using FISH analysis, Takahashi and associates (998) evaluated needle biopsy cores from randomly selected radical prostatectomy specimens and documented gains of chromosome 7 and 8 in 76% and 59% of aneuploid tumors (998). A higher Gleason score correlated with gains of chromosome 7 and 8 and advanced tumor stage with gains of chromosome 7. A similar analysis of paraffin-embedded radical prostatectomy specimens (997) noted that gains of chromosome 8, aneusomy of

chromosome 8, and aneusomy of chromosome Y correlated highly with systemic cancer progression. Multivariate analysis subsequently demonstrated that gains of chromosome 8 and aneusomy of chromosome Y were significant independent predictors of systemic cancer progression.

CaP allelotyping studies revealed frequent loss of heterozygosity (LOH) on chromosomes 8p (50%), l0p (55%), l0q (30%), 16q (31% to 60%), and 18q (17% to 43%) (132,545). Visakorpi and associates (1049) expanded these observations by performing CGH to screen for DNA sequence copy number changes along all chromosomes in 31 primary and 9 recurrent uncultured prostate carcinomas; 74% of primary prostate cancers showed DNA sequence copy number changes. Losses were five times more common than gains and most often involved 8p (32%), 13q (32%), 6q (22%), 16q (19%), 18q (19%), and 9p (16%). Of note, frequent gains of 7, 8q, and X were associated with prostate cancer progression and the development of hormone-independent growth.

Cher and associates (165) also used CGH to study CaP metastases in patients who had received no prior treatment and compared these observations with those generated from an analysis of primary or recurrent tumors in patients who had received long-term androgen-deprivation therapy. In treatment-naive metastatic foci, several altered chromosomal regions were documented, including 8q gain (85%), 8p loss (80%), 13q loss (75%), 16q loss (55%), 17p loss (50%), and 10q loss (50%). Of interest, the observations generated in the "treated" group were very similar to those of the "treatment-naive" group. The study also demonstrated several previously undetected regions of frequent loss including 2q (42%), 5q (39%), 6q (39%), and 15q (39%). Gains of chromosomes lp (52%), lq (52%), 3q (52%), and 2p (45%) also were documented. Of interest, African American patients demonstrated a significantly higher frequency of gain of the 4q 25 to q 28 region.

It is suspected that the regions of loss contained known or candidate tumor suppressor genes. Chromosome 5q31 contains the a-catenin gene, which is an obligatory component of the E-cadherin-mediated cell adhesion complex (325). PC-3, DU-145, and TSU-PRI HRPC cell lines have reduced or absent levels of a-catenin or E-cadherin (676). LOH at 7q31.1 (c-met oncogene locus) is correlated significantly with a higher Gleason score and lymph node metastasis (781,996). Chromosome 10q22. L-qter harbors the candidate tumor suppressor gene Mxil (248). The Mxil protein is thought to repress c-myc activity, and loss of this suppression may lead to c-myc activation (1129). LOH at 10q23.3, a region commonly deleted in CaP, may involve the loss of the candidate tumor suppressor gene designated PTEN/MMACI (994). Inactivation of this gene may contribute to the acquisition of metastatic potential in CaP. Another putative metastasis suppressor gene has been mapped to human chromosome llpll.2 and has been designated KA I1 (238). KAI1 expression is significantly reduced in human CaP cell lines derived from metastatic foci (PC-3, LNCaP, TSU-PRI, and DU-145). The retinoblastoma susceptibility gene (RBI) is located on 13ql4. Approximately one-third of CaP exhibit LOH at this locus (165,185). Chromosome 16q contains the E-cadherin locus. E-cadherin is required for normal calcium-mediated cell-to-cell adhesion. Its expression is frequently lost in high-grade, androgen-independent CaP involved with invasive/metastatic potential (1031,1032). Recent studies suggest that there is a separate region of 40% loss at 16q24 that may contain another important tumor suppressor gene (165). More than 50% of prostate cancers analyzed demonstrate allelic loss of at least one locus on chromosome 17q, which contains the BRCAI gene (336). Finally, the p53 tumor suppressor gene is located on 17p and is known to be mutated in 20% to 25% of metastatic prostate cancers (165).

Regions of gain contain dominant oncogenes whose expression is amplified with increased copy number. The epidermal growth factor receptor (erbB-I) is located on chromosome 7p (165). Chromosome 7 trisomy is associated with higher grade and advanced-stage CaP (11,36). The c-met oncogene maps to chromosome 7q31 and is amplified in 40% of metastatic HRPC (781). Chromosome 8q24 harbors the cMyc oncogene. Of note, CGH analysis suggests the presence of a potentially important oncogene at 8q21.3 (165). The H-Ras oncogene is located at llpIS.5, but this region is not identified as a common region of gain in prostate cancer. CGH analysis indicates a gain in the region of chromosome 17q that includes BRCAI (165). In distinction, the PCR-based analysis conducted by Gao and associates (336) noted a frequent loss of LOH at that locus. The erbB-2 oncogene is located at 17ql2 (543). Chromosome Xql2 contains the AR gene, which demonstrates a significant degree of amplification in patients with tumor recurrence following protracted androgen-ablative therapy (165). As stated previously, increased frequency of gains in the region 4q25-q28 is a prominent feature of prostate cancer developing in African Americans (165). It is theorized that a gene at that locus may be increased in activity and responsible for a more rapid rate of disease progression demonstrated in this cohort (97,773).

Konig and associates (524) performed a cytogenetic characterization of several androgen-responsive and unresponsive sublines of LNCaP. The hormone-responsive sublines did not show any aberrations in chromosome 8. In contrast, the unresponsive sublines showed rearrangement of the short arm of chromosome 8, resulting in deletion of the 8p23~pTer region. Thus partial deletion of the 8p region may be linked with the development of androgen-independence.

The Ten Steps of the Metastatic Cascade

The metastasis of androgen-dependent and androgen-independent CaP constitutes a multistep process, which involves many well-defined tumor cell–host cell and cell–matrix interactions. Indeed, a dynamic reciprocity appears to exist between the tumor cell and other nontransformed cellular elements that constitute the host microenvironment. It would appear that both unidirectional and bidirectional signals are elaborated that can facilitate or inhibit subsequent tumor growth and progression. Figure 33.89 illustrates some of these concepts. To be successful, those tumor cells endowed with invasive and metastatic capacity must successfully complete every step of this process. With respect to the latter, the following ten progression events have been identified: (a) the transforming event, (b) tumor vascularization, (c) local tissue invasion, (d) penetration of lymphatics and venules, (e) detachment of invading tumor cells, (f) embolization of tumor cell aggregates, (g) arrest in capillary beds, (h) extravasation through capillary beds, (i) growth in distant organ microenvironments, and (j) the development of "second order" metastasis. It is important to have a conceptual familiarity with these defined components of a metastatic cascade. Each progression event constitutes a unique "target" for future therapeutic intervention. Figure 33.90 schematically summarizes these ten critical steps responsible for the pathogenesis of a metastatic lesion.

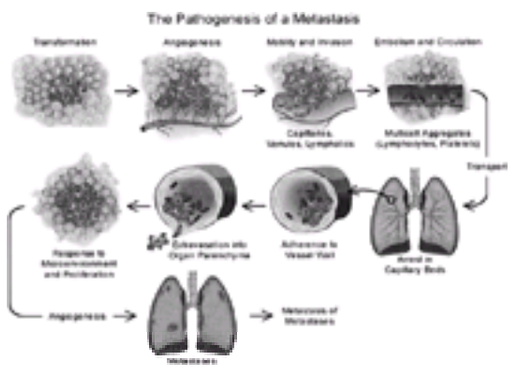

FIGURE 33.90. Successful completion of the metastatic process involves more than simply anatomic or "mechanistic" issues. It is now believed that an affinity exists between the tumor cell and the host microenvironment that is ultimately colonized. This phenomenon has been described as the "seed and soil" hypothesis. It should be emphasized that the process of metastasis consists of multiple sequential steps. All of these must be successfully completed to produce a clinically relevant metastasis. Angiogenesis must be induced to support the growth of both the primary neoplasm and its metastasis. See also Color Figure 33.90. (From Fidler IJ, Kumar R, Bielenberg DR, et al. Molecular determinants of angiogenesis in cancer metastasis [Review]. *Cancer J Sci Am* 1998;4[Suppl 1]:S58, with permission.)

Hormone-refractory State: The Role of Additional Hormonal Therapy

Patients with metastatic HRPC have a dismal prognosis, with a mean survival of less than 1 year (147). The majority of patients with stage D_3 disease (Table 33.37) ultimately demonstrate disease progression despite antecedent and ongoing hormonal therapy. The latter may be attributable to the existence of hormone-dependent, hormone-sensitive, and hormone-insensitive cellular subsets existing within the primary tumor and its metastases. An alternative theory suggests relative androgen dependence in all of the cells constituting the primary tumor with changes in androgen requirement developing after treatment and time. Despite numerous attempts, no durable benefit has been conferred by further efforts to eliminate androgens or their effects.

Even more informative from the standpoint of biologic phenomena is the conversion of the end-organ AR blockade compounds such as flutamide (Eulexin) and bicalutamide (Casodex) from an apparent physiologic antagonist to a physiologic agonist of HRPC. Whether the mechanism of this role reversal (see Antiandrogen Withdrawal Syndrome) is due to cellular alterations or to cellular selection phenomena, it has a sufficient measurable impact on the growth of HRPC to be identifiable in approximately one-third to more than one-half of the patients with a duration of over a year in some (246,877). Several possible basic mechanisms may account for this phenomena (see below). However, regardless of the cause, the observation of the "antiandrogen withdrawal syndrome" is important.

Many patients exhibit an excellent biochemical and clinical response to androgen-ablative therapy for periods ranging from a few months to several years (or longer). Once the serum PSA consistently rises from its posttreatment nadir, concern must exist regarding the emergence of HRPC. If such patients are being maintained on total androgen ablation, serious consideration must be given to the cessation of the antiandrogen component for fear that continuation of these agents will have an adverse impact. Conversely, if the patient has been treated with monotherapy (scrotal orchiectomy or LHRH agonist), consideration should be given to the addition of an antiandrogen with the anticipation that 30% to 40% of such patients may exhibit a diminution in the serum of PSA levels (and perhaps other objective evidence of improvement) for a finite period of time (generally less than 4 to 6 months). Figure 33.91 illustrates some commonly encountered clinical scenarios and provides reasonable management options.

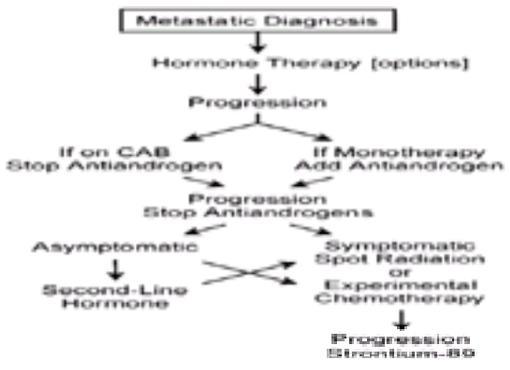

FIGURE 33.91. Treatment decision tree for patients with metastatic disease. (From Pienta KJ. *Advances in the treatment of metastatic prostate cancer.* Ann Arbor, MI: Biomedical Communications, University of Michigan, 1997:1, with permission .)

Following antiandrogen withdrawal (in an otherwise asymptomatic patient), a trial of observation should be entertained before any consideration is given to subsequent therapeutic intervention. *High-dose bicalutamide* (150 mg per day) exhibits modest efficacy in the management of HRPC, particularly in those patients who have received long-term flutamide therapy (475). Joyce and associates (475) reported 7 of 31 patients demonstrated PSA declines of greater than 50% for 2 months for an overall response rate of 22.5%. A surprising response rate of 43% was observed in those patients previously treated with flutamide. A favorable response was associated with an increased performance level and decreased analgesic requirements. Failure to achieve a flutamide withdrawal response did not preclude a subsequent response to high-dose bicalutamide. This regimen was well tolerated. Mild exacerbation of hot flashes was the most common side effect. Possible explanations for this response in flutamide-treated patients may reflect the selection of tumor cells with one of the following characteristics: (a) overexpression of AR, (b) alternations in AR associated coactivator proteins, or (c) presence of mutated AR.

Several studies have assessed *secondary DES administration* in patients who failed to benefit from orchiectomy. Most of these studies revealed transient objective improvement in 20% to 30% of patients, but no demonstrable objective benefit was discernible (711).

Citrin and associates (174) reported clinical improvement in 20% of patients treated with *high-dose Stilphostrol* after having failed previous endocrine therapy. Three of these patients also were noted to have a decrease in acid phosphatase levels. Conversely, several studies evaluated the effect of orchiectomy following the failure of estrogen therapy. Of particular interest was the study of Klijn and associates (514), who reported that patients treated with secondary orchiectomy following estrogen failure had enhanced survival as compared with those treated with estrogen following orchiectomy. The potential toxicity of DES is well known and is characterized by nausea, vomiting, fluid retention, gynecomastia, congestive heart failure, coronary artery disease, DVT, stroke, and pulmonary embolism. At 1 mg per day, DES does not produce consistent suppression of testosterone levels, but the observed therapeutic benefit appears to be equivalent to that of 5 mg per day. DES at 3 mg per day remains the basis for comparing the efficacy of new treatments for stage D CaP (157).

Antiandrogens and inhibitors of steroid synthesis have shown modest efficacy when used as secondary modes of endocrine therapy. *Flutamide* has been associated with favorable objective responses in between 20% and 30% of patients who have failed prior endocrine therapy. However, the duration of response was very short and no survival benefit was apparent (700,940,983). The data concerning *cyproterone acetate* are somewhat more perplexing in that several studies report favorable responses ranging between 50% and 70% in patients with advanced-stage prostate cancer (936,1087). These contrast sharply with the study of Tvetor and others (1028), who observed little demonstrable evidence of tumor regression in a similar group of patients.

Several studies have involved the assessment of *aminoglutethimide* as a second-line treatment modality with subjective improvement being noted in 9 of 12 patients in a study by Rostom and co-workers (844). In that study, however, no objective responses were noted. This is in contrast to the study of Worgul and associates (1107) who observed a surprising 48% objective response rate in 23 relapsing patients treated with aminoglutethimide. The concomitant administration of glucocorticoids in all of the aforementioned studies makes the assessment of subjective response all the more tenuous because these adrenal steroids are notorious for their ability to produce a sense of well-being approaching euphoria at times (662). Indeed, low-dose prednisone alone (10 mg per day) has been associated with a response rate of approximately 12% in patients with symptomatic HRPC (1001).

The results of ketoconazole studies are somewhat easier to interpret because concomitant corticosteroids were not used in the early studies. Objective responses were noted in 45% of patients treated with this agent following conventional endocrine therapy relapse (1093). A currently popular regimen includes *ketoconazole (400 mg every 8 hours) and supplemental hydrocortisone (20 mg per day).* Ketoconazole is an antifungal agent that blocks the 17,20-lyase enzyme in the adrenal gland and testis. Because the response to ACTH stimulation is blunted in the presence of high-dose ketoconazole, steroid supplementation is advisable. Caveats regarding the use of ketoconazole include the following: (a) Ketoconazole requires an acid environment for dissolution and absorption, and bioavailability in patients taking H_2 blockers is poor. (b) It is eliminated by hepatic metabolism and should be used with caution in patients with liver dysfunction. (c) Ketoconazole may induce GI/hepatic toxicity. Obviously, the physician must be attentive to the development of steroid-induced complications, including fluid retention, glucose intolerance, immunosuppression, poor wound healing, Cushing's syndrome, osteoporosis, and mental status changes. This combination regimen results in a transient PSA reduction in 60% of patients (926). Surgical adrenalectomy and hypophysectomy have been attempted in the past with little objective benefit and only transient subjective improvement (821). Finally, the potential utility of combining an antiandrogen (i.e. bicalutamide) and a 5a-reductase inhibitor (i.e., finasteride) awaits clarification.

In conclusion, it appears that further hormonal maneuvers remain a viable option in some patients with progressive prostate cancer following suppression of gonadal and adrenal androgen. Clearly, antiandrogen withdrawal is a mandatory maneuver before proceeding to other regimens. Certain patients will continue to respond to hormonal manipulation even after antiandrogen withdrawal. At present, it is not possible to dissect that cohort most likely to respond to additional manipulation from nonresponders. Such insight must await clarification provided by a detailed molecular analysis of their respective tumors (926). Bubendorf and associates (108) conducted an interesting, preclinical study. Using a cDNA microarray, they evaluated gene expression in the hormone-refractory prostate cancer xenograft designated CWR22R and its hormone-dependent counterpart (CWR22). Among 5,184 genes surveyed, expression of 37 (0.7%) was increased more than twofold in CWR22R. Conversely, the expression of 135 (2.6%) genes was reduced by more than 50% in that particular animal model. The genes encoding IGF-binding protein 2 and 27-kd heat-shock protein (HSP 27) were among the most consistently overexpressed genes in the hormone-refractory variant. Despite limited critical insights, the therapeutic approaches discussed may be reasonable in asymptomatic patients with low-volume metastatic disease who exhibit biochemical evidence of the hormone-refractory state (776).

Chemotherapy: A Historic Perspective

In the early 1970s, many clinical trials were initiated with the hope of identifying cytotoxic agents possessing demonstrable efficacy in the treatment of disseminated HRPC. The chemotherapeutic agents found to be modestly effective when used as single agents in the treatment of metastatic CaP were cisplatin, doxorubicin (Adriamycin), cyclophosphamide, fluorouracil, lomustine (CCNU), dacarbazine (DTIC), methotrexate, streptozotocin, and estramustine (154,1019,1113). The last two agents seemed best suited for use in patients with compromised bone marrow reserves as a result of antecedent radiation therapy (760,949,950). Unfortunately, only 10% of these patients demonstrated partial tumor regression when such agents were used, and the response was generally short-lived, averaging approximately 6 months (154,261). Although various drug combinations were used, none produced results that were statistically superior to single-agent therapy. Regrettably,

available studies have failed to demonstrate a significant survival advantage in patients with metastatic CaP undergoing conventional cytotoxic therapy. Table 33.38 and Table 33.39 summarize the early experience with single-agent and combination drug therapies that have been used in patients with disseminated prostate cancer.

Antitumor Agent	No. of Patients Treated	Responses (%)
Doxorubicin	76	14 (18)
Analine mustard	37	5 (14)
Cisplatin	137	40 (29)
Cyclophosphamide	119	43 (36)
Dacarbazine	55	15 (27)
Estramustine	163	45 (28)
Fluorouracil	81	17 (21)
Hydroxyurea[a]	58	19 (33)
Lomustine (CCNU)	10	4 (40)
Melphalan	15	1 (7)
Methotrexate	58	24 (41)
Semustine (methyl-CCNU)	27	8 (30)
Nitrogen mustard	23	10 (43)
Prednimustine	85	11 (13)
Procarbazine	39	5 (13)
Streptozocin	38	12 (32)
Vincristine	34	5 (15)

[a]Chlorotrianisene also administered with hydroxyurea.

TABLE 33.39. COMBINATIONS OF ANTITUMOR AGENTS TESTED IN PATIENTS WITH ADVANCED PROSTATE CANCER

In addition to the conventional systemic administration of such chemotherapeutic drugs to patients with stage D CaP, several alternative modes of administration have been attempted, including (a) the use of such agents in an adjuvant setting, (b) the initiation of chemohormonal therapy, (c) intraarterial infusion chemotherapy, and (d) cytotoxic therapy following androgen priming. Unfortunately, none of these initiatives proved to be of durable benefit.

Several studies have been conducted to assess the potential efficacy of the combined use of cytotoxic therapy in conjunction with androgen ablation. In a study by Murphy and associates (687), patients with stage D CaP who had not undergone previous therapy were randomized to the administration of DES or orchiectomy versus DES combined with cyclophosphamide versus cyclophosphamide and estramustine. Analysis of the data revealed no statistically significant difference in any of the treatment groups when assessed for duration of therapeutic response or overall survival. In an analogous fashion, there seems to be little benefit associated with the administration of systemic chemotherapy to untreated patients with disseminated prostate cancer before androgen ablation (451).

Sella and co-workers (899) reported their results of a phase II study that involved the use of *oral ketoconazole (1,200 mg per day) and doxorubicin (20 mg/m^2 in a 24-hour infusion administered once weekly).* These investigators observed a 55% PSA response rate. Moreover, partial responses were seen in 7 of 12 patients with measurable soft tissue disease. Serious cardiac toxicity was encountered and 45% of these patients required hospitalization for treatment-related complications. The development of clinical adrenal insufficiency in 63% of patients prompted a recommendation that subsequent studies include administration of corticosteroids.

One of the most controversial approaches involving the use of systemic chemotherapy was the initiation of androgen priming before the administration of chemotherapeutic agents. This approach hypothesized an enhanced sensitivity to chemotherapy as the result of the expected stimulation of tumor proliferation by administration of exogenous androgen. However, a study using a 10-mg daily dose of fluoxymesterone (Halotestin) as the priming agent for 4 days followed by IV cyclophosphamide and methotrexate (MTX) did not demonstrate any substantive benefits. Furthermore, exacerbation of bone pain occurred in many patients and cord compression was noted in one (990). These discouraging results tempered enthusiasm for similar studies. However, Dawson and associates (216) reported 3 complete and 8 partial responses in their study of 15 patients with hormone-refractory prostate cancer treated with fluoxymesterone (5 mg orally twice daily for 3 days) followed by carboplatin (800 mg/m^2) administered every 28 days and followed for 3 days by the same fluoxymesterone regimen. Of note, 9 of 15 patients were alive 42 months or longer. It remains a matter of conjecture whether these favorable responses can be attributed to the regimen of androgen priming used in this study as opposed to the impact of carboplatin alone (880).

Cytotoxic Chemotherapy: Current and Future Approaches

The development of more effective treatment strategies will require (a) the further assessment of drug analogs possessing reduced toxicity and/or enhanced antitumor activity, (b) the use of conventional agents via new schedules and routes of drug delivery, and (c) the development of compounds possessing novel mechanisms of action (217,880).

For example, doxorubicin is moderately effective in the treatment of metastatic CaP due to its ability to bind to DNA and inhibit DNA replication and DNA-dependent RNA synthesis. Unfortunately, it possesses well-defined cardiotoxicity, especially as the cumulative dose approaches 550 mg/m ^{2}. However, even low cumulative-dose regimens may be dangerous in patients with a history of ischemic heart disease, congestive heart failure, cardiac arrhythmia, and a low ejection fraction. For these reasons, the development of *mitoxantrone*, an analog of doxorubicin with reduced cardiac toxicity, is an important development that might expand the utility of this family of cytotoxic agents for the elderly population at risk.

Moore and associates (670) administered mitoxantrone (12 mg/m^2 IV every 3 weeks) and prednisone (10 mg orally daily) to 27 patients with HRPC. Methods of assessment included quality-of-life analyses, pain indices, analgesic scores, and the National Prostatic Cancer Project (NPCP) criteria. Of 25 assessable patients, 9 (36%) demonstrated improvement in social and emotional functioning, as well as in pain and anorexia. One of seven patients with measurable disease achieved a partial response and 12 exhibited stable disease. None of the patients experienced serious nonhematologic toxicity and there was no evidence of febrile neutropenia.

Tannock and associates (1001) randomized 161 hormone-refractory patients with pain to receive mitoxantrone (12 mg/m^2 body-surface area by IV infusion every 3 weeks) plus prednisone (10 mg per day) or prednisone alone. The primary endpoint was a palliative response defined as a 2-point decrease in pain as assessed by a 6-point pain scale completed by patients without an increase in analgesic medication and maintained for two consecutive evaluations at least 3 weeks apart. Secondary endpoint parameters included a decrease of 50% or more in the use of analgesic medication without an increase in pain, duration of response, and survival. In that study, a palliative response was observed in 23 of 80 patients (29%) who received mitoxantrone plus prednisone. In contrast, 10 of 81 patients (12%) who received prednisone alone exhibited a palliative response. The duration of response was longer in patients who received chemotherapy (median of 43 versus 18 weeks); 11 of 50 patients randomized to prednisone treatment responded after the addition of mitoxantrone. There was no difference in overall survival between the two groups. Most responding patients exhibited an improvement of quality-of-life parameters and a decrease in the serum PSA level. A parallel study was performed by Kantoff and associates (485) under the auspices of the Cancer and Leukemia Group B Study 9182. In that study, patients with HRPC were randomized to receive hydrocortisone alone or in combination withmitoxantrone. Table 33.40 provides the comparative outcomes of these two similar clinical trials.

Study	Therapy	No. of Patients	≥50% PSA Decline (%)	Symptom Relief (%)	Overall Survival (mo)
Tannock, et al.	Mitoxantrone + prednisone	80/161	33	29	12
	Prednisone	81/161	22	12	11.5
Kantoff, et al.	Mitoxantrone + hydrocortisone	119/242	33	14	11.1
	Hydrocortisone	123/242	18	8	12

PSA, prostate-specific antigen.

TABLE 33.40. STEROIDS WITH AND WITHOUT MITOXANTRONE

More recently, the favorable Canadian experience prompted a randomized phase III comparison of mitoxantrone plus prednisone versus prednisone alone (1001). In that study, palliative response was the primary endpoint. Of the 80 patients randomized to mitoxantrone and prednisone, 29% met the criteria for a palliative response in comparison with 12% of 81 patients who received prednisone alone. The duration of palliative responses was longer in the mitoxantrone plus prednisone arm period. However, there was no significant difference between median survival between the two groups. Table 33.41 provides a comparison of outcome in the mitoxantrone phase III Canadian trial and the Cancer and Leukemia Group B Study 9182. The latter study was designed with survival as its primary endpoint and quality of life as a secondary endpoint. In that study, no overall survival benefit was demonstrated. However, there was an improvement in pain control in the chemotherapy arm. Overall, studies of mitoxantrone plus glucocorticoids have demonstrated that as many as 40% of patents will have improvements in pain and quality of life as a result of this treatment, although impact on overall survival does not appear to be significant (929).

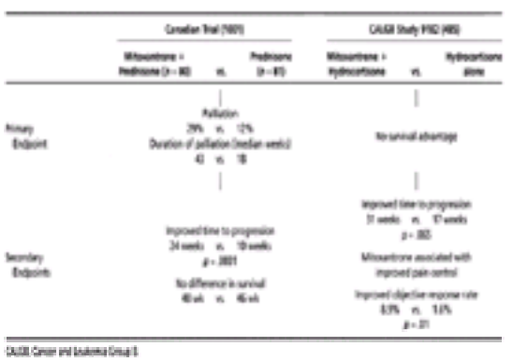

TABLE 33.41. MITOXANTRONE PHASE III CANADIAN TRIAL AND CALGB STUDY 9182

These studies highlight the fact that mitoxantrone plus prednisone is a well-tolerated regimen in this cancer cohort. This drug is a semisynthetic anthracenedione, which shares some structural similarities to doxorubicin. Mitoxantrone has a more favorable toxicity profile than doxorubicin and is associated with very little nausea, vomiting, or alopecia. The dose-limiting toxicity is myelosuppression, with neutropenia limiting the starting dosage to 12 to 14 mg/m ^{2} every 3 weeks (670). The study by Tannock and associates (1001) also indicates that measures of health-related quality of life are both objective and relevant endpoints to assess prognosis and outcome after the initiation of palliative therapy.

Recent studies have demonstrated that *estramustine phosphate* induces the disruption of microtubules and inhibits microtubule assembly by binding to MAPs (880). In addition, estramustine binds to P-glycoprotein and has been observed to favorably modulate the multidrug-resistant phenotype, which can abrogate the effectiveness of such agents as vinblastine and paclitaxel (Taxol) (956,1117). Because the antimitotic effects of vinblastine are mediated through its binding to tubulin, its use in concert with estramustine, which exerts its antimitotic activity through a different mechanism, is appealing.

Seidman and associates (898) treated 25 patients with progressive HRPC using estramastine/vinblastine. Of the 24 patients with an elevated serum PSA before therapy, 54% exhibited a greater than 50% decrease in PSA levels on at least three consecutive biweekly determinations. They also noted that the median decrease in PSA in responding patients was 64% and the median duration of response was 7 months. Two partial responses were noted in five patients who had biodimensionally measurable disease. In a similar study, Hudes and associates (438) treated 36 accessible patients with *oral estramustine phosphate (600 mg/m^2 on days 1 to 42) and vinblastine (4 mg/m^2 intravenously once a week for 6 weeks).* These treatments cycles were repeated every 8 weeks. They observed that PSA decreased from baseline by at least 50% in 61% of the patients. In eight patients, the PSA diminution was greater than 75% of the pretreatment baseline. In seven patients with measurable nonosseous disease, they observed one partial response and one minor response. However, 12 of 28 patients with assessable pain noted significant responses to this therapy. This drug regimen was easily administered and generally well tolerated. Leukopenia was mild, with only three episodes of grade 3 or 4 toxicity being recorded and no febrile neutropenic events or episodes of thrombocytopenia. Nausea related to oral estramustine was the chief nonhematologic toxicity. Other side effects attributable to estramustine included lower extremity edema and breast tenderness. There were four episodes of significant cardiovascular toxicity, which were probably related to the estrogenic effects of estramustine. The neurologic toxicity associated with vinblastine (paresthesia, constipation, and muscle cramps) was generally manageable. The combination of *estramustine plus vinorelbine* (another vinca alkaloid) also appears to have activity in the management of HRPC (119).

Paclitaxel (Taxol) also binds tubulin, inhibits microtubule disassembly, and suspends cells in mitosis. Despite the rather disappointing performance of Taxol monotherapy in the treatment of CaP, preclinical studies demonstrated its ability to abrogate the invasion and metastasis of human prostate cancer systems. In addition, Speicher and associates (955) demonstrated the synergistic cytotoxic effect of paclitaxel (Taxol) plus estramustine, *in vitro,* in both estramustine-resistant and wild-type DU145 human prostatic carcinoma cell lines. They also noted that the concentration of Taxol found to enhance the toxic effects of estramustine was 100-fold less than levels found in the serum of patients treated with that agent clinically. For these reasons, Hudes and associates (440) initiated a clinical study involving 17 patients with HRPC. They were treated with *Taxol (120 to 140 mg/m^2 by 96-hour infusion on days 1 to 4 every 3 weeks)* and *oral estramustine (600 mg/m^2 daily)*. Of 17 patients, 10 demonstrated a decrease in their baseline PSA of more than 50%. Moreover, of the six patients with measurable disease, three achieved a partial response. The most common reported toxicities were nausea, peripheral edema, fatigue, diarrhea, and transient rises in transaminase levels. Hematologic toxicity was mild.

Preclinical studies have suggested that *estramustine phosphate and etoposide (VP-16)* may constitute yet another drug combination capable of inhibiting the proliferation of HRPC (772). Etoposide exerts its antitumor effect by stabilizing the topoisomerase II–DNA cleavable complex, which ultimately leads to ligation inhibition (597). In addition to its ability to bind to microtubule-associated proteins and P-glycoprotein, estramustine phosphate is preferentially taken up by prostate epithelial cells and binds to the nuclear matrix (186). These observations prompted a phase II clinical trial evaluating this drug combination in patients with HRPC (775). This study involved 42 patients who received oral estramustine (15 mg/kg per day) and oral etoposide (50 mg/m ^{2} per day) in divided doses for 21 days. After a rest period of 7 days, the cycle was repeated until evidence of disease progression was noted. Of 18 patients with measurable soft tissue disease, complete responses were noted in 3 patients and partial responses in 6 patients. Furthermore, pretreatment PSA levels decreased by at least 50% in half of the patients and by at least 75% in 28% of the cohort tested. Finally, 25% of patients demonstrated improvement and 38% demonstrated stability in their bone scans. Table 33.42 summarizes the results of phase II of two-drug and three-drug regimens involving estramustine-based chemotherapy for the treatment of HRPC.

	No. of Patients	Response	
		Reduction in Measurable Disease	Decline in PSA Level
Two-drug Regimens			
Estramustine plus vinblastine	50	6/25 (24%)	48/88 (55%)
Estramustine plus vinorelbine	25	0/5 (0%)	9/24 (38%)
Estramustine plus etoposide	160	32/68 (47%)	74/115 (64%)
Estramustine plus paclitaxel	34	4/9 (44%)	17/32 (53%)
Estramustine plus docetaxel	34	5/18 (28%)	20/32 (63%)
Three-drug Regimens			
Estramustine plus etoposide plus vinorelbine	25	2/3 (67%)	14/25 (56%)
Estramustine plus etoposide plus paclitaxel	40	10/22 (45%)	26/40 (65%)

Note: Studies cited are from original source.

TABLE 33.42. RESULTS OF PHASE II CLINICAL TRIALS OF ESTRAMUSTINE-BASED CHEMOTHERAPY REGIMENS FOR HRPC[a]

Cyclophosphamide (Cytoxan) is an alkylating agent that has demonstrated activity against a wide variety of solid tumors. Unfortunately, early studies failed to demonstrate a profound impact of this agent when administered intravenously in standard doses. For example, Saxman and associates (869) performed a phase III clinical study assessing the impact of Cytoxan alone or in combination with doxorubicin plus methotrexate in the management of HRPC. The overall response rate in all patients with measurable disease was approximately 13% (in both arms). Furthermore, there was no apparent added benefit to the three-drug regimen when compared with cyclophosphamide alone (186).

More recently, Small and associates (925) administered *doxorubicin along with dose-escalated cyclophosphamide and granulocyte colony-stimulating factor (G-CSF)* in 35 patients with hormone-resistant prostate cancer. These patients were treated every 21 days with fixed-dose doxorubicin (40 mg/m ^{2}) and Cytoxan (800 to 2,000 mg/m^2) along with G-CSF. Of 15 patients, 5 (33%) patients with measurable disease obtained an objective response. Of 35 patients, 16 had a greater than 50% decrease in PSA levels. Although nonhematologic toxicity was minimal, approximately one-third of the cycles were associated with grade 4 neutropenia.

Raghavan (808) administered *oral cyclophosphamide* to 30 patients with HRPC at a dose of 100 mg/m^2 each day for 14 days. The patients received a 14-day rest period before the next cycle. This study contained six objective responses (20%); most patients demonstrated symptomatic improvement. Similarly, encouraging results were demonstrated in a study conducted by Maulard-Durdux and colleagues (624). In that study, *oral cyclophosphamide was administered with oral etoposide* to patients with HRPC apparent. Approximately 35% of patients exhibited a reduction in PSA level, and almost 75% of these treated patients acknowledged relief of bone pain.

Various new cytotoxic agents are under investigation. *Camptothecin and its analogs (irinotecan and 9-aminocamptothecin)* are inhibitors of the nuclear enzyme topoisomerase I. Like topoisomerase II, this enzyme plays an important role in DNA replication. In a study conducted by Hudes and associates (439), topotecan was administered to 34 patients with HRPC in a phase II trial. The drugs were administered using a standard schedule 1.5 mg/m ^{2} daily times five. Although only 1 of 13 patients with measurable disease had an objective response, 6 of 34 had a response by PSA criteria. Myelosuppression was a common side effect documented in this study. Other new agents being pursued in the management of HRPC are an oral platinum compound (JM-216) and an anthrapyrazole derivative (CI-958) (929).

Denmeade and associates (225) reported a very interesting preclinical study. In an attempt to target a set of toxic therapies, specifically to metastatic prostate cancer sites, these investigators *synthesized an inactive prodrug by coupling the primary amine of doxorubicin to the COOH-terminal carboxyl of a 7-amino acid peptide carrier (Mu-His-Ser-Ser-Lys-Leu-Gln-Leu)*. They previously documented that the 7-amino acid peptide could be hydrolyzed specifically by the serine protease PSA, which would then liberate the active cytotoxin (L-leucyl-doxirubin). They observed a significant cytotoxic response to the prodrug when targeting the PSA cell line LNCaP. This therapeutic vehicle, of course, had no cytotoxic effect on PSA-nonproducing TSU prostate cancer cells *in vitro*.

HRPC manifests a "pan-resistant" chemotherapy phenotype for several reasons. Prostate cancers exhibit rather long *in vivo* doubling times, estimated to range from 4 months to 2 years. It is assumed that a large proportion of the tumor population resides in the resting or dormant phase of the cell cycle (G_0). Tumor targets are generally most susceptible to cytotoxic agents when they are actively cycling. In addition, Sullivan and associates (992) evaluated paraffin-embedded formalin-fixed resected prostates that were chosen based on Gleason grade and surgical stage. Immunohistochemistry was used to detect the expression of multidrug resistance protein (MRP), topoisomerase II-a, and p53, glutathione S-transferase, bcl-2, and P-glycoprotein. They demonstrated that all of the proteins were expressed in resected prostate except for P-glycoprotein. The expression of the other proteins increased with the Gleason grade. In addition, the expression of MRP, topoisomerase II-a, and p53 increased with the surgical stage. These results suggested that drug resistance gene products are expressed in prostate cancer at the time of surgical resection. They postulated that the chemotherapy refractory nature of CaP appears to reflect a constitutive phenotype that is present in early prostate cancer.

Anti–Growth Factor Strategies: Rationale and Results

The actual cellular mechanisms underlying the mitogenic activity of androgens and the emergence of HRPC are unknown. Recent evidence suggests that androgens may modulate the response of benign and malignant prostatic cells through the "upregulation" of other hormone and growth factor receptors, including the epidermal growth factor (EGF) receptor (887,1023). Thus dihydrotestosterone (DHT) may be a strategic component in an elaborate autocrine "loop" involving a cascade of signaling events intimately associated with the expression of various growth factors and their receptors. In keeping with this hypothesis, the transformed phenotype may be associated with the uncontrolled production of mitogenic growth factors or receptors or the failure of malignant cells to synthesize or respond to specific inhibitory growth factors (i.e., TGF-b). For example, Wilding and associates (1091) showed that the secretion of transforming growth factor-a (TGF-a) by the hormone-responsive prostate cancer cell line LNCaP is increased by DHT. They hypothesized that androgens may increase EGF receptors by inducing the production of TGF-a, EGF, or both. The androgen-resistant phenotype may emerge when clonal populations of tumor cells attain the ability to constitutively produce the requisite mitogenic growth factors and bypass the need for androgen "priming." For example, Hofer and associates (427) demonstrated that the HRPC cell line PC-3 is capable of synthesizing and secreting factors that are mitogenic for other prostate cancer cells (e.g., DU-145). Subsequent studies confirmed that the mitogen in question is TGF-a (908).

The IGF system is comprised of two ligands (IGF-I, IGF-II), two receptors (IGFR-I, IGFR-II), and six unique binding proteins (IGFBP-1 to IGFBP-6). The IGF system appears to play a strategic role in the autocrine growth regulation of prostate cancer cell lines (777). IGF-I levels are elevated in the serum of patients with CaP (156). IGF-II expression is elevated in CaP compared with benign tissues. A higher concentration of IGFBP-2 is present in the serum of CaP patients compared with controls. Recently, Figueroa and associates (293) demonstrated differential expression of IGFBPs in high versus low Gleason score prostate cancers. Specifically, expression of IGFBP-2 and IGFBP-5 was higher, while that of IGFBP-3 was lower in high versus low Gleason score specimens. IGFBP-2 binds to IGF-II with a tenfold to twentyfold greater affinity than IGF-1. IGFBP-2 possesses an RGD sequence that may facilitate binding to cell surface receptors, thus potentiating IGF delivery to its mitogenic receptor. IGFBP-5 is preferentially expressed in stroma of both benign and malignant prostate tissue and has a high affinity for extracellular matrix components. Such binding is associated with decreased IGFBP-5 affinity for IGF-I, resulting in higher local IGF-I bioavailability and ensuring aggressive prostate cancers a readily available supply of mitogenic IGFs to support continued growth.

In contrast, IGFBP-3 is thought to function as a negative regulator of cell proliferation (810) by sequestering free IGFs and thus preventing interaction with their receptors. In addition, IGFBP-3 gene expression is induced by other growth-inhibitory (and apoptosis-inducing) agents. Finally, IGFBP-3 appears to induce apoptosis through a novel pathway independent of either p53 or the IGF/IGFR-mediated cell survival pathway. Expression of IGFBP-3 is increased in PIN but decreased in invasive cancer specimens (1006).

Based on these perceptions, a high IGFBP-2-to-IGFBP-3 expression ratio should result in enhanced tumor proliferation and aggressive behavior (293). In fact, tumors with a high Gleason score demonstrate 95% and 117% higher expression ratios compared with tumors of low Gleason score and benign tissue, respectively.

Novel strategies to block components of this growth factor "cascade" have been investigated. *Suramin*, a polysulfonated napthylurea developed 75 years ago to treat trypanosomiasis inhibits the binding of various tumor growth factors including PDGF, TGF-a or TGF-B, EGF, and IGF-I to their cell surface receptors when administered intravenously. It can abolish tumor cell stimulation by the mitogens (259). Furthermore, suramin inhibits nucleic acid–related, lysosomal, and

extracellular enzymes, as well as, angiogenesis and tumor cell motility. In addition, several studies document its ability to inhibit PC-3 cells *in vitro* (591,1144).

Several clinical studies using different continuous or intermittent IV administration regimens of suramin to HRCP patients have reported varying evidence of a desirable effect including serum PSA and soft tissue mass reduction (260,337,691). Table 33.43 provides an overview of the results of recently completed suramin trials. However, this drug is currently used with reservation for two reasons: (a) It has numerous and appreciable toxicities, including adrenal and renal failure; sensory and motor polyneuropathy; an allergic rash; hematologic abnormalities, including coagulopathy and thrombocytopenia; a reversible vortex keratopathy, and others (259,338,588). (b) In addition, other clinical observations indicating tumor response are suspect because of reports suggesting these, especially PSA reduction, are primarily the result of administration of hydrocortisone to control adrenal failure (840).

Study	Schedule	Evaluable Patients	≥50% PSA Response	Measurable Disease Response
Myers, et al.	Continuous infusion	38	21/38 (55%)	6/17 (35%)
Eisenberger, et al.	Intermittent infusion	31	24/31 (77%)	6/12 (50%)
Mendoza, et al.	Intermittent infusion	21	9/21 (43%)	2/11 (18%)
Perry/ak, et al.	Intermittent infusion	28	13/28 (46%)	2/11 (18%)
Reyno, et al.	Intermittent infusion	38	20/38 (52%)	0/4 (0%)

TABLE 33.43. RESULTS OF RECENTLY COMPLETED SURAMIN TRIALS

Recently, Tu and associates (1026) reported on their experience with *suramin and doxorubicin* in a phase I clinical trial. Doxorubicin was administered weekly (20 mg/m^2) and suramin was administered over 2 hours twice weekly at increasing doses. Of interest, the response rates in terms of measurable disease and serum PSA level were 50% and 60%, respectively. Not surprisingly, suramin therapy was associated with the development of neuropathy in 13% of the treated patients. Finally, Dawson and associates (215) recently completed an interesting study in which a poor-prognosis group of patients with previously untreated metastatic prostate cancer were treated with *suramin, leuprolide, and flutamide*. Forty-five patients had bone metastases and 25 had measurable soft tissue disease. Forty-one (82%) had severe disease. The overall response rate in 49 assessable patients was 3 complete responses and 30 partial responses for an overall response rate of 67%. These encouraging results have prompted a recommendation that a phase III trial be initiated to assess the impact of this drug combination with hormonal therapy alone.

Somatostatin, a cyclic tetradecapeptide found in high concentrations in the stomach, intestines, pancreas, and hypothalamus and other areas of the brain (876), inhibits the secretion of several important pituitary (prolactin, growth hormone) and GI (insulin, glucagon, gastrin, secretin, cholecystokinin, and vasoactive intestinal polypeptide) hormones (876,904). In addition to its endocrine effects, somatostatin inhibits various strategic growth factors, including IGF, EGF, PDGF, FGF, and TGF-a. The ability of somatostatin to inhibit prolactin and endogenous growth factors suggests a potential therapeutic role in the management of prostate cancer. However, despite evidence of enhanced inhibition of tumor cell lines such as Dunning R-3327H by administration of somatostatin or its analogs primarily along with LHRH agonists (875,916) and recent evidence that octreotide acetate, a somatostatin analog, inhibits experimental angiogenesis (211), these observations have not translated into significant clinical therapies.

C225 IgG_1 is a chimerized mAb that competes with both EGF and TGF-a for binding to the EGF receptor. Mendelsohn (644) and others have demonstrated that the antitumor properties of this chimerized antibody may be multifactorial and include inhibition of cell cycle progression, induction of apoptosis, inhibition of angiogenesis, inhibition of tumor invasion/metastasis, and inhibition of repair or recovery following exposure to chemotherapy or radiation. The ultimate role of this human:chimeric mAb C225 in the management of advanced-stage prostate cancer (either alone or in combination with other therapies) remains to be defined. The same holds true for the ultimate impact of the Herceptin mAb against HER-2.

Differentiation-inducing Therapy

The development of agents capable of inducing differentiation and favorably modulating adverse tumor phenotypes could be of great therapeutic benefit. Despite the theoretic appeal of this novel therapeutic approach, the clinical application of differentiation-inducing agents such as retinoic acid and its derivatives, sodium butyrate, somatostatin analogs, vitamin D_3 and its derivatives, sodium phenylacetate/phenylbutyrate, and 5-azacitidine has been hindered by insufficient bioavailability, patient toxicity, and/or lack of durable therapeutic benefit (392,934,1010).

Retinoids are differentiation-inducing agents thought to act on nuclear-binding proteins, which act as transcription factors (602). There are two types of retinoid receptors: retinoic acid receptors (RARs) and retinoid X receptors (RXRs). These receptors belong to the superfamily of steroid hormone receptors. The a-, b-, and g-subtypes of the RARs and RXRs have unique and conserved amino and carboxy terminal domains (602).

Kelly and associates (498) conducted an interesting study involving patients with HRPC. Fourteen patients were treated with daily oral dosing of all-trans-retinoic acid (ATRA), 50 mg/m^2 every 8 hours. In addition, their study involved the treatment of 16 androgen-independent and 4 androgen-dependent patients with a combination of 13-cis-retinoic acid (10 mg/kg per day) and interferon-a_2 (3, 6, or 9 million units daily). Both therapies were well tolerated, with fatigue and cheilitis being the most common adverse events. Clinical activity as assessed by radiographs and serum PSA was minimal, and the majority of patients progressed within 3 months. Of note, one patient with androgen-dependent disease had prolonged stabilization for more than 1 year. Although the majority of cases (95%) showed no gross histologic changes, an increased PSMA immunoreactivity was seen in 7 of 9 (78%) cases. Despite these very modest antitumor effects, this study suggests a role for retinoids in modulating the expression of PSMA on prostate cancer cells. The minimal antitumor activity demonstrated may in part reflect observations by Lotan and associates (602) who demonstrated that RAR-b and RXR-b mRNAs are selectively lost in both prostate cancer and adjacent morphologically normal prostatic tissue.

Finally, DiPaola and associates (233) reported on the results of the phase I clinical trial that involved the use of *13-cis-retinoid acid, interferon*-a *, and paclitaxel* in patients with advanced stage prostate cancer. They demonstrated that this regimen is surprisingly well tolerated. Furthermore, the combination of retinoic acid and interferon caused a 33% decrease in paclitaxel clearance probably secondary to an inhibitory effect on its metabolism. Finally, the combination of cis-retinoic acid and interferon favorably modulated the expression of bcl-2 *in vitro*. It is conceivable that a combination of differentiation-inducing agents, immune modulators, and cytotoxic agents can be used effectively in the management of advanced prostate cancer. Obviously, additional studies are needed to determine the validity of this perception.

Epidemiologic data suggest that *vitamin D_3,* obtained from dietary sources and sunlight exposure, protects against mortality from prostate cancer (187). The most active vitamin D metabolite, 25-dihydroxyvitamin D_3, regulates the growth and differentiation of several human CaP cell lines *in vitro* (661). The antiproliferative effects of $1,25(OH)_2D_3$ appear to require the expression of the nuclear vitamin D receptor (VDR) (661). *Vitamin D analogs,* which are less likely to promote hypercalcemia, may prove to be of some value alone or in combination with other agents in the management of advanced stage prostate cancer. Numerous analogs are currently under investigation. With respect to the latter, *in vitro* studies conducted by Chen and associates (162) suggest that both 25-hydroxy vitamin D_3 and 19-nor-1a, 25-dihydroxy vitamin D_2 may be useful in this regard.

Angiogenesis Inhibitors

As stated previously, the elaboration of angiogenic peptides is critical for the growth of the primary tumor and its subsequent metastatic foci. Prostate cancers have been shown to overexpress hypoxia-inducible factor 1-a. The latter activates transcription of genes, encoding glycose transporters, glycolytic enzymes, and vascular endothelial growth factor (1132,1133). This overexpression therefore fulfills the two universal characteristics of solid tumors—their need for neovascularization and increased glycolysis. VEGF signal transduction is believed to occur primarily by way of the high-affinity membrane receptor tyrosine kinases FLT-1 and FLK-1 (1007). Ferrer and associates (290) have documented the presence of both receptor subtypes in prostate cancer. In addition, Duque and associates (247) have confirmed the presence of increased plasma levels of VEGF in patients with metastatic prostate cancer. Clearly, therapeutic strategies designed to abrogate the angiogenic cascade

in HRPC could have strategic value.

TNP-470 is a semisynthetic analog of fumagillin, which possesses very potent antiangiogenic and antitumor activities. TNP-470 inhibits the *in vivo* growth of the HRPC cell line PC-3 and has a significant additive antitumor effect when administered with cis-platinum (1114).

Linomide, a quinoline-3-carboxamide, inhibits the growth and metastasis of rat prostate cancer *in vivo* (but not *in vitro*) by interfering with tumor angiogenesis and macrophage infiltration (1055). In an *N*-methylnitrosourea initiation-androgen promotion model, administration of oral linomide at a daily dose as high as 25 mg/kg per day for at least 1 year was without major toxicity and inhibited the development of seminal vesicle and prostate cancers in male rats by more than 50% (474). Tumor-associated macrophages can either promote angiogenesis in tumors by secreting tumor necrosis factor-a or inhibiting angiogenesis by producing granulocyte-macrophage colony-stimulating factor (GM-CSF), which in turn stimulates production of the antiangiogenic protein plasminogen activator inhibitor type 2 (473). Linomide is unique among the antiangiogenic agents tested, in that it inhibits the stimulatory effects of tumor-associated macrophages on tumor angiogenesis. The coordinated loss of androgen regulation of VEGF is associated with the progression of CaP to the HRPC phenotype (472). It appears VEGF is constitutively expressed and upregulated in HRPC by cellular hypoxia, not by androgens. In hormone-dependent CaP, VEGF levels are directly regulated by androgen. Indeed, a major reason underlying tumor regression following androgen ablation may be the marked diminution in tumor-associated VEGF levels.

COX-2 is an inducible enzyme that catalyzes the formation of prostaglandins from arachidonic acid. It is expressed in prostate cancer specimens and cell lines (593). COX-2 inhibitors possess antiangiogenic and antitumor activities (621). Preclinical studies conducted by Liu and associates (593) confirm that inhibition of COX-2 suppresses angiogenesis and the growth of prostate cancer *in vivo*.

Table 33.44 provides examples of novel classes of antiangiogenic drugs in clinical development. Figure 33.92 depicts the various components of the angiogenic cascade that are fertile targets for antiangiogenic drug therapy.

Class of Drug	Examples	Mode of Action	Stage of Clinical Development
Matrix metalloproteinase (MMP) inhibitors	Marimastat, AG-3340 Bay 12-9566	Inhibit MMPs, especially MMP-2 and MMP-9	Randomized phase II studies completed
Vascular endothelial growth factor (VEGF) Receptor inhibitors	SU-5416	Inhibits	Phase I trials completed, phase II open
Anti-VEGF antibody	Humanized anti-VEGF Antibody	Blocks VEGF activating Receptor	Phase II studies
Antiintegrin antibodies	Humanized $\alpha_v\beta_3$ integrin Antibody	Cause endothelial apoptosis By blocking $\alpha_v\beta_3$ integrin	Phase I studies completed
Endogenous protein inhibitors	Angiostatin, endostatin	Unknown, generated by MMP and other proteases	Awaiting formulation before phase I studies
Vascular targeting agents	CA4DX	Fixes complement, causing vasculitis in new vessels	Phase I studies completed

Inhibitors of Tumor Cell Adhesion

The oral administration of *modified citrus pectin* was capable of inhibiting spontaneous metastasis of the Dunning rat prostate cancer MAT-LyLu (773). This agent interferes with cell–cell interactions mediated by cell surface carbohydrate-binding galactin-3 molecules and inhibits adhesion of these prostate cancer cells to rat endothelial cells. More importantly, administration of the drug significantly reduced the incidence of pulmonary metastases in the experimental group compared with controls. Clinical trials are currently in progress. Hsieh and Wu (435) observed that modified citrus pectin can directly inhibit proliferation of HRPC cells *in vitro*, an effect associated with downregulation of cyclin B and p34cdc2.

Induction of Apoptosis

Programmed cell death (apoptosis) involves an epigenetic reprogramming of the cell that results in an energy-dependent cascade of biochemical and morphologic changes that occur within the cell, resulting in its death and subsequent elimination (224). Dysregulation of apoptosis is a hallmark of most cancers (817). As stated previously, prostate cancers evade the apoptotic pathway through many mechanisms, including increased bcl-2 expression, mutated p53, and upregulation of the antiapoptotic gene SGP-2 (clusterin) (652, 975).

Agents capable of inducing programmed cell death (i.e., apoptosis) in prostate cancer systems have shown promise in preclinical studies. *Thapsigargin* is a sesquiterpene g-lactone, which selectively inhibits the sarcoplasmic and endoplasmic reticulum calcium-dependent ATPase pumps. Studies conducted by Furuya and associates (326) demonstrate that the initiation of programmed cell death in HRPC cells exposed to this agent is a consequence of elevated intracytoplasmic calcium. It appears the endoplasmic reticulum calcium-ATPase pump constitutes a new therapeutic target for activating apoptosis.

b -*Lapachone* is a simple plant product that exhibits antitrypanosomal effects, inhibits reverse transcriptase and gene expression, impairs DNA repair, and inhibits the catalytic activity of DNA topoisomerase I through a mechanism different than camptothecin (577). b-Lapachone induces apoptosis in human prostate cancer cells by a mechanism independent of p53 expression. Furthermore, ectopic overexpression of bcl-2 does not confer significant resistance to b-lapachone–induced apoptosis.

Eiseman and associates (256) evaluated a *novel spermine analog (1,12-Diaziridinyl-4,9-Diazadodecane)* on the growth of hormone refractory prostate cancer cell lines *in vitro* and *in vivo*. They observed that this compound has potent antitumor effects against these tumors via induction of apoptosis. Furthermore, this compound increases the radiosensitivity of human prostate cancer cells by decreasing the apoptotic threshold to radiation.

Liu and associates (592) evaluated the impact of a *selective COX-2 inhibitor (NS 398)* on the growth of LNCaP cells. They observed that this compound induces apoptosis in this cell line and downregulates bcl-2 expression, concomitantly.

Finally, studies conducted by Miayake and associates (652) and Gleave and associates (364) confirm the potential utility of *antisense bcl-2 oligodeoxynucleotides* with respect to delaying the progression to androgen independence, inducing apoptosis, and promoting chemosensitization within Shionogi and LNCaP tumor systems.

Dietary Factors and Kinase Inhibitor Therapy

There appears to be a direct correlation between average dietary fat consumption and the death rate from CaP (19). Long-term, high-fat diets may predispose to increased androgen levels that are subsequently stimulatory to prostate growth (522). Indeed, the reduction of dietary fat has been shown to slow the growth of tumors established from CaP cells in murine xenograft models (1074).

Tomatoes are the primary dietary source of lycopene, a non–provitamin A carotenoid with potent antioxidant activity. Clinton and associates (179) identified the presence of lycopene in the prostate at concentrations that are biologically active in laboratory studies, supporting the hypothesis that lycopenes may have direct effects within the prostate and contribute to the reduced prostate cancer risk associated with the consumption of tomato-based foods. Other potentially beneficial dietary factors include increased fruit consumption and vitamin E/selenium supplementation (360,411).

The isoflavones contained in soy (particularly genistein) inhibit tyrosine kinase activities, and by this mechanism, probably exert their constraining influence on cellular growth (522). Receptor tyrosine kinases are glycoproteins consisting of an extracellular portion that binds ligands, a transmembrane helix, and a cytoplasmic portion. Receptor tyrosine kinase family members include the receptors for epidermal growth factor, FGF, platelet-derived growth factor, stem-cell factor, vascular endothelial growth factor, and nerve growth factor (640). Obviously, abrogation of this component of catalytic pathway could have strategic therapeutic importance.

Flavonoids such as quercetin and genistein have been shown to inhibit tumor cell growth *in vitro* and a significant degree of this inhibition is related to their ability to inhibit tyrosine kinase activities. The new flavone designated *flavopiridol (L86-8275) possesses selective antitumor activity in vitro* and *in vivo* for prostate carcinoma cells (243). Flavopiridol is a potent inhibitor of cyclin-dependent kinase type 1, the mediator of cell cycle progression from G_2M phase and cyclin-dependent kinase type 2, whose activity appears at the G_1-S boundary. Senderowicz and associates (901) reported the results of a recently completed phase I clinical trial using continuing infusion flavopiridol in patients with refractory neoplasms. Antitumor effect was observed in certain patients with renal, prostate, colon cancer, and non-Hodgkin's lymphoma.

TRK is a high-affinity tyrosine kinase–linked receptor for nerve growth factor and it has been implicated in prostate cancer growth (231). *The TRK tyrosine kinase inhibitor designated CEP-751 (KT6587)* has been shown to inhibit prostate cancer growth in nine different animal models independent of the tumor growth rate, androgen sensitivity, metastatic ability, and state of tumor differentiation (231).

Proline-directed protein kinase F_A is overexpressed many fold in various human cancers relative to normal controls (1116). *Antisense suppression of proline-directed protein kinase F_A* has been shown to enhance the chemosensitivity in human prostate cancer cells and suggests that this protein kinase may play an important role in controlling multidrug resistance in HRPC (1116).

Immunotherapy

Efforts to identify potential cellular targets for immunologic therapy and approaches to enhance, depress, or modify their roles in development and growth of CaP in man had been pursued with various degrees of vigor and very limited success for many years. These earlier efforts included attempts to use nonspecific immune potentiating agents, various cytokines, monoclonal antibodies acting directly or as carriers of cytotoxic cellular agents, and other approaches (533). For the most part, these efforts with the exception of those attempting to identify new antigenic targets and develop antibodies to them are the targets of limited current effort. On the other hand, efforts to develop and characterize tumor-specific monoclonal antibodies to form immunoconjugates capable of targeting disseminated prostate cancer seem to be escalating.

Ideally, this concept requires monoclonal antibodies reacting uniformly with benign/malignant prostate cells and lacking diverse cross-reactivity with nonprostatic tissues. Pastan and associates (751) isolated an IgM-k subtype monoclonal antibody, PRI, that reacted uniformly with the surface of 25 of 26 prostatic adenocarcinomas. It also reacted with the surface antigen on normal prostate epithelial cells and cells isolated from BPH specimens. Brinkmann and associates (101) demonstrated that the cloned variable regions of the light and heavy chains of the PRI antibody could be used to construct a recombinant immunotoxin that was very cytotoxic to antigen-positive LNCaP cells. It is proposed that recombinant Fab forms of PRI can be constructed to facilitate the delivery of isotopes or drugs to prostate cancer cells.

Promising preliminary studies also have been conducted using the In^{111} indium CY-356 radioimmunoconjugate designated *In^{111} capromab pendetide* for detection of occult prostate cancer recurrence (480). ProstaScint (capromab pendetide) is a murine monoclonal antibody 7EI 1-C5.3 directed against the cytoplasmic epitope of PSMA. The utility of this approach to detect sites of occult prostate cancer in postprostatectomy patients with an abnormal serum PSA has been discussed previously. A phase I dose-escalation study using Y-CYT-356 monoclonal antibody conducted in 12 patients with hormone-refractory prostate carcinoma demonstrated 58% of patients had at least one site of disease imaged (221). Myelosuppression was the dose-limiting toxicity. One patient developed a human antimouse antibody 4 weeks after treatment, indicating limited immunogenicity. No patient had a complete or partial response based on PSA antigen and/or radiologic criteria. Recently, Bander and associates have completed a phase I clinical trial assessing the efficacy of the antibody designated J591. The latter is a mouse monoclonal antibody to PSMA. J591 binds to the extracellular part of PSMA. Following binding, the complex is internalized into the cell. This targeted access to the prostate cancer cell suggests that the J591 antibody could be linked with toxins and that this complex might induce selective killing of prostate cancer cells.

Cytotoxic T lymphocytes recognize protein antigens as small peptides (9 to 10 amino acids) associated with class I molecules of the major histocompatibility complex (MHC) (1100). The identification of tumor-associated antigens (and individual epitopes) recognized by human T lymphocytes could prove to be highly beneficial. Correale and associates (188) identified *novel PSA peptides*, designated *PSA-1* (amino acids 141 to 150) and *PSA-3* (amino acids 154 to 163), capable of eliciting specific cytotoxic T-cell responses to prostate carcinoma cells. Each candidate peptide contains consensus amino acid motifs for binding to HAL-A2, the most common type of class I molecule; both these peptides lack strong homology with PSA-related kallikrein proteins; and both peptides are capable of stabilizing HAL-A2 class I molecules on the surface of human T-2 cells, which are defective in antigen presentation. The investigators generated four different cytotoxic T-cell lines to these peptides and demonstrated that these T-cell lines could lyse PSA-positive, HAL-A2–positive LNCaP. These studies provided the rational basis for the use of PSA peptides (or recombinant vectors) in the development of highly specific anticancer vaccine immunotherapy protocols.

Genetic Immunotherapy

Lack of an effective immune response in patients with HRPC may be due to weak tumor antigenicity or a tumor-immunosuppressive environment. The goal to improve this adverse tumor-host relationship and facilitate immune recognition and destruction of malignant CaP cells is worthwhile (659). Although still in its infancy, cytokine-mediated gene therapy for CaP may hold promise in this regard.

For example, efficient recognition of tumor cells by helper T lymphocytes requires the expression of unique tumor associated antigens in concert with class II MHC expression (Fig. 33.93). Immunotherapy based on GM-CSF or IL-2 gene transfer is capable of reconstituting this expression (860). Similarly, efficient interaction of cytotoxic T cells with their tumor target depends on the expression of these same tumor-associated antigens and tumor cell class I MHC. Immunotherapy using gene transfer of interferon-g or TNF-a augments this facet of immune interaction (860,861).

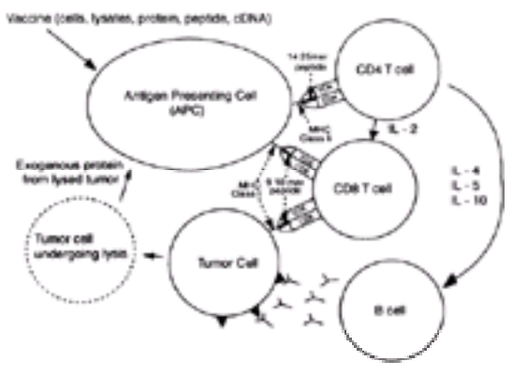

FIGURE 33.93. Activation of the immune system. (From Foon KA. *Vaccine therapies for epithelial cancers.* American Society of Clinical Oncology, 2000:730, with permission.)

Early phase I clinical trials involving gene therapy of urologic cancers used a relatively simple approach. In brief, portions of the primary tumor are removed and established in a tissue culture to expand this pool of malignant cells. A retroviral vector is used to incorporate a given immunostimulatory gene into the DNA structure of the tumor cell. The transfected tumor cells are then radiated to inhibit tumorigenicity. A series of inoculations of the resulting vaccine preparation was carried out in the tumor-bearing host (861). Simons and associates (920) reported on the results of a phase I human gene therapy trial involving eight immunocompetent prostate cancer patients who were treated with autologous, GM-CSF–secreting, irradiated tumor vaccines prepared from *ex vivo* retroviral transduction of surgically harvested cells. Their study demonstrated that both T- and B-cell immune responses to human prostate cancer could be generated by this approach.

Preclinical studies using the Dunning rat R3327-MatLyLu prostatic tumor model that is in some ways analogous to hormone refractory metastatic human prostate cancer were reported by Vieweg and associates (1044). The IL-2–secreting, irradiated tumor cell preparations were capable of curing animals with subcutaneously established tumors. Moreover, this treatment induced immunologic memory that protected these animals from subsequent tumor challenge.

Table 33.45 describes the characteristics of those vectors commonly used for therapeutic gene delivery. Table 33.46 summarizes the characteristics of currently active gene therapy strategies. Finally, Gotoh and associates (370) reported the feasibility of a *PSA promoter–based gene therapy* for androgen-independent human prostate cancer.

Vector	Duration of Therapeutic Gene Expression	Efficiency of Gene Transfer	Comment
Retrovirus	Stable long term	Variable	Labile in vivo
Adenovirus	Transient	Highly efficient	Immunogenic
Poxvirus (vaccinia)	Transient	Highly efficient	Immunogenic
Nonviral plasmid (liposomes or gene gun)	Transient	Inefficient	Fewer safety concerns than with other vectors

Adapted from Gansbacher MG. Biological principles and clinical development of prostate cancer gene therapy. Semin Urol Oncol 1997;15:42, with permission.

TABLE 33.45. CHARACTERISTICS OF VECTORS FOR THERAPEUTIC GENE DELIVERY

Therapeutic Gene	Extent of Potential Efficiency in Vivo	Relative Obstacles
Immunogene, ex vivo transfer	Systemic	Requires tissue procurement and cell culture
Immunogene, in vivo transfer	Systemic	Vector-specific immunity may interfere with the induction of tumor-specific immunity
Cytotoxicity/apoptosis	Local-regional	Requires highly efficient gene delivery in vivo; possibility of cytotoxic injury to normal cells
Anticoagene/antisense	Local-regional	Requires highly efficient gene delivery in vivo and durable expression of therapeutic gene
Tumor suppressor	Local-regional	Requires highly efficient gene delivery in vivo and durable expression of therapeutic gene

Adapted from Gansbacher MG. Biological principles and clinical development of prostate cancer gene therapy. Semin Urol Oncol 1997;15:42, with permission.

TABLE 33.46. CHARACTERISTICS OF GENE THERAPY STRATEGIES

Studies confirming the potential utility of adenovirus vectors to deliver therapeutic genes to prostate cancer targets are proliferating. A library of human prostate cancer cell lines has been transfected with *the recombinant adenovirus vector (AdWTp53) expressing wild-type p53* resulting in severe growth inhibition with evidence of apoptosis and death in comparison to untreated or control adenovirus vector-infected cells (959). Introduction of the gene for wild-type human p53 or p21 into a p53-deficient mouse prostate cancer cell line using *a recombinant adenoviral vector (AdSCMV-p53 or Ad5CMV-p21)* revealed significantly higher growth suppression after Ad5CMV-p21 infection. *In vivo* studies in syngenic male mice with established subcutaneous prostate tumors demonstrated a greater reduction in growth rate and final tumor volume in mice receiving intratumoral injection of the Ad5CMV-p21 construct.

In vitro and *in vivo* observations with a *recombinant adenovirus carrying the epithelium specific cell adhesion C-CAM gene*, the recombinant adenovirus AdCAM902, or its antisense construct, AdCAMIOI (control) using human PC-3 cells as the target demonstrated that C-CAM expression in viral-infected PC-3 cells is a long-lasting event; a single dose of C-CAM adenovirus is capable of repressing the growth of PC-3–induced tumors in nude mice for at least 3 weeks (513).

Many other promising gene therapy approaches are being developed. For example, *naked DNA* can be introduced into target cells using plasmid–liposome complexes obviating the need for a complex vector system (862). Other intriguing approaches involve the selective transfection of cellular toxin genes (429) or the *gene transfer of dominant apoptosis-inducing genes* (175). *The direct intratumoral injection of suicide genes* without the aid of the PSA promoter also can achieve target-specific, antitumor activity.

The use of antisense oligodeoxynucleotides as therapeutic agents has stimulated significant interest. DNA has a coding and a complimentary noncoding strand with the same sequence. When the noncoding strand is induced to transcribe, it produces antisense RNA molecules that combine to target mRNA in a fashion similar to the complimentary DNA double helix. Once attached, the RNA molecules cannot be “read” and the production of protein is blocked (684). Early antisense strategies involved the direct injection of short antisense oligonucleotides (974). More recently, recombinant vector systems have been used to deliver longer antisense and dominant negative mutation constructs (862).

Solid tumors cannot grow without the generation of new blood vessels. Tumor blood vessels are leaky and aberrantly organized, demonstrating unusual fan and spiral motifs, forming right angles and AV shunts (523). Upregulation of the avP3 integrins is also a feature of new blood vessel formation in tumors, a biologic process thought to be critical for the survival and differentiation of vascular cells undergoing angiogenesis (102). Because adenovirus vectors use VB3 integrins as an internalization signal, it may be possible to design such vectors specific for actively proliferating tumor vessels. In all likelihood, *antiangiogenesis gene therapy* strategies will be most effective in a state of low tumor burden. In this regard, gene therapy approaches that target the common signaling cascades in the endothelial cells, rather than specific angiogenic mediator or their receptors, may be more effective approaches to impart vasculogenesis.

Successful “vaccination” is contingent on several critical factors. The first involves the activation of antigen presenting cells (APCs), particularly *dendritic cells*, with uptake of antigen and its presentation in association with class I and/or class II MHC. This feature is a prerequisite for the initiation and propagation of an effective cell-mediated immune response. Dendritic cells are highly motile, widely distributed antigen presenting cells capable of producing interleukin-12 and actively forming clusters with T cells. A second requirement is the stimulation of both cytotoxic and helper T cells that recognize various different epitopes. Figure 33.94 illustrates the potential interactions between dendritic cells and T cells. The latter feature is important so that the tumor cell cannot escape immune detection because of antigenic drift or altered antigen presentation. Another prerequisite of successful gene therapy is the stimulation of the appropriate subpopulation of the CD4' helper T cells (Thi subset), which provide adequate cytokine support in the local microenvironment to maintain the antitumor immune response (587). The ultimate identification of

tumor-associated antigens (TAAs) would greatly facilitate this endeavor. Zhang and associates (1130) screened both primary and metastatic prostate cancers for their expression of 30 potential tumor-associated antigens. Their study provides the basis for selecting GM2, TF, Tn, sTn, hCGp, MUCI, KSA, and PSMA as target antigens for specific immunotherapy of CaP. They postulate that these nine antigens could be used to generate a polyvalent prostate cancer vaccine.

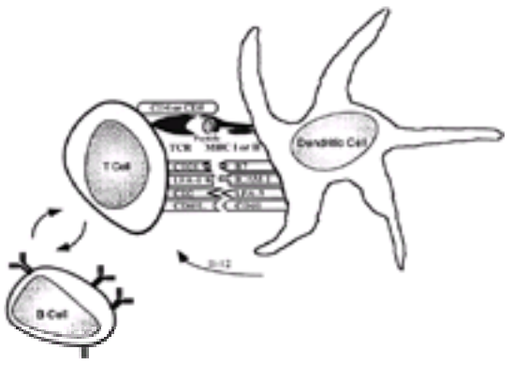

FIGURE 33.94. Potential interactions between dendritic cells and T cells. Dendritic cells can engage T-cell receptors *(TCR)* on CD4+ T cells with peptide presented in the context of MHC class II molecules or on CD8+ T cells, in the context of MHC class I molecules. Costimulatory and adhesion molecule interactions increase cell adhesion, prolong cell contact time, and enhance T-cell activation. (From Hsu FJ, Engleman EG, Levy R. Dendritic cells and their application in immunotherapeutic approaches to cancer therapy. In: DeVita VT, Hellman S, Rosenberg SA, eds. *Cancer: principles & practice of oncology,* 5th ed. Philadelphia: Lippincott-Raven Publishers, 1997:1, with permission.)

Early clinical trials of monocyte-derived dendritic cells included patients with prostate cancer who were vaccinated with *dendritic cells pulsed with 2HLA-A2.1 restricted peptides from PSMA* (686,689,856,1017). In a phase II trial of 37 patients, peptide-pulsed dendritic cells were infused intravenously at 6-week intervals in patients who had locally recurrent or metastatic prostate cancer. Fourteen patients exhibited a CR or PR by AUA criteria (595). However, the investigators could not conclude there was an association between augmented CD8 responses to PSMA peptides and clinical benefit. Burch and associates (109) treated 13 patients with two infusions, 1 month apart, of *autologous dendritic cells pulsed with PA2024. The latter is a fusion protein of human GM-CSF and human prostatic acid phosphatase*. The infusions were followed by three subcutaneous monthly doses of PA2024. Circulating PSA levels dropped in 3 of 12 patients (1082).

Finally, Weichselbaum and associates (1086) *linked the radiation-responsive DNA sequences of the early growth response (EGR-I) gene promoter to a TNF-*a *cDNA*. They transfected this construct into the HL525 human leukemia cells so that radiation activation of an exogenous inducible promoter could be used to control TNF-a gene activity in an experimental animal system. HL525 cells containing the EGR-TNF construct were injected into human xenografts of the radioresistant human squamous cell carcinoma cell line SQ-20B. They demonstrated an increase in tumor cures compared with animals treated with radiation alone. Of importance, there was no increase in local or systemic toxicity in these and other tumor-targeted therapies. Preliminary studies (400) suggest that targeted gene therapy radiation is capable of preferentially radio-sensitizing tumor cells.

Assessment of Treatment Efficacy

The quest for truly effective therapy in the treatment of HRPC is a critically important clinical and scientific endeavor. The pursuit of this goal has been hampered by various factors, including (a) the nature of the patient population at risk, (b) the patterns of metastasis common to prostate cancer, and (c) the difficulty in establishing response criteria to systemic chemotherapy in this disease (878).

The effectiveness of hormonal therapy as compared with the relative ineffectiveness and risk of systemic chemotherapy in patients with CaP is currently a major deterrent to early initiation of the latter in this disease. Similarly, once the patient has evolved to the stage of hormonal unresponsiveness, the impact of multisystem organ disease, general inanition, and reduced bone marrow reserves as a result of osseous metastases may likewise mitigate against the effective use of systemic cytotoxic therapy. At present, it seems appropriate to consider those patients with symptomatic disease progression for such therapy.

The standard patterns of metastasis in CaP preclude the existence of easily demonstrable and measurable tumor foci in the vast majority of patients. In patients receiving chemotherapy for CaP, approximately 85% or more have demonstrable osseous metastases, and pulmonary, liver, and regional lymph node involvement is documented in 10% to 20%, 10% to 15%, and 10% of patients, respectively (760).

Accurate and repetitive analysis of tumor volume in the primary lesion is difficult, although precise volumetric measurements performed via TRUS may aid in such future endeavors. TRUS has been used to monitor local tumor response to various treatment modalities. Fujino and Scardino (323) noted maximal reduction in prostatic size 9 months after radiotherapy and 3 months after chemotherapy. Studies by Resnick and associates (823) and Carpenter and associates (121) noted a 20% to 30% decrease in prostatic volume within 3 to 6 months of androgen-ablative therapy. TRUS can detect some local recurrences following radical prostatectomy (823).

A similar assessment of changes in tumor volume within obturator and hypogastric lymph node groups is fraught with great difficulty and frustration. Measurable superficial adenopathy is a rare occurrence. The majority of bony metastases are blastic or contain a mixed blastic and lytic component. When the latter undergo healing in response to therapy, a blastic reaction may occur and be misconstrued as evidence of disease progression, despite the use of MRI and CT scans. Pulmonary involvement tends to be of the diffuse lymphangitic variety, rendering accurate measurements of tumor volume all but impossible. It is apparent that few patients present with tumor burdens in such locations as to permit accurate bidimensional or unidimensional measurement. More often, the clinician must rely on evaluable parameters such as bone scans and various tumor markers, including serum acid phosphatase, PSA, alkaline phosphatase, the LDH isoenzyme pattern, D-dimer and carcinoembryonic antigen (CEA) determinations. With regard to the last-named, approximately 60% of patients with soft tissue lesions secondary to metastatic prostate cancer will have demonstrable elevations of this tumor marker. Obviously, such patients represent a unique subset of those with disseminated prostate cancer. The advent of RT-PCR for PSA/PSMA mRNA present in circulating tumor cells represents the latest addition to this “library” of tumor markers (457,492). Recent studies have questioned the utility of RT-PCR for the detection of PSA mRNA for the preoperative staging and follow-up of patients with CaP (272). For example, before radical prostatectomy a positive test was obtained in 13 of 75 patients (17.3%) with pT_2 disease and 10 of 46 (21.7) with pT_3 disease. There was no significant difference in serum PSA, Gleason score, or tumor volume in men with positive or negative results. With a median follow-up of 8 months, 6 of 7 patients in whom surgery failed had a negative result before radical prostatectomy. Of patients with known metastatic disease (or failed primary treatment), a positive result was noted in 32% to 75%. Although increasing tumor burden increases the likelihood of a positive result, a significant sampling error is associated with the use of this test in the peripheral blood.

These observations are in concert with those of other investigators who noted a poor correlation between RT-PCR results and pathologic/clinical stage (897,946). In contrast, other investigators have shown a correlation between RT-PCR results and clinical staging (350,464,733). Some potential reasons for these discordant results include (a) differences in assay methodology, (b) varied patient populations, and (c) the probability that CaP tumor cells are intermittently present in the peripheral circulation. The magnitude of tumor shedding is increased concomitant with expansion of the tumor volume. Preferential sequestration in the bone marrow may account for the observation that bone marrow aspirates may be RT-PCR positive when a similar analysis performed on peripheral blood may be negative (638,1105).

In this respect, several recent observations *regarding PSMA* are of interest. Studies conducted by Pinto and associates (778) have identified that PSMA is a pteroyl poly-g-glutamyl carboxypeptidase (folate hydrolase) and is expressed strongly in human prostate cancer. Of importance, those cancer cells that express this enzyme are resistant to methotrexate. The recent observations of Wright and associates (1108) further emphasize the potential importance of PSMA as a marker for the androgen-resistant phenotype. Following androgen ablation, PSMA reactivity was increased in 55% of posttreatment primary tissues and 100% of posttreatment metastatic specimens. In contrast, PSA expression was decreased in 70% of posttreatment primary and 100% posttreatment metastatic specimens. The significantly amplified expression of PSMA in metastatic tissues suggests that PSMA may constitute a clinically viable target for antibody and gene therapy of prostate cancer that recurs following androgen ablation. PSMA is a type II membrane protein that shares a 54% sequence homology with the transferrin receptor. Normal prostate cells produce a shorter alternative spliced variant, which encodes for a cytosolic form of the protein. With the onset of malignancy, transmembrane variant predominates

(by a factor approaching 100-fold). The other tissues in which the membrane antigen form of PSMA is highly expressed include the duodenal mucosa and a subset of proximal renal tubules (418). Of note, intense PSMA staining also can be detected in the endothelial cells of capillary vessels in peritumoral and endotumoral areas of certain tumors (renal cell, transitional cell, and colon cancers). The high level of transmembrane PSMA expression in the vast majority of prostate cancers and within the capillary beds of some cancers suggests that PSMA can be used for the activation of cytotoxic prodrugs.

The assessment of treatment efficacy becomes all the more difficult to interpret because there is no universal agreement among different cooperative groups and individual investigators with regard to the response criteria used in various treatment protocols (1112). For example, the term “objective response” is usually construed to note the achievement of complete response or partial remission. Because of the scarcity of measurable metastatic foci, the term “stabilization of disease” has been introduced to describe apparent absence of active progression. Slack and associates (923) considered the use of the stable category as a valid means to evaluate patient status in clinical trials assessing the efficacy of systemic chemotherapy. Other investigators question the validity of this concept (173). Further controversy exists regarding the association of fluctuations in levels of serum PSA/PAP and therapeutic response. Finally, many current studies use quality-of-life parameters as subjective indices of treatment efficacy.

Palliative Care

At present, there are no curative therapies for patients with metastatic HRPC. Although promising, none of the new and emerging treatments described in the preceding sections are likely to achieve this endpoint. For that reason, it is imperative to emphasize that the physician managing such patients must be ever-attentive to quality-of-life issues, particularly the relief of intractable pain.

The somatic and visceral pain associated with advanced-stage malignancy is optimally managed using the *analgesic “stepladder”* officially promoted by the World Health Organization in 1986 (282) (Fig. 33.95). Nociceptive (pain) signals are transmitted over peripheral nerves to the CNS, where farther ascending transmission and modulation occur at spinal and supraspinal levels. Both a human thalamic nucleus specific for pain and widely distributed cerebral cannabinoid receptors have been identified. A newly identified orphan opioid receptor also has been identified. The latter is widely distributed in the brain and its natural ligand “nociceptin or orphanin FQ” also may be involved in learning and memory (846).

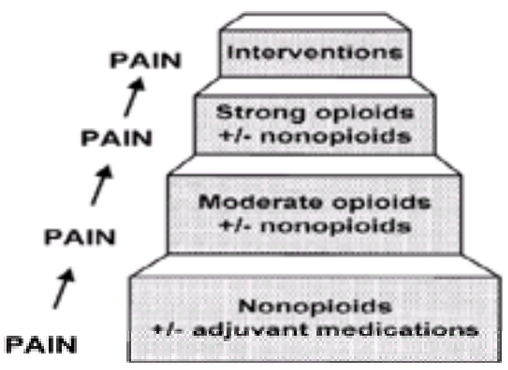

FIGURE 33.95. World Health Organization analgesic stepladder. In the event that cancer is not relieved using the first three steps of this approach, a fourth step should be considered and includes appropriate interventions, such as a simple nerve-blocks, spinal cord stimulation, spinal analgesia, and neuroablation. (From Krames ES. Practical issues when using neuraxial infusion. *Oncology* 1999;13:37, with permission.)

Pain may be classified as nociceptive (ongoing tissue damage) and nonnociceptive (neuropathic). Cancer patients usually suffer from pain due to more than one pathophysiologic mechanism (281). Chemical mediators of pain include substance P, prostaglandins, purines, norepinephrine, neuropeptide Y, endothelin, and nitric oxide.

Acetaminophen or NSAIDs may be sufficient for the management of low-intensity intermittent pain. This constitutes *step I* in the analgesic “ladder.” Although effective for mild pain, many of these agents will possess dose-limiting side effects. For moderate pain, *step 2* of the ladder is activated and involves the use of lower-potency opiate derivatives (i.e., codeine, hydrocodone, and oxycodone), alone or in combination with a step 1 agent. Severe and unrelenting pain should prompt the activation of *step 3,* which involves the use of high-potency opiates (i.e., morphine sulfate sustained release, fentanyl transdermal patch, hydromorphone, methadone). Once again, step 3 agents can be used in combination with an NSAID. In general, each medication should be given in maximum tolerated doses before advancing to medications of greater potency. Of great importance, *the analgesic regimen should be administered around the clock and not on an as needed basis*. The standard regimen may need to be augmented to treat breakthrough pain, which is best managed by the “as needed” use of short-acting medications (i.e., morphine sulfate elixir). *Neuropathic pain* may require the administration of a tricyclic antidepressant or gabapentin (Neurontin).

For patients with *insomnia*, the use of amitriptyline or doxepin may be particularly advantageous. The latter agent is also useful for the treatment of intractable narcotic-associated pruritus because of its antihistaminic properties. Conversely, desipramine and nortriptyline are less sedating and possess fewer anticholinergic side effects. The concomitant use of stool softeners and senna frequently obviate narcotic-associated *constipation*. If the latter does occur, magnesium-based laxatives are generally effective. When properly used, the WHO three-step analgesic ladder has been demonstrated to be effective in relieving 75% to 90% of cancer pain (1039).

External beam radiation therapy has a definite role in the management of pain associated with skeletal metastasis from CaP. Androgen-ablative techniques, particularly orchiectomy, can produce a rapid and profound improvement in such painful sites. Consideration of radiation therapy is warranted in those patients who fail to show an adequate response to androgen withdrawal, particularly those with lesions in the spine or weight-bearing areas. In the study by Benson and associates (54), 42% of patients had complete relief of pain following the completion of 3,000 to 3,500 cGy delivered to the painful site. Another 35% exhibited partial relief of symptoms. In addition to the prompt initiation of androgen ablation (usually orchiectomy), the emergency treatment of malignant extradural spinal cord compression has traditionally involved radiotherapy plus the use of moderate-dose (16 mg per day) dexamethasone. Some evidence suggests the steroid component of this regimen can be eliminated in patients who are nonparetic and ambulatory pretreatment. Radiation therapy also may be reasonable in patients with subclinical spinal cord compression (594). Patients with painful multifocal skeletal metastases may be benefited by the *technique of half-body or whole-body irradiation* (494,847). This technique involves the administration of a 600 cGy dose to the upper body followed by a 4- to 6-week hiatus, after which time approximately 800 cGy is delivered to the lower body half. The side effects of the treatment are not trivial and include severe nausea, vomiting, and the expected consequences of bone marrow suppression. Pain relief can be rapid and complete in 28% of patients, with another 70% demonstrating some improvement. As with the use of external beam therapy for focally painful lesions, the lumber spine seems to be a difficult area in which to provide effective palliation (143).

Robinson and associates (835) administered the calcium analog *strontium-89* to patients with prostate cancer who had painful multifocal skeletal metastasis. Response rates in excess of 80% were noted following the IV infusion of 50 to 60 Ci/kg. *Sr-89* b-emitting isotope that possesses a 50.5 day half-life and follows the biologic pathways of calcium; in theory this provides access to all sites of osteoblastic metastases. Sr-89 is available as a stable isotonic solution for IV administration as a single outpatient injection. Each vial contains a single dose of Sr-89 chloride (4.0 mCi) in saline solution. More recent studies have demonstrated pain relief in approximately 70% of patients (195,791). In general, pain relief is not immediate but begins within 10 to 20 days postinjection, with relief maintained for a mean of 6 months (range of 4 to 15 months). The treatment may be repeated at 3-month intervals contingent upon the patient's peripheral blood count. Therapy is well tolerated except for hematologic toxicity (especially thrombocytopenia), which may become manifest at higher dosages and following repeat dosing. Currently, the primary use for Sr-89 is for the treatment of symptomatic, multifocal skeletal metastases in patients with hormone-refractory prostate cancer who would otherwise be considered for hemibody radiation. Of interest, clinical trials using Sr-89 in conjunction with other antineoplastic regimens (estramustine-based chemotherapy; doxorubicin; suramin) are in progress. The ultimate utility of this novel combination of agents awaits results of multiinstitutional clinical trials.

New bone-seeking agents have been developed that combine more favorable nuclear properties (shorter half-life and lower-energy particle emissions) with chelating agents to form metal complexes that preferentially localize to sites of osteoblastic metastases. *Samarium-153 (Sm153) lexidronam (EDTMP)* (Quadramet) is rapidly cleared from the blood following IV injection and is deposited in the skeleton and excreted as the intact complex in the urine. Patients with metastatic bone cancer who received I.OrnCi/kg of active drug achieved pain relief in 62% to 72% of cases (903). Pain relief was observed within 1 week of administration and persisted until at least week 16 in the majority of responding patients. g-Ray images obtained after administration of this agent have shown uptake in skeletal lesions are

indistinguishable from that obtained with diagnostic bone-scanning agents. Hematologic toxicity, primarily leukopenia and thrombocytopenia, is dose-related, reversible, and occurs most often in patients with comprised marrow reserves.

More recently, *tin-117m (Sn-117m DTPA)* has been evaluated for the treatment of metastatic bone pain (958). This agent is an avid bone seeker and its biodistribution is virtually identical with that of the routinely used bone imaging radiopharmaceutical Tc-99m MDP. Sn-I 17m DTPA is theoretically attractive because the presence of low-energy electrons (g-emitter) should result in the relative sparing of the bone marrow while delivering a high radiation dose to sites of skeletal metastases. In contrast, p-emitters (e.g., Sr-89, Sm-153) tend to induce more marrow toxicity. In one study, 47 patients with bony metastatic disease were assigned to five different dose levels [ranging from 2.64 to 10.58 Mbq (71 to 286 inCi) per kg of body weight], with an overall response rate of 75%. The relief was complete in 30%. The time of onset of pain relief was 19 ± 15 days with doses £5.29 Mbq/kg and 5 ± 3 days with doses ³6.61 Mbq/kg (958). Myelotoxicity was minimal and less than that associated with Sr-89 and Sm-153.

Larger doses of radiation (5,000 to 6,000 cGy) may be required to relieve ureteral obstruction refractory to androgen withdrawal therapy. Although some authors have reported good results (120), others have been less enthusiastic about its efficacy (653). Satisfactory resolution of the obstruction may take many weeks, suggesting the wisdom of using double-J stents in the interim.

Radiation therapy to treating bladder neck obstruction due to locally aggressive CaP is a reasonable option in some patients. Androgen ablation (with or without tube decompression) can successfully relieve bladder neck obstruction in most patients within 3 to 6 months and may obviate the need for channel TURP in high-risk patients.

It is beyond the scope of this section to discuss every potential problem confronted by patients with advanced-stage HRPC. Nonetheless, brief consideration of a few additional supportive care issues is appropriate. *Anorexia and cachexia* have been observed in more than 60% of patients with advanced malignancy (239). The etiology of this problem is generally multifactorial and includes (a) the elaboration of tumor necrosis factor, cytokines, and small peptides produced by the tumor; (b) local side effects of the cancer itself; and (c) iatrogenic or treatment-related complications (282). Occasional benefit is derived from the use of corticosteroids (i.e., prednisone 10 to 20 mg per day), high-dose megestrol acetate (500 mg per day), or dronabinol (2.5 mg two to three times daily).

Anemia is commonly observed in patients with end-stage prostate cancer. The tumor cells have a high affinity for the red marrow sinusoids and selectively target those sites. Uncontrolled tumor proliferation ultimately leads to replacement of normal hematopoietic stem cells. Other potential causes of anemia include the myelosuppressive effects of external beam radiation, the use of Sr, and systemic chemotherapy. The resulting side effects can adversely affect quality of life. The first consideration is control of active bleeding, regardless of the source. In most instances, the anemia is chronic and insidious. Administration of epoetin alfa (Epogen) and/or transfusions of packed RBCs should be considered for any patient who is overtly symptomatic and in patients whose hemoglobin level is less than 8.0 g/dL (282).

Approximately one-fourth of patients with advanced malignancy experience clinically significant *depression*. Some of these patients will already be taking tricyclic antidepressants to control neuropathic pain. In such individuals, continuation of that therapy and cautious dose escalation is reasonable. Some potential drawbacks with respect to the use of these agents includes the obligatory 2- to 4-week period required to achieve therapeutic blood levels and GU/GI side effects due to their anticholinergic properties. The selective serotonin reuptake inhibitors (fluoxetine and sertraline) are very useful for the treatment of depression in this setting. In general, the latter agents are taken once daily, are generally well tolerated, and provide a favorable degree of psychostimulation. In addition, they possess a more rapid onset of action and have fewer anticholinergic side effects. It is important to emphasize that tricyclic antidepressants and selective serotonin reuptake inhibitors should not be administered concomitantly for fear of precipitating the “serotonin syndrome,” which is associated with flushing, elevated blood pressure, rapid heart rate, muscle spasms, diarrhea, and mental status changes.

Finally, it is particularly challenging and exceptionally rewarding to participate in the care of those patients with terminal prostate cancer during the final months of life. The doctor–patient relationship takes new meaning in this context. It is imperative that the physicians involved in the care of such patients have an unhurried attitude and encourage patients to speak about their lives, current or past relationships, and their immediate future concerns. Physical contact with the patient should not be discouraged, and the physician should manifest genuine concern for the patient and the grieving family. *Hospital and community-based hospice units* are invaluable to the patient, family, and managing physicians.

Conclusion

Sophisticated scientific approaches are beginning to yield significant insights into the genetic and biochemical aberrations associated with the uncontrolled proliferation and dissemination of HRPC. It seems likely that such advances will ultimately translate into the development of novel therapies whose impact will be well tolerated, effective, and durable. It is also highly probable that these treatments will be cytostatic rather than cytotoxic. Multimodality cytostatic approaches using treatments possessing diverse mechanisms of action may supplant traditional cytotoxic regimens, whose goal is the ultimate elimination of every tumor cell clone (Fig. 33.96). Providing such elderly patients with a number of good quality years would be tantamount to cure in many instances.

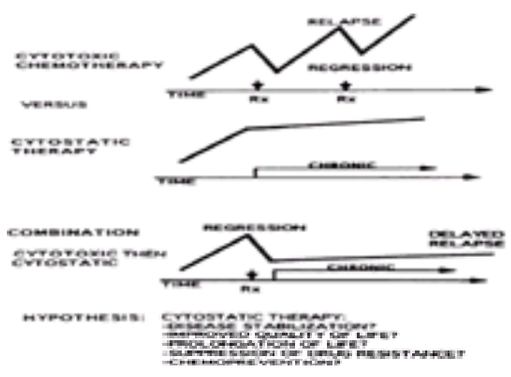

FIGURE 33.96. Cancer treatment paradigms. Cytotoxic therapy–induced regression is generally followed by relapse. Multimodal cytostatic therapy probably will be administered over a prolonged period of time. Indeed, the combination of these two treatment strategies could conceivably extend the time to recurrence and prolong survival. (From Kohn EC, Liotta LA. Molecular insights into cancer invasion: strategies for prevention and intervention. *Cancer Res* 1995;55:1856, with permission.)

Treatment of Unusual Primary Tumors of the Prostate

Although no well-established guidelines exist for the management of the unusual prostate cancers briefly described in the pathology section of this chapter, an analysis of sporadic case reports does permit certain generalizations.

Approximately 160 cases of primary and secondary intraductal prostatic adenocarcinoma have been reported in the literature. Available evidence suggests that when such lesions are localized to the prostate gland, their treatment should parallel that of the more common acinar tumors. Despite the fact that distant dissemination is often associated with osteoblastic skeletal metastases and elevated serum PSA and PAP levels, the response of these prostatic duct adenocarcinomas to androgen-ablative therapy is disappointing. Dube and associates (244) reported 5-year survival rates of 42.8% and 24% for primary and secondary prostatic duct adenocarcinomas, respectively.

Endometrioid carcinomas probably represent a variant of prostatic ductal tumor. Recent electron microscopic and immunohistochemical data support this contention and seem to negate the likelihood of utricular origin (1124). Of interest, these lesions appear biologically less aggressive than other ductal carcinomas. Various treatment options have been reported for locally contained tumors. Because these tumors are typically located in a periurethral distribution, small lesions are potentially amenable to TUR. Most cases, however, have been treated with radical prostatectomy, cystoprostatectomy, or external beam radiation therapy (526,1075). Despite early reports to the contrary, most of these tumors are androgen-dependent, and some form of androgen-ablative therapy is certainly warranted in the presence of metastatic disease (277,1070). Indeed, of the 72 reported cases, 61 demonstrated positive staining for PSA, PAP, or both (765). It has been proposed

that the PSA-negative tumors may represent a unique variant of endometrioid carcinoma, one derived from müllerian epithelium, which is PSA- and Leu 7-negative (970). Although these lesions tend to be refractory to currently available chemotherapy regimens, transient partial tumor regression was reported with the combination of 5-FU and doxorubicin (554).

Approximately 200 cases of transitional cell carcinoma of the prostate (TCCP) have been cited in the literature. Three distinct clinical subsets of TCCP are recognized and include (a) primary tumors arising in the absence of synchronous or metachronous urothelial cancers (25%), (b) secondary tumors that may be contiguous or noncontiguous with other urothelial lesions (65%), and (c) mixed tumors consisting of TCCP and prostatic adenocarcinoma (10%) (41,298,764,1099). In general, these tumors are very aggressive and often are associated with diffuse retrograde involvement of the prostatic ductal system, urethra, and bladder. The presence of a histologic continuum ranging from transitional cell hyperplasia with atypia to frank carcinoma *in situ* within the prostatic ducts would suggest a primary prostatic origin for the neoplasm in many instances (1030). Conservative treatment options such as TURP and the intravesical administration of BCG is feasible in a very small subset of patients with *in situ* disease (1075). Radical cystoprostatectomy is required for most tumors invading the fibromuscular stroma of the prostate owing to the presence of contiguous bladder neck and urethral involvement. If the latter can be excluded with certainty, radical prostatectomy might constitute a legitimate therapeutic alternative (298). Combined systemic chemotherapy and radiation therapy should be considered in those patients with gross disease beyond the prostatic capsule and in those patients with compromised surgical margins (or positive nodes) following anterior exenteration. Modifications of the CISCA [cisplatin, cyclophosphamide, adriamycin (doxorubicin)], and MVAC (*m*ethotrexate, *v*inblastine, *a*driamycin, *c*isplatin) regimens seem to be most effective coupled with sequential or concomitant radiation therapy (4,500 to 5,000 cGy). Salvage cystoprostatectomy should be considered in patients who respond to such combination drug treatment (298,385,848). It is hoped that these approaches will improve the average survival, which ranges from 17 to 23 months following radical surgery with or without preoperative radiation therapy (385). Androgen-ablative therapy seems to play little role in the presence of overt metastases because these tumors are uniformly androgen resistant. In this group, combination chemotherapy has been associated with complete (35%) and partial (22%) responses, some of which are sustained for significant periods (298). The interested reader will find the review of this subject by Matzkin and associates (623) very helpful.

Approximately 66 cases of squamous cell carcinoma of the prostate have been reported. This aggressive, androgen-resistant tumor probably represents a metaplastic variant of transitional cell carcinoma of the prostate, and the therapeutic options exercised should parallel those cited for the latter neoplasm (765). Consideration should be given to adjusting the chemotherapy regimen to include agents such as mitomycin C, 5-FU, bleomycin, or MTX, which tend to be more effective against squamous cell cancers. Again, most patients succumb to the disease, with a mean survival of 14 months (680). Although both PSA-positive and PSA-negative tumors have been reported, the observed skeletal metastases were osteolytic (765).

Mucinous (colloid) carcinoma and adenoid cystic carcinoma are rare neoplasms. Consequently, definitive statements regarding therapeutic options and survival are not available. It would seem that tumors confined to the prostate should be treated in a manner similar to that used for acinar tumors. The impact of other therapeutic modalities on locally aggressive or metastatic lesions cannot be ascertained at present. Although these tumors appear to be predominantly androgen resistant, a trial of androgen-ablative therapy would seem warranted in the presence of distant dissemination.

With regard to malignant mesenchymal neoplasms of the prostate, the treatment of rhabdomyosarcoma is thoroughly discussed elsewhere in this book. Carcinosarcomas and leiomyosarcomas of the prostate are similarly aggressive neoplasms that have most often been treated by multimodal approaches (296). This has included preoperative radiation therapy followed by anterior pelvic exenteration and systemic chemotherapy. Ahlering and associates (7) reported the results of their multimodal approach to the treatment of patients with leiomyosarcomas of the bladder (seven patients) and prostate (four patients). Anterior pelvic exenteration was performed for most patients with nonbulky disease. Postoperative external beam radiotherapy (4,500 to 5,000 cGy) and chemotherapy (cisplatin and doxorubicin) were administered in cases of compromised surgical margins or positive lymph nodes. Patients with bulky disease underwent cytoreduction with two to three cycles of preoperative chemotherapy, with or without radiation therapy, followed by salvage cystoprostatectomy. The preoperative therapy induced a striking degree of cystic necrosis within the tumor, resulting in an increase in size appreciated on follow-up CT scans. Of note, 9 of the 11 patients were without evidence of disease with a mean follow-up of 61 months. In the past, these neoplasms have been associated with a 5-year survival rate of approximately 10% (765). These figures are likely to improve with the advent of carefully orchestrated multimodal therapy.

The treatment of small-cell carcinomas of the prostate generally involves the use of regimens with demonstrated efficacy in the management of small-cell cancers of the lung. A typical protocol for tumors not amenable to initial surgical resection is concomitant radiotherapy and cisplatin/etoposide chemotherapy (with or without vincristine). Alternatively, sequential radiotherapy can be used in concert with cyclophosphamide, adriamycin, and vincristine (1012). A median survival of 17 months has been reported (726). Information regarding the more exotic tumors involving the prostate gland is based on anecdotal case reports, and their treatment, of necessity, must be highly individualized.

Acknowledgments

The authors are deeply indebted to Michael Mabaquiao, Erica Wood, and Sharon Stafford for their invaluable assistance in the preparation of this manuscript.

Summary
Chapter References

Prostatitis is diagnosed in adult men of all ages, and symptoms of prostatitis have been said to affect up to 50% of men at some point in their life (258). Data from the National Center for Health Statistics (163) showed that in the United States in 1965, there were actually more physician visits for prostatitis than for benign prostatic hyperplasia (BPH) or prostate cancer. In fact, for 1 year in the late 1970s, approximately 25% of outpatient visits for genitourinary complaints were for prostatitis symptoms (163). Prostatitis is the most common urologic diagnosis in men younger than 50 years of age and the third most common diagnosis in men older than 50 years of age (137). It is the most common urologic diagnosis encountered in the armed forces during peacekeeping deployment (60). In 1991, approximately 5% of visits to U.S. urologists were reported to be for inflammatory diseases of the prostate (240). Urologists in Canada see an average of 22 prostatitis patients per month (median of 11) (180), while urologists in Wisconsin saw an average of 173 (median of 99) prostatitis per patients per year (155). From the latter study, the prevalence of prostatitis in Wisconsin was estimated to be approximately 5% (155). In young men (younger than 50), independent researchers found that 4% to 5% of responders reported a history of prostatitis (44,153). Data from the Olmsted County study of urinary symptoms and health status among men (227) were used to estimate the prevalence of medically diagnosed prostatitis (based on a review of 2,113 men with a medium of 50 months of follow-up). The investigators noted the overall prevalence of a physician's diagnosis of prostatitis was 11%. A population-based study using a recently validated chronic prostatitis symptom index, reported the prevalence of prostatitis-like symptoms in men younger than 70 years old to be approximately 10% (59).

It is clear that recent studies have confirmed that prostatitis is an extremely common and important diagnosis and the symptoms associated with the diagnosis of prostatitis have significant prevalence within the male community at risk. But what is prostatitis? What causes the symptom complex that describes this clinical entity? How can we properly diagnose and classify these patients? And most important, how can we use the accumulated knowledge of a century of research in this clinical syndrome to rationally treat patients diagnosed with this clinical entity?

KEY INFORMATION

Epidemiology

- Five to ten percent of men are at risk (have either diagnosis or symptoms) for prostatitis.
- Prostatitis is the most common diagnosis made by urologists in men younger than 50 years of age.
- Prostatitis has a significant impact on quality of life.

CLASSIFICATION

Traditional Classification System for Prostatitis Syndromes

The four traditional categories of prostatitis were formally introduced to the urologic community in a letter to the editor published in the *Journal of Urology* in 1978 (61). This classification system primarily depended on analysis of prostatic fluid [expressed prostatic fluid (EPS)]. Purulent prostatic fluid was defined as having more than 10 to 20 white blood cells (WBCs) per high-power field (HPF) (the original authors could not decide on a significant level of WBCs in EPS) associated with WBC clumps, mucous debris and occasional lethicin and oval fat bodies, and large macrophages. The categories were further differentiated by culture of prostatic fluid or a urine specimen after prostate massage.

Acute bacterial prostatitis was diagnosed when bacteria were cultured from prostatic fluid, prostatic fluid was clinically purulent, and systemic signs of infectious illness were present. If prostatic massage was considered contraindicated during acute bacterial prostatitis, the diagnosis could be made on recovery of bacteria from the urine and detection of a “hot,” swollen, tender prostate on rectal examination. Chronic bacterial prostatitis could be diagnosed when pathogenic bacteria were recovered in significant numbers from a purulent prostatic fluid in the absence of concomitant urinary tract infection (UTI) or significant systemic signs. Nonbacterial prostatitis could be diagnosed when significant numbers of bacteria could not be cultured from prostatic fluid, but the fluid consistently revealed microscopic purulence. Prostatodynia or “pain in the prostate gland” was the diagnosis for those remaining patients who had persistent complaints similar to the previous two categories but no significant bacteria or purulence in the prostatic fluid.

This traditional classification system depended in large part on the rigid and standardized Meares-Stamey four-glass technique described to evaluate the lower

urinary tract inpatients with prostatitis (140). However, many urologists (and most primary care physicians and internists) did not routinely use this Meares-Stamey technique, and the routine practice of examining and culturing prostatic fluid became an uncommon practice (136,137,155,180). Therefore the classification of chronic prostatitis into the three traditional chronic categories became problematic because it relied wholly on examination and culture of the EPS. Further complicating this classification system was the realization that standard culture techniques may not be identifying possible pathogens in the so-called nonbacterial categories.

NIH Definition/Classification System for Prostatitis Syndromes

The urologic community generally recognized that significant confusion surrounded the diagnostic and treatment strategies in chronic prostatitis and many believed this was directly related to the poor definition, diagnostic criteria, and classification system used to date in this clinical syndrome. North American and International urologic researchers interested in prostatitis met at the 1995 Workshop on Chronic Prostatitis, convened by the National Institutes of Health/National Institute of Digestive, Diabetes and Kidney Diseases (NIH/NIDDK) to discuss this problem. A new definition of chronic prostatitis/chronic pelvic pain syndrome was incorporated into the 1995 NIH classification system for prostatitis (111,164). This new classification system divided the prostatitis syndromes into four main categories (Table 34.1). Categories I and II are similar to the traditional classification of acute and chronic bacterial prostatitis respectively. The new category, category III or chronic pelvic pain syndrome (CPPS), was based on the “presence of genitourinary pain in the absence of uropathogenic bacteria detected by standard microbiological methodology.” This new definition/category addresses the concern that we do not understand the etiology of the syndrome in the majority of patients diagnosed with a chronic prostatitis syndrome. CPPS was further categorized into category IIIA or inflammatory CPPS (based on the presence of inflammatory cells in expressed prostatic secretion, postprostatic massage urine or semen) and category IIIB or noninflammatory CPPS (no inflammatory cells in similar prostate-specific specimens). A fourth category, category IV (asymptomatic inflammatory prostatitis), addresses a major omission in the original traditional classification system. This category includes asymptomatic patients without any demonstrable prostate disease as well as patients with potentially related conditions of the prostate (BPH, prostate cancer, infertility). Patients would be classified into this category based on histopathologic/culture examinations of EPS, postprostatic massage urine specimens (VB3), prostate biopsies, transurethral resection of the prostate (TURP) specimens, semen analyses, and radical prostatectomy specimens. The 1st International Prostatitis Collaborative Network met in Washington, DC, in 1998, and although the limitations of the new classification system were evident after 3 years of use, it was universally acknowledged that the NIH classification system was an improvement over the traditional classification system and was effective in both clinical practice and research protocols (181).

Category I: acute bacterial prostatitis	Acute infection of the prostate gland
Category II: chronic bacterial prostatitis	Chronic infection of the prostate gland
Category III: chronic pelvic pain syndrome (CPPS)	Genitourinary pain without uropathogenic bacteria localized to the prostate gland using standard methodology
Category IIIA: inflammatory CPPS, Nonbacterial prostatitis	Significant number of white blood cells in expressed prostatic secretion, postprostatic massage urine sediment (VB3), or semen
Category IIIB: noninflammatory CPPS, Prostatodynia	Insignificant number of white blood cells in expressed prostatic secretion, postprostatic massage urine sediment (VB3), or semen
Asymptomatic inflammatory prostatitis (AIP)	White blood cells (and/or bacteria) in expressed prostatic secretion, postprostatic massage urine sediment (VB3), semen, or histologic specimens of prostate gland

TABLE 34.1. CLASSIFICATION SYSTEM FOR THE PROSTATITIS SYNDROMES

KEY INFORMATION

Classification

- Traditional classification systems have limitations.
- The new National Institutes of Health classification system of prostatitis is an improvement over traditional systems but is still unvalidated.

LOWER URINARY TRACT EVALUATION

Background

To adequately classify the patient according to either the traditional classification system or the more recently introduced NIH classification system for prostatitis, an evaluation of lower urinary tract specimens is required. Meares and Stamey originally described the four-glass urine collection technique as a method to distinguish urethral, bladder, and prostate infections in men (140). Although it is readily acknowledged that many urologists and primary care physicians do not carry out the four-glass procedure, it is still recognized as the premiere diagnostic test and classification tool, or in other words, the gold standard in all prostatitis/chronic pelvic pain syndrome evaluations. However, new, simpler modifications that are more cost-effective may be adequate for clinical practice.

Meares-Stamey Test

The Meares-Stamey four-glass technique provides samples for both microscopic analysis and bacterial culture. The background for this test was provided by researchers in the second and third decades of the twentieth century (169,271,272) who carried out careful culturing of the lower urinary tract in prostatitis patients. Meares and Stamey (140) extended this concept by adding a urethral specimen to the sampling technique. The voided bladder 1 (VB1) specimen includes the first 10 mL of urine. This specimen represents the cells and bacteria from the urethra and was believed to be important in the diagnosis of urethritis. The voided bladder 2 (VB2), or midstream urine specimen, represents the bladder urine. Expressed prostatic secretion (EPS) should be collected directly in a sterile container while the examiner digitally massages the prostate. EPS may not be obtainable in all patients. The voided bladder 3 (VB3) specimen is the first 10 mL of urine voided after massaging the prostate and includes any EPS that may be trapped in the prostatic urethra. An aliquot of VB1, VB2, EPS, and VB3 specimens should be quantitatively cultured (it may be difficult to quantitatively culture the EPS in most urologic clinical situations). The urine specimens (VB1 to VB3) should be centrifuged for 5 minutes and the sediment examined at high-power microscopy for leukocytes, macrophages, erythrocytes, bacteria, oval fat bodies, and fungal hyphae and their numbers recorded (per HPF or more accurately in a hemocytometer). The presence and density of WBCs (Fig. 34.1) and the quantitative bacteriologic cultures of the urethral, bladder, and prostate specimens are used to diagnose urethritis, cystitis, and bacterial and nonbacterial prostatitis. The quantification of bacterial cultures allows for this localization of infection to a specific segment of the lower urinary tract (i.e., urethra, bladder, or prostate). Traditionally, a tenfold or greater increase in the number of WBCs or colony forming units per cubic centimeter (culture results) in a specific specimen indicated the area of inflammation/infection. A description and interpretation of the four-glass test is shown in Fig. 34.2 and Fig. 34.3 and Table 34.2, respectively.

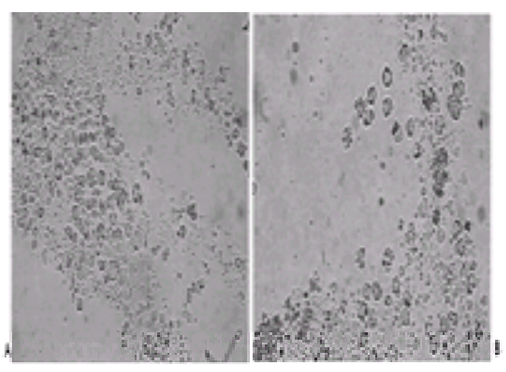

FIGURE 34.1. Photomicrographs showing individual white blood cells, clumps of white blood cells, and lipid-laden macrophages in the expressed prostatic secretion (EPS) of a patient with category IIIA CPPS. (**A:** 250× magnification; **B:** 400× magnification.)

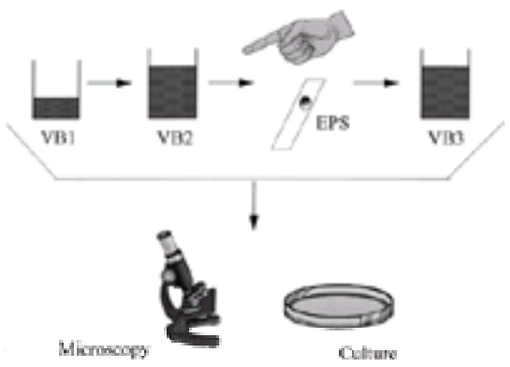

FIGURE 34.2. Meares-Stamey four-glass test. In the four-glass test, initially voided urine *(VB1)* and midstream or second-voided urine *(VB2)* represent urethral and bladder specimens, respectively. During prostate massage, expressed prostatic secretion *(EPS)* is collected and subsequently a voided bladder specimen after prostate massage *(VB3)* specimen is produced. Specimens are all cultured and a microscopic examination of the sediment of VB1, VB2, and VB3 and a wet mount microscopy of EPS is undertaken. See Table 34.2 for interpretation.

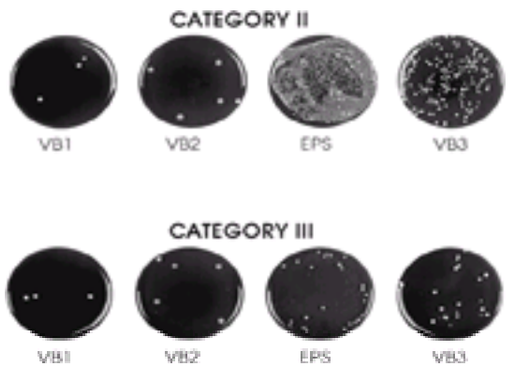

FIGURE 34.3. Culture plates from a representative Meares-Stamey four-glass test undertaken in a patient with category II prostatitis and category III chronic pelvic pain syndrome. Note the light background of Gram-positive bacteria in all specimens but the heavier growth of Gram-negative colony-forming units in the prostate-specific specimens (expressed prostatic secretion and VB3) from the category II patient. Note the light growth of Gram-positive colony forming units in all specimens from the category III patient.

TABLE 34.2. INTERPRETATION OF THE FOUR-GLASS TEST (MEARES-STAMEY) AND TWO-GLASS PREMASSAGE AND POSTMASSAGE TEST (PPMT)

The many limitations of this test include (a) the fact that EPS cannot be obtained all the time in all patients, (b) quantification of bacterial counts in the EPS may be difficult for many urologists, (c) interpretation of WBC counts varies widely, (d) most laboratories do not routinely attempt to culture chlamydia or ureaplasma or other difficult-to-culture organisms, and (e) significant controversy remains regarding the role of Gram-positive staphylococci and corynebacterium that may be localized to a specific (i.e., prostate) specimen (184,186).

Two-glass Test (Premassage and Postmassage Test)

The two-glass test originally was suggested by Weidner (277) and later was popularized by Nickel (187) to streamline and simplify lower urinary tract evaluation in the majority of patients presenting to the clinical urologic clinic. A description and interpretation of the two-glass test is shown in Fig. 34.4 and Table 34.2, respectively. It is based on two primary premises. The first is that significant urethritis usually can be diagnosed clinically without the employment of an expensive time consuming lower urinary tract evaluation. Asymptomatic urethritis (i.e., no significant urethral pain, urethral itchiness, or urethral discharge) is considered rare and not clinically significant. In a recent report of lower urinary tract evaluations in men presenting with chronic prostatitis/chronic pelvic pain syndrome, Krieger and co-workers (114) demonstrated that “significant” urethral inflammation is rare and did not appear to affect clinical diagnoses and treatment. The second premise is that postprostatic massage urine (the first 10 mL of urine voided after a vigorous prostatic massage) accurately reflects the microscopy and culture results of the expressed prostatic secretion. Krieger and others (114) demonstrated that postprostatic massage urine was as accurate as examination of EPS in determining prostate-specific inflammation. Ludwig and associates (127) further confirmed that examination of postprostatic massage urine accurately reflected the degree of inflammation detected on expressed prostatic secretion. Although not as accurate as the gold standard four-glass test, the two-glass or premassage and postmassage test results in the same diagnosis in more than 90% of patients tested (187). The premassage and postmassage tests are cost-effective and quick and easy to perform in classifying the patients presenting to the urologic clinic with a chronic prostatitis syndrome.

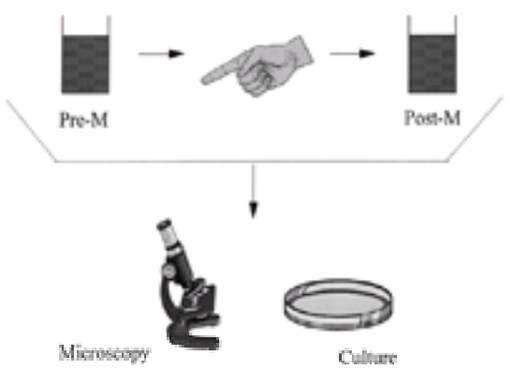

FIGURE 34.4. Premassage and postmassage two-glass test (PPMT). In this much simpler and cost-effective (compared with the Meares-Stamey four-glass test) screening, premassage and postmassage urine specimens are taken before prostate massage *(pre-M)* and after prostate massage *(post-M).* Specimens are sent for

culture and microscopy of the sediment. See Table 34.2 for interpretation.

KEY INFORMATION

Diagnosis

- The Meares-Stamey four-glass test remains the gold standard for lower urinary tract localization evaluation.
- For those who cannot or will not do the four-glass test, the simpler premassage and postmassage two-glass test is a reasonable screening evaluation of the lower urinary tract.

CATEGORY I: ACUTE BACTERIAL PROSTATITIS

Etiology

Category 1 prostatitis or acute bacterial prostatitis is defined as an acute bacterial infection of the prostate gland. The bacteria are typically uropathogenic fecal flora, very similar to the spectrum of bacteria associated with lower UTIs in females. As with simple lower UTIs in females, the route of infection in the typical case is likely an ascending urethral colonization by potentially pathogenic organisms. The most common organism found in acute prostatitis is *Escherichia coli* (58,145) with other Gram-negative organisms such as *Proteus* species, *Klebsiella* species, *Pseudomonas* species, and *Serratia* species accounting for 10% to 15% of cases (146). Gram-positive organisms are rare in acute prostatitis syndromes but *Enterococcus faecalis* may be an uncommon pathogen (146). Rarely, *Staphylococcus aureus* and other rare Gram-positive and Gram-negative organisms may cause an acute prostatic infection from either a blood-born or catheter-associated route. Coagulase-negative Gram-positive organisms such as *Staphylococcus saprophyticus* do not appear to cause an acute infection of the prostate gland.

Although most male patients develop acute bacterial prostatitis spontaneously, several host risk factors must be considered. Uncircumcised males (269), unprotected penetrative anorectal intercourse, acute epididymitis (17), Lewis Blood Group antigens (123), specific urethral antigens (49,165), meatal and urethral stricture disease (24), and patients who have undergone urethral manipulation and catheterization (212) are predisposed to acute prostatitis. Urovirulence factors may play a significant role in the pathogenesis of acute prostatitis. For instance, bacterial P-fimbria binds to urothelial receptors, which subsequently facilitates ascent into the urinary tract and establishes deep-seated tissue infections such as acute prostatitis (49,165). Numerous reports indicate that P-fimbriated *E. coli* is commonly isolated from the urinary tract in men with prostatitis (7,268). Colonization of the lower urinary tract by *E. coli* also is facilitated by the presence of type 1 fimbria, also known as *mannose-sensitive fimbria.* The receptor is a common moiety of the uroepithelial uromucoid and this association has been shown to be important in the development of cystitis in humans, and its presence in prostatitis also has been documented (40). Phase variation of type 1 pili during the establishment of acute bacterial prostatitis also has been postulated to occur in the setting of lower UTIs (239).

Confronted by bacterial presence within the prostatic ducts, the prostate gland mounts both a local and systemic immune response (73,116,142,147). Serum and prostatic fluid antigen-specific IgG are both present immediately after onset of infection and decline over the 6 to 12 months after successful antibiotic therapy to normal values. Antigen-specific IgA in prostatic secretion also becomes elevated immediately after inflammation and begins to decrease after 12 months, whereas serum IgA disappears after 1 month following successful antibiotic therapy. Prostate-specific antigen (PSA) can be significantly elevated during an episode of acute bacterial prostatitis (42,168), likely secondary to disruption of the prostatic epithelial cell membrane (152), and slowly resolves to normal levels over the course of 6 weeks (168), provided there is no recrudescence of the infection.

Clinical Presentation

The patient with acute bacterial prostatitis presents with a sudden clinical syndrome of lower UTI, specifically dysuria, frequency, urgency, and suprapubic pain in combination with systemic symptoms associated with generalized infection such as fever, chills, malaise, nausea, and vomiting. Most patients complain of significant obstructive voiding with decreased force and caliber of the urinary stream, dribbling, hesitancy, and in many cases, acute urinary retention.

Diagnosis

In most cases, the astute clinician can make the diagnosis of acute bacterial prostatitis by history and focused physical examination. The history of local and generalized symptoms of infection associated with irritative and obstructive voiding symptoms suggests the diagnosis. Suprapubic tenderness (or even distended bladder by palpation or percussion) in a patient with pyrexia, tachycardia, and perhaps even tachypnea and hypotension corroborates the diagnosis. The prostate examination discloses an exquisitely tender (tense and perhaps edematous and enlarged) prostate. Prostate massage is not necessary and is even discouraged because of the possibility of exacerbating the problem of urosepsis.

Urinalysis and midstream urine culture complete the initial evaluation. The diagnosis is more or less confirmed with the presence of significant pyuria (more than 10 leukocytes per HPF of a centrifuged specimen on microscopy) combined with an eventual urine culture revealing more than 10^5 uropathogenic organisms per cubic centimeter (191). The original traditional classification (61) of the prostatitis syndromes required an examination and culture of the EPS, even in acute bacterial prostatitis. No data in the literature substantiate the fears that prostatic massage causes serious morbidity (such as exacerbating urosepsis), but this procedure is now generally discouraged and is not necessary to make the diagnosis of acute prostatitis. If expressed prostatic secretion is obtained, it should disclose many WBCs and bacteria on microscopy and subsequent cultures should be positive for uropathogens.

Management

The following four major considerations must be taken into account when treating acute bacterial prostatitis (166):

1. *Antimicrobial use:* class, route of administration, and duration of therapy
2. *Urinary drainage:* need for bladder drainage and subsequent mode of bladder catheterization
3. *Hospitalization:* decision whether the patient must be hospitalized or whether he or she can be safely treated as an outpatient
4. *Ancillary measures:* other diagnostic and therapeutic maneuvers to enhance ultimate treatment outcome

Patients presenting with acute bacterial prostatitis are usually very ill. The culture and antibiotic sensitivity results are not available at the time a decision regarding treatment should be made. Therefore wide-spectrum antibiotics that achieve both adequate urinary and prostatic tissue levels are required as initial therapy. In ill patients, the parenteral route of antimicrobial therapy is preferred (even if it is only a single dose if outpatient therapy is warranted). Becopoulos and others (15) suggest that netilmicin (followed by aztreonam, cefuroxime, and the ticarcillin-clavulanic acid combination) is the agent of choice, but in most cases, a combination of aminoglycoside and ampicillin (and/or cephalosporin) provides adequate wide-spectrum coverage of the most likely organisms. This combination should provide coverage against the most common Gram-negative uropathogens as well as *E. faecalis.* This combination of antibiotics is highly concentrated in the tissue and urine (81), but once the acute and inflammatory phase resolves in the prostate gland, the concentrations in the prostate tissues do not remain at optimal levels. Once the patient has shown some initial improvement on intravenous antibiotics (or if it is planned to treat the patient as an outpatient), antimicrobial therapy should be switched to oral antibiotics. The most extensively studied antibiotics for the treatment of prostatic infection are trimethoprim-sulfamethoxazole and the fluoroquinolones (particularly norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin). The advantages, disadvantages, and pharmacokinetics of these two classes of antimicrobial agents are specifically covered in the treatment section for category II chronic prostatitis. Both of these antibiotics are well absorbed, achieve reasonably high prostatic tissue levels, and have an extremely broad spectrum, especially for the Gram-negative uropathogens associated with acute bacterial prostatitis. These antibiotics achieve almost universal cure rates in patients who have been treated for susceptible bacteria in acute prostatitis. No evidence in the literature substantiates a claim for a specific duration of therapy for acute bacterial prostatitis. However, antimicrobial therapy must be continued long enough to completely eradicate all bacteria because some believe that inadequately treated acute bacterial prostatitis can progress to chronic bacterial prostatitis (although this has never been proven in any clinical study). The length of therapy should be not so long as to cause an increased risk from adverse reactions or drug toxicity. Most writers suggest treatment should be continued for 2 to 4 weeks (193,195).

Significant obstructive voiding symptoms with subsequent development of acute and painful urinary retention are common in patients with acute bacterial prostatitis. The actual incidence of acute urinary retention in these patients is unknown. Most experts have advocated the insertion of a suprapubic catheter (usually accomplished by a simple percutaneous route under local anesthesia) in patients with urinary retention or extreme voiding difficulty. Many clinicians believe that this prevents the development of prostatic abscesses, which may result from the blockage of prostatic ducts with a urethral catheter (41,206,282). Although chronic urethral catheterization is associated with the development of prostatic abscesses (282), an increased risk of developing a prostatic abscess from short-term urethral catheterization in patients with acute bacterial prostatitis has never been substantiated. A single in-and-out catheterization to effect an initial bladder drainage may be all that is necessary. It is not unreasonable to consider the insertion of a small caliber Foley catheter and leave it indwelling for 12 to 24 hours, if reasonably tolerated by the patient. Although the use of a-blockers has become accepted in the treatment of the chronic prostatitis syndromes, its beneficial effect in treating the obstructive voiding symptoms associated with acute bacterial prostatitis has not been demonstrated.

Consideration for hospitalization of patients presenting with acute bacterial prostatitis is necessary if the patient has significant sepsis with an associated need for fluid replacement, cardiopulmonary monitoring, vasopressors, or other conditions requiring inpatient intervention. In many cases, the patient only needs to be observed (while on parenteral antibiotics, intravenous fluid, and so on) for a 24-hour or less interval. Ancillary measures to improve treatment outcomes include the previously mentioned urinary drainage procedures, intravenous fluid replacement, antipyretics, the administration of stool softeners, and even warm sitz baths (226,237,238). If the patient fails to improve with appropriate antibiotic therapy (i.e., continues to have fluctuating fever, pain, and urinary obstruction) the development of a prostatic abscess should be considered (41,91,144,206,282). Transrectal ultrasonography or pelvic computerized tomography establishes the diagnosis (228). In most cases, surgery is necessary to drain the pus, which has accumulated in the abscessed cavity. Transurethral drainage is probably the best treatment when the abscess has not penetrated beyond the prostatic capsule (206). Perineal incision and drainage might be used whenever the abscess has reached or is peripheral to the levator ani muscle (79,206).

A proposed treatment plan for category I acute bacterial prostatitis is illustrated in Fig. 34.5.

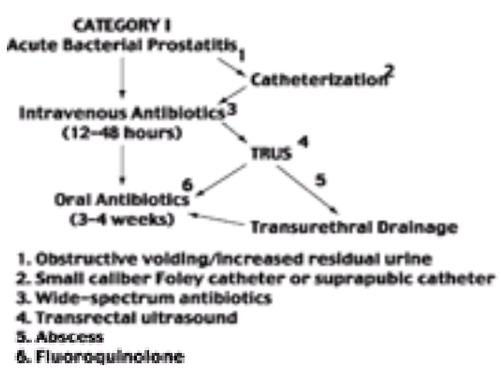

FIGURE 34.5. Proposed treatment plan for category I acute bacterial prostatitis.

CATEGORY II: CHRONIC BACTERIAL PROSTATITIS

Etiology

The diagnosis of category II chronic bacterial prostatitis depends on localizing bacteria to prostate-specific specimens using a multiple-glass test for bacterial localization described in the previous section. Most authors and researchers agree that chronic bacterial prostatitis is an important but rare prostate disease (125). Gram-negative pathogens, usually *E. coli,* are the most common organisms and are identified in 65% to 80% of chronic bacterial prostatic infections (279). *Pseudomonas aeruginosa*, *Serratia* species, *Klebsiella* species, and *Enterobacter aerogenes* comprise the isolated organisms in approximately 10% to 15% of cases (279). Although most chronic prostatic infections are caused by a single organism, multiple organisms associated with chronic bacterial prostatitis have been reported (146). The role of Gram-positive bacteria as pathogens in prostatitis remains controversial (94). Most authors agree that *Enterococci* may cause bacterial prostatitis and associated recurrent UTI (22,62,94,125,258,279), but the role of other Gram-positive bacteria such as coagulase-negative staphylococci, diphtheroids, and corynebacterium are thought by many to represent commensals of the anterior urethra (146,256). However, investigators have questioned the potential etiologic role of these bacteria in chronic prostatic inflammation (21,172,266). The etiologic role of these controversial potential pathogens is discussed in more detail in the etiologic section of category III.

How do the bacteria eventually reside in the prostate and cause the development of chronic inflammation? It is believed that reflux of urine into prostatic ducts, associated with high pressure and perhaps turbulent voiding is an important cause of both bacterial-induced and non–bacterial-induced prostatic inflammation (25,26,103). The ductal drainage of the peripheral zone of the prostate gland is more anatomically predisposed to facilitate reflux of urine (and any potential uropathogen present in that urine) into the peripheral zone (26). In fact, most prostatic infections are found in the peripheral zone. Challenged by host defenses and inadequate antimicrobial therapy, the bacteria may develop focal bacterial microcolonies (or biofilms) deep within the prostate protected by an endogenous glycocalyx or exopolysaccharide “slime” that makes them even more resistant to further therapeutic maneuvers (171,189). Prostatic calculi have been shown to be composed of constituents found only in urine (not in prostatic secretions) (220,263) and are present in patients with and without prostatic inflammation. These prostatic calculi may further protect pathogens, which have taken up residence in the interstices of the crystalline matrix, leading to recalcitrant and recurrent infections (69).

The composition of prostatic secretions in patients with chronic bacterial prostatitis is protective against bacterial colonization (71,131) but is altered and can even be diagnostic in chronic bacterial prostatitis. Fructose, citric acid, acid phosphatase, cations (zinc, magnesium, calcium), and the zinc-containing prostatic antibacterial factor (PAF) are decreased, whereas pH, the ratio of isoenzymes LDH5 to LDH1, and inflammatory proteins such as ceruloplasmin and complement C3c are increased (146,147). Although these changes may be nothing more than a consequence of subsequent inflammation, the secretory dysfunction can adversely affect the normal antibacterial nature of prostatic secretions.

In contrast to the immunologic situation that develops following acute bacterial prostatitis, in chronic bacterial prostatitis, no serum immunoglobulin elevation has been detected, whereas prostatic fluid IgA and IgG are both increased (116,244). If chronic bacterial prostatitis is cured by antibiotic therapy, IgG levels return to normal after months but IgA in prostatic secretions (particularly secretory IgA) is elevated for almost 2 years (73,247). In cases of antibiotic failure, persistently elevated levels of IgG and IgA have been measured (117,142,154). Antibody-coated bacteria are also another prominent feature of chronic bacterial prostatitis (222,223). Bacteria cultured from the ejaculate of patients with chronic bacterial prostatitis demonstrated a positive antibody-coated bacteria test compared with patients with nonbacterial prostatitis, prostatodynia, or control patients. Other immunologic alterations such as cytokine production, altered phagocytic activity, mast cell degranulation, increased sensory nerve density, and recurrence of autoantibodies in T-lymphocyte–mediated autoimmunity in the eventual development of inflammation has been described (154).

Clinical Presentation

The most important clue in the presentation of a patient with category II chronic bacterial prostatitis is a history of recurrent UTI. From 25% to 43% of patients with chronic bacterial prostatitis have had periods of recurrent UTI (281,284). The patients may have the typical genitourinary pain (perineal, suprapubic, penile, dysuria, or ejaculatory pain discomfort) and/or the irritative and obstructive voiding symptoms commonly associated with category III chronic pelvic pain syndrome patients (191,193). However, many patients are relatively asymptomatic between episodes of recurrent UTI (238). If the patient is suffering from a UTI at the time of initial presentation, the diagnosis of chronic bacterial prostatitis is difficult and hampered by the high bacterial count in the midstream urine. In these cases, 3 days of treatment with an antimicrobial agent such as nitrofurantoin before the performance of the lower urinary tract evaluation tests has been recommended (175,185). Nitrofurantoin can clear pathogens from the midstream urine (bladder specimen), but the number of bacteria in the expressed prostatic secretion is not affected because nitrofurantoin does not penetrate prostatic tissue.

Diagnosis

Men presenting with recurrent UTIs and/or symptoms of chronic pelvic pain syndrome (see Clinical Presentation) must undergo a rigorous evaluation of their lower urinary tract as described in the lower urinary tract evaluation section of this chapter. The microscopic findings of the EPS and/or postprostatic massage urine (VB3) will show numerous leukocytes and lipid-laden macrophages (140,277,281,284). In principle, it is best to perform sequential quantitative bacteriologic cultures of the urethra, bladder, prostatic secretions, and prostatic massage urine as described in the Meares-Stamey four-glass test (140); however, the simpler and more cost-effective two-glass test (187) is almost as conclusive in making the diagnosis. The diagnosis is confirmed when pathogenic bacteria can be clearly localized to the prostate gland (EPS and/or postprostatic massage urine). The growth of only small numbers of bacteria from prostatic fluid is pathognomonic of chronic bacterial prostatitis when the preprostatic massage specimens are sterile and no absolute count exists in terms of number of colony forming units per milliliter in the prostate-specific specimens to diagnose chronic bacterial prostatitis. Demonstration of more bacteria in the urine after prostatic massage (or in EPS) or postmassage urine specimen than in the midstream or premassage specimen is highly suggestive of chronic bacterial prostatitis. A significant increase (a log or more) in bacterial count in the prostatic specimens compared with the preprostatic massage specimens is considered diagnostic (140,281,185).

Management

Once the diagnosis of chronic bacterial prostatitis has been made, the role of therapy is to eradicate the pathogens associated with infection with appropriate antimicrobial therapy. In many cases, this proves to be impossible, and in those cases, inhibition of the bacteria residing in the prostate may be all that can be accomplished with therapy.

Several animal models (dogs and rats) (14,129,177,188) have been used to study the principles contributing to antimicrobial drug penetration into the various prostatic compartments. Although sound pharmacologic considerations have resulted from this particular line of animal study, the clinical implications of these results must be approached with caution. The original animal prostate studies, carried out by Stamey and others (257), discovered that acidic antibiotic drugs could not penetrate successfully into prostatic secretion even when plasma concentrations were very high while basic antibiotic drugs were found in concentrations greater than their plasma level. This was explained by the principles that govern the passage of drugs across biologic membranes, emphasizing the role of nonionic diffusion of weak acids and bases across membranes with a pH gradient. They and other researchers (130,159,242) discovered that the drug characteristics that determine simple diffusion concentrations of drugs within the prostate are lipid solubility, degree of ionization, degree of protein binding, and the size and shape of the molecule. In the dog prostate, there is a pH gradient across the prostate epithelium, with the pH of the plasma being more alkaline than that of the prostatic secretion. Most antimicrobials are weak acids or bases. The Henderson-Hasselbalch equation can be used to calculate the theoretic drug concentration ratio across a biologic membrane with different pH gradients and drug pKa once equilibrium is achieved. A more detailed review of the theoretic considerations involved in antibiotic penetration in animal models is available in the prostatitis chapter in the previous edition of *Adult and Pediatric Urology* (74).

A number of important therapeutic considerations have been defined by these important studies in animal models (159). Trimethoprim and the various fluoroquinolones concentrate well in prostatic secretions, while sulfamethoxazole, ampicillin, carbenicillin (which for many years was the only antibiotic approved by the U.S. Food and Drug Administration for the treatment of bacterial prostatitis), and amino glycosides do not concentrate in the prostatic secretion. The fluoroquinolones were also found to concentrate well in the prostate and prostatic secretions in experimental prostatic bacterial infection (177). However, it remains unknown whether the pharmacokinetic results determined in animal models (uninfected or infected) have any applicability to humans with chronic bacterial prostatitis. The pH of human prostatic secretion is not similar to a dog, and in fact, the pH of prostatic secretions in men with prostatic infection is significantly increased (27,213). Therefore this alkaline prostatic secretion in prostatitis patients is significantly different from the secretions with lower pH observed in dogs (257) or even in healthy, human, male subjects (70).

Drug diffusion studies carried out in humans have evaluated antimicrobial concentration in prostatic tissue in men with BPH or prostatic fluid in volunteers who did not have prostatic inflammation (159). The drug concentration in homogenized prostatic tissue and secretions in patients without prostatic inflammation may not be relevant to patients with actual bacterial prostatitis; however, the fluoroquinolones were found to have the best concentrations in human prostatic tissue and prostatic secretions in concentrations significantly higher than the minimal inhibitory concentrations (MICs) for most prostatitis-causing pathogens. At this time, the fluoroquinolones represent the antimicrobial class for optimal therapy in chronic bacterial prostatitis.

Researchers and urologic clinicians both agree that chronic bacterial prostatitis is difficult to treat. Naber (160) has reviewed all the clinical antimicrobial trials in chronic bacterial prostatitis. Trimethoprim-sulfamethoxazole or trimethoprim alone has been extensively used both in research trials and clinically for the treatment of chronic bacterial prostatitis with very poor results. Bacterial eradication rates range from a low of 0% to a high of 67%. Most studies using trimethoprim-sulfamethoxazole for more than 4 weeks resulted in a bacteriologic cure rate (following at least 3 months of follow-up) of 30% to 50% (160). Other antibiotic studies of chronic bacterial prostatitis, including minocycline, erythromycin, cephalexin, and carbenicillin, did not appear to improve this clinical outcome (160). Naber (160) subsequently analyzed 36 clinical studies evaluating fluoroquinolone therapy in which the diagnosis of prostatitis was deemed to be appropriate. These studies were difficult to evaluate because of unconfirmed bacterial infection, differing outcomes (bacterial eradication, clinical cure, or improvement), short follow-up periods, mixing of acute and chronic episodes, and differing diagnostic criteria as well as a wide range of treatment durations. We must therefore interpret the results of these many studies available to us in the literature with great caution. Of these studies, only one with norfloxacin (235), four with ciprofloxacin (83,216,278,280), and three with ofloxacin (106,219,221) presented results obtained during a follow-up period of 6 months. The results of these studies seem to be comparable with bacteriologic cure rates of 60% to 80% with a follow-up of at least 6 months. In general, therapeutic results were reasonable in chronic prostatitis due to *E. coli* and other members of the Enterobacteriaceae family but not in cases of prostatitis due to *Pseudomonas aeruginosa* or *Enterococci* (158).

The optimal duration of therapy is really unknown but for chronic prostatitis caused by *E. coli,* a treatment duration of 1 month with a fluoroquinolone seems to be superior to the usual 3-month treatment with trimethoprim-sulfamethoxazole. Whether or not a longer treatment with the fluoroquinolones would achieve a higher success rate is debatable. Nickel and associates (174) showed that 4 weeks of therapy with ofloxacin did not always predict the final results (in terms of symptom relief) of 12 weeks of continuous therapy. A European Consensus Statement (23) on the role of antibiotics in the treatment of chronic prostatitis empirically suggested that a 6- to 8-week course of therapy is warranted, but further antibiotics should not be given beyond this time without an appraisal of the effectiveness of the therapy. Studies evaluating direct injection of antibiotics into the prostate gland (8,95,285) have demonstrated promise, but direct injection has never become a popular route of administration. Future studies evaluating antibiotics in chronic bacterial prostatitis must use standardized valid protocols (157,181,281) including a follow-up of at least 6 months.

KEY INFORMATION

Antibiotic Therapy for Bacterial Prostatitis

- For prostatitis secondary to confirmed uropathogens, the fluoroquinolone antibiotics appear to be the optimal class of antimicrobial therapy.
- No real evidence substantiates the superiority of one fluoroquinolone over another.
- No good clinical study data substantiate a claim regarding duration of therapy.

Unfortunately, it is a clinical reality that some patients with bacteriologically documented category II chronic bacterial prostatitis have an immediate reappearance of bacteriuria and symptoms as soon as antibiotics are discontinued (relapse), or they have recurrence of infection and/or symptoms some time after antibiotics are discontinued (recurrent prostatitis). These patients can be considered for long-term low-dose suppressive (for refractory cases) or prophylactic (for recurrent cases) antibiotics. In a number of patients with chronic bacterial prostatitis, long courses of appropriate antimicrobial therapy are successful in eradicating the documented uropathogenic bacteria, but patients fail to show clinical improvement in their symptom complex. These may be the most difficult patients to manage with this category of chronic prostatitis.

It has been suggested that for category II chronic bacterial prostatitis, the addition of a-blockers to standard antimicrobial therapy may improve treatment. Barbalias and co-workers (12) retrospectively reviewed 270 consecutive patients with prostatitis treated with either antibiotics, a-blockers, or a combination of a-blockers and antibiotics. Of these patients, 64 were classified as having category II chronic bacterial prostatitis. All of these 64 patients were treated with antibiotics, and half were treated with a-blocker therapy with alfuzosin or terazosin. The recurrence rate of chronic bacterial prostatitis appeared to be reduced by combination therapy with both antibiotics and a-blockers compared with treatment by antibiotics alone. The symptomatic recurrence rate during a mean follow-up of 22 months dropped from 84% to

41% with the addition of a-blockers to the antibiotic therapy while the culture-positive recurrence rate dropped from 75% to 16%.

The addition of concurrent repetitive prostatic massage is believed to improve prostatic ductal drainage and subsequent antimicrobial penetration into prostatic secretions, and it may improve the cure rate in these recalcitrant cases (85,86,170,178,249). The concept of repetitive prostatic massage and the available clinical and experimental data are presented in more detail in the treatment section for category IIIA.

Surgery generally has been performed by surgeons who become desperate to do something concrete for patients with recurrent UTI and/or symptoms that remain refractory to antimicrobial therapy. The role of surgery is very limited in category II chronic prostatitis, unless the urologist can confirm the presence of uropathogenic bacteria within the prostate despite protracted antimicrobial therapy. This can be accomplished by using the Meares-Stamey four-glass test culture technique (140) or, alternatively, by performing a biopsy on the prostate using a sterile transperineal approach (19,171). If calculi are present, these intraprostatic stones might provide the protected nidus for bacterial persistence (141). Radical TURP (13,233) and radical prostatectomy (74) have been advocated, but no definitive clinical series or long-term follow-up has ever been reported in the literature.

A proposed treatment plan for category II chronic bacterial prostatitis is illustrated in Fig. 34.6.

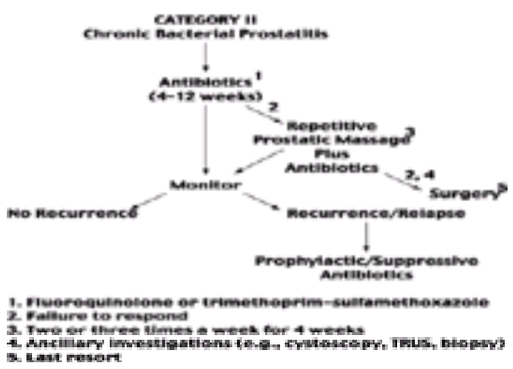

FIGURE 34.6. Proposed treatment plan for category II chronic bacterial prostatitis.

CATEGORY III: CHRONIC PROSTATITIS/CHRONIC PELVIC PAIN SYNDROME (CHRONIC NONBACTERIAL PROSTATITIS/PROSTATODYNIA)

Etiology

The diagnosis of category III chronic prostatitis/chronic pelvic pain syndrome rests on a clinical constellation of symptoms (loosely defined as genitourinary pain/discomfort) and negative cultures for uropathogenic bacteria (defined by most authorities as members of the Enterobacteriaceae Gram-negative rod family and *Enterococcus* Gram-positive bacteria) (111). Category III CPPS has been subclassified into an inflammatory category (category IIIA CPPS) and noninflammatory category (category IIIB CPPS). The definition of inflammation rests on the presence of excessive leukocytes in the prostate-specific specimens (expressed prostatic secretions or EPS, postprostatic massage urine, or VB3 and/or semen/ejaculate) compared with preprostatic massage urine specimens (i.e., VB1 and VB2). Although it is generally acknowledged that the infecting uropathogenic bacteria associated with category II chronic prostatitis are related to the subsequent prostatic inflammation, symptom complex, and history of recurrent UTIs, we do not know at this time the definitive etiology for the inflammation seen in category IIIA CPPS or the symptom complex seen in category IIIA and IIIB CPPS. A number of very attractive hypotheses are worth considering because our treatment strategies in many cases are directed towards these hypothetical pathogenic mechanisms. These proposed etiologic mechanisms are listed in Table 34.3.

1. A microorganism-based etiology: Uropathogens (Gram-negative rods and probably enterococci, but not cultured in expressed prostatic fluid) • Possible prostate pathogen—coagulase-negative staphylococcus, chlamydia, ureaplasma, anaerobic bacteria • Acknowledged prostate nonpathogens—diphtheroids, corynebacterium sp. • Nonculturable organisms—"biofilm" bacteria, viruses, "cryptic" nonculturable bacteria
2. Dysfunctional high-pressure voiding
3. Intraprostatic ductal reflux
4. Repetitive perineal trauma
5. Autoimmune disease
6. Chemical irritation (urine and its metabolites, i.e., uric acid)
7. Neurogenic (neuropathic)
8. Neuromuscular
9. Interstitial cystitis (similar mechanism?)

TABLE 34.3. POSSIBLE ETIOLOGIES DESCRIBED FOR THE PATHOGENESIS OF PROSTATITIS/CHRONIC PELVIC PAIN SYNDROME

Studies have suggested the possibility that there might be a microorganism-based etiologic mechanism in category III CPPS (19,52,63,124,132,194,225,245,246,190). The potential candidates include Gram-positive organisms such as coagulase-negative staphylococcus (21,22,35,62,172,214,274), corynebacterium (224,266), diphtheroids (55,56), anaerobic bacteria (132,196,265), chlamydia (1,37,53,80,105,108,126,133,217,251,275), ureaplasma (72,90,202,203,276), trichomonas (64,77,100,113,115), “biofilm bacteria,” (171,176,189), cell wall–deficient bacteria (55,56), fungi (32,78,89), or even viruses (16,51). Krieger and others (112), using polymerase chain reaction (PCR) techniques on prostate biopsies of 135 patients with chronic prostatitis/chronic pelvic pain syndrome noted that there was molecular biologic evidence of a bacterial presence in as many as 77% of the subjects. The question remains, however, whether these microorganisms identified in patients with chronic prostatitis are pathogenically involved in the inflammation or symptom complex (194). Controversy rages in the academic community as to whether or not there is a normal commensal or autochthonous microbial flora in the prostate (194). Keay and associates (101) using similar PCR amplification studies of bacterial 16s rRNA genes in prostate biopsies in men without chronic prostatitis found a similar spectrum of bacterial flora as did Krieger and co-workers (112) in chronic prostatitis and prostatodynia patients. However, Hochreiter and others (87) in a conflicting study using similar PCR techniques failed to duplicate these results, which led to their conclusion that bacteria are usually not present in a normal prostate gland.

Anatomic or neurophysiologic abnormalities of the lower urinary tract are hypothesized to cause a dysfunctional high-pressure voiding (10,11,25,26,28,84,97,98,156) that creates a cascade of events that begins with obstructive and irritative voiding symptoms and ends with the pain associated with the prostatitis symptoms. This could be as simple as a bladder neck problem, detrusor sphincter incoordination, or urethral stricture, or it may be a more subtle dysfunctional voiding pattern that can be picked up only by sophisticated urodynamic evaluation.

Other investigators have shown that many patients with the inflammatory type of prostatitis (category II and IIIA) have a higher frequency of intraprostatic ductal reflux (25,26,103). This has been shown to occur histologically (fine charcoal particles placed in the bladder find their way into the periphery of the prostate), radiologically (opaque dye refluxing into prostatic ducts), or chemically (urine constituents found in prostatic secretions). The ducts of the peripheral prostate appear to be more predisposed to this intraprostatic ductal reflux, and it is believed that the dysfunctional voiding described in the previous paragraph also may contribute to the subsequent phenomena. Investigators (210) have suggested that the simple reflux of urine metabolites (specifically urate) in the prostatic ducts and acini may stimulate subsequent, simple, chemical inflammation. It has been suggested (148) that the resulting inflammation, caused by whatever etiology, results in increased intraprostatic pressure, which subsequently leads to both the pain and voiding symptoms experienced by men with chronic prostatitis.

In chronic nonbacterial prostatitis, although both the total IgA and IgG immunoglobulins are elevated, they are not microorganism specific (244,245,246) as is the case in category II chronic prostatitis. Others (3,4,54,101) have described similar immunologic processes and cascades in nonbacterial prostatitis that do not appear to be

associated with microorganisms. Chronic prostatitis might be associated with immunologically mediated inflammation secondary to some unknown antigen or perhaps even related to an autoimmune process (57).

The pain associated with chronic pelvic pain syndromes is neuropathic in character and many investigators (6,67,205,288,289) have hypothesized a neuromuscular etiology for both the inflammatory and noninflammatory disease processes in the chronic pelvic pain syndrome.

Most authorities think that the key to the eventual diagnosis and successful management of chronic abacterial prostatitis/chronic pelvic pain syndrome lies in our eventual understanding of the etiologic mechanisms involved. It is likely that it will turn out that this clinical syndrome either has an underlying multifactorial pathogenic mechanism or represents an evolving (or progressive) pathogenic spectrum (Fig. 34.7).

FIGURE 34.7. Proposed etiology and pathogenesis of chronic pelvic pain syndrome (category III CPPS). An initiating stimulus such as infection, reflux of some “toxic” or “immunogenic” urine substance or perineal/pelvic “trauma” starts an interrelated cascade of events, beginning with either inflammation or neurogenic injury (or both). Immunologic or neuropathic mechanisms sustain the chronicity of the initial (or ongoing) event resulting in the clinical manifestation of chronic perineal/pelvic pain.

KEY INFORMATION

Etiology

- Current state of knowledge has not confirmed the etiologic factors in the pathogenesis of the majority of cases of prostatitis.
- Candidates include microorganisms, anatomic variations, and immunologic and neurogenic causes.

Clinical Presentation

Men with chronic prostatitis/chronic pelvic pain syndrome are distinguished by a rather specific symptom complex. These patients do not have a history of typical recurrent UTIs. The symptom best able to discriminate this prostatitis population in the symptom instruments devised by Nickel and Sorensen (173) and the most common severe symptom described by patients in a prostatitis clinic (67,110) and in a large Internet survey (2) was pain or discomfort. The pain is usually present in the pelvic region (perineum, suprapubic), but other common complaints include discomfort localized to the external genitalia, low back pain, and pain with or after ejaculation (2,67,110,173). Irritative and obstructive voiding symptoms, while not necessarily discriminatory, were found to be an important factor in all the early symptom questionnaire/indices devised to evaluate prostatitis patients (29,110,167,173). Complaints of sexual dysfunction, which seems to occur in association with the pain, are common, but significant sexual dysfunction (other than pain on ejaculation) has not been confirmed in clinical studies.

The symptom complex associated with chronic pelvic pain syndrome has severe implications for the quality of life of patients with the condition. It has been estimated that the quality of life of a patient with chronic prostatitis is equivalent to that of a patient with active Crohn's disease, unstable angina, or recent acute myocardial infarction (283). Although the physical domain of quality of life is impaired in men with chronic pelvic pain syndrome, the mental health impact is more profound (138). It is believed that this can lead to profound personality problems, rather than the personality variables causing the symptoms associated with the prostatitis syndromes (48,68). Optimal care of these patients requires attention to individual quality-of-life issues.

The development of the National Institutes of Health-Chronic Prostatitis Symptom Index (NIH-CPSI) (Fig. 34.8), published in 1999 by the NIH Chronic Prostatitis Collaborative Research Network (122), is described in more detail in the next section. In summary, however, this large, prospective study, which compared the presenting symptoms of hundreds of patients with chronic prostatitis to asymptomatic controls and men with BPH, confirmed that pain (including the number of locations, frequency, and severity of pain/discomfort), voiding symptoms (including irritative and obstructive symptoms), and quality of life/impact of symptoms on a patient's life are the predominant features associated with the clinical presentation of a patient with chronic prostatitis/chronic pelvic pain syndrome.

FIGURE 34.8. National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) captures the three most important domains of the prostatitis experience: pain, voiding, and quality of life. This index is useful in research studies and clinical practice. [From Litwin MS, McNaughton-Collins M, Fowler FJ, et al. The NIH Chronic Prostatitis Symptom Index (NIH/CPSI): development and validation of a new outcome measure. *J Urol* 1999:162;369-375, with permission.]

Diagnosis

The diagnosis of chronic prostatitis/chronic pelvic pain syndrome rests on an arbitrary definition of chronic genitourinary pain (of at least 3 months' duration) in the absence of uropathogenic bacteria detected using traditional culture techniques (111,164,181). The differentiation between the inflammatory subtype (category IIIA) and the noninflammatory subtype (category IIIB) relies on the determination of the number of leukocytes in the prostate-specific specimens. Therefore, to properly diagnose and differentiate category III CPPS, some form of lower urinary tract localization technique (either the four-glass test or the simpler two-glass test) must be performed.

What constitutes excessive leukocytosis in patients with no cultured uropathogenic bacteria? Normal individuals do possess leukocytes in their EPS and the suggested upper limit of normal varies from 2 (5) to as high as 20 (27) leukocytes per HPF (Fig. 34.4). However, most investigators (140,213,236) have reached a consensus that 10 leukocytes per HPF within the EPS is the upper limit of normal. But leukocytes are not the only cells seen in the EPS. The relationship between leukocytes and other inflammatory cells such as macrophages and lymphocytes is not clear (197,198). EPS is not always obtained and diagnosis then rests on the

finding of excessive number of leukocytes in the VB3 specimen. In centrifuged urine, the presence of 4 leukocytes or more per HPF is highly suggestive of prostatitis, whereas a figure of 10 is pathognomonic (277). However, to further confuse the issue, inflammatory cell density in the prostate-specific specimens appears to fluctuate over time (5,236) and with frequency of ejaculation (92).

Some patients with obstructive voiding symptoms or a history of stones, trauma, sexually transmitted diseases, flank or abdominal pain, or hematuria need further urologic investigations. This could include upper urinary tract evaluation (ultrasound, intravenous pyelogram, computerized scan), prostate assessment (PSA, transrectal ultrasound, and occasionally biopsy), and endoscopy (urethroscopy and cystoscopy). Urodynamic assessment (including videourodynamics) appears to be the most useful ancillary test in evaluating patients with category III prostatitis (98,99,156,267) to assess bladder outlet obstruction, although some investigators have not found this to be a problem in this particular cohort of patients (134). Transrectal ultrasound is the most useful imaging evaluation, and some investigators believe that it can be helpful in making the diagnosis or at least excluding other local diseases (43,46,50,128).

Once the diagnosis has been made based on a history of the symptom complex, focused physical examination, negative uropathogenic cultures, and an assessment of the degree of leukocytosis in the prostate-specific specimens and other related medical conditions have been ruled out, the most important evaluation then becomes an accurate assessment of the patient's symptoms. The National Institutes of Health (NIH) Chronic Prostatitis Clinical Research Network (CPCRN) has developed a reliable, valid index of symptoms and quality of life/impact in men with chronic prostatitis/chronic pelvic pain syndrome (122). A structured literature review and extensive focus group, patients' and experts' evaluation was followed by cognitive and validation studies in more than 500 men to finalize this prostatitis specific NIH-Chronic Prostatitis Symptom Index (NIH-CPSI). This new index of nine questions addresses the three most important domains of chronic prostatitis: (a) pain (location, severity, and frequency), (b) voiding (irritative and obstructive symptoms) and (c) impact/quality-of-life issues (Fig. 34.8). In the first report of the International Prostatitis Collaborative Network in which guidelines were suggested for prostatitis research (181), the NIH-CPSI was acknowledged as an appropriate outcome measure for clinical and research studies in chronic prostatitis. It also is a valuable assessment instrument for the evaluation and follow-up of patients with prostatitis in routine clinical practice (193).

Management

Although the differentiation between category IIIA and category IIIB CPPS has not been definitely validated, until it has been shown otherwise, it seems clinically appropriate to develop a best evidence approach for management of each category (109,186). As research trials that are presently in progress mature, it is likely that many therapies will be appropriate for both categories of CPPS, while some specific therapies may be more effective in one subtype compared with another (190).

KEY INFORMATION

Treatment

- The majority of patients cannot receive a truly “evidence-based” approach to therapy.
- Our present state of knowledge allows for a “best-evidence” approach to therapy.

Category IIIA: Inflammatory Chronic Pelvic Pain Syndrome (Nonbacterial Prostatitis)

A number of medical approaches to the treatment of category IIIA CPPS have been suggested and are currently being used in clinical practice. Most of these treatment modalities are based on anecdotal experience; case reports; and small, short, poorly designed pilot studies. Large, multicenter, randomized, placebo-controlled trials evaluating many of these therapeutic approaches are presently under way, and the urologist managing prostatitis must be ready to assess the results of these clinical trials once they are completed. Until the results of these ongoing trials are known, the urologist must use a best-evidence approach to managing category IIIA CPPS.

Antibiotics are not recommended for the treatment of chronic nonbacterial prostatitis by the well-known traditional experts in the field (143,215,237,258). However, evaluation of practice patterns by urologists shows that most patients with the diagnosis of prostatitis are treated with antibiotics, regardless of culture results (137,155,180). Antibiotics appear to be universally used in all categories of prostatitis because of the lack of other efficacious modalities of therapy, the rare use by urologists of appropriate quantitative segmented cultures of the lower urinary tract, and most important, clinicians' clinical perception that a significant number of patients do in fact improve while receiving antimicrobial therapy (184). Uncontrolled clinical trials do indicate that as many as 40% or more patients with a diagnosis of prostatitis (particularly the inflammatory categories) have a favorable response to antimicrobial therapy (18,22,23,45,174,203,266,281).

Antibiotics may be effective in “culture-negative” chronic prostatitis for three reasons. The definition of culture-negative prostatitis does not exclude the possibility of a bacterial cause, but rather simply means that a bacterial cause cannot be identified using our current standard microbiologic methodology and knowledge (194). Antibiotics appear to have a defined antiinflammatory effect independent of their antibacterial action. A number of researchers (76,287) have clearly demonstrated that antibiotics, especially the quinolones, have an immunomodulatory action on inflammatory cytokines that is independent of their antimicrobial activity. Finally, this “perceived” beneficial effect could be just a very significant “placebo” effect, and the reality might turn out to be that no evidence supports that antimicrobial therapy is superior to placebo for the treatment of category IIIA or, for that matter, category IIIB CPPS.

However, it is not unreasonable to suggest that patients with category IIIA chronic prostatitis/chronic pelvic pain syndrome be subjected to one 2- to 4-week course of antibiotics because of the real possibility that other organisms such as chlamydia, ureaplasma, nonculturable bacteria (e.g., “biofilm” bacteria, particularly in patients with a history of documented UTI), and Gram-positive organisms may be implicated in the pathogenesis of the prostate inflammation (194). A report by Tanner and others (266) suggests that patients with the presumed nonuropathogen, corynebacterium, localized to the urinary tract using molecular biologic techniques (PCR), improve while receiving specific antimicrobial therapy. Only one controlled clinical study examined antibiotic therapy in patients with category IIIA CPPS (nonbacterial prostatitis). Simmons and Thin (252) randomized 41 patients with chronic nonbacterial prostatitis to either minocycline or diazepam and found that there was no significant difference in symptom improvement or leukocyte count between the two groups. A European Consensus group evaluating the role of antibiotics in the treatment of chronic prostatitis (23) suggested that antibiotics should be considered empirical treatment for category IIIA CPPS, but the benefits should be appraised after 6 to 8 weeks of therapy.

KEY INFORMATION

Antibiotic Therapy for Category IIIA Inflammatory Chronic Pelvic Pain Syndrome (Nonbacterial Prostatitis)

- A 2- to 4-week trial of wide-spectrum antibiotic therapy appears to be justified.
- Long-term use of sequentially different antibiotics in refractory patients does not appear to be justified.

Therapy with a-blockers, particularly those that are not specifically prostate selective, appear to improve the voiding and discomfort associated with the prostatitis syndromes. In controlled clinical trials, Osborne and co-workers (205) and Dunzendorfer and others (66) demonstrated the superiority of phenoxybenzamine, a nonspecific a-blocker, in ameliorating several symptoms associated with prostatitis (although subjects were primarily prostatodynia patients or category IIIB CPPS) compared with placebo. De la Rosette and associates (47) randomized 20 patients to either alfuzosin or placebo, and although the patients treated with the a_1-blocker showed improvements in symptom score and although it was only just significantly better than placebo ($p = .01$), the change in maximal flow rate was significant in the treated group. In an uncontrolled open label study, Neal and Moon (167) treated 25 patients with nonbacterial prostatitis or prostatodynia with terazosin, another a_1-blocker for 1 month. Three-fourths of the patients indicated some form of symptomatic improvement (confirmed with a new recently developed prostatitis symptom score), and 2 months later, more than 50% of the responders remained asymptomatic (although 42% required reinitiation of therapy to relieve recurrent symptoms). This study suffered from the lack of a placebo control arm.

Barbaralias and associates (12) evaluated the effects of combining a-blockers and antibiotics in the treatment of chronic prostatitis syndromes. They retrospectively reviewed 270 consecutive patients who had been divided into three groups, 134 patients with chronic nonbacterial prostatitis (category IIIA), 72 patients with “painful male urethral syndrome” (prostatodynia or category IIIB), and 64 patients with chronic bacterial prostatitis (category II). All patients with chronic nonbacterial prostatitis were treated with a-blocker therapy, and half were treated with antibiotics. Overall, 47% of the nonbacterial prostatitis patients had resolution of their symptoms after 1

month; however, the study was not controlled with a placebo arm and in this category (IIIA) there did not appear to be any difference in combining antibiotics and a-blockers.

Repetitive prostatic massage has been the main therapeutic approach for the treatment of prostatitis for most of the twentieth century (170,201). Following the landmark paper by Meares and Stamey in 1968 (140), this therapy more or less fell out of favor with both patients and urologists. However, reports of spectacular success rates of repetitive prostatic massage (usually combined with antimicrobial therapy) (85,86) has led to the reemergence of this traditional older therapy as a potentially effective treatment modality. There are no controlled clinical trials on the use of repetitive prostatic massage, with or without antibiotics, for the treatment of prostatitis, and although many “prostatitis experts” have developed experience and expertise in the technique, no consensus on its value has been reached (170). In prospective clinical trials, one-third (178) to two-thirds (249) of patients realize some degree of symptom amelioration. Some think that frequent ejaculation (286) will accomplish the same improvement in symptoms or at least a decrease in recurrence once it has been treated.

Nonsteroidal antiinflammatory medication such as nimesulide (33,34) and indomethacin appear to alleviate the pain and discomfort in some patients with prostatic inflammation. Because of severe gastrointestinal side effects experienced with long-term high-dose administration, many patients cannot tolerate the dose and duration of therapy that may be required. The introduction of the new COX-2 inhibitors (rofecoxib and celecoxib) may provide significant benefit to some patients, and the results of large clinical trials will soon be available.

Prostate growth and development (including inflammation) are affected by the local hormonal milieu (162). It has been hypothesized that regression of ductal and glandular tissue in the prostate with 5a-reductase inhibition would improve flow parameters, reduce intraprostatic reflux, and perhaps even influence the degree of inflammation itself (192). Anecdotal case reports (88) and a randomized, placebo-controlled trial by Leskinen and others (120) would appear to support this hypothesis. However, a critical evaluation of this study (120) in which 31 patients were randomized to finasteride and 10 patients to placebo, shows that although symptom scores dropped significantly in the finasteride group, there was no significant difference in pain or symptoms between the two groups, perhaps because the treated and placebo groups were not similar in baseline characteristics. The results of a multicenter, randomized, controlled trial comparing finostende to placebo should be available in 2002.

Plant extracts (phytotherapy) are being used extensively by prostatitis patients and two such compounds, a pollen extract (30,229) and quercetin (250), both show some early promise. Shoskes and co-workers (250) used the NIH-Chronic Prostatitis Symptom Score in a randomized, controlled trial comparing 15 patients treated with quercetin to 13 patients treated with placebo. Twenty percent of patients taking placebo and 67% of patients taking the phytotherapeutic agent had an improvement of symptoms of at least 25%. Although the clinical importance of a 25% change in a symptom score that measures pain, voiding symptoms, and quality of life/impact is debatable, this study is provocative and should stimulate larger trials.

The clinical similarities between interstitial cystitis and chronic prostatitis have led many clinicians to use pentosan polysulfate (PPS), an oral exogenous glycosaminoglycan that has demonstrated modest symptom improvement in interstitial cystitis patients. Anecdotal reports and one small, randomized, controlled trial (273) of 30 patients (15 patients treated with PPS and 15 patients with placebo) demonstrated improvement of symptoms, particularly myalgia and arthralgia (with PPS compared with placebo). A prospective clinical pilot study (96) of men with category IIIA CPPS using validated symptom questionnaires to assess response were treated with PPS 100 mg three times a day for 6 months was encouraging enough (approximately 40% of patients had clinically significant improvement) to justify a large, multicenter North American randomized, controlled study evaluating PPS 300 mg three times a day compared with placebo (study initiated in 2000).

The authors of a randomized, placebo-controlled study comparing allopurinol with placebo (211) suggested that a 3-month trial of allopurinol to potentially control the inflammatory response caused by refluxing urate was appropriate. However, further evaluation of the results of this trial (183) did not confirm the beneficial effects of allopurinol, and the widespread adoption of this particular treatment modality may be premature.

Heat therapy applied to the prostate in the form of transrectal hyperthermia (151,243,261,270) and transurethral thermal therapy (173) consistently demonstrated symptomatic improvement of symptoms in men with CPPS. Although the previously noted studies were all controlled clinical trials, only three studies (173,243,270) used a sham or placebo control. The studies were also very small, the inclusion criteria varied, and the outcome measures were not always validated. The possible explanations for benefit in these patients include effecting an “intraprostatic” sympathectomy (209), accelerating the chronic fibrotic process that may be an end result of chronic prostatitis (173) or killing noncultured bacteria deep within the prostate gland (230). However, until a large, multicenter trial is completed, this mode of therapy should be reserved as a “last resort” therapeutic intervention for this category of CPPS.

Surgery is not recommended for most cases of category IIIA CPPS. If specific indications such as bladder neck hypertrophy or urethral stricture disease is discovered on specific diagnostic testing (i.e., videourodynamics or cystoscopy), treatment tailored to the specific abnormality may improve the patients voiding symptoms and perhaps even the pain and/or discomfort (98,104). Although prostatectomy has been advocated (75), long-term data and properly designed prospective trials have not been done to confirm that either radical transurethral resection of the prostate (TURP) or radical prostatectomy achieve any long-term beneficial response. Certainly these surgical therapies have the potential to cause considerable morbidity. It has been suggested that minimally invasive surgical procedures such as retrograde balloon dilation (119), transurethral radiofrequency hot balloon thermal therapy (182), transurethral balloon laser hyperthermia (264), transurethral needle ablation (TUNA) (36), and neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (241) may benefit some patients. These and other innovative modalities of minimally invasive therapy must be evaluated in rigorous clinical trials before they can be recommended.

A proposed treatment plan for category IIIA chronic prostatitis/chronic pelvic pain syndrome is illustrated in Fig. 34.9.

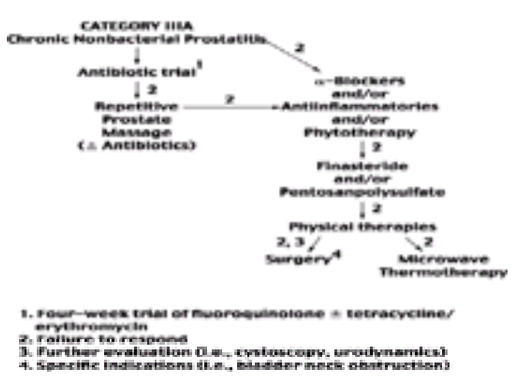

FIGURE 34.9. Proposed treatment plan for category IIIA chronic pelvic pain syndrome.

Category IIIB: Noninflammatory Chronic Pelvic Pain Syndrome (Prostatodynia)

Successful therapy for category IIIB CPPS appears to be more problematic than the treatment of the other prostatitis syndromes that have more specific characteristics (i.e., evidence of infection and/or inflammation) (186). There are few significant controlled clinical or randomized controlled trials specifically evaluating therapy in category III CPPS (prostatodynia patients). Many of the clinical trials described in the previous section (treatment of category IIIA CPPS) included patients with category IIIB characteristics as well. It is from these trials that we obtain some of the best evidence we have on appropriate therapy in this category.

Antibiotics are generally considered not indicated in this category (23); however, a number of trials (174,266) did not note any significant correlation between symptomatic results and degree of leukocytosis in prostate-specific specimens.

a-Blockers do appear to produce symptomatic improvement in patients with category IIIB CPPS. Osborne and others (205) noted symptomatic improvement in 48% of patients treated with phenoxybenzamine compared with 8% with placebo. Patients experienced significant retrograde ejaculation and 10% discontinued the drugs secondary to lethargy and asthenia. The study by Dunzendurfer and co-workers (66) with phenoxybenzamine, the study by de la Rosette and associates (47) with alfuzosin, and the study undertaken by Neal and Moon (167) with terazosin (reviewed in the previous section on treatment of category IIIA CPPS) did include patients with category IIIB CPPS/prostatodynia. In these studies, the response obtained in the inflammatory category (IIIA) could not be differentiated from the response

obtained in the noninflammatory category (IIIB). In the study reported by Barbalias and others (12) described in the previous section, 72 of the 270 patients were classified as prostatodynia or category IIIB. In this retrospective study (which was complicated with the addition of antibiotics in many patients), 58% of these patients had resolution of their symptoms with terazosin or alfuzosin therapy.

Muscle relaxants such as diazepam and baclofen appear to be helpful in patients with category IIIB CPPS, especially if sphincter dyssynergia or pelvic floor/perineal muscle spasm is confirmed. Osborne and co-workers (205) showed a satisfactory symptomatic response in 37% (10 of 27) of prostatodynia patients treated with baclofen compared with an 8% placebo response (4/10).

A significant proportion of the patients in the various controlled microwave hyperthermia and thermotherapy trials (reviewed in a previous section—category IIIA CPPS) included patients with prostatodynia (category IIIB CPPS). It is difficult to determine a differential effect of this therapy in patients with category IIIA and IIIB classification; however, it appears that some category IIIB patients obtained potential benefits compared with sham therapy (particularly with transrectal microwave hyperthermia).

Clinicians use analgesics for treating chronic pain and category IIIB CPPS is no different. While there is no doubt that analgesics, particularly the class of narcotic analgesics, can reduce pain, the long-term consequences of chronic analgesic use, particularly narcotics is unknown. There is no research available to determine an evidence-based approach for criteria to determine the type, dose, or duration of analgesics in category IIIB CPPS. A referral to a comprehensive multidisciplinary pain clinic may assist the urologist in long-term pain control in refractory category IIIB CPPS patients. Anecdotal evidence only supports the addition of tricyclic antidepressants such as amitriptyline in this syndrome, but it does appear to provide significant improvement in similar chronic pelvic pain syndromes such as interstitial cystitis in women.

Although variations of physical therapy may be one of the most poorly studied and evaluated modes of treatment, this therapeutic field actually may turn out to be the most effective in this particular syndrome. Various forms of physical therapy, including biofeedback (39,97), perineal and pelvic floor massage therapy, and pressure therapy for specific pelvic/perineal trigger points (6), have all been described as potentially beneficial to the patients. Other physical therapies that have been suggested include relaxation exercises, acupuncture, chiropractic therapy, and the use of ring or donut cushions when sitting. Controlled clinical studies will determine the ultimate benefits of these various modes of physical therapy.

Finally, most clinicians have the perception that supportive therapy, which includes reassurance and suggestions for lifestyle changes, benefits many patients. This supportive therapy could include reassurance that the patient does not have a prostate cancer, development of coping skills, advice regarding sports such as bicycle riding, and diet changes (e.g., avoidance of caffeinated and alcoholic beverages, spicy foods). At the very least, this approach causes no harm and may assist in helping patients live and cope with their disease.

A proposed treatment plan for category IIIB chronic prostatitis/chronic pelvic pain syndrome is illustrated in Fig. 34.10.

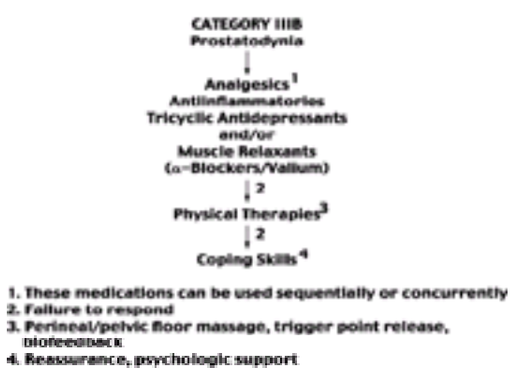

FIGURE 34.10. Proposed treatment plan for category IIIB chronic pelvic pain syndrome.

KEY INFORMATION

Therapy for Chronic Pelvic Pain Syndrome
Clinical evidence indicates that the following treatments (alone or in combination) may provide substantial improvement in symptomatology in some patients:

- Antibiotics
- a-Blockers
- Antiinflammatories
- phytotherapy
- 5a-reductase inhibitors
- Pentosan polysulfate
- Muscle relaxants
- Physical therapies
- Heat therapies

CATEGORY IV: ASYMPTOMATIC INFLAMMATORY PROSTATITIS

Etiology

Category IV prostatitis or asymptomatic inflammatory prostatitis (AIP) is defined as the presence of inflammation and/or infection in prostate-specific specimens such as expressed prostatic secretion, postprostatic massage urine, semen (or ejaculate specimen), BPH TURP chips, or radical prostatectomy specimens. Prostatic inflammation is an extremely common finding in patients with BPH symptoms who do not have symptoms of prostatitis (107,179), but there does not appear to be any correlation between the degree and pattern of inflammation, catheterization, presence of bacteria, serum PSA or PSA density, or even symptoms. A number of studies have examined the association of prostatic inflammation and prostate cancer (135,218,290). However, no clear relationship has been shown to exist between the histologic evidence of prostatic inflammation and prostate cancer or BPH. Acute bacterial prostatitis reveals a significant serum PSA elevation in the majority of patients (42,207), but the connection between PSA levels and patients with asymptomatic prostatic inflammation remains unclear (82,161,179,254).

Men with infertility (as many as 1 in 5) have evidence of an inflammatory process of the reproductive tract, usually detected with high concentrations of leukocytes in the semen, even when bacterial cultures fail to reveal any pathologic organisms (93). Although antibiotic therapy appears to improve some patients' semen parameters and may improve the possibility of fertility, the actual relationship remains unclear.

Category IV prostatitis also can occur in asymptomatic men without any genital urinary problems or pathology. Inflammation in autopsy series (many of whom did not have any prostate disease) is reported in 44% of adult prostates obtained at autopsy (139). The relevance of prostatic inflammation in these asymptomatic men, particularly those without evidence of BPH, infertility, or prostate cancer, is unknown.

Clinical Presentation

Since by definition, category IV asymptomatic inflammatory prostatitis is asymptomatic, the diagnosis is made incidentally in men being evaluated for prostate disease (BPH or prostate cancer) or infertility.

Diagnosis

Leukocytosis and/or bacteria are demonstrated in prostate-specific specimens such as expressed prostatic secretion, postprostatic massage urine, semen specimens, or histologic examination of BPH TURP chips or prostate cancer specimens (111,164).

Treatment

Because men diagnosed with category IV prostatitis are asymptomatic, no definitive therapy is required for amelioration of any symptom complex. Antimicrobial therapy may be indicated in men being evaluated for an elevated PSA, infertility, or in those men with BPH and prostate cancer in whom urinary endoscopy is being contemplated.

OTHER RELATED CONDITIONS

Granulomatous Prostatitis

Granulomatous prostatitis, characterized by heavy lobular mixed inflammatory infiltrates, which include abundant histiocytes, lymphocytes, plasma cells, and small discrete granulomas, is usually diagnosed during evaluation for possible prostate malignancy. On digital rectal examination nonspecific granulomatous prostatitis often exhibits induration, which varies from focal to diffuse and raises the concern of malignancy. Serum PSA levels can be mildly to significantly elevated (204,255), and a transrectal ultrasound pattern may simulate carcinoma (31,255). The patients' typical clinical manifestation of nonspecific granulomatous prostatitis includes dysuria and frequency, which may be associated with fever (260). In the majority of cases, differentiation of nonspecific granulomatous prostatitis from adenocarcinoma can be made readily using morphologic criteria. Granulomatous prostatitis also can occur as a complication of treatment of superficial transitional cell carcinoma of the urinary bladder with bacille Calmette-Guérin (BCG) immunotherapy (118,150,200). Mycobacterial prostatitis also can occur as a rare event in the setting of systemic tuberculosis (234).

Seminal Vesiculitis

Seminal vesiculitis can be a concomitant clinical entity to prostatitis and is probably diagnosed (and potentially cured) along with prostatitis. It is difficult to distinguish between the two diagnoses without detailed investigation because the signs and symptoms of seminal vesiculitis include genitourinary pain, painful ejaculation (± decreased ejaculate volume), hematospermia, irritative and obstructive voiding complaints, back and lower abdominal pain, and impotence. Some authorities think that seminal vesiculitis is a separate clinical entity and is not always associated with prostatitis. Stearns (259) estimated that 13% of the patients referred for prostatitis actually have primary vesiculitis. Most studies on seminal vesiculitis in the literature actually describe patients with seminal vesicle abscesses (102). Patients with abscesses present clinically with fever, chills, irritative voiding symptoms, dysuria, hematuria, testicular pain, and a palpable mass above the prostate on physical examination. Like prostatitis and lower UTIs, *E. coli* is the predominant organism. Historically, the seminal vesicles were evaluated with seminal vesiculography (9,65), but this particular examination has limited value. Computed tomography (208), magnetic resonance imaging (262), and transrectal ultrasonography (121) are favored means of imaging the seminal vesicle in patients suspected of having seminal vesiculitis. The findings of seminal vesicle cysts containing calculi and/or debris or significantly dilated seminal vesicles with thickened walls suggest the diagnosis is seminal vesiculitis (38).

Diagnosis not only relies on clinical symptomatology, careful digital rectal examination, and lower urinary tract localization tests (as described for prostatitis), but also includes an ejaculate culture followed by transrectal ultrasonography (probably the most cost-effective diagnostic maneuver). This can be followed by cytologic and culture verification using needle aspiration under transrectal ultrasound control. A vesiculogram using a nonionic contrast material can be contemplated to determine whether the specific vesicle is obstructed. If the ejaculatory duct is obstructed then a transurethral resection of the ejaculatory duct can be performed. Most patients can be adequately treated with a course of appropriate antibiotics, much the same way as patients with chronic bacterial prostatitis are treated. If the patient fails to respond, an operation to remove the affected seminal vesicle can be considered as a last resort.

Interstitial Cystitis in Men

Chronic prostatitis and interstitial cystitis are both chronic pelvic pain syndromes with very similar etiologic and clinical considerations. Microbiologic, immunologic, neuromuscular (or neurophysiologic), and anatomic etiologic mechanisms have been proposed for the pathogenesis of both these syndromes. Difficulties in definitions, categorization, diagnosis, and treatment continue to plague the fields of chronic prostatitis and interstitial cystitis. Certainly the symptom complex of chronic prostatitis overlaps that of interstitial cystitis occurring in men (149,199,232). This includes the irritative voiding and suprapubic pain symptoms, petechial hemorrhages on hydrostatic dilation (20), and urodynamic findings (253). This has led a number of authors to conclude that many cases of chronic prostatitis are misdiagnosed interstitial cystitis (231). Therapies that have demonstrated a modest improvement in interstitial cystitis (e.g., analgesics, antiinflammatory agents, amitriptyline, PPS) show similar benefit in patients with chronic prostatitis. These similar syndromes may in fact be related along the spectrum of chronic pelvic pain syndrome produced by multifactorial etiologic mechanisms.

SUMMARY

Prostatitis is an extremely common and clinically important urologic condition, rivaling prostate cancer and BPH in terms of prevalence, cost to society, impact on quality of life, and the time and effort the urologic community spends in dealing with this clinical condition. The urologist must have an understanding of the potential etiologic mechanisms involved in this disease, a commitment to properly diagnose and categorize these patients, and a sound and evolving knowledge of the results of therapeutic interventions so that patients with chronic prostatitis will not be relegated to the wastebasket of urologic practice.

Chapter References

The evaluation and treatment of male infertility have changed significantly with the introduction and widespread use of intracytoplasmic sperm injection (ICSI) in the 1990s. Men with testicular failure, who were considered hopelessly infertile, now have the opportunity to initiate their own biologic pregnancy. The most important changes in the field since the last edition of this text have been the genetic evaluation of azoospermic men and refinements in sperm retrieval procedures for ICSI. Despite the high-technology nature of these important advances, an in-depth knowledge of the basics of male reproductive physiology and the standard evaluation and treatment of the infertile male remains necessary.

PHYSIOLOGY

Anatomy and Embryology of the Testicle

The normal adult testes are a pair of ovoid structures measuring 4.0 to 5.5 cm in length, 2.5 cm in width, and 3 cm in the anteroposterior dimension. Their weight ranges from 20 to 30 g. The testes lie in the scrotum with the long axis upright and tilted forward and slightly lateral; the left testis generally is slightly lower than the right. The posterior aspect of the testis is attached to the spermatic cord with the epididymis lying on the posterolateral margin. The remainder of the testis is covered by the tunica vaginalis.

Scrotum

The layers covering the testis, starting from the outside, are the scrotal skin, dartos, external spermatic fascia, cremasteric fascia, internal spermatic fascia, and tunica vaginalis. With exposure to cold or exercise, the scrotal skin contracts, becoming thickened and highly folded and wrinkled. The dartos muscle is deep to the skin and is continuous with the scrotal septum. This septum divides the scrotum into a pair of separate compartments, the walls of which are formed by fusion of the tunica vaginalis, internal spermatic fascia, cremasteric fascia, and external spermatic fascia.

Fascial Investments of the Testis

Beneath the dartos lie three fascial layers, which are derived, during the descent of the testis, from the fascial components of the abdominal wall. These fascial coverings lie one within another in a saclike fashion and are continuous with the abdominal fascial structures from which they are derived. Most superficial is the external spermatic fascia derived from the external oblique aponeurosis. Beneath this lies the cremasteric muscle and fascia originating from the internal oblique muscle and its fascia. Innermost is the internal spermatic fascia, which is derived from the transversalis fascia.

Tunica Vaginalis

The processus vaginalis, an outpouching of fetal peritoneum from which the tunica vaginalis originates, precedes the testis in its descent into the scrotum. During normal development, the portion of the processus vaginalis that extends inferiorly from the internal inguinal ring to a point near the upper pole of the testis becomes obliterated. The lower portion, the tunica vaginalis, remains as a closed pouch folded around the testis and epididymis, which project into it from behind. The inner layer, known as the *visceral layer,* is reflected forward from the posterior wall of the scrotal chamber to cover the testis, epididymis, and lower portion of the spermatic cord. On the lateral margin of the testis, the tunica invaginates deeply as it passes from the testis to the epididymis, creating a pocket known as the *sinus* of the epididymis. The outer or parietal layer of the tunica vaginalis lines the walls of the scrotal chamber and is fairly well attached to the other coverings of the testis. The sac formed between the two layers of the tunica vaginalis contains a small amount of serous fluid. During development, the processus vaginalis may fail to be obliterated. Peritoneal contents that thus pass down the patent processus constitute a congenital hydrocele or hernia.

Testis

The outermost layer of the testis contains a dense, white, inelastic covering composed of interlacing bundles of fibrous tissue known as the *tunica albuginea.* The innermost aspect of the tunica albuginea gives off a number of thin septula, which converge posteriorly in a mass of fibrous tissue called the mediastinum testis. The mediastinum is a direct continuation of the posterior aspect of the tunica albuginea and supports the vessels and ducts of the testis as they pass to and form the gonad. As they proceed posteriorly from the tunica albuginea, the septula form a number of wedge-shaped lobules that are broader at their bases near the tunica albuginea and become narrower as they converge on the mediastinum. The estimated number of lobules in a single testis varies from 250 to 400 (148). The arteries (185), veins, and lymphatics enter the testis at its posterior margin, traverse the mediastinum, and spread out on the deep surface of the tunica albuginea to form the tunica vasculosa.

Within the framework formed by the mediastinum, septula, and tunica albuginea exists the parenchyma of the testis, which is light brown in color and composed of tiny

convoluted tubules known as the *seminiferous tubules.* These tubules, estimated to number 840 per testis, have an average length of 70 to 80 cm with diameters varying from 0.12 to 0.3 mm (148). Cross-sectional examination shows that the seminiferous tubules are composed of a complex germinal epithelium resting on a thin basement membrane. This basement membrane is surrounded by a layer of fibrous tissue and contractile cells, similar to smooth muscle cells, which are thought to promote the movement of the spermatozoa and fluid toward the rete testis. In the cortex of the testis, the seminiferous tubules are very tortuous and convoluted. As they converge on the mediastinum, they become less convoluted and follow a nearly straight course, joining with other seminiferous tubules to form 20 to 30 larger ducts, approximately 0.5 mm in diameter, referred to as the *tubuli recti.* The tubuli recti enter the mediastinum testis, where they progress to form a network of epithelium-lined channels in the stroma known as the *rete testis.* At the superior portion of the mediastinum, the rete terminates in 12 to 20 ductuli efferentes. These ducts perforate the tunica albuginea and carry the seminal fluid from the testis to the epididymis.

Epididymis

The epididymis is a curved structure slightly greater than 5 cm in length that is commonly referred to by one of its three portions and is located at the posterolateral aspect of the testis. The large upper portion, termed the *globus major* or *head (caput),* of the epididymis is firmly attached to the posterior upper pole of the testis by the efferent ductules. The corpus, or body, lies on the posterior part of the lateral margin of the testis but is separated from it by the sinus of the epididymis, an infolding in the tunica vaginalis.

The globus minor or tail (cauda) of the epididymis is loosely attached by areolar tissue to the lower portion of the testis. After the tunica albuginea of the testis is perforated, the ductuli efferentes proceed to the head of the epididymis. Initially assuming a straight configuration, they become enlarged and highly convoluted, forming a group of conical masses, the coni vasculosi. These combine to form the head of the epididymis, each cone being composed of a single convoluted duct 15 to 20 cm long. Within the head of the epididymis, these ducts open into a single, exceedingly convoluted duct that constitutes the greater bulk of the epididymis.

Arterial Supply of the Testis

The arterial supply of the testis consists primarily of the internal spermatic (gonadal) artery and is augmented by the deferential and cremasteric (external spermatic) arteries. The internal spermatic artery originates from the aorta just below the renal artery and crosses the ureter, sending a branch to that structure as it does so, and proceeds through the inguinal canal with the spermatic cord, arriving at the posterior aspect of the testis. On reaching the testis, the artery branches to form a network of vessels on the inner aspect of the tunica albuginea and sends terminal arteries backward along the septula to converge on the mediastinum. Within the proximal inguinal canal, two arteries are typically encountered (193). The deferential artery originates from the inferior vesical artery and travels in close contact with the vas deferens until it reaches the tail of the epididymis, where it branches into a capillary network. The cremasteric artery originates from the inferior epigastric artery and passes through the inguinal canal in the sheath of the cord. Thereafter, the artery continues to the parietal surface of the tunica vaginalis and anastomoses with capillary networks of the other arterial structures.

Blood Supply to the Testis

Artery	Origin
1. Internal spermatic artery	Aorta
2. Deferential artery	Inferior vesicle artery
3. Cremasteric artery	Inferior epigastric artery

Venous Drainage of the Testis

Venous drainage of the testis occurs along a major and minor route. The major route of drainage is the internal spermatic vein. The right internal spermatic vein usually drains directly into the inferior vena cava, whereas the left internal spermatic vein enters the left renal vein. The left internal spermatic vein follows a vertical course and is therefore 8 to 10 cm longer than the right. This is significant in that it produces increased hydrostatic pressure within the vein and contributes to the pathogenesis of varicocele formation.

The minor venous drainage routes of the testicle consist of the deferential vein, which follows the vas deferens and drains into the superior vesical vein and ultimately into the hypogastric vein and the cremasteric (external spermatic) vein, which leaves the spermatic cord at the external inguinal ring and empties into the pudendal vein and thereafter into the saphenous vein. The minor venous drainage system provides adequate drainage to permit preservation of testicular function after varicocele ligation involving the internal spermatic vein. The major and minor drainage systems communicate freely with one another and are subject to substantial anatomic variation.

Nerve Supply of the Testis

The nerve supply of the testis originates from approximately the lower three thoracic and the first lumbar segments. The testicular plexus is derived from the aortic plexus at the level at which the gonadal vessels originate and accompanies these vessels to the testis. Pain originating from the testis, therefore, is usually referred to the lower thoracic or upper lumbar region.

Developmental Sexual Differentiation

In the human, the gonadal anlage appears during the fourth week of embryonic life as a raised ridge on the posterior abdominal wall on either side of the dorsal midline. Covered by coelomic epithelium, it develops with time in a caudal direction and parallels the laterally developing mesonephric kidney. These two structures make up the urogenital ridge.

Initially, the gonad is a mass of mesoderm that eventually differentiates into the somatic elements of the testis (or ovary). The germinal elements (primordial germ cells or gonocytes, as they are usually called) have an extragonadal origin. They arise in the fourth week of embryonic life from the endoderm, which lines the posterior aspect of the yolk sac. These newly formed gonocytes migrate by ameboid movement up the side walls of the developing gut, through the dorsal mesentery, and move laterally into the adjacent genital ridges (Fig. 35.1) (108). The impetus for this directed migration is unknown, although some studies have suggested that the genital ridges contain a substance chemotactic to germ cells. This seems reasonable in terms of what is known about directed migration of somatic cells along a chemotactic gradient. The migratory process is remarkably efficient, and primary gonadal agenesis in males is rare. During migration, the gonocytes actively proliferate so that the cell population is greatly increased by the time the cells have reached the genital ridges. Although quantitative figures are not available for the human, in the mouse only 100 gonocytes differentiate primarily from yolk sac endoderm; however, 2 days after differentiation, migratory proliferation results in the approximately 5,000 gonocytes that enter the gonadal ridges (112,280). In humans, migration is completed by the sixth week of development.

Development of the testes and establishment of spermatogenesis. In: Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

Gonadal Differentiation

Differentiation of the testis from the bipotential gonadal ridge is initiated by the SRY gene (the sex-determining region located on the short arm of the Y chromosome) (385). Under the influence of the SRY gene, embryonic Sertoli cells align into cordlike structures and begin to secrete müllerian inhibiting substance (MIS), which causes regression of the müllerian duct. In the absence of MIS, the müllerian duct develops into the uterus, fallopian tubes, and upper vagina. It was previously thought that the histocompatibility-Y (H-Y) antigen was this testis determining factor (TDF), until deletions of the Y chromosome removing the H-Y antigen but maintaining the male-determining function of the Y chromosome were identified (398).

Initially, blood vessels and accompanying mesenchymal cells invade the hilum of the future testis. Subsequent growth occurs in such a way that, beginning at the cranial pole of the testis, a series of arched, branching, and anastomotic sex cords are carved out of the gonadal blastema (79). Most of the gonocytes are sequestered within these newly forming sex cords along with mesenchymal elements, which will ultimately differentiate into Sertoli cells. A basal lamina and mesenchymal cells gradually define the newly formed cords within a tubular wall. Those mesenchymal cells, which are not part of the sex cords themselves, will form the interstitium of the testis, including the Leydig cells. At their extremities the sex cords are continuous with a network of smaller cords located in the future mediastinum of the testis. The latter will eventually cavitate to form the rete testis (79) Those gonocytes that remain in the interstitium or are trapped in the rete cords eventually perish. While these events are occurring, the mesenchyme at the periphery of the gonad condenses to form a capsule, the tunica albuginea. By the eighth week of development, a recognizable testis exists.

The mesonephros, in lateral proximity to the developing testis, begins to regress during the second month of development (201). Most mesonephric tubules degenerate completely. However, 12 to 15 tubules that abut on the hilum of the testis grow toward and establish continuity with the network of rete cords. These will become the ductuli efferentes (Fig. 35.2). At their other extremities, the tubules maintain contact with the mesonephric (wolffian) duct, which will differentiate into the epididymis proximally and the vas deferens distally.

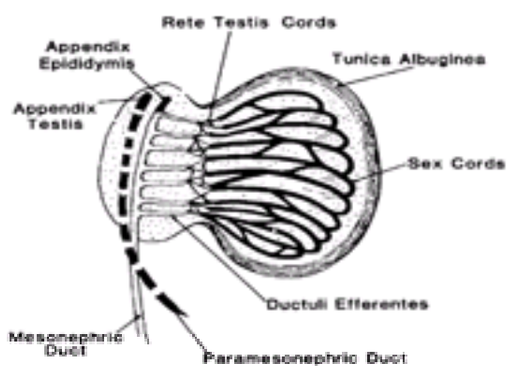

FIGURE 35.2. Diagrammatic representation of the developing testis and excretory duct system. (Modified from Langman J: *Medical embryology,* ed 4. Baltimore: Williams & Wilkins, 1975, with permission.)

Although there are reports that some mesonephric cells invade the gonad to contribute to the Sertoli cell population and to form the rete testis, there is little experimental evidence for this view (455). Serial reconstructions of the developing testis and mesonephros show that a solid rete testis is formed well before the mesonephric tubules establish contact with it (Fig. 35.3) (79).

FIGURE 35.3. Cross section at the hilum of a developing testis showing mesonephric tubules, the presumptive ductuli efferentes *(DE),* growing toward the still-solid rete testis *(RT).* SC, sex cords. (From Lipshultz LI, Howards SS. Development of the testes and establishment of spermatogenesis. In: Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

Conversion of the mesonephric duct into the male reproductive excretory tract appears to be regulated in two ways. A müllerian-inhibiting factor produced by the presumptive Sertoli cells causes regression of the paramesonephric (müllerian) ducts in the third month, while testosterone produced by the fetal Leydig cells concurrently promotes differentiation of the mesonephric system into a competent reproductive tract (120,404,428). The müllerian ducts persist in the female to form the uterus and fallopian tubes. Cranial portions of the mesonephric and paramesonephric ducts persist as embryonic remnants (Fig. 35.2). The appendix testis from the paramesonephric duct becomes attached by a narrow stalk to the upper pole of the testis, and the cranial mesonephric duct persists as the appendix epididymis connected to the head of the epididymis by a small pedicle.

Testicular Descent

The testis forms as a retroperitoneal organ high in the posterior abdominal wall. During the third trimester, the testis slips down the posterior wall, dragging its neurovascular “leash” (341,459). By the seventh month, it is at the level of the presumptive internal (deep) ring of the inguinal canal. Soon thereafter, the lower anterior abdominal wall is evaginated to form the scrotal sac. By birth, or shortly thereafter, the testis has moved into its extraabdominal location and is covered by the thinned-out component of the peritoneal cavity, the processus vaginalis. This pouch normally is pinched off from the parent peritoneal cavity, leaving a closed sac, the tunica vaginalis, which encloses the anterior and lateral aspects of the testis, serving as a lubricating bursa.

Endocrine Function of the Testis

The release of pituitary gonadotropins—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—is, in part, regulated by a decapeptide, LH-releasing hormone or gonadotropin-releasing hormone (GnRH) (361). GnRH is synthesized in the hypothalamus and travels to the anterior pituitary via the hypophyseal portal vessels (Fig. 35.4).

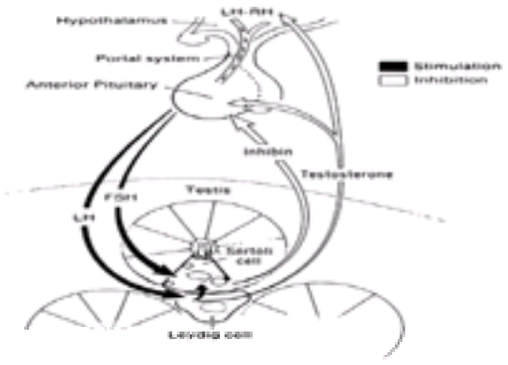

FIGURE 35.4. Hypothalamic-pituitary-testicular interrelationships. [From Lipshultz LI, Kessler DL. *Monogr Urol* 1986;7(April/May):28, with permission.]

The principal control of testosterone synthesis is mediated by LH, which stimulates the Leydig cells to produce androgen. LH binds to receptors on the Leydig cell surface and produces an increase in the activity of the enzyme adenyl cyclase. This enzyme speeds the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which stimulates intracellular increases in the concentration of several enzymes that accelerate the biosynthesis of androgen. The Leydig cells have the capacity to synthesize steroid hormones from either acetate or cholesterol. The process by which the androgen is released from the Leydig cell into the blood and the seminiferous epithelium is not understood. The production of androgen begins to increase in early puberty and reaches a peak of approximately 7 mg per day after puberty. Testosterone is released from the testis in episodic spikes. Other steroids, including dihydrotestosterone (DHT), 17-hydroxyprogesterone, and estradiol, are also secreted. Most of the circulating DHT and estradiol, however, are produced by enzymatic conversion of testosterone in peripheral tissues. Obese men are predisposed to increased peripheral conversion of testosterone into estrogen.

Normal peripheral plasma levels of testosterone and DHT are 300 to 1,200 ng/dL and 30 to 60 ng/dL, respectively. Approximately 98% of the circulating androgens are bound to plasma proteins, including specific b-globulin, testosterone-binding globulin (TeBG). The free testosterone in the blood is the physiologically important fraction.

Recent studies suggest that FSH and prolactin (PRL) may contribute to androgen biosynthesis in the Leydig cells. FSH, however, binds primarily to the Sertoli cells within the seminiferous tubule (Fig. 35.4). FSH stimulates the production of an androgen-binding protein (ABP) by the Sertoli cells, an action mediated by cAMP (422). Although the precise role of FSH is not defined, spermatogenesis requires the presence of FSH and high intratesticular levels of androgen. The presence of specific androgen receptors in the seminiferous tubule supports the view that high intratesticular concentrations of testosterone are necessary for spermatogenesis. Feedback regulation of LH secretion is controlled by serum levels of testosterone and estradiol.

There appears to be specific feedback regulation of FSH secretion by the seminiferous epithelium. Inhibin, a 32-kDa protein, is secreted by Sertoli cells in response to FSH (43). Inhibin acts primarily on the pituitary to inhibit secretion of FSH. It may also act on the hypothalamus to decrease GnRH release and thereby indirectly reduce FSH levels. Interestingly, inhibin appears to have testicular effects also. These effects include stimulation of androgen production by Leydig cells and inhibition of spermatogenesis within the seminiferous tubule (440). Activin, by stimulating the production of FSH, has the opposite effect of inhibin. Although activin, which is structurally related to inhibin, is primarily thought of as a testicular product produced by Sertoli cells, evidence exists that it may be found in a variety of extragonadal tissues such as adrenal, bone marrow, spleen, and kidney. Activin is believed to influence a wide variety of functions, including release or expression of pituitary gonadotropins, as well as growth hormone, adrenocorticotropic hormone, and gonadotropin-releasing hormone.

The endocrine function of the testis is gradually altered during aging. Histologic changes occasionally appear as early as the third decade of life and are increasingly common in older men (44). The most common degenerative changes are thickening of the tubule basement membrane and tunica propria, intratubular fibrosis, and reduction in the number of germ cells in the seminiferous epithelium. Mean levels of free testosterone decline in men after age 50 years, although total circulating testosterone declines later (285). These normally occurring changes in senescent testis function become important in the assessment of the fertility potential of older men.

Spermatogenesis

Spermatogenesis begins with the primitive germ cells, the spermatogonia, and eventually leads to the production of mature spermatozoa and the renewal of production of spermatogonia. Under normal circumstances, spermatogenesis consists of an orderly progression from spermatogonium to spermatocyte, spermatid, and mature spermatozoon (Fig. 35.5). In general, spermatogenesis is a relatively inefficient process. It has been established that half of the germ cells in rodents never differentiate into mature spermatozoa secondary to mechanisms related to apoptosis (177,206,217). Studies in men also suggest that a fine balance between proliferation and apoptotic degeneration probably results in normal spermatogenesis (242).

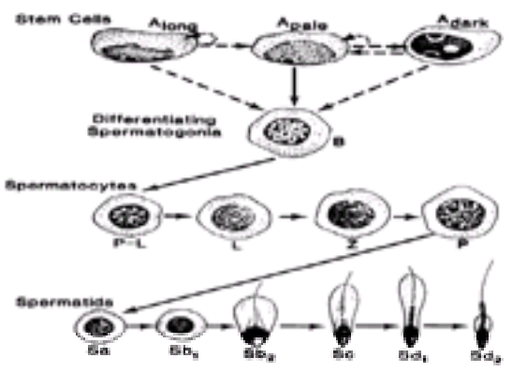

FIGURE 35.5. Individual cell types seen in the normal seminiferous epithelium. These depict the main steps of spermatogenesis in man. A_{dark}, dark type A spermatogonium; A_{pale}, pale type A spermatogonium; B, type B spermatocyte; L, leptotene spermatocyte; Z, zygotene spermatocyte; P, pachytene spermatocyte; Sa, Sb, Sb_2, Sd_2, spermatids at different stages of spermatogenesis. (From Lipshultz LI, Howards SS: Adult spermatogenesis; characteristics, kinetics, and control. In: Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

In humans, sequential maturation includes the dark type A spermatogonium (Ad), the pale type A spermatogonium (Ap), the type B spermatogonium (B), the resting spermatocyte (R), the leptotene spermatocyte (L), the zygotene spermatocyte (Z), the pachytene spermatocyte (P), the secondary spermatocytes (II), and the Sa, Sb, Sb_2, Sc, Sd, and Sd_2 spermatids (Fig. 35.5) (162). In addition to Ad and Ap spermatogonia, some workers recognize a more primitive type of spermatogonium, the A_1 cell, the purported stem cell.

As germ cells mature, they move within the Sertoli cell cytoplasm from the basement membrane of the seminiferous tubule to the adluminal compartment (Fig. 35.6). Thus the Sertoli cell plays an important nutritional role in the spermatogenic process. The various spermatogonia undergo mitotic division, but the diploid primary spermatocyte undergoes a meiotic reduction division, giving rise to a haploid secondary spermatocyte containing only half the chromosomes of the primary spermatocyte and either an X or a Y chromosome. All cells up to this point have a rounded shape. As the spermatid matures, however, it elongates, develops a tail or flagellum, and assumes a configuration similar to that of a mature spermatozoon. Very few spermatozoa are present in histologic sections of the testis, because as soon as they mature, they are released into the seminiferous tubular lumen and rapidly flow out to the rete testis.

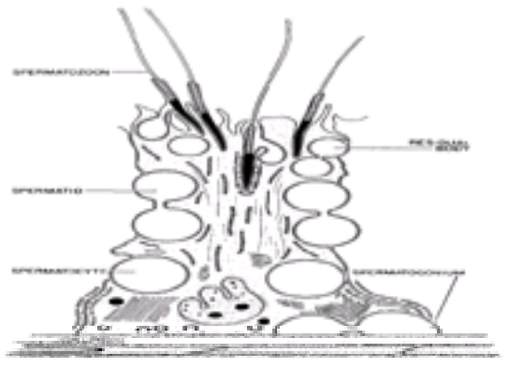

FIGURE 35.6. Compartmentalization of the germinal epithelium. Note the germ cells and their relationship to a columnar Sertoli cell. Spermatogonia are in a basal compartment, whereas the more mature germ cells are in an adluminal compartment. The adluminal compartment is separated from the basal area by tight Sertoli cell–Sertoli cell junctions at the lateral aspect of the Sertoli cell, near the base. These junctions form a blood-testis barrier, which is thought to protect the mature spermatocytes and spermatids. (Modified from Dym M, Fawcett DW. *Biol Reprod* 1970;3:308; and Dym M. The male reproductive system. In: Weiss L, Greep RO, eds. *Histology.* New York: McGraw-Hill, 1973, with permission.)

Observations of the seminiferous epithelium taken from testis biopsies reveal that specific cell types are repeatedly seen only in association with certain other cells, and that all spermatogenic cell types are not visible within one cross section of a tubule. These cell associations, or groupings, are known as stages in the cycle of the seminiferous epithelium. There are six stages or cell associations in humans (162). The cells in any given association progress together to the next cell grouping. Each stage represents a particular degree of maturation. Stages I through VI constitute one cycle of the germinal epithelium. The duration of each cycle in the human is 16 days. Approximately four cycles of the epithelium are required for an A_1 spermatogonium to mature to a spermatozoon. Heller and Clermont (162) have determined that in the human it takes 4.6 cycles, or 74 days, for a mature sperm to develop from an Ap spermatogonium.

A number of paracrine factors produced within the testis exert a local (paracrine) control on spermatogenesis (298), including cell proliferation and meiosis. These growth factors probably influence spermatogenesis by facilitating communication among various cell types within the testis (Sertoli cells, germ cells, Leydig cells, and peritubular cells). Growth factors that have been isolated from the testis, isolated testicular cell monolayer cultures, and testicular secretions include fibroblast-like growth factors, insulinlike growth factors, b-nerve growth factors, transforming growth factor-b, Sertoli cell–secreted growth factor, inhibin, and activin (298).

The molecular mechanisms regulating spermatogenesis are slowly being defined. This is undoubtedly one of the most exciting areas of research in male infertility. The importance of the genetic regulation of spermatogenesis has new clinical implications as a result of ICSI, which may bypass many of the previous barriers to conception and pass on abnormal genes to the offspring.

Functional Anatomy of Spermatozoa

The head of the human spermatozoon contains a nucleus that is composed of dense nucleoprotein. The nuclear chromatin is stabilized by S-S (disulfide) cross-links between molecules. The condensation and cross-linking combine to make the mature sperm nucleus highly resistant to chemical and physical insult and thus serve to preserve the sperm during epididymal storage. The acrosome is a thin, caplike structure that envelops the anterior four-fifths of the sperm head (Fig. 35.7). It contains many enzymes that are released at the time of fertilization. The tail represents 90% of the length of the human sperm and comprises a connecting piece, a middle piece, a long principal piece, and a short end piece. The motor apparatus of the sperm tail is called the *axoneme* or the *axial filament complex.* It runs the length of the tail, within its center, and is composed of a central pair of microtubular structures surrounded by a ring of nine pairs of microtubules. The major protein of these tubules is tubulin. The major protein of the arms of the microtubules is dynein. The tubulin–dynein system is distinct from the actin–myosin system in skeletal muscle. The ring of nine microtubules is surrounded by a circle of nine noncontractile dense fibers, which are thought to serve as supportive structures. The outer dense fibers are found within a circular fibrous sheath of mitochondria.

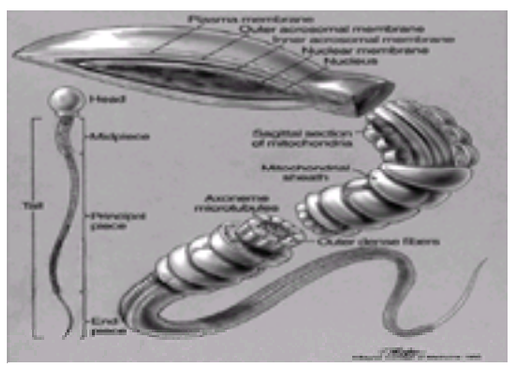

FIGURE 35.7. The illustration of the mature spermatozoon demonstrates the relationship between the head, midpiece, and other tail segments through a combination of external and sagittal section details. The insert depicts a normal spermatozoon as seen with light microscopy.

During transit through the epididymis, the spermatozoa and their milieu both undergo many dramatic changes. In addition to the changes in morphology, chemistry, motility, fertilizing potential, and metabolism, spermatozoa also undergo alterations in permeability, antigenicity, and surface membrane charge during epididymal passage (30). It is probable that in some complex yet unexplained way, these alterations are important to the sperm cell's ability to complete the fertilization process. An abnormality of any of these functions could lead to infertility in the male.

Morphologic changes in epididymal spermatozoa include changes that occur in the acrosomal membranes as the spermatozoa undergo epididymal transit. It is likely that these changes (“precapacitation events”) are necessary for capacitation, but their specific function is presently unknown.

Biochemical modifications in sperm occurring during epididymal maturation include an increase in cAMP content, loss of nonnuclear protein, shifts in free amino acid concentration, loss of palmitic acid, a decrease in the amount of most phospholipids, an increase in the amount of unsaturated fatty acids, changes in electrophoretic properties, and stabilization of the deoxyribonucleoprotein complex. Ejaculated spermatozoa meet most of their energy requirement by utilizing fructose from the seminal vesicles, although mammalian sperm can also anaerobically metabolize glucose and mannose to lactic acid. The sperm mitochondria have the enzymes of both the Embden-Meyerhof glycolytic pathway and the Krebs cycle. Therefore the metabolic function of the sperm is greatly enhanced by the epididymis.

Functional Role of the Epididymis

The epididymis is important for sperm maturation and the acquisition of sperm motility. In the unobstructed state, the best sperm motility is found in the cauda, and the least in the caput. The changing environment and physiology of the epididymis are critical to the maturation of the spermatozoa. However, with ICSI, sperm with normal fertilizing capability may be obtained from any portion of the epididymis. In addition to alterations in spermatozoa, the luminal fluid changes significantly in the epididymis. A large portion of the fluid secreted from the seminiferous tubules flows into the rete testis and is absorbed in the ductuli efferentes and proximal epididymis. Inositol, total lipid, and total protein decrease in concentration as the luminal fluid moves through the epididymis (198). In contrast, potassium concentration rises. Glyceryl phosphorylcholine (GPC), sialic acid, carnitine, hypotaurine, and acetylglucosmide are secreted in large quantities into the fluid, but their functions are not understood.

It has been known for some time that the epididymis depends on androgens for maintenance of histologic integrity (259). Subsequently, it was shown that the motility

and fertility of epididymal sperm and the secretion of carnitine, GPC, and sialic acid into the fluid are androgen-dependent processes. Vigersky and colleagues (450) have found androgens and androgen-binding protein in the fluid of the caput epididymis. Although androgen levels are higher in rete testis fluid than in the peripheral circulation, it is not clear whether most of the androgen enters the epididymal lumen from the blood or from the rete testis fluid.

Transport of Spermatozoa

Mature human spermatozoa are released from Sertoli cells into the lumen of the seminiferous tubule and then traverse approximately 6 m of duct in the male reproductive tract before they leave the urethral meatus to be deposited in the vagina. This ductal system can be subdivided into several components (Fig. 35.8). From the seminiferous tubule, the spermatozoa travel into the rete testis, a collection chamber for all the seminiferous tubules. The sperm leave the rete testis via the ductuli efferentes, which in the human are composed of 12 to 20 channels, and pass into a single, compact 3.6- to 4.6-m-long convoluted duct known as the *ductus epididymis.*

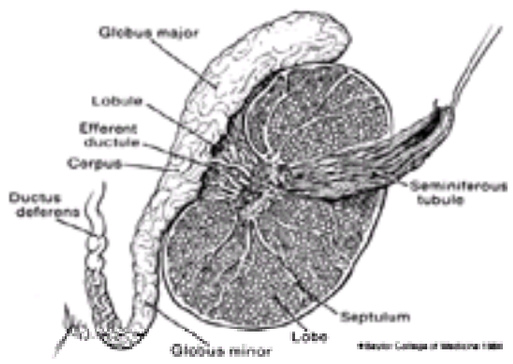

FIGURE 35.8. Cross-sectional representation of the testis and epididymis. (From Meacham RB, Huckins C, Lipshultz LI. Anatomy and embryology of the testicle. In: Javadpour N, ed. *Principles and management of testicular cancer.* New York: Thieme-Stratton, 1985, with permission.)

The epididymis has been traditionally divided into three regions: caput, corpus, and cauda epididymis. Before and during ejaculation, the spermatozoa move from the cauda epididymis into the vas deferens, which is approximately 38 cm long. The distal portion of the vas deferens is termed the *ampulla.* The ampulla terminates in the prostatic urethra after it has been joined by the duct of the seminal vesicle, forming the ejaculatory duct (Fig. 35.9).

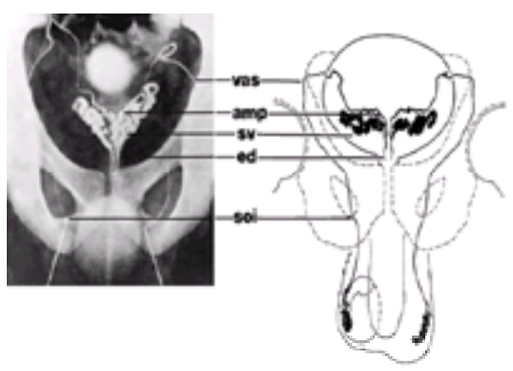

FIGURE 35.9. A bilateral vasogram *(left)* and a schematic drawing of the excurrent ducts of the male reproductive system *(right).* Amp, ampulla of the vas deferens; ed, ejaculatory duct; soi, site of injection; sv, seminal vesicles vas, vas deferens. (From Sherins R, Howards SS. Male infertility. In: Harrison JH et al, eds. *Campbell's urology.* Philadelphia: Saunders, 1978, with permission.)

The ductuli efferentes are lined with an epithelium that projects motile cilia into the lumen. In contrast, the cilia of the epididymal duct are not true cilia and possess no capacity for purposeful movement. The efferent duct's true cilia may have a role in sperm transport; the stereocilia of the epididymal duct do not. The fluid secreted in the testis flows into the epididymis. If the efferent ducts are ligated, the testis becomes tense and gains weight, and eventually pressure atrophy of the seminiferous tubules occurs (431). Because this phenomenon is not seen after ligation of the vas deferens, it is assumed that the epididymis is able to reabsorb the fluid secreted by the testicle. This absorptive capacity prevents permanent atrophy of the seminiferous epithelium after vasectomy in humans.

In the human there is a gradual proximodistal increase in the thickness of the muscle investment of the efferent ducts, epididymis, and vas deferens. Circularly arranged bundles of small, smooth muscle–like myoid cells predominate in the efferent ducts and caput epididymis, although some bundles are arranged in a spiral course. In the more distal cauda, smooth muscle cells predominate, forming the three interconnected layers of smooth muscle seen in the vas deferens (the inner and outer longitudinal layers and the intermediate circular layer). The ratio of the thickness of muscle to lumen in the human vas deferens is far greater than in any other structure in the human. The reason for such abundant musculature is not known, but it is generally accepted that muscular contractions cause rapid sperm transport at the time of ejaculation.

The epididymal duct and the efferent ducts contract spontaneously. These contractions are thought to aid in sperm transport even during periods of sexual abstinence, whereas the contractions of the vas deferens and distal epididymis propel the spermatozoa during ejaculation. Thus sperm movement into the epididymis may be attributed to several factors: (a) positive fluid pressure from the rete testis, (b) fluid currents established by the beating of cilia along the walls of the efferent ducts, and (c) peristaltic contractions of the efferent ducts. Contractions of the seminiferous tubules and contraction of the tunica albuginea may assist in the transport of spermatozoa from the testis. Spontaneous peristalsis-like contractions of the epididymal tubules have been promulgated as the sole operative factor in the transport of spermatozoa through the epididymis. Resting hydrostatic pressure gradients may also contribute to epididymal sperm transport (205).

The transit time of sperm through the caput and the corpus is consistently 3 to 5 days and is independent of ejaculation. In young men the transit time is 2 to 4 days. Thus the variation in total epididymal transmit time is probably related to differences in the rate of passage through the cauda epididymis, which in turn are due to changes in ejaculatory frequency. Ejaculations accelerate transit through the cauda epididymis, but they probably do not affect transport from the caput to the proximal cauda. Ejaculated spermatozoa come from the vas deferens and the distal epididymis. Pabst (311a) has calculated that the human vas deferens has a capacity of 0.45 mL, which is enough to account for roughly 10% of the volume of the normal ejaculate.

In the experimental animal and in humans, the vas deferens contains large amounts of catecholamines and is richly innervated by adrenergic fibers that can cause contractions when properly stimulated (311). There is increasing evidence that parasympathetic stimulation can also cause contraction of the vas deferens; however, the sympathetic system is physiologically predominant. There is no direct evidence that the vas deferens undergoes spontaneous peristaltic contractions similar to those in the ureters and the gastrointestinal tract.

Erection, Emission, and Ejaculation

To penetrate the vagina and deposit sperm in it, the penis must be erect. Erection following local stimulation (reflexogenic erection) is mediated through the sacral spinal cord, whereas erection following psychic stimulation (psychogenic erection) is dependent on cerebral erotic centers. Psychic stimuli can augment or inhibit reflex erections. Although, classically, erection has been thought of as a simple parasympathetic function, its neurophysiology is complex. The afferent nerves for reflex erection run in the pudendal nerves, and the efferent fibers are found in the S-2 to S-4 parasympathetic outflow or in the nervi erigentes. The afferent stimuli for

psychic erections travel through the thoracolumbar sympathetic outflow and the sacral parasympathetic fibers.

During erection, the vascular spaces in the corpora cavernosa and the corpus spongiosum fill with blood. The blood flows to the corpora via four branches of the internal pudendal artery: the urethral artery, the artery of the bulb of the penis, the deep artery of the penis, and the dorsal artery of the penis. There is extensive vascular communication between the two corpora cavernosa. Physiologic studies indicate that erections are the result of smooth muscle relaxation within the corpora cavernosa. As a result of sexual stimulation, cavernous nerves and the endothelial cells within the corpora cavernosa release nitric oxide (NO), which stimulates the formation of cyclic guanosine monophosphate (cGMP). This cGMP is directly responsible for the corporal smooth muscle relaxation, which enables increased arterial dilation and inflow. As the corporal bodies fill with blood and become distended, the draining venules between the external sinusoids and the tunica albuginea become compressed, thereby trapping the blood within the penis. Penile rigidity is dependent on a normal penile anatomy (e.g., elasticity of the tunica albuginea) and normal penile vasculature and nerve supply. Detumescence is initiated by the degradation of cGMP, a process that is enzymatically mediated by type V phosphodiesterase within the corpora cavernosa.

The ejaculatory process may be divided into two phases: the preejaculatory or emission phase and the ejaculatory phase. During emission, secretions from the periurethral glands, the seminal vesicles, and the prostate are deposited in the posterior urethra. In addition, sperm from the ampulla of the vas deferens, from the vas itself, and probably from the cauda epididymis are propelled by peristalsis into the posterior urethra. The emission process is primarily but not exclusively mediated through the sympathetic nervous system. At the time of ejaculation, the bladder neck (the so-called internal sphincter) closes under sympathetic control. Both emission and closure of the bladder neck can be prevented by a-adrenergic blocking agents.

The precise neurophysiologic mechanisms of emission and ejaculation are not known. The spinal center for these processes is in the lower thoracic and upper lumbar cord and possibly in the sacral cord. According to Shishito and Kimura (389), the pelvic and hypogastric nerves in the dog are involved in emission, and the pudendal and hypogastric nerves are associated with ejaculation. Fibers in the hypogastric nerve that are distinct from those stimulating emission were found to close the bladder neck at the time of ejaculation. There is also evidence that in the human emission and bladder neck closure are stimulated from different sympathetic ganglia. Patients with postlumbar sympathectomy may have either retrograde ejaculation or failure of emission.

During the final phase of ejaculation, the external urethral sphincter relaxes and the perineal and bulbourethral muscles contract, expelling the ejaculate from the posterior urethra through the urethral meatus. This phase of the ejaculatory process is thought to be triggered by the presence of seminal fluid in the posterior urethra. The fluids secreted by the prostate and seminal vesicles constitute approximately 95% of the ejaculate volume and serve as a vehicle of transport for the sperm (480).

Capacitation and Acrosome Reaction

Spermatozoa of rabbits and rats must reside in the female reproductive tract before they acquire the capacity to fertilize ova. This phenomenon is termed *capacitation.* There are several *in vivo* and *in vitro* bioassays that measure the capacitation of sperm (175,306). They are based on the assumption that only capacitated sperm can penetrate and fertilize eggs. Under the proper experimental conditions, certain species' capacitated sperm will fertilize cross-species ova *in vitro,* whereas noncapacitated sperm will not. Therefore, as discussed later in detail, sperm must undergo capacitation to result in a positive sperm–hamster egg penetration test. Complete capacitation is also a prerequisite for successful *in vitro* fertilization (IVF).

The acrosome reaction follows capacitation. It is a progressive fusion between the plasma membrane of the sperm head and the outer acrosome membrane, resulting in the formation of a series of vesicles. Pores between the areas of fusion allow a progressive loss of the acrosomal contents. This vesiculated complex is always missing from the sperm just before it penetrates the zona pellucida. Thus the acrosome reaction is a clear-cut morphologic change that follows capacitation and precedes fertilization. The enzymes released during the acrosome reaction facilitate fertilization by allowing sperm to penetrate the vestments surrounding the ovum.

EVALUATION OF THE INFERTILE MALE

Primary infertility affects 10% to 15% of married couples. In this group, about half of the men demonstrate a significant abnormality. In the last few years we have witnessed an increasing appreciation of the subtle abnormalities of gonadal and spermatozoal dysfunction that can contribute to seemingly unexplained male infertility. New diagnostic tests are emerging that may help define these previously obscure male factors. Only when these abnormalities have been clearly identified can more specific treatment regimens be introduced.

Although it has often been recommended that clinical evaluation of an infertile couple be undertaken only after 1 year of unprotected intercourse, we believe that the initial screening of the man should be considered whenever the patient has the chief complaint of infertility. This initial evaluation, however, should be rapid, noninvasive, and cost-effective. The basis of the evaluation for infertility should be a complete history, physical examination, and pertinent laboratory tests.

History

A history of specific childhood illnesses (Table 35.1) may be important in the evaluation of the subfertile man. It has been shown that in the male born with bilateral or unilateral undescended testes, regardless of the time of orchiopexy, overall semen quality is less than that found in normal men (243). In patients with a unilateral undescended testis, the defect in spermatogenesis is present not only in the undescended gonad but also in the descended contralateral gonad. Nevertheless, after orchidopexy, their fertility approaches that of men with normally descended testes. A history of testicular (spermatic cord) torsion has also been associated with decreased fertility (29), which may be due in part to preexisting changes in the contralateral testis. Prepubertal mumps do not appear to affect the testes. However, among men who have experienced mumps after the onset of puberty, 30% have unilateral orchitis and 10% have bilateral orchitis (460). Furthermore, the testicular damage can be severe and should be readily appreciated on physical examination because the involved gonad is markedly atrophic.

History of Infertility	Herniorrhaphy
Duration	Y-V-plasty, tranurethral prostate resection
Prior pregnancies	**Infections**
Present wife	Viral; febrile
Another partner	Mumps orchitis
Previous evaluations	Venereal
Previous treatments	Tuberculosis; smallpox (rare)
Sexual History	**Gonadotoxins**
Potency	Chemicals
Lubricants	Drugs (chemotherapeutic; cimetidine; sulfasalazine; nitrofurantoin; alcohol; marijuana; androgenic steroids)
Timing of intercourse	Thermal exposure
Frequency of intercourse	Radiation
Childhood and Development	**Family History**
Undescended testicles; orchiopexy	Cystic fibrosis
Herniorrhaphy	Androgen receptor deficiency
Y-V-plasty of bladder	**Review of Systems**
Testicular torsion	Respiratory infections
Testicular trauma	Anosmia
Onset of puberty	Galactorrhea
Medical History	Impaired visual fields
Systemic illness	
Previous or current therapy	
Surgical History	
Retroperitoneal surgery	
Pelvic injury	
Pelvic, inguinal, or scrotal surgery	

TABLE 35.1. INFERTILITY HISTORY

Men who have had operative correction (Y-V– plasty) of the bladder neck during childhood may have retrograde ejaculation because the internal sphincter has been ablated. This condition should be suspected in the man who gives a history of bladder surgery and whose ejaculate volume is less than 1 mL, oligozoospermic or azoospermic, and abnormally acidic. The diagnosis is confirmed by a finding of large numbers of sperm (10 to 15 per high-power field) in the uncentrifuged postejaculation urine. Another group of patients who may seek evaluation for infertility is those patients cured of testicular cancer. The infertility rate in this group has been estimated to be greater than 80%. Their infertility is secondary to the sequelae of chemotherapy, radiotherapy, retroperitoneal lymph node dissection, or a combination of all three. Frequently, the function of their contralateral “normal” testis is impaired before the institution of therapy (49). Prognosis regarding semen quality is uncertain if less than 4 years has elapsed since treatment, because the return of function to the radiated or chemotherapeutically exposed gonad may take as long as 4 to 5 years (89,275,297). The patient who has had retroperitoneal lymph node dissection with interruption of the sympathetic nodal chain or its peripheral long nerves (sacral plexus, hypogastric nerve) may show either aspermia with lack of emission or, less frequently, retrograde ejaculation (226).

The history should also include a review of past and present medical diseases. Cystic fibrosis is associated with a high percentage of abnormalities of the vas and epididymis. The population of males suffering from congenital bilateral absence of the vas deferens has also been found through DNA genetic testing to carry cystic

fibrosis trait in a significant proportion of cases. Such individuals generally show none of the stigmata of cystic fibrosis and potentially are treatable by microsurgical retrieval of epididymal sperm in combination with IVF and ICSI (301).

A history of recurrent upper respiratory tract infections or bronchiectasis may lead to the diagnosis of the immotile-cilia syndrome or Young's syndrome. In Young's syndrome, inspissated material in the epididymis produces an obstructive azoospermia. Spermatozoa proximal to this lesion, however, are normal and motile (115). The immotile-cilia syndrome (115,156) is a heterogeneous group of disorders characterized by ultrastructural defects of cilia. In this syndrome the spermatozoa have the same structural defect as the cilia and are immotile. Individuals with Kartagener's syndrome have the same ciliary defect but also have situs inversus (156).

Precocious sexual puberty may indicate endocrinologic dysfunction such as congenital adrenal hyperplasia (CAH), which has historically been cited as a cause of decreased fertility potential (95). It should be noted, however, that Urban and colleagues (437) described five untreated adult men with CAH whose fertility was normal. A history of anosmia, galactorrhea, impaired visual fields, or a marked or sudden decrease in libido along with infertility may indicate a pituitary tumor. A familial history of diabetes mellitus may be relevant, because diabetes may cause a lack of emission or retrograde ejaculation. A history of decreased ejaculate volume can be a clue to this disease (149) There may be a familial history of end-organ androgen insensitivity (i.e., partial androgen receptor defect) as seen in Reifenstein's syndrome. A history of delayed sexual maturation or anosmia can lead the alert clinician to a diagnosis of Kallmann's syndrome, with its associated hypogonadotropic hypogonadism. Information about trauma to the genitourinary organs or previous scrotal or inguinal surgery including pediatric herniorrhaphy should be obtained. Prior venereal disease may be associated with urethral strictures or vasal or epididymal obstruction. Tuberculosis can lead to scarring of the epididymis and vas deferens as well.

The history should also include a detailed inquiry into exposure to drugs and environmental toxins that may interfere with spermatogenesis, either directly or through alterations in the endocrine system (Table 35.2). A reversible effect of specific pesticides on gonadal function has been reported (247). However, once azoospermia has occurred, return to a normal state is highly unlikely. Medications such as sulfasalazine, calcium channel blockers (166), cimetidine, and high-dose nitrofurantoin and ingestants such as nicotine, alcohol, and marijuana have also been implicated as gonadotoxic agents. Elimination of these substances should enable return of normal spermatogenesis. Exogenous androgens, mistakenly thought by some clinicians to improve gonadal function, actually act as a “male contraceptive,” depressing gonadotropin secretion and interfering with normal spermatogenesis. The growing use of anabolic steroids by athletes makes this area of concern increasingly important. Consequently, if a patient is taking any of these medications at the time of initial interview, the medication should be stopped and the patient's semen reevaluated in approximately 3 to 4 months.

	Observed Effects			
Type of Exposure	Decreased Sperm Count	Abnormal Morphology	Altered Sperm Transfer	Altered Hormone/Sexual Performance
Lead	+	+	+	+
Dibromochloropropane	+			
Carbaryl (Sevin)		+		
Ethylene bromide	+	+	+	
Plastic production (Styrene and acetone)		+		
Ethylene glycol monoethyl ether	+			
Welding		+	+	
Mercury vapor				+
Heat	+		+	
Military radar	+			
Radiation (Chernobyl)	+	+	+	+
Carbon disulfide				+

TABLE 35.2. DRUGS AND ENVIRONMENTAL TOXINS THAT MAY INTERFERE WITH SPERMATOGENESIS

Any generalized metabolic insult (e.g., fever or viremia) can cause impaired testicular function. However, the effects may not appear in the ejaculate for 1 to 3 months after the gonadotoxic event because of the time required for spermatogenesis. Approximately 74 days pass between the initiation of the type B spermatogonia and the appearance of mature spermatozoa in the ejaculate. Including transit time in the ductal system, the duration from the beginning of spermatogenesis to ejaculation is approximately 2.5 to 3 months. The actual time lapse between the injurious event and the appearance of abnormal cells in the ejaculate varies, depending on which stage of the spermatogenic process is affected. For that reason, if a patient gives a history of significant medical problems in the 3 months before the first office visit and if the analysis shows subnormal semen quality, the evaluation should be repeated at monthly intervals for 4 to 6 months before a decision is made regarding the quality of sperm production.

The subject of sexual habits and coital factors must also be addressed during the initial history. Improper timing of intercourse is the most common coital factor responsible for the infertile couple's failure to conceive. Many couples do not understand the female cycle as to the ideal time for conception. Because sperm are viable for approximately 48 hours, and ova for 12 to 24 hours, intercourse should be planned at least every other day for approximately 1 week before ovulation and for several days thereafter to maximize the chance of placing viable sperm in contact with the ovum in the fallopian tube during the egg's period of viability, as suggested by Wilcox and colleagues (461). Precise prediction of ovulation may be accomplished via commercially available urine assay kits, such as OvuQUICK and ClearPlan-Easy, that measure the preovulatory LH surge. Artificial lubricants may result in a diminished motility and should not be used. One should also ask about the use of common vaginal lubricants, such as K-Y Jelly, petroleum jelly, saliva, skin lotions, and Astroglide, which all may have spermatotoxic effects (128,376,411). If lubricants must be used, light vegetable oils are the least spermatotoxic. Too-frequent periovulatory masturbation, which can deplete the sperm reserve, should be avoided.

Lifestyle Factors

These factors are important to identify because they are under the direct control of the patient. Although specific further treatments may not overcome their adverse effects, avoidance of continued exposure may improve sperm production or function.

Smoking

Although the results of individual reports vary, cumulative evidence suggests that cigarette smoking can be detrimental to male fertility. Studies by Vine and Hughes have demonstrated decreased sperm density in smokers as compared with nonsmokers (179,447). Elevated serum prolactin and estradiol levels have been noted in smokers, and both have been proposed as a contributing cause for the subfertility noted in this population. The seminal plasma from smokers has been shown to have a prominent adverse effect on the spermatozoa from nonsmokers (482). Smoking has also been reported to exacerbate the effect of other causes of infertility, such as varicocele (223). Clearly, cessation of smoking is a simple, specific step that may enhance the fertility potential of male and female patients.

Alcohol

Although chronic alcoholics can demonstrate testicular atrophy, diminished serum testosterone levels, and subfertility, moderate alcohol consumption has not been shown to deleteriously affect semen parameters (444).

Stress

The biochemical relationship between infertility and emotional stress is not well defined. Schenker and colleagues (364) postulated that emotional stress may impair the function of the hypothalamic-pituitary-gonadal (HPG) axis, resulting in gonadotropic dysfunction. It is important for the urologist treating the subfertile male to realize that the stress of infertility itself may be particularly troublesome. Ragni and Caccamo (339) noted a fivefold increase in the number of men with abnormal semen parameters 3 months after enrollment in an IVF program, suggesting that the emotional stress these men were experiencing had a negative impact on the quality of their semen. Similarly, Clarke and colleagues (78) found a significant decline in semen quality of male IVF patients on the day of egg retrieval compared with baseline semen analyses. Therefore it is reasonable to reduce emotional stress in the subfertile couple, especially through a team approach employing physicians, nurses, social workers, and psychologists.

Exercise

Endurance training at high levels, including running more than 100 miles per week or bicycling more than 50 miles per week, has been demonstrated to result in diminished sperm concentration and motility. Moderation of endurance training is therefore a reasonable step in the management of the subfertile male; however, the true effect of extreme exercise is unclear (23).

Nutrition

Dietary derangements have been loosely linked to male subfertility (470). This is an untapped research area that needs to be explored thoroughly to identify which dietary factors play a role in the metabolic pathways involved with the development of normally functioning sperm. As an example, in animals, vitamin A deficiency causes germ cell degeneration (441). It is always appropriate to recommend a healthy diet to all patients, particularly those who may be substantially overweight. Excess fat in the body can act as a storage reservoir for estrogens in the male, thereby throwing off the normal testosterone/estradiol ratio, which may have subtle effects on sperm development and function. Excess fat also enhances the peripheral conversion of testosterone to estrogens by aromatization.

Hyperthermia

The issue of “boxer shorts versus jockey shorts” is often raised by patients. The hypothesis that jockeys cause higher scrotal temperatures and are detrimental to semen quality is theoretic and unproven. It is unlikely that underwear type has a significant effect on male fertility, and routinely advising infertility patients to wear boxer shorts cannot be supported by available scientific evidence (289). Continuous exposure to high temperature levels, however, may affect the patient who is already borderline-low in some of his semen parameters, so it would seem prudent to discontinue the use of saunas, hot tubs, and so on in the subfertile male. An extensive review of the literature demonstrated an adverse effect of occupational heat exposure on male fertility (419).

Occupational Gonadotoxins

A careful history eliciting any exposure to occupational gonadotoxins is mandatory, and minimization of exposure is essential in the treatment of the subfertile male. General categories of harmful toxin exposure include chemicals, radiation, or extreme heat (Table 35.2) (345). Aromatic solvent exposures should especially be avoided (420). A detailed description of the detrimental effect of inhaled hydrocarbon exposure in rubber factor workers was recently reported by De Celis and colleagues (98).

Declining Sperm Counts

Recent reports have suggested that sperm counts have been declining worldwide over the last 50 years (24,63,181). However, these studies are controversial and have been refuted by other authors (124,343). Saidi and Fisch have also suggested that geographic variation may be present and that the highest sperm densities may be found in New York compared with other U.S. cities (357). Most of these studies have examined trends in semen quality from sperm banks. Environmental factors, such as those having estrogenic effects, have been implicated as the underlying cause (196). Carlsen and colleagues (63) argue that a concomitant increase in the incidence of genitourinary abnormalities such as testicular cancer and possibly cryptorchidism and hypospadias suggests a growing impact of factors with serious effects on male gonadal function.

Erectile Dysfunction

Erectile dysfunction must be evaluated and treated according to its etiology. From a psychologic perspective, because difficulties with the initiation of a pregnancy are still traditionally considered a “woman's problem,” the diagnosis of a male factor abnormality may have a significant and unexpected impact on a man's self-esteem and overall sense of manhood. A focus of increasingly more attention, studies of couples with a male factor subfertility disorder have clearly demonstrated higher anxiety levels, an increase in somatic symptomatology, periods of erectile dysfunction, and even feelings of rage by the wife toward the husband. Emotional issues of guilt and depression related to feelings of a loss of self-confidence, security, self-esteem, and health are commonly encountered and often result in erectile dysfunction. Organic erectile dysfunction may also be encountered, albeit less frequently in the reproductive age group. Treatments are focused on counseling and therapy for psychogenic etiologies and noninvasive treatment options for organic erectile dysfunction.

Premature ejaculation is not uncommon in young men, but only rarely is a cause of infertility if ejaculation occurs before vaginal penetration. Treatment is most successful using a combination of methods such as reconditioning, sexual therapy, and oral medications. Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, sertraline, and paroxetine have shown efficacy.

Medications

Prescription Drugs

Prescription drugs can impair fertility, and when possible, an equivalent medication should be substituted for one that causes infertility. The pharmaceuticals may be grouped according to the level at which they primarily affect spermatogenesis (Table 35.3).

Suppression of HPG Axis	Direct Gonadotoxicity	Impaired Fertilization
Anabolic steroids	Nitrofurantoin	Calcium-channel blockers
Cimetidine	Sulfasalazine	Colchicine
Steroidal antiandrogens (CPA)	Valproic acid	Nitrofurantoin
Cyclosporine	Spironolactone	Minocycline
Phenothiazine	Allopurinol	

HPG, hypothalamic-pituitary-gonadal.

TABLE 35.3. PRESCRIPTION DRUGS THAT CAN IMPAIR FERTILITY

Chemotherapeutic Agents

Chemotherapeutic agents are another important cause of infertility. Mechlorethamine, cyclophosphamide, chlorambucil, procarbazine, and nitrogen mustard have a particularly severe effect on the testis with relatively poor recoverability. In contrast, methotrexate has a minimal effect on the testis with excellent recoverability at 6 to 12 months. Pretreatment semen cryopreservation should be offered to young male cancer patients before initiating therapy. Recent animal studies by Meistrich and colleagues (276,277) have suggested a possible beneficial effect of luteinizing hormone–releasing hormone (LH-RH) agonist pretreatment in preserving spermatogenesis, but the role of this treatment in humans is still a largely unanswered question.

Illicit Drugs

Illicit drugs, including marijuana (225), cocaine (42,49), and heroin, may also impair spermatogenesis or affect sperm motility. Their use must be eliminated in couples trying to establish a pregnancy.

Dietary Supplements

Dietary supplements have experienced increasing popularity over the last decade, but their effect on male fertility is unknown, except in artificial laboratory conditions. Ondrizek and colleagues (307) briefly exposed donor sperm to echinacea purpura and St. John's Wort, resulting in sperm DNA denaturation. In contrast, saw palmetto and ginkgo had no effect, although the long-term potential effect of saw palmetto as a 5a-reductase inhibitor may be concerning. Further study in this area is needed.

Physical Examination

Physical examination of the infertile man should include a generalized and complete evaluation. Any factor that affects overall health can theoretically be responsible for abnormalities in sperm production; for that reason the physical examination should be thorough, with emphasis placed on the genitalia. If the patient appears to be inadequately virilized (androgen deficient), as evidenced by decreased body hair, gynecomastia, eunuchoid proportions, and so on, the diagnosis of delayed maturation due to an endocrine abnormality should be considered and appropriately evaluated. Penile curvature or the presence of tunical plaques should be assessed, as should the location of the urethral meatus. Abnormalities in these factors can result in improper placement of the ejaculate within the vaginal vault. The scrotal contents should also be palpated carefully with the patient in the upright position. Testicular size and consistency must be noted, and the length and width of the testes obtained to the nearest millimeter or the volume of the testis estimated with an orchidometer. It has been shown that a decrease in testicular size is often associated with impaired spermatogenesis (244). This is not surprising, because 85% of the testis is involved in sperm production; consequently, when the germinal epithelium atrophies, loss of testicular mass occurs. Standard values of testicular size have been recorded for the normal population. These data document that in the normospermic man, the length of the testis should be greater than 4 cm and the volume greater than 20 mL.

Examination of the peritesticular area is also critical. Epididymal induration, irregularity, and cystic changes should be noted, as should the presence or absence of the vas deferens and any nodularity along its course. Congenital bilateral absence of the vas deferens is found in approximately 1.4% of the infertile male population (20). Congenital vasal agenesis is characterized by complete or partial absence of both vasa deferentia. The caput epididymis is always present and is generally accompanied by a portion of the corpus or cauda. These individuals are generally found to have absent or abnormal seminal vesicles. The patients therefore have a low-volume acidic ejaculate and are invariably azoospermic. Experience has shown that testicular size is normal, and testicular function, in terms of both androgen production and spermatogenesis, is generally intact. Varicoceles represent an engorgement of the pampiniform plexus and can cause abnormalities of gonadal function (360).

Ideally, the patient should be examined in a warm room after standing for several minutes. Palpation for asymmetry of the spermatic cords followed by a Valsalva maneuver with repalpation of the spermatic cords should be routinely performed. An “impulse” can often be felt with the increase in intraabdominal pressure. Although venography candelineate the abnormal vessels, this is seldom necessary. Color Doppler sonography may be of some use in defining questionable lesions. Although this topic remains controversial, data exist that suggest, but do not prove, that correction of subclinical varicoceles may be beneficial in some subfertile men (272). Varicoceles can be classified according to size as follows: large, visible through the scrotal skin; moderate, easily palpable without increasing intraabdominal pressure; and small, palpable only with a concurrent Valsalva maneuver.

A scrotal varicocele is the most common surgically reversible abnormality found in the subfertile man (245) and is the most commonly identifiable abnormality in men with primary and secondary infertility (189) (Table 35.4). Whereas approximately 15% to 20% of the normal population can be found to have scrotal varices, this number approaches 40% in subfertile men (150). Not all varicoceles require surgical correction. However, if there is scrotal discomfort secondary to this lesion, if the testis ipsilateral to the scrotal varix is found to be atrophic, or if there is reasonable suspicion that impaired semen quality may be related to the presence of the varicocele, surgery should be considered. Bilateral varicoceles occur more frequently than previously reported; if the indications cited in the preceding sentence are present, bilateral varicoceles should be repaired concomitantly.

Diagnosis	Number	%
Varicocele	603	42

TABLE 35.4. CAUSES OF INFERTILITY: DISTRIBUTION ACCORDING TO FINAL DIAGNOSTIC CATEGORIES

A rectal examination may also be performed to evaluate the prostate and the seminal vesicles. Normally, the seminal vesicles are not palpable and the prostate is firm. Palpable seminal vesicles or a midline prostatic cyst may suggest ejaculatory duct obstruction and may require transrectal ultrasonography for verification.

Laboratory Tests

Endocrine

Although the extent of the hormonal evaluation is variable, an assessment of serum FSH and testosterone is commonly obtained. A more comprehensive evaluation would also consist of a serum LH and prolactin. In a retrospective review of a comprehensive evaluation at two infertility centers, only 99 of 1,035 men (9.6%) had abnormal endocrine studies on repetitive testing, with the majority having an isolated elevation of FSH levels (392). Only 1.7% had a clinically significant endocrinopathy that would have had an effect on disease management. The authors concluded that endocrinopathies are a rare cause of male infertility and that screening men with sperm counts of less than 10 million/mL with serum testosterone and FSH levels alone will detect the vast majority of clinically significant endocrinopathies.

The measurement of testosterone as a reflection of Leydig cell function may be especially useful if there is a history of delayed puberty, decreased libido, or impotence. Low levels of serum FSH and LH can help confirm the diagnosis of hypogonadotropic hypogonadism in an adult with incomplete sexual maturation. Gonadotropin deficiency in a sexually mature man suggests a pituitary tumor or another ablative cause of pituitary or hypothalamic damage. In these patients measurement of serum prolactin may be of diagnostic value, especially if galactorrhea is also present. However, in the routine evaluation of men with idiopathic infertility, measurement of serum prolactin is not frequently helpful. Estrogen determinations should be obtained if the patient has gynecomastia, is significantly obese, or is suspected to have end-organ resistance to testosterone. It has been suggested that a testosterone (ng/dL) to estrogen (pg/mL) ratio (T/E ratio) may help distinguish between types of underlying pathology, with a T/E ratio of 16 for normal men, 7 for men with nonobstructive azoospermia, and 4 for men with Klinefelter's syndrome (326).

A compensatory increase in FSH and LH can be found in response to testicular dysfunction, although LH changes are usually minimal. FSH, however, seems to increase progressively as the germ cells are lost and is almost always elevated when there is a marked reduction in the more mature sperm forms. An elevation of FSH greater than three times normal in the azoospermic or oligozoospermic patient strongly suggests severe spermatogenic failure. However, even azoospermic men with markedly elevated FSH levels may have sperm suitable for ICSI found on testis biopsy specimens (220).

Semen Analysis

Clinical studies of infertile patients have established limits of adequacy below which the initiation of a pregnancy becomes statistically increasingly difficult (Table

35.5). Nevertheless, men with high-quality spermatozoa may be fertile with very low sperm densities. Even men with sperm concentrations less than 10×10^6/mL, when treated medically for hypogonadotropic hypogonadism, are often fertile following medical therapy (387). A semen analysis is not a definitive test for fertility. Fertility determination requires the initiation of a pregnancy and therefore is a couple-related phenomenon. Furthermore, the interpretation of the semen analysis depends greatly on how the semen is collected and analyzed and how its normal values are defined.

On *at least* two occasions:	
Ejaculate volume	1.5–5.0 mL
Sperm density	>20 million/mL or >50–60 × 10^6 total sperm
Motility	>60%
Forward progression	>2+ (scale 0–4)
Morphology (routine)	>60% normal
And:	
No significant sperm agglutination	
No significant pyospermia	
No hyperviscosity or inadequate liquefaction	

From Lipshultz LI, Howards SS, eds. *Infertility in the male*, ed 3. St. Louis: Mosby, 1996, with permission.

TABLE 35.5. SEMEN ANALYSIS: MINIMAL STANDARDS OF ADEQUACY

Collection

Two to three semen analyses should be obtained for initial evaluation, although one analysis of very high quality may be sufficient for initial screening. All specimens should be collected with a consistent abstinence period of 2 to 3 days and brought to the laboratory for evaluation of sperm motility and forward progression within 1 hour of collection. If these specimens are within 20% of one another in terms of the bulk seminal parameters to be examined, it is usually not necessary to collect more specimens. If, however, the discrepancy is greater than 20%, additional specimens are needed.

The specimen container should be clean, not necessarily sterile, and wide mouthed to minimize collection error. Collection of the semen can be by masturbation or with a special condom or sperm collection device devoid of spermicidal agents. The first technique is preferable. The bottle label should indicate the patient's name, date, time of specimen collection, and abstinence period. It should be emphasized to the patient that an incomplete collection or one obtained following a prolonged or decreased period of sexual abstinence is not only inaccurate but often misleading.

Sperm Pellet

Semen centrifugation, referred to here as “sperm pelleting,” should be performed as a first, noninvasive method of sperm recovery in all men considered azoospermic by routine semen analysis, especially those with testicular failure and for whom ICSI is a possibility. Because ICSI requires only one sperm per oocyte, the finding of even several sperm has importance. A sperm pellet may be obtained by centrifuging a semen sample in a 15-mL conical tube for 10 minutes at 1,000 revolutions per minute (200 G) (184). Hyperviscous samples may be mixed with an equal volume of sperm-washing medium before centrifugation. After discarding the supernatant, the entire pellet is removed with a glass pipette, placed on a glass slide, and covered with a cover slip. The entire slide may then inspected by starting in one corner of the cover slip under 400× power using a left-to-right, right-to-left, “zigzag” pattern to ensure adequate examination. The exact number of sperm is recorded as either motile or nonmotile.

Sperm, both motile and nonmotile, may be found in the pellets of as many as 23% of men with unobstructed azoospermia and 19% with obstructive azoospermia on routine semen analysis (184). Similarly, Lemack and Goldstein (237) reported that 10% of men undergoing a vasectomy reversal had sperm found in a centrifuged pellet. The finding of sperm after centrifugation may save the patient from a more invasive procedure if ICSI is considered.

Safety Standards

Concerns regarding the transmission of infectious diseases via contamination from contact with body secretions, including semen, has led to the development of safety measures for the andrology laboratory. Guidelines call for the consistent use of gloves when handling semen or seminal plasma, use of safety glasses when handling frozen semen vials (which may explode while thawing), and use of surgical masks when there is a high potential for creating aerosols or droplets (such as centrifugation or vortexing of open containers). Centrifuges should be covered or placed in exhaust hoods during centrifugation of biologic fluids. Mechanical pipetting devices must be used, and pipetting by mouth must never be permitted (474).

Physical Characteristics

In accordance with the standardized techniques for semen analysis that have been reported (17,173,246), we allow the ejaculate to liquefy at 37°C for 30 minutes. Volume is measured in a graduated cylinder to the nearest 0.1 mL. A small drop of semen is mounted on a microscope slide with a coverslip for evaluation of motility, forward progression, and agglutination. An aliquot of a 1:20 dilution of semen (0.95 mL of distilled water and 0.05 mL of semen using an Eppendorf pipette) is placed on a hemocytometer for determination of sperm density and morphology.

Viscosity

Freshly produced semen is a coagulum that liquefies 5 to 25 minutes after ejaculation. The constituents of the semen responsible for coagulation originate in the seminal vesicles; the proteolytic enzymes that initiate liquefaction are found in the prostate. Following liquefaction, seminal fluid viscosity can be qualified. *Normal viscosity* is defined as occurring when the specimen can be poured “drop by drop.” Impaired liquefaction and increased viscosity remain equivocal causes of infertility and cannot be considered significant in the presence of a normal postcoital test.

Motility and Forward Progression

The motility of the sperm should be evaluated within 2 hours after the specimen is produced. If the specimen is then promptly refrigerated to prevent bacterial overgrowth, sperm density determinations can be delayed. *Motility* is defined as the average percentage of sperm moving in ten random high-power microscopic fields. If the count is low, motility can be more accurately quantitated. Estimates of motility by experienced individuals are highly consistent. The quality of motile sperm (the degree of forward progression) should also be observed. Classification of the quality of sperm movement is based on the pattern displayed by the majority of motile spermatozoa and ranges from 0 (no movement) to 4 (excellent forward progression).

Several investigators have designed tests to measure the velocity of motile sperm, but these require special computerized equipment and a trained technician and are not now widely used in routine clinical practice. Although velocity tests provide interesting data, they have not, thus far, significantly altered therapy. However, it is interesting to note that the average velocity of ejaculated sperm is 75 µmm per second (129). If none of the spermatozoa are moving, the patient is said to have “necrozoospermia.” This is actually a misnomer, because metabolic studies and special vital stains have revealed that the immotile spermatozoa may not necessarily be dead.

Agglutination

During the motility evaluation, any evidence of sperm agglutination should also be noted. Occasionally, clumps of agglutinated sperm are seen in semen specimens. However, increased clumping is suggestive of either an inflammatory or an immunologic process. Agglutination may be seen. In the absence of these conditions, sperm may agglutinate head to head, tail to tail, or head to tail.

Sperm Density

Spermatozoa are counted with a microscope at 400 power using the red cell section of a standard hemocytometer. Counting is faster if the spermatozoa have been allowed to settle to one focal plane. Five blocks of 16 squares each, representing one-fifth of the grid, are observed, and all spermatozoa within the area including those touching the lower and right-hand sides of each block are counted. This number is multiplied by 10^6. An average of two such readings represents the sperm density per milliliter. Alternative admixtures with corresponding changes in the calculations are suggested if the count is less than 5×10^6 (246). A Makler chamber is also commonly used with the microscope to determine density and motility (257).

Morphology

Human seminal cytology is a sensitive index of the germinal epithelium. Evaluation of the morphology of spermatozoa requires more patience and experience than determining sperm density or motility. Staining of the cells is preferable. Although a simple hematoxylin or more complicated Papanicolaou technique can be used, we prefer to use a small drop of fresh, well-mixed immobilized sperm and to observe this under the phase microscope. Using World Health Organization (WHO) criteria, cells are classified into one of five categories: normal (oval), amorphous (including large and small spermatozoa), tapered, duplicated, and immature. It has been shown that the morphologic classification of an individual's semen is remarkably consistent, and therefore a significant variation often reflects underlying testicular dysfunction.

Strict Morphologic Criteria

The morphology of human spermatozoa was first described by van Leeuwenhoek in 1677. During the last half century, various attempts have been made to enhance the evaluation of sperm morphology as part of the male fertility evaluation. Kruger and associates (230) made significant progress in defining a standardized technique for the evaluation of sperm morphology. They found that sperm located in the upper endocervical canal following intercourse were homogeneous in their morphology, and using these sperm as a reference population, they established strict criteria for morphologic evaluation (278).

The use of strict morphologic criteria for evaluating spermatozoa has found ready application in the area of IVF. Kruger and co-workers (230) performed 190 IVF cycles and evaluated their results as a function of sperm morphology. They observed a distinct threshold among patients having a percentage of sperm with normal morphology of 14% or lower. Pregnancy rates were markedly lower in this group than in couples in whom the male had exhibited 15% of sperm or greater having normal morphology. Further investigation showed that patients who have less than 4% of sperm with normal morphology are in a particularly poor prognostic group. Such individuals have achieved extremely low fertilization rates during IVF procedures (229). With use of a potentially less labor-intensive method, normal sperm morphology as evaluated by an automated semen analyzer was also found to be a significant predictor of IVF and pregnancy (81). However, the role of strict morphology analysis in non-IVF clinical settings is not clear.

Computer-assisted Semen Analysis

Several other techniques have been used in further study of sperm function. Computer-assisted semen analysis (CASA) has been widely investigated (212,254,443). To date, there is no conclusive evidence that it adds significantly to the clinical evaluation of the infertile patient. However, its ability to look objectively at sperm movement and especially at hyperactivation (347) may give a new dimension to our understanding of change in sperm movement in association with capacitation.

Semen White Blood Cell Assays

Wolff and colleagues (469) have shown that infertile men have higher white blood cell (WBC) counts in their ejaculates compared with normal men. Compared to the WHO definition of 1×10^6 cells/mL or below as normal for WBCs in the ejaculate, 23% of 179 infertile men had white cell counts above this normal range. Along with this inflammatory infiltrate, evidence is accruing that harmful substances such as cytokines and reactive oxygen species (ROS) may be secreted by such cells and further harm sperm motility and viability (9).

In a standard semen analysis, the round cells often visible may represent immature germ cells or leukocytes. Many laboratories erroneously report immature spermatogenic cells as being “leukocytes.” Monoclonal antibody assays are especially useful in the identification of leukocytes in semen, but they are expensive and not widely available (468). As an alternative, the peroxidase test is commonly used. The test is done by mixing 20 µmL of liquefied ejaculate with 20 µmL of peroxidase test working solution. This incubates for 5 minutes at room temperature. Then, 20 µmL of this solution is added to 20 µmL of saline immediately before counting. Ten microliters of the diluted specimen is loaded into a hemocytometer, and peroxidase-positive (intensely brown-stained round cells), as well as peroxidase-negative (unstained), round cells are counted at 400× magnification. Antibody-positive cells are stained red, and nonpositive cells are stained blue. The total number of WBCs per milliliter of semen is calculated by multiplying the percentage of positive cells by the total number of round cells per milliliter.

Biochemical Assays

The seminal vesicles contribute fructose and prostaglandins to the semen, and the prostate secretes zinc, magnesium, dehydrogenases, immunotransferases, citric acid, phosphate, and spermine. Several of these factors have been investigated extensively. Few, if any, of these studies have proved to be clinically useful. Production of fructose is an androgen-dependent process. Its presence should be determined qualitatively in any azoospermic patient and especially in those whose ejaculate volume is less than 1 mL, suggesting the possibility of ejaculatory duct obstruction or seminal vesicle atresia or hypoplasia. Transrectal ultrasound evaluation of the seminal vesicles adds valuable information in these patients, as discussed later in more detail. A colorimetric technique using a resorcinol reagent is best for fructose determination.

Genetic Evaluation

Genetic abnormalities related to male infertility must be considered in terms of being (a) causative for male infertility and (b) potentially transmissible to the offspring. When examining the offspring, the physician should keep in mind that abnormalities may be transmitted from either parent, or may arise *de novo,* depending on the specific defect. Present genetic screening of azoospermic and severely oligozoospermic men with testicular failure consists of Y chromosome microdeletion testing and karyotyping. In a consecutive series of 190 azoospermic men with secondary testicular failure undergoing testicular sperm extraction for ICSI, 17% had genetic abnormalities identified with screening (353). Those men with congenital absence of the vas deferens (CAVD) or unexplained bilateral obstruction should be offered cystic fibrosis gene mutation testing. Although somewhat expensive, these tests are necessary for proper genetic counseling regarding the potential for transmission of undesirable genes to the offspring. These tests are clearly only a starting point for genetic testing, as we decipher the genetic code regulating male infertility (Table 35.6).

Genetic Test	Abnormality
Cystic fibrosis gene mutation	Congenital absence of the vas deferens
DAZ gene mutations	Azoospermia, severe oligozoospermia
Karyotype analysis	Variable (e.g., Klinefelter's syndrome, XXY male)

TABLE 35.6. TESTING HUMAN GENETIC ABNORMALITIES RELATED TO MALE INFERTILITY

Cystic Fibrosis Gene Mutations

Men at risk for cystic fibrosis (CF) gene mutations have vasal or epididymal abnormalities, typically in combination with low-volume azoospermia. If the vas deferens is not palpable, CF gene mutation testing is recommended (Fig. 35.10). The most commonly encountered condition in this category is cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations. The most common presentation is congenital bilateral absence of the vas deferens, which occurs in 1% to 2% of men with infertility (150,197). The carrier status for this autosomal- recessive condition is common, being present in 1 out of 25 persons of Northern European descent and with over 550 CFTR gene mutations having been reported (96). Because of the potentially fatal nature of this autosomal- recessive disorder for the offspring, screening should now be considered routine when vasal or epididymal abnormalities are suspected.

FIGURE 35.10. Algorithm for male infertility evaluation—overview.

The CF gene is located on chromosome 7 at 7q31. The CFTR is 250 kb in length and contains 27 exons. µDF508 is a three–base pair deletion in exon 10 and accounts for approximately 70% of CF alleles (216). Testing should also be performed for the 5T (thymidine) allele on intron 8 because of the high frequency of abnormal findings. Chillon and colleagues (75) characterized the mutations in the CFTR gene in 102 patients with congenital bilateral absence of the vas deferens (CBAVD) and also analyzed a DNA variant (the 5T allele) in a noncoding region of CFTR that causes reduced levels of the normal CFTR protein. Studies of CFTR mRNA in tissues from normal persons have identified various mRNA molecules that lack exon 4, 9, or 12. Whether or not CFTR mRNA contains exon 9 depends on the variable length of a stretch of thymine residues in intron 8 of CFTR. This sequence, known as a *polyT sequence,* contains 5, 7, or 9 thymines (the 5T, 7T, and 9T alleles, respectively). Because the 5T allele causes reduced levels of normal CFTR mRNA, this variant would appear likely to be involved in the pathogenesis of CBAVD. In 19 of the 102 patients, mutations in both copies of the CFTR gene were found, and none of these had the 5T allele. A mutation was found in one copy of CFTR in 54 patients, and 34 of them (63%) had the 5T allele in the other CFTR gene. No CFTR mutations were found in 29 patients, but seven of them (24%) had the 5T allele. Chillon and colleagues (75) concluded that the combination of the 5T allele in one copy of the CFTR gene with a CF mutation in the other copy is the most common cause of CBAVD. The 5T allele mutation has a wide range of clinical presentations, occurring in patients with CBAVD or moderate forms of CF and in fertile men.

These CFTR gene mutations may result in wolffian duct (epididymis, vas, secondary involvement as absence of a kidney) abnormalities as the only somatic manifestation, because sperm production is typically normal. Other clinical manifestations include unilateral renal agenesis and seminal vesicle aplasia or hypoplasia, with the latter condition often resulting in low semen volumes. We routinely obtain a renal ultrasound in men with vasal agenesis. Schlegel and colleagues (369) observed that renal agenesis is evident in about 11% of men with bilateral and 26% of infertile men with unilateral congenital absence of the vas deferens. Ipsilateral renal ectopia, crossed-fused renal ectopia, and horseshoe kidneys have also been observed. When renal anomalies coexist with CAVD, a defect in the wolffian duct at or before the formation of the ureteral bud at 7 weeks results in malformation of the entire wolffian duct and subsequent vasal agenesis.

Between 50% and 82% of men with CBAVD and approximately 43% with unilateral absence of the vas deferens will have at least one detectable CFTR gene mutation (20,107,369). Furthermore, Jarvi and colleagues (195) reported that at least 47% of otherwise healthy men with idiopathic epididymal obstruction had a CFTR gene mutation.

If the man is a carrier of a CF gene mutation and ICSI is a consideration for the couple, his partner should be tested. If the partner is a carrier of the same mutation, rules of autosomal-recessive inheritance are followed. The offspring will have a 1 in 4 chance of having full-blown cystic fibrosis, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of having no gene mutations. Another viewpoint for testing for CFTR mutations is to assume that all men with CBAVD have a mutation, but that not all mutations are detected because of limited allele testing, typically for only 30 of the most common loci. Testing of the wife alone is then indicated. If both are carriers of the mutation, preimplantation blastomere biopsy analysis may be performed by several U.S. and U.K. specialty research centers under investigational protocol.

In men with CBAVD after sperm harvesting from the epididymis, pregnancy rates of up to 50% per cycle have been obtained with ICSI, in contrast to 10% with standard IVF (374,396). These excellent outcomes make genetic counseling and screening of the patient's wife important given the severity and risk of transmission (autosomal-recessive inheritance) of the classic form of cystic fibrosis. Approximate cost for this test, obtained from a peripheral blood specimen, is $300.

Y Chromosome Microdeletions

When testicular failure is manifest by azoospermia or severe oligozoospermia, we routinely screen for Y chromosome microdeletions and karyotype analysis if the couple is considering ICSI. Although the definition of severe oligozoospermia is debatable, we place a patient in this category if his sperm density is less than 5 million sperm/mL. Structural chromosomal abnormalities of the Y chromosome were initially suspected as having a role in male infertility by Tiepolo and Zuffardi (421) as early as 1976, but their findings and significance did not exert much clinical impact until the introduction and widespread use of ICSI.

It is well established that the long (q) arm of the Y chromosome is required for spermatogenesis. In the early 1990s, Ma and colleagues (253) and Chandley and Cooke (67) demonstrated that microdeletions on the Y chromosome were associated with infertility. The specific region of the Y chromosome implicated in male infertility based on mapping studies is called the azoospermia factor locus (AZF), present in band q11.23 (28). Four distinct interstitial deletions causing azoospermia or severe oligozoospermia occurring in nonoverlapping subregions of Yq11 are called AZFa, AZFb, AZFc, and AZFd (453). These subregions appear to regulate different stages of spermatogenesis. Testicular biopsies in these men have demonstrated a range of spermatogenic defects from Sertoli cell–only syndrome (no sperm-forming elements) to maturation arrests (sperm-forming cells present, but not mature sperm) at the spermatid stage (344). Deletions of the AZFb region especially have been correlated with the absence of mature spermatozoa and presence of round spermatids in testis biopsy specimen (53). AZFc coincides with the DAZ gene (deleted in azoospermia), which is a novel transcription unit that is usually present in the AZF region in men of normal fertility. Deletions of the DAZ gene result in severe impairments of spermatogenesis, but not always. AZFd, associated with mild oligozoospermia or even normal sperm counts associated with abnormal sperm morphology, has also been recently described (215).

Deletions in the DAZ gene are present in 10% to 15% of otherwise normal 46,XY men with nonobstructive azoospermia (295,344,452). (Table 35.7). This defect is clearly phenotypically diverse, because approximately 6% to 10% of men with severe oligozoospermia (sperm density less than 5 million sperm/mL) have this deletion (337,407). In contrast, DAZ deletions are found in only approximately 2% of normal men.

TABLE 35.7. MICRODELETIONS IN DAZ IN PATIENTS WITH OLIGOZOOSPERMIA AND AZOOSPERMIA

The immediate concern of this DAZ gene microdeletion is that transmission to the offspring may occur (68,224). The male offspring may have a similar infertility-type problem, but the answer may not be apparent for at least another decade. Interestingly, some fathers of infertile men with microdeletions have been found to have the identical deletions as their sons, whereas other microdeletions appear to arise *de novo* (214,312,337). Furthermore, it is unknown whether the male offspring may have other, presently unidentified, potential for increased abnormalities such as malignancies. Thus far, no untoward effects have been observed. Interestingly, after genetic counseling, the decision to proceed with ICSI remains unchanged for the overwhelming majority of couples (296). Approximate cost for this testing is $250 to $300.

Karyotyping

Karyotyping can uncover genetic abnormalities, including structural chromosomal disorders such as Klinefelter's (classic 47,XXY), mixed gonadal dysgenesis, chromosomal translocations, and XYY syndromes. For example, Klinefelter's syndrome is relatively common, with an incidence of 1 in 500 live male births, and the XYY male syndrome occurs in about 1 in 1,000 live births. These conditions are easily assessed from a peripheral blood smear for karyotyping. Identification of these disorders is important because with the advent of ICSI, men with abnormalities such as mosaic (118,231) and nonmosaic (300) Klinefelter's syndrome can have sperm harvested from testis biopsies and initiate a pregnancy with resultant genetically normal embryos (316). The incidence of these abnormalities is markedly increased above baseline population levels (267,279). The approximate cost for this analysis is $300.

It has been suggested that all men with severe male factor infertility have this cytogenetic analysis performed because of an increased risk for chromosomal translocations. In a study of 261 couples with male factor infertility, abnormal karyotypes were found in 4.2% of the men and 1.2% of the women (415). Five of eight fetuses from the 14 involved couples were found to have inherited a structural chromosomal abnormality. Meschede and associates (279) from Germany found a 2.1% chromosomal abnormality rate in men. Similarly, Pandiyan and Jequier (319) found that 3.6% of 1,201 men with abnormal semen analyses had either autosomal or sex chromosomal aberrations. Other ICSI series having a predominant male factor have similar findings (Table 35.8).

TABLE 35.8. ABNORMAL KARYOTYPE RATES IN MEN WITH SEVERE MALE FACTOR INFERTILITY

Chromosomal abnormalities detected in the offspring of male factor couples undergoing ICSI may be inherited from the father or mother, or may arise *de novo* in a nonfamilial fashion. In a very small series, In't Veld and colleagues (180) raised concerns in 1995 when they reported four (27%) cytogenetic abnormalities in 15 pregnancies initiated by ICSI. However, these pregnancies were screened because of advanced maternal age, and the series was small. Wisanto and colleagues (465), in contrast, studied a younger population and identified only six (1%) chromosomal abnormalities using chorionic villus sampling or amniocentesis from 585 prenatal diagnoses.

Algorithms for Evaluation of the Infertile Male

After performing a detailed history, a physical examination, and several semen analyses, hormonal testing may be obtained. Although it is difficult to summarize all facets of the evaluation of the infertile male, the following algorithms will help in providing a framework. After the initial evaluation, male factor infertility may be generalized into the following groups: azoospermia; decreased sperm density, motility, or morphology; hypogonadism; and no abnormality (Fig. 35.11). This categorization allows the clinician a method for obtaining pertinent information, to translate this information into a useful therapeutic plan, and to convey this information in a meaningful fashion to the patient.

FIGURE 35.11. Algorithm for evaluation of azoospermia. FSH, follicle-stimulating hormone.

Evaluation of the Azoospermic Male (Fig. 35.12)

FIGURE 35.12. Algorithm for evaluation of impaired semen parameters. FSH, follicle-stimulating hormone; EJDO, ejaculatory duct obstruction; ICIS, intracytoplasmic sperm injection; IUI, intrauterine insemination; TRUS, transrectal ultrasound.

Azoospermia on a routine semen analysis should be confirmed by examining a sperm pellet after centrifugation of the specimen. Even the finding of rare sperm has significance with ICSI. Consideration should be given to whether an obstruction or spermatogenic failure is present. A markedly elevated serum FSH level and testicular atrophy suggest spermatogenic failure. If spermatogenic failure is suspected, a testicular biopsy will be diagnostic and potentially therapeutic when sperm harvesting is successful. If the couple is considering ICSI, a Y chromosome analysis for microdeletions and a karyotype analysis may identify an underlying genetic defect in up to 17% of men (353). Genetic counseling should be offered to those couples with abnormal genetic testing. If sperm can be identified on testicular biopsy or in the semen pellet, ICSI is an option. Other couples may choose donor sperm intrauterine inseminations or adoption based on financial and personal preference.

If an obstruction is suspected, the volume of the ejaculate and perhaps a fructose determination will determine the direction of the evaluation. If the volume is normal, an obstruction within the vas deferens or epididymis may be present. A testis biopsy will confirm the presence of active spermatogenesis. The site of the obstruction may be identified with a vasogram performed at the same time as microsurgical reconstruction. If sperm are identified, the couple should be offered cryopreservation.

If the ejaculate volume is low, an ejaculatory duct obstruction or retrograde ejaculation may be causative. A postejaculate urine (PEU) will definitively determine the presence of retrograde ejaculation, which may be initially treated with sympathomimetic agents. Sperm within the bladder may be used for intrauterine insemination. If the PEU contains no sperm, a testis biopsy will be necessary to determine the underlying problem.

If the semen volume is low or the semen fructose (produced by the seminal vesicles) is absent, an ejaculatory duct obstruction should be suspected. Transrectal ultrasound (TRUS) is the method of choice for evaluating the prostate for an obstruction. Dilated seminal vesicles are typically present with an obstruction. If the TRUS findings are equivocal, seminal vesicle aspiration and vesiculography will provide a definitive answer. Ejaculatory duct obstructions may be successfully treated with a transurethral resection.

Vasal agenesis is diagnosed with physical examination and can usually be confirmed with TRUS of the seminal vesicles. Other clinical clues include azoospermia and a low-volume ejaculate. Further details are provided in the section on genetic evaluation.

Abnormal Density, Motility, and Morphology (Fig. 35.13)

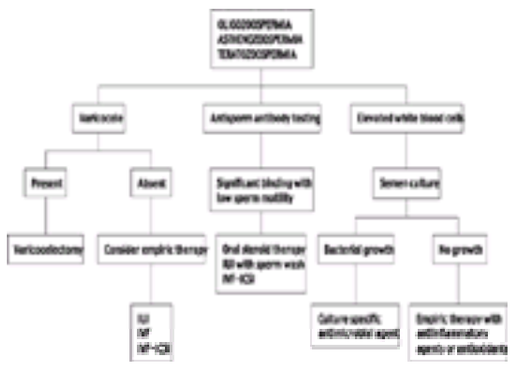

FIGURE 35.13. Algorithm for evaluation of a low serum testosterone level. IUI, intrauterine insemination; IVF, *in vitro* fertilization; IVF-ICIS, *in vitro* fertilization with intracytoplasmic sperm injection.

The differential diagnosis of abnormal semen quality includes the presence of a varicocele, presence of antisperm antibodies or WBCs, or no identifiable cause. The varicocele represents the most commonly identifiable anatomic abnormality associated with impaired semen parameters. In the absence of other significant causative factors, varicocele repair may be offered to the patient. If a varicocele is not present and the semen quality cannot be otherwise improved, intrauterine insemination (IUI), IVF, and IVF with ICSI (IVF-ICSI) may be offered to the couple. For IUI, the semen specimen is first processed using one of a variety of sperm-washing techniques. In general, best results for pregnancy outcome are obtained if the total number of motile sperm inseminated is greater than 5×10^6 and if the woman is treated with controlled ovarian hyperstimulation (62,105,176). A minimum of 500,000 to 1,000,000 motile sperm are necessary. As a general rule of thumb, sperm-washing procedures will remove approximately 50% of motile sperm from the semen specimen. IVF is optimal for female factor infertility, when the male factor is relatively normal. The indications for IVF-ICSI are discussed in detail later in this chapter.

The presence of antisperm antibodies can be determined in serum or semen by a variety of techniques (288). The immunobead test (IBT) is currently the antibody assay of choice in most laboratories and is considered positive when the antihuman Ig second antibody (bound to a bead) attaches to its target antibody on the surface of a swimming sperm as noted by bead attachment to the sperm on a microscopic slide. The percentage of motile sperm with visibly bound beads is then scored by IgG or IgA binding and by location of bead binding (58). Although each laboratory has its own criteria of percent binding necessary to achieve clinical significance, most consider clinically positive levels to be greater than 15% to 20% bound. Fertility potential declines as the antisperm antibody titer in the seminal plasma increases or if there are any antisperm antibodies in the seminal fluid (264). Measurement of antisperm antibody titers in the man's serum, the indirect method, is not routinely performed because it is the seminal plasma levels that are significant. Treatment of significant antisperm antibodies is most effectively addressed with IVF-ICSI.

When elevated seminal WBCs are present, a semen culture should be obtained. It is important to distinguish round cells, which may represent immature germ cells, from WBCs. Culture-positive semen may be treated with antimicrobial agents. Culture-negative WBC elevations may be treated with antiinflammatory agents and antioxidants, although demonstration of a clear benefit is still being determined.

Isolated abnormal seminal parameters occur in 37% of all patients with infertility and include low or high volumes, hyperviscosity, impaired motility or forward progression, and low sperm density. Patients may have an isolated disturbance or a combination of abnormalities in any of these parameters. Motility disorders are the most common (26%) isolated abnormality (Table 35.9) (247).

Azoospermia	8
Predominance of single abnormal parameter	37

TABLE 35.9. DISTRIBUTION OF SEMEN ABNORMALITIES IN 200 PATIENTS (%)

When isolated bulk parameters are being evaluated, a simple first step is to measure the semen volume. When semen volume exceeds 5.5 mL, sperm washing and concentration followed by IUI can be considered. If, however, the ejaculate volume is less than 1 mL, a collection error or retrograde ejaculation and the possibility of ejaculatory duct obstruction must be ruled out. Low volumes may also represent a rare hypoandrogenic state in which endocrine replacement therapy may be of benefit. Decreased ejaculate volumes may also be treated with IUI following seminal fluid washing. If viscosity is abnormally high, sperm processing with chymotrypsin should be considered.

Hypogonadism (Fig. 35.14)

FIGURE 35.14. Algorithm for evaluation of vasal agenesis. FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging.

A low testosterone level should be reconfirmed with a testosterone level in the early morning, when testosterone levels are the highest. To minimize the effect of GnRH pulsative activity on testosterone secretion, a common method is to obtained a pooled sample over 30 minutes. A free testosterone, FSH, LH, and prolactin should also be drawn. When FSH and LH are both decreased, this pattern is consistent with hypogonadotropic hypogonadism and may be associated with deficiencies in other pituitary hormones (panhypopituitarism) or as an isolated impairment in GnRH secretion. A history of anabolic steroid abuse should be identified. Replacement therapy with human chorionic gonadotropin (hCG) and human menopausal gonadotropin (hMG) should be initiated (see section on medical therapy). The decrease in gonadotropins may also be secondary to a pituitary tumor with an associated increase in serum prolactin. If the prolactin level is elevated or if there is clinical evidence of a pituitary tumor, further pituitary evaluation is indicated. This should include evaluation of serum levels of adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and growth hormone (GH) and magnetic resonance imaging (MRI) of the sella turcica.

No Abnormality

Some infertile men have “normal” bulk parameters in the routine semen analyses. If careful evaluation of their wives has revealed no abnormalities, or if problems adequately treated do not result in a pregnancy, more sophisticated testing of sperm function is in order. These men may then be evaluated through such tests as the sperm penetration assay (SPA) (hamster test) (475) or *in vitro* sperm migration through cervical mucus (13). If the sperm penetration assay is “normal,” further evaluation of the female factor is in order; if the sperm penetration assay is “abnormal,” reevaluation of the male factor should be undertaken.

Diagnostic Procedures

Transrectal Ultrasonography and Ejaculatory Duct Obstruction

Men with ejaculatory duct obstruction typically seek treatment initially because of primary infertility and azoospermia or severe oligoasthenozoospermia. Perineal pain and discomfort, hematospermia, pain with ejaculation, and epididymal pain have also been reported (458). Absolute indications for performing TRUS include low-volume azoospermia in the absence of testicular atrophy and low-volume severe oligoasthenozoospermia, when retrograde ejaculation is not present. A caveat is that although low-volume ejaculates are often present, a low normal–volume ejaculate does not exclude an ejaculatory duct obstruction (65). Another absolute indication for performing TRUS is the presence of a midline cyst or asymmetry palpated on digital rectal examination.

When an ejaculatory duct obstruction is suspected, TRUS should be the initial diagnostic modality (471). Previously, vasography, which is still considered the gold standard test, had been the only reliable way to evaluate a distal ductal obstruction. The invasive nature of vasography, with its attendant risk for vasal scarring, makes TRUS the ideal screening test. Although endorectal coil MRI can provide a highly detailed anatomic depiction of the pelvis, because of lesser costs and wider availability, TRUS remains the procedure of choice for imaging the ejaculatory ducts and prostate.

The ejaculatory duct measures approximately 4 to 8 mm in diameter with a 2-mm lumen (338) and may be difficult to image in its typically nondilated state. The ejaculatory duct is formed by the confluence of the seminal vesicle and the terminal ampullary portion of the vas deferens. The ampulla of the vas deferens can be imaged in both the transverse and sagittal planes. They appear as a pair of oval, convoluted, tubular structures medial to the seminal vesicles and cephalad to the prostate. The obstructed lumen of the ejaculatory duct may be best appreciated in sagittal images as a hypoechoic tubular structure entering the urethra at the level of the verumontanum. When dilation is evident, imaging for possible causes of obstruction is advisable (338). Ejaculatory duct cysts, ejaculatory duct calcification, ejaculatory duct dilation, and seminal vesicle dilation visualized on TRUS are all consistent with ejaculatory duct obstruction (Fig. 35.15 and Fig. 35.16).

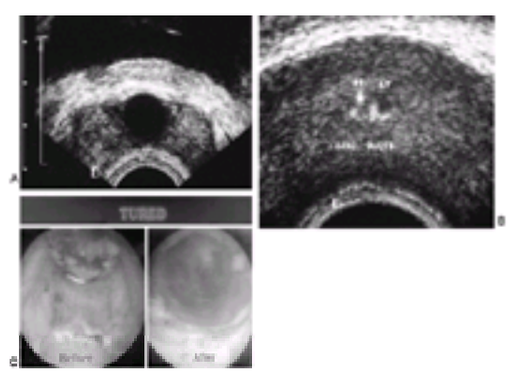

FIGURE 35.15. A: Large ejaculatory duct cyst. **B:** Ejaculatory duct calcifications, more extensive on the right. **C:** *Left panel*– the midportion of the verumontanum and the floor of the prostate distal to the bladder neck have been marked with loop cautery. This area represents the roof of the ejaculatory duct cyst. *Right panel*– after transurethral resection of this ejaculatory duct cyst, a smooth-walled cavity is identified. With further observation, efflux of milky white fluid may be observed.

FIGURE 35.16. Seminal vesicle dilation in a patient with an obstructing ejaculatory duct cyst. If the width, 18.6 mm in this case, is greater than 15 mm, ejaculatory duct obstruction should be suspected.

Intraprostatic cysts causing obstruction of the ejaculatory duct may be of müllerian duct, wolffian duct, or prostatic origin. Also known as *utricular cysts,* müllerian duct cysts are midline in location and do not contain sperm. In a series of 150 consecutive infertility patients, Jarow (186) demonstrated an 11% incidence of müllerian duct cysts in contrast to 0% in the control group. Wolffian duct cysts, also known as *ejaculatory duct diverticula,* are also located in the midline. These cysts do contain sperm and may be produced by a distal obstruction of the ejaculatory duct. Prostatic retention cysts are located in the periphery of the prostate and do not contain sperm. Jarow (186) found these cysts in 4 of 150 infertility patients.

The seminal vesicles, which are paired, symmetric, saccular, elongated organs that lie cephalad to the prostate and posterior to the bladder, should be carefully examined. Best visualized with transverse imaging and having a typical “bow-tie” appearance, they are homogenous with a few fine internal echoes. Serving as reservoirs of seminal fluid, the seminal vesicles have mean dimensions of 3.0 ± 0.8 cm in length, 1.5 ± 0.4 cm in width, and 13.7 ± 3.7 mL in volume (250,338,412). No significant change in volume has been demonstrated after ejaculation (164). The vasal ampulla have a mean diameter of 0.4 ± 0.1 cm and are best visualized in transverse section just medial to the seminal vesicles. Ejaculatory duct obstruction often, but not always, is associated with seminal vesicle dilation. Although obstruction should be suspected in patients with a transaxial seminal vesicle width of greater than 1.5 cm (65,250,274), seminal vesicle dilation does not occur in every patient. Asymmetry, however, should raise suspicions for ejaculatory duct obstruction.

As many as 90% of men with unilateral CAVD will have aplasia of the ipsilateral seminal vesicle, and as many as 20% may have aplasia of the contralateral seminal vesicle (154). In one series of men with CBAVD, 16% had bilateral aplasia of the seminal vesicles, and 21% had unilateral seminal vesicle aplasia and contralateral seminal vesicle hypoplasia (232).

TRUS is indicated in men with severe oligozoospermia and a low-volume ejaculate because a partial ejaculatory obstruction may be present (354). Although a partial ejaculatory duct can cause a low-volume, severe oligozoospermia, a functional ampullovesicular seminal tract disorder must also be considered (84). Patients with partial ejaculatory duct obstructions treated with transurethral resection of the ejaculatory ducts (TURED) had improvement in semen quality in 72% of cases, with 54% of improved men initiating a pregnancy (274).

Ejaculatory Duct Obstruction and Seminal Vesiculography

A recent advance has been TRUS-guided seminal vesiculography for those patients with suspected ejaculatory duct obstruction. The previous test of choice was vasography, an open surgical technique carrying a risk of iatrogenic vasal scarring. An alternative was cystoscopic cannulation of the ejaculatory ducts with retrograde infusion of contrast, a relatively difficult technique. TRUS-guided seminal vesiculography combined with seminal vesicle aspiration can effectively diagnose ejaculatory duct obstruction with substantially lower risks of vasal scarring.

The seminal vesicles may be aspirated using a 35-cm-long, 21-gauge Williams needle (or a 30-cm-long, 17-gauge oocyte retrieval needle). The patient should receive an enema and fluoroquinolone antibiotics before the procedure, in similar fashion to a prostate biopsy. The presence of numerous motile sperm in the seminal vesicles is highly suggestive of obstruction at the ejaculatory duct in men with azoospermia or severe oligozoospermia (187). Because numerous motile sperm are not typically observed in the seminal vesicle aspirate from a normal patient, it is believed that in a complete ejaculatory duct obstruction, sperm can reflux into the seminal vesicles. One report suggests that aspiration should be performed immediately after ejaculation (within the same day), because small numbers of sperm may be found in the seminal vesicles in normal men with just 5 days of abstinence (188). After aspiration, seminal vesiculography using methylene blue and a dilute nonionic contrast may be performed. Fluoroscopy, combined with radiographs after instillation of 5, 10, and 20 mL of contrast, provides ideal imaging. We have found the use of intraoperative flexible cystoscopy helpful in visualizing the egress of methylene blue from the ejaculatory duct. The pelvic and inguinal portions of the vas deferens may be seen in some patient (346).

Vasography

The primary indication for vasography is the assessment of vasal obstruction within the inguinal vas deferens. An inguinal vasal obstruction should be suspected in an azoospermic patient with normal spermatogenesis and a history of prior inguinal or scrotal surgery. In this situation, vasography should be performed only at the time of a potential microsurgical reconstruction.

Another situation in which we perform vasography is during a vasovasotomy or vasoepididymostomy. In these cases, we do not typically use contrast, but, rather, flush 10 mL of saline toward the prostate. If resistance is encountered, raising suspicions for an obstruction, methylene blue may be added to the irrigating solution, or formal vasography may be performed. Alternatively, a 0 Prolene suture may be gently threaded within the vas deferens toward the prostate. The length of suture passed is used to estimate the site of obstruction.

The open vasogram is performed by creating a hemivasotomy, or partial transection, at the junction of the straight and convoluted portions of the vas deferens. A 25-gauge, 0.5-inch angiocath sheath is gently placed into the prostatic end of the vas deferens and a dilute nonionic contrast injected. One should never inject the contrast toward the epididymis because of the potential for damaging the delicate epididymal tubules. Tilting the table approximately 15 degrees caudally (reverse Trendelenburg) allows the best-quality radiographs to be obtained because the potential blocking effect of the symphysis pubis is avoided. For normal criteria, the reader is referred to a study by Banner and Hassler (25). The presence of obstruction is confirmed by identifying the site of blockage, as well as evidencing resistance to the injection of the contrast. If methylene blue has been added to the nonionic contrast, a small urethral catheter may be placed into the bladder to assess for the blue discoloration if the diagnosis is still in doubt.

If an epididymal obstruction is suspected based on the finding of dilated epididymal tubules and the lack of distal obstruction, an epididymovasostomy should be performed at the same operative setting. If an inguinal vas deferens obstruction is diagnosed, one should proceed with a vasovasostomy. If an ejaculatory duct obstruction is diagnosed, the hemivasotomy site should be closed with standard microsurgical technique. We use interrupted 10-0 nylon sutures for the inner layer, and interrupted 9-0 nylon sutures for the outer layer.

Alternatively, the puncture technique employs a 30-gauge lymphangiogram needle placed through the wall of the vas deferens in the direction of the prostate. Contrast or saline may then be injected distally. In less experienced hands, one risks creating submucosal false passages within the vas deferens if the lumen is not

entered properly. The puncture technique and a partial-thickness vasotomy have been compared in a rat model with the findings that fertility studies, vasal patency, sperm granuloma formation, and flow characteristics were roughly equivalent (336).

Sperm Penetration Assay and Mucus Migration Tests

The sperm penetration assay takes advantage of the fact that most of the species' specificity in hamster ova is determined by the zona pellucida, which is easily removed by enzyme digestion. Since its initial description, the SPA (hamster test) has become popular in many clinical research laboratories as an *in vitro* test of sperm function and as a research tool for investigating the mechanism of fertilization. A survey of the available literature, however, reveals wide variability in the techniques and subsequent results reported from individual laboratories (282,303,309,348). Consequently, controversy persists as to what constitutes a negative assay and therefore a truly infertile patient. Although some investigators have arbitrarily set limits of less than “10% penetrated ova” to define an abnormal and, hence, infertile state, a disturbing number of false-negative findings have been detected when this level of discrimination has been used. Optimization of the SPA with very few false-negative results has been reported from our laboratory (202,203 and 204). Whereas other investigators define fertility in the SPA with respect to the percentage of total ova penetrated, our optimized assay conditions provide a more sensitive analysis, which we report as the sperm capacitation index (SCI), or sperm penetrations per hamster ovum. Of those patients who had a favorable IVF cycle (fertilizing at least 31% of the human ova), only 4 of 53 had an SCI less than 5, yielding a false-negative rate of 7%. In addition, of those patients who had a poor IVF cycle (fertilizing less than 31% of the human ova), none had an SCI greater than 5, yielding no false-positives in this group. Furthermore, no pregnancies have resulted from patients with an SCI less than 5.

Although the SPA may furnish important information as to the processes that occur once the sperm reaches the zona-stripped ova, abnormalities that affect migration of the sperm along the female reproductive tract are not taken into consideration. The postcoital test, or Sims-Huhner test, has been used for more than 60 years to measure the ability of sperm to migrate through the cervical canal (299). Unfortunately, because no standards have been established for this type of evaluation, the results may be difficult to interpret. Variations in human cervical mucus such as quantity, pH, or viscosity may impede the ability of sperm to progress through the cervical canal. The discovery that bovine cervical mucus closely resembles human cervical mucus in its biochemical and physiologic properties has allowed the creation of a uniform cervical mucus system, the Penetrak test, for analyzing this aspect of human sperm function. Liquefied semen was placed in a sample cup, and Penetrak tubes were inserted vertically in the cup and incubated for 90 minutes. The distance traveled by the farthest-moving sperm was recorded in millimeters.

Although the Penetrak assay provides reproducible information regarding the ability of sperm to penetrate bovine cervical mucus, it provides no information about the status of the cervical mucus of the patient's partner. The Tru-Trax system is similar in concept, but it can use human cervical mucus. The distance traveled by the farthest-traveling sperm is then evaluated after a 30-minute incubation (299).

Hemizona Assay

The hemizona assay provides a means of assessing the ability of sperm to bind to the zona pellucida of the human egg, a critical step in fertilization (27). This test is of historical significance because of the requirement of human ova and the availability of ICSI. In this assay, the divided halves of an oocyte are incubated separately with donor and patient sperm. A hemizona index is derived by dividing the number of bound donor sperm by the number of bound patient sperm. Researchers have found that hemizona assay results correlate with IVF rates.

Hypoosmotic Swelling Test

Jeyendran and colleagues (199) reported that under hypoosmotic conditions (150 mOsm/L), a normal spermatozoon will absorb fluid resulting in bulging of the plasma membrane and curling of its tail. This test is based on the principle that a living spermatozoon can maintain an osmotic gradient whereas a dead cell cannot. This curling is readily detected by using phase-contrast microscopy. This simple test measures the physical and functional integrity of the plasma membrane and therefore viability. In an abnormal sample, less than 50% of spermatozoa swell; in a normal one, more than 60% of spermatozoa react. These investigators believe that when performed properly, this test provides functional information independent of other fertility tests and is particularly useful when no swelling is seen, correlating in this instance with very poor IVF results. This assay can differentiate immotile but viable spermatozoa from necrospermia. A practical protocol for performing this test has been described in the WHO manual and by Jeyendran and colleagues (200). This test is now being used with increasing frequency to evaluate the viability of nonmotile frozen sperm that have been thawed (66,251,399) and nonmotile testicular-extracted sperm before selecting specific sperm for IVF-ICSI.

Venography

Venography, if properly performed, offers an objective diagnosis of testicular venous reflux. In experienced hands, venograms nearly always show reflux if a varicocele is clinically present (472). Some series have shown venous reflux in as many as 95% of left spermatic veins and 61% of right spermatic veins (146,380). The fact that many of these men did not have palpable varicoceles raises questions regarding the significance of “subclinical” varicoceles. Venograms are especially useful in the diagnosis of testicular reflux in a patient with ectatic scrotal vessels and persistent infertility after a surgical varicocele repair. In these patients delineation of the venous anatomy can explain the reason for recurrence or unsuccessful primary repair. Embolization of patient veins can provide therapy, as well as diagnosis.

Venography has a relatively low morbidity (284) and can be performed on an outpatient basis, but it is an invasive study. Therefore, until the significance of the subclinical varicocele is further defined, venograms should be employed selectively (i.e., for patients with suspected postsurgical recurrence).

Color Doppler Sonography

In 1991, Petros and associates (330) described the use of color Doppler sonography in the detection of varicoceles and found it to be more sensitive than physical examination in the detection of this lesion. Color-flow Doppler ultrasonography defines the anatomic and physiologic aspects of varicoceles by employing real-time ultrasonography and pulsed Doppler in the same scan. We consider a varicocele significant when it has a diameter of 3 mm or greater and retrograde flow on Doppler ultrasound examination. McClure and colleagues (271) defined a varicocele as the presence of three or more veins, with one having a minimum resting diameter of 3 mm, or an increase in venous diameter with the Valsalva maneuver. Others studies have used 2 to 3 mm as a cutoff (134,145). The reversal of flow characteristic of varicoceles is confirmed by prolonged flow augmentation within a colored flow area depicted as reversing (i.e., changing color) on real-time imaging.

Controversy continues about the clinical significance of varicoceles that can be identified with scrotal sonography but are too small to detect by routine physical examination. The use of high-resolution scrotal sonography, especially color Doppler sonography, may be helpful, however, when the physical examination is equivocal or when patients are suspected of having recurrent varicocele following surgical correction. Color Doppler ultrasonography is superior to the pencil-probe Doppler stethoscope because of a significant false-positive rate with the latter technique (168). The presence of a prolonged venous flow augmentation or reflux, usually detected as a venous rush during the Valsalva maneuver, is considered diagnostic with the pencil Doppler.

TREATMENT

Medical Treatment of Infertile Males

Previously, pharmacologic manipulation was employed empirically and often irrationally for all infertile males for whom there was no surgical remedy or in whom surgical remedies had failed. Today, attempts are first made to identify specifically treatable causes of male infertility (Table 35.10); based on these diagnoses, a specific therapy with a greater likelihood for success can then be chosen. Advances in biochemical and hormonal research in the area of male reproduction and improved methods of artificial insemination with IUI and IVF may be combined with medical therapy to improve a couple's fertility outcome.

Specific Areas of Concern	Empiric Therapy	Drugs of No Proven Use
Inaccurate timing of intercourse	Testosterone rebound	Liothyronine sodium (Cytomel)
Exposure to gonadotoxins	Gonadotropin (hCG, hMG)	Arginine
Gonadotropin deficiency	Clomiphene citrate	Vitamin E
Congenital adrenal hyperplasia	Tamoxifen	Selenium or zinc
Hypothyroidism	Gonadotropin-releasing hormone	Low-dose oral androgen (fluoxymesterone)
Hyperprolactinemia	Kallikrein	
Genital tract infection	Testolactone	Low-dose corticosteroids
Abnormal ejaculation		
Immunopathology		
Hyperviscosity of semen		

hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin.

TABLE 35.10. MEDICAL THERAPY

Specific Therapy

Endocrine Derangements

Hypogonadotropic Hypogonadism. This condition is present in fewer than 1% of all infertile males and represents a treatable form of male factor infertility. Hypogonadotropic hypogonadism may be congenital or acquired. Congenital forms include Prader-Willi syndrome (obesity; hypotonic musculature; mental retardation; small hands, feet, and stature), Laurence-Moon-Bardet-Biedl syndrome (retinitis pigmentosa, polydactyly, hypomentia), and Kallmann's syndrome (delayed pubertal development, anosmia). Acquired etiologies include radiotherapy, pituitary adenoma, and pituitary infarct. Treatment depends on the specific goals of therapy (Table 35.11).

Condition	Treatment Goal	Therapy	Dosage
Adult hypogonadism	Virilization, normal sexual function	Testosterone enanthate or cypionate	200 mg IM q14–28d (androgen replacement)
		Transdermal testosterone (Androderm; Testoderm TTS)	4 or 6 mg testosterone patch on scrotum daily
	Initiation and maintenance of spermatogenesis	hCG	1,000–1,500 IU IM or SC 2–3 times weekly for 12 mo
		Followed by combined administration of hCG plus:	
		hMG or hFSH	75–150 IU IM or SC 3 times weekly for 6–18 mo
		GnRH	2–40 μg SC q2h by infusion pump
Prepubertal hypogonadism (delayed puberty)	Stimulation of growth and puberty	Testosterone enanthate or cypionate	50–100 mg IM monthly, then increase to 150–100 mg IM q3mo, and then to adult replacement
		hCG	1,000–2,000 IU IM or SC weekly. Initially, then increase to adult replacement
		GnRH	2–40 μg SC q2h by pump infusion

GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; hFSH, human follicle-stimulating hormone; hMG, human menopausal gonadotropin.

TABLE 35.11. TREATMENT OF HYPOGONADOTROPIC HYPOGONADISM

Nachtigall and colleagues (290) have shown that men with adult-onset hypogonadotropic hypogonadism may have fertility restored with long-term therapy with GnRH alone. Fuse and colleagues (131) have similarly demonstrated the efficacy of hCG alone or in combination with GnRH therapy in restoring fertility, especially if severe atrophy was not present. With use of hCG for 3 to 6 months followed by the subcutaneous administration of highly purified urinary FSH in combination with hCG for 18 months, successful induction and maintenance of spermatogenesis was achieved in 25 of 28 men (89%) with primary, complete isolated hypogonadotropic hypogonadism (119).

Hyperprolactinemia. Although not a common finding, hyperprolactinemia can contribute to male factor infertility. Segal and colleagues (379) reported that 4% of subfertile men in their series had elevated prolactin levels. All individuals noted to have significant hyperprolactinemia should undergo computed tomography or MRI evaluation of the pituitary to rule out the presence of a pituitary tumor. Elevated serum prolactin levels impair reproductive function via a negative influence on the hypothalamic secretion of GnRH and by disrupting LH binding to the Leydig cells in the testes. Causes of hyperprolactinemia include pituitary tumors, hypothyroidism, liver disease, and central nervous system–acting drugs such as the phenothiazines and the tricyclic antidepressants. Normally, the release of prolactin is inhibited by the catecholamine dopamine. Thus the dopamine agonist bromocriptine may be administered to restore normal gonadal function in these patients. The usual dosage is between 2.5 and 10 mg per day, usually given in two to four divided doses. Although bromocriptine, introduced in 1971, is the reference preparation against which newer dopamine agonists are compared, up to 12% of patients cannot tolerate the drug at therapeutic dosages.

The newest medication used in the treatment of hyperprolactinemia is the long-acting dopamine agonist cabergoline, which requires administration only once or twice weekly. Ferrari and colleagues (122) have shown that cabergoline at a median dose of 1 mg weekly is an effective and well-tolerated form of therapy for patients with a prolactin-secreting macroadenoma. Normalization of prolactin levels was achieved in 82% of newly treated patients.

Congenital Adrenal Hyperplasia. Although CAH usually manifests in childhood, several cases of infertility secondary to CAH have been reported in adult men (46,438). However, men with untreated CAH may be normally fertile. This disorder is most commonly due to a deficiency in the enzyme 21-hydroxylase, resulting in decreased cortisol secretion and increased production of ACTH. Diagnosis in the normal, sexually mature male can be difficult and depends on the demonstration of elevated levels of serum 17-hydroxyprogesterone and urinary pregnanetriol, as well as a high index of suspicion. Infertility secondary to documented CAH is rare and may be treated with corticosteroids (95,290).

Anabolic Steroid Abuse. Anabolic steroids act as male contraceptives and are becoming more widely abused by athletes. Although little is known about anabolic steroid–associated male infertility, this is a treatable form of drug-related testicular failure (191). Turek and colleagues (435) reported on an azoospermic bodybuilder with a 5-year history of steroid use who underwent successful gonadotropin replacement and conception 3 months after therapy was initiated. This particular patient's sperm density, despite having markedly atrophic testes, around the time of conception was 26×10^6 sperm/mL with 60% motility. After discontinuation of all anabolic steroids, a suggested regimen is hCG, 2,000 units three times weekly for 4 weeks, followed by hCG, 3,000 units three times weekly for 3 months, based on the gonadotropin and testosterone response. Human menopausal gonadotropin may be added after 1 month of hCG therapy. Tamoxifen (10 mg orally twice a day) may be used to minimize hCG-induced gynecomastia.

Hypothyroidism. Hypothyroidism is a very rare cause of male infertility. Thyroxine replacement therapy generally restores fertility (69). Hyperthyroidism can also alter spermatogenesis and cause infertility. These conditions are usually obvious clinically, and screening of asymptomatic infertile men for thyroid dysfunction is not currently recommended.

Pyospermia

The significance of elevated concentrations of leukocytes within the semen is that their presence indicates infection or inflammation within the male reproductive tract. Based on the seminal leukocyte concentration, 10% to 20% of male infertility patients may have leukocytospermia. WBCs are deleterious because of their ability to stimulate the release of ROS, thereby inhibiting sperm motility and sperm function. The WHO (473), in its *Laboratory Manual for the Examination of Human Semen,* states that concentrations greater than 1×10^6 WBCs per cubic centimeter are considered elevated, and the ejaculate is termed *leukocytospermic.* However, despite an apparently abnormal threshold level for leukocytes within the semen, a wide range of conflicting evidence exists as to the significance of seminal leukocytes and infertility (12). Once suspected, appropriate leukocyte-specific testing, preferably with a monoclonal antibody technique, should be undertaken.

We evaluate leukocytospermia by obtaining a semen culture and a urethral swab for *Chlamydia, Ureaplasma,* and *Mycoplasma.* Unfortunately, the yield of these diagnostic modalities is low. Wolff and Anderson (468) summarized the semen microbiology in 100 consecutive leukocytospermic ejaculates, and almost 80% of these

samples were microbiologically negative. Thus, although it is important to exclude genitourinary pathogens by culture, leukocytospermia appears to be infrequently associated with a positive seminal culture. Although many patients with pyospermia do not have documented infection, Yoshida and colleagues (476) suggested that *Chlamydia trachomatis,* but not *Ureaplasma urealyticum,* infection, as detected with *in situ* hybridization, in the male genital tract correlated well with evidence of inflammation. In the absence of urethritis, most inflammatory cells (granulocytes, lymphocytes, and macrophages) originate from the epididymis, prostate, and seminal vesicles. Clinically silent prostatitis and epididymitis may exist in men without overt symptoms. If either of these conditions is suspected, a bacterial origin must be excluded.

Treatment. Specific genital tract infections should be identified and treated to prevent scarring to the seminiferous tubules or obstruction of the epididymis. The most common causes of epididymitis in males under age 35 are the sexually transmitted pathogens *Chlamydia trachomatis* and *Neisseria gonorrhoeae.* The treatment of choice for *Neisseria gonorrhoeae* is ceftriaxone 250 mg intramuscularly once plus doxycycline 100 mg orally twice a day for 10 days. When *Chlamydia trachomatis* is present, doxycycline 100 mg orally twice a day for 10 days or ofloxacin (Floxin) 400 mg orally twice a day for 10 days should suffice. An alternative regimen for treating *Chlamydia trachomatis* is tetracycline 500 mg orally four times daily for 10 days. Spectinomycin 2 g intramuscularly may be used in patients who are allergic to cephalosporins. An erythromycin-based product, 500 mg orally four times daily, may be given to patients who are allergic to or intolerant of tetracyclines.

Many clinicians believe that empiric therapy with doxycycline may be warranted in idiopathic infertility characterized by isolated motility impairment. Support for this concept is provided by a study of the effects of doxycycline therapy on men with idiopathic infertility and an abnormal SPA (40). Thirty-two such men were given 100 mg of doxycycline twice daily for 10 days, followed by 100 mg for 10 more days. The pregnancy rate for responders was 33% (6 of 18), and the nonresponders had a pregnancy rate of 7% (1 of 14). However, no controlled studies demonstrate improved pregnancy rates following tetracycline therapy for idiopathic infertility.

Culture-specific antimicrobial agents should be used if routine bacterial cultures indicate significant bacterial growth. Standard course of a fluoroquinolone or trimethoprim-sulfamethoxazole DS for 2 to 12 weeks should be adequate for most infections. Longer treatment courses when a chronic prostatitis is present result in higher eradication rates. Branigan and Muller (54) concluded that antibiotics combined with frequent ejaculation helped provide durable responses at 3 months. Antimicrobial therapy may be used even when cultures are negative, although results are variable. Sperm processing techniques (e.g., the swim-up, swim-down, sedimentation, Sephadex gel filtration) and density gradients have been used to separate the seminal plasma from sperm, as well as associated cellular contaminants from seminal plasma.

Antisperm Antibodies

The presence of semen antisperm antibodies is often associated with impairments of sperm function. However, not all antisperm antibodies interfere with reproduction. The detrimental effect of antisperm antibodies on sperm function is related to impaired penetration of the zona pellucida of the oocyte and to decreased sperm motility, depending on the site of sperm binding. Because of scientific limitations regarding the identification and isolation of distinctly pathogenic sperm antigens, a common initial approach has been to treat the male partner with systemic corticosteroids in an effort to decrease antibody production (382). Admittedly, this approach is highly controversial. Our regimen has been to use prednisone 20 mg orally every day for weeks 1 to 3, then 10 mg orally every day during week 4.

The risks of mood changes, altered glucose metabolism, aggravation of peptic ulcers, acne, and aseptic necrosis of the hip must be discussed with the patient and prescribed cautiously by an expert. However, with a short course of therapy in typically healthy young men, the risks are small. A second monthly course of prednisone is administered to those who fail to demonstrate a decrease in the quantity of antibodies or an improvement in the semen analysis. Large, placebo-controlled studies using corticosteroid therapy are lacking. Alexander and colleagues (14) administered 60 mg of prednisone for 7 days and observed a decrease in antisperm antibodies and a pregnancy rate of 37% (7 of 19) versus 25% (3 of 12) in the placebo group. Similarly, Haas and Manganiello (152) found a pregnancy rate of 15% (3 of 20) with methylprednisolone 96 mg per day for 7 days, versus 7% (1 of 15) in the control. Failure of corticosteroid therapy may lead to the recommendation of sperm-washing techniques for IUI. However, given only limited success in published series of IUIs in the presence of antisperm antibodies, proceeding directly to ICSI with IVF may be most efficacious.

Retrograde Ejaculation

The backward propulsion of seminal fluid from the urethra into the bladder, or retrograde ejaculation, results from failure of the bladder neck to close during ejaculation. Any condition that disrupts the normal sympathetic innervation of the bladder neck, such as retroperitoneal lymph node dissection, diabetes mellitus, previous bladder neck surgery, or spinal cord injury, can cause retrograde ejaculation. Rarely, urethral stricture disease may also be responsible for retrograde ejaculation. Medications used to treat psychoses (e.g., haloperidol) and certain antihypertensive medications (e.g., phenoxybenzamine) may result in retrograde ejaculation. The diagnosis of retrograde ejaculation is suggested by an abnormally low-volume ejaculate and is made by examination of the centrifuged postejaculatory urine specimen.

The strategy for treatment of retrograde ejaculation is the use of sympathomimetic agents orally to increase bladder neck tone (Table 35.12) (381). If a single agent is not successful, two agents may be combined. A popular regimen is to start with ephedrine sulfate or pseudoephedrine beginning 1 week before the woman's expected day of ovulation and for 3 days beyond. Intermittent dosing seems to prevent the tachyphylaxis seen in continuous dosing.

Medication	Dosage
Phenylpropanolamine	75 mg b.i.d.
Pseudoephedrine	60 mg q.i.d.
Ephedrine sulfate	50 mg q.i.d.
Imipramine HCl	50 mg q.h.s.

TABLE 35.12. MEDICATIONS USED IN THE TREATMENT OF RETROGRADE EJACULATION

Gilja and colleagues (137) reported on 17 diabetic men who were treated with ephedrine or imipramine (for ephedrine failures) during a 4-week period. Positive results were obtained in 5 of 17 patients (29.3%), specifically, in three (17.6%) and two (11.7%) patients taking ephedrine and imipramine, respectively. In the group with retroperitoneal lymphadenectomy, after treatment with ephedrine, only one patient (12.5%) had retrograde ejaculation, and the remaining seven patients continued to lack semen emission. These seven patients were treated with imipramine, and three of them (42.8%) achieved antegrade ejaculation. Depending on the agent used and the studies cited, success rates in correcting retrograde ejaculation may be as high as 40% (143).

If these medications fail to reverse the condition, sperm may be harvested from the bladder for use in IUI. Sperm function may be optimized by alkalinizing the urine with sodium bicarbonate, 650 mg four times daily for 1 day before and the day of sperm recovery, and by prewashing the bladder with an appropriate buffered solution [human tubal fluid (HTF)] just before ejaculation.

Empiric Therapy

Treatment of Idiopathic Oligozoospermia

There is no proven effective medical therapy for idiopathic oligozoospermia, although many different drugs have been tried. Many, such as liothyronine (Cytomel), low-dose androgens, zinc, and vitamin C, are clearly ineffective and irrational. However, there are several drugs for which there is a hint of efficacy in selected patients. This therapy is indicated if the male partner in an infertile couple has suboptimal semen quality, no known reversible causes for his subfertile state, and

normal gonadotropins and if the female partner has been completely evaluated and optimally treated (260).

Clomiphene Citrate. Clomiphene citrate is an antiestrogen that causes increased gonadotropin production and, in turn, increased circulating and intratesticular levels of testosterone. Theoretically, clomiphene should not be successful in men with elevated gonadotropin levels. Evaluation of various reports of the efficacy of the drug is difficult because of differences in dosage and treatment intervals and because of associated female pathology. In addition, few studies have been placebo controlled (126,351). Similar limitations apply to the studies of the other drugs discussed in the following sections. Nevertheless, reviews by Sorbie and Perez-Marrero (402) and Allag and Alexander (15) afford certain observations regarding the effects of clomiphene citrate on semen quality and make recommendations regarding optimal dose, duration of treatment, and selection of patients.

Dose Greater Than 100 mg. Dosages of 100 mg per day or more for durations of 1 to 12 months have generally yielded no consistent change in sperm concentration (126,163,241,318) and may decrease sperm density (163) by testicular hyperstimulation. The pregnancy rate was reported as 17% (126).

Dose of 50 mg. A generally favorable effect on sperm density has been noted at this dose given for intervals ranging from 1 to 12 months. Although improved sperm densities were noted in 25% to 60% of oligozoospermic patients (82,153,209,318,363), some investigators report either diminished response or no change in sperm density after administration of clomiphene citrate (19,287). At 50 mg per day for 3 months, Ronnberg and Tuimala (352) achieved a highly significant increase in sperm density in 33 normogonadotropic oligozoospermic males compared with response in a group with elevated serum FSH. Ronnberg (351) noted an overall pregnancy rate of 10%. Charny (70) observed no response to clomiphene citrate in patients who showed multiple abnormal semen parameters and an elevated serum FSH level. At present, there is no firm evidence that this high dose is superior to 25 mg per day.

Dose of 25 mg. Clomiphene citrate 25 mg given cyclically for 25 days with a 5-day rest period, has provided significantly improved results, although a 5-day “rest period” seems difficult to justify scientifically. Studies using this regimen for 6-month intervals have achieved sperm quality improvements in 72% to 92% of patients and have achieved pregnancy rates of 35% to 40% (72,207,322,324,325). Check's 1980 study (72) included patients whose semen parameters failed to improve after varicocele ligation. We have reviewed all available data for clomiphene therapy. Sokol and colleagues (400) have completed a controlled, double-blind study that showed no significant difference in semen parameters, sperm penetration assays, or fertility between the treated group and the placebo group. They concluded that clomiphene citrate is not a useful drug in the treatment of male infertility. Controlled and noncontrolled collated series are presented here for review (Table 35.13 and Table 35.14).

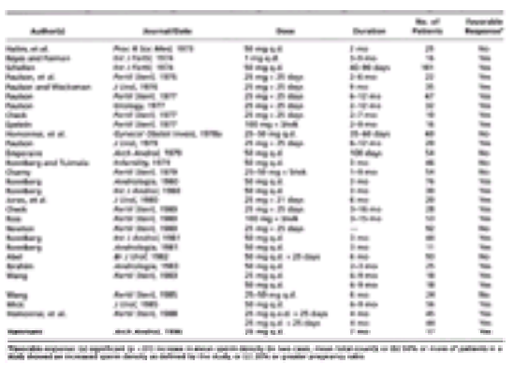

TABLE 35.13. CLOMIPHENE CITRATE THERAPY

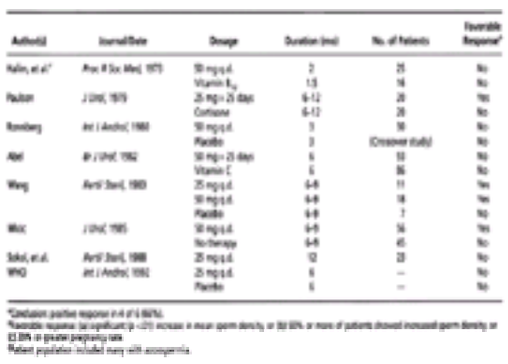

TABLE 35.14. CLOMIPHENE CITRATE: CONTROLLED STUDIES[a]

Tamoxifen. As a treatment for male infertility, tamoxifen has been studied only since the late 1970s (462). Because success rates with this agent apparently equal those with clomiphene but without the potential side effects of clomiphene, tamoxifen at a dose of 20 mg per day may be the drug of choice for idiopathic oligozoospermia if use of a pure antiestrogen is desired (368). Although some studies have noted increases in sperm density in 11% to 100% of patients, none has reported a significant increase in motility. Pregnancy rates have ranged from 11% to 40% (61,462). Some reports, however, have refuted the effectiveness of tamoxifen in the treatment of male factor infertility (227,406). Another attractive feature of tamoxifen is that it does not provide even the weak estrogen receptor stimulation noted with clomiphene.

Human Chorionic Gonadotropin

Human Chorionic Gonadotropin Alone. Human chorionic gonadotropin has been used empirically in the treatment of oligozoospermia. The rationale for its use is based on the intrinsic LH-like activity, which may increase the intratesticular concentration of testosterone that is thought to be deficient in these patients. Although the lack of uniform dose and treatment intervals may obviate conclusions regarding its optimal administration, its effect on semen parameters and pregnancy rates is less favorable than that seen with low-dose clomiphene. Overall experience regarding hCG therapy in a number of studies shows a 29% improvement in sperm density, a 42% increase in motility, and a pregnancy rate of 18% (74,169,260,281) (Table 35.15). Of note, Margalioth and colleagues (260) observed deterioration of sperm density and motility in 40%, probably secondary to high levels of estradiol caused by high-doses hCG. Therefore hCG should not be given at high dosages. Human chorionic gonadotropin has been said to be useful in patients with sperm densities of less than 10×10^6/mL following varicocele ligation, significantly increasing sperm density and pregnancy rates in this severely oligozoospermic group (111). However, this study was uncontrolled and has not been confirmed by a controlled study.

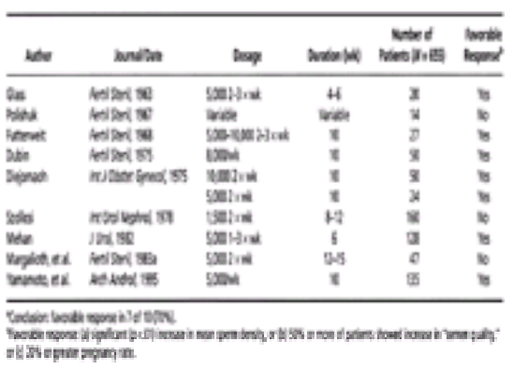

TABLE 35.15. HUMAN CHORIONIC GONADOTROPIN THERAPY, 1960–2000[a]

Human Chorionic Gonadotropin Plus Human Menopausal Gonadotropin. Human menopausal gonadotropin has been incorporated in different dosages with hCG in the treatment of idiopathic oligozoospermia. Whereas Schill (367) achieved an increased sperm density in 60% of patients, an increased motility in 40%, and a pregnancy rate of 30%, others (169,386) have noted only a moderate improvement in sperm density and no improvement in pregnancy rates. The total experience of combined hCG–hMG therapy shows improvements in sperm density in 41%, improvement in motility in 34%, and a pregnancy rate of 17%. These data indicate no benefit from the addition of hMG to hCG in the therapy for idiopathic infertility.

Follicle-stimulating Hormone Alone. Acosta and associates (1,2) noted marked improvement in fertilization rates following FSH administration in the treatment of men who were participating in an IVF treatment program and who had severe seminal abnormalities or fertilization failure. It should be noted that this reported improvement in fertilization rates occurred in the absence of an improvement in bulk semen parameters. Similarly, Ben-Rafael and colleagues (38) observed improved fertilization rates in eugonadotropic men who had previous IVF fertilization rates of less than 30% when FSH was administered at least 60 days before the IVF cycle. However, others have found no such improvements (210).

Testolactone. Testolactone (Teslac), an aromatase inhibitor, prevents the conversion of testosterone to estradiol and thereby minimizes the negative effect of the latter on spermatogenesis. Vigersky and Glass (449) treated ten idiopathic oligozoospermic patients with 100 mg of testolactone daily for 6 to 12 months, noting a significant increase in the ratio of serum testosterone to estradiol, no change in serum gonadotropins, a marked improvement in sperm density in 80% of patients, and a 33% pregnancy rate. Encouraging results were also reported by Vance and Thomer (439) in four oligozoospermic men. Although the exact role of testolactone cannot be determined from this limited experience, the most effective use may be in combination with antiestrogens and other drugs that simulate gonadotropins, because it would limit the downregulatory effect of testosterone aromatization on spermatogenesis. Vigersky and Glass (449) combined testolactone with tamoxifen in 15 oligozoospermic patients for 6- to 12-month periods. Although improvement in sperm density was noted in more than 70% of patients and four pregnancies (27%) resulted, the authors concluded that combination therapy was no more effective than the use of testolactone alone. Clark and Sherins (77) investigated 25 oligozoospermic men in a double-blind, placebo study and found no effect on semen quality or fertility. This study has been questioned because there also was no effect on endocrine parameters, and the average pretreatment total sperm counts were 7.5 million.

Anastrazole (Arimidex, Astra-Zeneca), an oral nonsteroidal aromatase inhibitor used for the treatment of advanced breast cancer, has been used in men with spermatogenic failure and decreased testosterone-to-estrogen ratios. Unpublished preliminary reports suggest benefit, but further study is clearly necessary.

Gonadotropin-Releasing Hormone. More recently, GnRH has been studied in the treatment of idiopathic oligozoospermia (22). This appears to be a more physiologic agent for increasing the pituitary's production of FSH and LH. However, investigation of GnRH as a therapeutic agent for infertility is still in its early stages, and data are limited. In preliminary studies, increases in sperm count and motility of 67% and 71%, respectively, have been noted, as well as pregnancy rates of 24% (22,439). GnRH has been given using postoperative programmable, portable mini-pumps to men with hypogonadotropic hypogonadotropism (45), and it has been recommended for the treatment of idiopathic oligozoospermia. Thus far, results are inconclusive.

Testosterone Rebound. Rebound spermatogenesis has been shown to occur after testosterone-induced azoospermia at what has sometimes been described as “an improved level.” Numerous types of preparations and routes of administration have been explored in an effort to supply androgen to the target organs before inactivation by the liver. However, the incidence of failure to return to pretreatment sperm counts following this therapy may be as high as 4% (71). Increases in sperm density have been reported to range from 20% to 70%, with pregnancy rates between 14% and 41% (71,439). The 4% risk of worsening the patient's condition and failure to provide better results than other empiric forms of therapy strongly suggest that this should no longer be considered an effective therapy.

Corticosteroids. Attempts have been made to stimulate spermatogenesis in idiopathic oligozoospermic patients using corticosteroids. The results of these efforts have been unrewarding: either no change in semen parameters has been noted, or sperm counts have been depressed even further. Mancini and colleagues (258), using 30 mg per day of prednisolone for 1 month, observed decreased sperm counts and spermatogenic arrest on testicular biopsy. McDonald and Heckel (273) noted no change in semen parameters or testis histology in 11 patients receiving 75 mg per day of cortisone for an interval ranging from 23 to 334 days. Uehling (436) reported no change in sperm density or motility in 38 patients treated with 2.5 mg of cortisone four times daily during a 6-month interval. Moreover, cortisone compared unfavorably with clomiphene citrate in patients with idiopathic oligozoospermia (323).

Kallikrein. Kallikrein, a tissue hormone–releasing polypeptide, causes the release of kinins in male and female genital secretions. In addition to vasodilator effects secondary to smooth muscle relaxation, kinins have been noted to enhance sperm motility (365). Although kallikrein is not available in the United States, European studies have noted that oral administration of the agent resulted in a 67% increase in sperm motility and pregnancy rates of 17% to 38% (170,366). A review of five randomized, placebo-controlled studies of oral kallikrein therapy indicated a statistically significant increase in pregnancy rates among the patients treated with kallikrein (302). Side effects are rare, but kinins may exacerbate epididymal or prostatic inflammation (368).

Pentoxifylline. Pentoxifylline, a methylxanthine derivative, is in the same pharmacologic class as caffeine and theophylline. Pentoxifylline is more useful clinically than caffeine, because it has a longer half-life and greater water solubility. Used to treat peripheral vascular disease, pentoxifylline has properties that decrease blood viscosity and improve impaired microcirculation. Agents in this class act via the inhibition of phosphodiesterase, generating an increase in intracellular cAMP, which in turn increases intracellular ATP production. It has been proposed that this increase in ATP may enhance sperm motility. Pentoxifylline has been used empirically in treating idiopathic oligozoospermia but has resulted in only a 17% pregnancy rate (369). Perhaps more clinically relevant is the use of pentoxifylline in the treatment of sperm *in vitro.* Treatment of washed sperm with this agent has been noted to increase hyperactivation of sperm among both normospermic and oligozoospermic men (214,270). The actual benefit of the use of pentoxifylline on the fertilization and cleavage rates achieved during IVF procedures remains unclear (425,477). (See Table 35.16 for a comparison of representative studies of the effects of empiric medical therapy on idiopathic infertility.)

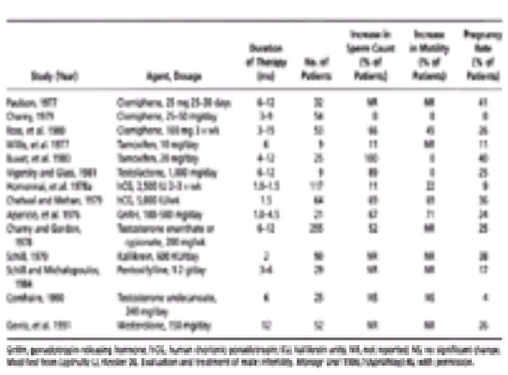

TABLE 35.16. REPRESENTATIVE STUDIES OF THE EFFECTS OF EMPIRIC MEDICAL THERAPY ON IDIOPATHIC MALE INFERTILITY

Antioxidants

Because high levels of ROS have been identified in the semen of up to 40% of infertile patients (183) but are not typically detectable in normal volunteers and azoospermic men, they have been implicated as a cause of idiopathic infertility (6). ROS have been linked with reduced fertility in men with varicoceles (8,238,269), spinal cordinjury (100), and immunologic infertility (479). Elevated ROS levels have been correlated with abnormal sperm concentration, motility, and morphology (4,8,342).

Ros are produced by sperm as a normal physiologic process and are important mediators of normal sperm function, capacitation, and the acrosome reaction (99).

However, pathologic states associated with a positive oxidative stress are created when an increased production of ROS occurs, rather than a decreased degradation of the ROS. It is likely that a significant amount of ROS-scavenging activity is provided by seminal plasma. The principal sources of ROS production are spermatozoa and leukocytes, which are capable of producing massive amounts of ROS (6). ROS damage spermatozoa by attacking the sperm membrane and causing lipid peroxidation by a chain reaction mechanism. Aitken and colleagues (10) have provided evidence that ROS may cause DNA damage in spermatozoa, thereby potentially causing problems in offspring conceived through ICSI.

Similarly, sperm-washing techniques, especially those involving repeated centrifugation, can result in significantly higher ROS levels. When centrifugation speeds of 200 to 500 G are used, ROS-negative specimens may become positive (384). More important, prolonged centrifugation time can increase ROS generation. The most effective techniques to minimize ROS generation appear to be Percoll washes and sperm swim-up methods.

The use of antioxidants in men with elevated ROS levels is an area of active investigation. During sperm preparation for IUI or IVF, steps such as using an antioxidant-supplemented culture medium (54) and removing contaminating leukocytes (55) appear to be beneficial. The use of oral antioxidants such as a-tocopherol (vitamin E) and ascorbic acid (vitamin C) also have shown mixed results (409). In a double-blind, randomized, placebo crossover–controlled trial using oral vitamin E or placebo for 3 months, Kessopoulou and colleagues (218) determined that although semen analyses were unchanged, the zona binding test, a functional assay, was significantly improved with vitamin E administration. In a randomized, placebo-controlled, double-blind study, Rolf and colleagues (349) investigated whether high-dose oral treatment with vitamins C (1,000 mg per day) and E (800 mg per day) for 56 days was able to improve semen parameters of infertile men with asthenozoospermia. No difference was found in semen profiles, and no pregnancies were initiated.

Glutathione also has antioxidant activity by its actions as a free radical scavenger. In a 2-month, placebo-controlled, double-blind, crossover trial of 20 infertile patients with dyspermia associated with unilateral varicocele or germ-free genital tract inflammation, patients received either glutathione (group 1) or placebo (group 2) for 2 months, then crossed over to the alternative treatment for an additional 2 months (238). The authors found that glutathione therapy demonstrated a statistically significant positive effect on sperm motility and morphology.

Carnitine

The introduction of proXeed has stimulated widespread interest in the use of carnitine for oligoasthenozoospermic men. L-carnitine and acetylcarnitine are highly polar, water-soluble, small quaternary amine vitamin-like compounds. Acetylcarnitine is important for membrane stabilization. L-carnitine and acetylcarnitine play a fundamental role in intracellular energy metabolism through the transportation of activated acyl groups and helps balance fatty acid oxidation and synthesis. In epididymal fluid, L-carnitine is present at a concentration 2,000-fold greater than that present in blood plasma. In normal human seminal plasma, approximately 50% of total L-carnitine exists as acetylcarnitine.

Uncontrolled clinical studies have demonstrated that L-carnitine (3 g per day) and acetylcarnitine administered orally for up to 6 months significantly increased sperm motility, sperm count, median sperm velocity, and rapid linear sperm progression in patients with idiopathic asthenozoospermia. Costa and colleagues (87) studied 100 patients receiving 3 g per day of oral L-carnitine for 4 months. Sperm parameters were studied before, during, and after this treatment. The results of the study indicate that L-carnitine is able to increase spermatozoal motility, quantitatively and qualitatively: percent motile spermatozoa increased from 26.9% ± 1.1% to 37.7% ± 1.1% (p<001); percent spermatozoa with rapid linear progression increased from 10.8% ± 0.6% to 18.0% ± 0.9% (p <.001); and linearity index increased from 3.7 ± 0.1 to 4.1 ± 0.1 (p <.001). An increase in spermatozoal output was also observed: total number of ejaculated spermatozoa increased from 142.4 ± 10.3 × 10^6 to 163.3 ± 11.0 × 10^6 (p<.001).

Similarly, Vitali and colleagues (451) observed a favorable effect on sperm motility and rapid linear progression in 37 out of 47 patients treated. Moncada and colleagues (283) administered acetylcarnitine at 4 g per day for 60 days and found no effects on sperm density and total motility, but a significant increase in progressive sperm motility (21.7% ± 3.2% versus 38.2% ± 4.7%). This parameter returned to basal value 4 months after therapy discontinuation. Five pregnancies occurred during treatment and only two during the 4-month follow-up after therapy discontinuation. Both L-carnitine and acetylcarnitine have been well tolerated. At present, placebo-controlled studies are being performed.

Surgical Treatment of Male Infertility

Varicocele Repair

The etiology of a scrotal varicocele is related to the specific and unique venous drainage of the testis, a mechanism that also allows for alternative drainage routes following varicocele ligation. The major draining route of the left testis, where varicoceles are more commonly found, is via the left internal spermatic (gonadal) vein, which directly enters the left renal vein. The left internal spermatic vein is 8 to 10 cm longer in its vertical course than the right internal spermatic vein, which enters the inferior vena cava below the right renal vein. The result is greater hydrostatic pressure in the left drainage system, especially in a person in an upright position. In conjunction with the absence or incontinence of venous valves in the proximal left spermatic vein, this increased pressure head predisposes the patient to left-sided varicocele formation. Secondary venous drainage routes of effluxing blood from the testis are via the deferential vein to the superior vesicle vein and via the cremasteric (external spermatic vein) to the pudendal vein. These systems provide for venous drainage after varicocele repair but may also be involved in recurrent varicocele formation after a standard varicocele ligation if refluxing alternate venous pathways are missed.

Abnormal testicular function in patients with varicoceles has been variously attributed to elevated testicular temperature, hypoxia secondary to venous stasis, hormonal imbalances, or reflux of renal or adrenal metabolites or both. Research is available, however, to both support and disprove most of these theories. The work of Saypol and colleagues (359) gives support to the theory that increased heat leads to reversible pathophysiologic changes in the testes of animals with surgically created varices. The most common indications for varicocele repair in the adult are impaired semen parameters and the presence of testicular atrophy. Varicocelectomy may also be helpful for the painful varicocele (329). The indications for adolescent varicocele repair are discussed in the pediatric section.

There are three basic surgical approaches to ligation of the internal spermatic vein: scrotal, retroperitoneal, and inguinal. We do not favor the scrotal approach, because the spermatic veins in the scrotum are multiple (pampiniform plexus); the procedure consequently requires more time, and it is difficult to be certain that all of the involved tributaries have been interrupted. In addition, it is possible to damage all three major sources of blood to the testis and epididymis: the spermatic, the deferential, and the cremasteric arteries. On the other hand, proponents of this approach believe that it offers the possibility of a more complete operation by permitting ligation of veins that may not anastomose with the internal spermatic vein and thus may reduce the failure rate. This procedure does not seem rational when compared with alternative techniques.

The two eponyms usually associated with the higher division of the scrotal veins are the Ivanissevich procedure (182) and the Palomo procedure (317). Palomo originally took a high retroperitoneal approach. Subsequently, the techniques have been modified so that in some descriptions the only difference between the “modified Ivanissevich approach” and the “modified Palomo approach” is in the name. To avoid eponyms, we will describe the “high ligation” versus the “low ligation” (inguinal approach) for varicocele correction. A mini-Doppler probe and a topical vasodilator (papaverine or lidocaine) aid in the identification of the spermatic artery. Use of an operative microscope can be helpful for precise identification of arteries, lymphatics, and the dilated spermatic veins (142), but magnifying loupes should be used at a minimum. Microsurgical varicocele repair results in lower rates of recurrence and hydrocele formation.

For the high retroperitoneal approach, a short transverse incision is made just medial to the anterior superior iliac spine approximately at the level of the internal ring (Fig. 35.17). This approach is commonly used by pediatric urologists for the repair of the adolescent varicocele. The procedure can be performed under local, regional, or general anesthesia. The external oblique fascia is incised in the direction of its fibers; the internal oblique muscle is retracted caudad with an abdominal retractor. The dilated vein is usually adherent to the reflected peritoneum and is often easily identified without any further dissection. The vein is then freed from the surrounding fat by blunt or, preferably, sharp dissection. The dissection is taken up toward the renal vein, as high as is convenient, so that anastomosing collaterals can be found. The vein is then ligated, and a segment may be removed. The area is inspected for additional veins, with care taken not to divide the artery. The vas deferens can often be found at the lower medial aspect of the incision as it curves into the pelvis. The internal oblique is tacked back in position, and the external oblique is closed with nonabsorbable sutures. A subcuticular skin closure is performed for aesthetic reasons and to eliminate the need for suture removal. The procedure is done on an outpatient basis.

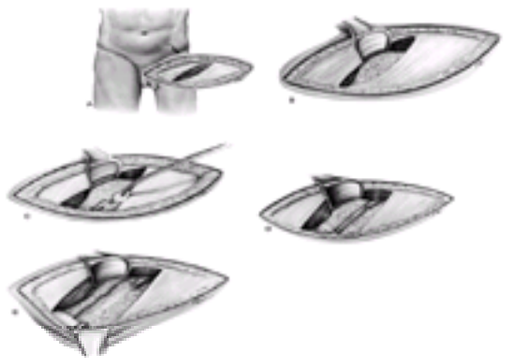

FIGURE 35.17. The high retroperitoneal approach to varicocele repair. **A:** Incision for abdominal approach: a short transverse incision is made just medial to the anterior superior iliac spine approximately at the level of the internal ring. **B:** The external oblique fascia has been incised. The internal oblique muscle is retracted with a Richardson retractor. **C:** The dilated internal spermatic vein, adherent to the reflected peritoneum, is teased away with a Kitner. **D:** The vein is freed from surrounding fat and ligated nonabsorbable suture. **E:** A segment of vein may be removed for identification. (From Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

The incision for the inguinal approach (Fig. 35.18) is made two fingerbreadths above the symphysis pubis. The medial aspect of the incision should coincide with the lateral edge of the scrotum. The patient is placed in the reverse Trendelenburg position to fill the veins. The skin incision is carried down to the external oblique aponeurosis, which is divided in the direction of its fibers. After the cord is mobilized, the external spermatic fascia is then incised and the dilated vessels are identified. Each vein is then isolated and doubly ligated with nonabsorbable suture. Excision of a vein segment is not necessary, especially with the placement of a double ligature. Two to three veins are commonly found in the inguinal canal, although four or five may be encountered. It is also important to look for an enlarged cremasteric vein as it courses from the cord at the level of the external ring toward its juncture with the pudendal vein and, ultimately, the saphenous vein. When enlarged, this vein should likewise be ligated and incised, because it may contribute to varices in a small proportion of patients. The external oblique aponeurosis is then closed with interrupted 2-0 polyglactin 910 (Vicryl) or permanent suture, the subcutaneous tissue reapproximated with 3-0 plain catgut, and the skin closed with either a subcuticular or interrupted skin closure using Steri-Strip reinforcements.

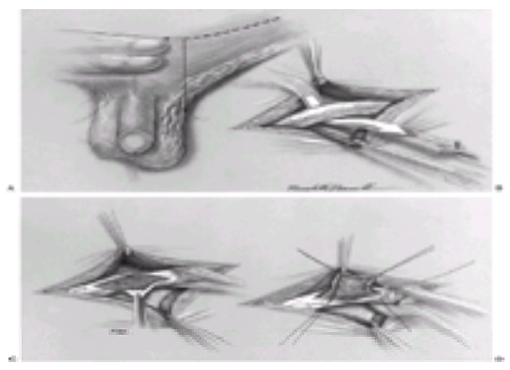

FIGURE 35.18. The inguinal approach to varicocele repair. **A:** An inguinal incision is made two fingerbreadths above the symphysis pubis with the medial aspect in line with the lateral edge of the scrotum. **B:** The external oblique aponeurosis is incised and the spermatic cord isolated with a Penrose drain. **C:** The internal spermatic fascia is stripped from its location surrounding the cord and the veins visualized. **D:** The dilated veins are isolated with vascular forceps and ligated with nonabsorbable suture. (From Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

The subinguinal approach is also commonly used. Using this technique, a transverse incision is made at the level of the symphysis pubis so that the spermatic cord may be mobilized just distal to the external ring (263). Complications of these open techniques are minimal but include hydrocele formation, persistence or recurrence of the varicocele, and testicular atrophy (142).

In recent years, percutaneous venographic occlusion has been promoted in the treatment of varicoceles. Once radiographically identified, refluxing internal spermatic veins may be occluded with sclerosing solutions (380), wire coils, or detachable balloons (284). Proponents of this technique support its use as a time- and cost-effective outpatient procedure. Although the cost of outpatient surgery is actually quite comparable, the morbidity of venography is reported to be from 0.5% to 9.0% (284), whereas the reported surgical morbidity is 1% to 3%. However, there is a risk of peripheral migration or embolization of a coil or balloon, as well as the disadvantage of increased radiation exposure. A collection of data from five large series indicated that of 1,894 attempted percutaneous occlusions, 1,469 (78%) were successful (123).

Laparoscopy has been used to correct varicoceles (463,464). However, Hirsch and colleagues (167) showed no superiority of laparoscopic techniques over the standard open subinguinal technique with respect to hospital stay, analgesic requirements, or return to work. Furthermore, laparoscopic techniques require excessive operative time and carry an increased risk of damage to major vascular or abdominal structures. The laparoscopic approach is infrequently used and unlikely to gain in popularity.

Results of surgical varicocele correction are varied. Review of many collated studies indicates that 50% to 70% of surgically treated patients may show some improvement in semen quality, and 30% to 50% may initiate pregnancies within 6 to 9 months after surgery (Table 35.17 and Table 35.18) (248). Although many of these studies have been retrospective, a randomized, prospective, controlled study confirmed that varicocelectomy is an effective treatment for male subfertility (256). In group A of this study, 20 couples with a varicocele were observed for 1 year, and only two pregnancies (10%) were initiated. Those men who were not able to initiate a pregnancy had a varicocele repair, and within 2 years, 12 (66%) were successful in initiating a pregnancy. Meanwhile, 25 men in group B had a varicocele repair immediately. Within the first year, 15 (60%) initiated a pregnancy, and by 3 years, an additional four (16%) were able to father a child. Semen parameters improved in all men who had varicocele repair, regardless of pregnancy occurrence. Semen parameters were unchanged for those men in group A during their 1 year of observation. This important study concluded that the varicocele is associated with reduced fertility and reduced testicular function and that correction improves sperm parameters and fertility rates.

TABLE 35.18. VARICOCELE STUDIES SHOWING PREOPERATIVE AND POSTOPERATIVE SPERM CONCENTRATION

In general, infertile men with a large varicocele have poorer preoperative semen quality, but repair of the large varicocele in those men results in greater improvement than repair of a small or medium-sized varicocele (403). Varicocele repair may also have demonstrable benefits for azoospermic men with spermatogenic failure. Two recent series have identified improvements in spermatogenic function as evidenced by the presence of sperm in the ejaculate in approximately 50% of men (222,265). Those men most likely to benefit had either severe hypospermatogenesis or maturation arrest at the spermatid stage. Although these couples will still probably require ICSI, varicocelectomy may be considered to produce motile sperm in the ejaculate; avoid more invasive procedures such as testicular sperm extraction, which risk loss of testicular tissue; and allow the possibility that natural, spontaneous pregnancy may occur.

Ductal Obstruction

Occlusion of the excretory ducts of the testis is an important diagnostic entity because of its potential reversibility. The incidence of ductal obstruction among infertile men has been reported as 7.4% (110). The causes of ductal obstruction include congenital absence of the ductal system, ductal stricture following infection, vasectomy, iatrogenic injury, and functional obstruction.

The ductal system may be congenitally absent. Usually, there is an associated absence of the seminal vesicles, ampulla, vas deferens, and a major portion of the epididymis. In males, cystic fibrosis is almost always associated with congenital hypoplasia or absence of these excretory ducts. Because of the absence of seminal vesicles, these patients have, in addition to azoospermia, a low ejaculate volume, semen that does not coagulate at the time of ejaculation, and absence of fructose in the seminal plasma (454).

Stricture of the excretory ducts acquired following infection of these structures may be remediable. Before the antibiotic era, gonorrheal urethritis frequently progressed to an obstructive epididymitis. Currently, gonorrhea is an unusual cause of male infertility. Vasoepididymal anastomoses may successfully bypass the obstruction and restore normal fertility potential to men with this lesion. Currently, vasectomy is the leading cause of infertility secondary to ductal obstruction.

Classically, the most important hallmark of men with obstruction of the excretory ducts is azoospermia in association with a normal testicular examination. Usually, testis size, Leydig cell function, and serum FSH and LH levels are in the normal range following obstruction of the ducts, although subtle alterations do occur. Ligation of the ductuli efferentes directly adjacent to the testis in rats invariably induces loss of germinal elements within the seminiferous tubules (161). Thus men with complete, longstanding, proximal obstruction may have testicular atrophy.

Vasovasostomy

Technique. There are many recognized methods for performing a vasovasostomy; none has definitely proved to be superior. The experience of the surgeon is obviously the most important component. We present two techniques for vasal reanastomosis: the first employs a microscope and the second employs optical loupes. The technique of microscopic vasovasostomy was introduced by Owen (310) and popularized by Silber (393). The following equipment is helpful, although significant variations in instruments and technique are present between microsurgeons: an operating zoom microscope with foot pedals to control focus, magnification, position, and zoom; a standard plastic surgery instrument tray; microsurgical instruments, including a 5.75-inch curved Heifetz nonlocking needle holder, two Castro-Viejo suturing forceps with teeth (0.12 mm), two 4.5-inch straight-smooth number 3 jeweler's forceps, and 4.6-inch curved Westcott pointed microscissors; lacrimal duct dilators; a vas deferens approximator clamp; Dermalon 10-0 double-swedged suture on TE-100 needles and Dermalon 9-0 suture on an LE-100 needle (Davis and Geck); an operating table that allows the surgeon to sit comfortably with the knees under the field; biopolar microdiathermy; and a small syringe and needle for irrigation. Alternatively, many experienced microsurgeons prefer to stand during surgery.

With the patient under general, epidural, or local anesthesia, a vertical scrotal incision is made (Fig. 35.19), and the testicle, epididymis, and proximal vas deferens are delivered with the tunica vaginalis intact. A platform of towels can serve as a rest for the surgeon's hands to stabilize them during the microsurgical phases of the operation. The site of the vasectomy is identified. Healthy vasal tissue adjacent to this scarred area is placed on an empty knife blade slot as a groove director and is sharply divided with a scalpel. Alternatively, a nerve cutter can be used. This scarred vasal remnant may be sharply excised or left *in situ.*

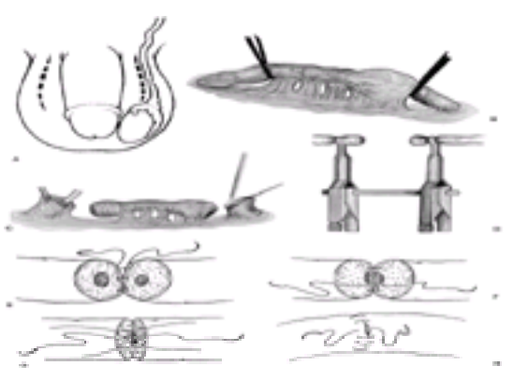

FIGURE 35.19. The microscopic technique for vasovasostomy: strict two-layer anastomosis. **A:** A longitudinal, upper scrotal incision is made. The testis is delivered into the operative field without opening the tunica vaginalis. **B:** The site of vasectomy is identified and isolated. **C:** The proximal end *(right)* of the vas is then incised until fluid is seen. The distal end *(left)* is irrigated with saline via a 25-gauge angiocath sheath to ensure patency of the abdominal end of the vas deferens. **D:** A vasal clamp may be used for approximating the vasal ends. Alternatively, 7-0 PDS sutures in the perivasal tissue may be used for reapproximation of the vasal ends (not shown). **E:** Three 9-0 nylon sutures are placed on the posterior aspect of the outer, serosal layer. **F:** The initial 10-0 mucosal suture is placed at the 6 o'clock position. Another two inner (mucosal) layer 10-0 nylon sutures may then be placed and tied. **G:** The last three “anterior” sutures are tied one at a time after all have been placed. **H:** The outer (serosal) layer is begun anteriorly and requires two to three 9-0 sutures between each of the mucosal sutures. (From Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 3. St. Louis: Mosby, 1997, with permission.)

The fluid is then milked from the proximal (testicular) end of the vasal lumen. The fluid is aspirated using a 25-gauge angiocath and a small syringe, and fluid is immediately transferred by a direct-touch technique to a sterile glass slide and viewed in the operating room. The decision making for whether to perform a vasovasostomy or epididymovasostomy is based on the quality of the fluid (Fig. 35.20). The most desirable finding is actively motile sperm. Any sperm elements found in the fluid indicate patency from the testis to the proximal vas. The finding of fluid without sperm does not mean that an effective vasovasostomy will not eventually occur, but the chances are significantly impaired. The presence of thick, creamy fluid without sperm or the total absence of fluid is a poor prognostic finding and

usually indicates an epididymal or efferent duct obstruction, either functional or anatomic. Such individuals are best served by the performance of microsurgical vasoepididymostomy.

FIGURE 35.20. Algorithm for decision making during vasovasostomy or epididymovasostomy.

The distal (abdominal) end of the vas is prepared in a similar fashion until a normal lumen and a well-vascularized wall are seen. The distal lumen is very gently dilated with jeweler's forceps. The patency of the distal segment may be confirmed quickly and easily by irrigation with saline via a 25-gauge angiocath sheath. Bleeding is carefully controlled with microbipolar cautery. Care should be taken to avoid excessively devascularizing the outer wall of the vas. The two ends of the vas are then placed in a vas deferens approximator clamp. Alternatively, a suture of 7-0 PDS or Maxon can be placed through the perivasal tissue of each end of the vas to bring and hold the two ends in proximity to each other. A strict two-layer anastomosis may then be performed.

Initially, three approximating and stabilizing 9-0 nylon sutures are placed posteriorly through the serosa to include only the most superficial portion of the muscularis (Fig. 35.19). Three 10-0 nylon sutures are placed through the mucosa of the testicular vas at the 6 o'clock position. If using double-armed sutures, the needles may be placed in inside-out fashion on both sides. The sutures are then tied, with care taken to place the knot outside the lumen. These sutures do not enter the lumen and serve to decrease tension on the mucosal sutures. A total of six to eight inner mucosal layer 10-0 sutures should be present at the completion of the inner layer. It is easiest to leave the “anterior” mucosal sutures to be tied at one time, after they have all been placed. The mucosal anastomosis is reinforced with a layer of seromuscular 9-0 sutures that do not enter the lumen. This second layer begins anteriorly and requires two to three sutures between each of the mucosal stitches. The anastomosis is carefully examined to verify the absence of leaks. The testis and epididymis are then replaced within the scrotum, and the dartos muscle and skin are closed in separate layers.

The procedure is done on a day-surgery basis. Patients are able to return to work within a few days but are advised to wear a scrotal support and to avoid heavy lifting and ejaculation for 2 weeks. Three months postoperatively, the semen analysis often reveals a good sperm count with poor motility. After 6 months, the count is usually stable or slightly improved, and the motility is significantly improved.

Although a strict two-layer anastomosis is preferred by some surgeons (393), there is no convincing evidence that it yields results superior to those of a modified two-layer microscopic anastomosis. An important benefit of the strict two-layer technique is that the discrepancy in luminal diameters between the testicular and abdominal ends of the vas may be minimized. Some surgeons still use optical loupe magnification and a single-layer anastomosis with 8-0 polypropylene, but experts rarely use this approach (Fig. 35.21). In the macroscopic approach, however, both the first and second layers are anastomosed with 8-0 suture, whereas in the microscopic approach, 9-0 suture may be employed for the first layer of the anastomosis.

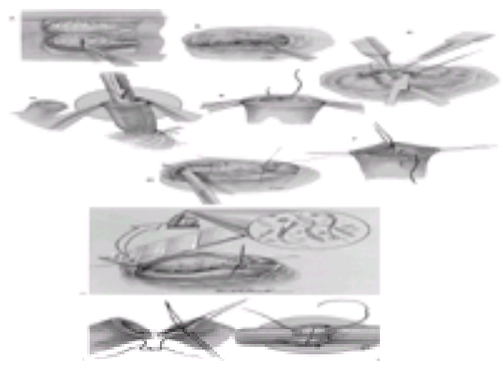

FIGURE 35.21. The macroscopic technique for vasovasostomy: modified two-layer anastomosis. **A:** A transverse scrotal incision is made. **B:** The site of previous vasectomy is identified and isolated with a towel clip. **C:** The vas is incised sharply with a no. 11 blade using the groove of an empty knife handle as a director. **D:** The abdominal vasal stump is dilated progressively with lacrimal duct dilators. **E:** A through-and-through suture of 8-0 polypropylene is placed first in the 6 o'clock position. **F:** Four 90-degree sutures of 8-0 polypropylene are ultimately placed, thus opening the vasal lumen symmetrically. **G:** The testicular vas is likewise isolated. **H:** After the testicular vas is incised, effluent fluid is immediately transferred to a glass slide and checked for the presence of sperm. **I:** Sutures from the abdominal vas are then passed to their corresponding positions in the testicular vas, again creating a four-quadrant (90-degree) anastomosis using a total of four luminal stitches. **J:** Serosal-muscularis sutures of 8-0 polypropylene are also placed between the original four-quadrant stitches to ensure a watertight closure. (From Lipshultz LI, Howards SS, eds. *Infertility in the male,* ed 2. St. Louis: Mosby, 1991, with permission.)

The Vasovasostomy Study Group series is the largest multiinstitutional report of vasectomy reversal outcomes (35). During a 9-year period, 1,469 men who underwent microsurgical vasectomy reversal procedures were studied at five institutions. Of 1,247 men who had first-time procedures, sperm were present in the semen in 865 of 1,012 men (86%) who had postoperative semen analyses, and pregnancy occurred in 421 of 810 couples (52%) for whom information regarding conception was available. Important predictive factors for success included time elapsed since vasectomy and quality of fluid from the testicular end of the vas deferens. If the interval had been less than 3 years, patency was 97% and pregnancy 76%; 3 to 8 years, 88% and 53%; 9 to 14 years, 79% and 44%; and 15 years or more, 71% and 30%. The patency and pregnancy rates were no better after two-layer microsurgical vasovasostomy than after modified single-layer microsurgical procedures, and they were statistically the same for all patients regardless of the surgeon. When sperm were absent from the intraoperative vas fluid bilaterally and the patient underwent bilateral vasovasostomy rather than vasoepididymostomy, patency occurred in 50 of 83 patients (60%) and pregnancy in 20 of 65 couples (31%). Neither presence nor absence of a sperm granuloma at the vasectomy site nor type of anesthesia affected results. The length of the testicular end of the vas deferens appears to be another significant predictor of outcome and correlates with the intraoperative status of the vasal fluid. Witt and colleagues (467) reported that testicular vasal remnant length greater than 2.7 cm predicted the presence of fluid with whole sperm present in 30 of 32 testicles (94%), whereas a testicular vasal length of less than 2.7 cm predicted the presence of fluid without whole sperm in 17 of 20 testicles (85%). These fluid findings determine whether a vasovasostomy or vasoepididymostomy should be performed.
